danger. It has evolved the ability to detect key odorants with high sensitivity and to perceive a wide variety of general odorants at higher doses. Table 2 shows that *Drosophila* is particularly sensitive to a variety of esters, most likely because these are often generated by fermentation processes. Many phytophagous species have a variety of ORNs to detect terpenoids (Bruce et al. 2005), which seem to be underrepresented in the *Drosophila* ORN responses (de Bruyne et al. 2001; Hallem and Carlson 2006). The cockroach *P. americana* has several ORN classes that detect small alcohols and fatty acids (Sass 1976; Boeckh et al. 1987). While many odorants evoke responses from ORNs across insect species with very different ecologies, the part of the chemical world covered by an insect's repertoire of ORNs is likely to reflect the evolutionary history of the taxa.

In discussing tuning width of ORNs, it is important to realize that statements in the literature are rarely quantitative and depend highly on the breadth and variety of the set of odorants tested. Nevertheless, the ability of different OR proteins to bind a range of different odorant molecules varies widely (Hallem and Carlson 2006). In general, most ORNs of insects exhibit a higher degree of odorant specificity than previously thought, when they were labeled as broadly tuned odorant generalists as opposed to the more specialist receptors for pheromones (Hildebrand and Shepherd 1997). Work on heliothine moths has shown that many ORN classes respond to a relatively narrow set of plant odorants (Stranden et al. 2003; Rostelien et al. 2005). A similar reassessment of the tuning width of insect ORNs has resulted from studies performed on two species of beetle (Stensmyr et al. 2001).

ORNs that are tuned to components of insect sex pheromones exhibit some of the highest degrees of odorant specificity. Extremely specific responses to small differences in carbon chain length, functional group, or double bond positions are well known from different moth species. For instance, in *Heliothis* species, male ORNs are tuned to only one compound out of a series of closely related structural analogs (cf. Berg and Mustaparta 1995; Cossé et al. 1998; Baker et al. 2006). Highly specific responses also have been shown to stereoisomers of beetle pheromones, with one species responding only to the *R*-isomer while the other picks out the *S*-isomer (Wojtasek et al. 1998). Nevertheless, cross-reactivity does occur. A *Heliothis subflexa* ORN that mediates male attraction responds to a component of its own pheromone as well as to a different compound emitted by *H. virescens* (Baker et al. 2006), as does an ORN type in a species of *Yponomeuta* (Löfstedt et al. 1990). Genetic experiments on hybrids between the heliothine species suggest that such instances may be due to two related ORs being expressed in a single ORN (Baker et al. 2006).

Flexible Noses: Life Stages and Induced Genes

An insect's genome needs to encode several noses, each adapted to different ecological needs. The peripheral olfactory system of larval and nymphal stages can be quite different from that of the adult. Hemimetabolous insects add more olfactory sensilla with each molt, and the adult in particular has ORN classes that do not occur in earlier stages (Zacharuk and Shields 1991). In holometabolous insects, larvae often have a small set of ORNs with each individual one having different properties (Roessingh et al. 2007; Zacharuk and Shields 1991). *Drosophila* larvae have a single sensillum with 21 ORNs, each expressing a different OR gene (Fishilevich et al. 2005; Kreher et al. 2005). Some of these genes are expressed only there, while others occur in both larval and adult ORNs (Couto et al. 2005; Fishilevich et al. 2005) indicating that there is only partial overlap between the coding properties of adult and larval systems. Mosquito larvae, although aquatic, show a similar partial overlap in OR expression (Bohbot et al. 2007). Together with earlier electrophysiological analysis of olfactory perception in air and water (Behrend 1971), these results also indicate that odor detection needs no major adjustments upon transition from water to air.

Adult olfactory systems often differ between males and females. In moths, males often have larger antennae that carry many thousands of the same two or three classes of sex pheromone receptors. This presumably increases the chance of detecting the weak signal emitted by females. In females, specific ORN classes tuned to plant compounds appear to replace pheromone-sensitive ones (Heinbockel and Kaissling 1996, King et al. 2000). Consequently, small sets of moth OR genes show female-specific expression (Wanner et al. 2007). Finally, adult ORNs can adapt their response properties to external or internal conditions. Mosquito ORNs sensitive to the host chemical lactic acid are tuned down after a blood meal when females stop orienting to host odors and turn to oviposition stimuli instead (Davis 1984). Expression of an OR gene for 2-methyl phenol, a urine-related compound, is also turned off (Hallem et al. 2004). Ray et al. (2007) also provide some evidence that transcription factors can alter OR gene expression levels in adult flies.

Tuning to Mates: Pheromone Receptors

Recent rapid expansion of knowledge in insect olfaction owes a great deal to the study of pheromone perception, particularly of sex pheromones in moths. Moth sex pheromones epitomize the development of an exquisitely sensitive and fine-tuned communication system. The majority of moth sex pheromones are blends of 10- to 18-

carbon-long unbranched primary alcohols, acetates, or aldehydes, emitted from the female pheromone gland. They are synthesized from C_{16} or C_{18} fatty acids, and initial species-specific structural differences are imparted by one or more desaturases that place double bonds at specific locations (Roelofs and Rooney 2003). Species specificity is achieved even if females emit only simple blends of two or sometimes three pheromone components in precise ratios (along with other behaviorally inert compounds). Conspecific males fly upwind only to blends that closely approximate this ratio. Further specificity is imparted by males' cessation of upwind flight if the blend contains these components in the correct ratio but also contains an additional odd component emitted by heterospecific females as part of their pheromone blend (Vickers and Baker 1997, Quero et al. 2001).

Lepidopteran pheromone molecules are detected by ORNs in extra-long trichoid (sw) sensilla on the antennae of male moths (Kaissling 1987; Steinbrecht 1999). Usually there are two, but sometimes three, ORNs that co-compartmentalize within one sensillum. Pheromone-sensitive neurons are exclusive to males in most species and occur in large numbers (up to 40,000). Neurons that detect components of a pheromone blend can be together in a single sensillum (e.g., in Tortricidae and Crambidae) or in different sensilla (in Noctuidae). Their axons invariably converge on a small set of closely apposed enlarged glomeruli (macroglomerular complex or MGC) in the antennal lobe near the entrance of the antennal nerve (Hansson and Christensen 1999).

The genes that encode sex-pheromone-component-sensitive ORs of *B. mori* have been characterized and shown to respond to the two pheromone components bombykol and bombykal (Sakurai et al. 2004; Krieger et al. 2005; Nakagawa et al. 2005; Syed et al. 2006). These receptors are expressed in adjacent neurons in a single trichoid sensillum. In *H. virescens*, six related ORs have been characterized, and three were shown to respond to its pheromone components (Krieger et al. 2002, 2004; Grosse-Wilde et al. 2007). One of these is expressed in the most abundant type of trichoid sensillum, while the other two co-inhabit another type. It is likely that the choice of an OR for placement in a moth-pheromone-sensitive ORN relies upon the same genetic processes as described for *Drosophila* ORs for general odorants (Ray et al. 2007).

Flying to an Odor Source: The Need for Speed

Detailed studies of flying moths orienting to sex pheromones have taught us how insects move towards an odor source (see contribution by Cardé and Willis this issue). The activation properties of insect ORNs are in tune with the physical properties of odor strands and pockets of clean air that occur in natural odor plumes due to turbulence (Vickers et al. 2001). It is the intermittency of stimulation from the plume strands that promotes sustained upwind flight (Kennedy et al. 1981; Baker et al. 1985). Such sustained attraction and source location is based on reiterative upwind surges in response to odor strands, interrupted by cross-wind casting reversals in response to clean air pockets (Mafra-Neto and Cardé 1994; Vickers and Baker 1994; but see Justus and Cardé 2002). In-flight attraction and source contact is optimal when males discriminate the "correct" pheromone blend sufficiently rapidly in each of the pheromone plume strands they contact. Hence, the performance of insect ORNs is optimized for fast, repetitive responses to ensure accurate odor identification of strands arriving irregularly, often in intervals of less than 100 ms, but also with gaps between strands of more than ten times that (Baker and Haynes 1989; Vickers et al. 2001).

The optimal ratio of components in the blend most closely approximates the natural ratio emitted by females. Linn et al. (1986) convincingly demonstrated for several species that for such optimal blends, male behavioral thresholds are lower, and more males initiate upwind flight and from greater distances than for partial blend compositions or suboptimal ratios. Moreover, in heliothine moths blend-quality evaluations take place on a strand-by-strand basis, within fractions of a second. If components of another species' blend are perceived in a strand, male upwind flight is instantly affected. Strands of the optimal blend tainted with small amounts of such heterospecific antagonist are poorer at eliciting long upwind surges than strands of the untainted blend (Vickers and Baker 1997, Quero et al. 2001). ORNs tuned to such heterospecific pheromone component are often slightly more broadly tuned than are ORNs sensitive to a moth's own pheromone components. They may have evolved to detect pheromone components of several sympatric species, turning off attraction to plume strands that contain an alien compound and preventing orientation toward females of the wrong species (Cossé et al. 1998; Linn et al. 2007). To do this, most moths have ORNs co-compartmentalized in the same sensillum, one for these important heterospecific compounds and another for one of their own pheromone components (Cossé et al. 1998).

Why are insect ORNs generally combined in sensilla in stereotypic combinations? In *Drosophila*, the same two classes of ORNs are always found together in a single sensillum (de Bruyne et al 1999, 2001). The special ecology of moth pheromone systems suggests an answer. Blend compositions of pheromone compounds in individual plume strands that are traversed at high speed need to be assessed in split-second behavioral choices (Vickers and

Baker 1997; Quero et al. 2001). Stereotypical pairing of ORNs in the same sensillum is likely to ensure a high fidelity of on-site ratio reporting, regardless of differences in odor flux, and with the optimal spatio-temporal precision (Todd and Baker 1999). It has been shown that moths can discriminate between two overlapping pheromone plumes, due to incomplete mixing of their intertwined strands (Witzgall and Priesner 1991; Liu and Haynes 1992). Baker et al. (1998) estimated the temporal precision of blend ratio assessment to be close to 1 ms.

Nikonov and Leal (2002) suggested that in the Japanese scarab beetle *Popillia japonica* pheromone components are not only detected in parallel but processed within single sensilla before integration in the antennal lobe. On-site, within-sensillum mixture interactions can alter ORNs' reporting capabilities. However, it remains to be seen whether such cases constitute interactions within a neuron or between neurons. On-site mixture interactions were also demonstrated in *Helicoverpa zea* sensilla, in which the major pheromone component mixed with certain plant volatiles elicited greater ORN activity with a more tonic response profile than the pheromone component alone (Ochieng and Baker 2002).

It is just as crucial for the insect to respond quickly to the pockets of clean air between pheromone strands as it is to respond to the strand itself because the upwind, clean-wind direction of a large gap due to large-scale turbulence (wind-swing) does not lead to the source; a fast switch from upwind flight to cross-wind casting flight is required to increase the chance of recontacting odor-laden air (David et al. 1982). The latency of behavioral response to both the onset (upwind surges) and loss of pheromone pulses (cross-wind casting reversals) can be as fast as 0.15 s (Baker and Haynes 1987), but is usually between 0.3 and 0.6 s (Baker and Vogt 1988; Vickers and Baker 1996). This response speed does not seem specific to pheromones, as the latency to casting flight from upwind flight after the loss of host-odor is only slightly lower (0.7 s) in female moths (Haynes and Baker 1989).

Integrating Odor Identity and Intensity in Time

The biochemical, neurophysiological, and molecular processes that contribute to the propagation of behavior after contact with airborne pheromone strands all emphasize high-speed processing related to temporal resolution of the strand encounters. The frequency of action potentials in response to each pulse is significantly reduced under rapid stimulation and would make concentration coding less accurate. However, there is no evidence thus far that male moths need, or use, strand concentration information to locate females. This explains why such ORN adaptation nevertheless retains a high fidelity of reporting the temporal aspects of strand presence or absence, while losing the ability to report absolute concentration (Kaissling 1987).

There is some evidence that the speed of both ON- and OFF-responses in pheromone-sensitive ORNs is influenced by perireceptor proteins such as PBPs and pheromone degrading enzymes (PDEs; Syed et al. 2006). Some experiments indicate that binding dynamics of PBPs can be within the order of ms (Leal et al. 2005). The half-life of pheromone component molecules of *Anthaerea polyphemus* in the presence of an *A. polyphemus* PDE has been calculated to be less than 15 ms (Ishida and Leal 2005).

Pheromone-sensitive ORNs display a wide variation in the phasic or more tonic elements of their responses to pheromone components (Kaissling 1987; Berg and Mustaparta 1995). Phasic ORNs are fast to disadapt and are able to track (respond to) strands of pheromone in natural plumes (Vickers et al. 2001; Justus et al. 2005); they can also reliably respond to mechanically generated pulses at 10 Hz (Almaas et al. 1991) or even more than twice that (Bau et al. 2002). More tonically firing neurons (often called phasic–tonic) are usually slower to return to baseline firing levels, sometimes taking minutes or tens of minutes to do so (Rumbo and Kaissling 1989).

The frequency of action potentials in response to each short pulse of pheromone, normally correlated with the flux intensity of pheromone contained in each pulse, is significantly reduced under rapid stimulation, but the fidelity of response with regard to the temporal presence (pheromone strand) or absence (clean-air pocket) of the pheromone is accurate. Differential adaptation of ORNs specific to one pheromone component in each blend-strand without concomitant adaptation of ORNs specific to other components can result in a shift in ORN firing ratios being received by higher-order neurons and being registered through combinatorial coding as an off-blend, resulting in a reduction in attraction (Hansson and Baker 1991).

In *Drosophila*, there is also wide variation among different classes of ORNs for non-pheromonal odorants in the temporal response characteristics, particularly in the waning of responses after stimulus offset. Within a single ORN class, some odorants evoke responses that are cut off immediately with stimulus removal, while other odorants evoke long-lasting stimulation. This variation is independent of odorant chemistry and concentration. Instead, these temporal characteristics are dictated by the way a specific odorant interacts with a specific OR, as evidenced by experiments in which a single ORN type was transfected with many different ORs (Hallem and Carlson 2006). This variability can affect the temporal accuracy of reporting odor strands, but it may also enrich the coding possibilities for odor discrimination (de Bruyne et al. 2001).

ORNs detecting moth pheromones are the best studied examples with respect to temporal coding of natural odor stimuli. However, many insect species employ pheromones whose components can be chemically diverse, and their perception relies on a wide variety of ORN types. Many insect pheromones are related to plant volatiles, e.g., terpenoids such as periplanone (related to germacranes) in cockroaches (Persoons et al. 1976). Pheromone-sensitive neurons also reside in non-trichoid types of sensilla. For instance, in scarab beetles, placoid sensilla house the pheromone-sensitive receptor neurons (Nikonov and Leal 2002). Because of strong selective pressures, highly specialized olfactory subsystems have evolved from different elements of the general olfactory system in different insect groups, but fundamental mechanisms of olfactory coding appear to be conserved (Christensen and Hildebrand 2002)

Evolution of Pheromone Communication Systems

The evolution of pheromone communication systems is thought to be driven by changes in the biosynthesis of pheromone components that are tracked by shifts in male olfactory response (Phelan 1997; Roelofs et al. 2002). Major shifts in moth pheromone blends have been hypothesized to occur when previously unexpressed desaturase genes become expressed in the pheromone glands of some females in a population (Roelofs et al. 2002). If a few males in the population are able to respond to both the new and old blend, a new population of males and females communicating with this new blend would be formed through a process of asymmetric tracking over generations by males (Phelan 1997; Roelofs et al. 2002).

For this to occur, tuning properties of pheromone-sensitive ORNs would have to show a degree of variability for selection to act upon. It has been shown that the numbers of ORNs tuned to different pheromone components vary among European and West-Asian populations of the noctuid moth *A. segetum*, correlating with the differences in female blend ratios and male behavioral response occurring in different geographic regions (Hansson et al. 1990). Response profiles of pheromone-sensitive ORNs in hybrids between closely related heliothine species also reveal underlying genetic variability by the occurrence of new response types in addition to pure parental types (Baker et al. 2006). In some *Yponomeuta* species that use unusual pheromone components compared to their congeners, the male pheromone-sensitive ORNs display a correspondingly enlarged response spectrum (Löfstedt et al. 1990). Such cases may perhaps be due to a novel OR specific for the unusual component being co-expressed on these ORNs, or else a singly expressed, more broadly tuned OR for a wider range of compounds (Domingue et al. 2007).

The Stuff of Life: Volatiles from Primary Metabolism and Microbial Decay

While pheromones are usually produced from specific glands as secondary metabolites, many odorants that insects respond to are generated from primary metabolism of their hosts or associated microorganisms. Detection of some of these odors appears widespread across insect species.

Carbon dioxide (CO_2) is an atmospheric gas, omnipresent, and at relatively high concentrations for an odor. Insects can sense fluctuations around ambient concentrations (ca. 0.03%). Sensory neurons for its detection show modified dendrites with increased membrane surface and have been found in antenna of honeybees, ants, tsetse flies, fruit flies (Tephritidae), and *Drosophila* (Stange and Stowe 1999). In other insects, CO_2-sensitive neurons are found on the maxillary palps (mosquitoes, Grant et al. 1995) or labial palps (moths, Stange 1992). Larval stages of moths (Roessingh et al. 2007) and *Drosophila* (Faucher et al. 2006) also possess such neurons, but interestingly in both cases, they appear less sensitive than in the adults. In *Drosophila,* CO_2-sensitive neurons are found in basiconic sensilla on the antenna (de Bruyne et al. 2001; Suh et al. 2004). Although they are housed together with other ORNs, they do not express the *Or83b* gene nor any other member of the OR family. Instead, two members from the gustatory receptor (GR) family, *Gr21a* and *Gr63a*, mediate the response to CO_2 (Jones et al. 2007; Kwon et al. 2007). Orthologs of these genes have been found in the genomes of mosquitoes, moths, and beetles (Kwon et al. 2007) but not in the honeybee (Robertson and Wanner 2006). In the honeybee and other hymenopterans, CO_2-sensitive neurons are found in a different category of sensilla in deep pits on the antenna. The neurons appear less sensitive (Lacher 1964; Kleineidam et al. 2000), and may well use a different mechanism for CO_2 detection.

While CO_2 is produced in large amounts by all living cells, alkyl amines are metabolic by-products commonly formed from protein degradation. Attraction to ammonia and small amines is common in hematophagic insects such as flesh flies and mosquitoes, but other insects, such as fruit flies (Tephritidae), also need protein-rich food sources to complete egg maturation. In Carribean fruit flies, antennal responses to ammonia peak with deposition of yolk-proteins (Kendra et al. 2005). ORNs sensitive to amines commonly occur in dw sensilla. They are found in hematophagous insects such as mosquitoes (Meijerink et al. 2001) and triatiomine bugs (Taneja and Guerin 1995), but also in *Periplaneta* (Sass 1976) and even *Drosophila*. In

Drosophila, one ORN class responds to ammonia and another to 1,4-diaminobutane (putrescine; Yao et al. 2005). Like CO_2, amine perception might employ a different molecular mechanism. Neither of these neurons are known to express an identified OR gene (Table 2).

A well-documented attractant for hematophagous insects is 1-octen-3-ol. It was first associated with cattle breath, attracting tsetse flies (*Glossina* spp.). These flies bear at least two ORN classes on their antennae that detect it (van der Goes van Naters et al. 1996). Mosquitoes possess receptors on antennae and maxillary palps (Syed and Leal 2007). Actually, 1-octen-3-ol is a typical fungal odor and has been shown to signal fungal/mold infestations at oviposition sites (Steiner et al. 2007). In *Drosophila*, several ORN classes show high sensitivity to this odorant (de Bruyne et al. 2001). This volatile appears to excite different ORN classes in many insect species, and ORNs that detect it tend to be broadly tuned.

Plant Secondary Metabolites

The group of insects that are most studied because they interfere with our agriculture are those species that feed on plants. Phytophagous species make up a large proportion, and insect–plant interactions have driven evolution of sophisticated host location and defense mechanisms in insects and plants. Plants produce the largest variety of odorants as evidenced by our own use of these in spices and perfumes. The largest class of volatiles produced by plants in dazzling variety of mixtures is that of the terpenoids, all produced by well-known biosynthetic pathways. There are many ORN classes described for terpenoids, predominantly in moths. Receptors for commonly occurring terpenoids such as linalool, geraniol, β-ocimene, and β-caryophyllene are found in several moth species (Anderson et al. 1995; Shields and Hildebrand 2001; Rostelien et al. 2005). Terpenoid-sensitive ORNs are often housed in trichoid sensilla, and many of them are narrowly tuned. This highlights an important limitation in our understanding of insect olfaction. Many ORN types are not studied simply because they are tuned to natural compounds we have not tested. In several *Heliothis* species, an abundant type of ORN is tuned to the sesquiterpene germacrene-D, which occurs in many plants but cannot be obtained commercially (Stranden et al. 2003). It is likely though that narrowly tuned ORNs are also involved in a combinatorial type of coding. For instance, in the hawkmoth *M. sexta*, two narrowly tuned ORNs were found to respond to E-nerolidol and farnesol, respectively, but both also showed responses to the more common geraniol (Shields and Hildebrand 2001). Interestingly, a few of the many ORN classes described for *Drosophila* are activated by terpenoids. Instead, terpenoids such as linalool appear to inhibit some ORNs (de Bruyne et al. 2001), a phenomenon that may be more general (Kaissling et al. 1989).

The second largest group of plant volatiles, phenylpropanoids, contains an aromatic ring derived from the amino acid phenylalanine. They may serve to protect plant tissues from microorganisms. Methylsalicylate is a product of a signaling cascade that follows tissue damage (Turlings and Ton 2006) and has been shown to excite insect ORNs (de Bruyne et al. 2001; Shields and Hildebrand 2001). Methyleugenol is a powerful attractant for tephritid flies (Raghu 2004), although it is still not fully understood why. It has been suggested to be a case of pharmocophagy, where male flies pick up methyleugenol and use it to attract females.

The third group consists of derivatives of various fatty acids and contains mainly short-chain aldehydes, alcohols, and esters. E2-hexenal is a green leaf volatile (GLV), one of several compounds typically released after damage to leaves (Visser 1986) but also found in many flower and fruit odors. Highly sensitive ORNs to GLVs have been found in moths (Anderson et al. 1995) beetles (Visser 1986; Blight et al. 1995; Hansson et al. 1999) and flies (Guerin et al. 1983; de Bruyne et al. 2001).

Many insects have developed specific interactions with a select group of host plants. In theory, they could use host-specific cues to locate them. While some insects certainly use specific chemicals that identify distinct plant taxa, e.g., isothiocyanates for cruciferous plants (Blight et al. 1995), host finding more often involves mixtures of odorants that are common to many plants (Fraser et al. 2003). It seems that most phytophagous species home in on specific ratios among components (Visser 1986). As in moth pheromone systems, stereotypical pairings of ORNs in single sensilla may facilitate this, and it has been suggested that these are often excited by odorants from different biosynthetic pathways (Blight et al. 1995). Compared to pheromone systems, there are many more compounds in plant-produced mixtures, and their ratios are more variable. Here, selection probably favors robust adaptable systems rather than finely tuned specialized ones. Recent comparative work on phytophagous insect species with differing host specificities suggest that ORN response properties do not easily specialize. Closely related tephritid species show similar responses even if their behaviors towards plant odors differ considerably (Olsson et al. 2006). Studies on *Heliothis* (Rostelien et al. 2005) and *Drosophila* (Stensmyr et al. 2003) also suggest that insect noses maintain a generally broad sensitivity with small modifications. Finally, it should be borne in mind that insects probably detect many compounds or evaluate ratios between them that are indicative of non-hosts or toxic substrates.

Concluding Remarks

These are exciting times in the study of insect olfactory ecology. The convergence of genomic, physiological, and ecological data will elucidate the physiological and genetic basis of odor-mediated behaviors. The availability of newly sequenced insect genomes will shed new light on how olfactory systems evolve to fit different ecological niches. Despite the millions of years of evolution and the different chemical ecologies that separate some of the insects we have discussed, they share common sensitivities. It will be interesting to see how much of this is homology and how much is convergent evolution.

The selectivity of the olfactory system depends on processes between odor molecules and OR proteins, but how odors activate ORs is still largely unclear. Because insect ORs have evolved independently from those in vertebrates, solving this mystery in both groups may teach us what fundamental biochemical interactions link chemical ecology with molecular evolution. The visual system can provide useful analogies. Compound eyes are relatively uniform in shape and composition across insect orders. Olfactory epithelia have many ORN classes, enveloped in different sensory structures that express OR genes and some GR genes. They may employ other mechanisms as well. We know which physical properties of light dictate the uniformity of eyes and what drives variability in opsin genes, but we know little about how the chemical environment molds olfactory genomes of insects.

Photoreceptor cells are accompanied by cells that generate lenses, and absorption spectra of receptors are modified by screening pigments. By analogy, we should keep our minds open for modifications in vivo to the response properties of ORs. For instance, because OBPs and PBPs are insect-specific, extracellular, and highly expressed, they provide good targets for novel strategies in pest control. Although we have learned much about the unifying principles of olfactory function, we still have much to understand about the ecological mechanisms that drive the amazing variety in form and function of insect noses.

REVIEW ARTICLE

Neural Processing, Perception, and Behavioral Responses to Natural Chemical Stimuli by Fish and Crustaceans

Charles D. Derby · Peter W. Sorensen

Received: 2 April 2008 / Revised: 22 April 2008 / Accepted: 28 April 2008 / Published online: 3 June 2008

Abstract This manuscript reviews the chemical ecology of two of the major aquatic animal models, fish and crustaceans, in the study of chemoreception. By necessity, it is restricted in scope, with most emphasis placed on teleost fish and decapod crustaceans. First, we describe the nature of the chemical world perceived by fish and crustaceans, giving examples of the abilities of these animals to analyze complex natural odors. Fish and crustaceans share the same environments and have evolved some similar chemosensory features: the ability to detect and discern mixtures of small metabolites in highly variable backgrounds and to use this information to identify food, mates, predators, and habitat. Next, we give examples of the molecular nature of some of these natural products, including a description of methodologies used to identify them. Both fish and crustaceans use their olfactory and gustatory systems to detect amino acids, amines, and nucleotides, among many other compounds, while fish olfactory systems also detect mixtures of sex steroids and prostaglandins with high specificity and sensitivity. Third, we discuss the importance of plasticity in chemical sensing by fish and crustaceans. Finally, we conclude with a description of how natural chemical stimuli are processed by chemosensory systems. In both fishes and crustaceans, the olfactory system is especially adept at mixture discrimination, while gustation is well suited to facilitate precise localization and ingestion of food. The behaviors of both fish and crustaceans can be defined by the chemical worlds in which they live and the abilities of their nervous systems to detect and identify specific features in their domains. An understanding of these worlds and the sensory systems that provide the animals with information about them provides insight into the chemical ecology of these species.

Chemical Senses in the Aquatic Medium

Aquatic organisms evolved in a world of dissolved chemicals, and this resulted in the appearance of numerous types of chemosensory systems. As in terrestrial organisms, the senses of olfaction and gustation are usually identified as the main chemosensory systems in aquatic organisms, although the distinctions between them are somewhat blurred. This is because the primary distinction between these senses in terrestrial organisms—the physical medium through which chemical molecules are delivered to animals (air for olfaction and water for gustation)—does not apply in aquatic systems. Thus, a second basis for distinguishing between olfaction and gustation—neuroanatomy—becomes particularly relevant for aquatic animals. However, this distinction is more useful for vertebrates than invertebrates, whose neuroanatomy differs. In aquatic vertebrates, like all vertebrates, olfaction is defined as the sense mediated by neurons with axons in the olfactory nerve (cranial nerve I). In addition, a common feature of olfaction in vertebrates and many invertebrates is that the first-order processing regions in their brains are organized into glomeruli, which contain the synapses between the olfactory receptor neurons

and interneurons, and that these brain regions have a chemotopic organization such that different odorants generate distinctive patterns of glomerular activity (Hildebrand and Shepherd 1997; Eisthen 2002; Ache and Young 2005). Gustation in vertebrates, on the other hand, is mediated by non-neuronal, modified epithelial cells that are innervated by the facial (cranial nerve VII), glossopharyngeal (cranial nerve IX), and vagal (cranial nerve X) nerves that project to different brain structures and appear to have different functions (Atema 1977; Caprio et al. 1993). Another way that olfaction and gustation can be distinguished is by their function: Gustation is more apt to mediate simple and reflexive behaviors, food consummatory behaviors in particular, whereas olfaction tends to mediate more complex behaviors such as searching for distant sources of chemicals, courtship behavior, and learning about odors (Atema 1977).

Besides olfaction and gustation, both fish and crustaceans have a diversity of other, less understood chemical senses. Fish have a trigeminal system and solitary chemoreceptor cells that cover their bodies (Kapoor and Finger 2003), whose functions are not yet clearly established. Crustaceans have a diversity of chemoreceptor neurons that differ in their packaging within sensilla, their connections and organization in the central nervous system, and the behaviors that they mediate (Horner et al. 2006, 2008b). One pathway of crustaceans—the aesthetasc sensilla and the olfactory lobe pathway—is considered 'olfactory' because of organizational similarities between it and the olfactory pathways of vertebrates and insects. While other crustacean chemosensors are typically packaged with mechanosensors into sensilla, these sensilla are extremely diverse in structure and distributed differently across the animal's body surface where they serve different behavioral functions (see "Processing of Natural Chemical Stimuli"). Regardless of how chemosensory systems are defined, it is important to recognize that aquatic organisms have a variety of chemosensory systems whose neuroanatomical structures and functions vary dramatically.

The Chemical World Perceived by Fish and Crustaceans

Aquatic animals detect, discriminate, and respond to a wealth of chemicals in their natural environment. This diversity is immense, as aquatic organisms in general release literally thousands of small and soluble products that can carry information. Notably, most of the compounds found in aquatic environments are relatively unspecialized metabolic products (Atema 1988; Carr 1988). With the possible exception of some pheromones (Sorensen and Stacey 1999), there is little evolutionary pressure for organisms to produce specialized chemicals that facilitate their discrimination. Chemoreception is basic to meeting most biological needs of organisms, including those related to reproduction, social interactions, acquiring food and shelter, and defense from predators. Of course, this is particularly true in waters with low light levels. For the most part, chemoreception in aquatic ecosystems requires the detection of small differences in mixture composition in complex backgrounds, as opposed to detection of a few specialized compounds. In the next section, we give select examples of the discriminatory abilities of fish and crustaceans that focus on the nature of their chemical worlds and their abilities to detect, discriminate, and respond to them. A discussion of the molecular identity of important chemicals and how they are neurally processed follows later.

Fish

Fish use chemicals that mediate many key aspects of their lives, most of which are poorly understood but appear highly complex. Among the most important are habitat recognition, food finding, conspecific identification, and predator avoidance. Fish are the most diverse group of vertebrates, represented by more than 26,000 species that live in an immense variety of habitats. The type, concentration, and distribution of chemicals in their environments are all important factors in determining the chemical ecology and life history strategies. Because of this vast diversity, our review considers only a small number of fish species and situations, so we have selected representative examples.

Most species of fish are highly mobile and exhibit a variety of complex behaviors, many of which depend on them having information about their environment. Ablation studies often demonstrate that the type and location of habitat is determined by using environmental chemicals as cues. Although some species, such as freshwater bass, live in and compete for limited territories, other species are migratory and travel great distances only to return to very specific locations to reproduce. For example, Pacific salmon are born in small inland streams and then migrate to oceans to feed but eventually return 'home' by using olfactory cues (Hasler and Scholz 1983). A variety of studies demonstrate that the chemical nature of 'home stream' odor is learned. Salmon select between proximate streams when returning home by choosing the stream in which they were raised many years earlier. Given the proximity and ecological similarities of the streams among which Pacific salmon must choose, it has been suggested that the odor that they learn is complex and comprised of mixtures of compounds from minerals, plants, and animals (Hasler and Wisby 1951; Nordeng 1977). Salmon can identify stream odors after many years at sea and

environmental change, demonstrating their remarkable ability to recognize patterns. Another interesting example of olfactory-driven migration is the parasitic sea lamprey, which has a similar life history to salmon except that it does not return to home streams but rather selects streams that contain young lamprey. Lamprey recognize home streams by using innately recognized pheromones released by larval lamprey in combination with other unknown compounds found in all stream waters (Sorensen et al. 2003, 2005; Sorensen and Hoye 2007). A third example is the use of olfactory cues by non-migratory fish to identify home ranges within streams—difference in the odor mixtures they discriminate must be subtle (Gunning 1959; Arnesen and Stabell 1992). These three examples demonstrate that fish discriminate complex matrices of waterborne chemicals and can remember and track them through space and time by using their olfactory systems that demonstrate sophisticated perceptual abilities.

As most fishermen know, fish are also adept at using chemicals to identify and locate food, even in turbid, deep, or dark waters. This highlights the outstanding ability of fish to perceive chemicals associated with food and may even be partially responsible for the evolutionary success of fish in exploiting diverse feeding niches (Moyle and Cech 2000). Both olfaction and gustation are used in distinguishing between similar types of food. Most fish are 'feeding generalists' with keenly developed abilities to identify and locate a range of foods based on their nutritive values, even in changing environments in which the relative abundance of specific prey may dramatically shift. Notably, fish have evolved multiple suites of feeding behaviors, including appetitive and consummatory behaviors (Jones 1992; Valentinčič 2005). These behaviors are mediated by both olfaction and gustation, which can detect overlapping sets of relatively common metabolic products. L-Amino acids are the most important of these, but other classes are known (see below). Species differences in sensitivity to these classes of chemical stimuli are common, and almost certainly, there are innate abilities to learn certain types of stimuli (Jones 1992). These abilities may be mediated by the gustatory sense, which is generally more narrowly tuned and often linked to mechanistic responses. Nevertheless, in the natural world, most feeding chemical stimuli appear to be discriminated as complex mixtures. For example, Carr (1982) reports that mixtures of 17 to 22 amino acids plus betaine could account for the majority, though not all, of the feeding activity elicited by four natural food items for the pigfish but not the related pinfish. Finally, as one might expect, selection of food by at least some marine fish is influenced by their detection of deterrent molecules, such as alkaloids, tetrodotoxin, and acids. This subject has received considerable attention from chemical ecologists but, unfortunately, little work from neuroscientists (Hara 1994; Hay 1996; Kicklighter et al. 2005; Hayden et al. 2007; Kamio et al. 2007; Cohen et al. 2008).

Of course, fish do more than hide and eat. Pheromones, here defined as sets of chemicals that convey information about an individual's identity and condition to other members of its species, play essential roles in the sexual and social life histories of most fishes (Stacey and Sorensen 2005). Olfactory blocking studies consistently demonstrate that olfaction mediates the perception of sex pheromones, which are often so important that anosmic fish simply fail to mate (Stacey and Kyle 1983). Finding and identifying conspecifics of appropriate maturity in complex natural environments can be challenging, so mating in even highly visual species such as swordtails is almost always assisted by pheromones (Wong et al. 2005). Intraspecific cues and pheromones can have multiple functions. Among these, species recognition for the purpose of aggregation or schooling is paramount. Although the chemical basis of aggregation is not clear, variations in metabolite production—rather than production of novel, species-specific compounds—are likely responsible (Sorensen and Stacey 1999). Odor recognition systems tuned to small variations in mixture composition should provide species-specific information. In addition to using olfaction for species recognition, some fish, including sticklebacks and salmon, use odors to determine kinship. These odors may include major histocompatibility complex-related peptides (Reusch et al. 2002; Ward and Hart 2002). Finally, almost all fish are able to discriminate reproductive state by using sex pheromones that they detect with high sensitivity and specificity (Stacey and Sorensen 2005). Hormonally derived signals are especially important, presumably because of their inherent relevance (Stacey and Sorensen 2005). However, hormone systems are highly conserved, thus providing little latitude for the evolution of novel hormonal products and their receptors, and some species have evolved to use a wider range of products (Li et al. 2002; Yambe et al. 2007).

In addition to sex pheromones, many fish can detect intraspecific chemicals that indicate danger, in particular, chemicals from conspecifics injured by predators (Smith 1992; Døving et al. 2005). However, injured fish release a variety of chemicals, some of which (e.g., amino acids) may be food cues in some contexts. Since the first description of the alarm response in European minnows in the field by von Frisch (1938), at least six types of compounds or their mixtures have been proposed to mediate alarm responses, with the purine hypoxanthine-3-*N*-oxide receiving the most attention (Pfeiffer et al. 1985; Brown et al. 2000, 2003). However, none of the suggested bioactive molecules has received supporting evidence from electrophysiological recordings or chemical measurements.

Interestingly, several studies suggest that the alarm cues can be learned (Wisenden 2000), raising the possibility that multiple types or mixtures of chemicals may be involved. The observation that fish recognize chemicals released by predators that have eaten conspecifics—presumably conspecific alarm cues that remain functional after being digested by the predators (Brown et al. 1993)—supports this possibility. Alarm cues from injured conspecifics are mediated by the olfactory system (Maniak et al. 2000; Døving et al. 2005).

In summary, fish live in complex environments wherein they face extreme challenges in finding shelter, mates, and food, while at the same time avoiding predators. They use their chemical senses in these behaviors by discriminating complex (though, at present, often incompletely defined) chemical mixtures of relatively common molecules. These abilities have allowed fish to succeed and diversify, becoming the majority of planet's vertebrate biomass and biodiversity.

Crustaceans

Crustaceans, like fish, rely on combinations of sophisticated chemosensory systems to identify and locate food, mates, and predators in noisy chemical environments filled with a multitude of products. The best studied chemosensory behavior in crustaceans is the selection and acquisition of food. Crustaceans use antennular chemoreception to identify attractive food (Derby 2000; Derby et al. 2001) and locate it from a distance (Atema 1996; Zimmer and Butman 2000; Grasso and Basil 2002; Weissburg et al. 2002; Keller and Weissburg 2004). Amino acids and nucleotides are two major sets of molecules that they use. Once near the food, ingestion is based on input from their gustatory systems on legs and mouthparts (Derby 2000; Derby et al. 2001). Food selection and ingestion is influenced by the blend of attractive and deterrent compounds, although we know more about the former than the latter (Derby et al. 2001; Prusak et al. 2005; Kamio et al. 2007). Some crustaceans can learn to avoid food associated with gastric malaise (Wight et al. 1990).

Crustaceans make use of chemical signals in most aspects of their reproduction. They use sex pheromones to identify and locate conspecifics of the opposite sex. Copepods, amphipods, shrimp, crabs, lobsters, and crayfish are leading examples (Gleeson 1991; Asai et al. 2000; Hardege et al. 2002; Kamio et al. 2002, 2008; Stebbing et al. 2003; Ting and Snell 2003; Caskey and Bauer 2005; Ekerholm and Hallberg 2005; Belanger and Moore 2006; Atema and Steinbach 2007). Some sex pheromones are detected from a distance, others seem to be used in close range, even requiring contact. Chemical cues are also used in other aspects of reproduction. For example, many female crustaceans incubate their fertilized eggs, and chemicals released from hatching eggs induce abdominal pumping, fanning, and other behaviors from the females that facilitate the rapid and synchronized hatching of eggs and release of larvae (Tankersley et al. 2002; Rittschof and Cohen 2004).

Crustaceans use chemical cues during intraspecific interactions and social behavior. These chemicals are often in their urine and under controlled release so that they can be used at appropriate times during behavioral interactions (Breithaupt 2001; Breithaupt and Atema 2000; Breithaupt and Eger 2002; Moore and Bergman 2005; Moore 2007). Some crustaceans, such as lobsters and hermit crabs, use cues to recognize individual conspecifics (Johnson and Atema 2005; Gherardi et al. 2005). Others, such as crayfish, use cues to determine social status (Moore and Bergman 2005; Moore 2007). Lobsters use chemical information in aggressive interactions with conspecific (Breithaupt and Atema 2000). Spiny lobsters, which are highly social animals that often live in aggregations, use chemicals to identify each other and find safe shelter (Zimmer-Faust et al. 1985; Nevitt et al. 2004; Briones-Fourzán and Lozano-Álvarez 2005; Horner et al. 2006, 2008b). Spiny lobsters even recognize diseased conspecifics through chemical cues and avoid aggregating with them (Behringer et al. 2006). Young crayfish, which associate with their mother for some days after hatching, can locate her, as well as the shelter that she provides, by means of chemicals that she releases around the time of hatching (Little 1975). This cue appears not be specific to mother but is sex specific (Little 1976).

Crustaceans use chemicals to locate high-quality shelter or places to live. A well-known and long-studied example is the selection of sites to settle by larval barnacles (Dreanno et al. 2006a, b). Crustaceans such as pea crabs that live as commensals or symbionts with other organisms use chemical cues to locate their future hosts (Grove and Woodin 1996). Chemical cues are also used by hermit crabs to recognize shells as future homes (Rittschof and Cohen 2004).

Crustaceans also use chemoreception to avoid predators. Some can sense predators from a distance and thereby avoid them. Examples include crayfish and spiny lobsters (Berger and Butler 2001; Bouwma and Hazlett 2001). Predator avoidance can also be mediated through a less direct mechanism. Some crustaceans release chemicals when damaged, via leakage of body fluids, or when disturbed, via controlled release in urine, and these chemicals are avoided by conspecifics. Examples of species that use alarm cues include crayfish, spiny lobsters, and hermit crabs (Hazlett 1994; Zimmer-Faust et al. 1985; Rittschof et al. 1992; Nevitt et al. 2000; Zulandt Schneider and Moore 2000; Shabani et al. 2006; Bouwma 2007).

The Molecular Identity of Chemical Cues and Signals

Methods of Identification

The identity of bioactive molecules can be elucidated by using natural products chemistry techniques together with bioassays, based on any of several experimental approaches. Bioassay-guided fractionation is a standard technique that makes no assumptions about the nature of the bioactive substances. By this method, a natural product is separated into fractions based on any of a number of properties, including solubility in solvents of different polarity, molecular mass, and molecular charge. One method is a Kupchan partition scheme or modifications thereof, which is based on partitions differing in solubility—hexanes, chloroform, ethyl acetate, butanol, or water (Kupchan et al. 1975). With each separation, the resultant fractions are tested for bioactivity, usually with behavioral or electrophysiological assays. Comparison of the bioactivity of the fractions vs. the original material and a negative control allows identification of fractions that contain active molecules. When a natural product has more than one active ingredient, more than one fraction may have activity. It is often possible to separate bioactive molecules to sufficient purity to identify them through mass spectroscopy, nuclear magnetic resonance (NMR), or other analytical procedures. Databases such as Marinlit (http://www.chem.canterbury.ac.nz/marinlit/marinlit.shtml) and Chenomx NMR suite (http://www.chenomx.com), which contain known molecules, can be searched using known features of the bioactive molecules to identify possible molecular structures. Potential problems with this approach include degradation of bioactive molecules during separation and purification, and synergistic interactions among bioactive molecules that partition into different fractions such that their activity cannot be followed.

A second experimental approach to the molecular identification of chemical cues and signals is to determine which molecules are in relatively high concentration in the natural extracts that contain them. For example, when seeking a female sex pheromone in crustaceans, one might identify molecules in higher concentration in water from reproductive females compared to water from conspecifics that do not produce the pheromone. An example of this is the use of metabolomics to identify sex pheromones in blue crabs (Kamio et al. 2006). Metabolomics is a high-throughput approach to identify molecules enriched in or unique to one stimulus vs. another, usually focusing on small metabolites. Metabolomics has the advantage of not requiring purification of a component but can be based on spectra from mixtures (Daviss 2005). It can use data from either mass spectroscopy or NMR. This approach does not guarantee identification of bioactive molecules, in part because the bioactive molecules are not necessarily those in high concentrations, especially in the fishes whose pheromones can be common hormonal products (Sorensen and Scott 1994).

A third approach is searching for specific types of chemicals based on knowledge of the chemistry or biology of a system. For example, when ink secretions from sea hares were found to excite lobster chemosensory neurons, knowing that many of those neurons are sensitive to amino acids prompted amino acid analysis of the sea hare secretions and the eventual demonstration that amino acids in those secretions play an important defensive role (Kicklighter et al. 2005; Derby et al. 2007).

Fish

Fish perceive complex mixtures that contain a diversity of types of chemicals. Although there is presently no complete explanation for these perceptual abilities, electrophysiological studies have identified seven major classes of chemical stimuli that explain some of these abilities. These classes are amino acids, amines, nucleotides, bile acids (reduced steroids produced by the liver), aminosterols (a special class of bile steroids conjugated with amines), sex steroids, and prostaglandins. These compounds are all small (<8 kD), polar, and ubiquitous (Carr 1988; Hara 1994, 2007; Carr et al. 1996; Caprio and Derby 2007). There is overlap among classes—for example, both bile acids and sex steroids are steroids, and the relationship between olfactory receptor type and ligand class is not yet clear, so these categories of chemicals may mean more to biochemists than they do to the fish. Almost certainly, more classes of chemical stimuli await identification. Here, we briefly review our current understanding of known stimuli and how they are perceived by fish.

The chemical nature of food cues is best understood. Amino acids appear to be universally used by fish in this regard, likely because most are predators and have high protein requirements, and thus, amino acids are good indicators of high-quality food. Laboratory studies consistently demonstrate that specific mixtures of L-amino acids can attract many fish species and that single amino acids sometimes trigger reflexive snapping and biting behaviors, which at least on occasion are linked with the gustatory sense (Mackie 1982; Caprio et al. 1993; Hara 1994; Carr et al. 1996). Electrophysiological recordings demonstrate that fish olfactory systems detect all primary L-amino acids with high (nanomolar) sensitivity and specificity (Hara 1994, 2007). Fish external gustatory systems also detect L-amino acids, although often with much narrower ranges of sensitivity and, generally, in species-specific manners (Hara 2007; see below). This difference in the sensitivity of fish olfactory and gustatory systems is correlated with the

different but overlapping functions of these systems (see "Processing of Natural Chemical Stimuli").

Although amino acids are critical to food recognition, other molecules also are employed. The detailed studies on food recognition and ingestion show that L-amino acids rarely can explain all behaviors (Atema et al. 1980; Carr 1982; Carr et al. 1996). Indeed, in the case of marine fishes, betaine (a methylated amino acid) and D-amino acids, both present in marine environments, are important gustatory stimulants that can enhance the actions of amino acids (Carr 1982; Carr et al. 1996; Sorensen and Caprio 1998). Polyamines, which are protein breakdown products, are powerful stimulants of feeding arousal and search in goldfish due to their activation of specific olfactory pathways (Rolen et al. 2003). Nucleotides, which stimulate the olfactory and gustatory systems of many fish, have roles too (Carr 1988; Carr et al. 1996). Other bioactive chemicals will almost certainly come to light with further investigation. The blend of chemicals in a mixture is important to its efficacy, especially in olfactory-driven arousal and search behaviors. In summary, a wide variety of nitrogenous products serve as feeding cues for fish, although other bioactive chemicals, some yet to be identified, surely contribute.

With the exception of the sea lamprey (see below), little is known about the identities of chemical cues employed by fish to recognize the location or type of habitat. For species such as landlocked masu salmon that learn locational odors, the challenge is especially complex, although behavioral tests suggest that mixtures of L-amino acids are an important part of home stream odor recognition (Shoji et al. 2003). It is difficult to envision that amino acids are the sole contributors to home stream odor in more complex ecosystems because they are ubiquitous and their concentrations change with time and location. Suggestions that bile acids that originate from fish contribute to home stream odor (Døving et al. 1980) are intriguing, especially because they are detected by fish olfactory systems with great sensitivity and specificity. However, they are relatively generic and vary little among species (Sorensen, unpublished). Complex mixtures that contain many classes of chemicals are most likely to be important. Even for the relatively simple sea lamprey, mixtures are important. Using bioassay-guided fractionation, Sorensen et al. (2005) discovered three new sulfated steroids—petromyzonamine disulfate, petromyzosterol disulfate, and petromyzonol sulfate—that are released by larval lamprey and attract adults at concentrations below 10^{-13} M. All three components stimulate the olfactory system with great specificity, and while they will attract migratory adults on their own, they synergize each other's actions, especially in the context of stream water (Sorensen et al. 2003). Other unidentified minor components exist in this mixture (Fine et al. 2004, unpublished). Why the ancient and relatively simple lamprey has evolved a multi-component pheromone is unclear, but it may relate to the challenges they face in locating home streams at great distances.

The vast majority of fish species appear able to detect and discriminate sex steroids and F-series prostaglandins as hormonal pheromones (Stacey and Sorensen 2005). Indeed, the olfactory systems of dozens of species from a variety of taxa (cyprinids, salmonids, and gobids) are able to detect hormonal products with high sensitivity and specificity, and in about half a dozen instances, biological responses have been noted as well (Stacey and Sorensen 2005). Critical to the detection of sex steroids is the number of carbons in the steroid nucleus, absence or presence of a conjugating group, and side-chain position and structure (Sorensen et al. 1990; Stacey and Sorensen 2005). Most sex steroid products are relatively common, and for the most part, species from the same genus share the same sensitivities. Thus, sex steroids alone cannot be responsible for species specificity. To date, only prostaglandin F2α and its immediate metabolites have been shown to be especially active stimulants for an entire taxonomic group (e.g., minnows; Stacey and Sorensen 2005). We speculate that signal specificity resides with contextual cues such as body odor and acute sensitivity to the composition of odorant mixtures,

To address how fish employ sex pheromones, we briefly review the goldfish, the best understood example. Similar to many external-fertilizing temperate freshwater fish, goldfish ovulate in the spring in response to a surge in a luteinizing hormone, which triggers a series of gonadal hormonal surges whose by-products function as potent sex pheromones. This system may have evolved because males that could predict female spawning by detecting released hormonal metabolites had a reproductive advantage. Three sets of female cues are known. The first is released by mature females and is associated with estradiol (Kobayashi et al. 2002). The second is released 12 h before spawning by ovulatory females and functions as a preovulatory primer with endocrinological actions. This pheromone is comprised of a mixture of at least two common sex steroid hormones, androstenedione and 17,20β-dihdroxy-4-pregnen-3-one (17,20βP), and one metabolite, 17,20β-dihdroxy-4-pregnen-3-one-20-sulfate (17,20βP-S), the ratio of which shifts during the course of the reproductive cycle during which time dozens of steroids are released (Sorensen and Scott 1994). All three components are potent olfactory stimulants and detected by different, specific receptor sites. Male fish identify these chemicals as a mixture and exhibit a strong endocrine response (leading to sperm production) when 17,20βP is highest and a behavioral response when 17,20βP-S is highest (Sorensen et al. 1995; Poling et al. 2001). The third, post-ovulatory pheromone is a mixture of

F prostaglandins that is released by ovulated females in their urine in pulses, thus suggesting that odor concentration and context are also important to cue function (Sorensen et al. 1988; Appelt and Sorensen 2007). Recent data also suggest that cue specificity is determined by critical but unknown components in goldfish body odor, for if this odor is modified, responses to hormonal pheromones are greatly reduced (Sorensen et al. 2000). The reliance of goldfish on common hormonal mixtures together with context is so striking that we believe that this strategy is probably commonplace in fish.

Finally, several studies have investigated the chemistry of alarm signals, without clear resolution. Hypoxanthine-3-*N*-oxide, peptides, purines, proteins, and their mixtures have all been suggested to function as alarm signals (Brown et al. 2000, 2003; Døving et al. 2005). Some evidence exists that mixtures of nitrogen oxides may mediate alarm responses in somewhat taxon-specific manners (Brown et al. 2003), but data on release of these chemicals by fish and chemosensitivity to them are lacking.

In summary, substantial subsets of various metabolic products, some specialized and most not, are identified by fish olfactory and gustatory systems as meaningful chemicals that are then used to mediate an array of behaviors. Other unidentified chemicals are undoubtedly important. These stimuli occur and only have biological relevance as mixtures.

Crustaceans

Feeding stimulants are some of the most studied and best understood molecules in the chemical ecology of crustaceans. Trophic level accounts for some of the differences in the identity of feeding stimuli of crustaceans. Carnivores such as lobsters (*Homarus*) and spiny lobsters (*Panulirus*) respond best to small, nitrogen-containing compounds that are prevalent in tissues of their animal prey. These compounds include many that are also feeding stimulants for fish, including amino acids, amines, nucleotides, and peptides (Zimmer-Faust and Case 1982a; Carr 1988; Derby and Atema 1988; Zimmer-Faust 1993). Carnivorous crustaceans are relatively insensitive to carbohydrates and sugars. Herbivores and omnivores, such as fiddler crabs, ghost crabs, kelp crabs, and crayfish, are often sensitive to sugars common to plants, bacteria, and diatoms, as well as to some amino acids (Robertson et al. 1981; Zimmer-Faust and Case 1982b; Trott and Robertson 1984; Weissburg and Zimmer-Faust 1991; Archdale and Anraku 2005; Corotto et al. 2007). Selection of food by crustaceans is also controlled by the presence of feeding deterrents, yet the molecular identity of these deterrents is much more poorly understood than for the stimulants. An example of identified feeding deterrents is in crayfish, which are deterred from ingesting plants that contain phenylpropanoid-based natural products and a C-18 acetylenic acid (Prusak et al. 2005; Lane and Kubanek 2006; Parker et al. 2007).

Larval settlement factors have been studied with great interest for decades due to their economic impact. Therefore, the recent molecular identification of the factor was highly anticipated and gratefully received (Dreanno et al. 2006a, b). The bioactive molecule is a 169-kD glycoprotein called settlement-inducing protein complex, which has 30% similarity to α_2-macroglobulins. The observation that small and specific peptides evoke settlement (Rittschof and Cohen 2004) makes sense in light of knowing the identity of the protein.

Sex pheromones in crustaceans also have been intensely investigated but without much success in identifying the active molecules. The pheromone used by male copepods (*Tigriopus japonicus*) to recognize females has been partially characterized—and interestingly, it too has similarity to α_2-macroglobulin (Ting and Snell 2003). Efforts to identify sex pheromones in decapod crustaceans, such as crabs, crayfish, clawed lobsters, and spiny lobsters, have not led to the conclusive identification of the molecular structures (Gleeson 1991; Asai et al. 2000; Hardege et al. 2002; Kamio et al. 2002, 2006; Atema and Steinbach 2007). Efforts to identify pheromones on these and other species continue (J. Hardege, personal communication; M. Kamio, personal communication).

Plasticity

The Importance of Plasticity

The ability to adaptively modify chemically mediated behaviors through experience is critical to the survival of most animals. This is particularly true for animals that are long-lived, mobile, and omnivorous, which is the case for many fish and crustaceans. Plasticity occurs in several contexts in chemoreception of fish and crustaceans, including selection of food, social interactions with conspecifics, and even in responses to pheromones. Some examples are given in the next sections.

Fish

Fishes have well-developed abilities to recognize and learn natural chemical cues. The most impressive example is that of olfactory learning in migratory pacific salmonids, which imprint to bouquets of stream odors during sensitive developmental periods (Dittman et al. 1996). Although this ability is partially attributable to developmental changes in their olfactory epithelia (Nevitt et al. 2004), the ability of

adults to recall olfactory memories many years later presumably involves higher brain centers. Surely pattern recognition is paramount to this process, which appears sophisticated enough that fish can discriminate and remember the presence of trace amounts of chemicals to which they are relatively insensitive, such as morpholine for salmon (Hasler and Scholz 1983; Hara et al. 1984). It is also apparent that combinations of odorants can be identified as distinct 'bouquets' that may give the impression of mixture synergism. For example, goldfish cannot be trained to respond to morpholine alone, but they can learn to respond to odorant mixtures that contain morpholine (Dodson and Bitterman 1989). Mixture perception and the ability to learn unique odors clearly are important to place location in salmon, which do not have a particularly notable olfactory system from an anatomical perspective. Presumably, other fishes are similar, as suggested by the examples of food recognition in pinfish and sex pheromone discrimination in goldfish. Glomerular processing in the olfactory bulb probably plays a role in this process as described below.

Feeding studies also provide evidence of the ability of fish to discriminate and learn complex chemical mixtures. Fishermen and behavioral ecologists enumerate examples of fish that develop the ability to recognize and select especially desirable food items as their abundance fluctuates (Jones 1992). Olfaction plays a major role in this process. For example, responses of yellowfin tuna to prey odors shift as their diet changes (Atema et al. 1980). Ablation studies suggest that olfaction alone mediates this response through formation of 'chemical search images' (Atema et al. 1980). In this case, olfaction appears to guide arousal and search, and vision assumes the final role of food location. In other species, gustation rather than vision plays the consummatory role. This plasticity does not signify a lack of innate predisposition to respond to particular types of prey. There are several anecdotal examples of naive young fish responding to specific food items (Jones 1992), a phenomenon once termed 'specific appetite,' which may be a gustatory attribute (see below). The interplay between these senses warrants specific investigation by using natural cues.

Not surprisingly, laboratory studies of associative and instrumental learning show that some fish are adept at learning to discriminate among different amino acids. The channel catfish is the best understood in this regard, and many studies demonstrate its ability to learn to discriminate among amino acids when presented individually or in mixtures (Valentinčič et al. 2000; Valentinčič 2005). Channel catfish can identify binary mixtures as unique entities and as the sum of their components. Other studies suggest that channel catfish can discriminate mixtures that contain up a half a dozen amino acids (Valentinčič 2005), an important ability in the natural world where feeding stimuli are complex. While two behavioral studies suggest these abilities are mediated by the olfactory system alone (Atema 1977; Valentinčič and Caprio 1994), another that used different techniques suggests that fish can learn to recognize single amino acids via their external gustatory system (Holland and Teeter 1981). Nevertheless, many young fish that have not fed before respond to individual amino acids with increased biting and swallowing, suggesting at least that the internal gustatory system is innately responsive (Jones 1992; Valentinčič and Caprio 1997; Hara 2007). Catfish also can learn to avoid eating palatable food items that have been previously associated with distasteful chemicals (Little 1977). Olfactory-blocked goldfish can be trained to preferentially acquire more nutritious food (Bitterman 1982) and to touch funnels through which amino acids are injected, although in the latter case, their sensitivity is reduced (Zippel et al. 1993). In summary, the roles of olfaction and gustation in feeding can differ with the former being more flexible. However, how experience modifies responsiveness to natural odors is incompletely known at present.

Finally, a few studies suggest that olfaction can mediate learning to a wide variety of relevant stimuli. For example, wild minnows recall the odor of predators more than 1 year after experiencing them (Smith 1992). Goldfish may be able to associate simple organic molecules, acids, and even steroidal sex pheromones with feeding (Zippel et al. 1993; Sorensen 2007).

Crustaceans

Crustaceans provide many interesting cases of experience-dependent plasticity and learning (Krasne 1973), including several varieties of chemosensory learning. These include habituation, classical and operant conditioning, aversive associative learning, and one-trial flavor avoidance learning (Abramson and Feinman 1988; Daniel and Derby 1988; Fine-Levy et al. 1988; Wight et al. 1990; Derby 2000; Shuranova et al. 2005). Such learning can influence the selection of food by crustaceans.

Learning is involved in identifying and remembering the odor of conspecifics, including individual recognition in crayfish, lobsters, hermit crabs, and mantis shrimp (Caldwell and Dingle 1985; Karavanich and Atema 1998; Breithaupt and Atema 2000; Hazlett 2003; Gherardi et al. 2005; Atema and Steinbach 2007). The formal nature of this learning has not been fully characterized, but memories of these odors can last for many days.

Experience can also influence selection of hosts by commensal crabs (Derby and Atema 1980). This ability might be useful for these crabs to relocate hosts after leaving them to mate.

The ability of spiny lobsters to learn food odors has been explored intensively, largely within the context of defining the neural basis of olfactory discrimination of mixtures (Derby 2000; Derby et al. 2001). Spiny lobsters are able to learn to associate food odors with danger and subsequently to avoid searching for those odors. Differential conditioning shows that spiny lobsters can learn to discriminate chemical mixtures that differ only in the ratios of their components. They can remember these odors and perform discrimination tasks for several days (Fine-Levy et al. 1988).

A form of plasticity in chemical communication in blue crabs has recently been demonstrated (Kamio et al. 2008). This is not experience-dependent plasticity but context-dependent plasticity. In this case, male crabs detect reproductive females, move toward them, and quickly pair-bond with them if they are immediately accessible. If they can sense but not grab the female, however, the males will perform a courtship display behavior that directs his pheromone toward her. This context-dependent chemical signaling is a form of behavioral plasticity that should enhance reproductive success.

Processing of Natural Chemical Stimuli

Many studies of neural processing in fish and crustaceans have used natural products and their components as chemical stimuli. Tested stimuli include single compounds of known biological importance and synthetic mixtures of these components in varying degrees of complexity (Derby 2000; Valentinčič 2005). Much is known about processing of individual food-related chemicals because their molecular identity is defined. Coding of natural products other than food has been less thoroughly examined for sex pheromones and chemical deterrents. Little work has been conducted on natural mixtures. In this section, we describe the organization of the chemosensory systems of fish and crustaceans, and how they code natural stimuli.

Fish

The olfactory and gustatory systems of fish are distinctly different senses that mediate different aspects of chemical recognition and drive different behaviors. Olfaction, not gustation, is used to identify and locate pheromones. On the other hand, both olfaction and gustation mediate aspects of feeding, though the specific roles of each appear to depend on the species, feeding experience, and other factors. Information from the olfactory and gustatory systems is probably integrated at higher neural levels, driving what to an outside observer might seem to be a single continuum of behaviors. Exactly where this occurs in the brain is not yet known. Here, we describe the neurobiology of these systems, elements of which are recently reviewed by Caprio and Derby (2007), with the aim of outlining how natural chemical mixtures are perceived by fish.

The basic neural structure of the fish olfactory sense is fundamentally similar to that of other vertebrates. It is comprised of three elements: olfactory receptor neurons (ORNs) located in the olfactory epithelium, glomeruli in the olfactory bulb into which ORNs converge, and output neurons (mitral cells) that convey information from the glomeruli to the forebrain where further processing occurs (Michel 2006; Caprio and Derby 2007). Fish have three major types of ORNs: ciliated, microvillar, and crypt cells. These cells express particular types of olfactory receptor molecules, second messengers, channels, and other molecules associated with transduction, suggesting that they have specific and different roles. Current evidence suggests that microvillar cells detect amino acids and that ciliated cells detect all other cues and perhaps some amino acids. Nevertheless, the coding of olfactory information commences with the olfactory receptors, which are seven-transmembrane G-protein linked proteins, and the receptor cells containing them (Caprio and Derby 2007; Saraiva and Korsching 2007). Although the process of receptor discovery is ongoing, fish species are thought to express over 100 members from three families of receptors (ORs, V1Rs, and V2Rs; Ngai et al. 1993; Saraiva and Korsching 2007). Of these, only one class has been functionally expressed to date. It detects amino acids, with a specific bias to arginine, and its activity can be predictably altered with site-directed mutations (Luu et al. 2004). The current view is that fish olfactory systems encode most chemical stimuli by using a combinatorial code, whereby particular attributes of molecules are discriminated by the activity of specific combinations of receptors, the pattern of which conveys identity of the molecules. Such a code should be both versatile and specific, but it would require neural mechanisms capable of encoding complex patterns of receptor binding—an attribute of the olfactory bulb. In addition to a combinational scheme for identifying general odors, such as those associated with food, a simpler scheme based on one or a few receptor types may be used to identify sex pheromones (Friedrich and Korsching 1998; Sorensen and Sato 2005).

All ORNs that share the same receptor type converge on the same glomeruli in the olfactory bulb, where the neural signal is enhanced and modulated by interneurons that extend from other glomeruli or by centrifugal input from higher levels of the central nervous system. Because glomeruli with similar chemosensitivity are located close to each other, the result is a systematic three-dimensional chemotopic map of chemical identities across the bulb (Friedrich and Korsching 1998; Nikonov and Caprio 2001). Odorants such as sex pheromones appear to be detected by fewer, specialized neurons (Friedrich and Korsching 1998),

although electroencephalogram recordings from goldfish bulb suggest that these units receive significant inhibitory input (Hanson 2001), so they are not true 'labeled lines.' Indeed, glomeruli in the olfactory bulb are extensively interconnected, as mitral cells project to more than one glomerulus and local interneuronal connections are extensive. Thus, there is considerable potential for complex but orderly processing of mixture information, perhaps from multiple classes of odorants, in the fish olfactory bulb (Hara 1970), likely creating distinctive olfactory 'fingerprints' for natural odor sources including conspecifics, as occurs in the mouse (Schaefer et al. 2001)

Chemical information is passed from the olfactory bulb to the forebrain through a series of lateral and medial olfactory tracts whose functions have been studied in the carps by using single odorants, as described below. Behavioral and electrophysiological studies in the goldfish show that the medial tracts convey sex pheromone information (Stacey and Kyle 1983; Sorensen et al. 1991), and the lateral tracts convey amino acid and food odor information (Stacey and Kyle 1983; Hamdani et al. 2001). Responses to alarm cues appear to be conveyed by special parts of the medial tract in the closely related crucian carp (Hamdani et al. 2000). Interestingly, some amino acid information is also conveyed by the medial tracts in the goldfish (Sorensen et al. 1991), suggesting that amino acids might be perceived as part of the background body odor component of pheromones. The forebrain of catfish contains a chemotopic map (Nikonov et al. 2005). Connections from the forebrain to higher brain regions would allow integration of olfactory information with that from visual and other systems, including gustatory, as is required for driving multimodal behaviors such as feeding and mating. In summary, the olfactory system contains a network of connections that encodes the identities of complex odor mixtures and perhaps their concentrations in highly precise manners that should permit learning and memory. Tests of natural odors are now needed to ascertain the full potential of this system and whether it can explain all of the behaviors observed in wild animals to natural stimuli.

The anatomy and neural functions of the gustatory system in fish are remarkably different from the olfactory system except that the chemosensitivities of the two overlap for food stimuli. These differences emphasize what seem to be important distinctions in their respective roles in food procurement. Gustation is mediated by taste buds, groupings of receptor cells that are derived from epithelial tissue. These cells synapse onto primary gustatory neurons, with each neuron typically receiving input from cells in many buds. Several classes of genes for gustatory receptors have been cloned in fish (Ishimaru et al. 2005), and their chemosensitivity is beginning to be understood (Oike et al. 2007). Some taste cells express more than one type of receptor, which distinguishes them from olfactory cells (Ishimaru et al. 2005). The expression and connectivity properties of taste cells result in gustatory fibers that respond to multiple classes of chemical stimuli but still with specificity. Responses are concentration-dependent, and stimulus quality seems to be encoded by overall firing rate. There is no evidence of special processing of mixture information (Caprio and Derby 2007). Taste bud abundance and distribution vary enormously with fish species, especially for the external gustatory system (facial nerve; VII), which innervates the barbels (if present) and/or the lips, and projects to the highly structured facial lobe. Taste buds in the oropharyngeal cavities and gill arches of all fish are innervated by the vagal (X) and glossopharyngeal nerves (IX), which project to the vagal lobe and other regions of the hindbrain. This topographic mapping scheme appears to reflect an emphasis on processing the spatial distribution of chemical concentrations, an attribute correlated with catfish's ability to track chemical plumes by using gustation alone (Bardach et al. 1967). Similar topographic maps are found in the carp vagal lobe and appear to mediate food sorting in the mouth (Finger and Morita 1985; Finger 2008). Swallowing and ingestion do not appear to be highly specific processes, as most detected amino acid will evoke the response (Caprio and Derby 2007).

In summary, the olfactory and gustatory systems are both designed to process natural chemical mixtures but in quite different manners. While olfaction is organized to adaptively integrate information associated with a wide range of chemical stimuli for various functions, gustation is specialized for sensitivity and localization of food source. Tests of the natural function of these neural systems in free-swimming animals to complex, natural stimuli await. It will be particularly important to examine function in species other than catfish, which are somewhat unusual in their possession of a highly developed and broadly tuned external gustatory system but for which sex pheromones are not yet available for testing.

Crustaceans

A Diversity of Organs Mediating a Diversity of Behaviors The chemical sensors of crustaceans differ in their sensillar organization, central connections, and behavioral role. One pathway that is conserved in many crustaceans is that of the aesthetasc sensilla and olfactory lobe. This is considered an 'olfactory' pathway because the aesthetascs are innervated only by chemosensory (and not mechanosensory) neurons and because of structural similarities with the insect and vertebrate olfactory pathways (Schachtner et al. 2005). All other sensilla that contain chemosensory neurons also contain mechanosensory neurons. But these bi-modal

chemosensilla are extremely diverse in structure, are distributed differently across the animal's body surface, and serve different behavioral functions. This suggests that crustacean chemoreceptors cannot be categorized according to a dichotomous olfactory–gustatory classification.

Functions of Different Chemosensory Pathways Together, the diverse chemosensors across the body of crustaceans gather information about conspecifics, predators, attractive and defensive properties of prey, and more. These sensors connect differentially within the central nervous system, leading to the control of different aspects of behavior. The olfactory (aesthetasc) and gustatory pathways differ in the behaviors controlled. In spiny lobsters, the antennules drive detection of and orientation to distant, attractive chemicals, including food-related chemicals and intraspecific chemicals such as aggregation or alarm cues (Derby et al. 2001; Horner et al. 2004, 2008b; Shabani et al. 2006). In blue crabs, however, leg chemoreceptors can play a major role in mediating orientation to distant odors, as the wide spacing between legs on the animal's two sides provides spatial information that helps the crabs locate the plume's boundaries (Keller and Weissburg 2004). In lobsters, chemosensors on the legs of lobsters are used to locate food once the animal has reached the source (Derby and Atema 1982). Mouthpart chemoreceptors then assess the food for phagostimulants and phagodeterrents that lead to its ingestion or rejection (Derby and Atema 1982; Derby et al. 2001; Garm et al. 2005; Kicklighter et al. 2005; Garm and Høeg 2006).

The antennules are the most intensively studied of all of the crustacean chemosensory pathways. The two major antennular chemosensory pathways—the aesthetasc/olfactory lobe pathway and non-aesthetasc/lateral antennular lobe pathway—of spiny lobsters have some functional redundancy: Both assess the quality of food, both mediate olfactory learning, and both enable orientation to distant food odors (Derby et al. 2001; Steullet et al. 2001, 2002; Horner et al. 2004). Unique functions of the aesthetasc pathway include encoding intraspecific cues used in sexual and social interactions (Gleeson 1982, 1991; Johnson and Atema 2005; Horner et al. 2008a, b). Unique functions of the non-aesthetasc pathway include mediating antennular sensory-motor tasks. One example is the class of non-aesthetasc sensilla—the asymmetric sensilla—that are necessary and sufficient for mediating chemically evoked antennular grooming behavior (Schmidt and Derby 2005). Detectors of pheromones and social cues are not exclusively located in the aesthetasc/olfactory pathway, however. For example, male crayfish have sensors on their claws that detect female odors (Belanger and Moore 2006).

How are mixtures coded by the peripheral olfactory system of decapod crustaceans? Information about different classes of chemicals is carried by different types of chemoreceptor neurons (CRNs). CRNs have different specificities, with some being most sensitive to one or several amino acids, others most sensitive to one or several adenine nucleotides, others most sensitive to ammonium ions, and so on (Voigt and Atema 1992; Derby 2000; Garm et al. 2005). Single CRNs can be stimulated by compounds that belong to different classes of molecules. For example, taurine-best CRNs can also be sensitive to other amino acids, AMP, ammonium, and other compounds, although the thresholds for taurine are 100 to 10,000 times lower than other stimuli (Cromarty and Derby 1997). Stimulus quantity, at least for food-related chemicals and their mixtures, is coded by CRN population responses or across-fiber patterns rather than labeled lines (Derby 2000; Caprio and Derby 2007). Such codes enable discrimination of highly similar mixtures, such as binary mixtures or 30+ component mixtures that contain the same components but at different blend ratios (Steullet and Derby 1997; Derby 2000; Derby et al. 2001).

Our understanding of how crustaceans process sex pheromones, social cues, anti-feeding compounds, and other chemical stimuli besides feeding stimulants is in its infancy. Not knowing the identity of these bioactive molecules is a major reason, and such identification is urgently needed. One example of how chemical defenses are processed is a set of recent studies on spiny lobsters' responses to defensive secretions of sea hares (Kicklighter et al. 2005; Kamio et al. 2007). The studies suggest that these secretions function by 'phagomimicry,' in which the defensive secretion stimulates the feeding pathway to deceive spiny lobsters into attending to a false food stimulus, and by sensory disruption, in which the sticky and potent secretions cause high-amplitude, long-lasting sensory stimulation. Distasteful feeding deterrents also occur in these secretions, although their identity and neural processing are just now being studied (Kamio et al. 2007). Thus, chemical defenses may act in complex ways, even against a single predatory species.

General Conclusions and Future Directions

The chemical milieu of aquatic environments shapes how animals living there perceive their chemical world. Our paper discussed the chemosensory abilities of two major groups of aquatic animals—fish and crustaceans—within the context of the chemical ecology of the aquatic environment. Fish and crustaceans use chemoreception in many of their inter- and intraspecific interactions, including identifying and locating high-quality food, mates, and

suitable habitat and shelters, avoiding predators and low-quality or toxic food, and interacting with conspecifics in social and agonistic encounters. The compounds that mediate these interactions are diverse but typically are mixtures of small, water-soluble compounds. The responses of many fish and crustaceans to some chemicals are somewhat hard wired, but others, particularly for species that live in complex and diverse habitats, and may live for decades, show enormous plasticity. Aquatic animals have a diversity of chemical senses to detect these chemicals, including but not limited to those that can be placed into the classical categories of 'olfaction' and 'gustation.' In general, olfactory systems are well adapted for discrimination of complex stimuli, and gustatory systems control proximate identification, location, and ingestion of palatable food and rejection of distasteful or toxic food.

A conceptualization of the approaches to studying the chemical ecology of chemoreception is presented in Fig. 1. Individual disciplines can be used to make important contributions. For example, current techniques in analytical chemistry can determine what molecules are present in organisms and their environment and, thus, might serve as chemical cues or signals. Neuroscience brings molecular, cellular, and systems level analyses that can be used to ascertain what chemicals are detected, as well as mechanisms of reception and integration of these chemicals. Ethology allows evaluation of the behavioral relevance of detected chemicals. Evolutionary ecological approaches allow investigations of phylogenetic relationships, and how the habitat in which organisms live can influence the nature of their chemical senses. Reliance upon only one of these approaches can lead to, at best, partial understanding of a system and often leads to misunderstandings. We and others (e.g., Zimmer and Derby 2007; Zimmer and Zimmer 2008) advocate using multiple approaches and working at the intersection of these disciplines using the integrated approaches of neuroethology, neuroecology, and chemical ecology.

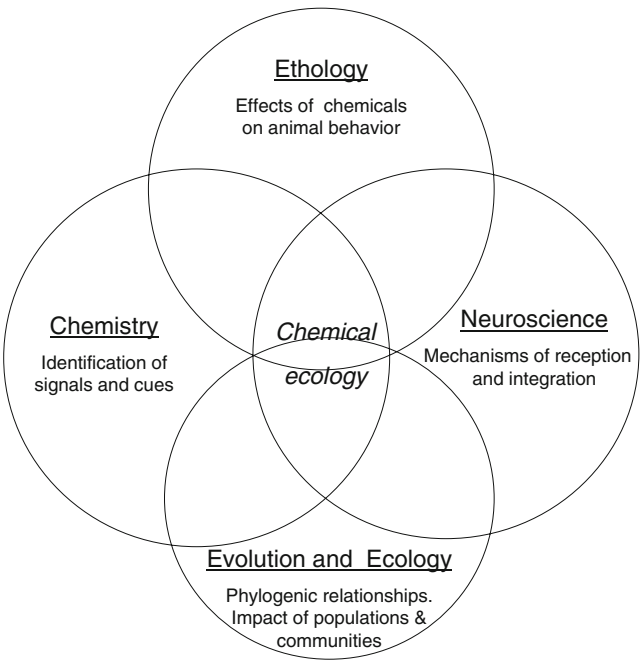

Fig. 1 A visual depiction of approaches to the study of chemical ecology. Disciplinary approaches are shown in the *circles*. We advocate using integrated and multidisciplinary approaches to most effectively understand issues in chemical ecology. See the text for further explanation

Although our understanding of neural processing of fish and crustaceans has advanced in recent years, we still have many challenges facing us. We have almost no information on how entire categories of chemicals are processed. For example, how pheromones and other intraspecific cues are processed by crustacean nervous systems is virtually unknown, and scant information exists for fishes. In the former case, this is largely a result of not knowing the molecules involved. In general, our knowledge of the identity of ecologically relevant chemicals is limited to a few contexts (especially feeding) and a few species (often the commercially important ones). However, with the advent of sensitive and sophisticated analytical chemical equipment and techniques, the challenge of identifying bioactive chemicals is not nearly so daunting, and we expect major advances to be made in this area.

Advances in molecular techniques also have given us tools to elucidate mechanisms of sensory processing. These tools have helped in identifying olfactory and gustatory receptors and other molecules involved in sensory transduction, especially in animals whose genomes have been sequenced, most notably zebrafish (Oike et al. 2007; Saraiya and Korsching 2007). The first crustacean with a sequenced genome is *Daphnia pulex* (Colbourne et al. 2005; see Daphnia Water Flea Genome Database at http://wfleabase.org), which provides a useful tool for studying the chemical senses of this and other crustaceans. Nonetheless, having a sequenced genome for a more established model organism, such as a decapod crustacean, will be a prized contribution. In the meantime, other molecular tools will have to suffice to identify molecules involved in chemical sensing (McClintock et al. 2006). Advances in methods of simultaneously recording from ensembles of neurons by using multielectrode arrays or imaging with voltage- and calcium dyes opens up exciting possibilities for understanding how sensory systems process and discriminate mixtures.

On a final note, we urge that mechanistic approaches to the study of chemical sensing be applied within the framework of chemical ecology and with an eye toward broader contributions of this type of work. What we learn about neural processing of ecologically and economically important

species, such as salmon, lamprey, lobsters, and crabs, can and should have broader applications to be used by community and systems ecologists and fisheries scientists.

Acknowledgment We thank our many colleagues who have contributed to work in this field. We also thank our current funding sources for support during preparation of this review (NIH DC00312, NSF IBN-0614685, Legislative Citizen Commission for Minnesota Resources, and the Minnesota Agriculture Experiment Station).

REVIEW ARTICLE

Central Processing of Natural Odor Mixtures in Insects

Hong Lei · Neil Vickers

Received: 27 September 2007 / Revised: 10 April 2008 / Accepted: 21 April 2008 / Published online: 25 June 2008

Abstract In nature, virtually all olfactory stimuli are mixtures of many single odorants. Behavioral experiments repeatedly have demonstrated that an animal's olfactory system is capable of discriminating behaviorally relevant from irrelevant odor mixtures. However, the sensory mechanisms that underlie such discriminative capability remain elusive. The limited anatomical and physiological evidence collected from both insect and vertebrate models that pertains to this topic is scattered in the literature dating back to early 1980s. Thus, a synthesis of this information that includes more recent findings is needed in order to provide a basis for probing the fundamental question from a new angle. In this review, we discuss several proposed models for mixture processing, along with experimental data gathered from both the initial stage of olfactory processing (i.e., antennal lobe in insects or olfactory bulb in vertebrates) and higher areas of the brain, with an emphasis on how the lateral circuits in the antennal lobe or olfactory bulb may contribute to mixture processing. Based on empirical data as well as theoretical modeling, we conclude that odor mixtures may be represented both at the single-neuron level and at the population level. The difference between these two types of processing may reside in the degree of plasticity, with the former being hard-wired and the latter being more subjected to network modulation.

Introduction

Virtually all organisms are capable of detecting and orienting to chemical stimuli. For many animals, odorous signals represent a rich source of information about the environment. Odorant molecules are detected by peripheral sensory cells and transduced into electrical potentials that can be conveyed to central processing structures in the brain. Over the past 20 years, there has been a rapid expansion of our knowledge of the olfactory system both at the peripheral and central levels. In this review, we focus on the coding of olfactory stimuli that occurs within the central nervous system. We discuss how the brain utilizes its anatomical resource to organize peripheral inputs and how this facilitates the recognition and discrimination of behaviorally relevant odor blends. A variety of approaches have been employed to investigate the neural basis of olfactory coding in insects. These include single-cell electrophysiology, multi-unit recording, and population-level studies that use voltage or calcium-sensitive dyes. In some instances, these neurobiological paradigms have been augmented by the use of modeling. We consider the evidence that these different techniques have provided for various coding schemes with a primary focus on insect systems. Where informative, comparisons between olfactory information processing in vertebrate and invertebrate systems are made.

Encoding Odor Mixtures at the Early Stage of Central Processing

Environmental odorous signals such as sex pheromones and volatiles emitted from a flower are first detected by olfactory receptor cells (ORCs) located at the periphery and then processed in central circuits across multiple synaptic levels, ultimately leading to specific olfaction-based behaviors. Unlike the pheromone-responsive ORCs that are strictly tuned to single pheromone components (but see Takanashi et al. 2006), ORCs that respond to plant odorants can be classified roughly into two categories, narrowly tuned or broadly tuned, when comparing their response spectra (Hansson et al. 1999; Hillier and Vickers 2007; Hillier et al. 2006; Rostelien et al. 2000; Shields and Hildebrand 2001a, b). Depending on the chemical identity, some plant odorants may activate a few specialized types of ORCs, whereas others may activate a large group of ORC types. ORCs that express the same olfactory receptor protein converge onto a single glomerulus in the antennal lobe (AL) of insects or olfactory bulb (OB) of vertebrates, the first processing stage along the olfactory pathway (Mombaerts et al. 1996; Ressler et al. 1994; Vosshall et al. 2000), thus extending the diversity of ORC tuning properties to the AL circuitry that includes glomerular output neurons or projection neurons (PNs) that are the equivalent of mitral/tufted (M/T) cells in OB.

Natural odor stimuli are almost always mixtures of numerous single components at certain concentrations and relative proportions, e.g., floral volatiles emitted from a flower. Detection, encoding, and discrimination of such complex stimuli are important functions for an animal's olfactory system. The anatomical organization of olfactory systems determines that information about natural odor stimuli is first deconstructed by the receptor array located at the periphery, then processed and distributed in the circuits of OB/AL, and finally reconstructed as a unitary odor percept at second- or higher-order synaptic centers, such as the olfactory cortex in vertebrates or the lateral protocerebrum in insects (Davis 2004). Little is known about the mechanisms by which the distributed information channels are combined to produce a perceived image of an odor mixture. In the following sections, we discuss several possibilities regarding mixture-coding mechanisms based on recent advances mainly in insect olfaction research but inevitably including some vertebrate literature.

Elemental and Configural Processing of Odor Blends

Overwhelming evidence from animal taxa ranging from insects to mammals indicates that a basic function of ORCs is to analyze the chemical composition of a natural odor by transforming the information of a complex chemical mixture into the combinatorial activation patterns of different types of ORCs, i.e., a so-called receptor code (Duchamp-Viret et al. 2000; Hallem and Carlson 2006; Korsching 2001; Ma and Shepherd 2000; Touhara 2002; Yao et al. 2005). Once the information about an odor mixture is distributed into different ORC channels, a process of regrouping all or a subset of these channels would conceivably create a unique perception of the original blend. This regrouping process may occur as early in processing pathway as the OB/AL.

The insect AL and vertebrate OB consist of a species-specific number of glomeruli, which collect the converging axonal inputs of ORCs expressing the same olfactory receptor protein (Mombaerts et al. 1996; Vosshall et al. 2000). The combinatorial receptor-code for odors is, therefore, also transmitted to the first processing stage and represented by odor-specific patterns of glomerular activity (Malnic et al. 1999). Imaging studies in both vertebrates (Friedrich and Korsching 1998; Rubin and Katz 1999; Uchida et al. 2000; Meister and Bonhoeffer 2001; Fried et al. 2002) and insects (Joerges et al. 1997; Galizia et al. 1999; Wang et al. 2003; Skiri et al. 2004; Carlsson et al. 2005) have provided ample evidence that supports this view. However, only a handful of physiological studies have been conducted to compare specifically the glomerular-activity patterns evoked by odor blends with that by the blend constituents. Nonetheless, it is generally accepted that for survival, animals must be able to discriminate behaviorally important odor mixtures, which may vary in their composition, blend ratio, and overall concentrations from other similar but behaviorally irrelevant odor mixtures in the animal's environment.

A general model to describe how an animal's olfactory system discriminates odor blends relates to information processing of blend constituents. A binary blend (A+B), for example, may be perceived as a linear summation of the individual representation for A or B alone or as a non-linear integration of the individual representations that discards information about the individual components but gives rise to a new percept of the odor mixture. The former type of processing has been labeled dissociative, analytical, or elemental and the latter associative, synthetic, or configural (Westbrook and Charnock 1985; Erickson et al. 1990; Alvarado and Rudy 1992; Kay et al. 2003, 2005). Elemental and configural processing are not mutually exclusive. Therefore, central processing of an odor mixture may result in a unique representation, while still preserving information about single components.

Evidence from Single-Cell Studies Evidence from several lines of research has revealed that the elemental and/or configural processing of odor blends may occur at the earliest processing stage of olfactory pathway (the OB or

AL). In the OB of the channel catfish, extracellular recordings have shown that most of the OB neurons respond to binary mixtures in a way that is similar to one of the components; however, when mixing one excitatory compound with an inhibitory compound, the response to the mixture became less predictable (Kang and Caprio 1995). Component dominancy, a form of elemental processing, also has been reported in a study on rat OB, where 90% of the binary mixtures were found to evoke responses in M/T cells if one of the two components also evoked responses (Giraudet et al. 2002). In a recent electrophysiological study on mouse OB, M/T cells typically responded to the effective compounds presented both as single compounds and in mixtures, although the mixture-evoked responses were often partially suppressed (Davison and Katz 2007). The overall conclusion from these studies was that OB circuits maintain elemental representations of single components when processing odor blends. However, a study on zebrafish OB demonstrated that the M/T cells displayed elemental or configural representations of odor mixtures depending on the compounds that were present in the odor mixture (Tabor et al. 2004). The responses of M/T cells to mixtures of amino acids often were dominated by one of the component responses, i.e., component dominance. In contrast, responses to mixtures of food extracts, which have more complicated compositions than amino acid mixtures, were significantly different from the responses to any of the individual food extracts that comprise the mixtures. This phenomenon was thought to be related to the degree of overlap between the representations of blend constituents (Tabor et al. 2004). In their experiment (Tabor et al. 2004), the food extracts contained many more components than the mixture of amino acids. Afferent inputs to M/T cells were, thus, more overlapping when using a mixture of food extracts versus a mixture of amino acids. With such highly overlapped inputs, the representation of the mixture (food extract 1+food extract 2) became less related to those of the constituents (food extract 1 or food extract 2) due to a strong activation of the lateral inhibitory pathways. Thus, the M/T cells appeared to acquire novel response properties. This model predicts that the more components used to make an odor blend, the less likely the blend representation would be to preserve the identities of the single components—in other words, trending away from an elemental toward a configural representation—because the degree of overlapping representation increases with the number of components. Indeed, results from human psychophysical experiments have demonstrated that discrimination of single components from an odor mixture become nearly impossible when the number of components exceeds 3 or 4 (Laing and Francis 1989; Livermore and Laing 1996). This model also predicts that the perception of odor mixtures should acquire more novel qualities with the increasing similarity of the components. Associative conditioning experiments in rats support this notion (Wiltrout et al. 2003). Animals in this experiment could not reliably identify the components in binary mixtures of similar, but not dissimilar, compounds.

Both elemental and configural representations of odor blends by the second-order output neurons have been reported in the insect AL (Christensen et al. 1989a, b, 1991, 1995; Hartlieb et al. 1997; Anton and Hansson 1995; Wu et al. 1996; Anton et al. 1997). The macroglomerular complex (MGC) of the male moth AL provides advantages in studying this question because it is devoted to processing female-produced pheromone blends, odor mixtures with obvious biological relevance. In the hawk moth *Manduca sexta*, for example, the uniglomerular projection neurons (uPNs) that arborize in one of the MGC glomeruli, the cumulus, show excitatory responses to the converging input from the ORCs that are specialized for one of the major pheromone components (*E*10,*E*12,*Z*14-hexadecatrienal) and show inhibitory responses to the input of another population of ORCs selective for a secondary pheromone component (*E*10,*Z*12-hexadecadienal) that specifically activates an adjacent glomerulus, the toroid (Christensen and Hildebrand 1997; Lei et al. 2002; Heinbockel et al. 2004). When combined, the two-component blend evokes excitatory responses in the uPNs despite the presence of the inhibitory component in the blend, a phenomenon that can be described as "elemental," because the blend-evoked response resembles the component-evoked response (Fig. 1; also see Heinbockel et al. 1999). However, examples of configural processing also have been reported in insect AL. In *Helicoverpa zea* male moths, some AL neurons were found that showed no or weak response to *Z*11-hexadecenal and *Z*9-tetradecenal, but the mixture of these two pheromone components evoked long-lasting-excitation that exceeded stimulus duration six times (Christensen et al. 1991). In contrast, some pheromone-responsive neurons in the AL of male *Agrotis segetum* were excited by each of the four pheromonal compounds but inhibited by the mixture of all these components (Hartlieb et al. 1997). These mixture-selective neurons, however, were not morphologically characterized. Single-cell studies on identified neuron types in the honeybee AL, including the homo-/hetero-local interneurons and uni-/multi-glomerular projection neurons, supported the hypothesis of configural processing of odor mixtures, i.e., responses to mixtures do not resemble the responses to single components. Particularly, mixtures tended to evoke stronger responses on multi-glomerular projection neurons (mPNs) and suppressed responses on uPNs in comparison with single-component-evoked responses on these two types of neurons (Sun et al. 1993).

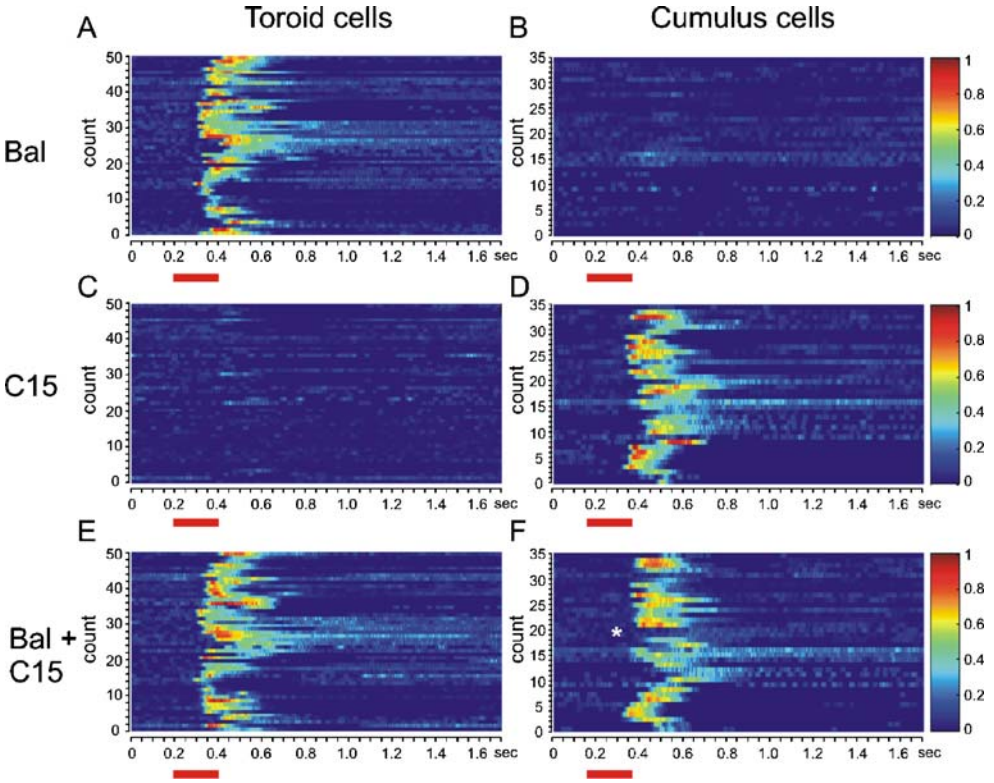

Fig. 1 Response specificity of MGC neurons—50 toroid cells (**a**, **c**, **e**) and 35 Cumulus cells (**b**, **d**, **f**)—recorded from the antennal lobe of male *M. sexta*. Toroid cells showed specific excitatory responses to Bal stimuli (**a**), inhibitory or no response to C15 stimuli (**c**), and excitatory responses to the binary mixture of Bal and C15 (**e**). Similarly, the cumulus cells were specifically excited by the C15 stimuli (**d**) and inhibited or not affected by the Bal stimuli (**b**). The binary mixture evoked responses that were similar to that evoked by C15 (**f**). Both types of cells exhibited elemental processing of the binary mixture, as demonstrated by the similarity of the active-compound-evoked responses and the mixture-evoked responses. However, some cells were exceptional (for example, the few cumulus cells indicated with *asterisk* in **f**), which were responsive to a single component but not to the mixture. The stimulus concentration was not consistent for all cells. The *bar below each panel* indicates the odor stimulation. The response magnitude is normalized to the maximum within cells

What type of neurons are likely the candidates in AL or OB that perform the configural processing of odor blends? Based on discoveries from the honeybee (Sun et al. 1993), we infer that a neuron serving such a function should possess two morphological features: (1) innervation of multiple glomeruli to gather information from different receptor channels and (2) termination at a higher synaptic center to supply the integrated information for further processing. Although no such type of neurons has been found in the OB of vertebrates, mPNs have been described in crustaceans (Wachowiak and Ache 1994) and insects (Homberg et al. 1988; Kanzaki et al. 1989; Stocker et al. 1990; Fonta et al. 1993; Malun et al. 1993; Abel et al. 2001; Ro et al. 2007). In *Drosophila*, unilateral mPNs bypass the mushroom body (MB) calyx, to which the uPNs send collateral branches, and directly terminate in the lateral protocerebrum (Stocker et al. 1990). The mPNs of honeybees, on the other hand, target a variety of places in the protocerebrum, including the MB calyx and the lateral protocerebrum (LP; Fonta et al. 1993). In *M. sexta*, the number of mPNs approximately comprise 50% of the total number of PNs (Homberg et al. 1988). Some of these mPNs densely innervate one or two neighboring glomeruli and send a few branches to other glomeruli nearby, while other mPNs innervate many glomeruli more or less evenly. The morphological characteristics of mPNs strongly suggest that they may play important roles in encoding odor blends.

A reasonable speculation on the response characteristics of mPNs is that they may display differential responses to an odor blend versus the blend constituents presented separately. This assumes that separate ORC populations, each of which encodes a constituent of a blend, send their axonal terminals to different glomeruli innervated by the mPN in question. If the responses of the mPN signal the presence of an odor blend, one should observe a blend-selective response of the mPN. The insect MGC offers an opportunity for studying this question because each glomerulus of the MGC exclusively receives input from ORCs that are tuned to one of the pheromone components. Although limited, some physiological data support the idea

that mPNs encode pheromone blends instead of the blend components. For example, in *A. segetum*, a type of mPN that innervates three subcompartments of the MGC showed no response to any of the four components of the female sex pheromones of this species but was strongly activated by the blend of these four components (Hansson et al. 1994). Similar results were reported in a later study on the same species (Wu et al. 1996) and also in another moth species, *Heliothis virescens* (Christensen et al. 1995). In an antennal transplant experiment that used *H. virescens* and *H. zea*, mPNs innervating multiple subcompartments of MGC responded to the two behaviorally attractive pheromone components as well as to the binary mixture of these components. However, these neurons responded more strongly to the blend and also followed a higher rate of repetitive blend pulses than that of single-component pulses (Vickers et al. 2005). The results from this experiment also indicate that the ORC input dictates the response specificity of the MGC PNs, including both uPNs and mPNs. The physiological responses of mPNs outside the MGC are rarely studied in great detail. An mPN, however, was reported in *Spodoptera littoralis* that innervates several glomeruli in the lateral region of the AL and that responded to two green leaf volatiles, *E*-2-hexenal and octanol (Anton and Hansson 1994). Unlike the cases in the MGC, however, it remains to be seen if these responses were mediated by one or more types of ORCs, thus making it difficult to assess the role of such particular mPNs in blend coding. These results emphasize the need for more systematical studies on the functional roles of the mPNs that innervate the sexually isomorphic glomeruli of the AL.

An important consideration in evaluating various coding strategies concerns the temporal structure of the stimulus itself (Vickers et al. 2001). Odor plumes released by an advertising female moth have an intermittent structure due to eddies and turbulence in the moving air stream. This structure has been shown to have dramatic effects upon the behavioral performance of male moths (Baker 1990; Girling and Carde 2007), presumably due to its advantage in keeping a signal's integrity against noisy chemical background (Liu and Haynes 1992) as well as in preventing sensory adaptation to the signal (Baker et al. 2003). As a consequence of the natural stimulus dynamics, further accentuated by the movement of the male through the plume, pheromone-laden filaments arrive at the antennal surface intermittently. The ability of AL PNs to accurately follow these pulses has important consequences for the behavior of these insects. Existing evidence demonstrates that this ability is enhanced by odor blends (Christensen and Hildebrand 1997; Heinbockel et al. 2004), suggesting that PNs' response dynamics could emerge as a new coding feature that results from the configural processing of odor blends in the AL. The inhibitory inputs to these PNs mediated by GABAergic local interneurons (LNs) are believed to account for the blend-associated response dynamics (Christensen and Hildebrand 1997; Heinbockel et al. 2004).

Owing to the fact that ORCs that express the same type of OR proteins converge onto a single glomerulus where they directly transmit information to uPNs, these AL neurons are expected to inherit the odor information transduced by the ORCs (Wang et al. 2003). The degree of configural processing of odor blends at the ORC level is limited; therefore, the responses of uPNs to odor blends are likely dictated by the effective components in the blend. In other words, uPN response may contain mainly information about single components. However, each glomerulus is a functional information-processing unit rather than merely a relay station. The involvement of LNs in glomerular processing will likely modify the output of uPNs (Olsen and Wilson 2008), either by enhancing or inhibiting uPNs' activity (see below for more details of uPNs receiving information laterally). The mPNs, on the other hand, may receive concurrent inputs from multiple ORC types, which may carry information about constituents of an odor blend. Depending on the arborization pattern of an mPN, none of the ORC types might be able to dictate the mPN's response. The final output of the mPN may be entirely determined by the balance between all concurrent ORC inputs and the result of local processing, thus rendering little similarity to the response evoked by single components alone (Hansson et al. 1994; Christensen et al. 1995; Vickers et al. 2005; Wu et al. 1996).

While the uPNs carry information about the identity of single components, they may still produce responses that contain novel features signaling the presence of an odor blend. Such features are likely the result of glomerular processing that is affected by the stimulation with odor blends. For instance, some uPNs that innervate the MGC of *M. sexta* AL followed stimulus dynamics with greater fidelity when stimulated with the pheromone blend compared to single components, probably because one of the components activated interglomerular inhibition that facilitated the process of repolarization and fast post-stimulus recovery (Christensen and Hildebrand 1997; Heinbockel et al. 2004). Furthermore, in addition to individual responses, uPNs may also collectively develop some group features to encode odor blends. For example, the spiking activities of MGC PNs in *M. sexta* are better synchronized to each other in the context of the pheromone blend (Lei et al. 2002). Interglomerular inhibition may contribute to such enhanced synchrony.

Evidence from Population Studies Are the principles of mixture processing revealed at the single-neuron level maintained at the glomerular level? Results obtained with

various optical imaging methods provide an approximate answer to this question. Because imaging data are usually collected over a large portion of OB/AL surface area, these methods not only allow assessment of the difference in activity level within individual glomeruli in response to odor blends and blend components but also facilitate a comparison of AL/OB-wide spatial patterns of glomerular activity evoked by odor blends with that by single components. The importance of the spatially distributed glomerular-activity pattern in encoding odors has been demonstrated by an increasing amount of evidence from various animal models (Vosshall 2001; Leon and Johnson 2003; Nikonov et al. 2005).

Application of voltage-sensitive dyes on the honeybee AL revealed that in some glomeruli the odor mixtures elicited transient responses, the magnitude of which was approximately the summation of the responses evoked by the individual components of that mixture, and in other glomeruli the mixture-evoked response was reduced; the responses in some glomeruli showed no differences for odor mixture and single components (Galizia et al. 2000). These data suggested that mixture interactions were a glomerulus-dependent phenomenon. An earlier calcium imaging study also in honeybee but using mixtures made from simpler odorants (e.g., citral, hexanol) showed that these mixtures suppressed glomerular responses as compared with the arithmetic summation of the component-evoked responses; and the more components included in a mixture, the stronger the suppression effect (Joerges et al. 1997). Although the validity of using arithmetic summation for studying mixture interactions is arguable (Tabor et al. 2004), mixture suppression was also evident in another calcium imaging study on the honeybee AL where the authors compared the mixture-evoked responses with the strongest response evoked by single components (Deisig et al. 2006). Results from a recent study that used the same technique on a moth AL, however, did not support the conclusion from the honeybee data. The mixture-evoked glomerular responses in *S. littoralis* AL were neither significantly suppressed nor enhanced as compared with the component-evoked responses, a result in favor of elemental processing of odor blends (Carlsson et al. 2007).

The spatial distribution of glomerular response patterns also show evidence of mixture interactions but dependent on odors as revealed by another calcium imaging study (Galizia et al. 1999). Antennal stimulation with a mixture of orange and clove oil odors on honeybees resulted in an activity pattern that was qualitatively different from the pattern predicted from the summation of actions of the individual odors. However, the pattern evoked by the mixture of clove oil and peppermint odors was nearly identical to the sum of the patterns produced by the two odors alone (Galizia et al. 1999). Similarly, two intrinsic imaging studies on mouse OB showed that mixture-evoked glomerular-activity pattern was a simple summation of the individual patterns evoked by the mixture components (Belluscio and Katz 2001; Lin et al. 2006). The most systematic approach along these lines so far was taken in a calcium imaging study in the honeybee, where two salient and two less salient odorants were used to make binary, ternary, and quaternary mixtures (Deisig et al. 2006). Then, the response similarity between mixture-evoked and single-component-evoked responses was quantified by calculating the Euclidean distances between them within a multi-dimensional space defined by all 24 glomeruli activated by the four single components and their mixtures. The results showed that the mixture-evoked response patterns were always more similar to the patterns evoked by salient odorants than to that by less salient (or weaker) odorants—a clear example of component dominance or elemental processing.

Taken together, an interesting picture emerges from these optophysiological studies. First, mixture suppression seems more prominent than mixture synergism (but see Carlsson et al. 2007). This phenomenon may be related to the action of the global and/or local inhibitory network in the insect AL (Lei et al. 2002; Sachse and Galizia 2002). GABAergic LNs are most likely activated upon odor stimulation. The more components included in an odor mixture the greater activation of the LN network and presumably the stronger suppressive effect (Deisig et al. 2006). Second, mixture representations seem to follow more closely the elemental rule of mixture processing. In other words, the response to a mixture may be predicted simply from the response to single components. This phenomenon may be related to the cellular sources that contribute to the calcium signal. Bath application of calcium dye may allow mainly observations on the response dynamics of ORCs (Galizia et al. 1998; Sachse and Galizia 2003) and possible contribution from glial cells (Galizia and Vetter 2004). Since there are limited mixture interactions at the ORC level, the glomerular responses to mixtures appear to be elemental as observed from the calcium dynamics of pre-synaptic terminals. However, this does not exclude the possibility that the glomerular output neurons may use configural principles to encode odor mixtures.

Circuit Mechanisms that Underlie Encoding of Odor Blends

What are the possible mechanisms that would allow glomerular output neurons not just to carry the information transmitted by ORCs converging onto a particular glomerulus but also information processed in other glomeruli? This is essentially equivalent to asking how a uPN

associated with a particular glomerulus can encode an odor mixture when the information concerning the blend is distributed beyond the glomerulus that the uPN innervates. The answer to this question must pertain to a process of lateral information transmission within the glomerular array, either through lateral excitatory or lateral inhibitory pathways.

Interglomerular Excitation and its Potential Role in Blend Coding Glomeruli in the OB/AL are interconnected by diverse types of interneurons, many of which are known to be GABAergic, thus serving as a substrate for lateral inhibition (Egger et al. 2003; Wilson and Laurent 2005; Vucinic et al. 2006). A recent report demonstrated the existence of cholinergic LNs in the AL of *Drosophila* (Shang et al. 2007), also providing an explanation for an earlier observation where PNs were shown to have a broader molecular receptor range than their cognate ORCs (Wilson et al. 2004). However, these results contradict another study in which the PNs faithfully transmitted information from their presynaptic ORCs (Wang et al. 2003). One of the functions of such interglomerular excitation, according to Shang et al. (2007), may be to boost PN signals and enhance their transmission to third-order neurons (mushroom body Kenyon cells) in a mechanism akin to stochastic resonance. We argue that, on the other hand, interglomerular excitation could be used by the AL circuits to combine information from a subset of glomeruli, which may participate in encoding an odor mixture. The heterogeneous local interneurons (hetero-LNs), described in the ALs of honeybee and moth (Christensen et al. 1993; Sun et al. 1993), could be a potential neural substrate for gathering information from a group of glomeruli and relaying it to a "core" unit, i.e., the glomerulus that is most densely innervated by the LN arbors. The uPNs innervating the "core" unit could theoretically be presented with all pieces of information about the mixture collected by other branches of the hetero-LN. To test this hypothesis, two key issues need to be resolved: (1) verification of the cholinergic properties of the hetero-LNs; (2) verification of the polarity of hetero-LN synapses, i.e., the dense arbors in the "core" glomerulus comprise mainly output synapses while the sparser arbors in neighboring glomeruli have only input synapses. These data are not yet available.

Interglomerular Inhibition and Its Potential Role in Blend Coding Except for the recently reported cholinergic LNs in the fly AL (Shang et al. 2007), LNs in insect AL and granule cells in vertebrate OB have been long considered as the major source of inhibition mediated by γ-aminobutyric acid (GABA) receptors in the AL/OB (Nowycky et al. 1981; Jahr and Nicoll 1982; Hoskins et al. 1986; Python and Stocker 2002; Wilson and Laurent 2005). Interglomerular inhibition plays important roles in enhancing contrast of odor representation (Yokoi et al. 1995; Sachse and Galizia 2002; Vucinic et al. 2006), shaping the response of glomerular output neurons (Wilson and Laurent 2005; Olsen and Wilson 2008) and strengthening intraglomerular synchrony (Lei et al. 2002). Additionally, such inhibitory mechanisms have also been proposed in a modeling study of the rat OB to underlie the behaviorally observed perceptual properties of complex odor stimuli, i.e., configural, elemental, or a mixture of the two odor interactions (Linster and Cleland 2004). In this model, interglomerular inhibition could be either removed or kept intact with comparisons made between the overlap of M/T cells' response patterns evoked by single components A and B, A (or B), and the binary mixture AB. The higher degree of overlap the mixtures, the more similar the responses. They found that with the interglomerular inhibition removed, the overlap between A- (or B-) and AB-evoked responses was positively correlated with the overlap between A- and B-evoked responses, but the overlap between AB and A (or B) was always greater than the overlap between A and B (Fig. 2). In other words, adding B (or A) to the mixture did not bring significant "new" features to the responses, as would be predicted by the principle of elemental processing of odor mixtures. In contrast, with the interglomerular inhibition intact, when the M/T cells' responses to the individual odors A and B were very similar, the M/T cells' responses to the binary mixture AB was dissimilar to either of the two individual odorant responses (Fig. 2). In other words, the mixture-evoked responses did not represent information for any single component, thus exhibiting characteristics of configural processing. The dissimilarity between mixture and component decreased as the dissimilarity of A and B increased until A and B evoked responses beyond the range of mutual inhibitory interactions, at which point interglomerular inhibition had no effect, resulting in elemental representations of odor mixtures (Linster and Cleland 2004; Fig. 2).

The significance of this work is that it provides a mechanistic explanation for conflicting behavioral or physiological observations where, in some instances, odor mixture evokes novel percepts or neural representations that are completely independent of that evoked by single components, while in other circumstances, the effect of odor mixture is a simple summation of the effects from single components. If two dissimilar odorants A′ and B′ evoke non-overlapping representations in OB, the mixture (A′B′) will produce a pattern of glomerular activity that is a linear summation of the individual patterns induced by A or B alone. However, when A and B become more similar, their corresponding glomerular responses become more

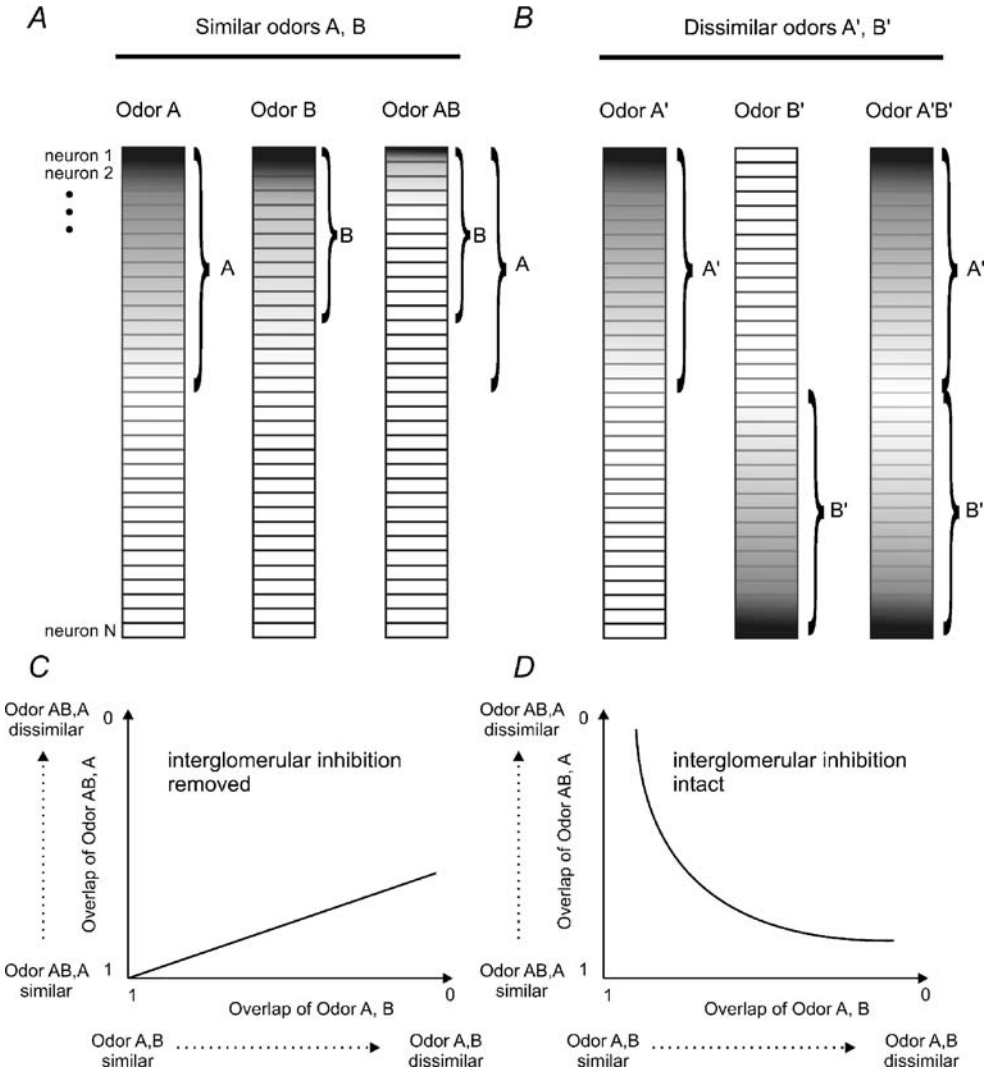

Fig. 2 A schematic representation of a conceptual model that explains how interglomerular inhibition in antennal lobe or olfactory bulb may enable configural and elemental processing of odor mixtures (adapted from Linster and Cleland 2004). **a** Two similar odors (*Odor A*, *B*) produce a highly overlapped representation on an array of olfactory neurons, i.e., almost the same set of neurons is activated by these two odors. The *shading levels* represent different magnitude of neural activation by these odors. Due to the interference of the interglomerular inhibitory circuits that are commonly activated by Odor A and B, the mixture of these two odors (*Odor AB*) produces an activation pattern that bears no resemblance to either A or B. Thus, the total representation for the mixture contains no information of its constituents—a main feature of configural processing. **b** In contrast, two dissimilar odors (*Odor A′*, *B′*) are represented by the array of olfactory neurons in distinctly different ways, with Odor A′ mainly encoded by the top 50% of neurons and Odor B′ by the bottom 50%. The interglomerular inhibitory circuits associated with the stimulation by A′ and B′ are non-overlapping, causing no interference to the total representation. The mixture of these two odors (*Odor A′B′*) additively activates the entire array of olfactory neurons. The neurons that encode Odor A′ are equally activated by Odor A′B′; thus, the total representation of Odor A′B′ contains the same amount of information on Odor A′ as it would if using Odor A′ alone—a main feature of elemental processing. The same is true for Odor B′. **c**, **d** In this model, after mathematically removing the interglomerular inhibition, the degree of overlap for neural representations of Odor A and B is positively correlated with that of Odor AB and A. However, when the interglomerular inhibition is kept intact, this relationship is reversed, meaning the more similar the Odor A and B, the less degree of overlap the representation for the mixture (Odor AB) and its constituent (Odor A)

overlapped; the mixture AB then will activate the interglomerular inhibitory circuits in such a way that the M/T cells activated by AB mixture will exert inhibitory effect on each other to various degrees, thus resulting in a final representation of the mixture that is not predictable from A- and B-evoked responses (Fig. 2). Moreover, the strength of interglomerular inhibition may be dependent on odors as well as the inhibitory neurons. Therefore, it is reasonable to expect that some odor mixtures will induce partially elemental and partially configural interactions. In a network with such inhibitory capability, one could observe all three types of mixture interactions: elemental, configural, and both.

Encoding Odor Blends at Later Stages of Central Processing

In vertebrates, odor information is transmitted from the OB to the olfactory cortex, which comprises five main areas: the anterior olfactory nucleus, the anterior and posterior piriform cortex (the largest cortical area that receives OB inputs), the olfactory tubercle, and parts of both the amygdala and entorhinal cortex. In insects, the anatomical organization of some of the olfactory centers downstream from the AL is similar to that of downstream olfactory brain areas in vertebrates. For instance, as in vertebrates, axons of glomerular output neurons project widely to second-order olfactory centers in the protocerebrum and overlap with the projections of output neurons from other glomeruli (Marin et al. 2002; Wong et al. 2002; Kanzaki et al. 2003; Tanaka et al. 2004; Zou et al. 2005; Komiyama and Luo 2006; Jefferis et al. 2007; Lin et al. 2007). It has been suggested that some protocerebral olfactory centers such as the MB and LP in insects are at the same hierarchical level as the mammalian piriform cortex (Davis 2004). Thus, in both vertebrates and insects, synthesis of olfactory stimulus features into "objects" (Hopfield 1991; Wilson 2003; Jefferis et al. 2007) could be produced by convergence of output axons from different glomeruli onto individual neurons in the piriform cortex or the MB and/or LP. How are odor mixtures and single components represented at this level of processing?

Mixture-Selective Responses in Higher-Order Neurons

Theoretically, cortical neurons may respond to combined afferental (M/T cells) inputs, reflecting a configural type of mixture interaction, thereby creating a novel cortical representation of odor mixtures. However, an electrophysiological study on rat olfactory cortex, particularly the anterior and posterior piriform cortex (aPCX and pPCX), did not report any evidence for such mixture-selective cortical neurons; instead, all neurons encountered showed responses to mixture and at least to one of the mixture components (Kadohisa and Wilson 2006). Interestingly, this study also showed that after training the animals to distinguish odor mixtures from their components, the aPCX neurons decorrelate their population response to mixtures with that to single components, indicating that the departure of mixture representation from component representation is an experience-dependent phenomenon at the population level. In insects, blend-selective responses at higher-order olfactory centers have been reported in male *M. sexta*, where some neurons arborizing in a third olfactory center, the lateral accessory lobe, exhibited weak or no response to single pheromone components but a remarkable long-lasting-excitation (LLE) response to the blend of two major pheromone components (Kanzaki et al. 1991). In a different moth species (*A. segetum*), about 15% of protocerebral neurons were blend selective, and about 45% were component selective (Lei et al. 2001). Blend-evoked LLE response was also observed in this study. However, in *Bombyx mori*, LLE could be evoked by a single pheromone component (Kanzaki and Shibuya 1992).

Spatial Segregation of Odor Representations at Second-Order Olfactory Centers

The common organization of the olfactory pathway up to the OB/AL level in vertebrates and insects has determined that information about odor mixtures is first segregated by ORCs then distributed among the glomerular output neurons. Psychophysical evidence, however, strongly suggest that olfaction is configural or synthetic (Laing and Francis 1989; Livermore and Laing 1996), indicating that the distributed OB/AL outputs are regrouped somewhere along the olfactory pathway. Where does the synthesis take place?

Examination of the connectivity pattern between the second-order (PNs) and the third-order (MB Kenyon cells and LH (Lateral Horn) interneurons) neurons in *Drosophila* revealed three projection zones in MB and LH that are formed by the terminals of PNs that receive information from particular subgroups of glomeruli in the AL, thus suggesting that the chemotopical representation produced at the AL persists in these two second-order olfactory centers (Tanaka et al. 2004). Indeed, a later study confirmed this hypothesis by revealing segregated zones for representations of fruit odors and putative pheromone compounds in the LH, with the former focusing on the posterior-dorsal and the latter on anterior-ventral portion of the LH (Jefferis et al. 2007). Electrophysiological evidence from channel catfish indicates that feeding cues and social cues are processed in distinct regions of the forebrain, a brain structure downstream from the OB (Nikonov et al. 2005). In *M. sexta*, it was long established that PNs that innervate MGC and other sexually isomorphic glomeruli project to different regions in the second-order olfactory center, namely, inferior lateral protocerebrum (ILPC) and LH, respectively (Homberg et al. 1988), and a similar segregation pattern has been reported in other insect species (Malun et al. 1993; Kanzaki et al. 2003; Kirschner et al. 2006). In *B. mori*, PNs that arborize in different subcompartments of the MGC project to different sub-regions of MB calyces and ILPC (Kanzaki et al. 2003).

Although it is clear that the output tracts from the AL project to distinct zones of MB and/or LH, is the information from AL further synthesized in these regions? Results from single-cell labeling studies on *Drosophila* demonstrate that MB Kenyon cells integrate information across all three projection zones of AL PNs distributed in

the calyces and send output to the lobe region of the MB. In LH, however, the third-order neurons only link segregated subgroups of PNs to specific brain areas (Tanaka et al. 2004). These data seem to suggest that configural processing of odor mixtures may be more likely occurring in the MB than in the LH, as the Kenyon cells are connected to many more types of PNs across all three calycal zones. Physiological data on this particular issue is limited at present, but some Kenyon cells recorded in locust showed mixture suppression and synergism when tested with two odorants (citral and geraniol) and their binary mixture (Broome et al. 2006).

Concluding Remarks and Future Directions

Blend coding is a complicated process that involves neural circuits at multiple synaptic levels along the olfactory pathway. Data discussed in this review strongly suggest that both elemental and configural processing of odor mixtures occur in the first stage of central processing as well as in the later stages. It is unclear at this point if this is because the olfactory systems are evolved to segregate information about a mixture and its constituents along the entire olfactory pathway, or because the central structure where the information about odor blends is synthesized is yet to be discovered. Data that address this issue will likely come from insect models because of their anatomical simplicity and experimental tractability. For example, a recent study of tracing olfactory neural pathway in the honeybee AL revealed that multiglomerular PNs terminate at a distinct area in the lateral protocerebrum (Kirschner et al. 2006), thus suggesting there may be specific pathways for transmitting information about odor blends.

Multiglomerular PNs are a particularly interesting population of neurons in the insect AL when considering the possible roles for mixture processing. Their anatomical features suggest that this population of neurons may function as hard-wired devices for encoding odor mixtures that are undoubtedly processed in multiple glomeruli. The uPNs, on the other hand, are highly efficient in transmitting information that is processed in single glomeruli. However, both lateral excitatory and inhibitory circuits in the AL may render these PNs capable of carrying information from other glomeruli, possibly related to odor mixtures. The difference in encoding odor mixtures by these two types of PNs may lie in the degree of plasticity. Experience may modify the strength of lateral interactions in the AL circuits, thereby affecting the coding efficiency for those odor-mixtures that activate the lateral circuits. The action of mPNs may represent a coding strategy for innately preferred odor blends such as sex pheromones or a particular food source. Another possibility is that the same odor mixture may be encoded by both types of PNs, thus rendering the olfactory system a capability to regulate its coding for innately preferred odor blends based on experience (Anderson et al. 2007). It is also possible that configural processing of odor mixtures may take place at the second-order olfactory centers (MB and/or LH) where the third-order neurons integrate information across multiple zones of the centers that receive parallel inputs from uPNs. Obviously, systematic, comparative studies on mPNs and uPNs are needed to understand fully their functional roles in encoding odor blends.

In summary, mixture interactions of odorants may appear to be elemental, configural, or both, depending on what level of processing and what type of cells are being observed. There may not be a universal rule on how odor mixtures are processed in the central olfactory system. Thus, a comparative approach to this question by using different animal models within an evolutionary context is essential.

REVIEW ARTICLE

Neural Computations with Mammalian Infochemicals

A. Gelperin

Received: 9 August 2007 / Revised: 28 December 2007 / Accepted: 23 April 2008 / Published online: 14 June 2008

Abstract The mammalian olfactory system is the most sensitive and discriminating molecular recognition system known, able to detect a few dozen critical molecules in the face of strong and variable background odorants. The set of information-containing volatile molecules used to transmit information within and between mammalian species shows both great molecular and informational diversity. Chemosensory neuroscientists that apply traditional reductionist methods to the analysis of information processing and computational principles in the olfactory system find great value in understanding the ecological and ethological context in which mammalian olfactory communication occurs. This review highlights a subset of the molecular armamentarium and information transmissions relevant to understanding the uses of olfactory communication by mammals in an ecological context.

Keywords Olfaction · Information processing · Odor learning · Pheromones · Scent marking · Olfactory bulb · Piriform cortex · Chemical signaling · Olfactory models · Olfactory computation · Active sampling · Receptor mapping · Neural information processing

Abbreviations

2DG	2-deoxyglucose
AOB	accessory olfactory bulb
CA1	cornu ammonis field 1
CA3	cornu ammonis field 3
c-FOS	cellular-Finkel osteogenic sarcoma
Egr-1	early growth response protein 1
fMRI	functional magnetic resonance imaging
HLA	human lymphocyte antigen
kDa	kiloDalton
MHC	major histocompatibility complex
MOB	main olfactory bulb
MOE	main olfactory epithelium
M/T	mitral/tufted
MTMT	(methylthio)methanethiol
ORN	olfactory receptor neuron
VNO	vomeronasal organ

Dedicated to Tom Eisner, for his inspiring example of how to do science well and joyfully.

Introduction

There is a variety of direct ecological implications that arise from basic properties of mammalian odor information-processing systems. This is because chemical communication via odorants is a critical sensory channel for many mammalian species and is used to transmit and receive information relating to many factors of ecological significance, including the identity of predators, prey, territory, gender, reproductive status, social status, food safety, disease burden, and nutritional status. Information transmission via infochemicals, a generic term for chemicals that convey information to conspecifics or members of other species, has direct and dramatic effects on the structure of food webs in both terrestrial and aquatic environments (Vos et al. 2006) and is widespread among vertebrate species (Sbarbati and Osculati 2006). Mammalian social odor processing recently has been reviewed (Brennan and Kendrick 2006), so I focus on computational issues that arise when odorant stimuli and response systems of direct ecological relevance are considered.

To understand the possible functional implications of chemical communication among mammalian species, we

must first consider the special characteristics of the multiple channels of sensory input and chemical information processing available to receive and decode chemical messages. The mammalian olfactory system has four distinct arrays of receptors (see below), with partially overlapping functions. The spatial and temporal dispersion of information carried by odorants due to turbulent flow (Murlis et al. 1992; Vickers 2000; Balkovsky and Shraiman 2002; Vergassola et al. 2007) places special constraints on olfactory receptor arrays and odorant information-processing circuits, which must balance the conflicting requirements for maximum sensitivity to transient signals carried by turbulent flow *versus* generation of false-positive messages due to noise fluctuations in receptors maintained at high sensitivity. Odorant information processing by mammalian brains is also notable for allowing access of chemical sensory information to cortical circuits that bypass the thalamic gating applied to visual, auditory, and tactile stimuli (Shipley and Ennis 1995; Shepherd et al. 2004; Kay and Sherman 2007), which is one reason that olfactory cues can elicit immediate and emotion-laden memories (Chu and Downes 2004; Jellinek 2004). Olfactory information processing often involves reliable and robust memory formation (Wilson and Stevenson 2006) so that decision making about an odorant cue on subsequent presentations is conditioned by the consequences and contingencies of the prior presentations of the odorant. Odorant receptors are also used for multiple functions, for example to guide the chemotactic behavior of mammalian sperm (Vanderhaeghen et al. 1993; Spehr et al. 2003, 2006), with direct implications for reproductive fitness. Odorant receptors also respond to stimuli in the gut lumen to trigger serotonin release from enterochromaffin cells (Braun et al. 2007). These aspects of mammalian olfaction and others with direct ecological implications are explored in more detail below.

Functional Organization of the Olfactory System

Odorant Receptor Genes

The functional dissection of mammalian olfaction was given great impetus by the discovery of a large gene family that codes for putative olfactory receptor proteins (Buck and Axel 1991), recognized by the Nobel award in 2004 (Axel 2005; Buck 2005). Subsequent genetic studies of olfactory receptor genes (Zhang and Firestein 2002) have clarified the evolutionary processes that lead to the diversification or decimation of receptor arrays in diverse species (Bargmann 2006), including rodents, humans, and nonhuman primates (Young et al. 2002; Young and Trask 2002; Gilad et al. 2003; Hoppe et al. 2006). For example, loss of olfactory receptor genes in some primates coincides with the appearance of full trichromatic vision (Gilad et al. 2004). Human–mouse receptor gene comparisons have made testable predictions about the nature of the odorant-binding site used when the odorant receptor protein is in its natural habitat, the membrane of the olfactory cilium (Man et al. 2004; Abaffy et al. 2007). Odorant receptor genes can be classified into two types: fish-like class I genes and mammalian-specific class II genes (Hirota et al. 2007).

The ability to genetically manipulate properties of the olfactory sensor array in rodents has clarified aspects of the transduction process in olfaction (Restrepo et al. 1996; Kini and Firestein 2001; Rawson and Gomez 2002), including the role of cyclic nucleotide-gated ion channels (Kelliher et al. 2003; Lin et al. 2004). Genetic tools have also been employed to examine aspects of the central organization of olfactory circuits (Zou et al. 2005; Zou and Buck 2006) including the generation of transgenic mice that express a channelrhodopsin fusion protein that allows localized light application to the olfactory bulb in anesthetized mice to activate mitral cells while recording the effects of mitral cell activity in the piriform cortex (Arenkiel et al. 2007). A glutamate receptor gated by light pulses has also been demonstrated (Szobota et al. 2007), which is of direct relevance to the analysis of the multiple types of glutamate receptors in olfactory information-processing circuits (Lowe 2003; Davila et al. 2007; Ma and Lowe 2007).

Multiple Olfactory Receptor Arrays

The olfactory system receives input from four distinct groups of sensory receptors, including those located in the main olfactory epithelium (MOE) and vomeronasal organ (VNO; Fig. 1), septal organ, and the Grueneberg ganglion (Breer et al. 2006; Storan and Key 2006). The hydrodynamics of air flow within the tortuous passages of the nasal cavity (Zhao et al. 2006) combines with the chemical nature of the olfactory mucus (Kurtz et al. 2004) or other fluids containing the cilia of the olfactory sensory neurons, in combination with the water solubility of the odorant molecule (Mozell and Jagodowicz 1974; Kent et al. 1996, 2003), to determine which types of odorant molecules interact most effectively with each anatomically distinct group of sensory receptors. The MOE responds to volatile odorants and some pheromones while the VNO responds to pheromones and some volatile odorants (Halpern and Martinez-Marcos 2003; Dulac and Wagner 2006; Spehr et al. 2006; Lin et al. 2007). The cilia of sensory neurons in the VNO are located in a fluid-filled trench (Keverne 1999; Leinders-Zufall et al. 2004) while the cilia of sensory neurons in the MOE are embedded in a 30-μm-thick mucus layer (Getchell et al. 1984). These physical and chemical considerations suggest that chemical signals that are conveyed by physical contact of the recipient animal's

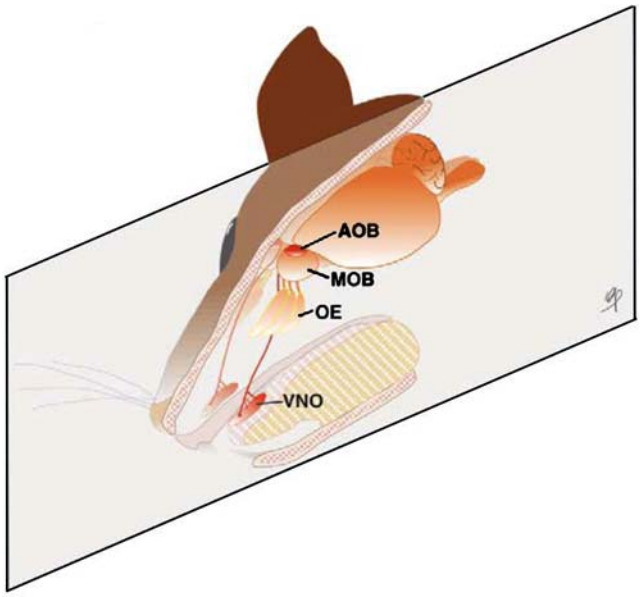

Fig. 1 Two major components of the rodent olfactory system are shown, the olfactory epithelium (*OE*) connected to the main olfactory bulb (*MOB*) and the vomeronasal organ (*VNO*) connected to the accessory olfactory bulb (*AOB*). This figure is taken from part C of Fig. 1 from Baxi et al. (2006)

nose with the body surface of the animal emitting the chemosignal are likely to involve the VNO, although not exclusively the VNO (Wysocki et al. 1980). Some VNO sensory neurons are remarkably sensitive to components of conspecific urine (Holy et al. 2000; Leinders-Zufall et al. 2000), as are some sensory neurons in the MOE, as inferred from selective responses of mouse mitral cells to (methylthio)methanethiol (MTMT), an infochemical present only in male mouse urine (Lin et al. 2005).

Central Neural Circuitry for Olfactory Processing

The major central sites of olfactory information processing are shown in Fig. 2, which also indicates the extent of feedback connections in addition to multiple feed forward pathways. Immunohistochemistry for cellular-Finkel osteogenic sarcoma (c-Fos) and early growth response protein 1 implicates several areas of the brain in individual recognition in hamsters, particularly the anterior piriform (olfactory) cortex, the CA1 and CA3 regions of the anterior

dorsal hippocampus, anterior and posterior dentate gyrus, and perirhinal cortex (Lai et al. 2005). There are correlates of olfactory recognition memory in orbitofrontal cortex (Ramus and Eichenbaum 2000), but the orbitofrontal cortex is involved in much more general computations (Murray et al. 2007). Field potential recordings in central olfactory structures have been used to track the results of olfactory processing during behavior (Chabaud et al. 2000; Martin et al. 2006). The dynamics of these central oscillations is dependent on the behavioral task being performed during the recording (Kay 2003; Gelperin 2006; Rinberg and Gelperin 2006). For example, gamma oscillatory power (65–85 Hz) in the rat olfactory bulb during a two-alternative choice task is modulated in the intact system according to task demands with dramatic increases in gamma power during the discrimination of molecularly similar odorants in contrast to dissimilar odorants (Beshel et al. 2007). Recordings in young rats question the computational necessity of coherent network oscillations for olfactory recognition (Fletcher et al. 2005). The tracking of the progress and results of olfactory information processing in the mammalian brain is greatly facilitated by the development of an isolated guinea pig brain preparation retaining the olfactory epithelium that allows access to olfactory areas during natural odor stimulation (Ishikawa et al. 2007). Initial results with this preparation in which both odor-evoked local field potentials and unit activity were recorded found neural response patterns consistent with previous results obtained in recordings from both brain slices and anesthetized preparations. Depending on the state of anesthesia of the isolated guinea pig brain *in vitro*, results can be compared directly to those obtained in the awake head-fixed rodent preparation (Verhagen et al. 2007) and the awake behaving mouse (Rinberg et al. 2006).

Odorant Processing and Neurogenesis

On the time scale of days and longer, olfactory experience can influence odorant information processing by altering the actual cellular composition of the processing circuitry. Neurogenesis in the adult brain provides new cells in the main olfactory bulb (MOB) and in the hippocampus (Lois and Alvarez-Buylla 1994; Carleton et al. 2003; Gould 2007), both of which are involved in the processing and storage of olfactory memories (Olariu et al. 2005). Infochemical interactions among conspecifics, by using both pheromones and nonpheromones, can have effects on the dynamics of neurogenesis, a process that continually populates the MOB with new interneurons (Lledo et al. 2006; Gheusi and Lledo 2007; Mizrahi 2007) and sensory input fibers (Graziadei and Graziadei-Monti 1979; Leung et al. 2007). The turnover of juxtaglomerular neurons, an important category of local inhibitory interneurons in the

glomerular layer of the MOB (De Marchis et al. 2007), is approximately 3% per month (Mizrahi et al. 2006). The survival rate of some elements of olfactory circuitry, for example granule cells (Petreanu and Alvarez-Buylla 2002), is modulated by olfactory experience (Alonso et al. 2006; Mandairon et al. 2006a,b). Recently generated adult-born olfactory granule neurons and older pre-existing granule neurons undergo contrasting experience-dependent modifications *in vivo* (Magavi et al. 2005). Different stem cells that originate in the subventricular zone have different embryonic origins and generate different neuronal progeny in the adult olfactory bulb (Young et al. 2007). The pheromones of dominant but not subordinate male mice stimulate neurogenesis in both the MOB and the hippocampus of female mice. The blocking of this pheromone-induced neurogenesis eliminates the preference of females for dominant males (Mak et al. 2007). This completes the feedback loop from odorant-induced brain plasticity to brain preference for conspecific odorants that trigger the plasticity. Any realistic model of mammalian mating system dynamics must include these newly demonstrated feedback loops.

Types of Olfactory Information

Chemistry of Infosignals

The diverse sources of chemical infosignals, such as glands (Kimoto et al. 2005), excretia (Vendruscolo et al. 2006), breath (Galef et al. 1988), body (Beauchamp and Yamazaki 2003), and tears (Haga et al. 2007), result in both lipid-soluble and water-soluble components, which tend to be absorbed into the olfactory mucosa at different rates during the transit of the inspired air over the sensory surface of the MOE (Mozell and Jagodowicz 1973). This has direct consequences for the regions of the MOB that will be activated by the infosignal (Johnson et al. 2007a,b; Johnson and Leon 2007) and hence for the central representation of the chemosignal. The influence of relative solubility of components of the chemosignal is also dependent on flow rate of the inspired air during sniffing and the periodicity of sniffing (Scott 2006; Scott et al. 2006; Schaefer and Margrie 2007), which determine the strength and timing of the sensory input to the mitral/tufted (M/T) cells of the olfactory bulb (Buonviso et al. 2006; Roux et al. 2006). Modeling of nasal airflow (Zhao and Dalton 2007) is essential to understanding the effects of flow rate on differential absorption.

Predator Signals

The analysis of the chemical nature and neural processing of olfactory signals from predators has focused on odors produced by carnivores and omnivores and the processing of distinctive predator odors by rodents, particularly rats, mice, and voles (Dielenberg and McGregor 2001; Apfelbach et al. 2005; Fendt et al. 2005). Sources of predator odors include urine, feces, and anal gland secretions, as well as skin and fur (Kats and Dill 1998). Predator odors that produce strong behavioral responses in rodents are 2,4,5-trimethylthiazoline (TMT), a component of fox feces (Rosen et al. 2006; Staples and McGregor 2006), 2-propylthietane, a synthetic weasel odor (Heale and Vanderwolf 1994), and mustelan, derived from the anal glands of mink (Schildknecht et al. 1976). The chemical complexity of the chemosignals in male and female ferret urine has been clarified recently by the application of a range of chemical analysis techniques that have identified 30 volatile compounds in urine and 26 volatile compounds in anal gland secretions (Zhang et al. 2005). Based on the findings of Lin et al. (2006), it is possible that only a small subset of these identified components actually carry information to the recipient.

Are predator odors processed in a distinctive way by the olfactory bulb and olfactory cortex? Early data indicated that weasel and fox odors selectively activated beta oscillation (15–30 Hz) in the rat dentate gyrus (Heale et al. 1994), an indicator of coherent activity in the central circuit. More recent investigations indicate that beta-band oscillations of local field potential in the olfactory bulb are not specific to predator odors but rather depend on the concentration (vapor pressure) of the odorant stimulus (Lowry and Kay 2007). Direct analysis of the glomerular activation pattern in ferrets set up by chemosignals from conspecifics has been obtained by analyzing patterns of c-Fos immunoreactivity of juxtraglomerular cells in the MOB (Woodley and Baum 2004). Considerably less activation of ventral glomeruli was seen when volatile male odors were used as compared to direct physical contact with a male (Batterton et al. 2006). It will be instructive to compare the topology of the activation of glomeruli in the olfactory bulb set up by predator odors with the mapping of monomolecular odorant activation patterns in the MOB of rats (Johnson and Leon 2007). The mouse glomerular map is different from the rat glomerular map (Soucy et al. 2007), so the published activation maps for the rat MOB based on 2-deoxyglucose uptake patterns are of limited utility for studies of mouse MOB activation patterns.

Recent work has shown that genetic ablation of olfactory receptor neurons (ORNs) in specific regions of the olfactory epithelium can yield a mouse able to detect a predator odor, e.g., fox odor (TMT), but no longer exhibiting the normal fear responses (freezing, avoidance) to the source of the predator odor (Kobayakawa et al. 2007). One interpretation is that some sets of glomeruli receiving input from receptors activated by a predator odor lead to the activation

of the amygdala and generation of fear responses, while other glomeruli receiving input for receptors activated by the same predator odor are processed differently to allow odorant recognition in the absence of fear or avoidance responses. These observations on altered predator responses in mice with reduced populations of ORNs may provide part of the mechanism for alterations in aversion to predator odors (urine) in rats caused by the infection with *Toxoplasma*, although other mechanisms are possible, as parasite cysts are found in the rat's amygdalar structures (Vyas et al. 2007a). Since the effects of *Toxoplasma* infection are dose dependent with an inverted U-shaped curve (Vyas et al. 2007b), the fitness costs associated with the change in host odor processing suggest that the effect is optimized rather than maximized.

Sexual Signals

The placing of sexual infomolecules in their ecological setting indicates the complexity of the analytical task facing the olfactory system. For example, female meadow voles (*Microtus pennslyvanicus*) can identify clearly the individual male whose scent mark is on top of another male scent mark (Johnston et al. 1997). The olfactory system, particularly the VNO (Lepri and Wysocki 1987), must be able to differentiate and identify the stronger scent blend that belongs to the male with the topmost scent mark in the face of distracting components of very similar nature from the male that deposited the bottommost scent mark. Meadow voles may take longer to process a complex odorant blend of two scent marks as compared to a single scent mark, by analogy with recent findings concerning odorant-sampling patterns in mice. To maintain accuracy of odorant discrimination, mice must take longer samples of odor mixtures that are hard to analyze (54% odor A plus 46% odor B vs. 46% odor A plus 54% odor B) than odor mixtures that are easy to analyze (70% odor A plus 30% odor B vs. 30% odor A plus 70% odor B; Rinberg et al. 2006; Slotnick 2007a). When given the opportunity, mice will take a single sniff of an odorant and suffer reduced accuracy of identification on a hard odor discrimination (Uchida and Mainen 2003; Uchida et al. 2006). Proteins in urine scent marks, particularly lipocalins, slow the release of semiochemicals (infochemicals) such as 2-*sec*-butyl-4, 5-dihydrothiazole and 2,3-dehydro-exo-brevicomin, used by male mice to indicate their state of aggression (Hurst et al. 1998; Robertson et al. 2007; Stopkova et al. 2007). The sex and reproductive status of both the sender and receiver influence responses to scent marks, as shown clearly in recent work that measures responses to isolated scent marks by the ring-tailed lemur (*Lemur catta*), a socially complex species with a functional VNO (Knapp et al. 2006; Scordato et al. 2007).

A large body of work has associated the reception of sexual signals with the VNO (Wysocki 1979; Beauchamp et al. 1982; Boehm et al. 2005; Boehm 2006; Brennan and Kendrick 2006; Kelliher et al. 2006). VNO stimulation by components of male mouse urine can trigger ovulation (More 2006). Genetic manipulations of laboratory mice have shown the behavioral consequences of genetically eliminating function in a large class of VNO sensory neurons. The elimination of the cation channel transient receptor potential 2 normally expressed in VNO sensory neurons showed that this channel is necessary for normal direction of aggressive behavior and selection of sexual partners by male mice (Del Punta et al. 2002; Leypold et al. 2002; Stowers et al. 2002). Olfactory sensory neurons in the VNO project directly to the accessory olfactory bulb (AOB). Single-unit recordings from mitral cells in the AOB obtained while the instrumented mouse explored an anesthetized conspecific demonstrated remarkably strong and prolonged activation of AOB mitral cells during the exploration of the head and anogenital areas of the anesthetized conspecific (Luo et al. 2003). Some neurons in the AOB showed selective activation depending on the sex and strain of the anesthetized conspecific emitting the social signals. The VNO also plays an important role in processing nonpheromonal signals (Restrepo et al. 2004; Baxi et al. 2006) and contains ORNs that express odorant receptor genes in common with the MOE (Levai et al. 2006). The findings of a more general role for the VNO were presaged by results that show that the vascular pumping mechanism of the VNO was activated in hamsters during novel stimulation accompanied by arousal, not just in situations where the VNO is known to be important (Meredith 1994). The MOE and MOB are also involved in reception and processing of sexual signals. By using functional magnetic resonance imaging to quantitate odorant responses in the MOB and AOB, it was found that 2-heptanone, a known mouse pheromone, produced strong signals in the MOB as well as the AOB, while urine odor, containing both pheromone and nonpheromone odors, produced clear signals in limited regions of the MOB and large regions of the AOB (Xu et al. 2005). Genetic analysis has provided extremely useful insights into pheromone signaling (Dulac and Wagner 2006), particularly the spatially selective projection pattern used by VNO neurons to connect with the AOB (Wagner et al. 2006). The use of pheromones for mammalian communication, including human communication, has recently been reviewed (Wysocki and Preti 2004, 2008).

The remarkable variability of the role of the VNO in rodent social communication is highlighted by studies in the naked mole rat (*Heterocephalus glaber*), a eusocial species with a small VNO that shows no postnatal growth in volume, thus implying a minor role of the VNO in

maintaining the social structure of the colony. This is in contrast with other rodent species (Weiler et al. 1999; Smith et al. 2007) with quite different mating strategies (Maico et al. 2003). The VNO undergoes continual turnover of its sensory receptors during adult life (Martinez-Marcos et al. 2005), as found in the MOE, which may be modulated by exposure to species-specific infochemicals.

Individual Identity Signals

One goal of olfactory information transmission for sexual selection is to control and optimize the diversity of alleles in the major histocompatibility complex (MHC) genes (the MHC haplotype) that regulate important functions of the immune system (Boyse et al. 1987; Penn 2002; Knapp 2005; Restrepo et al. 2006). Receptors activated by the complex blend of MHC-related urinary chemosignals (Willse et al. 2005) are located in both the VNO and MOE (Wysocki et al. 2004). Volatile and nonvolatile signals coded by MHC genes are complementary determinants of the rodent odortype (Restrepo et al. 2006). MHC class I peptides have been identified as compounds that elicit the pregnancy block effect (Bruce 1959) via the VNO (Leinders-Zufall et al. 2004; Thompson et al. 2007). The protein products of the MHC haplotype plus the genetic background in which the MHC genes reside combine to produce a unique individual odor signature or odortype (Penn et al. 2007), by which an individual can be recognized by conspecifics (Willse et al. 2006) or members of other species (Gilbert et al. 1986).

Measurement of event-related evoked potentials set up by human lymphocyte antigen-associated odorants in humans is a promising technique for studying neural processing of odortype-related chemosignals (Pause et al. 1998, 2006). Olfactory event-related potentials can have a reliability equivalent to that of visual and auditory event-related potentials (Lorig 2000; Thesen and Murphy 2002). The use of functional magnetic resonance imaging (Ogawa et al. 1990) during olfactory stimulation allows initial localization of brain modules participating in the processing of olfactory stimuli in humans (Winston et al. 2005) and in mice (Schafer et al. 2006). Work on humans has highlighted the activation of the amygdala and orbital prefrontal cortex (Dolan 2007) by odorant stimuli.

Health Status Signals

The unique odortype of an individual can signal its state of health, including nutritional status, parasite load, and active disease processes. This is to be expected, as any process that alters body chemistry is likely to produce alterations in body (Thom and Hurst 2004) and breath odor (Whittle et al. 2007). For example, mice that harbor the mammary tumor virus have an altered body odor that can be decoded by conspecifics, even in the absence of tumors (Yamazaki et al. 2002). Female mice avoid the body and urine odors of infected males, an effect that is blocked selectively by genetic lesions of the oxytocin gene (Kavaliers et al. 2005a, b). Female mice can discriminate the chemical cues from malaria-infected male mice *versus* healthy male mice (Barthelemy et al. 2005). The influence of MHC genes on mate choice is often interpreted as a mechanism to augment disease resistance of the offspring. The avoidance by females of parasitized males is taken as evidence for the "contagion indicator" hypothesis of parasite-mediated sexual selection (Hamilton and Zuk 1982; Able 1996). There are tradeoffs in the allocation of resources between sexual signals and the immune system (Peters 2007).

Nutritional state is another general indicator of health status that is reflected in the odor signals emitted by an individual. The state of food deprivation directly affects the interest of meadow voles (*Microtus pennsylvanicus*) in interacting with conspecifics of the opposite sex, as measured by their responses to scent marks (Pierce et al. 2007). Recent evidence suggests that leptin, a 16-kDa hormone that plays a key role in regulating energy intake and energy expenditure, acting through leptin receptors, modulates olfactory-mediated preingestive behavior (Getchell et al. 2006), as measured using a buried food paradigm. Leptin receptors are also found in sustentacular cells and sensory neurons in the MOE (Baly et al. 2007). Thus, there is both a central and peripheral mechanism for a direct link between the regulation of nutritional state and olfactory responsiveness and central processing (Aime et al. 2007). Anther peptide involved in appetite and energy regulation, orexin (Sakurai et al. 1998), also has direct effects on M/T cell activity (Hardy et al. 2005) and olfactory perception (Gorojankina et al. 2007; Julliard et al. 2007).

Computational Issues in Olfaction

Sparse Coding

An important issue in computational olfaction is how to code the spatial and temporal patterns set up by natural odorants, particularly complex blends of multiple components, so that similar but behaviorally distinct odorant blends can be discriminated (Jortner et al. 2007; Stopfer 2007). Sparse coding, in which a small number of distributed neurons represent stimulus features (Olshausen and Field 2004), is a general feature of sensory systems (Willmore and Tolhurst 2001) and offers multiple computational advantages, such as increased storage capacity in memory, energy conservation, and perhaps ease of readout.

There is evidence that the network of M/T cells in the mammalian olfactory bulb uses a sparse representation for monomolecular odorants (Kay and Laurent 1999; Rinberg et al. 2006; Davison and Katz 2007). M/T cells have a high spontaneous rate of action potential production (25–30 Hz). After a mouse learns that the delivery of an odorant predicts the delivery of a water reward, M/T cells increase their activity prior to delivery of an odorant. Responses of M/T cells in the awake behaving rodent cannot be predicted from their responses in the anesthetized animal (Rinberg et al. 2006), so issues of coding of natural odors of ecological relevance must be addressed with *in vivo* recording, by using either multisite electrical (Luo et al. 2003; Martin et al. 2004; Lehmkuhle et al. 2006; Calu et al. 2007) or optical (Cinelli et al. 1995; Singer et al. 2007; Verhagen et al. 2007) recording, during the execution of odorant-guided behavior (Mainen 2006; Rinberg and Gelperin 2006).

An issue central to any consideration of the spatial and temporal aspects of odorant coding in the MOB (Schaefer and Margrie 2007) and in higher centers such as the piriform cortex (Rennaker et al. 2007) is how the array of olfactory sensory receptors in the MOE maps onto the array of glomeruli in the MOB. In rodents, each ORN expresses only one of the set of 1,000 olfactory receptor genes, and all receptors that express a given receptor gene project to two of the 2,000 glomeruli in each MOB. Since even a monomolecular odorant excites a number of different types of olfactory sensory neurons (Malnic et al. 1999; Kajiya et al. 2001) and since each receptor is activated by several related odorants (Araneda et al. 2000), most natural odorants elicit a spatial pattern of glomerular activation on the bulbar surface. If the odorant is a complex blend, then the spatial pattern is more complex (Lin et al. 2006). The relationship between odorant receptor activation, glomerular activation patterns, and perception in awake animals remains to be clarified. It is interesting to note that alterations in some single odorant receptor genes can make subtle contributions to the odorant percept (Keller and Vosshall 2007).

Olfactory Feature Detectors

The canonical view of olfactory coding is that any given odorant stimulates a set of different types of olfactory receptors and thence a set of olfactory glomeruli, with significant temporal evolution of the firing patterns of the activated sensory neurons and M/T cells during even short bouts of odorant sampling (sniffing). A variety of measurements of glomerular activation patterns support this view of a distributed representation (Xu et al. 2000; Chen and Shepherd 2005; Mori et al. 2006; Wachowiak and Shipley 2006; Youngentob et al. 2006). An alternative view is that some receptors and glomeruli have very narrow chemical tuning curves, perhaps to mediate hard-wired behavioral responses. In flies, some narrowly tuned ORNs connect with narrowly tuned projection neurons to trigger a reliable behavioral response, while other narrowly tuned receptors connect to broadly tuned projection neurons involved in combinatorial coding (Schlief and Wilson 2007). In mice, some complex natural odorants with direct relevance to social communication, such as the odor of urine, contain single components with potent effects. Of the hundreds of compounds present in mouse urine, single mitral cells can have extremely narrowly tuned response spectra, such that single M/T cells can be tuned to a single urine component, such as MTMT, present only in male mouse urine (Lin et al. 2005). The addition of synthetic MTMT to mouse urine makes it more attractive to female mice. It will be important to determine if the same pattern of selective responsiveness is present in mitral cells recorded in the awake mouse. Clearly, the broad-tuning and narrow-tuning mechanisms are complementary. Some mitral cells may have specific response spectra while others are broadly tuned during neural decoding of the same complex natural stimulus. Our understanding of glomerular and, by inference, M/T cell processing of odorant input has been significantly enhanced by the recent demonstration, by using localized microinjections of a retrograde-specific pseudorabies virus into the rat MOB (Willhite et al. 2006), of a striking columnar organization extending across all layers of the olfactory bulb from the glomerular layer to the deep granule cell layer.

Separating Target from Background

A general problem in odor target recognition is how to separate (segment) an olfactory target odorant of interest from the odor background. Part of the target recognition mechanism involves adaptation to steady-state stimuli, also known as background subtraction. There are mechanisms at the receptor level (Reisert 2005; Goyert et al. 2007), bulbar level (Fletcher and Wilson 2003), and cortical level (Kadohisa and Wilson 2006; Wilson et al. 2006; Linster et al. 2007) to achieve the adaptation of neural activity to a constant background stimulus while maintaining sensitivity to a novel stimulus. Cortical contributions were clarified in a recent study showing that the infusion of a glutamate receptor antagonist bilaterally into the anterior piriform cortex can reduce the habituation of exploratory behavior to a novel odor or the odor of a conspecific (Yadon and Wilson 2005).

Olfactory enrichment can increase the ability of rodents to discriminate components of a mixture (Mandairon et al. 2006c). Whether a blend of odors will be perceived as a unitary odor object (configural perception) or as a mixture of components (elemental perception) is dependent on past experience as well as the nature of the components (Kay

et al. 2003, 2005). If the animal always experiences the components in a constant proportion and never experiences a component in isolation, the perception is more likely to be configural (Hopfield and Gelperin 1989). These factors bear directly on how an odorant representation is stored and on what aspects of the odorant stimulus are available for association with other cues and consequences. When a meadow vole samples the odor of a scent mark, all the components are present in fixed proportions. If the components of the scent mark volatilize at different rates, then an older scent mark will appear to have different proportions of the components due to selective depletion of odor components from the source. This might provide a means to distinguish the top (fresh) scent mark from the bottom (depleted) scent mark (Ferkin and Pierce 2007). The central representation may achieve a signal independent of absolute concentration by using a relational representation based on relative levels of activity in glomerular components (Chalansonnet and Chaput 1998; Cleland et al. 2007).

Fault Tolerance in Olfaction

As might be anticipated in a sensory system of such critical importance, the olfactory system has considerable redundancy in its sensor arrays, as evidenced by the ability to maintain sensitivity and discrimination ability in the face of massive destruction of the sensory sheet (Slotnick 2007a; Slotnick et al. 2007). Similarly, the distributed representation of odorants in the olfactory bulb allows the central circuitry to retain significant function in the face of extensive central lesions (Slotnick et al. 2004; McBride and Slotnick 2006). These findings (Bisulco and Slotnick 2003; Slotnick and Bisulco 2003) have been interpreted as challenges to a model of localized and fixed components of the glomerular spatial coding of odorants (Johnson and Leon 2007). From a system design point of view, it is remarkable that rats with one MOB removed completely and only 20% of the remaining bulb available retain significant olfactory ability (Lu and Slotnick 1998). Given the accessibility of the MOB to pathogens traveling up the olfactory nerve (Mori et al. 2005), it may be adaptive to have sufficient redundancy in MOB processing circuits that olfactory function survives bacterial or viral assault.

Network Models in Olfaction

As studies of olfactory information processing and olfactory biophysics progress, structural models that incorporate essential elements of neuronal circuitry and response dynamics have appeared (Meredith 1992; Hopfield 1999; Laurent et al. 2001; Brody and Hopfield 2003; Davison et al. 2003; Bathellier et al. 2006; de Souza and Antunes 2007). These models have used receptor array and M/T cell activation functions taken from experimental measurements and have made suggestions about the critical role of local inhibition in shaping network dynamics (Cleland and Linster 2005). A model that uses glomeruli with only two states of activity, on or off, can account for several aspects of observed behavior in olfactory psychophysics, including effects of olfactory bulb lesions (Koulakov et al. 2007). When these models have evolved to process multicomponent mixtures with very brief sampling times, they may suggest solutions to olfactory processing problems of direct relevance to ecological interactions via infochemicals. A model that incorporates unsupervised learning and adaptation shows how new neurons incorporated into the circuitry of the MOB can optimize odor processing under changing conditions (Cecchi et al. 2001; Chambers and Conroy 2007).

Stimulus Sampling Strategies

The responses of M/T cells show a temporal structure in the odor-specific patterns of their onset latencies (Schaefer and Margrie 2007), so there are both spatial and temporal aspects of the central representation of odorants. In some tasks, rodents make a decision about an odorant in a single sniff (Uchida and Mainen 2003; Abraham et al. 2004; Kepecs et al. 2006; Slotnick 2007b), as do humans (Laing 1986; Mainland and Sobel 2006), who are better at scent tracking (Novotny et al. 2007) and olfactory acuity (Shepherd 2004) than previously believed. For example, the smelling of a single component of male sweat, androstadienone (4,16-androstaien-3-one), can alter salivary levels of cortisol in women (Wyart et al. 2007). Humans have been suggested to be an excellent animal model for the study of system-level olfaction (Zelano and Sobel 2005).

The reliance on input from a single sniff in making some forms of olfactory recognition may relate to the pattern of odor dispersal by turbulent flow in which at some distance from the source, the odorant is present in packets that may only allow sampling with a single sniff (Murlis et al. 2000; Miller et al. 2007). An understanding of these issues is critical for design of robots equipped with electronic olfactory systems that actively sample odor plumes (Settles 2005; Vergassola et al. 2007).

Conclusions

The mammalian olfactory system is an extremely sensitive analytical device, able to respond to small numbers of ligands (34) bound to receptor proteins in the ciliary membranes of olfactory receptor cells (Menini et al. 1995;

Bhandawat et al. 2005). The analysis of the spatiotemporal pattern of activity from receptors activated by chemically diverse natural chemosignals is able to extract weak known signals from a background of strong time-varying signals, segment components of odor objects, and perform concentration-invariant recognition and discrimination (Wilson and Mainen 2006). A variety of reliable and robust learning mechanisms, associative and nonassociative, operate on the central representations of odors to bias future responses based on previous exposures. This exquisite analytical system operates during chemical communication events with conspecifics, predators, and prey to detect and decode chemosignals relevant to ecological interactions of every type. The task for future studies of ecologically relevant central processing of olfactory signals is to use stimuli of clear relevance to ecological information transmission and study processing events in the awake behaving animal while relevant stimuli are being processed.

Acknowledgments I thank Gary Beauchamp and Charles Wysocki for insightful comments on the manuscript. I thank Lex Kravitz for drawing my attention to the work on *Toxoplasma* infection and altered odor processing. Work from the author's laboratory was supported by funds from the Whitehall Foundation.

Precise Manipulation Through a Modeling Study

Editorial Preface (Papers by M.E. Puente, G.G. Kennedy, F. Gould, and K. Magori)

Marcel Dicke

Published online: 2 May 2008

Organisms are characterized by a suite of characteristics that collectively constitute a phenotype. Interactions with the biotic and abiotic environment result in modifications of the phenotype, and consequently in modifications of the interactions of the individual with community members. Chemical ecologists have a keen interest in the information component of phenotypes. They unravel the mechanisms that underlie phenotypic changes in terms of the emission of information-conveying chemicals and the ecological consequences of such phenotypic changes. For instance, feeding by a pierid caterpillar on a brassicaceous plant results in the production of a complex bouquet of volatiles that include fatty-acid-derived compounds, terpenoids, and glucosinolate-derived compounds (Geervliet et al. 1997). The induced volatiles can evoke a range of behavioral responses. They result not only in the attraction of parasitic wasps that attack the caterpillars (Scascighini et al. 2005), but also in the attraction of *Plutella xylostella* moths for whom the *Pieris*-infested plant provides enemy-free space (Shiojiri et al. 2002).

Induced phenotypic changes allow organisms to adjust to local conditions. However, this requires that an individual perceives environmental changes and responds to them at a speed that results in timely phenotypic change. The expression of phenotypic plasticity is usually thought to be an indication of costs related to the expressed characteristics, either in terms of energy or in terms of ecology (Agrawal 2001). The ecology of herbivore-induced plant volatiles (HIPV) has shown a rapid development since the late 1980s (Dicke and Sabelis 1988; Turlings et al. 1990). In the past decade, molecular genetic tools have been embraced by students in this field (Van Poecke and Dicke 2002; Kessler et al. 2004; Halitschke et al. 2008). In doing so, certain characteristics could be eliminated from or enhanced in plants with a chirurgic precision at the level of individual genes. This approach has allowed us to study individuals that had been modified in the expression of individual genes, usually in a digital method where the gene of interest was knocked out or silenced or where the expression of the gene of interest was enhanced. These methods have revolutionized the field of insect–plant ecology (Dicke et al. 2004; Kessler et al. 2004). They allow the investigation of the effects of individual characteristics on species interactions as well as community dynamics.

Apart from molecular genetical tools, mathematical modeling is another powerful tool that allows researchers to investigate the effects of individual characteristics on species interactions. If sufficient knowledge about a system has been gathered to develop an adequate model, the model parameters may be modified to assess their effects on species interactions. Within the field of chemical ecology, modeling has not been a tool that has been exploited frequently (but see e.g., Vos et al. 2001; Kobayashi et al. 2006). Analytical tools have mainly dominated the field. The following two papers by Puente and colleagues have taken a detailed modeling approach to the study of herbivore-induced parasitoid attraction. They especially address the temporal and spatial aspects of plant–parasitoid interactions through HIPV. Timing of HIPV emission relative to herbivore presence is likely to be important, as it determines the reliability of the cues. The induction dynamics of volatile emission vary with the type of volatiles and their biosynthesis. However, after herbivores have been eliminated, continuation of the emission is no

e-mail: marcel.dicke@wur.nl

longer needed for the plant, and if the emission continues, this is likely to devaluate the volatiles as a signal to carnivorous arthropods. In the research field of HIPV, more attention has been paid to the induction of volatiles (Scascighini et al. 2005; Maffei et al. 2007) than to the relaxation of their production and emission (Fatouros et al. 2005). To investigate the effects of genetic variation in parasitoids, fewer tools are available at present. Although this may change with the rapid development of molecular genetic tools for parasitoids, at present a modeling approach is one of the few options.

In their papers, Puente and colleagues take a behavioral ecological approach to the role of HIPV in plant–parasitoid interactions. In doing so they modify characteristics of the emission dynamics as well as the response characteristics of parasitoids. This results in an interesting approach that yields new insight into the role of HIPV in the foraging success of parasitoids and in the success with which plants improve the effectiveness of herbivore attack by parasitoids. In this manner, they can modify the dynamics of HIPV signaling in ways that molecular geneticists can only dream of. For instance, Puente et al. (2008a, b) can investigate the effect of the time interval between herbivore attack and HIPV emission by comparing five plant types that differ in the induction delay in a linear manner. Their approach results in new hypotheses that can be investigated through an experimental approach. This approach is a valuable, yet not often employed, tool to chemical ecologists that complements analytical, molecular genetic, and behavioral approaches.

The Impact of Herbivore-Induced Plant Volatiles on Parasitoid Foraging Success: A General Deterministic Model

Molly E. Puente · George G. Kennedy · Fred Gould

Received: 21 July 2007 / Revised: 15 January 2008 / Accepted: 6 February 2008 / Published online: 16 April 2008

Abstract Parasitoids respond to volatiles that plants produce when injured by herbivores. A considerable body of literature addresses the chemical pathways of herbivore-induced volatile production. However, there is almost no theory or data on how timing of volatile release in relationship to host availability for parasitization impacts the utility of these cues to parasitoids and on the extent that this volatile release timing might increase or decrease the percent of herbivores that become parasitized. This kind of information is critical in judging the benefits that might accrue from a breeding program aimed at enhancing herbivore-responsive volatile production. We developed a general model to begin examining this issue by using available parameters from two tritrophic systems. The model uses herbivore oviposition, development, and mortality rates, linked to a range of plant volatile induction and cessation periods for calculating the proportion of plants in a field that are (1) not producing volatiles but occupied by suitable herbivore hosts, (2) producing volatiles and occupied by suitable herbivore hosts, (3) producing volatiles but not occupied by suitable herbivore hosts, and (4) not producing volatiles and not occupied by suitable herbivore hosts. The impact of the plant volatiles on parasitoid foraging success is then determined by comparing the expected number of hosts parasitized when the parasitoid focuses solely on the volatile-producing plants to when it forages randomly among all plants. Under some conditions, parasitoids can attack three times more herbivores if they focus on volatile-producing plants. However, when we simulate plants that take several days to cease volatile production after pupation or death of the herbivore, parasitization rate does not increase when parasitoids use volatiles as cues. The utility of the volatile cues is consistently greater when a smaller proportion of plants is occupied by herbivores, indicating that their usefulness may be reduced to zero in fields saturated with volatiles.

Introduction

Plant volatiles induced by herbivory have been documented in numerous systems (Karban and Baldwin 1997). There are many examples of parasitoids orienting to herbivore-induced plant volatiles as a means of finding hosts, both in the field (e.g., DeMoraes et al. 1998; Oppenheim and Gould 2002) and in wind tunnels (e.g., Kaiser and Carde 1991; DeMoraes and Lewis 1999). One hypothesis about the evolution of this plant/parasitoid interaction suggests that plants evolve volatile production because those genotypes that produce herbivore-induced volatiles are more successful in attracting predators/parasitoids and therefore have higher fitness (Janssen et al. 2002). In contrast, a simpler hypothesis holds that plants produce herbivore-induced volatiles as a by-product of plant biochemistry and that parasitoids happen to have receptors that enable detection of these volatiles (Agrawal and Karban 1999). The value of attraction is hypothesized to be determined by the relative reliability and detectability of the plant signal (Vet et al. 1991). While host cues are under

selection to be as undetectable as possible, plant cues are not under such selection. Parasitoids that are attracted to these cues are rewarded when these cues are a reliable indicator of presence of a suitable host.

However, even though plant cues are not directly selected against, they may not always provide a reliable signal to parasitoids. One potential source of misleading signals occurs when plants produce similar volatiles in response to a number of herbivore species, only some of which are hosts of a specific parasitoid (Rose et al. 1998; van Poecke et al. 2003). Another occurs when parasitoids respond to plants when the inducing herbivore is either too old to be attacked (Mattiacci and Dicke 1995; Brodeur and Vet 1995) or has left the plant (Mattiacci et al. 2001). The aim of this paper is to examine the extent to which variation in timing of volatile emission impacts utility of these cues for parasitoids.

In addition to natural sources of temporally misleading signals, crop breeding for over-expression of volatiles may produce situations where parasitoids gain less from response to the volatile. There has been considerable interest in breeding plants to produce increased quantity and quality of volatiles (Bottrell et al. 1998; Degenhardt et al. 2003; Lou et al. 2006). It is also possible that properly timed, increased volatile quantity could improve the efficiency of biological control agents by allowing parasitoids to target their foraging only to damaged plants with little cost to the plants. Initial investigations show the metabolic costs to the plant may not be significant enough to rule out breeding for constitutive volatile production. Several papers that propose this strategy mention that plant signals should be synchronized with herbivore presence to avoid a "calling wolf" scenario (Bottrell et al. 1998; Degenhardt et al. 2003); however, none specifies precisely how plant signals need to be synchronized. While a number of studies examine the chemical pathways plants use to produce signals (e.g., Kessler and Baldwin 2002), there are no published reports that we could find elucidating the regulation of specific genes that turn off volatile production when herbivory ceases.

As demonstrated by Holling (1959), predator and parasitoid foraging success is limited by three parameters: handling time, total available foraging time, and host encounter rate. Predators and parasitoids can take advantage of many visual, olfactory, and auditory cues in their environment to optimize host encounter rate. If herbivore-induced volatiles from plants can be used by the parasitoid to optimize these three parameters, then response to the volatiles can increase parasitoid foraging success. On the other hand, if parasitoid response to the volatiles increases handling time, decreases the available foraging time, or decreases the host encounter rate, response to induced volatiles could become less valuable.

The number of systems in which parasitoids are attracted to herbivore-induced plant volatile signals indicates that there must be some advantage to this attraction behavior; however, the few studies that quantify the fitness advantage parasitoids gain by following volatiles tend to focus on patch abandonment and modulating giving-up time (Vos and Hemerik 2003) rather than parasitoid attraction to individual plants in a larger environmental context. One purpose of this paper is to use modeling to examine the extent to which both the herbivore's life history and the temporal pattern of the plant's response to herbivory determine the benefit to the parasitoid of responding to herbivore-induced plant volatiles. Modeling has been instrumental in identifying other key aspects of parasitoid–host interactions, such as the value of refuges and asynchrony in parasitoid–host population dynamics (Takagi 1999).

The structure of the model is based on an extension of the Holling predation equation (Holling 1959). Life history and behavioral traits of two specific tritrophic systems that are potential candidates for genetic modification of volatile signal production were used in setting default parameters in our model. The first consists of tobacco, *Heliothis virescens*, and *Cardiochiles nigriceps*. De Moraes et al. (2001) found that female moths avoided ovipositing on plants emitting herbivore-induced volatiles, so for this system, we examined the consequences for parasitoid wasps if moths limit their oviposition to uninfested plants. The second system consists of *Brassica oleracea*, *Pieris* spp., and *Cotesia glomerata*. Females of the parasitoid *C. glomerata* are attracted to plant volatiles induced by all instars of *P. brassicae* (Mattiacci and Dicke 1995); however, parasitoid larvae suffer greater mortality due to increased encapsulation if laid in third or later host instar caterpillars. Geographically isolated populations of *C. glomerata* vary in their foraging behavior and host range (Vos and Vet 2004). Given the general nature of the model developed here, we did not address intraspecific variation, and we used data from congeneric species when needed. We used our model to examine the consequences of narrowing the window of available host instars that a parasitoid could attack. While parameter values from these two tritrophic systems were used as starting points, we also explored a wider set of parameter values to gain a broader understanding of the impacts of signal–host synchronization.

Overall, we expected that signals more closely synchronized with host presence would be more relevant to foraging parasitoids, so that plants in a field that could respond to herbivory in 1 day would produce more relevant signals than plants that took 5 days. However, before analysis with this model, we did not know whether the cost of delaying a signal from 1 to 5 days would be substantial or hardly noticeable. Similarly, while we expected herbivore density to impact the relevance of the volatiles to

parasitoids, we did not know whether this would be a major or a minor effect. Our use of general characteristics of two systems, with varying herbivore life histories, allowed us to identify what variables were more sensitive to initial conditions when predicting the relevance of volatiles to parasitoids. A companion paper describes a more detailed stochastic and spatial model of the interactions between *Cotesia rubecula* and *P. rapae* (Puente et al. 2008, following paper).

Methods and Materials

Incorporating Plant Volatiles into Holling's Equation The fitness of a solitary parasitoid can be correlated directly with the number of hosts successfully attacked, as each host can lead to one offspring. Therefore, the relevance of herbivore-induced plant signals can be defined as a ratio of the number of hosts attacked if a parasitoid follows signals, compared to if it randomly forages with respect to plant signals.

$$\mathrm{Rel} = \frac{N_{\mathrm{ASig}}}{N_{\mathrm{ARan}}} \tag{1}$$

where *Rel* is the signal relevance to the parasitoid, N_{ASig} is the number of hosts attacked by parasitoids that focus only on plants that are producing herbivore-induced volatile signals, and N_{ARan} is the number of hosts attacked by randomly searching parasitoids. If *Rel* is equal to 1, either foraging method yields the same fitness; if $Rel>1$, then a parasitoid is more efficient by responding to plant signals, and if $Rel<1$, then the parasitoid is more efficient when it ignores plant signals.

The predation equation developed by Holling (1959) provides a way of predicting the number of prey (or hosts in this case) attacked, given the predator's (or parasitoid's) behavior and the host density.

$$N_{\mathrm{A}} = \frac{T_{\mathrm{t}} \times a \times x}{1 + a \times b \times x} \tag{2}$$

where T_{t} is the total time available for foraging, a is the "instantaneous rate of discovery," b is the handling time for a single oviposition, and x is the density of hosts. If we substitute this into the previous equation, we get

$$Rel = \left(\frac{T_t \times a_{Sig} \times x_{Sig}}{1 + a_{Sig} \times b_{Sig} \times x_{Sig}}\right) \Big/ \left(\frac{T_t \times a_{Ran} \times x_{Ran}}{1 + a_{Ran} \times b_{Ran} \times x_{Ran}}\right) \tag{3}$$

The definitions of the variables in the Holling equation and the units of measure are system-specific. In our model, we can assume that the induction phenomenon occurs systemically throughout a plant (e.g., Mattiacci et al. 2001) and that it is constrained to a single plant. The density of hosts, x, in the Holling model is traditionally provided in hosts per square meter, but because induction is occurring at the level of plants, not meters, we assume one plant per square meter and thus give our density measurements in "hosts/plant."

The total time available T_{t} is the amount of time the parasitoid remains foraging in the relevant environment. We assume that T_{t} is for a single day and that the parasitoid forages only in the field of interest for that day, thus giving us a daily attack rate. To keep all time units equal, T_{t} is measured in seconds.

The instantaneous rate of discovery a, also known as the area of discovery, is traditionally given in the units of area per unit of time (the lower case "a" should not be confused with upper case "A" in N_{A}, which is the total attack rate). We are interested in how many plants the parasitoid can visit rather than the area that can be covered; therefore, we make a few assumptions about the area of discovery. We assume that the parasitoid forages by visiting the nearest neighboring plant or, in the case of following volatile signals, the nearest neighboring signaling plant. To calculate the area of discovery, a, for randomly foraging parasitoids, we take the parasitoid flight speed (in meters per second) and multiply by the density of plants (plants per meter). Multiplying T_{t} by a gives the maximum number of plants a parasitoid can visit during the total foraging time. Multiplying that result by x gives the maximum number of hosts the parasitoid could possibly encounter if no time were required to find and handle the host once the parasitoid arrived at a plant.

Because a fraction of that total time is spent in handling hosts, the actual number of the hosts attacked is less than the maximal number of plants that the parasitoid could encounter. The more plants encountered, the more time that must be invested in both searching for and handling hosts. The handling time, b, is the amount of time the parasitoid spends from the time it encounters a host to the time it stops handling the host. Because this model follows just a single host per plant, the parasitoid is assumed to leave the plant immediately after handling the host. However, in cases where multiple larvae could be encountered on a single plant, b, the term we add to describe on-plant searching, could be modified with functions to describe continued on-plant searching behavior. The total time spent in handling hosts is $a \times b \times x$. The actual number of plants a parasitoid can visit is then $a \times \mathrm{x} \times$the time available for searching, which is only a fraction of the total time available for foraging. This fraction can be calculated as $T_{\mathrm{t}}/(1\, a \times b \times x)$.

However, this assumes that handling time is fixed for each encounter. While the time it takes for a parasitoid to sting a found host may be equal regardless of the plant's state, the amount of handling time a parasitoid searches a plant before finding (or giving up on) a host may depend on

how the parasitoid perceives the plant state. For example, when encountering herbivore-induced plant volatile cues, some parasitoids search plants longer before leaving (Nealis 1990; Horikoshi et al. 1997; Sato and Ohsaki 2004). By prolonging a parasitoid's giving-up time, herbivore-induced plant volatiles can impact the time budget for foraging parasitoids. To account for a difference in giving-up time, as part of the overall handling time, we modified the Holling equation as follows:

$$N_A = (T_t \times a \times x)/(1 + a \times b \times x + a \times c \times E + a \times c/2 \times O) \quad (4)$$

Where c is the giving-up time per plant, E is the proportion of plants that are empty of hosts, and O is the proportion of plants in the field that are occupied by a host. The total time a parasitoid must devote to searching if no herbivore is present is $a \times c \times E$, which is the probability of a parasitoid landing on an empty plant ($a \times E$) multiplied by the rate of giving-up time per arresting plant. If an herbivore is present (O), we assume that the searching time ceases as soon as the host is found. If we assume that the probability that the host is found per unit time is the same from the instant that a parasitoid lands up to the moment the search time expires, then the average time spent will be half the giving-up time. Therefore, the time spent searching occupied plants is $a \times c/2 \times O$.

Given these definitions of the variables, we can ask how a parasitoid's decision to follow or ignore induced plant volatiles can change the values of these variables. There have been many hypothesized mechanisms through which herbivore-induced plant volatiles can influence parasitoid foraging. For example, parasitoids may change their turning radius (Kareiva and Odell 1987), alter their flight speed (Norlund 1981), or change their total time budget to spend more time feeding per day (Siekmann et al. 2004). While our model is flexible enough to examine these hypotheses, in this paper, we will explore only the impact of parasitoids bypassing non-signaling plants on signal relevance; for further exploration of the model, see Puente (2007).

By identifying the preferred host–plant complex out of a mixed background, parasitoids can bypass uninformative plants. When the parasitoid bypasses non-signaling plants, we assume it maintains the same flight speed and handling time but restricts its environment to signaling plants only. In natural settings, a parasitoid may also pick up on other cues (such as herbivore frass) that may induce it to investigate non-signaling plants but that is beyond the scope of this model. The parasitoid may, therefore, encounter a different density of hosts if it preferentially forages on signaling plants rather than foraging randomly. The impact this has on the signal relevance depends on the underlying host density and the plant signal reliability.

At any point in time, a plant could be in one of four possible qualitative states. Individual plants are either emitting volatiles that could act as signals (S) or not emitting (N) and are either occupied (O) by a suitable herbivore host or empty (E) of a suitable host; thus, a plant's state can be NO, NE, SO, or SE. While a single plant does not retain its state for an entire season, a field may reach an equilibrium distribution of plants in those four categories.

A parasitoid responding to plant signals perceives the host density as the number of SO plants (n_{SO}) divided by the sum of all signaling plants ($n_{SO}\, n_{SE}$), while a parasitoid randomly foraging perceives the host density as the sum of all occupied plants ($n_{SO}\, n_{NO}$) divided by the total number of plants in the field. Mathematically,

$$x_{Sig} = n_{SO}/(n_{SO} + n_{SE}) \quad (5a)$$

$$x_{Ran} = (n_{SO} + n_{NO})/(n_{SO} + n_{NO} + n_{SE} + n_{NE}) \quad (5b)$$

All other variables being held constant, if ($x_{Sig} > x_{Ran}$), signal relevance will be greater than one, and if ($x_{Sig} < x_{Ran}$), signal relevance will be less than one. However, because density is not linearly correlated with signal relevance (x appears in both the numerator and the denominator), the magnitude of this advantage in terms of number of hosts attacked depends on the actual values of n_{SO}, n_{NO}, n_{SE}, and n_{NE}.

Additionally, these four states impact the values of E and O in Eq. 4, so if we include arrestment in our equations, we can make the following substitutions:

$$E_{Sig} = n_{SE}/(n_{SO} + n_{SE}) \quad (6a)$$

$$E_{Ran} = (n_{SE} + n_{NE})/(n_{SO} + n_{NO} + n_{SE} + n_{NE}) \quad (6b)$$

Additionally, we can substitute Eq. 5a and 5b for O in both the signaling and randomly foraging equations.

When we have finished making these substitutions, we have the following equations:

$$N_{ASig} = \frac{T_t \times a_{Sig} \times \left(\frac{n_{SO}}{n_{SO}+n_{SE}}\right)}{1 + a_{Sig} \times b_{Sig} \times \left(\frac{n_{SO}}{n_{SO}+n_{SE}}\right) + a_{Sig} \times c_{Sig} \times \left(\frac{n_{SE}}{n_{SO}+n_{SE}}\right) + a_{Sig} \times \frac{c_{Sig}}{2} \times \left(\frac{n_{SO}}{n_{SO}+n_{SE}}\right)} \quad (7)$$

$$N_{\mathrm{ARan}} = \frac{T_t \times a_{\mathrm{Ran}} \times \left(\frac{n_{\mathrm{SO}}+n_{\mathrm{NO}}}{n_{\mathrm{SO}}+n_{\mathrm{SE}}+n_{\mathrm{NO}}+n_{\mathrm{NE}}}\right)}{1 + a_{\mathrm{Ran}} * b_{\mathrm{Ran}} * \left(\frac{n_{\mathrm{SO}}+n_{\mathrm{NO}}}{n_{\mathrm{SO}}+n_{\mathrm{SE}}+n_{\mathrm{NO}}+n_{\mathrm{NE}}}\right) + a_{\mathrm{Ran}} \times c_{\mathrm{Ran}} \times \left(\frac{n_{\mathrm{SE}}+n_{\mathrm{NE}}}{n_{\mathrm{SO}}+n_{\mathrm{SE}}+n_{\mathrm{NO}}+n_{\mathrm{NE}}}\right) + a_{\mathrm{Ran}} \times \frac{c_{\mathrm{Ran}}}{2} \times \left(\frac{n_{\mathrm{SO}}+n_{\mathrm{NO}}}{n_{\mathrm{SO}}+n_{\mathrm{SE}}+n_{\mathrm{NO}}+n_{\mathrm{NE}}}\right)} \quad (8)$$

Finally, when parasitoids bypass non-signaling plants, we assume that the parasitoid's flight speed does not change, but the distance between perceived nearest neighbors increases. The area of discovery for parasitoids following signals must be adjusted to account for the increase in distance:

$$a_{\mathrm{Sig}} = a_{\mathrm{Ran}} \times \sqrt{\frac{n_{\mathrm{SO}} + n_{\mathrm{SE}}}{n_{\mathrm{SO}} + n_{\mathrm{SE}} + n_{\mathrm{NO}} + n_{\mathrm{NE}}}} \quad (9)$$

If we assume that our field is square, then the number of plants in each row is the square root of the total number of plants in the field (the sum of the number of plants in the four states). Likewise, if we assume the signaling plants are distributed equally between the rows, then the number of signaling plants per row is the square root of the total number of signaling plants (the sum of the number of plants in SO and SE states). If we assume that the parasitoid forages along a straight path, then the density of signaling plants encountered is the square root of the density of signaling plants in the field.

To understand what distribution of plant states may occur in natural populations, we use an age–class transition model for two herbivore examples. Figure 1 demonstrates transition of plants between the different states.

The model begins with all of the plants neither occupied nor induced (NE) and runs for 100 time steps. Each time step represents a single day. A set fraction of plants ranging from 0.1 to 0.9 are newly "occupied" by herbivores at each time step. For a lepidopteran herbivore, the occupation rate is equivalent to the rate of eggs hatching in a single day, which is equivalent to a daily oviposition rate, assuming there is no significant egg mortality. Occupation rate is expected to correlate with the proportion of plants infested. As plants become occupied, they move either from NE to NO or from SE to SO.

A plant remains occupied as long as a suitable larval host is feeding. Pupation, mortality, and dispersal are all potential ways for plants to be abandoned by larvae, and the probability of these events depends on the age of the larva. The maximum number of days a plant can remain infested by a single larva and thus the maximum number of infestation age classes is the development time for the herbivore larva. When larvae pupate, the plants on which they resided are moved into the SE class unless a plant is simultaneously occupied by a younger larva. When a parasitoid cannot attack an herbivore because it has matured beyond its vulnerable instars, the plant is considered "empty," similar to what happens when the herbivore pupates; however, because the herbivore continues to feed, the plant continues to produce volatile signals. Because these unsuitable hosts are classified as empty, a parasitoid encountering these hosts spends no handling time (b) in the current model, but it would be appropriate to add handling time of unsuitable hosts in specific systems.

Because herbivore mortality rate depends on larval age, the model includes different infestation age classes for each day of larval occupancy. At each time step, each age class is multiplied by the appropriate mortality rate, which accounts for density-independent mortality sources for that larval age class such as weather and diffuse predation. The fraction of plants with dying larvae are moved into the SE state if they were on a signaling plant and moved into the NE plant state for non-signaling plants, while the remaining plants are advanced to the next infestation age class. For the systems

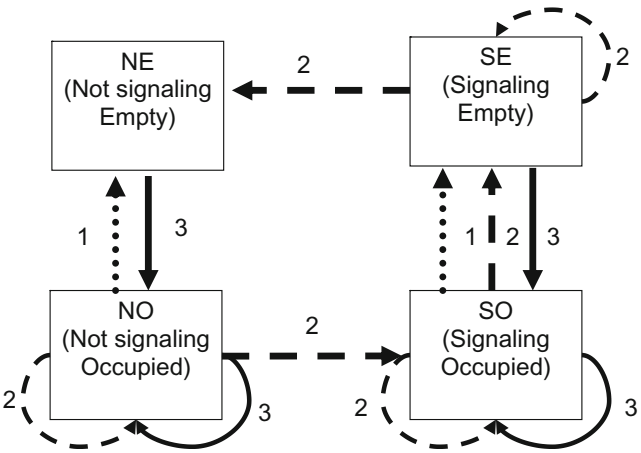

Fig. 1 Flow diagram describing transitions between the four plant states, with each plant state represented by a box. Age classes of herbivores are modeled within each of the occupied (O) states, and relaxation rate-time classes are modeled within the signaling empty (SE) state (not shown). Each time step consists of the following three sequential operations: (1) Occupied plants are multiplied by the mortality rate, and the fraction of plants with dying larvae move to one of the two empty states (dotted line). (2) Larvae on occupied plants are matured by one time step (*dashed line*). Plants with larvae that become older than the induction time move from the not signaling occupied (NO) state to signaling occupied (SO) state, and plants with larvae that become pupae move from SO to the signaling empty (SE) state. Plants in SE long enough to turn off the signal moved from SE to the not signaling empty (NE) state. (3) All age classes and states are multiplied by the occupation rate (*solid line*) and the fraction of plants receiving new larvae have the larval age class set to 1

explored here, dispersal of larvae to other plants was not a major factor, so dispersal was left out, but when expanded to other systems, herbivore migration would both cause occupied plants to become empty and empty plants to become occupied.

When a plant is reinfested, it is classified by its youngest larva, i.e., placed in the first infestation age class, but remains in the "signaling" state if it was previously signaling. This allows for plants to remain signaling for longer than the time of a single larva's development when multiple larvae reside on a plant. However, this introduces a potential bias to the model. In the situation in which the youngest larva dies before the others, the plant would be moved into the "empty" category before the plant was in fact abandoned. This bias is unavoidable because the model cannot follow the fate of individual larvae on each plant.

Although volatile production is probably a continuous function in real plants, we modeled it as a discrete binary function. This means that we assumed that the parasitoids have a perception threshold for volatile concentrations; a plant was "signaling" if it was producing enough volatiles to be perceived by the parasitoid and "not signaling" if the concentration was below the parasitoid's perception threshold. In addition to describing induction as an "on–off" function, we assumed that the concentration of volatiles only changed at the beginning of a daily time step. The induction delay at which plants move from N to S after the onset of herbivory is set at values ranging from 1–5 d for this model. The relaxation delay at which plants move from S to N after the cessation of herbivory is also fixed at values ranging from 1–5 d.

This model can allow us to generate the proportion of plants in each state over time, and we can take these distributions and substitute them into Eqs. 7 and 8. Because we are primarily concerned with the impact of herbivore population density on signal relevance, we hold a, b, and T_t constant, using parameters from the literature for the two-system examples we provide. For more information on the assumptions made in this model, see Puente (2007).

Model Parameters We used life history data on *H. virescens* and *P. rapae* for setting parameter values in the model. *H. virescens* is a generalist in the taxon Noctuidae and attacks many important crop plants including cotton and tobacco (Neunzig 1969). It has many well-known parasitoids and predators, both specialists and generalists. *C. nigriceps*, a parasitoid that attacks all stages of *H. virescens* larvae (Lewis and Vinson 1971), is preferentially attracted to *H. virescens* on certain host plants and can distinguish *H. virescens* infestations from infestations by closely related *Helicoverpa zea* (DeMoraes et al. 1998). In field studies, *C. nigriceps* preferred hosts on tobacco rather than on cotton, regardless of the dominant host plant available (DeMoraes and Lewis 1999; Tillman and Mullinix 2003). While difference in volatile production may explain how parasitoids can distinguish between cotton and tobacco, it does not explain why *C. nigriceps* prefers tobacco. Understanding the temporal dynamics of induction may help us understand host preferences.

Daily mortality rates for *H. virescens* were calculated for each larval stage by using data from Johnson and Gould (1992). Because *H. virescens* varies widely in its survival rates, a low and a high mortality scenario are examined (see Table 2). *H. virescens* adults avoid ovipositing on plants that are already occupied by larvae or eggs (DeMoraes et al. 2001). Under the special case that adult herbivores avoid ovipositing on already-infested plants ("limited oviposition" condition), only plants in the NE state are multiplied by the occupation rate. When this assumption is lifted to allow the default multiple ovipositions on a plant ("multiple oviposition" condition), all plant age classes are multiplied by the occupation rate. Both oviposition scenarios are considered for this herbivore.

Parameter values for *C. nigriceps* were obtained from Tillman and Mullinix (2003) and are summarized on Table 1. The parasitoids are typically active between 0900 and 1500 hours, and spend about half of that time engaged in host foraging behaviors, which translates to a T_t of 3 hr or 10,800 sec. On the host plant tobacco, parasitoids spend 11.6 sec hovering and 11.7 sec searching around a plant for a total of 23.3 sec searching per plant, giving an estimate of

Table 1 Variables in the model

Parameter	*Heliothis virescens*	*Pieris rapae*
	Cardiochiles nigriceps	*Cotesia glomerata*
Tt (sec)	10,800[a]	14,400[b]
a (plant/sec)	0.043[a]	0.33[c]
b (sec/hosts)	20.5[a]	13.1[d]
c (sec/plant)	128.7[a]	73.5[d]
Occupation rate (new larvae/total plants/day)	0.1–0.9	0.1–0.9
Induction delay (days)	1–5	1–5
Relaxation delay (days)	1–5	1–5
Oviposition[e]	Limited and multiple	Multiple
Host attack stage (instar)	5	1–5

[e] 'Oviposition' refers to whether the host limits oviposition to plants that are neither occupied nor signaling (Limited) or will place multiple larvae on one plant (Multiple).

0.043 plants per second for *a*. The handling time for oviposition and preening (*b*) was 20.5 sec per host. Finally, the time spent in what Tillman and Mullinix (2003) refer to as "agony search," a measure of the giving-up-time estimate for *c*, was estimated to be 128.7 sec for wasps on tobacco.

The *P. rapae* tritrophic system has been extensively studied both because it is tractable and because it has economic relevance for many crops. *P. rapae* is a butterfly in the taxon Pieridae that specializes on brassicacean plants, including crops such as cabbage, broccoli, and Brussels sprouts, and the experimental model system, *Arabidopsis thaliana* (Courtney 1986). A major larval parasitoid for *P. rapae* in some geographic areas (Vos and Vet 2004), *Cotesia glomerata*, is restricted to surviving in only the early instars of *P. rapae* but cannot distinguish the age of the larvae based on plant volatiles alone (Mattiacci and Dicke 1995). The temporal pattern of herbivore-induced plant volatile production has been documented only for a few systems, including *P. rapae*. Geervliet et al. (1998) found that Brussels sprouts were most attractive to braconid parasitoids after 3 d of feeding by *P. rapae*. Additionally, a wind tunnel study found that Brussels sprouts fed on by *P. brassicae*, a close relative to *P. rapae*, were most attractive to *C. glomerata* 3 d after feeding and ceased being attractive to the parasitoids 1 d after the herbivores were removed (Mattiacci et al. 2001).

P. rapae larvae go through five instars of approximately 3 d each. Daily mortality rates were taken from Dempster (1967; see Table 2). Because *C. glomerata* survives only on the first two instars, in this model, encountering a plant with a fifth instar larva would have the same effect as encountering an empty plant because no host could be attacked. To simulate this system, the mechanisms for classifying signaling from non-signaling states as described previously were maintained, but the definitions of empty and occupied were reassessed to include the parasitoid's age preference. The term "attack preference" refers to the maximum age of larva a parasitoid is able to attack successfully. We examined the impact that attack preference has on signal relevance by setting the attack preference at 3 d (first instar), 6 d (second instar), 9 d (third instar), 12 d (fourth instar), and 15 d (fifth instar). It is possible that parasitoids encountering a host that is beyond the attack preference may spend more or less time investigating before leaving the plant (and thus "c" would not be the same as it would for a truly empty plant), but we chose not to consider those special conditions in this initial model.

To calculate signal relevance for this system, we can use parameter estimates derived from the literature (see Table 1). The parasitoids are most active in the late morning and early afternoon (Kaiser and Carde 1991), so we assumed a maximum of 4 hr of foraging per day; the total time (T_t) is 14,400 sec. Sato and Ohsaki (2004) observed that, for *C. glomerata* searching for *Pieris* larvae, the time spent searching one leaf (*c*) was 73.5±11.9 sec, and the handling time (*b*) was 13.1±3.9 sec. We can use the mean of these observations as our parameter estimates. The recorded flight speed for *C. rubecula*, a closely related species that also parasitizes *P. rapae*, was 0.33 m/sec (Kaiser et al. 1994), so we can use this to estimate the parameter *a*; area of discovery as 0.33 plants per second.

Table 2 Daily mortality of larvae as a proportion of the individuals at a specific age within a larval instar

Heliothis virescens[a]				*Pieris rapae*[b]

Results

Fixed Parameters Total foraging time, handling time, area of discovery for random foraging, and giving-up time were held constant for all simulations investigated for a particular herbivore system. Handling time and giving up time were shorter for the *Pieris* system, while area of discovery and total foraging time were shorter for the *Heliothis* system. This leads us to predict that for one foraging day, *Cotesia glomerata* would be capable of attacking more *P. rapae* than *C. nigriceps* is capable of attacking *H. virescens*. In fact, if we set all other parameters (induction delay, relaxation delay, host attack preference, occupation rate, high mortality) equal, then the N_A for *Pieris* is between two and four times as large as N_A for *Heliothis*. However, when all other parameters are equal, there is not a considerable difference in signal relevance between the *Pieris* and *Heliothis* systems, except at the lowest occupation rates when, for example, if plant signal delays are both held at 1 day, a parasitoid of *H. virescens* could see a threefold improvement by following plant cues, compared to only a 2.5-fold improvement for parasitoids of *P. rapae*. This means that even though more *P. rapae* larvae can be attacked per day, parasitoids for both herbivores have the same threshold for when they should not follow cues.

Occupation Rate As occupation rate increases, the proportion of plants occupied increases but approaches an asymptote rather than being linearly correlated with occupation rate. The asymptote is a product of the model design. Plants are infested by multiplying each stage class by the occupation rate, ensuring that a fraction of plants will remain unoccupied for any occupation rates less than 1. At very high occupation rates, the proportion of plants unoccupied can be infinitesimally small so that, in a real field, all plants would in fact be occupied. As described in "Methods and Materials," the fact that the multiple oviposition scenario reaches an asymptote below 1.0 is a result of the model following only the youngest larva on a plant. In the limited oviposition scenario, the asymptote is at an even lower proportion due to the ovipositing host's avoidance of plants induced and empty (SE). Although this may make the model less realistic for natural outbreak conditions, in agricultural settings, growers would be advised to spray long before 90% of the field is occupied; therefore, our model is acceptable over the range to probable herbivore infestation rates.

One consistent trend for most parameter combinations is that, as occupation rate is increased from 0.1 to 0.9, the *Rel* value decreases. As occupation rate increases, the proportion of plants infested increases, so the number attacked (N_A) increases for both wasps following signals and wasps randomly foraging. However, the patterns of increase differ between the foraging strategies (Fig. 2a). The N_A for random foraging increases after a type II functional response, with a large initial increase in attacks slowing down as handling and giving up time become a greater limitation. We see this type II response because occupation rate regulates the transition from NE to NO, and thereby directly changes the density of occupied plants (Eq. 5b). The N_A for parasitoids that respond only to signaling plants, however, does not increase as drastically. The transition from SO to SE is primarily due to the mortality rate, so changing the occupation rate does not change the density of occupied signaling plants compared to all signaling plants

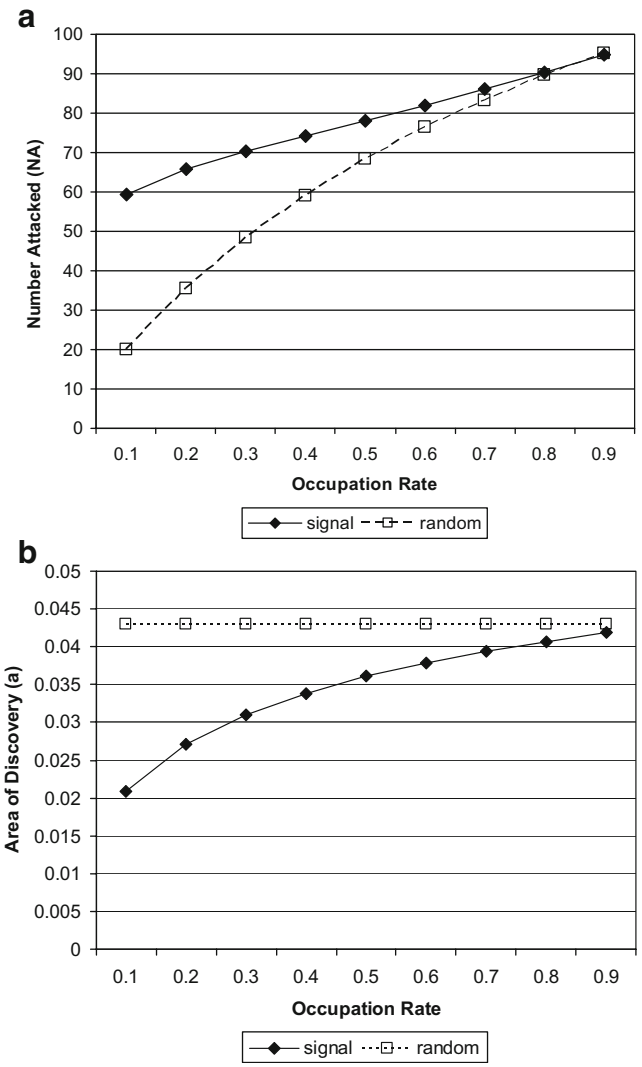

Fig. 2 The impact of occupation rate. These sample data came from the parameters of high mortality and multiple oviposition for *H. virescens*, and plant induction and relaxation delays of one day each. **a** The relationship between occupation rate and number of hosts attacked (N_A) for parasitoids following signals (signal) compared to parasitoids randomly foraging (random). **b** The relationship between occupation rate and area of discovery (a) for parasitoids following signals (signal) compared to parasitoids randomly foraging (random)

(Eq. 5a). However, an increase in occupation rate does change the density of occupied signaling plants compared to all plants (Eq. 9), which results in an increasing area of discovery as occupation rate increases (Fig. 2b). Additionally, in the case of multiple oviposition by *H. virescens*, the chance of a signaling plant being reinfested before relaxing the signal increases with greater occupation rates, which also can lead to a modest increase in density of signaling plants with increasing occupation rates. At high occupation rates, virtually all plants that are occupied are also signaling, resulting in *Rel* approaching one. The only exception to these general patterns was in the case of setting host attack stage to first instars, which will be discussed in the section on host-stage attack.

For the remainder of this paper, we present results for occupation rates less than 0.5, as data for higher occupation rates both represent unrealistic field densities and are less reliable due to the inherent bias in the model toward younger larvae when plants are multiply occupied.

Induction Delay While we are presenting the data only for the *Pieris* system, the impact of induction delay was similar for both *Heliothis* and *Pieris* systems. In most cases, varying induction delay from 1 to 5 d resulted in less than a 0.1 difference in *Rel* values (Fig. 3a). Induction delay determines the transition from NO to SO plants; for randomly foraging parasitoids, this does not change the density of hosts because NO and SO appear in both the numerator and denominator of the density calculations (Eq. 5b). For signal-following parasitoids, once plants are in SO, the transition to SE is not dependent on the induction period, so this does not change the density of available hosts (Eq. 5a). A change in ratio of SO to NO plants can impact the area of discovery, and therefore, we see that a 5-d induction delay leads to a lower *Rel* than a 1-d induction delay, but the change is small, and the parasitoid would benefit from following signals regardless of the induction delay. It should be noted that this result rests on the assumption that the resources in the field are infinitely abundant, so that even though signaling plants are rare in the field, there is still a large enough number of plants in the field to exhaust the parasitoid's total foraging time. The only exception to this general pattern was in the case of setting host-attack stage to first or second instars, which will be discussed in the section on host-stage attack (Fig. 3c).

Relaxation Delay In most cases, as the delay for plant signal relaxation increased from 1 to 5 d, the relevance of the signal decreased (Fig. 3b); the only exception was the case when host-stage attack was limited to first instars (Fig. 3d). Relaxation delay determines the transition of plants from SE to NE. A long delay increases the number of plants remaining in the SE state, which has the effect of lowering the relative density of occupied signaling plants without changing the overall density of occupied plants. In other words, a long relaxation delay means that parasitoids following signals will spend more time foraging on unoccupied plants, thus decreasing the number of hosts attacked.

For the *Heliothis* system, we compared signal relevance when oviposition was limited to empty plants and when there was no limitation. When multiple ovipositions per plant are allowed, the impact of relaxation delay decreases at higher occupation rates because signaling plants are likely to be reinfested. However, when oviposition is limited, the effect of relaxation delay continues even at higher occupation rates.

Mortality Rate Because reported mortality rates vary greatly for *H. virescens*, we looked at the impact of herbivore mortality for that system only. At low occupation rates, signal relevance was higher when the host mortality rate was higher (Fig. 4); however, at higher occupation rates, lower mortality led to higher signal relevance. Mortality can either cause plants to shift from NO to NE states or from SO to SE states, and the impact of mortality on signal relevance depends on the balance of these two transitions. A transition from NO to NE will decrease the density of occupied plants while having no effect on the density of signaling plants that are occupied; thus, x_{Sig} will not be affected by the transition but x_{Ran} will. However, the transition from NO to NE also limits the number of plants in the NO state that can then enter the SO state, thus reducing the n_{SO}, which has the effect of decreasing a_{Sig}. A transition from SO to SE will decrease both the overall density of occupied plants and the density of signaling occupied plants. Because mortality is concentrated at the earliest part of the *H. virescens* life table, the number of transitions from NO to NE is greater than from SO to SE, and therefore, initially increasing mortality causes an increase in signal relevance. In other words, at low occupation rates, the distance between signaling plants is so great that a parasitoid stopping at an empty signaling plant is at a great disadvantage; when mortality is high, herbivores die before plants begin signaling, thus reducing the number of false signals in the field. However, once the herbivore density becomes high enough so that the area of discovery is similar for both foraging strategies, the impact that mortality has on herbivore density becomes much more important. The number of signaling plants is less than the number of plants in the field, and, therefore, the transition of a single plant due to herbivore mortality will have a greater impact on the signaling density than on the overall density. Increasing the mortality decreases the signal relevance as occupation rate increases.

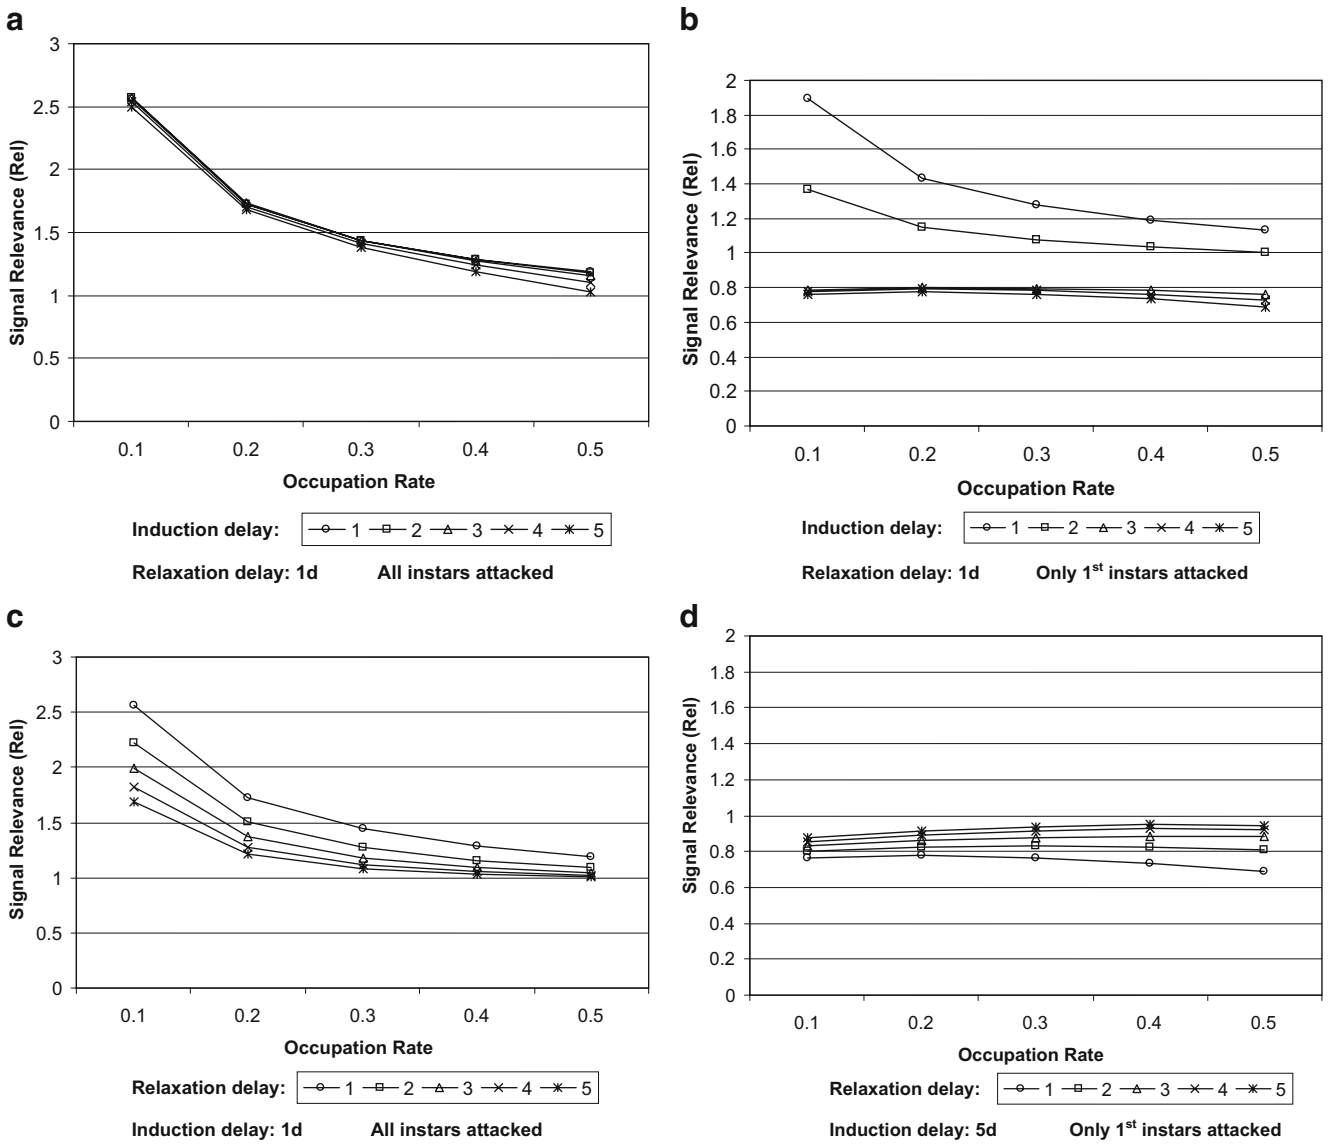

Fig. 3 The relationship between induction delay, relaxation delay, host-stage, attack preference, and signal relevance. For all four cases shown, mortality rates and parasitoid foraging parameters were set to resemble those of *P. rapae* and *Cotesia glomerata*. **a** Numbers in the legend reflect days for induction delay. Relaxation delay was fixed at 1 d. Host-stage attack preference was fixed at fifth instar. **b** *Numbers in the legend* reflect days for relaxation delay. Induction delay was fixed at 1 d, and host-stage attack preference was fixed at all instars attacked. **c** *Numbers in the legend* reflect days for induction delay. Relaxation delay was fixed at 1 d. Host-stage attack preference was fixed at first instar. **d** Numbers in the legend reflect days for relaxation delay. Induction delay was fixed at 5 d, and host-stage attack preference was fixed at first instar

Oviposition Preference We only tested oviposition preference for the *Heliothis* system because *Pieris* females do not avoid ovipositing on occupied or signaling plants. When herbivores limit their oviposition to only NE plants, the signal relevance to the parasitoids decreases (Fig. 4). By avoiding signaling plants, herbivores are increasing the proportion of SE plants relative to SO plants, so parasitoids following signals are more likely to waste time encountering empty plants. When multiple ovipositions per plant are allowed, signaling empty plants can be occupied before the entire relaxation period is complete, and thus, the signal created by the previous herbivore can still be an indicator of the current herbivore. The impact of this behavior depends on the density of signaling plants in the field. At very low densities, limiting oviposition does not greatly decrease signal relevance because the probability of a moth laying multiple eggs on the same plant is low, so there is not much difference in field distribution for the limited or multiple oviposition conditions. At higher densities, *Rel* for multiple oviposition is greater than for the limited oviposition case because more plants can be reinfested before the signal turns off. When herbivores limit their oviposition, it narrows the density range where parasitoids benefit from following signals.

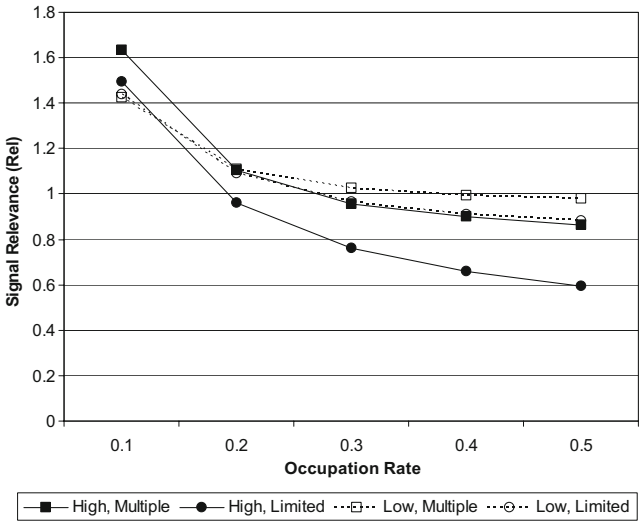

Fig. 4 The relationship between mortality rate, host oviposition, and signal relevance. Parameters were set for *H. virescens*; plant induction and relaxation delays were both set at 5 d. In the legend, "high" and "low" refer to the high and low mortality values on Table 2, "multiple" and "limited" refer to whether a plant could be infested multiple times or if new host infestations were limited to only non-signaling, empty (NE) plants

Host-Stage Attack Preference As alluded to above, host-stage attack preference can interact with other parameters to decrease signal relevance. Specifically, when the parasitoid was limited to a host stage that was shorter than the induction period, the signal relevance decreased. For example, a parasitoid that could attack only first-instar *P. rapae* would have a $Rel>1$ if the host-plant induced after 1 or 2 d but $Rel<1$ if host plant induction took longer than 3 d (Fig. 3c). In the case of higher induction delays and a parasitoid limited to first instars, the SO state occurred only if the plant was reinfested with a new larva, while an older larva induced the signal, which happened at a greater frequency with high occupation rates. In this limited case, *Rel* increases as occupation rate increases, but it never is greater than one.

Discussion

Parasitoid foraging in response to herbivore-induced plant volatiles is a complex behavior, and it will take a combination of multiple models that focus on different aspects of the same system to understand fully this phenomenon. Models that focus on how parasitoids forage in the micro-habitat of the plant canopy (such as Vos and Hemerik 2003) complement this model's approach of looking at parasitoid foraging across an agricultural field. Results from this model identify several biological parameters that should be more thoroughly studied empirically. First, the relationship between herbivore density, plant volatile production, and parasitoid response has traditionally been studied at the single-plant level. However, in this model, field-level herbivore density was shown to affect the relevance of plant volatile signals when the same quality of volatiles was produced by all signaling plants. This indicates that to understand the value of a plant's volatiles to a foraging parasitoid, herbivore population dynamics at the landscape spatial scale must be considered.

The second point is that a delay in the initiation or cessation of volatile signal production may, in certain conditions, decrease signal relevance for a foraging parasitoid. It is not enough to measure simply whether volatiles are produced and whether parasitoids can respond physically to the cue. It is also important to ask if these volatiles are being produced in a time frame relevant to the parasitoid's foraging behavior. This assessment should include relevant physiological constraints on the parasitoid, such as which instars are viable hosts.

The possibility has been raised in several papers of breeding for "calling" plants to enhance biological control (Takabayashi and Dicke 1996; Dicke et al. 2003). In a few studies, it has been found that parasitoids respond more strongly to some cultivars or genotypes within a plant species, indicating that genes for the volatile cues may have inadvertently been bred out of other cultivars (Fritzsche Hoballah et al. 2002; Lou et al. 2006). Part of this discrimination may be due to the specific chemicals that comprise the plants' volatile cues. These preferences may have developed because certain plant–host complexes produce more relevant signals than others.

In addition to examining the presence or absence of volatile signal production in plants, it may be important for plant breeders to look at the relevance of signal production by plants to the parasitoids and predators of interest. A plant volatile that is useful in one geographical region may be useless in another area that has a different insect community. For example, in regions where the main parasitoid is *Cotesia rubecula*, which can successfully attack *P. rapae* in later instars, plants with later volatile releases can still manipulate the third trophic level. However, in geographic areas where the main parasitoid is *C. glomerata*, which can only attack the first two instars of *P. rapae*, the same plants will produce volatiles that are irrelevant to the third trophic level. Additionally, in some geographic regions, the presence of potential parasitoid hosts may overlap with herbivores that are non-hosts but that also trigger plants to produce volatile signals. If these volatiles are not unique for host herbivore, there may be a disproportionate number of signaling but empty (SE) plants induced by the non-host, resulting in irrelevant signals. While past emphasis has been placed on the ability to breed plants that are capable of turning on signals, it may be as

important to focus on breeding plants that can also quickly cease signaling when herbivory ceases. Within the scenarios examined with our model, we found that the greatest increase in parasitoid attack rate due to the presence of signals was fourfold. Plant breeders must therefore determine if less than a fourfold increase in attack rate will lead to economic and environmental gains substantial enough to justify a complex breeding program.

How signal relevance impacts a parasitoid species depends on their plasticity of response. Parasitoids have shown both inherent (Fritzsche Hoballah et al. 2002) and learned ability (Dicke 1999; Fukishima et al. 2002) to follow plant-produced volatile cues. A parasitoid that can learn may adjust its foraging strategy among days or even within one foraging bout based on the relevance of the signal. For a parasitoid with inherent preferences, signal relevance is more likely to act on an evolutionary timescale.

There are many possible ecological pathways through which herbivore-induced plant volatiles could affect parasitoid attack rates. We chose to focus on bypassing non-signaling plants, but there are other processes that may be at work. By altering the assumptions we made in this study, modelers can address some of these other differences. We assumed that the spatial unit of induction was a plant. Some plants begin producing volatiles when nearby plants are induced to create neighborhood effects (Karban 2001). We did not include this type of interaction, but we can speculate that this would have an effect of increasing the signaling empty (SE) plants and may also impact the area of discovery, a, if parasitoids increase their time spent foraging in signal-rich areas. If a parasitoid approaches a field and the overall volatile cloud causes it to fly slower and increase its turning radius, then this impacts the number of plants the parasitoid can land on over time ($a_{\mathrm{Sig}} \leq a_{\mathrm{Ran}}$).

We assume that the field in which the parasitoid forages is sufficiently large so that the parasitoid will run out of time before it runs out of available hosts. The number of signaling plants in a field must be less than or equal to the total number of plants in the field, so a parasitoid's relevant environment is smaller if it is restricted to signaling plants. If a parasitoid is capable of exhausting all the hosts in its environment, we can assume it will leave the field. If then we assume that a parasitoid leaving one field will simply fly to another field with similar characteristics and continue foraging until the total time has expired, then there is no change to the variables. However, once abandoning one field, if the time it takes to reach another field is considerable or a high risk of death during transit occurs, this can effectively reduce the total time the parasitoid has available for foraging. Thus, $T_{\mathrm{tSig}} \leq T_{\mathrm{tRan}}$ in all cases where hosts are a limiting factor and fields are isolated.

We assumed that handling time was constant regardless of host-plant volatiles. If handling time increases on signaling plants where the parasitoid has a positive oviposition experience, as would occur when the parasitoid spends extra time learning the cues of a plant after a successful oviposition, then this could lead to a difference in handling time for signaling and random plants ($b_{\mathrm{Sig}} > b_{\mathrm{Ran}}$).

Because plants were categorized by their youngest infesting larvae, cases where the youngest larva dies first were misclassified. This biases the model toward empty plants in the multiple occupation scenarios because there is higher mortality for first instar larvae, especially in the case of *H. virescens*. This bias is especially troublesome at the higher occupation rates where multiple occupation is more likely to occur. This shortcoming is addressed in the following companion paper (Puente et al. 2008) that reports results with a spatially explicit model that follows the fate of multiple larvae on a single plant. The value of this general model lies in its attempt to capture various interactions brought about by behaviors of all three trophic levels, and its ability to produce system-specific predictions.

The oviposition behavior of *H. virescens* poses a challenge to foraging parasitoids. If *H. virescens* limits oviposition to uninfested plants, the signal relevance that plants provide to parasitoids at high herbivore densities is reduced. However, as long as the density of herbivores remains low, the model predicts that parasitoids will benefit from following plant signals.

Additionally, we looked at two different life tables for *H. virescens* and found that, at low herbivore densities, plant volatiles were more relevant when mortality was high. This indicates that using other pest control methods to suppress the population produces conditions where plant signals are more relevant to parasitoids for biological control. This model supports the notion that complementary methods of pest control are better than relying on a single method such as biological control.

Because *C. glomerata* has a narrow range of host stages, we were curious to see if that would make signals less relevant. As long as *C. glomerata* is able to successfully attack second instars, following plant signals is the preferred strategy for the entire range of parameters we tested for *P. rapae*. However, when parasitoids are limited to just the first instar, they would be better off randomly foraging than following plants that take longer than 2 d to induce signals. We can predict that it would be detrimental for *C. glomerata* to follow plant signals that are not induced until larvae reach the third instar because *C. glomerata* specifically forages on the first two instars. However, in systems where it has been measured, plants responded to herbivory with volatile production well before the third instar would have been reached (Geervliet et al. 1998; Mattiacci et al. 2001; Scascighini et al. 2005).

The general deterministic model presented here quantifies the potential impact of a number of ecological factors

on the importance of induced volatiles to parasitoids. As the first biologically based model of this general system, it brings forth more questions than it answers. More detailed models tailored to specific tritrophic systems and more detailed experimental data on those systems will be needed to answer these questions.

Acknowledgment We thank Krisztian Magori for programming assistance and Coby Schal, Marcel Dicke, Nick Haddad, and anonymous reviewers for feedback on earlier versions of this manuscript. Funding for this research was provided by a National Science Foundation Pre-doctoral Fellowship and by the Keck Center for Behavioral Biology.

Some argue that artificially enhancing volatiles in the field will arrest parasitoids in the area, leading to better control, while others argue that artificially enhanced volatiles will produce misleading signals, thus, reducing the receptiveness of parasitoids to volatiles. In a few field studies conducted in small plots, artificially enhanced volatiles have led to higher parasitism, but it is unclear whether this is due to better attraction of parasitoids from outside the plot, better retention of parasitoids within the plot, or increased efficiency of parasitoids within the plot (e.g., James and Price 2004).

Research on the quality of volatile signals has looked at the specificity of volatile production (Dicke and Takabayashi 1991; Blaakmeer et al. 1994) and the parasitoid's ability to discriminate between odors (Agelopoulos and Keller 1994; Fritzsche-Hoballah et al. 2002). However, being able to discriminate between volatiles does not mean that predators and parasitoids will respond to specific plant volatiles in the wild. Many parasitoids have the ability to learn new signals based on past experience (Lewis and Martin 1990). Additionally, there is heritable variation in parasitoids for responding to plant volatiles (Lewis and Martin 1990; Wang et al. 2004). The proximate incentives for a parasitoid to learn a response to a signal or for a population of parasitoids to evolve a response to a signal are the same; the herbivore-induced volatiles must correlate in time and space with herbivore availability. When the volatiles are not consistently correlated with herbivore presence, there is selection for parasitoids to maintain variation in this response, either through maintenance of genetic variation or evolution of phenotypic plasticity (Wang et al. 2004). In studies where the volatile signal has been uncoupled from herbivore presence, such as by saturating fields with volatiles, parasitoid response to the signals has decreased (Lewis and Martin 1990).

Some work has been done to document the lag time between herbivore damage and production of volatiles that elicit parasitoid responses (Mattiacci et al. 2001). Relating this time course to parasitoid efficiency at host finding, however, has not been thoroughly investigated. Mattiacci et al. (2001) found that *Cotesia glomerata* responded to Brussels sprout plants only after herbivores had been feeding for at least 3 days, but they stopped responding to plants if the herbivores had been removed for more than 1 day. Additionally, Agelopoulos and Keller (1994) found that induced cabbage plants where the herbivores had been removed were just as attractive to *C. rubecula* 22 h after herbivore removal as immediately after removal. This seems to indicate that the plant's lag time for commencing volatile production is longer than the lag time needed to cease volatile production, but that both lag times are expected to be of biological importance. This leads to the question addressed in this study: how long can a plant's lag time be without reducing the relevance of the volatiles as signals to the parasitoid?

While it has been shown that herbivore-induced volatile emission can result in attraction of parasitoids to plants within a wind tunnel type of environment (Agelopoulos and Keller 1994) and that induced plants can arrest predators and parasitoids (Agelopoulos and Keller 1994), we have no record of the distances over which these induced cues may act in the field. Designing field experiments to test attraction to induced plants is a difficult task. Identifying the point at which an insect switches from random movement to directed flight as well as identifying which environmental cues out of the complex volatile environment triggered the change is a challenge that has yet to be successfully tackled in the field.

While not a replacement for field studies, computer simulation models can be used to predict how parasitoids should respond to a complex environment (e.g., Dunning et al. 1995). This allows simultaneous testing of more variables than is possible in a laboratory setting while affording more control over parameters than is possible in most field experiments. By artificially establishing diverse patterns of environmental parameters, we can identify which combinations of plant, herbivore, and parasitoid behaviors are predicted to have the strongest impact on parasitoid foraging success. This information can then be used in designing more efficient field studies.

In this paper, we use the tritrophic system of *Cotesia rubecula*, *Pieris rapae*, and *Brassica oleracea* to ask how the temporal and spatial patterns of herbivore-induced plant volatiles impact parasitoid foraging success. The extensive work on volatile signals in this system, as well as the extensive life history data available for these three species, renders this an ideal tritrophic system for detailed simulation analysis. *P. rapae*, the cabbage white butterfly, is a cosmopolitan herbivore that feeds primarily on Brassicaceae (Kaiser and Cardé 1992). While these plants generally share similar chemical defensive profiles (Kaiser and Cardé 1992; Geervliet et al. 1994), there is also variation in form and distribution of the plants, and it has been shown that *P. rapae* prefers certain host types over others, even within the species *B. oleracea* (Jones and Ives 1979). *C. rubecula* is a specialist parasitoid that can attack all stages of *P. rapae* caterpillars, but this parasitoid's larvae suffer greater mortality when attacking older hosts (Nealis 1990; van Driesche et al. 2003). This species has been shown repeatedly to be responsive to herbivore-induced plant volatiles with positive experience reinforcing this response (Kaiser and Cardé 1992; Blaakmeer et al. 1994; Geervliet et al. 1994). The larval parasitoid *C. rubecula* will respond to plant volatiles multiple times after caterpillars have left (Nealis 1990), so they could be negatively affected by asynchronous signals in the field.

Methods and Materials

Plants We modeled a rectangular, contiguous, grid-like field of *Brassica oleracea* plants with the center of each plant located 1 m from its nearest neighbors. For the analyses, the field was fixed at a 20×20 size (a total of 400 plants). Individual *Brassica* plants were assumed to be induced by the feeding of *Pieris* larvae to produce volatiles that attract parasitoids. Plants were assumed to start effective volatile production following the onset of herbivore feeding (*induction delay*, ranging from 1 to 5 days). Plants continued to emit volatiles throughout herbivore feeding, and stopped the emission of volatiles (*relaxation delay*, ranging from 1 to 5 days) after the cessation of herbivore feeding (due to death or pupation of all herbivore larvae on the plant). Therefore, some plants in the field without herbivores did emit volatiles and potentially misguide parasitoids that were attracted to the volatiles.

Population Dynamics of Herbivores Population dynamics of *Pieris rapae* infesting a field were simulated by using an age-structured model based on field-collected life table data. The model tracked up to 20 *Pieris* larvae per plant. The model assumed that all damage-induced plants produced the same concentrations of volatiles, regardless of how many larvae were infesting the plant. However, it has been found that *C. rubecula* is more responsive to plants that host more larvae (Kaiser and Cardé 1992; Kaiser et al. 1994; Geervliet et al. 1998), so being able to follow multiple larvae opened up the possibility in the future of simulating a change in volatile strength due to the herbivore load on a particular plant.

Life table data for *P. rapae* immature stages were gathered from several sources (Harcourt 1966a; Dempster 1967; Parker 1970; Jones et al. 1987). Overall preadult mortality ranged from 69.1 to 95.9%. If the data provided by Harcourt (1966a) which included no egg parasitism were ignored, the average preadult mortality was 91.6%± 3.0% SD (N=7); this is surprisingly consistent considering the variety of host plants and geographic regions these data were collected from. We chose to use the life table from Dempster (1967) because it was consistent with the majority of published life tables and covered the herbivore's lifespan in more detail. The daily herbivore mortality rates used in the reported simulations are given in Table 1. Individual larval death was a stochastic process; for each simulated larva on each day, a random number between 0 and 1 was selected by the computer, and if the number was less than the probability of mortality, the larva was "killed". In a large field, this process should produce roughly the same overall mortality rate as in found in Table 1.

Table 1 Life table for *Pieris rapae*

Stage	Day	Mortality	Mortality (Deterministic)

All adult female *P. rapae* were stored in a single cohort regardless of the day they eclosed. Richards (1940) found that adult *P. rapae* populations usually had a 1:1 sex ratio; therefore, half of all final stage pupae were assumed to be males and were excluded from the adult cohort upon eclosion. Adult female *P. rapae* live for about 3 weeks, so for each daily time step, the number of adults was reduced by the number of new adults present 21 days prior to that time step. No other adult mortality is considered.

P. rapae eggs are disproportionately aggregated at the edges of fields (Harcourt 1966b). This is primarily due to the movement patterns of adult butterflies, which have been studied extensively (e.g., Jones 1977; Root and Kareiva 1984). In natural populations, individual butterflies were observed to fly in a roughly straight path (Jones 1977; Root and Kareiva 1984).We based our herbivore distribution on an algorithm developed by Jones (1977) to recreate the movement patterns of ovipositing *P. rapae* females. In the model, each adult was given a starting position and a directional bias at random. The adult either remained at her current location or moved to an adjoining plant; the direction the adult moved was determined by using the probability of a butterfly turning from an initial directional

flight bias (Root and Kareiva 1984) (see Fig. 1). Following movement, the probability that the adult would oviposit was 0.23, the median probability found by Jones (1977). Field observations found that butterflies crossed patch boundaries without stopping (e.g., Root and Kareiva 1984). In order to reflect this and maintain the same field densities, adults that reached the edges of the simulated field are 'mirrored' to the opposite side of the field. Adults continued to follow this algorithm until they had laid a set number of new eggs. To prevent butterflies remaining indefinitely in a field that had reached its capacity of eggs and larvae, when butterflies encounter ten successive plants that are fully occupied, they leave the model field.

We wanted herbivore populations to reflect natural population sizes, so we set the initial adult population size to 1, included adult movement dynamics, and set the number of eggs to 1, 2, 5, 10, 15, or 20 eggs/butterfly/day. After five runs, the daily average of eggs, larvae, and adults for each of the oviposition rates were calculated for 100 days trials. We then compared the average simulated values to reported field densities, correcting for field size. The density of eggs observed in Parker (1970) was higher than any values we obtained, but the densities observed in Jones et al. (1987) were approximated relatively well by either 15 or 20 eggs/butterfly/day, especially in the second and third generations. The first instar densities observed by van Driesche (1988) in kale were closely approximated by 10 eggs/butterfly/day (see Fig. 2), while the first instar densities observed by van Driesche and Bellows (1988) in collards were approximated by the second generation of simulations for 15 or 20 eggs/butterfly/day (an offset of about 30 days) (see Fig. 2). The number of adults in the field observed by van Driesche (1988) was similar to the results of 10 eggs/butterfly/day. Therefore, for the remainder of the experiments, we assumed 10 eggs/butterfly/day as "low herbivore density" and 20 eggs/butterfly/day as "high herbivore density".

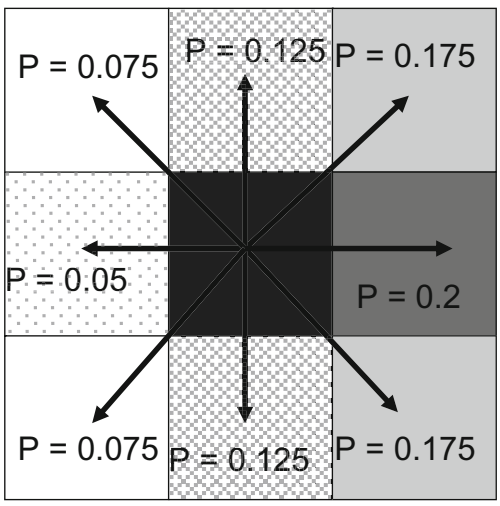

Fig. 1 Spatial bias for *Pieris rapae* butterflies. Assuming a butterfly begins on a plant in the center square and has a bias to the right, the probability that a butterfly will travel to each square is shown by the *P* value in that square

Parasitoid Behavior and Parasitism In essence, the model assesses the fitness of a single parasitoid entering an herbivore-infested field that has had no prior parasitism. Therefore, the parasitism behavior of individual adult *Cotesia* was modeled in detail but its population dynamics were not included. The range of host stages suitable for parasitoid development has been shown to be an important biological parameter for many parasitoids, including the closely related species, *C. glomerata* and *C. rubecula*. The parasitoid *C. glomerata* is unable to attack *P. rapae* larvae older than the third instar because the hosts are able to encapsulate the parasitoid larvae at that stage, so there is higher parasitism on host plants that slow the growth of *P. rapae* larvae (Benrey and Denno 1997). Similarly, *C. rubecula* face higher risks of damage from counterattacks by larvae older than the second instar (Nealis 1990). It has been shown that *C. glomerata* cannot identify the stage of an herbivore based on plant volatile cues (Mattiacci and Dicke 1995) and, therefore, may be attracted to plants with unsuitable larval stages. In the model, parasitoids are only able to successfully attack larvae of the host up to a model-specified instar (*host stage*). Since, in the model, plants that harbor larvae too old to be attacked by parasitoids still emit volatiles, parasitoids that follow signals might be further misled. We varied model parameter values to consider cases where parasitoids could attack first instars only, first and second instars only, or all five instars.

Because we are specifically interested in how herbivore-induced plant volatiles impact parasitoid foraging success, we chose to focus on how underlying host distributions, timing of plant volatiles responses, and parasitoid sensitivity to odor impact parasitoid efficiency. Numerous environmental factors that influence parasitoid foraging efficiency such as wind speed (Keller 1990), light intensity, or previous experience (Keller 1990; Kaiser and Cardé 1992; Geervliet et al. 1998) can also be important, but they are beyond the scope of this paper. We assumed the following constants for both randomly foraging and selectively foraging parasitoids. Sato and Ohsaki (2004) observed that for the closely related *C. glomerata* searching for *Pieris* larvae, the time spent searching one leaf was 73.5±11.9 s, so this was used as the time spent in fruitless search if the parasitoid arrived on a plant with no host. There is some evidence that *C. glomerata* avoids superparasitizing already parasitized larvae (Fatouros et al. 2005), so a parasitized larva was considered "nonhost" but was still capable of inducing a plant to produce volatiles. We assumed a

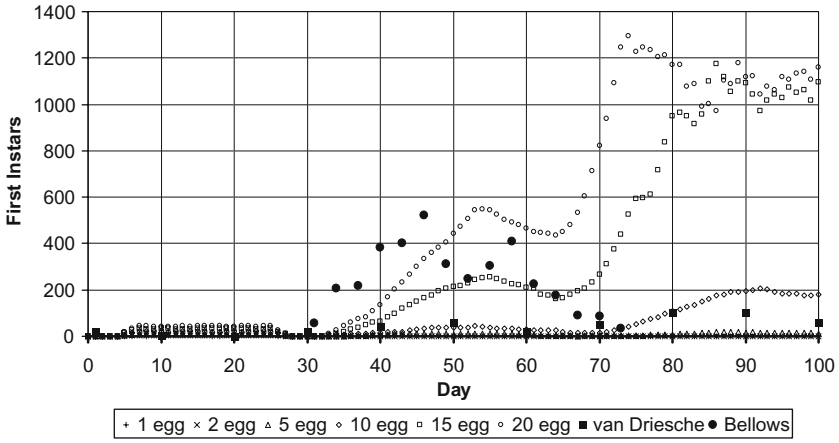

Fig. 2 Comparison of simulated herbivore population dynamics with published field data. The *larger black symbols* are counts of first instars obtained from published studies by van Driesche (1988) and van Driesche and Bellows (1988), adjusted to match the size of our simulated field (400 plants). The *numbers in the legend* refer to the maximum number of eggs each female butterfly could lay per day

parasitoid would be equally likely to find a host early or late in that search time interval; so on average, a parasitoid would spend half as much time searching if it encountered a host on that plant. Although there are circumstances that would prevent parasitoids from discovering available hosts (e.g., plant architecture), we assumed that if a viable host was available, the parasitoid would find it. The time it took for a parasitoid to successfully sting a host was 13.1±3.9 s (Sato and Ohsaki 2004). The recorded flight speed for *C. rubecula* was 0.33 m/s (Kaiser et al. 1994).

Parasitoids were given 3,600 s (i.e., 1 h) of total foraging time per day. The exact amount of time they spend foraging in the field is unknown, but 1 h per day was considered a low but feasible estimate given that most parasitoids only forage during the brightest hours of daylight and must divide time between foraging for food and foraging for hosts (Bartlett 1964). A greater period of time for foraging per day often resulted in all volatile-emitting plants being visited in our small field and produced artifactual results. A parasitoid started its foraging in a field location randomly selected by the simulation model and immediately searched the plant it was on. If no viable host were present, the giving-up time was discounted from the total foraging time and the parasitoid moved to the next plant. If a viable host were present, the host was marked as parasitized, the handling time was discounted from the total foraging time, and half the giving-up time was discounted from the total foraging time to account for search time. After successfully parasitizing a host, parasitoids had a 0.67 probability of leaving a plant. Otherwise they remained to continue searching (Tenhumberg et al. 2001) with a new giving-up time discounted from the foraging time. For many other systems, a more complicated algorithm for calculating giving-up time would be more appropriate; however, because *P. rapae* is not a gregarious host, this method of resetting the giving-up time following each successful oviposition is a close approximation of what occurs in nature (Vos et al. 1998). In wind tunnel experiments, the presence and concentration of host odors did not affect *C. rubecula*'s flight speed or direction of travel, but did impact a parasitoid's "willingness" to take off and whether a parasitoid completed a flight away from the initial location (Keller 1990; Kaiser et al. 1994). Therefore, we used a 0.67 flight probability for both randomly and selectively foraging parasitoids.

The spatial aspects of parasitoid foraging are poorly understood, so we had to make many assumptions in this part of the model. The following assumptions we believe to be reasonable:

- Plant volatiles are diluted over space, so the closer an emitting plant is to a parasitoid the more likely it is to be detected.
- Parasitoids use volatiles to detect a potential host plant, even if they are not *herbivore-induced plant volatiles*, so a randomly foraging parasitoid is also more likely to detect plants that are closest to it (Nordlund et al. 1988).
- Parasitoids decide which plant they will fly to before they leave the plant they are on (Keller 1990).

We used two different shapes of dispersal for the weighting: linear and exponential. According to Elkinton et al. (1987), over short distances, volatiles such as pheromone plumes spread out in a linear fashion, therefore, one dispersal shape was "linear". We assumed that the strength of signal had a value of one at the distance of 1 m and zero at a distance of 6 m and decreased linearly from the highest to lowest value (Table 2, Linear Diffusion). This created a bias where a parasitoid was five times as likely to go to a plant 1 m away compared to a plant 5 m away. The other dispersal shape we assumed was an exponential diffusion. In diffusion models, where plumes are not as well delineated, dilution of volatile concentrations happen at a

Table 2 Volatile distance biases

Distance	Linear		Exponential		
	Expected	Bias	Expected	Relative	Bias
1	1	5	1	25	25
2	0.8	4	0.25	6.25	6
3	0.6	3	0.11	2.78	3
4	0.4	2	0.06	1.56	2
5	0.2	1	0.04	1	1

rate relative to the inverse of the radius squared (Murlis et al. 2000). This created a bias in the model where a parasitoid was 25 times as likely to go to a plant 1 m away compared to a plant 5 m away (Table 2, Exponential Diffusion). Although it is likely that the actual spatial dynamics of detection distances is not either of these two options, we felt this would be adequate for looking at the sensitivity of the model to a parasitoid's odor detection bias.

The plant the parasitoid would fly to was randomly selected from the weighted list of possible destination plants. Parasitoids were prevented from immediately returning to the plant they came from. In the case of parasitoids that responded to herbivore-induced volatiles, only induced plants (emitting volatiles) were added to the weighted list of possible destination plants. If none of the plants on the weighted list of possible destination plants was signaling, then the weighted list was remade with the random movement algorithm, and the parasitoid was moved to a random non-induced plant.

Model Verification Predictions of the present model cannot be immediately tested against lack of empirical data. However, it was possible to assess whether there were errors in the coding of this simulation model by comparing predictions of this stochastic model to predictions of a simpler stage-specific model described in Puente et al. (2008, preceding article) that modeled the same phenomena in a nonspatial, deterministic manner.

The maximum number of hosts a parasitoid could attack in the deterministic model is limited by the time it has to forage rather than the number of hosts in the field, Therefore, by comparing the results of our stochastic model with the deterministic model run with the same parameters, we could identify the minimum field size that led to time-limited, rather than space-limited, foraging. For all parameter combinations explored, randomly foraging parasitoids were able to exhaust their time in fields with greater than 70 plants. Parasitoids foraging with signals needed larger fields to exhaust their time budget. Except for unrealistic parameters, a field size of 400 plants was sufficient for the signal-foraging parasitoids.

Additionally, we were also able to use results from the deterministic comparison to identify how many runs were necessary to account for the stochastic variation caused by herbivore oviposition and mortality. We calculated the mean and standard error of the number of hosts attacked for both signal-following and randomly foraging parasitoids for a number of successive runs with extreme values of parameters (induction and relaxation delays, viable host stage, etc.), and determined how many runs were necessary for the standard error to fall within 5% and 10% of the mean. Under most circumstances, the standard error was within 10% of the mean after fewer than five runs, and 20 runs were sufficient to reach a standard error within 5% of the mean for both number of hosts attacked for signal-following parasitoids and number of hosts attacked for randomly foraging parasitoids. This indicated that for most parameters 20 runs are sufficient. A summary of the variables and constants used in this simulation can be found in Table 3.

Results

We examined time series of the mean number of herbivores attacked by parasitoids randomly foraging and by parasitoids following signals, for both linear and exponential distance biases, for the 54 combinations of parameters we considered. In all parameter combinations, the mean number of hosts attacked by randomly foraging parasitoids with linear biases was within one standard deviation of the mean number of hosts attacked by randomly foraging parasitoids with exponential dispersal of volatile compounds. Averaging over all parameter combinations, parasitoids that randomly foraged visited about eight more plants per day than parasitoids following signals, regardless

Table 3 Parameters used in the model

Parameter	Values
(Oldest viable) Host stage	1, 2, 5
Induction delay (in days)	1, 3, 5
Relaxation delay (in days)	1, 3, 5
Occupation rate (in eggs/plants/field)[a]	0.1–0.9
Herbivore density (in eggs/butterfly/day)	Low (10), high (20)
Total foraging time (T_t) (in seconds)	3,600
Flight speed (a) (in meters/second)	0.33
Handling time (b) (in seconds/host)	13.1
Giving-up time (c) (in seconds/plant)	73.5
Foraging style	Random, signal following
Distance bias[b]	Linear, exponential

[a] Occupation rate was used solely in validating the model; for actual runs, herbivore density values were used
[b] Distance bias is more thoroughly explained in Table 2

of the type of volatile dispersal. By looking at the difference in mean number of larvae attacked for each 5-day-sampling interval for parasitoids following signals versus parasitoids randomly foraging, each of the combinations of induction delays, relaxation delays, herbivore densities, and viable host stages could be classified as one of four patterns:

A. (6 of 54) Following signals was *on average disadvantageous*, but individual runs could be advantageous due to large variances,
B. (12 of 54) Following signals was *not significantly different* from random foraging for any time interval sampled,
C. (5 of 54) Following signals was *advantageous* for at least one host generation, as long as the parasitoid flight bias was *linear*,
D. (31 of 54) Following signals was *advantageous* for at least one host generation, regardless of parasitoid flight bias.

In pattern A, parasitoids following signals generally attacked as many hosts as parasitoids not following signals through the first two generations of herbivores, but fell much lower in the third generation (Fig. 3a). Of the 54 parameter combinations, six combinations fell into this pattern. In the most extreme loss of efficiency, parasitoids that followed signals attacked 40% fewer hosts than randomly foraging parasitoids, under the conditions of a 3-day induction, 1-day relaxation, low herbivore density, only first instars as viable hosts, and linear distance bias. In these simulations, the variance of hosts attacked in the third generation of herbivores was quite large such that the mean for parasitoids randomly searching was well within a single standard deviation of the parasitoids following signals. This first pattern was seen only when the induction delay was greater than one and the oldest viable hosts were either first or second instars.

In pattern B, parasitoids that followed signals generally attacked as many hosts as parasitoids not following signals throughout the year (Fig. 3b). Over a season, this could result in average of up to 40% more hosts attacked or 20% fewer hosts attacked, but for any day sampled, the means for number of hosts attacked if the parasitoids followed signals were well within one standard deviation of the means for number attacked if the parasitoids foraged randomly. Of the 54 combinations we tested, 12 combinations fell into this pattern. In all such cases, the oldest susceptible host stage was either first or second instars, and in almost all of these cases, the induction delay was 5 days; the only exception being two cases where the induction delay was 3 days and only first instars were attacked. In all of these cases, the signals were produced after the inducing host had matured beyond the viable attack stages; therefore, it is not surprising that the resulting host attack rates for parasitoids following signals should not be significantly different from randomly foraging parasitoids.

In pattern C, there was an effect of volatile dispersion on parasitoid success in the first generation of herbivores (Fig. 3c). When volatiles were assumed to have a linear dispersal pattern, parasitoids that followed volatiles attacked between 50% to 200% more hosts than randomly foraging parasitoids. For these same conditions, when volatiles were assumed to have an exponential dispersal pattern, the difference between the signal foraging parasitoids and the randomly foraging parasitoids ranged from attacking 10% fewer hosts to attacking 25% more hosts than randomly foraging parasitoids. Pattern C occurred in five of the 54 combinations, all of which had first and second instars as viable hosts and an induction delay of either 1 or 3 days. Because this advantage was apparent only in the first generation of the herbivores when they are rare in the field, it is likely that a linear dispersal of the volatiles that allowed parasitoids to detect plants from greater distances also allowed them to encounter more patches of viable hosts, and a well synchronized induction then led to their remaining in the patch of viable hosts. Randomly foraging parasitoids with linear volatile dispersion patterns were just as likely to leave a patch of viable hosts as they were to enter a patch, thus giving parasitoids following signals the advantage. Signal foraging parasitoids with exponential volatiles dispersion patterns were less likely to encounter a patch because they did not stray far from a patch they had already exploited.

The remaining 31 parameter combinations (57.5% of all combinations) fell into pattern D, where parasitoids that followed signals attacked more hosts than randomly foraging parasitoids in at least one generation of herbivores, regardless of parasitoid distance bias (Fig. 3d). The advantage occurred primarily in the first herbivore generation but sometimes extended into the second generation. By the third generation, there were sufficiently dense populations of hosts that parasitoids were reaching their saturation point regardless of their foraging strategy. This can be seen by the small standard deviations from day 80 onward. If all five instars were viable hosts, parasitoids benefited from following signals for all herbivore generations regardless of the volatile dispersal patterns. When only first instars were viable hosts, pattern D occurred only when the induction delay was 1 day. When second instars were the oldest viable hosts, if the host density was high and the induction delay was 1 or 3 days, pattern D occurred, but when host densities were low, pattern C occurred.

A summary of all simulations can be found in Supplementary Table 1, where results are reported as "relative advantage" to the parasitoid from following volatiles (i.e., the number of hosts attacked by parasitoids following signals minus the number attacked by parasitoids randomly foraging divided by the number attacked by

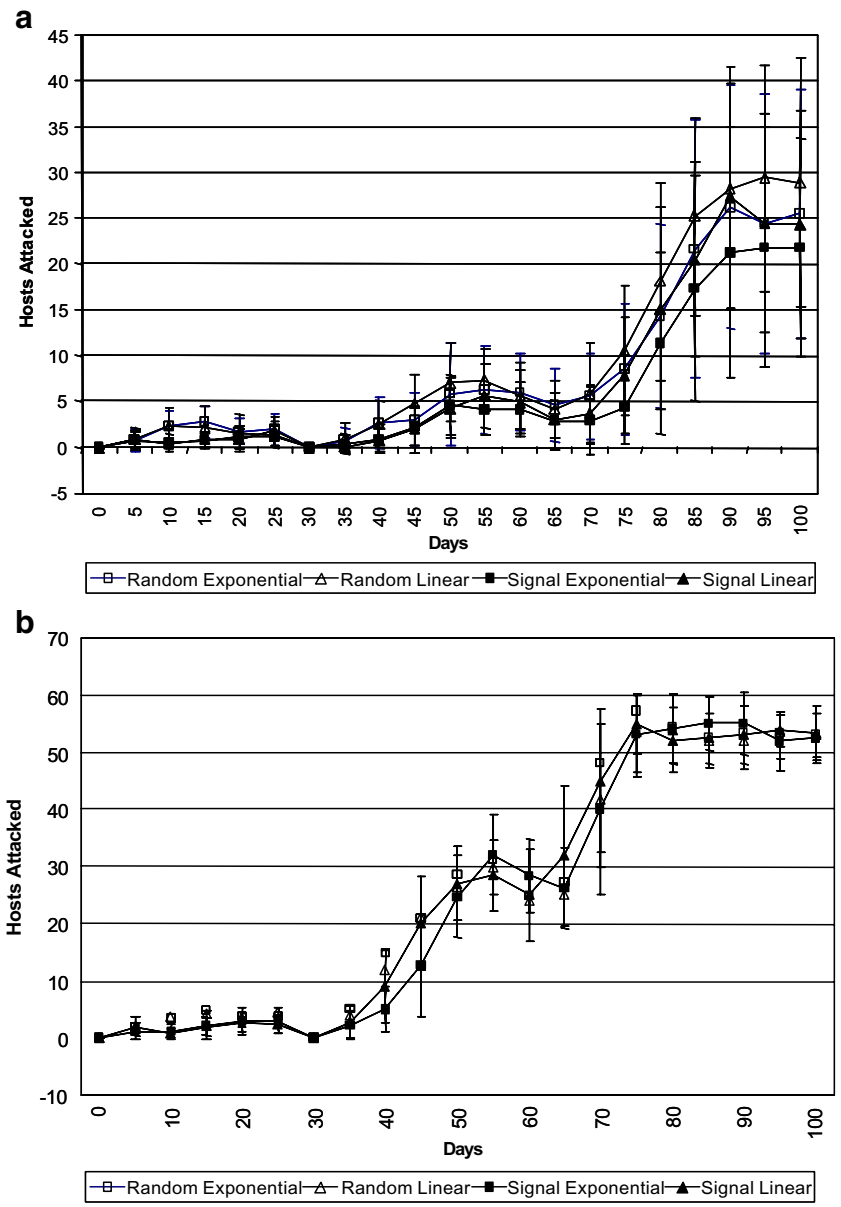

Fig. 3 Examples of how signals can impact the number of hosts attacked. **a** Detrimental signals (*Pattern A*); shown here is the case where induction delay is 3 days, relaxation delay is 3 days, herbivore density is low, and viable host stage is first instars only. **b** Signals no better or worse (*Pattern B*); shown here is the case where induction delay is 5 days, relaxation delay is 5 days, herbivore density is high, and viable host stage is first instars only. **c** Signals beneficial as long as the parasitoid distance bias is linear (*Pattern C*); shown here is the case where induction delay is 1 day, relaxation delay is 1 day, herbivore density is low, and viable host stages are second and first instars. **d** Signals beneficial (*Pattern D*); shown here is the case where induction delay is 1 day, relaxation delay is 1 day, herbivore density is high, and all instars are viable host stages. For each example, four cases were plotted: parasitoids randomly foraging where plants produce volatiles with an exponential diffusion (random exponential), parasitoids randomly foraging where plants produce volatiles with a linear diffusion (random linear), parasitoids following volatile plant cues where plants produce volatiles with an exponential diffusion (signal exponential), and parasitoids following volatile plant cues where plants produce volatiles with a linear diffusion (signal linear). For all four graphs, vertical bars are ±1 SD

randomly foraging parasitoids.). The overall patterns of when parasitoids benefited from following signals was the same if we looked at relative advantage or absolute number of hosts attacked; however, by looking at relative advantage, the gains from the beginning of the season were more pronounced compared to the gains at the end of the season. This is a more biologically relevant measure, as a fitness gain for a parasitoid early in the season would account for a larger overall gain in fitness if we had followed the long-term population dynamics of the parasitoid population.

Although relaxation delay did not impact qualitatively which pattern a simulation fell into, the relaxation delay did impact the overall gain in expected fitness over a season. For example, in the case where all five instars were viable

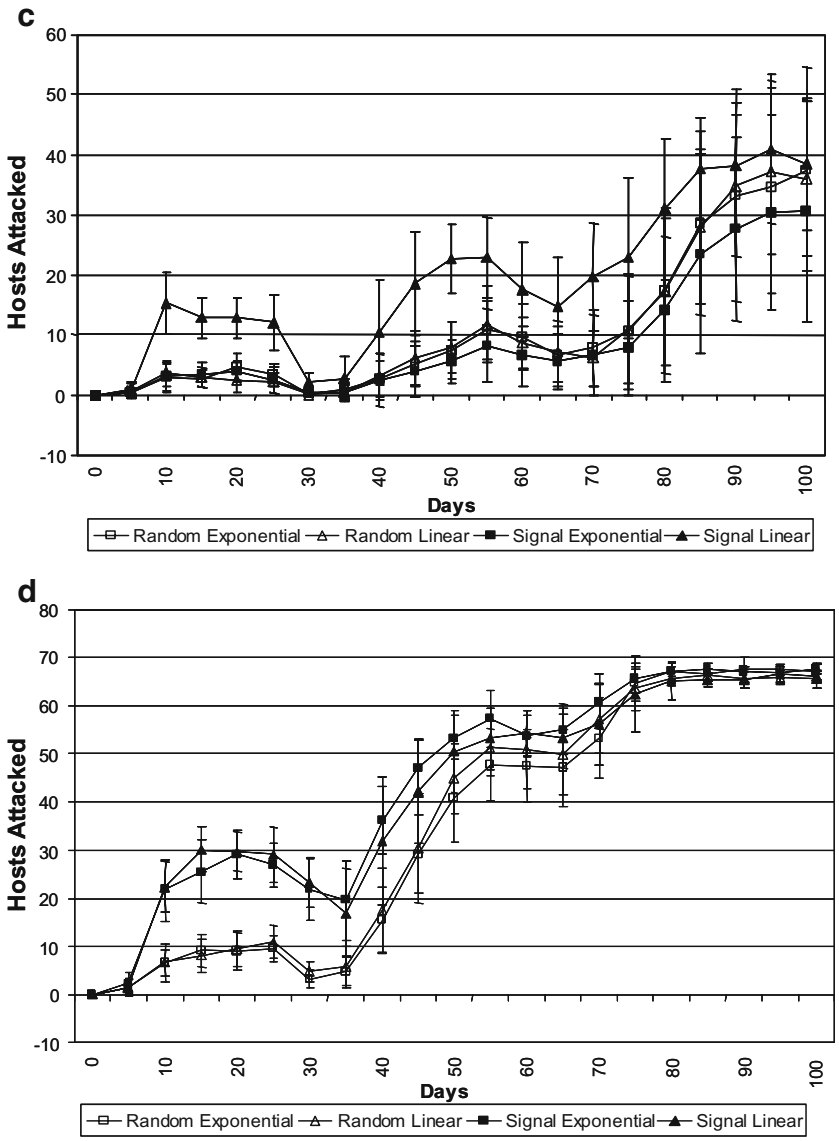

Fig. 3 (continued)

hosts, induction delay was 5 days and host density was high; if the relaxation delay was 1 day, the parasitoids that followed signals could attack on average 130% more hosts compared to randomly foraging parasitoids; if the relaxation delay was 3 days, this gain was reduced to 92% more hosts; and if the relaxation delay was 5 days, this gain was reduced to 78% more hosts.

Discussion

For the majority of parameter combinations (57.5% with exponential shape of dispersal and 66.6% with linear shapes of dispersal), the following of herbivore-induced plant volatiles was a beneficial strategy for parasitoids, but the degree of benefit varied depending on values of a number of parameters. While this result indicates that herbivore-induced plant volatile cues can be a robust indicator for parasitoids in many types of environments, we note that the most likely environment, (where host attacks are limited to first or second instars, and relaxation and induction delay vary between 1 and 3 days), is where there is a transition between the volatile cues being useful all of the time (pattern D) and only in certain volatile dispersal conditions (pattern C). We found that induction delay had an important impact on the utility of volatile signals. Plants with patterns A and B, where plants with induced volatiles were irrelevant or possibly detrimental to the parasitoids, tended to have an induction delay of 3 or 5 days. Relaxation delay was also important for determining the magnitude of effect of following signals could have on parasitoids. These results differ slightly from our deterministic model (Puente et al. 2008, preceding article), where relaxation delay was more important than induction

delay in determining relevance. The difference between results of the two models is due to the fact that the deterministic model assesses attack rate when the plant population has reached an equilibrium frequency of individuals in each of the four states. In the stochastic spatial model, the impact of following signals is assessed throughout the season while frequencies of plants in each state are changing and herbivore density is changing.

Both models show that understanding the molecular mechanism responsible for inducing signals will be important for engineering volatile producing plants that optimize parasitoid foraging efficiency. Future work in the *P. rapae* system can test our prediction by examining how the natural variation among cultivars in volatile induction and cessation impacts parasitoid behavior and attack rates. We predict that *C. rubecula* should have a preference for varieties of *B. oleracea* that can begin volatile production within a day of onset of herbivory and can cease volatile production within a day of the end of herbivore attack.

Our model shows that how parasitoids perceive volatiles in space can be important for determining whether or not it gains an advantage by following signals. Volatiles are considered important cues for "long-distance" foraging (Geervliet et al. 1998), but what constitutes "long-distance" has not been described quantitatively in the literature. If this means that parasitoids can detect signals 1 m away, that would be comparable to our exponential volatile dispersion where parasitoids were 25 times more likely to visit a plant one meter away compared to a plant 5 m away; in this case, parasitoids gained nothing from following signals in several cases. However, if parasitoids can detect and respond to signals from five times that distance, as in our linear bias example, signals more often had at least some positive impact on parasitoid foraging success. While this differentiation (pattern C) only occurred in five cases, these cases all occurred in simulations where second instars were the oldest viable host stage, which is biologically relevant for *C. rubecula*. In all of these cases, herbivore density was low, which would be the desirable state for an agricultural setting. Because of the potential likelihood of these parameter conditions occurring in nature, understanding how volatile plumes disperse in space and how parasitoids perceive these volatiles in space could be important for knowing whether breeding for inducing plants will be a successful endeavor.

Finally, as with our deterministic model, the current model shows the importance of herbivore density to the relevance of volatile cues. In the first herbivore generation, when the number of herbivores was at its lowest (Fig. 2), signals had the greatest impact (Fig. 3c,d). In the third generation, when herbivores were at their highest densities, volatile signals were typically irrelevant or had a negative impact. Most studies of induced volatiles examine just a single volatile source, which misses the potential importance herbivore densities can have on parasitoid foraging success. Predictions from our model argue for looking at larger populations of plants and herbivores before determining whether a volatile signal has a substantially positive effect on parasitoids. We also argue that if breeding plants for volatile production is going to be a successful strategy, the appropriate volatile production by young plants is needed early in the season if it is to improve parasitoid foraging efficiency.

While our simulation model has identified important parameters that should be studied more closely, several modifications to the model could be made in the future that would improve its value. One assumption we made in this model is that parasitoids are either foraging randomly or foraging in response to signals. We did not allow for parasitoids to change patterns within a lifetime. Other models have shown that evolving parasitoid systems can change host-parasitoid dynamics (Abrams and Kawecki 1999). Therefore, incorporating parasitoid learning into this model would be an important next step.

We specifically chose to focus on a naïve parasitoid entering a field of nonparasitized larvae, rather than following an entire parasitoid population's dynamics over a season. Following parasitoid population dynamics would be an interesting model extension but would require considerably more parameters. Parasitoid and host eclosion are not always synchronized in nature (van der Meijden and Klinkhamer 2000); parasitized herbivores can consume different amounts of foods than their nonparasitized congeners (Fatouros et al. 2005) and parasitized larvae can have different mortality from nonparasitized larvae (Jones 1987). These factors may all alter the relevance of volatiles in host plants over several herbivore generations. In many cases, less efficient individual predators or parasitoids will lead to more stable population dynamics over longer periods of time (van der Meijden and Klinkhamer 2000); therefore, following long-term dynamics could lead to different conclusions.

We framed our research question from the naive parasitoid's perspective: when should a parasitoid follow an induced volatile coming from a plant, and how much of a fitness benefit can it obtain from following the volatile plume? These questions could also be framed from the plant's perspective: how accurate does a plant need to be to attract parasitoids? However, this implies that parasitoids can exert a positive evolutionary pressure on plant fitness. There is some evidence that parasitized *Pieris* species consume less, and that the plant can gain fitness by recruiting parasitoids (Fatouros et al. 2005). It is also possible, however, that parasitism has no effect on individual plant fitness within a single generation of parasitoids and hosts (Coleman et al. 1999), thus, making

the question from the plant's point of view inconclusive (Janssen et al. 2002). To have evolutionary relevance this model needs to be modified to include long term plant fitness.

We hope the model will stimulate future research on the timing and spatial dynamics of herbivore-induced plant volatiles. While these are difficult parameters to measure in natural systems, they appear to be ecologically relevant and are important aspects to study, especially, if this phenomenon is to be applied practically in agriculture.

Some compounds emitted as part of the sex pheromone blend of a particular species can cause reduction in or cessation of upwind flight when they are admixed with the pheromone blend of another species. Such compounds, originally termed behavioral "inhibitors", have more recently come to be known as heterospecific behavioral "antagonists" because they interfere with the attraction of heterospecific males. Thus, these *behavioral* antagonists have been considered to act differently from conspecific pheromone components, which are sometimes termed behavioral "agonists" (c.f., Linn et al. 2003; Baker and Heath 2004). However, one critical factor that usually has been overlooked is that pheromone components themselves have the ability to decrease or even eliminate attraction of conspecifics, depending on their amounts in a blend relative to other components. When emitted at the wrong rates relative to other components, the resulting blends no longer comprise the "pheromone" of that species, and it follows that the compounds, in terms of the responses that they elicit, can be both pheromone components and behavioral antagonists, with the behavioral outcome dependent upon the ratio in which they are presented. Here, I propose that the underlying mechanism that results in these various behavioral outcomes is olfactory antagonistic balance, a concept that may facilitate our understanding of the evolution of moth pheromone systems.

Odorants, Odors, and Pheromone Components

It is important to recognize the difference between odorants and odors. Odorants are single volatile compounds; the use of odorants as stimuli allows us to understand neurophysiological and behavioral responses at a simple chemosensory level. Whereas a particular odorant may cause neurophysiological activity in designated olfactory receptor neurons (ORNs), behavioral activity may not result from exposure to this odorant. In contrast, odors are blends of odorants, and odors often produce behavioral responses only when presented in a limited range of blend ratios. Pheromones are odors, inasmuch as they are blends of odorants (i.e., the individual pheromone components), presented in the "correct" blend ratios for a particular species.

Olfactory Antagonistic Balance

I suggest that we should rethink the way we have traditionally distinguished pheromone components as being distinct from heterospecific pheromone antagonists, in terms of olfactory processing. I propose that *all* sex-pheromone-related compounds (including heterospecific antagonists) that mediate behavioral responses should be considered to act as antagonists through olfactory pathways, resulting in a continuum of various levels of attraction. When the antagonistic olfactory inputs are not balanced the compounds causing the imbalance, even including the compounds that at the optimal ratios would have comprised the pheromone, result in reduced attraction. Olfactory balance with regard to sex-pheromone-related compounds is consonant with the concept of "combinatorial coding" (c.f., Hildebrand and Shepard 1997; Vickers et al. 1998; Christensen et al. 2000) that has prevailed since the days of Vincent Dethier (1971) when it was called "across-fiber patterning". For sex-pheromone-related compounds, however, an advantage of the olfactory antagonistic balance concept is that it eliminates heterospecific, behavioral antagonist compounds from being viewed as acting differently on olfaction and subsequent behavioral responses than do conspecific pheromone components.

Consider, for instance, two-component sex pheromones that involve specific ratios of the components in *Yponomeuta* spp. moths [(i.e., (*E*)-11-tetradecenyl acetate and (*Z*)-11-tetradecenyl acetate; (E11-14:OAc and Z11-14:OAc)] (Löfstedt et al. 1990, 1991). For a given *Yponomeuta* species (Fig. 1), when one component is present in too high a ratio, attraction is diminished, or eliminated altogether. In such cases, the blend can no longer be considered to comprise that species' sex pheromone, and the out-of-range "pheromone component" now acts as a behavioral antagonist. For example, when E11-14:OAc is emitted in excessive amounts relative to Z11-14:OAc in any of the species in Fig. 1, creating an off-blend ratio, it acts antagonistically to stop or reduce attraction. Similarly, too much Z11-14:OAc that creates an off-ratio also stops or reduces attraction, and thus Z11-14:OAc can also act antagonistically.

Furthermore, it can be seen that blending the two pheromones of *Yponomeuta cagnagellus* and *Yponomeuta plumbellus*, which share only these same two 'components' but at widely disparate ratios, will result in the blended component ratios from the two species exerting behavioral antagonism on males of the other species, to the extent that little or no attraction will occur. Thus, pheromone components are only components of the pheromone odor when they are emitted at optimal ratios for the pheromone blend of that species. Otherwise, these olfactory antagonists also act as behavioral antagonists.

The only time the two components do not seem to act as behavioral antagonists is when they produce olfactory inputs, relative to the other pheromone-related odorants, that are centered around that species' pheromone blend ratio. I propose that in the behaviorally optimal pheromone blend, pheromone components could appropriately be viewed as balancing each others' olfactory antagonism at a particular position in that species' defined sex pheromone

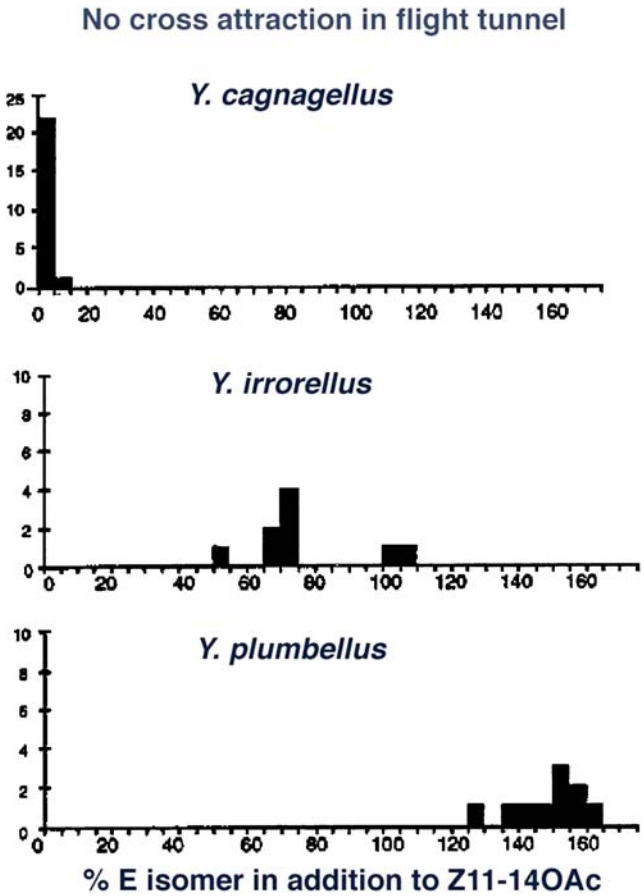

Fig. 1 Attraction of three *Yponomeuta* species that share the same host-plant (European spindle tree) to blends of their pheromone components in the wind tunnel (Löfstedt et al. 1991). There is no overlap in attraction to any of the cross-specific blends. Löfstedt et al. (1991) hypothesized that the species-specific blends arose as a result of blend interference between these sympatric and synchronic species that share the same host plant

"odor space" (Hallem and Carlson 2006). To use an analogy, opposing muscle groups are termed 'antagonists', and it is the balance of the forces exerted by each muscle group that results in various limb positions. Similarly, olfactory neuronal elements may be considered to act antagonistically, producing optimal behavioral outcomes only when their antagonism is balanced.

All pheromone-related inputs to the brain from the ORNs on the antennae, even those tuned to heterospecific behavioral antagonists, are transmitted in the form of excitatory action potentials to glomeruli in the macroglomerular complex (MGC). Among the first synaptic transmissions from the axon terminals of ORNs in the glomeruli are the excitation of gamma-aminobutyric acid (GABA)-ergic local interneurons, as well as direct synapses of ORN terminals with the dendrites of projection interneurons (Anton and Homberg 1999). There is evidence from neurophysiological studies of such synapses (Christensen et al. 1993) that the GABA-transmitted inhibition of one local interneuron can disinhibit a second local interneuron, resulting in excitation of projection interneurons that exit that glomerulus. These projection interneurons then send their excitatory outputs to higher centers such as the mushroom body and lateral protocerebrum (De Belle and Kanzaki 1999). Here, two negatives, through mutual disinhibition, can produce a positive, and this might be one of the neuronal bases for balanced olfactory antagonism. There may be other neurophysiological contributing factors as well. Excitation and further possible balanced antagonism in higher centers, such as the lateral protocerebrum and mushroom body, could also contribute to the ultimate behavioral outcome, that is, olfaction-stimulated, visually mediated flight that results in attraction to the correct blend.

I also propose that with regard to sex pheromone olfaction, the addition of a heterospecific behavioral antagonist to the pheromone blend is no different than the addition of excessive amounts of one of the sex pheromone components to the blend. In both instances, the new blend falls outside an optimal olfactory odor space, and the off-ratios result in an olfactory antagonistic imbalance due to an excessive amount of a given compound. The increased level of inhibition alters the balance of mutual disinhibition-related excitatory outputs, and ultimately results in reduction or even elimination of attraction.

This concept of olfactory antagonistic balance of sex-pheromone-related mediators of behavior does not require changing our definition of sex pheromones or of heterospecific behavioral antagonists. Rather, it provides a different way of thinking about the olfaction-related effects of the individual chemical components, and how they might influence sex pheromone olfaction-related pathways in ways that result in optimal or suboptimal attraction to the odor source.

Another reason that it makes sense not to label one set of pheromone component molecules as agonists (pheromone components, attractants) and another set the other way (antagonists) is because pharmacologically and neurophysiologically, they all act in the same way, as *agonists* to the odorant receptor (OR) that receive them on the ORNs. The ORNs all produce various frequencies of excitatory action potentials both in response to pheromone components and heterospecific antagonists. General odorants can produce both excitatory and inhibitory effects on action potential outputs of the ORNs on which the specific ORs are expressed (c.f., Hallem et al. 2004), but the odorants' initial interactions with their ORs are as pharmacological agonists, and the ORNs' outputs are still various levels of excitatory action potential frequencies.

In pheromone systems comprised of two or more pheromone components, attraction of males can occur in response to a partial blend or even a single component of the blend, but such partial blends are not optimal for

attraction (Linn et al. 1986, 1987). Even when the complete blend *is* emitted, impairment of a component-specific olfactory pathway through habituation or sensory adaptation due to pre-exposure to that single component can temporarily shift the balance of olfactory inputs to create a new, optimal blend ratio and render the true pheromone blend ratio as suboptimal (Linn and Roelofs 1981). In other cases that involve sensory impairment but with no pre-exposure, if the optimal blend ratio is emitted but at an excessively high rate such that upwind flight ceases, especially near the pheromone source, the underlying cause of suboptimal attraction can be found to be due to a suboptimal balance of inputs due to sensory adaptation. That is, the ORNs for one of the component-specific olfactory pathways can become differentially adapted to the excessive flux of that component in the blend, whereas the other ORNs tuned to the remaining two components retain their fidelity in reporting the flux specific to those components, thus creating an imbalance in the antagonistic interactions (Baker et al. 1989; Hansson and Baker 1991).

If we continue to compartmentalize the olfaction of pheromone components and heterospecific antagonists in our minds, instead of considering them as elements of an olfactory continuum, it will hamper progress in understanding the olfactory basis for shifts in male behavioral responses to novel sex pheromone blends, and our understanding of the evolution of divergent blends. With our ever-advancing knowledge of olfactory pathways, it is time to unify our thinking regarding the underlying processes involved in pheromone component and heterospecific antagonist olfaction. A unified model of pheromone and antagonist olfaction also may enhance and unify discourse between those who work on the evolution of sex pheromone olfaction and those who study the molecular and evolutionary aspects of olfaction of general odorants. For example, host-fruit odors attractive to one species of tephritid fruit fly cause a cessation of upwind flight by a second tephritid species when they are added to the latter species' preferred blend (Linn et al. 2005). Labeling the first species' host-fruit volatiles as being behaviorally antagonistic to the second species' is certainly appropriate, and yet I suggest that progress in understanding the evolution of these responses will be slowed if we structure our thinking along the lines of searching for special "antagonist"- or "agonist"-related *olfactory* pathways in such general odorant systems.

Asymmetric Tracking

In the concept of sex pheromone component antagonistic balance, a relaxation of the antagonism that would have otherwise occurred in response to excessive amounts of one compound, which we termed "olfactory antagonistic release" (Domingue et al. 2007), can be envisioned as a way for pheromone blends to shift away from their mean ratio in a first stage of reproductive character displacement, as particular types of "rare" males "track" the widely disparate blends of odd females, while retaining their responsiveness to the majority of females emitting blends centered around the norm of the population (Löfstedt 1990, 1993; Löfstedt et al. 1991; Phelan 1992, 1997). Such a scenario might explain the broadening of behavioral response profiles of male *Trichoplusia ni* (Liu and Haynes 1994; Haynes 1997). That is, after more than 40 generations of laboratory breeding, male *T. ni* subsequently were attracted as readily to the off-ratio blends produced by mutant females as they were to the blend of normal females. At the outset of these breeding experiments, males were attracted to mutant females' blends only at very low response rates, well below their level of attraction to the normal blend (Liu and Haynes 1994; Haynes 1997).

To illustrate this scenario in another way, the assortment of Z11/E11-14:OAc ratios (Fig. 1) seen in the three species of *Yponomeuta spp.* briefly discussed above were suggested to be the result of adaptive responses to "blend interference" from the pheromone blends of sympatric species sharing the same host plant (Löfstedt et al. 1991). We might view the three ratios, each of which is optimal for its respective species, as the result of an optimal antagonistic olfactory balance that is specific to that species. One of many ways we can hypothesize this end result as having occurred is that all three species' blends were originally closer to a 50:50 E/Z ratio (Fig. 2a). A broadening of males' responses then could have occurred in two of the species to include responses to rare (mutant) females that emit off-ratios different from the original blends. This broadening would have been facilitated by a relaxation ("olfactory antagonistic release") (Domingue et al. 2007) of the original degree of antagonism that otherwise would have been imposed in response to excessive amounts of either component. Olfactory antagonistic release could have occurred due to a desensitization or reduction in the number of neuronal elements somewhere along the ORN or central nervous system (CNS) pathway specific for carrying information initiated by the excitation of one of the two ORN types that respond to either Z11- or E11-14:OAc (Fig. 2b, left and right response curves, respectively).

Reproductive Character Displacement and Reinforcement

On the other hand, "olfactory antagonistic imposition" (strengthening of antagonism) (Domingue et al. 2007) would subsequently be involved in moving the shift in mean male responsiveness further away from the former mean, with the strength of antagonism on the other isomer's olfactory pathway being increased through increased ORN

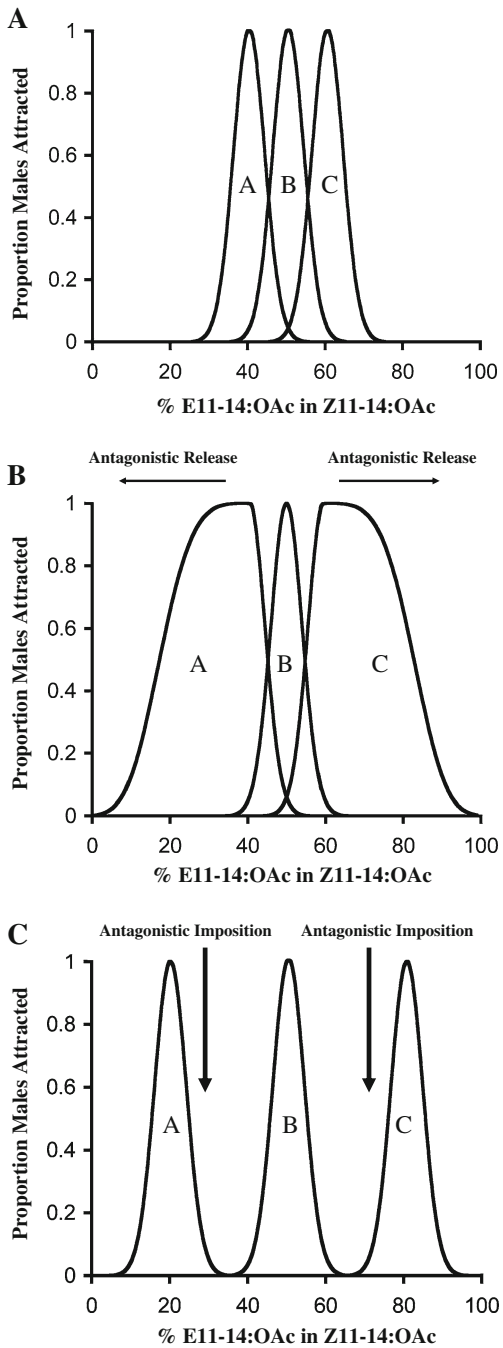

Fig. 2 Illustration of antagonistic release and imposition of changes in blend ratios that elicit male attraction in three hypothetical species that utilize Z11- and E11-14:OAc. **a** Original populations, in which there is a narrow range of Z11- and E11-14:OAc ratios to which males will be attracted. **b** After antagonistic release has occurred in males, the blend ratios to which males can respond are expanded in either direction to include off-ratios that may be emitted by rare mutant females in the population. The males' ranges of responsiveness include these variant blends, but males retain responsiveness to ratios in the previous norm so that such males can respond to both ancestral and derived pheromone blends. **c** After antagonistic imposition has occurred, males respond to new, tighter blend ratios in the derived populations, and thus assortative mating occurs in the new populations

or CNS sensitivity to that second isomer (Fig. 2c). If such a shift occurred as a response to blend interference (Löfstedt et al. 1991) between already existing species, then reproductive character displacement would result (Butlin and Ritchie 1989; Butlin and Trickett 1997). Alternatively, if this two-part process occurred during a speciation event, the imposition of increased antagonism would be implicated in reinforcement and subsequent reproductive isolation that is favored by selection (as the fitness of hybrids between the derived and ancestral populations decreases) so that males and females from the two populations can avoid fitness-related mating mistakes (Phelan 1992, 1997).

The addition of a third component to the sex pheromone blend can also impart species specificity to the new blend through this same two-part process. *Yponomeuta padellus*, a derived species of *Yponomeuta*, may have diverged in this way (Löfstedt et al. 1991), and its three-component blend sets it apart from two other *Yponomeuta* species that have similar two-component E11- and Z11-14:OAc blend ratios (Fig. 3). The process by which the third component might have been added, thus creating a three-component blend that males tracked, is hypothetically depicted in Fig. 3.

We hypothesize that there was first a broadening of responsiveness in rare males to include behaviorally beneficial olfactory antagonistic input from Z11-16:OAc, so they could respond to and track rare females emitting small amounts of this compound in addition to the original Z11- and E11-14:OAc blend (antagonistic release). This would have been followed by olfactory antagonistic imposition to keep *Y. padellus* males in the derived population from being attracted to the ancestral blends of *Yponomeuta viginctipunctatus* or *Yponomeuta evonomellus* females, which were emitting *only* ratios of the original two components, without Z11-16:OAc. These latter females, therefore, will have had antagonistically excessive amounts of this two-component blend in their emissions (Fig. 3).

Similar evolutionary scenarios for shifts in balanced antagonism can likely be constructed for the well-investigated pheromone systems in the Tortricidae and in heliothine moths. Two- and three-component pheromones in sympatric tortricid species, as in yponomeutids, often rely on tightly regulated, differing ratios of E11- and Z11-14:OAc, as well as on various additional components (Cardé et al. 1977; Roelofs and Brown 1982). In the sex pheromone systems of heliothine moths, although male behavioral response profiles to varying 2-component blend ratios are not as tightly regulated as in tortricids and yponomeutids, there is at least some degree of ratio specificity (Vickers et al. 1991; Vickers 2002). Also, upwind flight is inhibited in response to single "components" (Vickers et al. 1991), and by addition of heterospecific compounds to otherwise optimal pheromone component blends (Vickers and Baker 1997; Baker et al. 1998; Quero and Baker 1999). Notably,

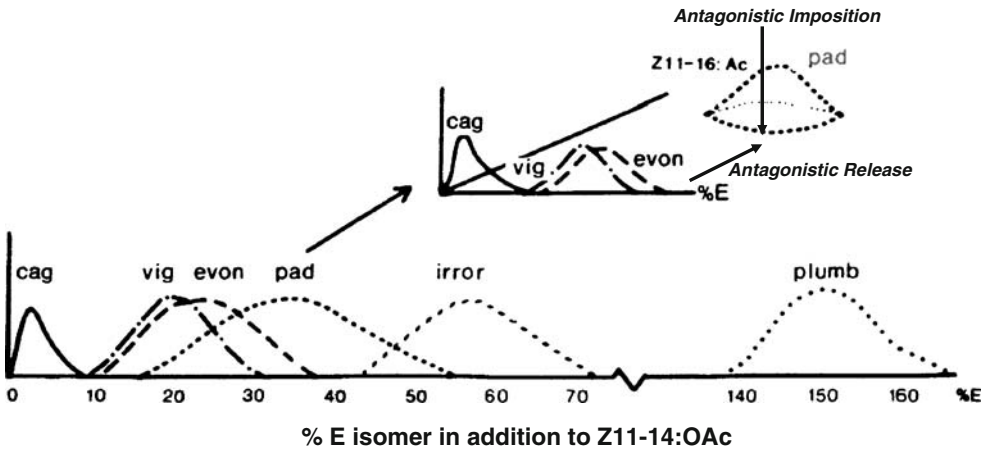

Fig. 3 Illustration of the pattern of antagonistic release, followed by antagonistic imposition, in the *Yponomeuta* species depicted by Löfstedt et al. (1991). *Y. padellus*, a derived species, has added a third pheromone component, Z11-16:OAc, to its blend, along with Z11- and E11-14:OAc. First, we hypothesize that antagonistic release has occurred to allow expansion of male responsiveness to this new, three-component blend. Then, we hypothesize that antagonistic imposition evolved to reinforce the assortative mating that will occur because of decreased fitness of hybrids from matings between the derived and ancestral populations, through increased sensitivity to blends emitting now-excessive amounts of the Z11- plus E11-14:OAc's (lacking Z11-16:OAc)

as in all other moth species in which antennal lobe neuroanatomy has been studied (Hansson and Christensen 1999), the glomeruli in heliothine males that receive inputs from ORNs tuned to heterspecific antagonists occur together in the MGC in close association with glomeruli that receive inputs from ORNs tuned to conspecific pheromone components (Christensen et al. 1995; Vickers et al. 1998; Berg et al. 1998, 2005; Vickers and Christensen 2003; Lee et al. 2006a, b). Alterations in balanced antagonism due to the mutual-inhibition (disinhibition) activities of GABA-ergic local interneurons would be most pronounced in this typical lepidopteran arrangement of closely spaced glomeruli for conspecific and heterospecific pheromone components in the MGC.

Single-component Pheromones and Balanced Antagonism

A saltational pheromone shift (Baker 2002; Roelofs et al. 2002) seems to have occurred in another derived species of yponomeutid, *Yponomeuta rorellus* (Löfstedt et al. 1986, 1990, 1991). This species' pheromone odor appears to be solely comprised of the unusual pheromone component, tetradecyl acetate (14:OAc). One of the types of ORN known to be involved in attraction in *Y. rorellus* responds with high activity to 14:OAc, but it also responds to E11- and Z11-14:OAc that are emitted by other sympatric *Yponomeuta* species in the environment. Attraction to other *Yponomeuta spp.* females that emit the ancestral blends containing Z11- or E11-14:OAc is prevented because of the activity of an ORN involved in behavioral antagonism that is stimulated by both E11- and Z11-14:OAc (Löfstedt et al. 1990, 1991). We view the broadened activity of this ORN that accepts either E11- and Z11-14:OAc as ligands as an example of olfactory antagonistic imposition (Domingue et al. 2007). Importantly, this behaviorally antagonistic ORN pathway is not merely responsive to any generic type of pheromone-related compound. Its lack of response to 14:OAc, as well as to the odd compounds (*E*)-6-tetradecenyl acetate and (*E*)-12-tetradecenyl acetate (E12-14:OAc) is apparently responsible for allowing equally high levels of attraction of *Y. rorellus* males to all three of these single compounds, all of which cause high firing rates in the attraction-related ORN (Löfstedt et al. 1990), despite the fact that only 14:OAc is the *Y. rorellus* pheromone component.

Single-component pheromone blends are rare in the Lepidoptera, but I maintain that they still fit the concept of attraction being due to balanced olfactory antagonism. First of all, even single component pheromones must be considered to be *blends* at the neurophysiological level because of the combinatorial coding process that compares the ratio of inputs into a single-component glomerulus (and out through projection interneurons) relative to the lack of activity occurring in other glomeruli in the absence of other pheromone-like odorants. Thus, even for single-component pheromones, inputs to the MGC are analyzed by the CNS as patterns of stimuli, i.e., "blends", with parts of the pattern consisting of the absence as well as the presence of activity in various glomeruli and along the rest of the pathways in the system. To make an analogy, in the auditory realm, the combinatorial code that produces recognition of single musical notes, as it does for chords, depends as much on the absence of many notes as it does on the presence of others.

Olfactory Pathways

Studies of *Drosophila* ORNs that respond to general odorants have shown that ORN activity is determined almost exclusively by whatever OR is expressed on that ORN (Hallem et al. 2004). In pheromone olfaction, modulating perireceptor factors such as binding proteins seem to affect the presentation of the pheromone component ligand to the OR more than in general odorant systems (Du and Prestwich 1995; Leal et al. 2005). The effects of degradative enzymes specific for pheromone components also seem to affect the time-course of ORN excitation more than in general odorant systems (Syed et al. 2006). Nevertheless, olfactory antagonistic release and imposition in moth sex pheromone systems will depend to a large degree on the up- or downregulation of OR gene expression on particular pheromone-component sensitive ORNs. Coexpression of two ORs on single ORNs is also possible in insects (Dobritsa et al. 2003; Goldman et al. 2005) and in moths might potentially contribute to shifts that broaden behavioral responsiveness to a wider array of pheromone blends (Baker et al. 2006), that affect both reinforcement and assortative mating.

Alternatively, a single OR itself might possibly have biochemical cross-affinities to two or more structurally related pheromone odorants, just as many ORs for general odorants do (c.f., Hallem and Carlson 2006). There are many examples in moths of ORNs that are tuned to a particular sex pheromone component, but they are also highly responsive to other molecules, even including totally synthetic analogs of the pheromone component that could not possibly comprise part of a sex pheromone blend of any species (c.f., Grant et al. 1989; Löfstedt et al. 1990; Berg et al. 1995).

It is difficult to imagine that there are OR genes in the genome specific for producing ORs having specific affinities for every one of such odd, non-naturally occurring molecules, and that they have suddenly become coexpressed on the dendrites of pheromone-component-responsive ORNs to cause this cross-responsiveness. Rather, cross-reactivity to structurally similar compounds by a single, broadly accommodating pheromone-component-tuned OR might provide a more logical explanation for such phenomena. Such ORs might be viewed as being preadapted to respond to odd conspecific females emitting such compounds, should such rare occurrences ever happen. Thus, such pheromone-odorant-related ORs that (perhaps serendipitously) accommodate structurally similar compounds might provide the basis for broader sex-pheromone-related ORN responsiveness (Linn et al. 2007a), which can result in either broader or narrower behavioral responsiveness, depending upon on which ORNs the ORs reside. Learning more about ORN coexpression of two ORs versus single expression of broadly tuned ORs should help guide our interpretations of the evolution of sex pheromone blends, particularly as they relate to shifts in sex-pheromone-related behavior.

Because the glomerular projection addresses of ORNs in insects do not change with whatever ORs are expressed on the ORNs (Dobritsa et al. 2003; Hallem et al. 2004; Goldman et al. 2005), shifts in the olfactory balance that change behavioral response specificity to certain sex pheromone blend ratios, therefore, might begin with ORN response profile shifts. Ultimately, the response profiles of ORNs, both chemically and temporally, rely on the expression of ORs that dictate stereotypical temporal spike-train characteristics and odorant tuning profiles of the ORNs (Hallem et al. 2004). Of course, changes in synaptic connectivity in the antennal lobe, such as the number, types, and targets of synapses in particular glomeruli, could affect the amount of inhibitory local interneuron activity as well as projection interneuron output to the mushroom body and lateral protocerebrum (Anton and Homberg 1999; De Belle and Kanzaki 1999; Hansson and Christensen 1999). Thus, shifts in olfactory antagonistic balance are not necessarily entirely dependent upon pheromone odorant OR gene expression and levels of ORN excitation.

Nevertheless, the predominance of OR gene expression in insects in determining both the overall activity levels and temporal characteristics of ORN action potential output (Hallem et al. 2004) indicates that the study of the response profiles of ORNs (DeBruyne et al. 1999, 2001) may to a large extent explain what occurs during shifts in pheromone-related olfactory pathways and in optimal attraction to various blends. This perspective has been supported by the neuroethological studies that concern geographic variation in moth sex pheromone communication systems, as exemplified in *Agrotis segetum* (c.f. Löfstedt 1990, 1993; Hansson et al. 1990). Further neuroethological studies on species that utilize highly "unusual" (from an anthropomorphic perspective) sex pheromone blend components should be particularly instructive for understanding how shifts in olfactory antagonistic balance might explain the evolution of sex pheromone blend shifts.

Possible Examples With *Ostrinia spp.*

Recent studies with *Ostrinia furnacalis*, the Asian corn borer (ACB), and *Ostrinia nubilalis*, the European corn borer (ECB), have implicated a mechanism involving ORNs on male antennae that explains how a few "rare" males (Roelofs et al. 2002; Linn et al. 2003, 2007b) in the population are attracted to both their own ECB or ACB sex pheromone blend, as well as to the entirely different blend of the other species (Domingue et al. 2007; Linn et al. 2007b). The ACB is considered to be a derived species

(Ishikawa et al. 1999), and is the only *Ostrinia* species that uses ~ 1:2 to 1:1 E:Z blends of E12-14:OAc and (*Z*)-12-tetradecenyl acetate (Z12-14:OAc) as its sex pheromone. The vast majority of ACB males are attracted only to their own ACB blend, and Takanashi et al. (2006) and Domingue et al. (2007) found that these "normal" ACB males, as with the rare males, have attraction-related ORNs that respond to both the Z11-/E11-14:OAc components of ECB and also to the Z12-/E12-14:OAc ACB components. However, normal ACB males have an ORN tuned to (*Z*)-9-tetradecenyl acetate (Z9-14:OAc) that is involved in heterospecific behavioral antagonism and which responds also to Z11-14:OAc (Takanashi et al. 2006; Domingue et al. 2007), preventing attraction to the ECB blend (Domingue et al. 2007). This heterospecific behavioral antagonism-related ORN in *rare* ACB males does not respond to Z11-/E11-14:OAc, and thus it does not impede attraction to the ECB blend, nor does it impede attraction to the ACB blend due to its lack of activity to Z12-/E12-14:OAc (Domingue et al. 2007).

Domingue et al. (2007) considered the rare ACB males as being similar to the type of male that existed when ACB diverged from Z11/E11 species, during the first stage of asymmetric tracking (Phelan 1992, 1997). In this context, broadly tuned males would be able to be attracted to both the unusual ACB females emitting Z12- and E12-14:Oac, while retaining their responsiveness to the ancestral pheromone blend comprised of Z11- and E11-14:OAc. This stage of divergence of pheromone blends in the Lepidoptera had been previously noted as producing 'asymmetrical reproductive isolation" (Löfstedt et al. 1991) (as represented by the rare ACB males in our study) because males from the derived population (Fig. 2b) could respond to both the derived and the ancestral females, whereas ancestral population males could only respond to ancestral females.

The second stage of asymmetric tracking (Phelan 1992, 1997) involves the occurrence of assortative mating between females that emit the new blend and the derived males that respond to it. In a speciation event, the impetus for assortative mating would be a fitness disadvantage that arises in hybrids resulting from matings between the ancestral population females and males from the derived population (Phelan 1992, 1997). Ancestral females then should be selected to reject derived males for mating, and such males should subsequently be selected to not be attracted to these females because of the (ultimately) fruitless mating encounters with these females. The lack of responsiveness in derived males to the ancestral blend (here represented by the normal ACB males) could be accomplished by the emergence of behavioral antagonism to the old blend. Domingue et al. (2007) suggested that the responsiveness of the Z9-14:OAc behaviorally antagonistic pathway-related ORNs to Z11-/E11-14:OAc in these normal ACB males is evidence for this second step. After olfactory antagonistic imposition has occurred (Fig. 2c), full premating reproductive isolation would result (Löfstedt et al. 1991; Phelan 1992, 1997).

There are species of *Ostrinia* in Asia that have three-component pheromone blends comprised of Z11- and E11-14:OAc plus Z9-14:OAc (Ishikawa et al. 1999). These appear to have been derived from ancestral populations that use only Z11- and E11-14:OAc (Ishikawa et al. 1999). The scenario for the addition of this third component may have been the same as outlined above for the addition of Z11-16:OAc into the *Y. padellus* blend (Fig. 3).

Other studies are emerging that support the concept of olfactory antagonistic balance, with OR gene expression being a predominant factor (Hansson et al. 2007). The ECB "E"- and "Z"- pheromone strains' ORN glomerular projection destinations in MGC glomeruli, the MGC morphologies, and the projection interneuron sex pheromone component tuning profiles were investigated. The only difference between the blend-specific behavioral responsiveness of males of the two ECB strains was shown to be due to a swapping of the expression of ORs specific for Z11-14:OAc and E11-14:OAc in one strain onto the opposite colocalized ORNs (in the same sensillum) in the other strain (Hansson et al. 2007).

The specificities of the two ORNs thus seem to have been switched to respond now to the opposite isomer, without a concomitant switch in the glomeruli of the MGC to which the ORNs project. The new olfactory antagonistic balance that allows for the potential responses to the two widely disparate blends of the ECB Z-strain and E-strain females apparently has occurred only by a swapping of expression of the ORs, leaving the rest of the pathways unchanged to impart the same balanced olfactory inputs in the antennal lobe and farther up in the CNS, but now through reversed ORN specificities of response.

A similar interpretation that uses antagonistic olfactory balance also can be made regarding the study of Cossé et al. (1995) on F2 hybrids between the E- and Z-strains of ECB. This study showed that as predicted (W.L. Roelofs, unpublished), a significant portion of the F2s in one cross that were behaviorally E-strain males would readily fly upwind to the E-strain pheromone blend, even though neurophysiological studies on these males showed that they had Z-strain ORN architecture (spike-size relationships). The large-spiking ORNs in the antennal sensilla of this portion of the F2 males responded to Z11-14:Oac, and the co-compartmentalized small-spiking ORN responded to E11-14:OAc. Normally, E-strain behavioral responders have the reverse situation, with the large-spiking ORN responding to E11-14:OAc and the small-spiking ORN responding to Z11-14:OAc.

As in the study by Hansson et al. (2007), the results of Cossé et al. (1995) lend themselves to the interpretation that the ORs specifically responsive to each of the two pheromone components in these males have been swapped onto the neighboring, colocalized ORN, perhaps due to regulatory genes (Clyne et al. 1999; Endo et al. 2007; Ray et al. 2007). Because the same olfactory antagonistic balance has been maintained, even though the balance is now the result of a different ratio of components, strong upwind flight behavior can occur. The two MGC glomeruli receiving input from the same two ORNs cannot discern that the inputs are now coming from these ORNs responding to the geometric isomers opposite to those than they normally do. No changes in CNS wiring or CNS integration of these inputs need to have occurred in order for optimal attraction to continue to take place. Rather, the fact that strong behavioral responses are elicited provides strong evidence that the remainder of the pathway has remained unchanged, and that only a switch of ORs has occurred.

Summary

I propose this new model of olfactory antagonistic balance of sex-pheromone-related compounds as a possible way of unifying our thinking and discussions about the sex-pheromone-mediated behaviors that we observe, the olfactory pathways involved, and the evolution of sex pheromones. I suggest that the concept of olfactory antagonistic balance can revitalize our thinking and suggest new possibilities for research on the evolution of divergent sex pheromone blends, and on the combinatorial coding that is involved in the positive or negative behavioral outcomes displayed by individual male moths based on their olfactory discrimination abilities.

The upwind flight behaviors of male moths that are elicited or not elicited by correct or incorrect blends of moth sex pheromone "components" are directly related to reproductive success. Thus, a detailed knowledge of such behaviors provides a foundation for understanding speciation, reproductive character displacement, and hence the evolution of insect communication systems and olfaction in general. Studies of shifts in sex-pheromone related ORN response profiles and their regulation by expression, coexpression, or shifts in expression of putative OR genes, may uncover general principles that govern how such factors might cause evolutionarily important olfactory and behavioral shifts in response to general odorants, such as the host cues that mediate feeding and oviposition in insect general odorant olfactory systems (c.f. Linn et al. 2005; Olsson et al. 2006a, b). Finally, I suggest that studies of possible shifts in sex-pheromone-related ORN response profiles that are related to shifts in behavior and to pheromone OR gene expression will complement and augment continuing advances with identified OR/ORN systems such as those in *Drosophila, Anopheles, Aedes*, and *Culex spp*.

Acknowledgments I am indebted to Wendell Roelofs, Charles Linn, Jr., and Ken Haynes for many comments and heart-felt constructive criticisms of this paper during its formative stages. I also thank the two anonymous reviewers and Jocelyn Millar of UC Riverside for helping hone this contribution to its present state. The end result does not imply an agreement on their part about the conclusions. Nevertheless, they helped shape the discussion of these issues, which I offer to our semiochemical community through the Journal of Chemical Ecology for inspection, introspection, and perhaps a new way of looking at things. I think I echo my colleagues in saying that I am indebted to the late Professors Robert M. (Milt) Silverstein and John Simeone for their inspiration in leading the founding of the International Society of Chemical Ecology and the Journal of Chemical Ecology.

General Guidelines for Authors for Submission of Manuscripts that Contain Identifications and Syntheses of Compounds

Published online: 8 July 2008

These guidelines have been developed to provide assistance to authors, with the goal of ensuring that compounds reported in the Journal, including both compounds that were previously known and compounds new to science, have been rigorously and unequivocally identified. The editors recognize that in some circumstances, because of the small amounts of material available from natural sources, it will not be possible to provide all the information suggested in the guidelines below. It is also impossible for the editors to anticipate all possible scenarios, given the variety of different types of structures, and the relative ease or difficulty of unambiguous identification of different types of compounds. In such cases, the editors will use their best judgment in determining whether:

1. authors are justified in claiming full identification of a compound,
2. the identification should be reported as tentative only, or
3. there is insufficient evidence to support the identification of a compound at all. In such cases, the editor may request that a compound be designated as an unknown.

The editors stress that these guidelines are not intended as barriers to publication. Rather, the intent is to help authors determine the information that is required to identify compounds properly, and to the extent possible, to prevent publication of information or structures that are incorrect. Publication of incorrect information is detrimental to the reputations of both the authors and the Journal. If authors are in doubt with regard to the data required to claim identification of new compounds, please contact the editors for guidance.

The editors also encourage authors to submit reasonable tentative identifications (clearly designated as such) for compounds for which they have partial but not necessarily conclusive identification information. As an example, such compounds might include analogs or homologs of a compound that is completely identified in a manuscript, where the spectral, chromatographic, or other data strongly suggest structural similarities. In short, the editors encourage the careful and responsible publication of results in a way that maximizes new information available to the research community while minimizing errors.

Please note the following:

1. It *will not be acceptable under any circumstances* to claim conclusive identification of a compound based only on a "match" with a computerized mass spectral data base spectrum. Any such claims will be rejected by the editors.
2. Normally, it will not be acceptable to claim *conclusive* identification of a compound when it is possible or even likely that the compound could be, for example, a different isomer or even a different compound than claimed. As an example, it may be difficult or impossible to claim conclusive identification of a monounsaturated alkenyl acetate by close matches of mass spectra and retention times alone because of uncertainty about the position and stereochemistry of the double bond. In cases such as this, wherever possible, the retention index and mass spectral data should be supported by, for example, microscale derivatizations that unambiguously demonstrate the double-bond position and geometry. This is used as an example: Different types of compounds will require different methods and pieces of information for proper identification.

I. Identification of Compounds

A. Conclusive Identification of Compounds New to Science

For the types of data listed below, authors are asked to use their *best judgment* as to the information required to identify a compound unequivocally. This will vary with the types and complexity of the molecules involved. Authors should use as many of the methods listed below (and additional methods as appropriate) as are required to completely and unequivocally identify a compound.

In cases where authors have data that strongly suggest, but do not conclusively prove, a particular structure, they are requested to list identifications as tentative. As mentioned above, a match with a database mass spectrum, *in the absence of other supporting data*, will not be sufficient to claim even a tentative identification.

Acceptable Methods

1. Mass spectral data or other confirmation of molecular weight/molecular formula. Determination of the molecular weight by chemical ionization mass spectrometry (CI-MS) or exact mass determination is encouraged. Elemental composition by combustion or elemental analysis is an acceptable alternative.
2. NMR data:
   (a) Basic proton spectral data, fully analyzed.
   (b) Basic carbon spectral data.
   (c) Other NMR data required to prove unequivocally the structure (e.g., results of NOE, COSY, HMBC, HSQC, other NMR experiments).
3. Matches with a standard synthesized to prove the structure.
4. Optical rotation for chiral compounds is desirable but not mandatory. Chromatographic analysis on a chiral stationary phase, or other more reliable and accurate methods of demonstrating enantiomeric purity, are preferred.
5. Optional: other supporting information such as results of microchemical tests, UV and IR data, chromatographic characteristics/retention indices, boiling or melting points, etc.
6. If applicable, unequivocal X-ray crystal structure data would be an asset.

For Very Small Amounts

1. Mass spectral data.
2. Results of microchemical tests to confirm the presence and positions of functional groups, or other methods that can provide structural information on very small quantities, are recommended.
3. Confirmation of structure with a standard synthesized to prove the structure, including exact matches of chromatographic and mass spectral data, taken under equivalent concentration and other operating conditions.
4. Any other information that helps to prove the structure unequivocally.

B. Previously Known Compounds for Which Data are Available in the Literature

It is not necessary to provide full and detailed structural information on compounds that are well known in the literature. Nevertheless, authors are strongly encouraged to confirm identification with an authentic standard whenever possible to minimize the possibility of errors.

In general terms, authors are requested to provide as many of the following types of information as necessary to support the identification of known compounds:

1. One or more literature references in which the compound has been properly identified from a particular source.
2. Matching mass spectrum with a known standard.
3. Matching chromatographic properties with a known standard. Corroborating analyses by using two or more chromatography columns with different stationary phases.
4. If necessary, matching NMR or other spectral data with a known standard.
5. Any other data required to prove the structure unequivocally. For example, microchemical tests to prove the presence or positions of functional groups, retention index matches, IR or UV spectral matches, etc.
6. If a compound is chiral, determination of its absolute configuration by comparison with known standards by using enantioselective gas chromatography. Chromatographic methods that provide unequivocal information on both absolute configuration and enantiomeric composition are preferred over measurements of optical rotation and comparison with rotations of known standards or literature values, which are affected by impurities, traces of solvent, etc.

II. Synthetic Routes and Synthesized Compounds

A. Synthesis of Compounds New to Science

1. Sufficient information should be provided to enable complete replication of the work by someone with a reasonable knowledge of synthetic chemistry.
2. Any novel or special sets of conditions, *particularly with regard to safety*, should be described in detail.

3. Sufficient spectral data, particularly NMR and MS data, should be provided for purified key intermediates that, in combination with the synthetic route and reagents used, will allow unequivocal identification of those intermediates.
4. For intermediates that were previously known, and which were made according to previously published syntheses, the conditions used should be summarized briefly, with a reference to the previous synthesis. Full spectral data for such intermediates are not required so long as the spectral data matched those previously reported; authors should provide an explicit statement to that effect, along with the relevant citation(s). Any changes of conditions from the published route should be described.
5. For intermediates that were not previously known, and for the final product, full details of the reaction conditions should be provided. In cases of common and well-known reactions (e.g., acetylation, tosylation, $LiAlH_4$ reduction), abbreviated descriptions of conditions are sufficient (reagents, temperature, solvent, time, other relevant conditions).
6. For intermediates that were not previously known, and for the final product, sufficient spectral data should be provided to prove the structures unequivocally. This typically should include proton and carbon NMR data, mass spectral data, and optical rotation data if applicable. Other requisite data might include IR and UV, ORD, etc. For chiral compounds, determinations of enantiomeric excess are recommended. However, if the enantiomeric excess has been determined for an intermediate that is then carried through several subsequent steps, in which there is no chance of epimerization of the chiral center(s), it is not necessary to determine the enantiomeric excess for each intermediate.
7. It is not necessary to provide full spectral data on intermediates that were carried through a series of *straightforward* steps without isolation and purification. However, it is expected that authors will provide corroborative spectral data on, at a minimum, every third or fourth intermediate.
8. Yields, chemical purities, and isomeric purities should be provided for all steps in which compounds are isolated and purified, and particularly for the final product.

B. Synthesis of Previously Known Compounds

a. By a Previously Published Route

1. Authors need only provide a reference, a statement that the compound was made as previously described, and sufficient spectral data to prove that they do indeed have the correct compound. Alternatively, an explicit statement that the spectral and physical properties of their product matched literature values, with the citation (s) given, will be sufficient.
2. Any deviations from the published route should be described.
3. Yield, chemical purity, and isomeric purity (including enantiomeric excess if applicable) should be provided for the final product.

b. By a New Route

1. Requirements are the same as for synthesis of previously unknown compounds, see above.

New Hemiketal Steroid from the Introduced Soft Coral *Chromonephthea braziliensis* is a Chemical Defense against Predatory Fishes

Beatriz G. Fleury · Bruno G. Lages · Jussara P. Barbosa · Carlos R. Kaiser · Angelo C. Pinto

Received: 7 October 2007 / Revised: 21 April 2008 / Accepted: 19 May 2008 / Published online: 27 June 2008

Abstract Recent studies show that chemical defenses in the exotic soft coral *Chromonephthea braziliensis* Ofwegen (Nephtheidae, Alcyonacea) can be one of the reasons for the success of this introduced species. We report for the first time the detailed composition of the monohydroxylated sterol fraction and a new hemiketal steroid, 23-keto-cladiellin-A, isolated from the unpalatable hexane extract from *C. braziliensis*. Bioassay-guided fractionation of this extract revealed that this hemiketal steroid exhibits potent feeding deterrent properties against a natural assemblage of fishes at the natural concentration. The major sterol fraction, containing the monohydroxylated sterols, was inactive in the bioassay. The results suggest that this active molecule may be driving the observed success of the invasion of this soft coral along the Brazilian Atlantic coast.

Introduction

Biological invasions in marine environments are one of the lesser understood aspects of global change (Vitousek et al. 1996). They represent a serious ecological and economic threat leading to decreased biodiversity, unbalanced ecosystems, and fishery and tourism impairment (Reise et al. 2006; Occhipinti-Ambrogi 2007; Olenin et al. 2007).

Biological invasions have been considered to be rapid evolutionary changes (Lee 2002), but little is known about their patterns and processes in marine ecosystems (Sax et al. 2007). Recent studies, however, have demonstrated that chemical defensive strategies may facilitate the invasion of the Indo-Pacific exotic soft coral *Chromonephthea braziliensis* Ofwegen (2005) in the Brazilian Atlantic coast (Lages et al. 2006).

Soft corals are among the major benthic invertebrates that compete for space on tropical reefs, particularly in the Indo-Pacific Ocean (Coll 1992). Their evolutionary success in areas of high levels of predation has been attributed to their production of significant amounts of complementary (secondary) metabolites (Sammarco and Coll 1997; Blunt et al. 2007) in their tissues, which may function as predator-deterrents and serve other ecological functions (Coll 1992; Sammarco and Coll 1992; Mizobuchi et al. 1996; Slattery et al. 1999; McClintock and Baker 2001; Fleury et al. 2004, 2006; Paul et al. 2006).

The ecological and evolutionary consequences of complementary metabolites have been considered only recently, and their effects on marine biodiversity are now recognized (Hay and Fenical 1996). There is currently little evidence, however, of the adaptive response of marine invasive species under selective pressure from a new environment.

As part of our continuing interest in the complementary metabolites responsible for the invasive success of *C.*

braziliensis, we conducted a bioassay-guided fractionation of the components of the organic extract of this exotic coral. The results indicate an active molecule that may be driving the observed success. We report the isolation and identification of a new hemiketal steroid, 23-keto-cladiellin-A, that acts as a chemical defense against a natural assemblage of fishes in the natural environment.

Methods and Materials

Coral Sampling Colonies of the exotic soft coral *C. braziliensis* Ofwegen 2005 (Nephtheidae, Alcyonacea) (identified before as *Stereonephthya* aff. *curvata*, Ferreira 2003) were collected in May 2004 in a sheltered rocky shore, by SCUBA diving at about 8-m depth at Saco dos Cardeiros, Arraial do Cabo region (23° 44′ S–42° 02′ W), state of Rio de Janeiro, southeastern coast of Brazil. This region is a marine harvest reserve and sustains unique reef systems characterized by different hydrodynamic regimes. It exhibits a rich benthic community and associated ichthyofauna (over 150 fish species) (Ferreira et al. 2001). Colonies of *C. braziliensis* were kept frozen (−25°) until analysis in the laboratory.

Field Assay Field assays were performed at Pedra Vermelha, Arraial do Cabo, Brazil. Crude extract, fractions, and pure compound were incorporated at their natural volumetrically concentrations reconstituted into a matrix of carrageenan-based artificial diet at the same concentration as occurred in the fresh soft coral tissue (Lages et al. 2006). Carrageenan (Sigma C-1013 type 1) food strips were prepared by an established methodology (Fenical and Pawlik 1991; Pawlik and Fenical 1992), involving combination of 3.75 g carrageenan, 60 ml distilled water, and 30 ml commercial tunafish purée packed in water (Pawlik and Fenical 1992; Epifanio et al. 1999, 2007). The extract, fractions, or pure compound dissolved in methanol were added to this mixture. For each experiment, 20 treated and 20 control food strips (1.0×0.6×5.0 cm each) were prepared and arranged in pairs and attached to 20 ropes that were randomly deployed at Pedra Vermelha coast. During the experiments, several common tropical fishes were observed in the studied area (Chaetodontidae, Haemulidae, Labridae, and Pomacentridae families) (Ferreira et al. 2001). After 4 to 6 h, the ropes were retrieved, and the amount of each strip eaten was measured. The *Wilcoxon paired-sample test* (one-tail) was used to analyze the results (Zar 1996).

Bioassay-Guided Fractionation Freeze-dried colonies of *C. braziliensis* (286 g dry wt) were cut into small pieces and exhaustively extracted with *n*-hexane under ultrasonication at room temperature. After removal of the solvent under reduced pressure, 9.2 g of a brownish gum was obtained and used for assays of antifeeding activity. Part of this organic extract (4.26 g) was fractioned by silica gel chromatography, employing *n*-hexane with increasing concentrations of ethyl acetate. The fractions with similar chemical compositions were combined after thin-layer chromatography (TLC) analysis to yield five fractions (F1 to F5). Fraction 2 (F2; 1.81 g) was further purified by repeated flash chromatography, yielding in order of elution, fractions A and B, which were both crystallized from methanol to give two different white solids, identified by spectroscopic methods [gas chromatography (GC)/mass spectrometry (MS), ultraviolet (UV), infrared (IR), MS, ^{1}H and ^{13}C and 2D nuclear magnetic resonance (NMR)], and comparison with literature data (Fleury et al. 1994; Zhang et al. 2005). Procedures for structure elucidation of fraction 1 and compound 1 are described below.

Analytical Procedures The Fourier transform IR spectrum was recorded on a Nicolet-Magna 760 spectrophotometer in KBr pellets. The UV spectrum was determined with a UV-visible Cary 3E Varian spectrophotometer. Electron spectroscopic imaging (ESI)–MS was obtained in positive ion mode on a Q-TOF mass spectrometer (Micromass, Manchester, UK). GC–MS analysis was carried out on an HP Model 5973 with electron impact ionization at 70 eV. The monohydroxylated sterol fraction was submitted to GC/MS analysis on capillary DB-5 column (i.d.: 0.25 mm; length: 30 m; thickness: 0.33 μm), in program mode from 200 to 290°C, 10°min^{-1}, and 10 min at the upper limit (split injection 1:20). Sterol mixture compositions were calculated (%) from the GC peak areas and identified by comparison with literature data (Fleury et al. 1994) and Wiley 275 Mass Library. The NMR spectrum was performed on a Bruker AVANCE-300 spectrometer operating at 300 and 75 MHz, for ^{1}H and ^{13}C, respectively (c=10 mg/0.6 mL in $CDCl_3$+ 0.05% TMS using a 5-mm tube, at 298 K). Melting point was measured by using a Melt Temp® apparatus and is uncorrected. Isolation procedures were monitored by employing TLC on pre-coated silica gel plates (Merck, Whitehouse Station, NJ, USA, Kieselgel 60 F-254) and UV inspection, and with ceric sulfate/heat pretreatment.

Results

Field Assays Initial field assays performed with the *n*-hexane extract revealed that it deterred a natural assemblage of fish consumers (P<0.05), as previously found (Lages et al. 2006). This assay was a guide to subsequent purification

of the active compound. Five fractions from this crude extract also were incorporated into artificial diets at their natural volumetric concentrations, and tested in situ, against fish consumers. The results showed significant inhibitory activity for F2 ($P<0.05$, Fig. 1).

Similar bioassay-guided separation of the active component F2, via repeated silica gel chromatography purification afforded two fractions A and B. These were further purified by crystallization using methanol, yielding, respectively, the monohydroxylated sterol mixture as fraction 1 (535 mg, 0.20% dry wt soft coral) (see Table 1) and the pure compound, a new hemiketal steroid, 23-keto-cladiellin-A (**1**) (357 mg, 0.12% of dry wt soft coral) (Fig. 2). The major fraction had no significant inhibition on feeding relative to controls ($P>0.05$; Fig. 3). In fact, we observed fish consumers feeding on several test strips. On the other hand, feeding deterrent properties were restricted to the more polar compound (1), which significantly reduced consumption of food strips by fishes relative to controls ($P<0.01$; Fig. 3).

Monohydroxylated Sterols Fraction The mixture of nine monohydroxylated sterols showed four dominant compounds: cholesterol, campesterol, epibrassicasterol, and 22-dehydrocholesterol. Table 1 reports the molecular ion and identification of the sterol fraction by GC/MS in comparison with literature data (Fleury et al. 1994) and Wiley 275 Mass Library. Diagnostic fragment ions at *m/z* 255, 213, 145, and 105 indicated the presence of a δ^{5-}3β-ol structure (Budzikiewicz et al. 1964) substituted with different side chains.

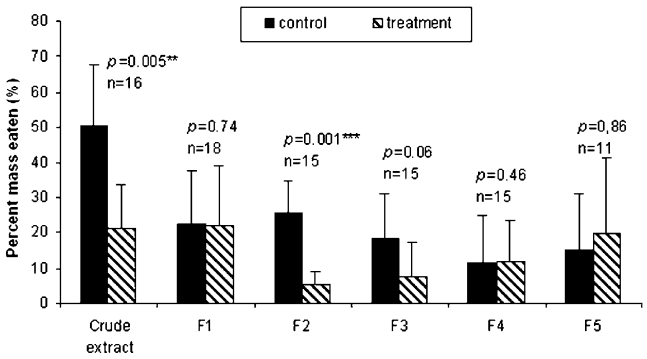

Fig. 1 Consumption of fishes on paired bait-strips with (treated) and without (control) hexane extract (crude extract), and five different fractions (F1 to F5) from this bioactive extract of *C. braziliensis*. *Vertical bars*, ±95% confidence limits. *n*, Number of pairs retrieved of 20 deployed. *P*, probability calculated by the Wilcoxon paired-sample test, one-tailed. *Asterisks*, statistically significant ($P<0.05$) reductions in feeding relative to palatable control

Structural Elucidation of the 23-keto-cladiellin-A Compound 1 (Fig. 2) had a molecular formula $C_{27}H_{38}O_4$, as determined by HRMS-ESI (nine degrees of unsaturation). Carbon-13 and DEPT NMR analysis showed the presence of four methyl groups, eight methylenes (all sp^3), nine methines (three sp^2 and six sp^3), and six quaternary carbon atoms (three sp^2 and three sp^3). The UV maximum at 242 nm was typical of a cross-conjugated cyclohexadienone functionality, which was substantiated by an IR absorption at 1,660 cm^{-1} and $^{13}C/^{1}H$ NMR signals at δ 186.4 (C-3), 123.9 (C-4), and 6.09 (H-4, d, 1.7 Hz), 127.6 (C-2) and 6.26 (H-2, dd, 10.2 and 1.7 Hz), 155.7 (C-1) and 7.09 (H-1, d, 10.2 Hz). The IR spectrum also showed an absorption at 1,716 cm^{-1}, characteristic of a ketonic carbonyl group, supported by ^{13}C NMR chemical shift at δ 208.3 (C-23). The remaining degrees of unsaturation of compound 1 could be accommodated by a steroid nucleus (3) and an additional ring (1). From the HMBC spectrum (Table 2), correlations between H-19/C-1, C-5, C-9, C-10 and H-4/C-2, C-6, C-10 were observed, elucidating rings A and B, as well as correlations between H-8/C-11, H-15β/C-8, C-13 constituting the C and D rings typical of the cholesta-1,4-dien-3-one steroidal skeleton. In this spectrum, two methyl group signals at δ 0.95 (H-26, d, 6.7 Hz) and 0.94 (H-27, d, 6.7 Hz) were correlated with C-25 (δ 23.9) and C-24 (δ 43.6), and H-24α,β was correlated with C-23 (δ 208.3). This framework was confirmed in the mass spectrum by the presence of the base peak at *m/z* 341 (^{+}O = C-CH_2-isopropyl, or M^{+}-85). The unusual quaternary carbon signal at C-22 (δ 98.8) indicated the presence of two oxygen atoms linked to it. Correlations between H-18α/C-12 and C-22, H-18β/C-12, C-13, C17, and the remaining degree of unsaturation demanded by the molecular formula, suggested the presence of a ring, part of an ether bridge. A hemiketal seemed most likely. Correlations in the NOESY spectrum observed between H-19 with H-6β and H-11β and H-18β with H-8β were in agreement with the relative stereochemistry of a normal 5α-cholestane skeleton (8β, 9α, 10β, 13β, 14α, 17β) (Mellado et al. 2005). The β-orientation of H-20 was confirmed by the correlation with H-17. Thus, the NOE correlation between H-21 and the hydrogen from the hydroxyl group on C-22 justify the β position of both. This was also supported by the correlation between H-18α,β and the hydrogen from the hydroxyl group. These assignments enabled us to conclude that the proposed structure represents a new marine steroid (Fig. 2). It was named as 23-keto-cladiellin-A because it is closely related to cladiellin A isolated from the soft coral *Cladiella* sp. (Zhang et al. 2005). However, cladiellin A is unstable in both pyridine-d_6 and $CDCl_3$ solutions yielding dehydration products, but this is not the case of the present 23-keto-cladiellin-A, which is stable even in DMSO-d_6.

Table 1 Monohydroxylated sterols composition of exotic soft coral *C. braziliensis* determined by GC/MS analysis

M	Molecular formula	Area (%)	Compounds[a]
384	$C_{27}H_{44}O$	14.0	22-Dehydrocholesterol = 22(*E*)-cholesta-5,22-dien-3 β-ol
386	$C_{27}H_{46}O$	23.4	Cholesterol = cholesta-5-en-3 β-ol
398	$C_{28}H_{46}O$	16.0	Epibrassicasterol = 22(*E*), 24 (*S*)-Ergosta-5,22–3β-ol

Discussion

Octocorals provide an interesting model system to test for the presence of defensive interactions because they express physical and chemical defenses (Van Alstyne et al. 1994; Kelman et al. 1999; Koh et al. 2000). Generally, the physical protection afforded by a more highly calcified polypary in Nephtheidae family (Alcyonacea) appears to be associated with the lack of chemical defense (Sammarco et al. 1987). In fact, some Nephtheidae species commonly use spicules as physical defense (Coll 1992), although there are more known examples of chemical defenses in this family (Coll 1992; Lages et al. 2006).

The secondary metabolites from marine invertebrates that play a defensive role against predation usually are structurally complex and frequently present in high concentrations in animals that lack obvious physical defenses (Paul 1992; Pawlik 1993). We found the major sterol fraction, isolated from the exotic soft coral *C. braziliensis*, that contained the monohydroxylated sterols to be inactive in the field assay. A minor component, however, the steroid 23-keto-cladiellin-A, appears to have an antipredatory function. This new compound joins with a small number of metabolites from octocorals with proven antifeedant properties (e.g., Harvell et al. 1988; Wylie and Paul 1989; Fenical and Pawlik 1991; Pawlik and Fenical 1992; Gerhart and Coll 1993; Cronin et al. 1995; Epifanio et al. 1999, 2007; Maia et al. 1999). There are no clear correlations between the active and inactive metabolites. It is still early to make any generalizations about structure–function relationships and chemical defenses. A minor change in the stereochemistry, structure, or functionality of a deterrent compound may render it inactive (Pawlik 1993).

The field assay reported in this work was done under ecologically realistic conditions, in Brazilian waters, far from the natural habitat of *C. braziliensis*. Although the results reported herein were seen to be relevant, further studies, both in the laboratory and in the field, under more

controlled conditions, with selected predator fish species are planned.

Recent studies of invasive marine species have highlighted the utility of using exotic species as model organisms (Sax et al. 2007), and, therefore, they outline a conceptual framework uniting the various mechanisms by which exotic species promote evolutionary diversification (Vellend et al. 2007). The absence of coevolved specialist enemies and the preferential consumption of native species by native generalists putatively generally give exotic species a competitive advantage over their native counterparts (Keany and Crawley 2002; Shea and Chesson 2002; Siemann and Rogers 2003). Further research on differential grazing between predators and co-occurring prey species is necessary to yield information that might support the enemy release hypothesis (Keany and Crawley 2002; Colautti et al. 2004). This theory may explain the effectiveness of the invasive species expansion in the new habitat.

Acknowledgements We thank IBAMA at the Arraial do Cabo Harvest Reserve (Rio de Janeiro state) for the work permits. We specially thank Dr. John Coll, who generously contributed to the present study with valuable comments and suggestions on manuscripts. The authors express their gratitude to Drs. C. M. Rezende, M. C. K. Ramos, N. C. Lucas, and E. Petronilho and to the Department of Inorganic Chemistry from UFRJ; Drs. R. C. Pereira and C. E. L. Ferreira (UFF); and J. Creed (UERJ), A. B. B. Ferreira (UFRRJ), and the Analytical Central of FIOCRUZ. B.G.F. gratefully thanks FAPERJ for providing a Visiting Research Fellowship. A.C.P. thanks FAPERJ and CAPES for financial support and CNPq for Productivity Fellowship. J.P.B. is grateful to CNPq for a Post-Doctor Research Fellowship.

Essential oils traditionally have been used to repel or kill insects and protect stored grain (Isman 2000). Molluscicidal actions have been less well studied, but certain essential oil constituents are toxic to aquatic snails, including species that act as vectors for disease-causing parasites in vertebrates (De Souza et al. 1991; Singh et al. 1997; Lahlou and Berrada 2001).

Despite the wealth of literature on ecological and pesticidal effects, few studies of essential oils have considered the mechanisms of their toxic action. In insects, several workers have reported that some essential oils such as eugenol show high-affinity binding to octopamine receptors, and they suggest that effects on octopamine receptors are responsible for the insecticidal properties of at least some oils (Enan 2001, 2005; Kostyukovsky et al. 2002). This seems plausible in view of the very low doses needed for octopamine receptor binding and activation compared to most other effects of essential oils. Unfortunately, hardly any electrophysiological studies have been made on effects of the oils in insects (see Price and Berry 2006).

The situation in molluscs is even less clear. Essential oils reduce neuronal excitability, alter spike configuration, and block responses to some neurotransmitters, although octopamine or other monoamines have not been tested (Szabadics and Erdélyi 2000). No attempt has been made to relate the effects to toxic, repellent, or antifeedant actions. In the present study, we tested the effects of three essential oil constituents (citral, geraniol, and eugenol) on the nervous system of the freshwater pulmonate snail *Planorbis corneus*. This snail does not encounter the oils naturally, but we used it as a model because the buccal ganglia, which control feeding, are well characterized in some freshwater pulmonates and contain octopamine receptors (Hiripi et al. 1998). Behavioral experiments showed that the oils stopped the animals from feeding when added to their aquarium water and eventually killed them. Accordingly, we focused on electrophysiological effects in the buccal ganglia, which play a major role in coordination of feeding in pulmonate molluscs (Benjamin 1983; Vehovszky and Elliott 2002). Furthermore, most neuronal octopamine is located in the buccal ganglia (Hiripi et al. 1998), where it acts as a neurotransmitter and neuromodulator (Elliott and Vehovszky 2001), thus giving the opportunity to study effects of the oils on octopamine receptors and hence make comparisons with insects.

Methods and Materials

Animals Specimens of *P. corneus L.* were purchased from Blades Biological Supplies Ltd. (UK). They were maintained in freshwater aquaria (containing dechlorinated tap water) at room temperature (18–22°C) and fed on lettuce leaves.

Chemicals All chemicals and components of the physiological saline were purchased from Sigma-Aldrich (UK). Essential oils were citral [3,7-dimethyl-2,6-octadienal] (95%), geraniol [3,7-dimethyl-2,6-octadien-1-ol] (98%), and eugenol [2-methoxy-4-(2-propenyl)phenol] (99%). Citral is a mixture of the stereoisomers geranial and neral (Nakamura et al. 2003) and is structurally similar to geraniol; eugenol has an unrelated structure. (±)-Octopamine hydrochloride and the octopamine antagonists phentolamine hydrochloride, metoclopramide hydrochloride, and yohimbine hydrochloride were used to distinguish different subtypes of octopamine receptor and to test for activation or block of octopamine receptors by the oils. Dopamine hydrochloride and acetylcholine chloride were used to examine the specificity of effects of the oils on octopamine receptors.

In behavioral experiments, chemicals were dissolved in dechlorinated tap water. For electrophysiology experiments, they were dissolved in physiological saline containing: NaCl, 80 mmol l^{-1}; KCl, 4 mmol l^{-1}; $CaCl_2 \cdot 2H_2O$, 7 mmol l^{-1}; $MgCl_2 \cdot 6H_2O$, 5 mmol l^{-1}; 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, 20 mmol l^{-1} (pH 7.2). Care was taken to ensure that the essential oils, which are relatively insoluble, were actually in solution (see Price and Berry 2006, for details).

Behavior

Feeding Experiments Single snails, which had been deprived of food for 24 h, were placed separately into 100 ml of test solution (concentration 10^{-5}–10^{-3} mol l^{-1}). The same volume of water alone was used for controls. Solutions were changed every 24 h to prevent buildup of waste products and to avoid any possible loss of chemical potency that could occur through separation, degradation, or evaporation. Thirty animals per treatment were used and 30 nontreated controls.

At the start of experiments, a 4-cm^2 piece of organic lettuce was washed in dechlorinated tap water and placed in the center of each dish, and one snail was placed directly onto the lettuce. After 24 h, the area of lettuce that had been consumed was estimated by drawing its outline onto a graph paper. A new piece of lettuce was then added, and the procedure was repeated for 7 days.

Assessment of Animals The condition of the animals was assessed every 15 min for the first 2 h of exposure, then every 24 h by touching the tentacles with a pair of fine forceps. A healthy individual responded to the stimuli by rapidly retracting the tentacles or its whole body. Dead snails were unresponsive to stimuli, withdrawn into their shell, and often had a shriveled appearance.

Statistical Analysis LC_{50} values were calculated by using probit analysis (Finney 1952). Mean (±SE) amounts of food consumed were calculated and evaluated by two-tailed Student's *t* tests to determine significance between means.

Electrophysiology For intracellular recordings, isolated buccal ganglia were pinned with their dorsal surface uppermost to the Sylgard base of a Perspex experimental bath (volume 1 ml) that was perfused with physiological saline at 3 ml min^{-1} by using a peristaltic pump (Gilson Minipuls3). Individual neurons were impaled with a glass microelectrode filled with 3 mol l^{-1} KCl (15–25 MΩ). Extracellular recordings were made from buccal nerves in isolated preparations of the buccal mass (with attached buccal ganglia, salivary glands, and esophagus) by using a glass-tipped suction electrode. Substances were applied by perfusion at known concentration. Octopamine, dopamine, and acetylcholine also were applied locally by iontophoretic injection from a microelectrode filled with the substance at a concentration of 0.1 mol l^{-1} in distilled water (filtered through a 0.1-μm Millipore filter). Iontophoretic current was monitored to ensure constancy, and the saline flow was stopped during applications. Retaining currents were found to be unnecessary. Sufficient time was allowed between applications (at least 5 min) to avoid receptor desensitization.

Conventional electrophysiological apparatus was used (see Price and Berry 2006, for details). Recordings were further displayed and stored on a computer by using a micro1401 ADC interface (Cambridge Electronic Design, UK; sampling rate 60 KHz) and subsequently analyzed with Spike2 software (Cambridge Electronic Design, UK).

Statistics For effects on spike frequency, the frequency is expressed as mean (±SE), and significance of effects was evaluated by two-tailed Student's *t* tests.

Measurement of Esophageal Contractions The esophagus was isolated, without its connection to the buccal ganglia, and separate pieces of thread were tied to each end. It was then suspended vertically in a glass flask (10 ml) by anchoring it posteriorly to a weight at the base of the flask and tying it anteriorly to a transducer (SRI, UK) to record isotonic contractions that were monitored and displayed in the same way as the electrophysiological data (above). The preparation was maintained in saline, and the oils were added (dissolved in saline at their final concentration) from the bottom of the flask and overflowed at the top. Use of dyes in separate experiments showed that almost full substitution occurred within 20 s. This procedure in itself did not affect spontaneous contractions; initial attempts to remove some or all of the saline and then replace it with saline that contained an essential oil showed that esophageal contractions could change irrespective of the presence of the oil and, therefore, this method was not used. The tension was adjusted to about 2×10^{-4} N.

Results

Behavior

Symptoms of Toxicity Eugenol, citral, and geraniol were all toxic to *P. corneus* (threshold approximately 2.5×10^{-4} mol l^{-1}). During the first 2 h of exposure to the two highest doses (5×10^{-4} and 10^{-3} mol l^{-1}), all snails were inactive compared to controls. The tentacles were limp; the response to tactile stimulation was reduced, and the snails appeared swollen, causing the radula to protrude; these symptoms were labeled as "knockdown." Separate experiments showed that if snails displaying these symptoms were placed into fresh water, they always recovered; however, when kept in the experimental solutions, they were always dead by the end point of the experiment (168 h), thus making these symptoms good indicators of eventual mortality (all dead individuals displayed these symptoms prior to death). Dead snails tended to have a shriveled rather than swollen appearance. About 20% of knocked down individuals had everted genitalia after exposure to the oils for 24 h.

Analysis of Mortality At the end point of the experiment, the order of potency was eugenol > citral > geraniol (LC_{50} values 2.26, 2.93, and 3.28×10^{-4} mol l^{-1}, respectively; see Fig. 1a). LC_{50} values of the oils decreased with time, and the steepest decline occurred within the first 96 h (Fig. 1a).

Feeding The amount of lettuce eaten was recorded for all individuals that were considered healthy at the time of assessment. Figure 1b shows the results after 24 h; later time points are not shown because the number of animals (*N*) became too variable (due to mortality–knockdown). Eugenol caused a significant reduction in food consumption at 10^{-4} mol l^{-1} ($P<0.01$). Citral and geraniol decreased food consumption at 2.5×10^{-4} mol l^{-1} ($P<0.001$ and $P<0.05$, respectively). The two highest doses (5×10^{-4} and 10^{-3} mol l^{-1}) were not included in the analysis because of the high levels of knockdown that occurred after 24 h.

Electrophysiology

Biphasic Dose-Dependent Effects of Essential Oils on Buccal Ganglion Neurons Attention was focused mainly on the largest neuron in each ganglion, referred to here as the giant buccal cell (GBC). Citral and geraniol (5×10^{-5}–10^{-3} mol l^{-1}) produced an increase in the rate of

Concentrations of 5×10^{-4} and 10^{-3} mol l^{-1} were omitted from the analysis because of high levels of knockdown

spontaneous firing in the GBCs and all other cells tested in the buccal ganglia, while higher doses produced a reduction in firing rate (Fig. 2a). Eugenol was variable in its effects; at 10^{-3} mol l^{-1}, it decreased or blocked spontaneous firing within 5 min of application ($N=16$; Fig. 2b; threshold approximately 10^{-4} mol l^{-1}). In four of the above cells, however, there was an initial excitation lasting for 1–5 min (not shown; it was similar to the response to citral and geraniol). At doses that reduced spontaneous firing, all three oils reversibly blocked impulses elicited by applied depolarizing current (Fig. 2c).

Essential Oils Mimic Octopamine in Initiating Burst Firing in Buccal Ganglion Neurons The increased firing rate produced by the oils was generally a result of initiation of burst firing. In extracellular recordings from the buccal nerves, burst activity was induced by perfusion of the oils (Fig. 3a) or octopamine (Fig. 3b). Citral and geraniol elicited bursting in the GBCs or any cells recorded intracellularly from groups 3, 4, 5, or 7 (Fig. 3c; see Arshavsky et al. 1988 for classification of groups). Bursting did not appear to be endogenous because the frequency was unchanged when cells were hyperpolarized by applied current, and phase relationships with other neurons in the buccal ganglia were maintained. Spike bursts became shorter at higher doses of geraniol and citral (10^{-3} mol l^{-1}), and firing was eliminated at approximately 2×10^{-3} mol l^{-1}.

Perfusion of octopamine (threshold approximately 10^{-6} mol l^{-1}) also produced burst firing in quiescent and spontaneously active neurons in the buccal ganglia ($N=22$; Fig. 3d, upper). In the GBCs, however, octopamine (threshold approximately 10^{-6} mol l^{-1}) produced a hyperpolarization of 10–15 mV and usually elicited discrete inhibitory postsynaptic potentials that progressively de-

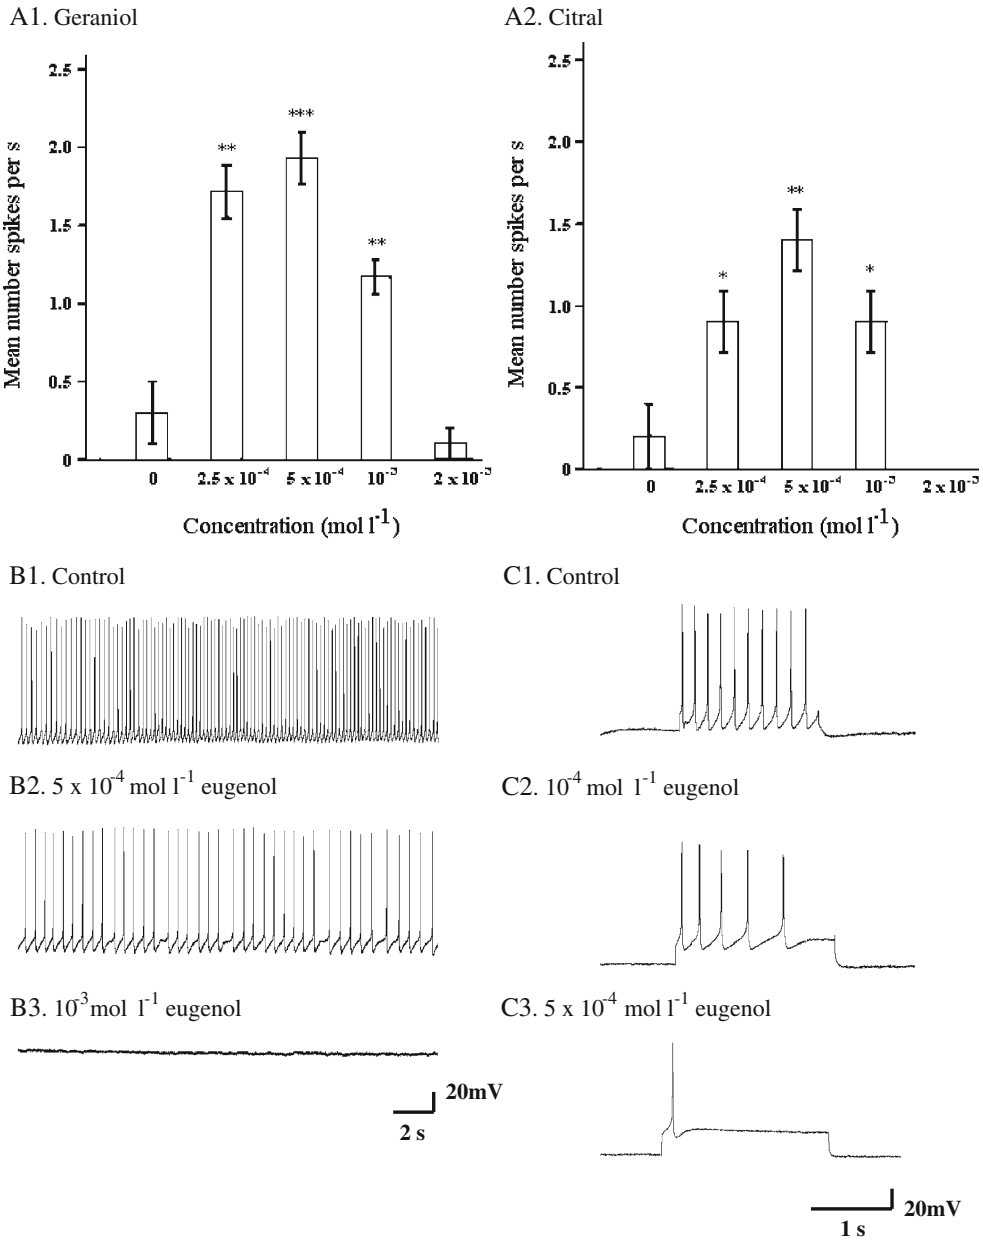

Fig. 2 Geraniol and citral have biphasic dose effects on the spontaneous firing rate of buccal ganglion neurons from groups 3, 4, 5, or 7, while eugenol is mainly depressant. **a** Bar charts showing biphasic effects of geraniol and citral on mean (±SE) spontaneous impulse frequency (N=8). Measurements were made for 5 min before introduction of the compound (control) and for 5 min after introduction (following a delay of 1 min). *Significantly different from control, $P<0.05$; **$P<0.01$ ***$P<0.001$. **b** Eugenol reversibly abolishes spontaneous activity (recovery not shown). (*B1*) Control. (*B2*) 5×10^{-4} mol l^{-1} eugenol reduces spike frequency. (*B3*) 10^{-3} mol l^{-1} eugenol abolishes spikes and synaptic input. **c** Eugenol reversibly abolishes spikes elicited by applied depolarizing pulses (different cell; amplitude of the current was the same in each recording; recovery not shown). (*C1*) Control. (*C2–C3*) Progressive reduction in response with increasing concentration. Similar effects were produced by citral and geraniol at approximately 2×10^{-3} mol l^{-1}; lower doses had no apparent effect on firing threshold

creased in amplitude with the hyperpolarization and were in phase with inputs in other buccal ganglion neurons that were induced to burst fire (N=27; Fig. 3d). Octopamine decreased excitability of GBCs and usually rendered them unexcitable at 10^{-4} mol l^{-1}.

The Oils Do not Appear to be Octopamine Receptor Agonists Since the oils mimicked octopamine in initiating and modulating burst firing, we investigated pharmacological evidence for their possible actions as octopaminergic agonists (as found in insects), and for this purpose we focused on the GBCs. The oils did not appear to activate octopamine receptors that mediate inhibition since they did not mimic octopamine in hyperpolarizing the GBCs; citral, geraniol, and (in some cases) eugenol produced a depolarization and excitation. They did, however, mimic effects of octopamine on GBCs following exposure to phentolamine.

Phentolamine (threshold approximately 10^{-7} mol l^{-1}) blocked the hyperpolarizing response of GBCs to octopamine, converting it to an excitatory response (N=15). This occurred whether octopamine was applied by perfusion (Fig. 4a) or iontophoresis (Fig. 4b) and suggested the unmasking of a depolarizing octopamine receptor on the GBCs (in two GBCs, there was a biphasic response to iontophoresis of octopamine, with a small depolarization preceding the hyperpolarization; not shown). In the presence of phentolamine, perfused octopamine produced a depolarization and (in four out of eight preparations) burst

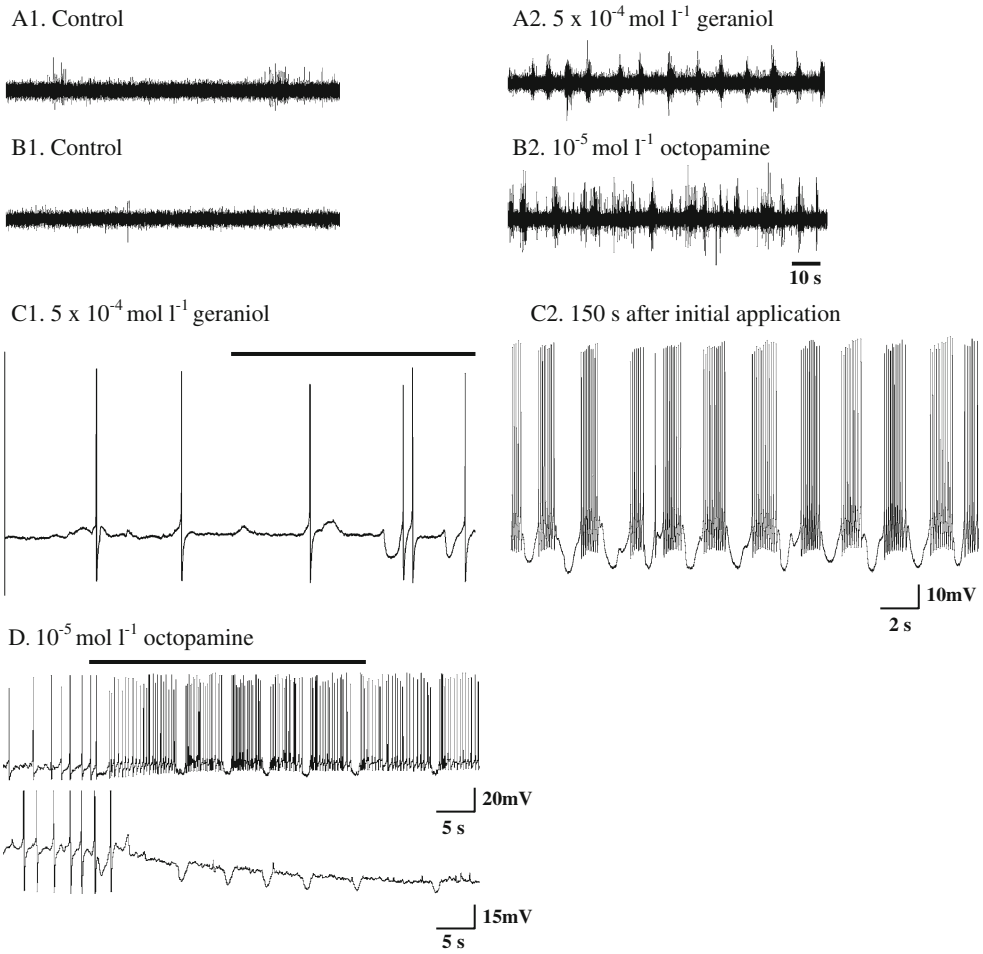

Fig. 3 Recordings to illustrate that citral and geraniol generally mimic octopamine in inducing burst firing in buccal ganglion neurons. Geraniol (**a**) and octopamine (**b**) induce burst firing in the right dorso-buccal nerve of an isolated preparation of the buccal mass. The extracellular recordings are from different preparations. Each pair of recordings is separated by approximately 2 min and the chemical was added within 10 s of the end of the control recording. (**c**) Geraniol elicits burst firing in a giant buccal cell. (**d**) Octopamine elicits burst firing in a group 5 neuron (*upper*) but the effect on a GBC (recorded simultaneously, *lower*) is hyperpolarizing, though it initiates inhibitory postsynaptic potentials that are in phase with those that cause bursting in the other neuron. The black bar represents addition of chemicals

firing in the GBCs similar to that produced by geraniol (Fig. 4, A2, compare Fig. 3c). Recovery from phentolamine was very slow, beginning at least 2 h after washout. Phentolamine (up to 5×10^{-4} mol l^{-1}) did not affect the excitatory (burst firing) response to octopamine in other buccal ganglion neurons (not shown). Yohimbine had similar effects to phentolamine on the response of GBCs to octopamine (conversion of hyperpolarization to depolarization), but higher doses were required (approximately 5×10^{-4} mol l^{-1}; N=4, results not shown).

Metoclopramide (10^{-4} mol l^{-1}) had no effect on hyperpolarizing octopamine responses in GBCs (N=5) but it blocked the excitatory responses to octopamine that occurred after administration of phentolamine (N=5; Fig. 5a). It also blocked the initiation of burst firing normally caused by octopamine in other cells tested (N=5; Fig. 5b). Thus, it provided a useful test for activation of excitatory octopamine receptors by the oils. None of the antagonists (up to 10^{-3} mol l^{-1}), however, had any effect on responses to eugenol, citral, or geraniol (N=5 for each oil; results not shown). There was, therefore, no pharmacological evidence to support activation of octopamine receptors (excitatory or inhibitory) by the oils.

The Oils Are not Specific Octopamine Receptor Antagonists The oils were tested for octopamine receptor antagonism by observing their effects on the response of the GBCs to octopamine. Submillimolar doses of eugenol had no effect on the hyperpolarizing response of GBCs to octopamine applied via perfusion or iontophoresis (N=5). Higher doses (approximately 10^{-3} mol l^{-1}) reduced the response, although these doses also greatly reduced or blocked spike activity. Total block occurred at 2×10^{-3} mol l^{-1} (not shown). Similarly, for citral and geraniol, doses below 10^{-3} mol l^{-1} had no effect on the hyperpolarizing response of GBCs to octopamine (N=5), even when the cell was burst firing as a result of oil application. Higher doses (approximately 2×10^{-3} mol l^{-1}) of geraniol and citral blocked the response (not shown). In other buccal ganglion cells, and in GBCs exposed to phentolamine, excitatory responses to octopamine were reduced by eugenol at 10^{-3} mol l^{-1} and blocked at 2×10^{-3} mol l^{-1} (N=4). Citral and geraniol also blocked excitatory responses at 2×10^{-3} mol l^{-1} (N=4); this dose affected spiking, but lower concentrations could not be tested because they were themselves excitatory. All blocking effects were reversible.

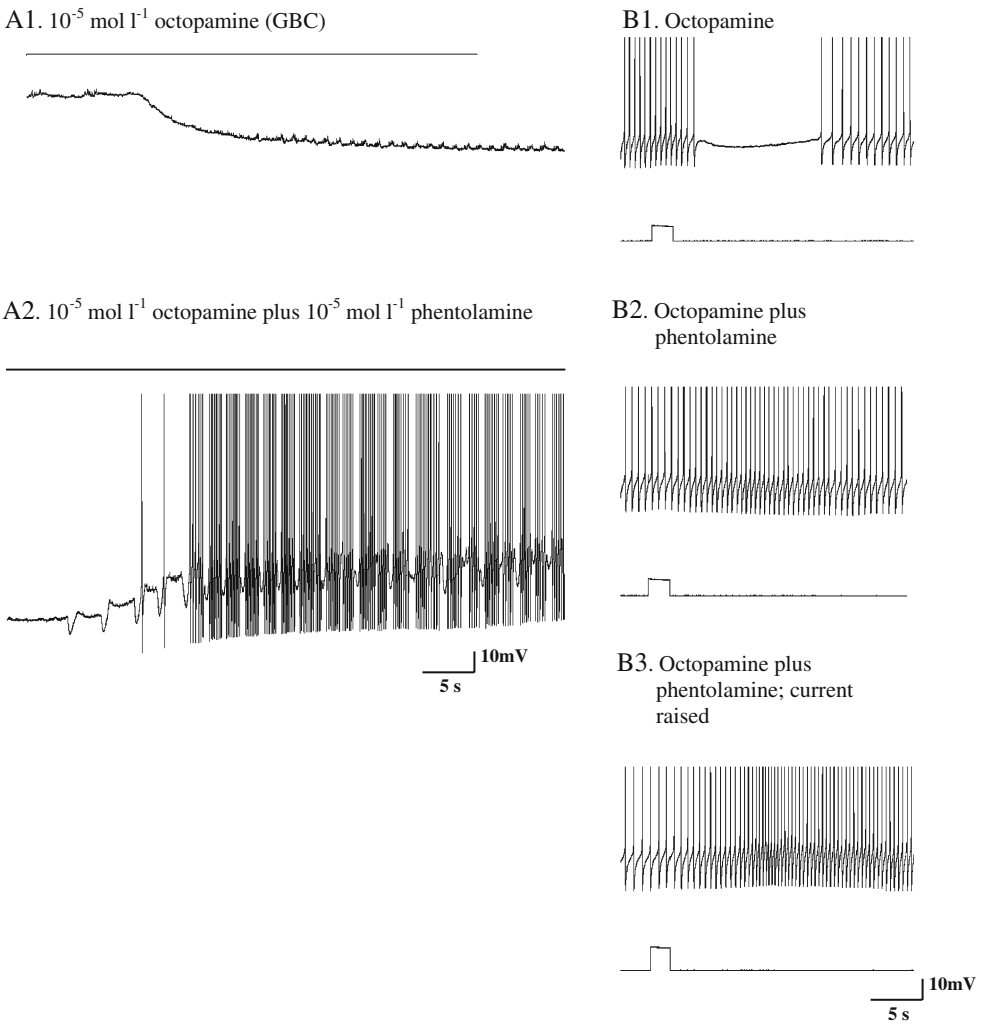

Fig. 4 Phentolamine reverses the inhibitory response of a giant buccal cell (GBC) to octopamine applied by perfusion (**a**) or iontophoresis (**b**). (*A1*) Perfusion of 10^{-5} mol l^{-1} octopamine hyperpolarizes a GBC. (*A2*) After 20-min exposure to 10^{-5} mol l^{-1} phentolamine, octopamine excites the same GBC and elicits burst firing similar to that induced by geraniol (see Fig. 3c). (*B1*) Control. Octopamine produces inhibition (iontophoretic current is shown below the recording; 250 nA). (*B2*) 20 min after introduction of 10^{-5} mol l^{-1} phentolamine, the response is a weak excitation. (*B3*) A larger current (350 nA) increases the excitation. The black bar represents addition of chemicals

The effects of these relatively high concentrations, however, were not specific to octopamine. Depolarizing and hyperpolarizing responses to dopamine also were reduced by the oils; these were tested by iontophoresis and by recording dopamine-mediated postsynaptic potentials in visceral ganglion neurons following stimulation of the giant dopamine neuron in the left pedal ganglion (Berry and Cottrell 1975). Excitatory responses were reduced by the oils at approximately 10^{-3} mol l^{-1}, while hyperpolarizing responses needed 2×10^{-3} mol l^{-1} (not shown; N=3 in each case). Depolarizing responses to iontophoretically applied ACh were reversibly reduced or abolished by all three oils at 5×10^{-4} mol l^{-1} (N=4; not shown).

Effects of Essential Oils on Gut Movements Effects of the oils on movements of the innervated buccal mass were in accord with their effects on the buccal ganglia. The buccal mass was reversibly excited into rhythmic activity by citral and geraniol (5×10^{-5}–10^{-3} mol l^{-1}) for up to 2 h (N=5 for each oil). Eugenol (threshold 10^{-4} mol l^{-1}) reversibly reduced spontaneous movements of the buccal mass (N=5).

Eugenol, citral, and geraniol (10^{-5}–2×10^{-3} mol l^{-1}) all had the same effect on the isolated esophagus of reversibly increasing the frequency of contractions and progressively reducing their amplitude (Fig. 6a; N=9 for each oil). There was often an initial increase in amplitude (Fig. 6b), and at 5×10^{-4} mol l^{-1} and above there was always a transient sustained contraction (Fig. 6c). In preparations that showed complex patterns of activity, this became simplified by abolition of the smaller contractions. At low concentrations, the effects were short lasting (approximately 5 min at 10^{-5}–5×10^{-5} mol l^{-1}), and at higher concentrations there was at least partial recovery of amplitude and frequency in the continued presence of the oil.

The esophagus also responded to octopamine (N=10; Fig. 6d). At 5×10^{-4}–10^{-3} mol l^{-1}, there was always a transient sustained contraction, but at lower concentrations there was considerable variation in sensitivity among preparations. A reduction in amplitude and increase in frequency of contractions occurred at 5×10^{-6} mol l^{-1} in four preparations and at 5×10^{-4} mol l^{-1} in the others. There was at least partial recovery in the continued presence of octopamine.

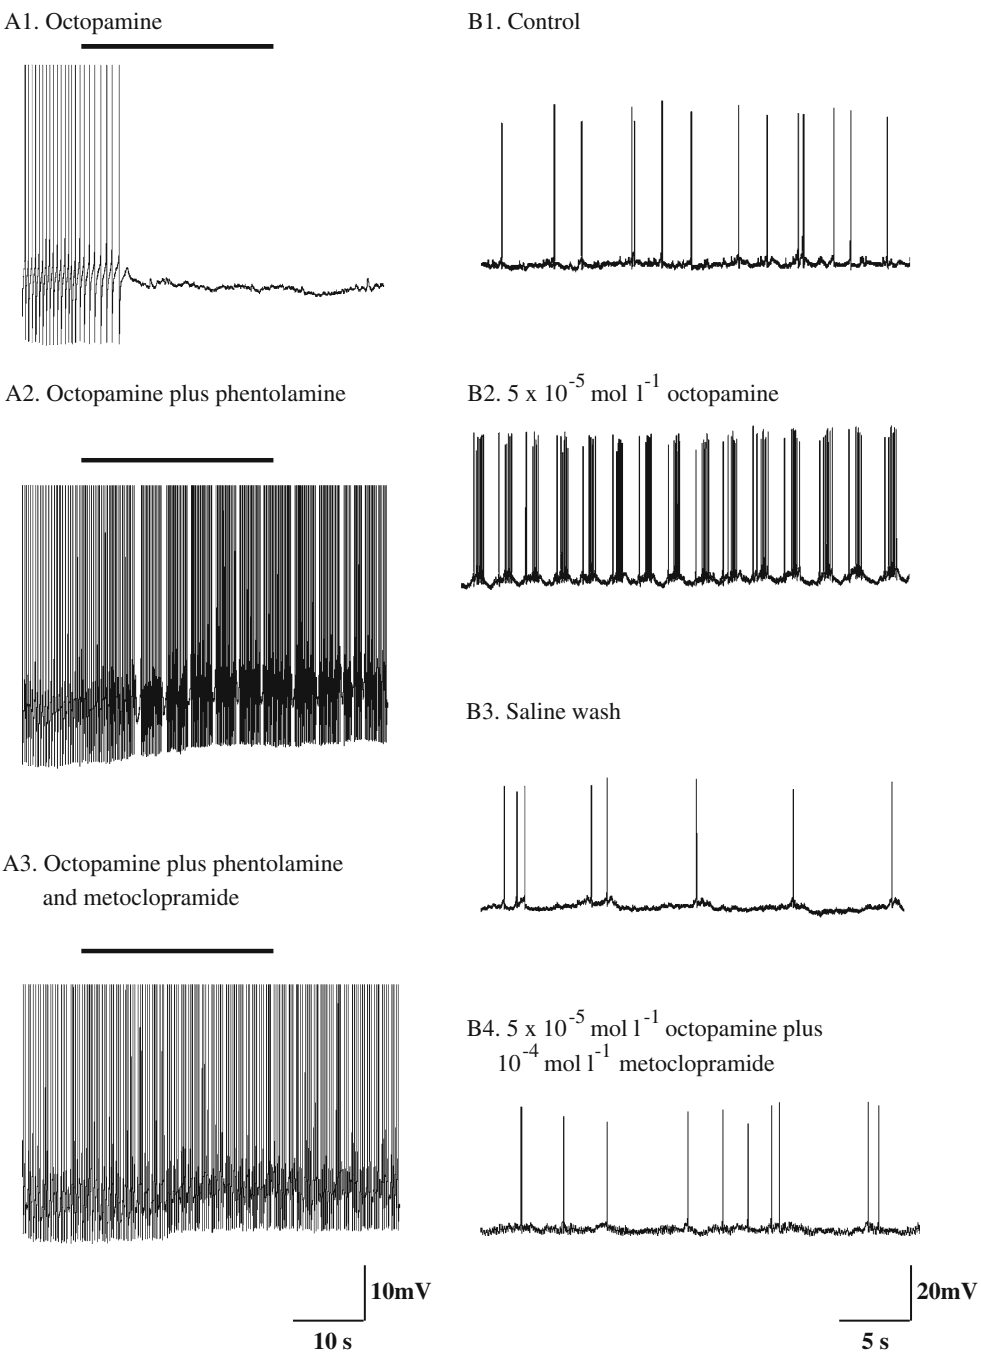

Fig. 5 a Metoclopramide blocks excitatory (burst initiating) responses to octopamine in buccal ganglion neurons. (*A1*) Normal inhibitory response of a giant buccal cell to octopamine (10^{-5} mol l^{-1}, indicated by *horizontal bar*). (*A2*) In the presence of phentolamine (10^{-5} mol l^{-1}), the response to octopamine reverses and becomes excitatory, producing burst firing. (*A3*) Burst firing is eliminated by metoclopramide (10^{-4} mol l^{-1}). **b** Metoclopramide blocks the initiation of burst firing by octopamine in a group 5 neuron. (*B1*) Control. (*B2*) Burst firing 60 s after exposure to octopamine (5×10^{-5} mol l^{-1}). (*B3*) Recovery after washout of octopamine. (*B4*) The same dose of octopamine does not initiate burst firing in the presence of metoclopramide (10^{-4} mol l^{-1})

None of the effects of the oils was blocked by phentolamine (10^{-5} mol l^{-1}) or metoclopramide (10^{-4} mol l^{-1}), applied for at least 1 h. Also, exposure to octopamine (10^{-4} mol l^{-1}) for 30 min to try to desensitize any octopamine receptors did not affect responses to the oils. Thus, in spite of the similarity of effects, the oils did not appear to work via activation of octopamine receptors.

Discussion

All three essential oil constituents were toxic to *P. corneus* in a dose- and time-dependent manner. Acute symptoms of exposure to lethal doses (approximately 2.5×10^{-4} mol l^{-1}) included a lack of response to tactile stimulation of the tentacles, swelling of the body, and sometimes protrusion of

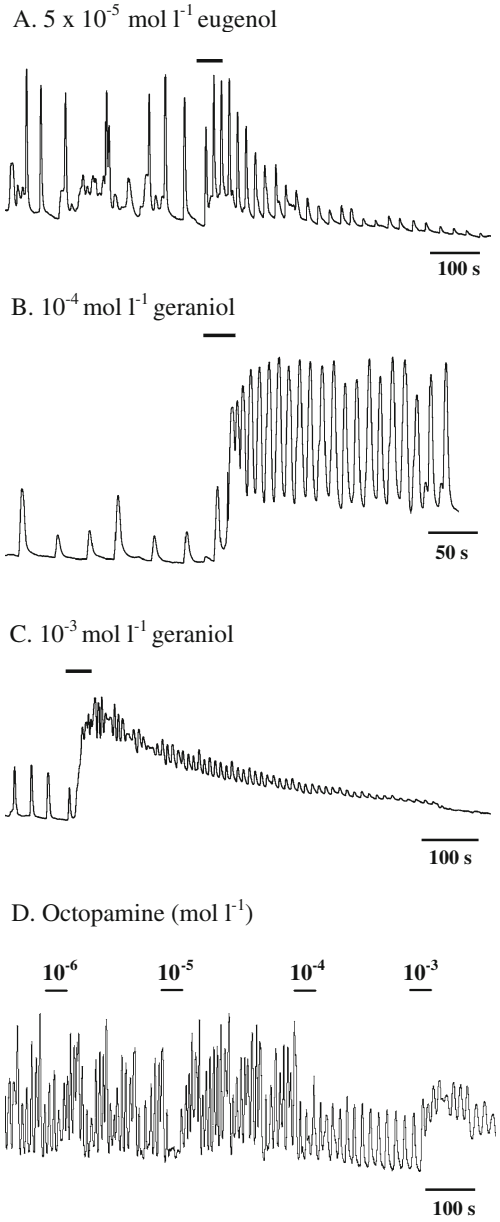

Fig. 6 Effects of essential oils and octopamine on spontaneous contractions of the isolated esophagus. **a** Eugenol (5×10^{-5} mol l^{-1}) produces an increase in frequency and progressive reduction in amplitude. **b** Geraniol (10^{-4} mol l^{-1}) increases frequency and produces an initial increase in amplitude. **c** Geraniol (10^{-3} mol l^{-1}) produces a transient sustained contraction in addition to increasing the frequency and reducing the amplitude of spontaneous contractions. **d** Octopamine has little effect at 10^{-6} or 10^{-5} mol l^{-1} but reduces amplitude of contractions at 10^{-4} mol l^{-1} and produces a transient sustained contraction at 10^{-3} mol l^{-1}

the mouthparts and genitalia, which were good indicators of eventual death (after 7 days) but were reversible up to about 5-h exposure. De Souza et al. (1991) found that *O*-methyleugenol had a similar effect in *Biomphalaria glabrata* and caused the copulatory and urethral organs to project from the body. Lahlou and Berrada (2001) showed that some essential oil constituents caused *Bulinus truncatus* to "inflate and extend out of the shell." In addition to this, in our study, all three essential oil constituents (approximately 2.5×10^{-4} mol l^{-1}) significantly reduced the amount of food consumed within 24 h.

Essential oils have a wide variety of biological effects, possibly related at least in part to their lipophilic nature, so it is difficult to specify precise mechanisms of action. In insects, oils tend to cause symptoms that suggest neurotoxicity (Coats et al. 1991; Kostyukovsky et al. 2002), typified by tremors, hyperactivity, rapid knockdown, and eventual death (Coats et al. 1991; Enan 2001). A possible target in insects is the octopamine receptor in the brain (Enan 2001, 2005). Whereas most effects of the oils generally have been found to occur at millimolar concentrations (in any animal), certain insect octopamine receptors are activated by micromolar doses of some essential oils and show high-affinity binding (Enan 2001, 2005; Kostyukovsky et al. 2002). Price and Berry (2006), by using electrophysiological techniques, were unable to demonstrate specific effects on octopamine receptors in the nerve cord of cockroaches, but these might have been different subtypes from those studied by other workers (see Evans and Robb 1993, for review of octopamine receptor classification).

In the few electrophysiological studies on the nervous system, effects of essential oils generally have been reported as depressant, such as blockage of responses to neurotransmitters (Szabadics and Erdélyi 2000) and reduced neuronal excitability (local and general anesthetic effects have been found in mammals; Brodin and Røed 1984; Ghelardini et al. 1999). The present results also demonstrated a blocking of action potentials and responses to octopamine, dopamine, and ACh at millimolar concentrations, which might contribute to the death of snails exposed to the oils in their aquarium water.

Lower concentrations of the oils, however, excited buccal ganglion neurons, appearing to produce the rhythmic pattern of fictive feeding. This did not correlate with their antifeedant actions, but such excitatory effects might be relatively short lasting or offset by other effects (e.g., on the ability of snails to detect appetitive signals), or the normal burst pattern that underlies feeding might be altered. The biphasic dose-dependent effects of citral and geraniol on impulse activity and esophageal contractions were similar to those in the nerve cord and foregut of cockroaches (Price and Berry 2006). The variability in response to eugenol (depression, sometimes preceded by transient excitation) might result from a lower concentration needed for inhibition of spiking, perhaps offsetting an excitatory effect in most cases.

In the GBCs (and some other neurons), octopamine produced a prolonged hyperpolarizing response when applied by perfusion and a short-lasting, relatively rapid

hyperpolarizing response when applied by iontophoresis, both of which were blocked by phentolamine. This suggests a direct effect of octopamine and the presence of octopamine receptors on these cells. Unlike octopamine, none of the oils hyperpolarized the GBCs or other neurons that appeared to possess inhibitory octopamine receptors, indicating that they did not activate this particular octopamine receptor subtype. They also showed no selectivity as receptor antagonists; they blocked inhibitory responses to octopamine (and dopamine) only at millimolar concentrations and were more effective at blocking excitatory ACh responses.

Citral, geraniol, and (on some occasions) eugenol did, however, mimic octopamine in initiating or modulating the presumed fictive feeding sequence in the buccal ganglia. In order to determine whether this was a result of octopamine receptor activation, we used receptor antagonists. In order to try to block excitatory and inhibitory responses to octopamine independently, phentolamine and yohimbine were chosen as potent antagonists of octopamine$_1$ receptors, and metoclopramide was selected as an example of a different (octopamine$_2$) receptor antagonist (Evans and Robb 1993; see Evans and Maqueira 2005, for new classification scheme in insects).

Phentolamine, which blocked hyperpolarizing responses to octopamine in the GBCs, did not affect the excitatory and burst-producing effects of octopamine or citral and geraniol (although phentolamine inhibits feeding when injected into *Lymnaea stagnalis*; Vehovszky et al. 1998). Since concentrations as high as 5×10^{-4} mol l^{-1} were ineffective on excitation, this shows a high specificity of the drug for octopamine receptors that mediate inhibition. Metoclopramide blocked the burst response to perfused octopamine but was ineffective on similar responses to geraniol and citral even when used at doses that were at least ten times higher. Metoclopramide also blocked the depolarizing responses to iontophoresis of octopamine in the GBCs, which occurred after treatment with phentolamine, without blocking the depolarizing responses to geraniol and citral (the change from octopamine-mediated inhibition to excitation following phentolamine suggests the presence of two receptor types on the GBCs). Care must be taken with interpretation because, unlike octopamine, the lipophilic oils are able to enter neurons and produce direct intracellular effects that could perhaps mask any octopamine-receptor-mediated actions (see Enan 2005). There also is the possibility that the oils couple an octopamine receptor to a different second messenger pathway from that of octopamine (Evans et al. 1995). Nevertheless, the fact that the effects of the oils were not blocked by high concentrations of three octopaminergic antagonists suggests that they do not produce their effects by activation of excitatory or inhibitory octopamine receptors.

Knowledge of the mechanism of action of essential oils is relevant to their allelochemical properties as attractants, repellents, and toxins, and also to their use as pesticides. Concerns over increasing costs, human and environmental safety, and resistance to currently used synthetic pesticides have increased interest in the use of plant-derived compounds such as essential oils to control pests (Clark and Appleton 1997; Ngoh et al. 1998; Lahlou and Berrada 2001). Overall, our results with the oils suggest nonspecific effects rather than direct receptor targeting. This is further supported by our unpublished findings that ethanol, high $[K^+]_o$, and a variety of other essential oils (eucalyptus, lavender, Tea Tree, and menthol) also produced depolarization, burst firing, and blocking of spike activity. Whatever the mechanism, the sensitivity of the feeding network may contribute to the antifeeding and lethal effects of the oils, which would be expected to enter the animals from the water (irrespective of feeding) because of their lipophilic nature.

have developed mechanisms to downregulate inhibitor genes due to this mechanical wounding (Kessler and Baldwin 2002). Protease/amylase inhibitors also may be important to plant defense against insects with sucking mouthparts. For example, a proteinase inhibitor accumulated at a significantly higher level in barley leaves infested with aphids (Casaretto and Corcuera 1998). Elevated levels of protease inhibitors either through artificial diet or via transgenic plants resulted in the suppression of aphid growth and development (Rahbe et al. 2002, 2003; Ceci et al. 2003).

Despite this progress, little is known about the role and regulation of inhibitor genes during compatible (virulent parasites in susceptible hosts) and incompatible (avirulent parasites in resistant hosts) interactions in plant–insect systems that have a gene-for-gene interaction. The wheat–Hessian fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae), system follows a typical gene-for-gene interaction, and provides a good model for studying the scheme of attack and counter-attack between insects and plants (Harris et al. 2003). From a previous analysis of wheat gene expression with Affymetrix microarrays, we identified a group of inhibitor-like genes whose expression was affected by *M. destructor* attack (Liu et al. 2007). In this study, we investigated the dynamic expression of the inhibitor-like genes in wheat seedlings attacked by virulent or avirulent *M. destructor* larvae. We found that the expression of the inhibitor-like genes was suppressed strongly during compatible interactions. On the other hand, dramatic induction of these genes was observed during incompatible interactions.

Methods and Materials

Plants and Insects Two wheat, *Triticum aestivum*, cultivars, Molly and Karl-92, and two *M. destructor* biotypes, Great Plains (*GP*) and *vH13*, were used. Both *GP* and *vH13* were derived from the same population. Karl-92 carries no *M. destructor* resistance (*R*) genes, and was used for maintaining the population and for complementary DNA (cDNA) cloning. Molly carries the *M. destructor R*-gene *H13*, and is compatible to *vH13* but incompatible to *GP* insects (Patterson et al. 1994; Rider et al. 2002). Molly seedlings were susceptible plants (compatible interaction) when they were infested with *vH13*, and were resistant plants (incompatible interaction) when infested with *GP*. *GP* was maintained on two-leaf seedlings of Karl-92, and *vH13* was maintained on Molly seedlings in growth chambers at 20°C and 12:12 hr (L/D) photoperiod.

Cloning and Characterization of Inhibitor-like cDNAs Expressed sequence tags (ESTs) corresponding to specific inhibitor-like genes were identified from a previous microarray analysis (Liu et al. 2007). To clone full-length cDNAs, an individual EST was used to blast the GenBank EST database to identify other ESTs that share high sequence similarity. Contigs were then assembled with all similar EST sequences by using the CAP3 Program (http://pbil.univ-lyon1.fr/cap3.php, Huang and Madan 1999). A pair of primers was synthesized according to the contig sequence, and was used for polymerase chain reaction (PCR) amplification. DNA template for PCR amplification was derived by reverse transcription of total RNA extracted from Karl-92. The PCR fragments were either sequenced directly or ligated into the pPCR2.1-XL-TOPO plasmid by using a TOPO TA cloning kit (Invitrogen, Carlsbad, CA, USA). If ligated into the plasmid, individual clones were picked up and plasmid DNA samples for the individual clones were then sequenced. DNA sequencing was carried out either at Kansas State University, Manhattan, KS, USA or at the Jamie Whitten Delta States Research Center of USDA-ARS at Stoneville, MS, USA.

Sequence alignments were generated with ClustalW (www.ebi.ac.uk/Tools/clustalw/index.html). Secretion signal peptides were predicted using SignalP v. 1.1 (Center for Biological Sequence Analysis, Technical University of Denmark, www.cbs.dtu.dk/services/SignalP) or PSORT II (http://psort.nibb.ac.jp).

Experimental Treatments and RNA Extraction Wheat seedlings were grown and infested with different biotypes of *M. destructor* in a growth chamber set at 20±1°C (daytime) and 18±1°C (night) with a 14:10 hr (L/D) photoperiod. Seedlings were infested with a mean of 10 larvae at the two-leaf stage. Larval hatching time was monitored with additional infested plants under the same growth chamber conditions. Specifically, plants for monitoring hatching time were cut off at the base and were put into a test tube. Newly hatched larvae migrated along the leaves and between leaf sheathes. Initial attacking time was recorded when the larvae moved out of the leaf sheath into the test tube.

Wounding was accomplished with a dissecting pin (size 1, Benz Microscope, Ann Arbor, MI, USA) mounted onto a pin-vise (Cat#: 4845, Bioquip, Rancho Dominguez, CA, USA). Ten penetrations per plant were made above the base of a plant, where *M. destructor* larvae feed. For the combinational treatments of wounding plus larval attack, wounding was carried out immediately before larval migration to the feeding site. Unwounded *H13* plants at the same developmental stage were taken as controls.

Tissue samples from 20 plants per replicate were collected and pooled at 4, 12, 24, 48, 72, 96, and 120 hr after initial larval attack. Only those plants with 10 to 15 larvae per plant were chosen for tissue collection by using only the tissue at the feeding site. Approximately 1 cm of leaf-sheath tissue was collected for RNA extraction. The *H13* seedlings infested with v*H13* were taken as plants during compatible interactions, whereas the *H13* seedlings

infested with *GP* were taken as plants during incompatible interactions. Seedlings under the same conditions, but without infestation, were used as controls. Each experiment contained three independent sets of seedlings (biological replicates) that were treated in the same way at different times in different chambers.

Total RNA was extracted from wheat tissue by using TRI reagent™ according to the manufacturer's guidelines (Molecular Research Center, Inc. Cincinnati, OH, USA). The RNA samples were further purified through an RNease kit according to the manufacturer's instructions (QIAGEN Inc., Valencia, CA, USA). The RNA concentrations were measured by using a NanoDrop-1000 Spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA).

Real-Time PCR Analysis After removing potential DNA contamination by DNase I, total RNA was reverse-transcribed into cDNA by using superscript reverse transcriptase following the manufacturer's instructions (BD Biosciences, San Jose, CA, USA). After removing the RNA in the reaction by DNase-free RNase A, the cDNAs were used as template for real-time PCR (RT-PCR) analysis.

Real-time PCR was performed with iQ SYBR Green Supermix on a iCycler real time detection system (Bio-Rad, Hercules, CA, USA). Each reaction was carried out with 2 μl of a 1/40 (*v*/*v*) dilution of the first cDNA strand, and 0.5 μM of each primer in 25 μl total volume. The cycling conditions were: 95°C for 5 min followed by 45 cycles of denaturation at 95°C for 20 sec, annealing and extension at 62°C to 64.5°C, depending on the primer set, for 45 sec. At the end of the cycles, PCR specificity was verified by obtaining a dissociation curve, derived by cooling the denatured samples to 55°C and raising the temperature 0.5°C for 10 sec for each cycle, for a total of 80 cycles until reaching 95°C. The PCR products were analyzed on 1.5% agarose gels, and subsequently purified and sequenced to confirm specific amplification.

Primers (Table 1) were designed by using the Beacon Designer (v. 2.0) software from Biosoft International (Palo Alto, CA, USA). Plasmid DNA containing the corresponding insert was used to generate a calibration standard curve, where Cycle Threshold (Ct) values were plotted to serve as standard concentrations. The transcript concentration for each sample was calculated based on the standard concentrations. A negative control without template was always included for each primer set. Template concentrations of different samples were normalized against the ribosomal protein gene 21 (AF093630). For each sample analyzed, results represent the mean of values obtained from at least two independent PCR reactions and from at least three independent biological replicates.

Results

cDNAs Encoding Inhibitor-like Proteins Four groups of cDNAs were identified, and all the four groups encode small proteins with 76 to 131 amino acids (Fig. 1). All of the putative proteins contain a secretion signal peptide and have eight to 12 conserved cysteine residues in the mature protein region. However, there is no sequence similarity among members from different groups.

Group I was previously identified as defensins that were specifically induced in wheat during cold acclimation (*AI-L4*, *BAC10287*) (Koike et al. 2002). Sequence comparison revealed that proteins in Group I share high sequence similarity with a sorghum inhibitor (P21924) that inhibited α-amylases from two insect species, a locust, *Locusta migratoria*, and the American cockroach, *Periplaneta americana* (L.) (Fig. 1a) (Bloch and Richardson 1991). Because of this structural similarity, we refer to this group of cDNAs as α-amylase inhibitor-like cDNAs 1 to 4 (*AI-L1* to *AI-L4*). The specific functions of the inhibitors, however, need to be determined since protease and amylase inhibitors share structural similarities (Rawlings et al. 2005), and some can inhibit multiple types of enzymes (Odani and Ikenaka 1976).

Group II encodes proteins with >80% sequence similarity to a wheat Bowman–Birk type trypsin inhibitor (P81713) (Fig. 1b) (Poerio et al. 1994). Accordingly, members in Group II were named trypsin inhibitor-like protein 1 (*TI-L1*) to trypsin inhibitor-like protein 4 (*TI-L4*).

Unlike Groups I and II, which share sequence conservation with functionally defined proteins, Groups III and IV encode proteins that share sequence similarity with GenBank proteins whose functions have not been defined. Group III encodes proteins that belong to a large family referred to as "protease inhibitor/seed storage/LTP" (Fig. 1c) (Marchler-Bauer et al. 2007). This family is composed of protease and amylase inhi-

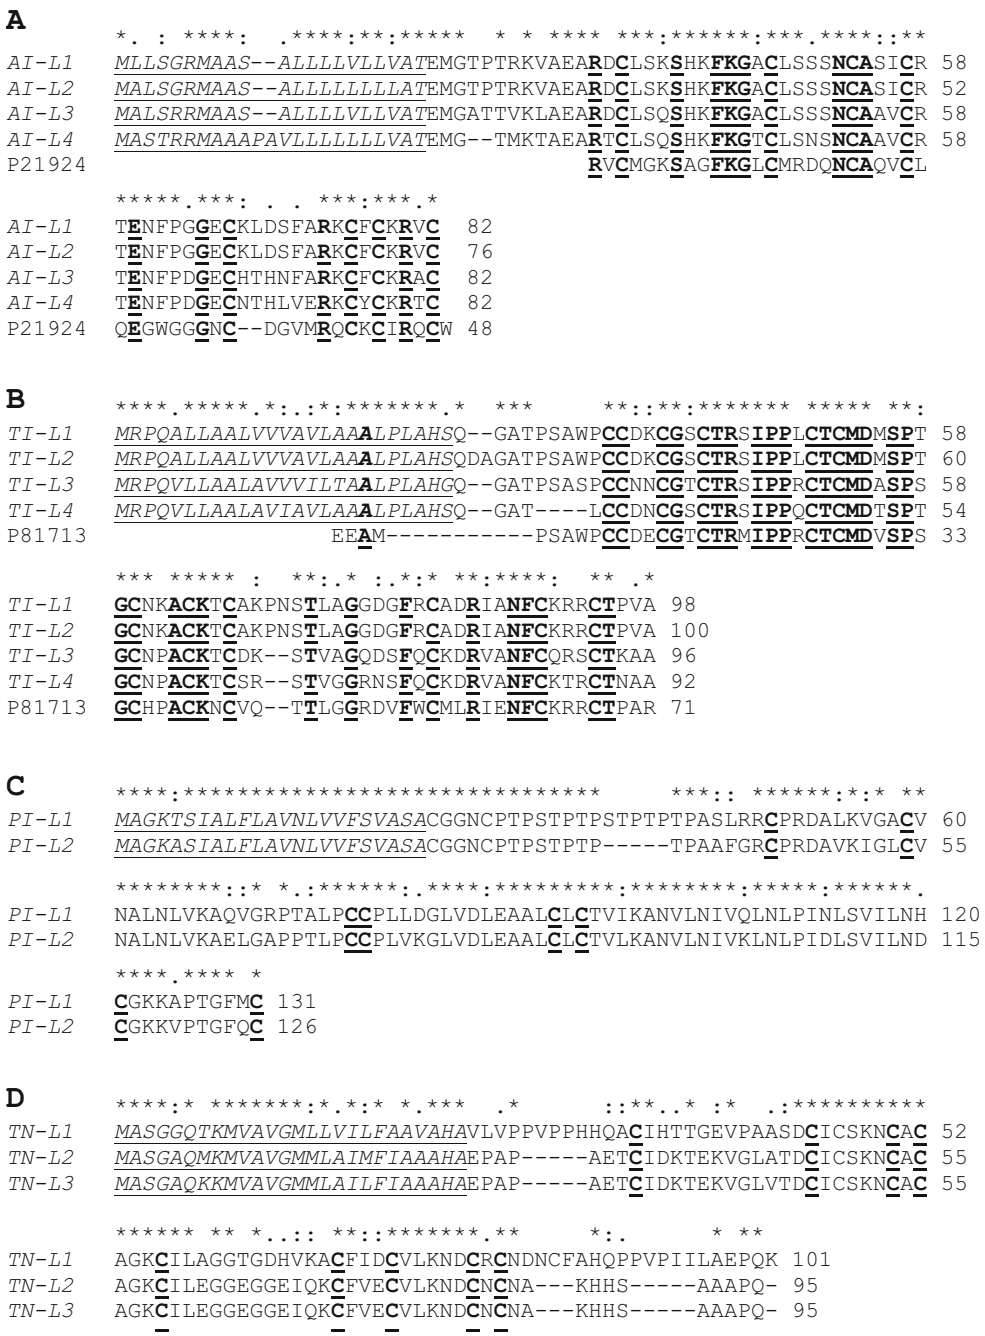

Fig. 1 Sequence alignments of inhibitor-like proteins from wheat, *Triticum aestivum*. The alignments were made by using the program *ClustalW* (see "Methods and Materials"). The *asterisk* represents conserved residues, the symbols ":" and "." represent conserved substitutions, whereas the dash (-) represents a deletion or insertion in the alignments. Bold and underlined letters represent residues that are either identical with a functionally defined protein or cysteines that are representative of the family. Predicted secretion signal peptides at the N-termini are italicized and underlined. (A) A group of proteins with sequence similarity to an inhibitor of insect amylases. (B) A group of proteins with sequence similarity to a characterized Bowman–Birk type trypsin inhibitor. (C) A group of proteins with sequence similarity to a conserved family named protease inhibitor/storage protein/lipid transfer protein (Marchler-Bauer et al. 2007). (D) A group of proteins with sequence similarity to thionins. The nucleotide GenBank accession numbers are EU293126 (*AI-L1*), EU293127 (*AI-L2*), EU293128 (*TI-L1*), EU293129 (*TI-L2*), EU293130 (*TI-L3*), EU293131 (*TI-L4*), EU293132 (*PI-L1*), EU293133 (*PI-L2*), and EU293134 (*TN-L1*). The Affymetrix identification numbers for the original ESTs are: Ta.14568.1 (*AI-L1*), Ta.28550.1 (*AI-L2*), Ta.7756.2 (*TI-L1*), and Ta.5208.1 (*TN-L1*). Other sequences previously published are nucleotide sequences AB089942 (*AI-L3*) and BT008925 (*AI-L4*), and protein sequences AAC49286 (*TN-L2*) and AAP12730 (*TN-L3*)

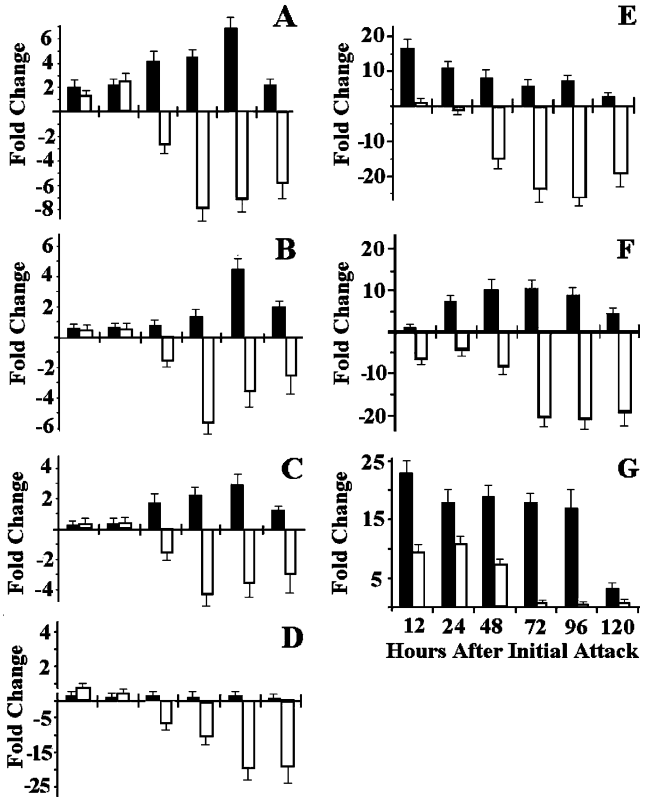

Fig. 2 Differential expression of inhibitor-like genes from wheat, *Triticum aestivum*, during incompatible and compatible interactions with Hessian fly, *Mayetiola destructor*. Solid bars represent fold changes during incompatible interactions, whereas open bars represent fold changes during compatible interactions. Samples were collected at 12, 24, 48, 96, and 120 hr after initial attack by larval *M. destructor*. A to G are for genes *AI-L1, AI-L2, AI-L3, AI-L4, TI-L1, PI-L1*, and *TN-L1*, respectively

bitors, seed storage proteins, and lipid transfer proteins from plants, but the specific function of this family has not been established. Many proteins in this family may have multiple functions such as serving both enzyme inhibitors and storage proteins.

Group IV encodes proteins referred to as thionin-like proteins because of their high cysteine content (Ray et al. 2003). This group of genes was rapidly induced in wheat upon attack by a fungal pathogen. Again, the specific functions of the thionin-like proteins remain to be determined. Many proteins previously characterized as thionins have been found to be protease inhibitors later (Bloch and Richardson 1991).

Upregulation during Incompatible Interactions (GP Insects in H13 Plants) To examine the expression patterns of these genes during incompatible interactions, RT-PCR was carried out with specific primer pairs (Table 1). During incompatible interactions, a similar pattern was observed for the four members of Group I (Fig. 2a–d), except for *AI-L4*, which was not significantly affected by *M. destructor* attacks during incompatible interactions. For the other three genes, significant upregulation began at 24 hr and maximum upregulation was reached at 96 hr. The upregulation declined at 120 hr and returned to normal at 144 hr (data not shown).

Because of high sequence similarity among members in Groups II to IV, primer pairs specific for each cDNA were not found. As a result, a common pair of primers was designed for each gene group. *TI-L1* was strongly (>15-fold) upregulated at 12 hr (Fig. 2e). Upregulation became weaker thereafter and returned to normal at 120 hr. In comparison, *PI-L1* was gradually upregulated beginning at 12 hr and reached maximum at 48 to 72 hr. *TN-L1*, on the other hand, was upregulated strongly (>20-fold) at 12 hr during incompatible and remained high up to 96 hr, followed by a sudden drop at 120 hr (Fig. 2g).

Downregulation during Compatible Interactions (vH13 Insects in H13 Plants) All inhibitor genes except *TN-L1* were strongly downregulated during compatible interactions (Fig. 2a–f). Downregulation began at 48 hr and reached maximum between 72 to 96 hr. *TN-L1* was the only gene that was upregulated during compatible and incompatible interactions (Fig. 2g). However, upregulation was much weaker during compatible interactions than during incompatible interactions, resulting in an incompatible/compatible expression ratio (I/C ratio) of 1.8 to 42 at different time points (Table 2).

Wound-induced Expression Since inhibitor genes responsive to insect feeding are also inducible by wounding (Ryan and

Table 2 Ratios between the expression levels of wheat, *Triticum aestivum*, inhibitor-like genes during incompatible and compatible interactions with Hessian fly, *Mayetiola destructor* (*I*/*C* ratio)

Gene	12 Hours	24 Hours	48 Hours	72 Hours	96 Hours	120 Hours
AI-L1	3.5±0.81	0.91±056	13±3.2	32±8.7	46±6.9	11±2.1
AI-L2	1.8±0.31	1.1±0.24	2.3±0.33	10±1.8	20±4.2	2.4±0.62
AI-L3	1.5±0.22	1.2±0.17	3.5±0.35	8.8±1.4	9.8±1.3	3.3±0.35
AI-L4	0.38±0.18	0.46±0.22	2.2±0.15	4.6±0.18	25±2.1	19±2.3
TI-L1	43±3.4	28±3.5	68±5.4	83±6.5	128±10	59±3.8

TN-L1	2.3±0.13	1.8±0.22	3.3±0.18	36±2.5	42±2.8	6±0.36

Moura 2002), we examined the effect of wounding on the expression of the five inhibitor-like genes, *AI-L3, AI-L4, TI-L1, PI-L1*, and *TN-L1*. All five genes exhibited higher expression levels at 12, 24, and 72 hr following wounding (Fig. 3). Induction by wounding reached maximum (1.5 to 3.5 fold) at 12 hr for *TI-L1* and *TN-L1*, and at 24 hr for *AI-L3, AI-L4*, and *PI-L1*. The wound effect on all five genes declined to baseline levels after 72 hr.

Since both wounding and avirulent larvae upregulated inhibitor-like genes, we then examined possible synergistic effect on gene upregulation. Gene upregulation by wounding and by avirulent larvae appeared additive at some time points (Fig. 3b), but no synergistic effect was observed between these two factors. During compatible interactions, the wound-induced upregulation was suppressed by virulent larvae (Fig. 3c).

Discussion

This research represents the first systematic analysis of the expression patterns of inhibitor-like genes in a plant–insect system that follows a typical gene-for-gene interaction. Several groups of diverse inhibitor-like genes were found to be strongly downregulated by insect feeding during compatible interactions, whereas the same genes were upregulated during incompatible interactions. The combination of upregulation during incompatible and downregulation during compatible interactions resulted in dramatic differences in gene expression between resistant and susceptible plants (Table 2), which strongly suggests inhibitor-like genes are part of defense mechanisms in wheat plants against *M. destructor* attacks. There are diverse proteases including various trypsins and chymotrypsins, cysteine proteases, and different carboxypeptidases in the *M. destructor* digestive system (Zhu et al. 2005; Liu et al. 2007). Elevated inhibitors along with other toxic substances may reduce nutrient uptake and absorption by *M. destructor* larvae.

For chewing insects, upregulation of inhibitor genes is achieved, at least in part, through wounding (Ryan and Moura 2002). For *M. destructor*, the mechanism for upregulation of the inhibitor-like genes appeared independent of the wounding pathway. First, wound-induced upregulation exhibited similar expression for all inhibitor-like genes examined (Fig. 3a), whereas avirulent larva-induced upregulation during incompatible interactions exhibited different patterns for different genes. Second, wound-induced upregulation was relatively weak (two- to three-fold) and for a short time. These differences suggest that the stronger upregulation for longer time is associated with avirulent larval attacks and might be mediated through an alternative pathway(s) mediated by the *R*-gene present in the wheat plants. Further research is required to delineate the mechanism(s) of the avirulent larva-induced upregulation.

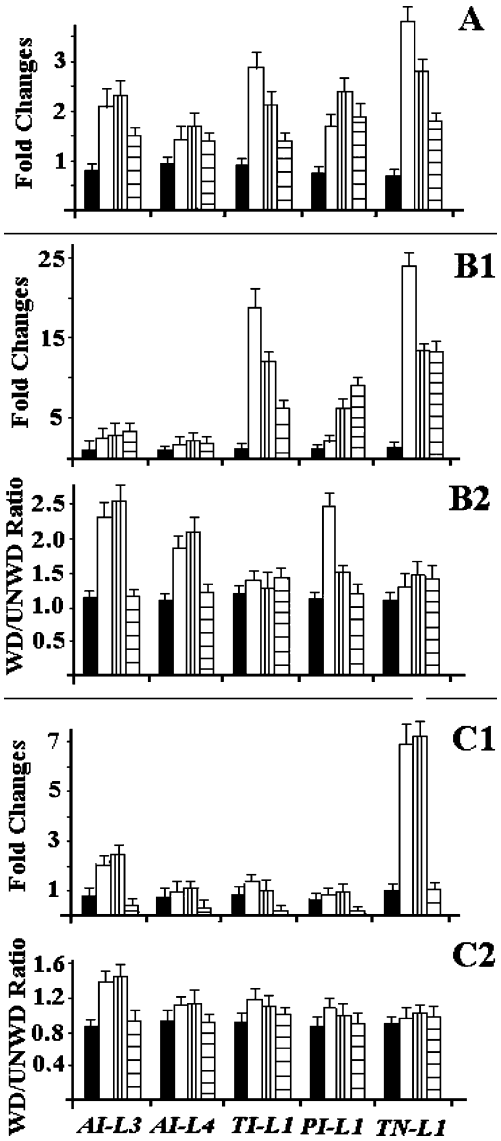

Fig. 3 Impact of wounding on the expression of inhibitor-like genes from wheat, *Triticum aestivum*. Solid, open, vertically striped, and horizontally striped bars represent data obtained from 4, 12, 24, and 72 hr after wounding or initial larval attacks by the Hessian fly, *Mayetiola destructor*. WD/UNWD represents ratios of expression levels between wounded and unwounded samples. (A) Fold changes of gene expression after wounding. (B, upper portion) Fold changes of gene expression after wounding and avirulent (biotype *GP*) larval attacks. (B, lower portion) Ratios between the expression levels of plants that were wounded mechanically and also attacked by avirulent larvae, and the corresponding expression levels of plants that were only attacked by avirulent larvae. (C, upper portion) Fold changes of gene expression after wounding and virulent (biotype *vH13*) larval attacks. (C, lower portion) Ratios between the expression levels of plants that were both wounded mechanically and attacked by virulent larvae, and the corresponding expression levels of plants that were only attacked by virulent larvae

In comparison with various patterns of gene upregulation during incompatible interactions, the downregulation of the inhibitor-like genes by virulent larvae during compatible interactions was similar for all the inhibitor-like genes (Fig. 2a–f).

Significant downregulation was at 48 hr, maximum downregulation at 72 hr, and it remained strong thereafter. The timeframe for the downregulation of the inhibitor-like genes was similar to that of the upregulation of nutrient metabolism genes during compatible interactions (Zhu et al. 2008). The same time frame for the downregulation of defense genes and the upregulation of nutrient genes indicated that gene regulation during compatible interactions was achieved by a common, coordinated mechanism(s). This coordinated mechanism might be related to the ability of virulent larvae to manipulate wheat plants for the creation of nutritive cells at the feeding site (Harris et al. 2006; Anderson and Harris 2006). Hessian fly larvae inject a large number of proteins and other substances into host plants during feeding (Haseman 1930; Hatchett et al. 1990; Chen et al. 2004, 2006, 2008). These injected proteins might target primary and secondary metabolic pathways, resulting in the suppression of plant defense and induction of nutrient supply. The suppression of defenses and formation of nutritive cells provides conditions favorable for a larva to grow and develop.

Host plant resistance is an effective way to control *M. destructor* damage. The challenge with the host plant resistance strategy is that *M. destructor* can develop new biotypes that can quickly overcome deployed resistance (Ratcliffe et al. 2000). The upregulation during incompatible interactions and downregulation during compatible interactions suggests strongly that the inhibitor-like genes are part of the mechanism of *R*-gene mediated defense against *M. destructor*. Further research on the regulatory pathways of defense genes may lead to a more durable resistance by by-passing the major dominant *R*-genes, which are easy to be overcome by new, virulent biotypes.

Acknowledgments This work was supported by grants USDA-04-35607-14861, and USDA-2005-35302-16254. This paper is contribution No. 08-194-J from the Kansas Agricultural Experiment Station. Voucher specimens of *M. destructor* are located in the KSU Museum at Manhattan, Kansas. The authors thank Drs. John Fellers and Guihua Bai for reviewing an earlier version of the manuscript. sible for photosynthesis and general metabolism are usually repressed by insect infestation. This compromises plant growth and productivity.

One factor that appears to mediate interactions between an herbivorous insect and its plant host is the composition of the regurgitant or saliva produced by the insect. Specific elicitors isolated from the regurgitant of pest insects applied to mechanically wounded leaves often results in a plant response that more closely mimics the response to insect feeding. A variety of different elicitors have been characterized to date. For example, glucose oxidase from the salivary glands of *Helicoverpa zea* (Boddie) altered defense responses when applied to wounded leaves of tobacco (Eichenseer et al. 1999; Musser et al. 2002). Recently, a small peptide, inceptin, resulting from the proteolysis of the plant-derived enzyme cATP synthase, was identified as an elicitor from the caterpillar *Spodoptera frugiperda* (Schmelz et al. 2006). Elicitors can alter the composition of volatile defensive blends that are generated by the plant during the defense response, illustrating that the plant's response to insect herbivory at the molecular level is different from that to wounding alone. For instance, application of a β-glucosidase isolated from *Pieris brassicae* (L.) regurgitant to a wounded leaf of cabbage resulted in the generation of a volatile blend that is also produced by herbivory (Mattiacci et al. 1995).

Not all elicitors are peptides. Fatty acid–amino acid conjugates (FACs) are perhaps the best characterized elicitors of volatile production (e.g., Pohnert et al. 1999). Application of volicitin, a FAC component of *S. exigua* (Hübner) saliva, to a wounded leaf elicited volatiles similar to those produced by insect infestation rather than those resulting from mechanical injury alone (Alborn et al. 1997). Work from the Baldwin group (Halitschke et al. 2001, 2003; Schittko et al. 2001; Roda et al. 2004) has examined the effect of regurgitant from *Manduca sexta* (L.) on *Nicotiana attenuata* and has isolated FACs that mimic the effect of the regurgitant. Roda et al. (2004) found that regurgitant treatment led to differential expression of 138 genes, 63 of which were upregulated and 75 that were downregulated. FACs in the regurgitant were responsible for 53 upregulated and 56 downregulated genes. In a comparison of wounded poplar leaves versus application of regurgitant from forest tent caterpillar, *Malacosoma disstria* Hübner, to negligibly wounded leaves, Major and Constabel (2006) found that 38 genes were induced by both treatments, and these genes tended to be involved in stress and secondary metabolism. In contrast to the study in tobacco, only two genes were unique to regurgitant treatment, suggesting that regurgitant in this case only augmented the wound response. Clearly, a number of insect elicitors may affect the plant response to insect attack. However, it is less clear to what extent these observations of specific plant–insect interactions can be extended to interactions between other species.

Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae), is a serious pest of potato, *Solanum tuberosum*, and other solanaceous crops. This herbivorous insect results in hundreds of millions of dollars of crop losses annually. Despite the economic impact of CPB on solanaceous crops, little is known about the components of CPB regurgitant, or how CPB regurgitant affects the defense response of potato at the molecular level. We have recently begun to characterize CPB regurgitant produced from insects reared on tomato and have concluded that it contains a proteinaceous component that inhibits genes that encode proteinase inhibitors in tomato (Lawrence et al. 2007). Kruzmane et al. (2002) have shown that CPB regurgitant enhances peroxidase and polyphenol oxidase activity in potato; these studies also demonstrated that ethylene is increased in regurgitant-treated wounded leaves. It has been shown that potato plants produce a suite of volatiles—including 2-phenylethanol—upon attack by CPB that attract the CPB predator *Perillus bioculatus* (F.) (Heteroptera: Pentatomidae; Schütz et al. 1997; Weissbecker et al. 1999). However, a molecular examination of the specific CPB/potato interaction by examining the effect of regurgitant treatment has not been undertaken.

As part of our ongoing studies to characterize CPB–potato interactions at the molecular level, we have used an 11,421 EST Solanaceae microarray to identify additional genes in potato whose expression is altered by putative elicitors present in the regurgitant of CPB raised on potato. Experiments that compared gene expression profiles of mechanically wounded leaves to which CPB regurgitant was applied versus mechanically wounded leaves without regurgitant revealed that the plant's molecular response to wounding plus CPB regurgitant is not the same as that induced by wounding alone. This set of regurgitant-responsive genes likely comprises both genes that are responsive to regurgitant but not wounding, as well as those genes that are responsive to wounding, but for which this response is augmented by the presence of regurgitant. The addition of CPB regurgitant alters the expression of a suite of defense-associated genes compared to wounding alone, including a gene putatively involved in the synthesis of 2-phenylethanol. Our study provides evidence that CPB modulates the potato's defense response against this devastating herbivore potentially via elicitors present in its regurgitant.

Methods and Materials

Plant Material Potato tubers from *S. tuberosum* var. Kennebec were planted in individual 10-cm pots contain-

ing Metromix® (Scotts, Marysville, OH, USA) and Osmocote® (Scotts). Plants were grown for 4 weeks in a greenhouse, and only plants with at least eight leaves were used in the tests. For real-time polymerase chain reaction (PCR) experiments, plants were grown for 4 weeks in a growth chamber with a 16:8 (light to dark, L to D) cycle at 25°C during the light phase and 20°C during the dark phase.

CPB Rearing and Regurgitant Isolation CPB came from a colony at the USDA—ARS Insect Biocontrol Laboratory that originated from eggs provided by the New Jersey Department of Agriculture in 1996. Field-collected insects from potato fields at the USDA—ARS Beltsville Agricultural Research Center (Beltsville, MD, USA) were introduced annually to maintain genetic diversity. CPB were reared on *S. tuberosum* var. Kennebec and maintained in a laboratory under a 16:8 (L to D) cycle at approximately 25°C. Regurgitant was collected from the oral cavity of fourth instar CPB with a P200 Pipetteman (Gilson, Oakland, CA, USA). The regurgitant was centrifuged for 5 min at 10,000×*g* and the supernatant was collected and stored at −80°C.

Wounding, Regurgitant Treatment, and Infestation Two separate series of experiments were carried out—one for microarray analyses and a second for real-time PCR analyses. Mechanical wounding involved crushing the leaf from the sixth node from the bottom with pliers, while avoiding the major veins, at 1-cm intervals. One hundred microliter of a 1:3 aqueous dilution of the regurgitant or 100 µl of water (control) were added to wounded leaves. Plants were incubated for 4 h after which the wounded leaves were excised and frozen rapidly in liquid nitrogen. For microarray experiments, five plants were pooled for each sample, and the experiments were repeated three times, i.e., there were three biological replicates.

In the second series of experiments for real-time PCR analysis, five treatments were carried out: control (untreated) plants, water-treated wounded plants, regurgitant-treated wounded plants, mildly CPB-infested plants, and acutely CPB-infested plants. Water- and regurgitant-treated wounded plants were treated as described above. For infestation treatments, plants were divided into two groups; the sixth leaf from the bottom was covered with a fine mesh sleeve, and ten third- to fourth-instar CPB larvae were added. The first infestation level was achieved by leaving the ten CPB on the plant for 1 h and then removing them. The plants were harvested 3 h later. The second infestation level was achieved by leaving the ten CPB on the plant for 4 h, removing them, and then harvesting the plant immediately. For real-time PCR (Fig. 1), two plants were pooled for each sample, and experiments were repeated four times.

RNA Isolation for Microarray and Real-Time PCR For microarray analyses, RNA was isolated from *S. tuberosum* leaves with Qiagen's RNeasy kit by using the protocol recommended by the manufacturer (Qiagen, Valencia, CA, USA). The protocol is available at http://www.tigr.org/tdb/potato/microarray_SOPs.shtml. For real-time PCR, RNA was isolated by using Qiagen's RNeasy Plant Mini kit

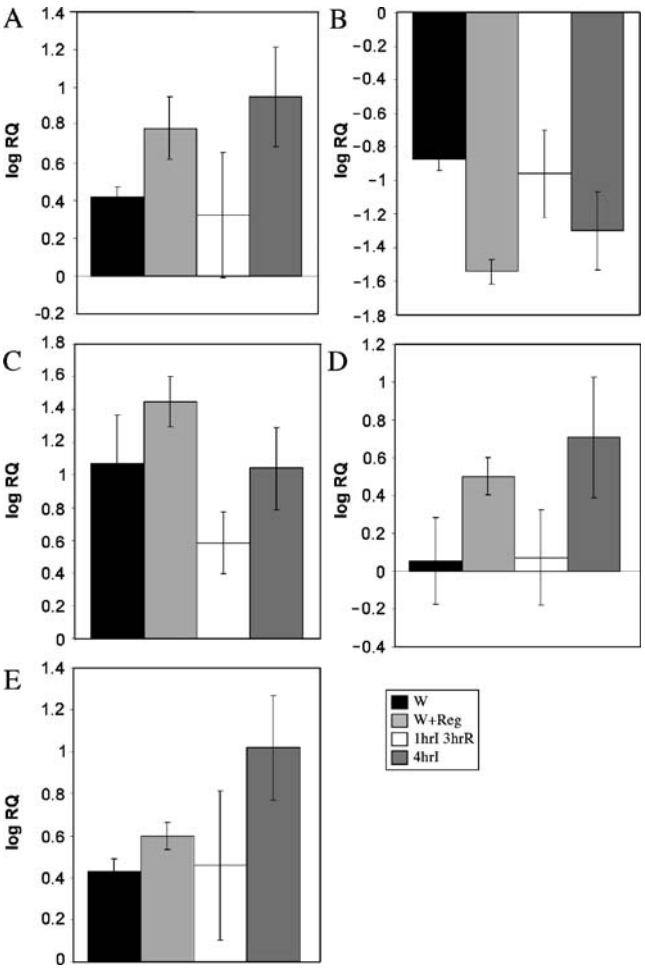

Fig. 1 Real-time PCR of five genes from *S. tuberosum* var. Kennebec that are differentially expressed by treatment of wounded leaves with regurgitant of *L. decemlineata*. *W*=wounded+water, *W+Reg*=wounded+regurgitant 1:3, *1hI3hR*=1 h infestation followed by 3 h recovery, *4hI*=4 h continuous infestation. **a** *STMEV47*, ZPT2–13 transcription factor; **b** *STMCK44*, carbonic anhydrase; **c** *STMFB59*, class IV chitinase; **d** *STMEP88*, aromatic amino acid decarboxylase; and **e** *STMDJ96*, Zim domain protein 1, JAZ 1, transcription factor. Fold change levels of gene expression were expressed as RQ. As such, an RQ of 1 indicates a sample exhibiting the same relative transcript abundance as the control. The data were $\log_{10}$ transformed prior to graphing; hence, equal relative transcript abundance in control and treatment samples result in a log RQ value of 0. Each *bar* represents four biological replicates with *error bars* representing standard error

adding an RNase free DNAse step using the manufacture's protocol (Qiagen).

Microarrays Two-color spotted cDNA microarrays were used to carry out gene expression profiling experiments. The TIGR 10K EST Solanaceae microarray contains 11,412 annotated cDNA clones spotted as randomized duplicates on the array. Because our primary objective was to identify regurgitant-responsive genes, hybridizations were carried out in which wounding plus regurgitant leaf samples were cohybridized (paired) with wounding plus water leaf samples. This direct comparison provides greater ability to identify genes differentially expressed in response to regurgitant. The variance is smaller in the direct comparison technique than in indirect comparisons where arrays pairing wounding plus water vs. control leaf samples are compared to arrays pairing wounding plus regurgitant vs. control leaf samples (Dobbin and Simon 2002). For each treatment–control comparison, three biological replicates were analyzed; for each biological replicate, a dye swap of technical replicates was performed. In total, six arrays for wound and wound plus regurgitant were carried out. The TIGR Solanaceae Expression Profiling Service performed all the microarray procedures including cDNA labeling, hybridization, data quantification, and data normalization by using LOWESS (protocols available at http://www.tigr.org/tdb/potato/microarray_SOPs.shtml). The data from the microarray experiments are available from the TIGR Solanaceae Gene Expression Database (http://www.tigr.org/tigr-scripts/tdb/potato/study/potato_study_hybs.pl?study=86&user=&pass=&sort=id&order=asc).

Exported data were analyzed in R (Ihaka and Gentleman 1996) with the BioConductor suite of packages (Gentleman et al. 2004). Quality assessment of the raw and background-corrected data was carried out by inspection of ratio–intensity plots (also known as minus–add (MA) plots)—pairwise correlations of ratio (M) values between slides; and distribution and density of intensity (A) values. Data were analyzed with the linear models for microarray data package (Smyth 2005) and exploratory analysis for two-color spotted microarray data (marray) package (Yang and Paquet 2005) by using methods described in Dudoit and Yang (2002), Smyth and Speed (2003), Smyth (2004), and Smyth et al. (2005). Within-array data were normalized by two-dimensional spatial loess and print-tip loess detrending procedure. Data were then scaled to have the same median-absolute-deviation across arrays. Nonspecific filtering was applied to reduce false discovery rate by removing invalid and low intensity genes. Intensity filtering was done with the genefilter package to remove genes whose A values were smaller than 7 in at least 75% of the samples. Linear models were fitted to the normalized data by using duplicate correlations, and empirical Bayes analysis was used to compute moderated *t*-statistics, which were then used to obtain *P*-values. For multiple testing, the *P*-value adjustment method of Benjamini and Hochberg (1995) was applied to control the false discovery rate (i.e., expected proportion of truly nondifferentially expressed genes among the rejected hypotheses). An adjusted *P*-value cutoff of 0.01 was used to generate differentially expressed gene lists. Differentially expressed genes were chosen if the fold change was >1.5 (induced) or <0.67 (repressed).

Real-time PCR TaqMan Reverse Transcription reagents (Applied Biosystems, Foster City, CA, USA) were used to synthesize cDNA. Reaction conditions were 1× TaqMan RT buffer, 5.5 mM $MgCl_2$, 500 μM dNTPs, 2.5 μM random hexamers, 0.4 U/μl RNase Inhibitor, and 1.25 U/μl multiscribe reverse transcriptase and incubated at 25°C 10 min, 48°C 30 min, and finally 95°C 5 min.

Real-time PCR was performed with a 7500 Real-Time PCR System (Applied Biosystems) by using the following parameters: 50°C 2 min, 95°C 10 min, followed by 40 cycles of 95°C 15 s, 60°C 1 min. *Power* SYBR Green PCR Master Mix (Applied Biosystems) was used in a final reaction volume of 25 μl. Target gene primers were used at a final concentration of 900 nM and 18S ribosomal endogenous control primers at 100 nM.

To utilize the comparative C_T method of relative quantitation of gene expression, validation experiments were performed on all target gene primers (primer pairs listed in Table 1). The primers used for 18S rRNA were as described in Nicot et al. (2005). All target gene primers had amplification efficiency similar to the 18S amplicon (absolute value of the slope of ΔC_T (target gene-18S) vs. log input RNA were all <0.1). Dissociation curves were performed for all primer pairs to check specificity of primers for the target gene. Fold change levels of gene expression were expressed as relative quantitation (RQ) values by using a "calibrator" sample as a reference with Sequence Detection Software version 1.4 (Applied Biosystems). As such, an RQ of 1 indicates a sample exhibiting the same relative transcript abundance as the control. The data were $\log_{10}$ transformed prior to graphing; hence, equal relative transcript abundance in control and treatment samples resulted in a log RQ value of 0.

Results and Discussion

Genes are Both Induced and Repressed by CPB Regurgitant As an important step towards our long-term goal of better understanding the contribution of CPB to the CPB–potato interaction, we set out to use microarray gene

expression profiling to identify genes whose expression is modulated by the presence of CPB regurgitant. Regurgitant-responsive genes can serve as vital reporter genes for investigations of CPB–potato interactions and particularly for identification of components of CPB regurgitant that act as elicitors to induce or repress the expression of these genes. Accordingly, leaves were wounded and treated with either CPB regurgitant at a 1:3 dilution or with water. Two-colored microarrays were performed to compare these two conditions. This experimental design provided the most direct means to identify genes whose expression is modulated by CPB regurgitant, since our primary objective was to identify regurgitant-responsive genes rather than investigate the effect of regurgitant on the expression of wounding-responsive genes. Four hours following wounding was chosen as the most appropriate time point for these analyses, based on the rationale that most genes that are induced early in the defense response would still be upregulated at 4 h; genes that are induced only later in the defense response would be commencing upregulation at 4 h, and genes that are differentially expressed only as an indirect consequence of the wounding plus or minus regurgitant treatment would not yet have been upregulated at 4 h, i.e., allowing us to minimize secondary effects of the plant/insect interaction. Korth and Dixon (1997) have demonstrated that while the timing of maximum expression of genes in response to wounding or wounding plus regurgitant can differ over the course of the defense response, both treatments result in a local induction of gene expression over baseline levels within a few hours of treatment, and that this induction persists for many hours. This and other studies (e.g., Christopher et al. 2004; Delessert et al. 2004) suggest that while the timing of sample harvest is critical to detect *peak* levels of gene expression during the defense response, a relatively broad window of opportunity exists to detect *statistically different* levels of gene expression for the majority of genes differentially expressed during the defense response. Consequently, we decided to focus on a single time point following wounding of the leaves for our microarray analysis. A limitation to this approach is that the time course of the regurgitant-associated induction or repression of gene expression is not known, which affects to some extent our ability to make biological inferences from the data. It is also possible that the analysis failed to identify those regurgitant-responsive genes that are significantly induced or repressed very early or very late in response to the treatment but not at 4 h following wounding. Similarly, this analysis would not reveal regurgitant-responsive genes that are not present on the TIGR Solanaceae microarray.

Analyses of the microarray data revealed 127 genes whose transcript abundance was significantly different in plants treated with mechanical wounding plus regurgitant compared to plants that were treated with mechanical wounding alone. The genes selected as significantly differentially expressed had an adjusted P-value of <0.01 and a fold changed of >1.5 (induced) or <0.67 (repressed). The regurgitant-responsive gene set can include genes that are regurgitant but not wounding responsive, as well as genes that are wounding responsive but whose expression patterns are intensified by regurgitant. Annotations for these differentially expressed genes are based on similarities to annotated sequences at the National Center for Biotechnology Information queried using Basic Local Alignment Search Tool (BLAST)X (Altschul et al. 1997).

There were 73 genes found to be induced (adjusted P-value<0.01, fold change>1.5) by adding CPB regurgitant to wounded leaves compared to the addition of water to wounded leaves (Table 2). They include proteins involved in secondary metabolism, general metabolism, protein expression, transcriptional regulation, stress, and pathogen responses. Not unexpectedly, a number of genes that encode proteins of unknown function were also induced. This can be in part ascribed to the lack of complete coding sequence information for a number of cDNAs represented on the array, which reduces the probability of retrieving a significant match from a sequence similarity search.

Interestingly, a total of 54 genes were repressed (adjusted P-value<0.01, fold change<0.67) in wounded leaves in the presence of regurgitant (Table 3). Genes associated with photosynthesis and stress were the most prevalent among downregulated genes. Genes were considered repressed if, in addition to a P-value of ≤ 0.01, the fold change was <0.67. Genes of secondary metabolism were more abundant

Table 2 Genes of *S. tuberosum* var. Kennebec induced by treatment of wounded leaves with regurgitant of *L. decemlineata*

when compared to genes repressed by regurgitant treatment (Tables 2 and 3).

Expression patterns of five genes found to be differentially expressed by CPB regurgitant with the microarray were confirmed with real-time PCR with independent experimental material (Fig. 1). The genes were chosen to represent different functional categories. These experiments further compared transcript abundance in water-treated and regurgitant-treated wounded leaves to that of control (unwounded) leaves as well as to two infestation treatments. The latter one provided an additional control to determine whether wounding plus regurgitant was a reasonable substitute for infestation in generating a defense response. All five genes showed expression patterns in regurgitant-treated wounded leaves and water-treated wounded leaves that were in agreement with the microarray data. For four genes—*STMEV47* (similar to ZPT2–13 zinc finger protein), *STMFB59* (similar to class IV chitinase), *STMDJ96* (similar to ZIM domain protein), and *STMEP88* (aromatic amino acid decarboxylase)—real-time PCR data demonstrated that transcript abundance in regurgitant-treated wounded leaves was significantly higher than in water-treated wounded leaves. With the exception of *STMEP88*, each of these genes was also upregulated by wounding alone relative to control untreated plants; for these three genes, the presence of regurgitant served to amplify the induction of gene expression over wounding alone. The fifth gene that was tested, *STMCK44* (similar to carbonic anhydrase), was downregulated by wounding and further downregulated by wounding plus regurgitant, consistent with the microarray data. Each of these five genes was also differentially expressed in response to CPB infestation of leaves in the same pattern produced by mechanical wounding plus regurgitant (Fig. 1), lending validation to the wounding/regurgitant method. Two different infestation treatments were carried out to contrast the effect with the addition of regurgitant to wounded leaves. Infestation consisted of either 4 h of continuous infestation (4hI) or the leaves were subjected to 1 h of infestation followed by 3 h of recovery (1hI3hR). Neither of these infestation treatments was specifically designed to mimic the wounding treatment in intensity or timing and, as such, comparison of the amplitudes of gene responses to mechanical wounding plus or minus regurgitant to those

evoked by the infestation treatments should be interpreted with care. Each of the genes examined by real-time PCR showed a greater response to 4hI than to 1hI3hR; additionally, transcript abundance for most genes exhibited greater variance in the 1hI3hR treatment. Taken together, the quantitative real-time PCR experimental data demonstrated that four genes are differentially expressed by wounding, the expression is enhanced by regurgitant and infestation also results in differential expression of these genes.

Photosynthesis and Carbohydrate Metabolism Twenty percent of the genes repressed by regurgitant encoded photosynthetic proteins (Table 3). Examples include genes involved in photosynthetic electron transport such as a photosystem II reaction center protein and a thylakoid lumenal 16.5 kDa protein. This observed downregulation of photosynthetic genes is consistent with the findings of Hermsmeier et al. (2001). A number of genes associated with the utilization of carbon resources were repressed by regurgitant, including carbonic anhydrase, glyceraldehyde-3-phosphate dehydrogenase, and Rubisco. However, this was not an overriding pattern, as other genes involved in carbohydrate metabolism were induced when regurgitant was added to wounded leaves. For example, genes that encode pyruvate decarboxylase, glyceralydehyde-3-phosphate dehydrogenase, and uridine diphosphate (UDP)-glycosyltransferase were induced by regurgitant. Glyceraldehyde-3-phosphate dehydrogenase poses an interesting case in our study, as different genes that encode this enzyme showed upregulation or downregulation at 4 h after wounding plus regurgitant. Enzymes encoded by different members of this gene family are targeted to different cellular compartments and participate in different biochemical pathways: Chloroplastic glyceraldehyde-3-phosphate dehydrogenase catalyzes a step of the reduction phase of the Calvin cycle (photosynthetic carbon reduction cycle), while cytosolic glyceraldehyde-3-phosphate dehydrogenase is an enzyme of glycolysis. Furthermore, different forms of cytosolic glyceraldehyde-3-phosphate dehydrogenase exist that allow carbon flux through glycolysis even under non-favorable energy status conditions, such as when low concentrations of ATP are encountered (Dennis and Blakeley 2000). Clearly, CPB exerts an influence through its regurgitant not only on the plant's carbon acquisition via photosynthesis but also on the plant's utilization of its carbon resources. That some genes associated with carbon metabolism are upregulated by regurgitant while others are downregulated indicate that this modulation is not a wholesale induction or repression of resource utilization; rather, it would appear that the presence of CPB regurgitant signals changes to the plant that result in more subtle redirection of carbon flux through metabolic networks in the attacked leaves. It will be of interest to determine how CPB regurgitant influences carbon flux through the biochemical pathways associated with the genes shown to be regurgitant responsive in this study.

Protein Synthesis and Nitrogen Metabolism We detected a suite of differentially expressed genes associated with nitrogen-based biochemical pathways. Notably, genes that encode allantoinase were induced by CPB regurgitant in potato. Allantoinase is an enzyme of ureide metabolism that catalyzes the conversion of allantoin to allantoate. The ureides are nitrogen-rich organic compounds that are important for nitrogen transport and remobilization. Ureides are best characterized in nitrogen-fixing legumes, but recently enzymes implicated in ureide metabolism have been described in nonureide-type legume (Yang and Han 2004) and nonlegume species (Yang and Han 2004; Todd and Polacco 2006). The potato putative allantoinase genes, along with a putative allantoinase gene from tomato, show high sequence similarity to a functionally characterized

Arabidopsis allantoinase; these genes were distinct from genes that encode a phylogenetically related enzyme, dihydroorotase (Yang and Han 2004). Complementation studies with the Arabidopsis allantoinase gene confirmed the biochemical activity of the enzyme encoded by this gene, and mutagenesis studies were used to show that allantoinase allows the plant to utilize allantoin as a sole nitrogen source. In black locust, there is an upregulation of allantoinase in the fall and spring and, hence, is proposed to play a role in seasonal nitrogen cycling (Yang and Han 2004). Allantoinases have been linked previously to plant defense in potato. A putative allantoinase was induced in potato tuber by treatment with a crude elicitor made from hyphal wall components of the fungus *Phytophthora infestans* (Nakane et al. 2003).

Other genes associated with nitrogen utilization that were upregulated in the presence of regurgitant include glutamine synthetase (likely associated with nitrogen reassimilation and recycling) and a gene that encodes a protein similar to an amino acid transporter. Together, these results suggest that plants alter their nitrogen utilization strategies in response to elicitation by regurgitant over and beyond changes brought about in response to wounding. Our data suggest that these changes invoke enhanced recycling and remobilization of nitrogen resources in attacked leaves. While considerable attention has been paid to the effect of soil nitrogen availability on allocation of plant resources to defense and the effect of leaf nitrogen content on the performance of herbivorous insects (e.g., Stamp 2003 and references therein), much less is known about repartitioning and reallocation of nitrogen resources in plants upon infestation and how this may affect not only the insect's performance but also the plant's ability to resist attack to promote damage repair and to resume growth and development following attack. Clearly, nitrogen resource utilization in plants under attack by herbivorous insects requires further investigation.

Secondary Metabolism Genes involved in secondary metabolism were prominent in the list of upregulated genes of plants that had been wounded and treated with regurgitant. Eight different genes that encode cytochrome P450s were induced. Cytochrome P450s are a complex superfamily. In fact, 272 genes have been identified in the Arabidopsis genome (Schuler and Werck-Reichhart 2003). They are involved in biosynthetic reactions that produce such compounds as phenylpropanoids, alkaloids, and terpenoids. Terpenoids make up a portion of the volatiles created by infestation-induced plants, which could play a part in attraction of predator insects and parasitoids to the infested potato. Two genes encoding proteins involved in terpene synthesis are induced in these plants as well. In addition, several genes that may encode proteins involved in phenylpropanoid biosynthesis are induced: tyramine hydroxycinnamoyl transferase, copper amine oxidase, and peroxidase.

A gene that encodes aromatic amino acid decarboxylase was induced, and confirmation of this result by real time RT-PCR is presented in Fig. 1d. This enzyme is involved in the production of phenylalanine-derived volatile compounds important for insect attraction (Tieman et al. 2006). Phenylpropanoids are often anti-insecticidal compounds. Aromatic amino acid decarboxylase is the enzyme responsible for the precursor of 2-phenylethanol (Tieman et al. 2006), which is a volatile specific to CPB-damaged plants (Schütz et al. 1997) and is found to be particularly attractive to the CPB predator *P. bioculatis* (Weissbecker et al. 1999). This suggests that 2-phenylethanol is a volatile produced in response to regurgitant treatment of wounded potato plants. This plant response is part of a tritrophic interaction, which may indirectly result in plant defense.

Genes Implicated in Pathogen Defense and/or General Stress Response Many of the genes identified as differentially expressed in response to regurgitant application to wounded leaves have been associated either with defense against pathogens or as part of general stress response. Generally, pathogen-induced genes are induced by the phytohormone salicylic acid, while wounding-associated genes are induced by jasmonic acid. However, overlap in these pathways is well-documented, and it will be of interest to test the regulation of these genes by these compounds.

Chitinases were among those pathogen-associated genes affected by regurgitant application. Two chitinase genes were identified as regurgitant-induced (a class IV and class II). The class IV chitinase identified by BLAST search and the class II chitinase were found to be involved with the response to pathogen attack (Büchter et al. 1997; Shinya et al. 2007). The induction of the class IV chitinase is confirmed by real-time PCR data in Fig. 1c. Three genes with homology to pathogenesis protein 10 were also induced by regurgitant. The homolog of this gene is induced by methyl jasmonate and salicylic acid in *S. surattense* (Liu et al. 2006). This suggests that the protein may have a broad defense function.

A noteworthy category of repressed genes are those genes associated with stress. In tomato, we have found that proteinase inhibitors PinI and PinII are repressed by CPB regurgitant (Lawrence et al. 2007). There are 16 type 1 and type 2 proteinase inhibitor clones on the potato microarray. Three of these inhibitors are repressed by CPB regurgitant. Since proteinase inhibitors act by inhibiting digestion of proteins in the insect midgut, this repression may represent a mechanism by which the insect subverts the plant's defense mechanism.

Other potentially interesting genes that are repressed by regurgitant are the germins. Of the eight germin genes found on the potato microarray, four are repressed by CPB regurgitant. Germins are a large multigene family, which may contain superoxide dismutase activity, and some subfamilies may be induced by pathogens and herbivores (Lou and Baldwin 2006; Zimmermann et al. 2006). For example, the silencing of a germin from *N. attenuata* results in increased mass of *M. sexta* feeding on the plant and increases *Tupiocoris notatus* preference for the transgenic plant (Lou and Baldwin 2006). In Arabidopsis, 32 germins have been identified (Zimmermann et al. 2006). An extensive study of germins from barley examined members of each of the six identified subfamilies (Zimmermann et al. 2006). The barley sequence of HvGER2a showed the greatest similarity to the potato CPB repressed germin genes when examined by using BLASTX. The gene in barley is wound and cold-induced (Zimmermann et al. 2006) but the protein does not seem to have superoxide dismutase activity. Therefore, it is unclear how this protein or the potato germins might function. Perhaps knowing how CPB regurgitant inhibits germins in potato may offer insight into transgenic approaches that may circumvent this repression.

In summary, we have presented the first examination of transcriptional profiling of genes affected by CPB regurgitant. This is a valuable first step given the agronomic importance of this plant/insect interaction. It also affords the opportunity to characterize promoters from a number of regurgitant-induced genes. We found both induced and repressed genes due to regurgitant addition to wounded leaves. Characterization of the regurgitant may further elucidate the components involved in induction of potato genes by CPB regurgitant. CPB regurgitant affects the expression of a diverse set of genes: While many of these genes can be associated with classical stress and defense-associated mechanisms, including defensive chemistry biosynthesis, a number of these genes are related to the utilization of carbon and nitrogen resources. Interestingly, at least one of these regurgitant-responsive genes may be implicated in tritrophic interactions. As such, this study demonstrates that CPB regurgitant affects the expression of genes beyond those typically associated with the host's defensive arsenal and illustrates the complexity of the interactions that occur between herbivorous insects and host plants and potentially with other organisms.

Acknowledgments We are indebted to the TIGR Expression Profiling Service for providing and performing the microarrays and the data acquisition, to Y. Lui for assistance with the statistical analyses of the microarray data, and to R. Bennett for providing the potato plants. We thank E. Clark and L. Liska for providing CPB. Finally, we thank S. Seybold and three anonymous reviewers for constructive feedback on earlier versions of this work.

Glucosinolates are generally considered to be feeding and oviposition stimulants for specialist insect herbivores and deterrents for generalist insects (Mithen et al. 1995b; Stowe 1998). There is evidence from laboratory and field experiments that differences in glucosinolate quantity and quality can mediate plant–insect interactions by influencing insect feeding behavior and damage levels (Mauricio 1998; Li et al. 2000; Lambrix et al. 2001; Barth and Jander 2006; Zhang et al. 2006). However, there is no consistency regarding previously reported insect herbivore responses to glucosinolate variation. Herbivory by diverse specialized insects has been either positively, negatively, or not associated with glucosinolate concentrations (or with the presence/absence of certain types of glucosinolates; Nielsen et al. 2001). For example, in a previous experiment, *B. napus* lines with augmented glucosinolate concentrations attracted more cabbage butterflies (*Pieris rapae*) and had increased damage by flea beetles (*Psylliodes chrysocephala*) compared to low glucosinolate lines (Giamoustaris and Mithen 1995). Conversely, Mauricio (1998) found decreased damage by two specialist flea beetles (*P. convexior* and *Phyllotreta zimmermani*) when feeding on *A. thaliana* genetic lines with high levels of total glucosinolates. In addition, although glucosinolates or their by-products repel birds, rabbits, gastropod mollusks, and generalist insects (Mithen et al. 1995b), Lambrix et al. (2001) found that certain glucosinolate hydrolysis products, such as nitriles, are less defensive than isothiocyanates against feeding by the generalist cabbage looper *Trichoplusia ni*.

Contrasting selection pressures exerted by different herbivores of natural plant populations may explain the variation in glucosinolate profiles observed in the Brassicaceae (Rodman 1980; Rodman et al. 1981; Kliebenstein et al. 2001; Windsor et al. 2005; Lankau 2007). Within *A. thaliana*, there are at least 16 different glucosinolate chemotypes. Five of these are prevalent in wild *Arabidopsis*, and they are focused on here, as in previous studies (Lambrix et al. 2001; Kliebenstein et al. 2001). Glucosinolate variation among natural populations of *A. thaliana* has been explained by the combination of functional and nonfunctional (null) alleles at five specific loci. These include: *GS-ELONG*, which regulates the carbon side-chain elongation of aliphatic glucosinolates; *GS-ALK*, which controls the production of alkenyl glucosinolates; *GS-OHP*, which regulates the production of hydroxypropyl glucosinolate; *GS-OH*, responsible for the conversion of 3-butenyl to 2-hydroxy-3-butenyl glucosinolate; and *GS-OX*, which regulates the conversion of methythioalkyl to methylsulfinylalkyl glucosinolates (Mithen et al. 1995a; Kliebenstein et al. 2001). A flexible "modular genetic system" that involves polymorphisms at these five loci has been proposed as responsible for generating the substantial natural variation in glucosinolates found in *A. thaliana*, which may allow this plant to adjust rapidly (or respond by evolution) to a myriad of biotic and physical environmental challenges (Kliebenstein et al. 2001).

Although several studies have evaluated herbivore selectivity among different plants, little is known regarding the relationship between intraspecific variations in glucosinolates and herbivory in the field (Raybould and Moyes 2001). In a common garden experiment, we specifically assessed whether there is natural variation in glucosinolate quality and quantity in 20 *A. thaliana* genotypes and whether this variation is associated with patterns of distribution of insect herbivores among plants, and, thus, insect damage levels and plant fitness. Evaluation of the link between variation in secondary chemistry and both herbivore damage and plant fitness is important because differential levels of herbivory can impose selection for plant resistance or tolerance, which in turn may affect population structure and dynamics. Changes in frequency of chemical types or concentrations that result from herbivory-imposed selection may be dependent on the specific insect community associated with the natural plant populations. For example, while insect generalists may inflict selection for increased production of specialized defensive chemicals (Muller and Martens 2005), a specialist-dominated insect community like the one associated with the experimental plants in this study may select for low levels of specialized chemical defenses.

Materials and Methods

Study Species The annual plant *A. thaliana* (Capparales: Brassicaceae) originated in Eastern Europe and is widely distributed throughout the temperate regions of North America, with records of its introduction in the mid-1800s (Murren et al. 2005; Vander-Zwan et al. 2000). Little is known regarding the genetic structure of *A. thaliana* populations in nature (Vander-Zwan et al. 2000). However, due to a selfing mode of reproduction and short-distance seed dispersal, natural populations appear to consist mostly of single genotypes (Bergelson et al. 1998). For this study, we selected 20 *A. thaliana* natural accessions (provided by the Arabidopsis Biological Resource Center, Ohio State University) from Europe, Asia, and northwest (NW) of Africa (Table 1). None of these accessions has either glabrous or hairy trichome phenotypes (unpublished data). Seed stocks were propagated as a single seed descent from each population. Thus, populations/accessions are composed essentially of a single genotype (hereafter, referred as "plant genotypes"). Selection of these genotypes from a wide array of geographical locations allowed sampling a broad range of the natural variation in glucosinolates present in *A. thaliana* populations.

Experimental Design and Plant Growth Conditions A common garden experiment was performed in NW Ohio (Bowling Green State University Research Station, Bowling Green, OH, USA) to evaluate the potential link between plant secondary chemistry (i.e., quality and quantity of glucosinolates) and both natural levels of insect herbivory and plant fitness. The experimental design consisted of a nested randomized block design including three blocks (plots) and 20 genotypes nested within plots. In this location, insect herbivores generally become more abundant by mid-June (Bidart-Bouzat, personal observation), approximately 1 month after seedlings were transplanted to the field.

Twenty-four individuals from each of the 20 selected genotypes were randomly planted among three plots in the field accounting for a total of 480 plants (from which 338 survived to reproduction). Individual plants of each genotype were grown from seeds in standard flats (24×45 cm^2×7 cm deep), which underwent a cold treatment (at 4°C and under dark conditions) in a growth chamber for 1 week to eliminate dormancy and ensure uniform germination. Afterwards, seeds were allowed to germinate with progressively increasing temperatures and light periods up to 20°C and periods of 14/10 h (L:D), respectively. Germination date was recorded, and approximately 1-week-old plants were transplanted to the field. To minimize microenvironmental variation and interplant competition, each individual plant was planted directly in the field in a 750 cm^3 hole filled with a mixture of 1:3 sand/commercial potting mix (composed of compost, field soil, and sphagnum moss) 20 cm apart. Plants dying from transplant shock were replaced during the first week after transplantation. Plots were covered with mulch for weed control and manually weeded and watered as necessary. Since the purpose of this study was to evaluate natural insect herbivory, each experimental plot (18 m^2) was surrounded by wire mesh to prevent potential mammalian herbivory (Weinig et al. 2003).

Measurement of Phenotypic Traits Individual plants were examined daily to record the presence/absence of associated herbivores and to sample a few of these for identification at the species level (lepidopteran larvae, flea beetles, aphids, and thrips). Insect sampling was performed during daytime. Lepidopteran larvae collected from experimental plants were grown on *A. thaliana* plants in the laboratory for species identification. During the first 25 days, almost no insect activity was observed. Insects became more abundant as weather conditions tended to be warmer and dryer (mid-June). Damage by herbivory was evaluated on the rosette at bolting time, and on buds and flowers (aerial damage) approximately 10 days after the plants first flowered (on all 338 plants that survived to reproduction). Rosette damage was measured through a qualitative index of plant damage on rosette leaves (adapted from McCloud and Berenbaum 1999). This index was calculated by assigning leaves to four size categories (1=6–8 cm; 2=4–6 cm; 3=2–4 cm; 4=0–2 cm), and three damage classes dependent upon the amount of tissue removed (25% or less, 25–75%, or more than 75%). Aerial damage was determined by the ratio of the number of damaged to total buds and flowers. The average of both rosette and aerial damage was considered as an index of total herbivore damage on each plant. Three-to-four apparently undamaged plants (rosettes) per genotype were collected for glucosinolate analyses at early bolting (chemical analysis protocol explained below). Total number of fruits and seed number per fruit (estimated from 20 randomly chosen fruits per plant) were measured at harvesting. An index of fitness was calculated by multiplying total fruit number by seed number per fruit for each plant.

Glucosinolate Analysis A modification of Hogge et al. (1988) extraction and purification protocol was used to quantify glucosinolate concentrations in *A. thaliana* rosette leaves. Rosette leaves collected from the field were flash frozen immediately in liquid N and later freeze dried. For glucosinolate extraction, 50 mg freeze-dried leaf tissue of each plant were ground with 2 ml 90% methanol and three 2.3-mm ball bearings. Samples were mixed at high speed with a paint shaker. Samples were subsequently centrifuged at full speed for 15 min; 1 ml of the sample supernatant was

added to 250 μl of DEAE Sephadex solution and further incubated for 60 min at room temperature. Glucosinolate-containing pellets were washed twice (first with 1 ml of methanol and then with 1 ml of water) and incubated overnight at room temperature after adding 500 μl of water and 10 μl of sulfatase solution (Sigma-Aldrich). To identify and quantify glucosinolates, 150 μl of each sample were run on an Agilent 1100 high-performance liquid chromatography (HPLC) with diodearray detection as previously described (Kliebenstein et al. 2001). Identity and area of HPLC peaks were determined by comparing them with those of purified standards (Reichelt et al. 2002).

Glucosinolate content is presented as μmol g^1 of freeze-dried rosette leaves. The following glucosinolates were identified across the plant genotypes: alkenyl (2-propenyl and 3-butenyl), hydroxyalkyl/alkenyl (3-hydroxypropyl, 4-hydroxybutyl, 2-hydroxy-3-butenyl), methylsulfinyl (3-methylsulfinylpropyl, 4-methylsulfinylbutyl, 7-methylsulfinylheptyl, 8-methylsulfinyloctyl), methylthio (3-methylthiopropyl, 4-methylthiobutyl, 7-methylthioheptyl, 8-methylthiooctyl), and indolyl (indol-3-ylmethyl, 4-methoxyindol-3-ylmethyl, *N*-methoxyindol-3-ylmethyl, 4-hydroxyindol-3-ylmethyl) glucosinolates (Reichelt et al. 2002). Glucosinolate profiles in the studied genotypes were determined on the basis of allelic variation at two loci *GS-ELONG* and *GS-AOP*. The *GS-ELONG* locus controls the production of glucosinolates containing side chains with three or four carbons (3C and 4C, respectively). Three allelic variants at the *GS-AOP* locus: *GS-NULL*, *GS-ALK*, and *GS-OHP* control the production of methylsulfinylalkyl, alkenyl, and hydroxyalkyl glucosinolates, respectively (Kliebenstein et al. 2001).

Statistical Analyses All statistical analyses were performed with SAS software (SAS Institute 1999, Version 8e), and all phenotypic variables were rank transformed. Rank transformation stabilizes the variance of the data, thus, correcting or minimizing heteroscedasticy (Potvin and Roff 1993). This approach is particularly useful for analyzing glucosinolates, since commonly used transformations for parametric procedures often do not correct for heterogeneity of residual variances. To evaluate the effect of glucosinolate profile (fixed effect) and plant genotype nested in profile (random effect) on glucosinolate contents, a mixed model analysis of variance (Proc. Mixed), was performed for each of the detected individual glucosinolates as well as for total aliphatic and indolyl glucosinolates, and total glucosinolate contents. The same approach was used to evaluate the effect of profile and genotype on herbivore damage levels and plant fitness. Mean damage levels and fitness among profiles were compared by using protected least-significant difference (LSD) tests. In addition, an analysis of covariance was carried out to infer whether differential damage levels affected fitness and to evaluate genotypic variation in damage by using the following model: Fitness=damage+genotype+damage×genotype. The effect of blocks (field plots) was removed from the final model because it was only marginally significant (P=0.053). Regression analyses were performed to evaluate the association between individual glucosinolates and damage levels as well as between total glucosinolate concentrations and both damage and fitness. Finally, a cluster analysis that used the unweighted pair group method with arithmetic means (UPGMA) was carried out. This grouped *A. thaliana* genotypes on the basis of the distribution of insect herbivore species. This grouping was statistically corroborated by using the nonparametric analysis of variance (ANOVA)-type statistic (ATS), which is based on an approximated F distribution (Brunner et al. 2002). Analyses of variance were additionally performed to compare glucosinolate concentrations, damage levels, and fitness among the groups of genotypes identified by the cluster analysis.

Results

Natural Variation in Glucosinolates Selected genotypes from diverse geographical areas were highly variable in both glucosinolate composition and quantity (Fig. 1; Tables 1 and 2). We measured all glucosinolates, both aliphatic and indolic, prior to (apparent) herbivory. However, potential glucosinolate induction (resulting from herbivory and/or mechanical damage) was not measured, and, thus may account for part of the genotypic variation in these chemicals. We identified variation at three of the known naturally variable glucosinolate loci, *GS-ELONG*, *GS-AOP*, and *GS-OH*. We focused on five glucosinolate profiles generated by allelic variation at the two loci, *GS-ELONG* (3C and 4C) and *GS-AOP* (*NULL*, *ALK* and *OHP*; Fig. 1). Hereafter, we refer to these profiles with the following abbreviations: 3C OHP, 3C ALK, 4C OHP, 4C ALK, and 4C NULL. Genotypes with 3C OHP and 3C ALK profiles accumulated primarily 3-hydroxypropyl (93% of total aliphatic glucosinolates, TAG) and 2-propenyl (79% of TAG), respectively. The 4C NULL and the 4C OHP profiles produced predominantly 4-methylsulfinylbutyl glucosinolates (about 60% of TAG). In addition, 2-butenyl and 2-hydroxy-3-butenyl glucosinolates made up more than 70% of the TAG in genotypes with the 4C ALK profile. Although the effect of profile was significant for most individual aliphatic glucosinolates, both absolute and relative concentrations of indolyl as well as total glucosinolates did not differ significantly among profiles (see Table 2). Conversely, pronounced variation among genotypes was detected for all aliphatic, indolyl, and total glucosinolate concentrations, in terms of

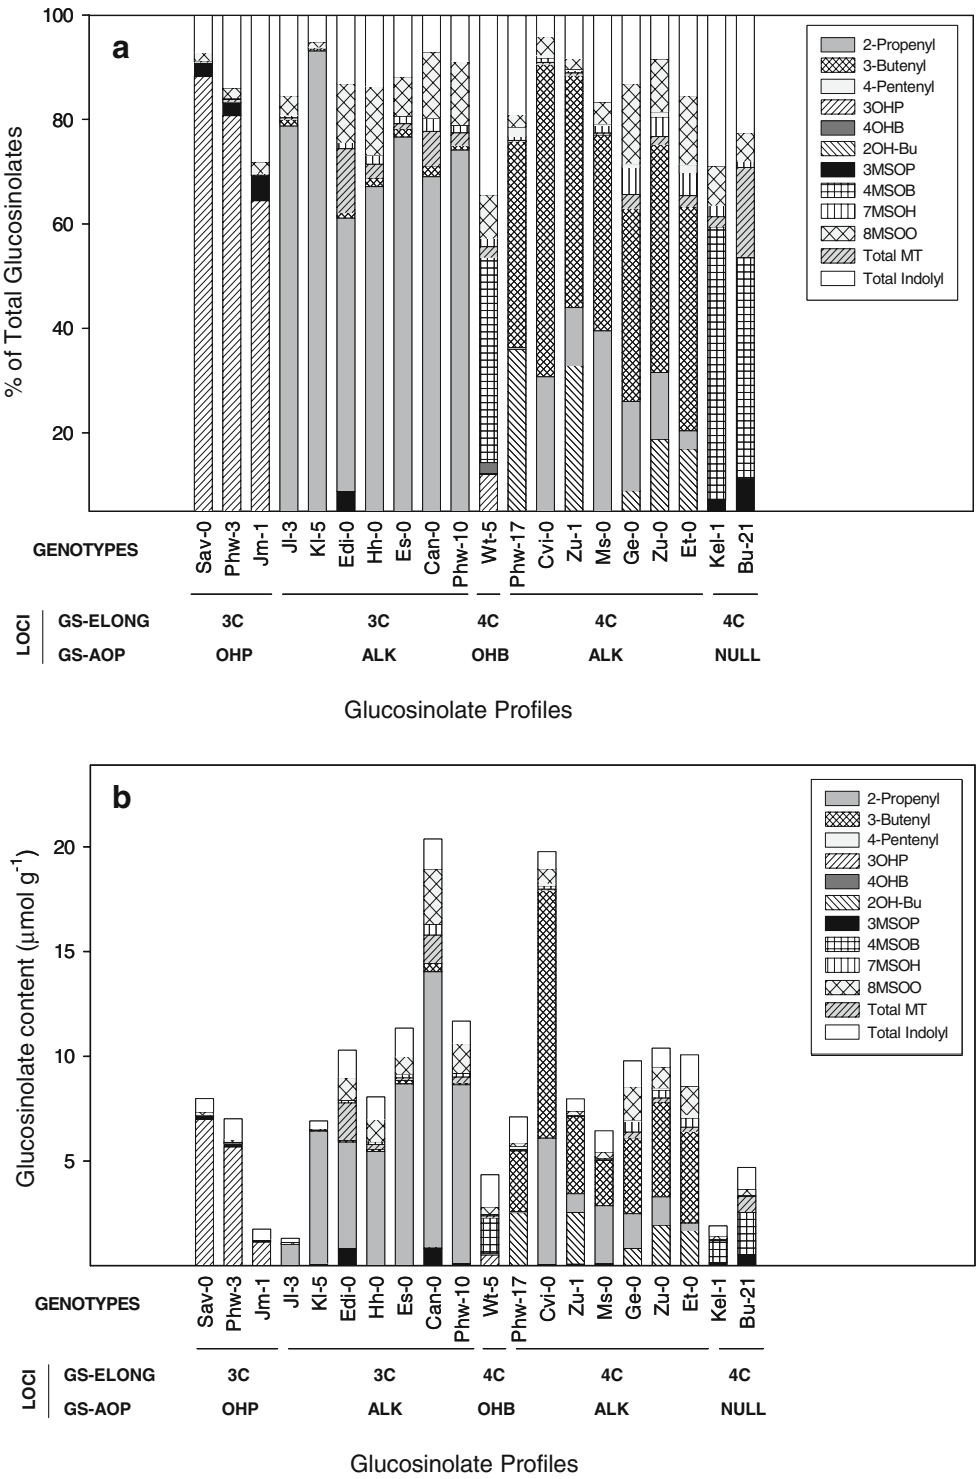

Fig. 1 Natural variation in glucosinolate profiles in *A. thaliana* determined on the basis of allelic variation at two loci, *GS-ELONG* (*3C* and *4C*) and *GS-AOP* (*NULL*, *ALK*, and *OHP*) and genotypic variation in the **a** relative and **b** absolute concentration of glucosinolates (µmol g^{-1} dry weight). Refer to Table 2 for glucosinolate abbreviations

both absolute and relative amounts (Table 2; Figs. 1 and 2). Although we tested indolyl glucosinolate type and content, we focused on the aliphatics, which showed stronger variation and because they are predominant in *A. thaliana* (in terms of concentrations). However, indolyl glucosinolates also have been shown to have a role in defense against insects (Kim and Jander 2007).

Glucosinolates, Insect Damage and Plant Fitness Herbivore damage levels as well as plant fitness were both apparently controlled by genetic variation among the *Arabidopsis* accessions (ANOVA $P<0.001$). As expected, higher levels of insect damage were associated with decreased fitness (Fig. 3). An analysis of covariance corroborated this pronounced relationship between fitness

Table 2 Variation in individual and total glucosinolate contents among chemical profiles and genotypes in *A. thaliana*

[a] Only one genotype with this glucosinolate type

and damage (covariate) as well as a significant interaction between damage and genotype, which is indicative of genetic variation in the fitness response to insect herbivory (i.e., genetic variation for tolerance of herbivory damage; Fig. 3). The observed genotypic variation in plant damage and fitness was related to differences in both glucosinolate quantity and quality (Figs. 4 and 5). Glucosinolate levels were associated directly with damage (y=4.15+0.58x; Slope=0.58; P=0.003) and inversely related to fitness (y= 17.68–0.77x; Slope=−0.77; P<0.001; Fig. 4). The results are based on total glucosinolate concentrations since regression relationships between damage and either indi-

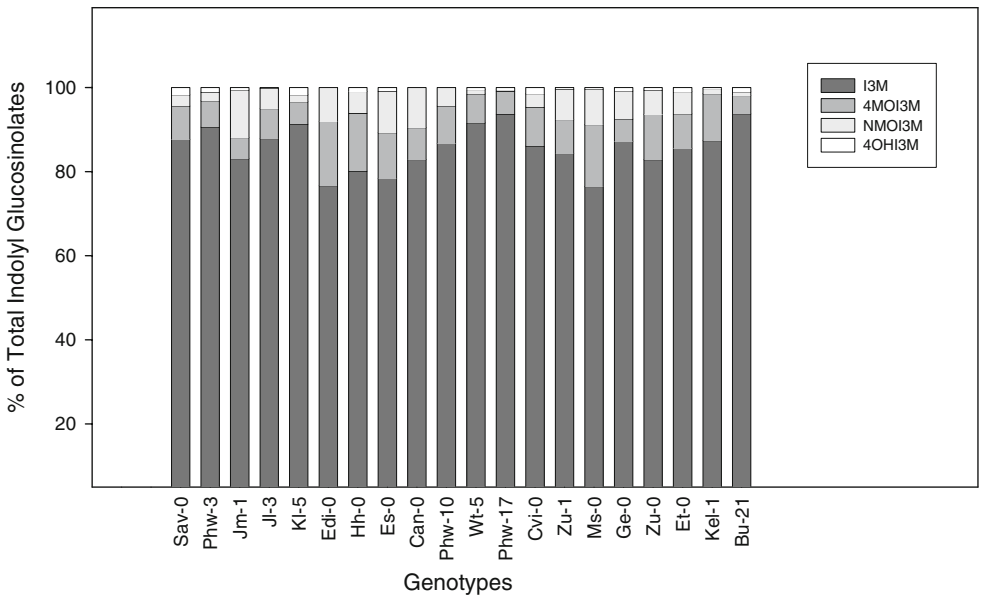

Fig. 2 Relative concentrations of individual indolyl glucosinolate in *A. thaliana* genotypes. Refer to Table 2 for glucosinolate abbreviations

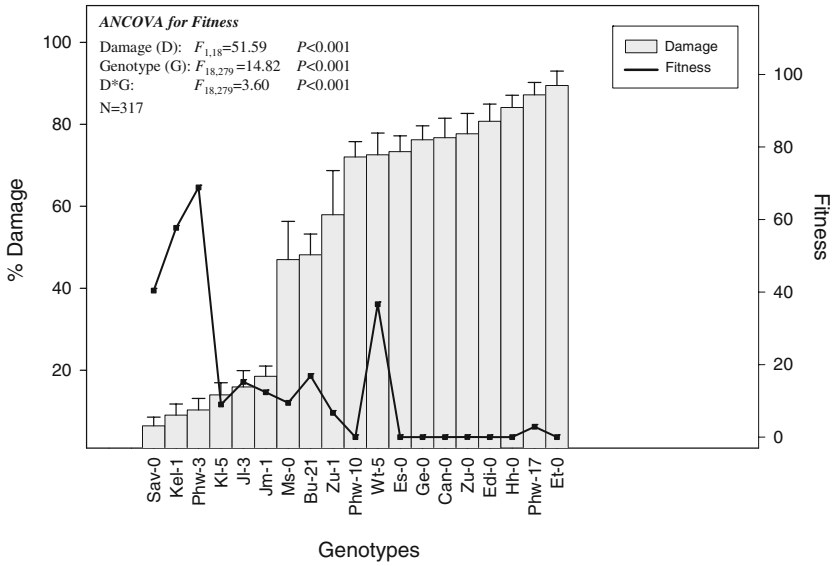

Fig. 3 Analysis of covariance estimating the effects of plant damage by natural levels of insect herbivory, genotype, and genotypic variation in damage on plant fitness (total number of seeds per plant $\times 10^2$)

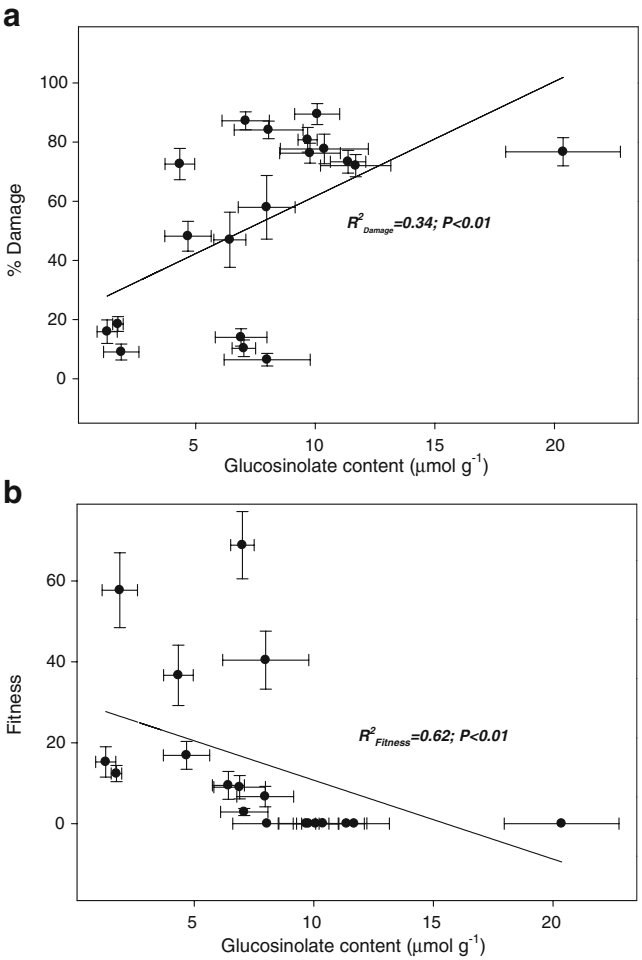

Fig. 4 Relationships between total glucosinolate concentrations (μmol g^{-1} dry weight) in *A. thaliana* and **a** damage and **b** fitness (total number of seeds per plant $\times 10^2$). Each *circle* denotes a genotypic mean

vidual aliphatic or indolyl concentrations were generally significant and consistent in the direction of their response; i.e., most glucosinolates revealed positive regression coefficients ranging from 2.20 to 8.57 and *P*-values ranging from <0.001 to 0.03. The exceptions were 3-hydroxypropyl and 3-methylsulfinylpropyl glucosinolates, which were inversely related to damage levels (both *P*-values <0.001). These associations between glucosinolates and both damage and fitness should be interpreted with caution because induction by subsequent herbivory and/or ontogenetic changes in glucosinolate levels might alter these relationships. The effect of glucosinolate profile was significant for mean damage levels ($P<0.001$, see Fig. 5) and plant fitness

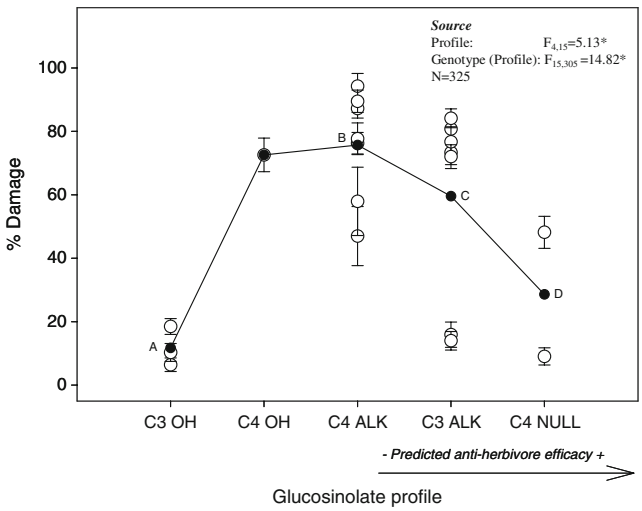

Fig. 5 Glucosinolate profiles in *A. thaliana* and damage by natural levels of insect herbivory. Chemical profiles in the *x* axis are ordered with increasing antiherbivore efficacy for the generalist cabbage looper (as previously described in Kliebenstein 2004). Means with *the same letter* are not significantly different at $P<0.05$ (based on least significant difference tests). *$P<0.01$

(P=0.002). Overall, genotypes that contained the *GS-ALK* allelic variant (regardless of the allelic status at *GS-ELONG*) had more damage and lower fitness than those that contained other alleles at the *GS-AOP* locus (Fitness: 3C/OHP=4C/OHP=4C/NULL >>> 3C/ALK=4C/ALK; significance based on protected LSD tests). However, variable outcomes were found for different plant genotypes (within profiles) in terms of both damage (P=0.008) and fitness (P<0.001). In other words, some genotypes differed in the amount of damage (and/or fitness) regardless of their specific chemotype. In addition, we compared the detected variation in natural insect herbivory with known preferences of the generalist cabbage looper (*T. ni*) for the same glucosinolate profiles (Lambrix et al. 2001; Kliebenstein 2004; Fig. 5). Results were in accordance with the previously ranked order preferences of the cabbage looper, in terms of increased feeding in genotypes with metabolites produced by 4C/ALK and 3C/ALK compared to 4C/NULL profiles. Nonetheless, results summarized in Fig. 5 (as well as the effect of profile on fitness) should be interpreted with caution because of the significant effect of genotype and because profile groups contained an unequal (and sometimes minimal) number of genotypes.

Glucosinolates: Patterns of Plant Utilization by Insect Herbivores in the Field Because there is potential for specialist and generalist insects to have different glucosinolate mediated interactions, we recorded the identity of insect herbivores that interacted with plants in the field. Several species were detected feeding on the plants, including diamondback moths (*Plutella xylostella*; Plutellidae, Lepidoptera), striped and western cabbage flea beetles (*P. striolata* and *P. pusilla*, respectively; Chrysomelidae, Coleoptera), cabbage aphids (*Brevicoryne brassicae*; Aphididae, Hemiptera), and onion thrips (*Thrips tabaci*; Thripidae, Thysanoptera). Although most of the insect damage was concentrated on the rosette leaves, which were attacked primarily by diamondback moths and flea beetles, aphids and thrips affected mostly plant aerial parts such as buds and flowers. Consequently, constitutive levels of glucosinolates (as well as quality), which were measured only on rosette leaves are likely more important for explaining selective feeding of diamondback moths and flea beetles rather than that of aphids and thrips. However, the overall glucosinolate chemotype within *Arabidopsis* has not been found to alter with tissue or herbivory (Kliebenstein et al. 2001). Four of these five herbivores are specialists on

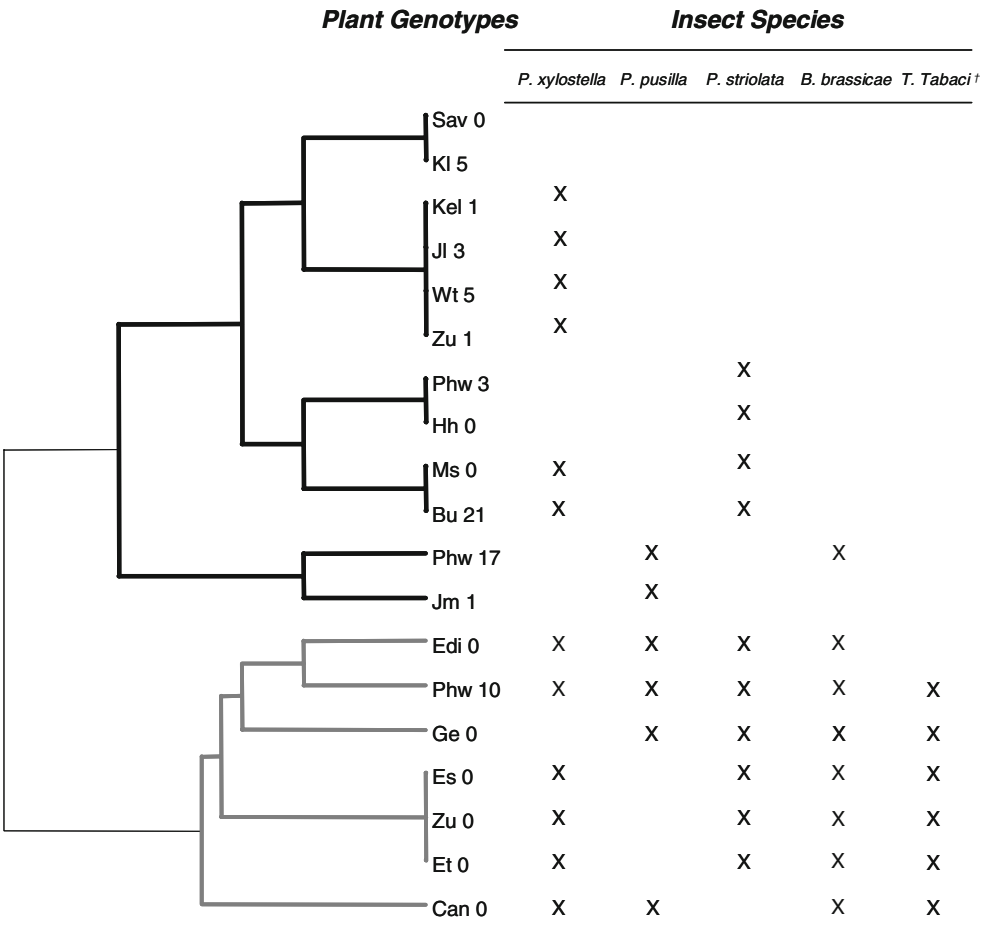

Fig. 6 UPGMA cluster analysis showing the association among *A. thaliana* genotypes with similar distribution of insect species feeding on the plants. The two identified clusters are indicated by different line colors (*black and gray*). *dagger* Only generalist insect

glucosinolate containing plants, while only *T. tabaci* is a generalist. As such, our herbivore community that attacked *Arabidopsis* in the field was composed predominantly of specialists. Only one genotype (Cvi-0) was heavily attacked by a downy mildew (Peranosporales), and all individuals in this genotype eventually died from fungal attack. The distribution of insect species among the studied plant genotypes was evaluated graphically by cluster analysis (Fig. 6). The Cvi-0 genotype was excluded from this analysis since it succumbed to a fungal attack rather than to insect herbivory. The cluster analysis revealed two groups of plant genotypes: one clustered genotypes with 1–2 associated insect species and the second clustered genotypes with 4–5 insect herbivores (Fig. 6). This grouping was corroborated by the nonparametric ATS test (F_{ATS}=29.37, P<0.001, N=19). It is interesting that these two groups of genotypes had nonoverlapping lower (1.3–8.05 μmol/g) and higher (9.68–20.36 μmol/g) total glucosinolate concentrations (significant differences in mean glucosinolate concentrations, P<0.001). These clusters also differed in their mean damage levels (P=0.003) and fitness responses. Specifically, the group of genotypes with lower glucosinolate levels was associated with lower numbers of insect species feeding on the plants and, consequently, lower mean damage levels (39% of the plant damaged) than genotypes with higher glucosinolates (mean damage index, 78%). In addition, only genotypes with lower glucosinolate concentrations contributed to fitness; all genotypes in the other group succumbed to insect herbivory. The outcome summarized in this section combined with results on the overall association between glucosinolate levels and both damage and fitness in this study suggest that glucosinolates might have been an important factor that influenced plant utilization patterns by insect herbivores in this experimental garden.

Discussion

Few studies have evaluated the potential link between intraspecific variation in secondary chemistry and patterns of plant use by insect herbivores in the field (Cronin and Abrahamson 2001). In an experimental garden, we demonstrated genotypic variation in the type and concentration of glucosinolates in *A. thaliana*, as well as significant relationships between glucosinolates and both herbivore damage and plant fitness. Even though correlational associations do no imply causation, this study suggests that genotypic variation in glucosinolates may be a factor that explains patterns of plant use by insect herbivores in the field (as estimated by plant damage and fitness). Specifically, genotypes with higher glucosinolate levels were associated with augmented damage levels and decreased fitness.

These results are contrary to the general expectation that enhanced chemical defense should result in decreased insect herbivory. Previous studies have shown that glucosinolate–insect relationships may be strongly influenced by the physical and biological context in which they develop. For example, Bidart-Bouzat et al. (2005) found that the performance of the diamondback moth, *P. xylostella*, was associated with glucosinolate type and concentration. However, this relationship was correlated with CO_2 levels and insect gender; that is, only performance of females (but not males) reared on elevated CO_2 grown plants was inversely related to 3-butenyl glucosinolate levels and positively associated to 2-propenyl, indolylmethyl, and total glucosinolates. Likewise, the interaction between secondary chemicals and insect herbivores also may be contingent on the type of insect herbivore community associated with the plants (Strauss and Irwin 2004). For example, Lankau (2007) provided evidence that high concentrations of the 2-propenyl glucosinolate resulted in increased damage by the specialist cabbage aphid but deterred attack by a generalist guild.

A specialist-dominated insect community, like the one associated with our experimental plants, may exert selection for decreased glucosinolate concentrations. As previously mentioned, *A. thaliana* genotypes with lower glucosinolate concentrations were associated with decreased damaged and, as a consequence, had higher fitness than those with higher amounts of these chemicals. Both herbivore damage and glucosinolate levels in this study were highly variable among plant genotypes as well as significantly correlated with fitness. This variation is a necessary condition for insect herbivory to impose selection on plant secondary chemistry (Marquis 1992). Thus, insect herbivory emerges as a potential selective factor that influences the type and concentration of glucosinolates in our common garden experiment. In contrast to our findings, a previous field study documented a reduction in damage levels by a suite of insect herbivores in plant genotypes with higher glucosinolate concentrations as well as directional selection favoring increased glucosinolate levels (Mauricio 1998; Mauricio and Rausher 1997). These authors reported the presence of specialist flea beetles as well as unidentified insect herbivores (lepidopteran larvae, leaf miners, beetles, and aphids), but it is not possible to ascertain if their herbivore community had a similar predominance of specialist herbivores. However, if their herbivore community had a predominance of generalists, this could explain the difference in genetic correlation between damage and glucosinolates in the two experiments. Since glucosinolates can stimulate feeding by specialist insects but deter generalist insect attacks (Bones and Rossiter 1996), the type and direction of selection that acts on these chemicals would depend on which herbivore type is more prevalent

and/or more detrimental to the plants and whether insect herbivory is maximal at lower, intermediate, or higher glucosinolate concentrations (Siemens and Mitchell-Olds 1996; Lankau 2007).

In addition to the total amount of a chemical class, individual constituents can have contrasting effects on insect herbivore behavior or performance. For example, while 2-propenyl glucosinolate is an effective feeding stimulant for the cabbage aphid, 4-pentenyl inhibits reproduction of this specialist, at least under laboratory conditions (Raybould and Moyes 2001). In our study, most individual glucosinolates (both aliphatic and indolyl) as well as their total amounts (total aliphatic, total indolyl, and the sum of these two) were positively associated with damage in the experimental population. The only two exceptions consisted of 3-hydroxypropyl and 3-methylsulfinylpropyl glucosinolates, which were negatively related to damage. It is interesting that 3C/OHP, the chemical profile of genotypes that accumulates 3-hydroxypropyl glucosinolates (see Fig. 5), has been considered one of the least effective profiles in deterring herbivory by the generalist *T. ni* in previous laboratory experiments (Lambrix et al. 2001; Kliebenstein et al. 2002; Kliebenstein 2004). Conversely, we found that the three genotypes with this chemical profile were minimally visited by insect herbivores and minimally damaged (Figs. 4 and 5). Thus, one could hypothesize that low herbivory levels in these genotypes might have resulted from the presence of the 3-hydroxypropyl glucosinolate, which may have not been an effective feeding or oviposition stimulant for the specialist insects attracted to the experimental plants.

In contrast to the 3C/OHP plants, genotypes that contain the *GS-ALK* allelic variant (regardless of the allelic status of *GS-ELONG*) had higher mean damage levels and lower fitness. Alkenyl glucosinolates, such as 2-propenyl and 3-butenyl glucosinolates, produced by the 3C/ALK and 4C/ALK profiles, respectively, are known for their ability to stimulate feeding and oviposition by numerous specialist insects such as cabbage aphids, cabbage seed weevils, brassica pod midges, cabbage root flies, turnip aphids, flea beetles, white cabbage butterflies, and diamondback moths (reviewed in Raybould and Moyes 2001). Hence, it is not surprising that the specialist insects attracted to our experimental garden preferentially attacked plant genotypes that contained higher amounts of these glucosinolate types.

Although secondary chemistry plays a major role in the evolution of plant–insect herbivore interactions (Zangerl and Berenbaum 1993), other physical properties or life history traits also influence herbivore distribution among plants (Jaenike 1990). For example, characteristics such as increased size or abundance (in addition to chemical properties) that make plants more "visible" to insects can affect host plant choice (Feeny 1976). In our study, plant size (i.e., aboveground vegetative biomass using damage as a covariate) was not associated with damage levels (data not shown). In addition, life history characteristics such as early flowering phenology and rapid growth may allow plants to escape damage in time, e.g., by flowering before insect herbivores become abundant later in their reproductive season (Pilson and Decker 2002). Genotypes of *A. thaliana* used in this experiment included both accessions considered to behave as early and late flowering as well as those with variable flowering phenology; however, all accessions flowered in the field within a relatively small 13-day interval. In addition, we found considerable overlap in the flowering time ranges of the two genotype groups identified by the cluster analysis. Thus, we believe flowering time was likely not a critical factor in this study.

Since our outdoor garden represented a novel environment for the plant genotypes used, the study also may have implications for the potential role of the genotype factor in the colonization success of nonnative habitats by invasive plant species. It is interesting that only half of the genotypes contributed to fitness and only four had considerably high fitness levels. Higher fitness in three of these genotypes (Sav-0, Kel-1, and Phw-3) could have resulted from their lower glucosinolate contents and/or low "attractant" property of the glucosinolate types that these genotypes produced, which apparently allowed them to "escape" herbivory by the associated insect specialist community. Genotype Wt-5 had the fourth highest mean fitness response among all genotypes studied, and it likely was able to compensate for the fairly high herbivore impact (approximately 69% of the plant damaged) mainly through its ability to tolerate herbivore damage by increasing branching and vegetative growth (data not shown). These results highlight the importance of intraspecific variation in plant resistance and tolerance to natural enemies when assessing the potential of alien species to become invasive in nonnative habitats.

In summary, although we do not discard the potential influence of other plant properties on herbivory levels in our study, the results suggest that variation in glucosinolate type and content is an important factor that affects insect selectivity among plant genotypes in the field. The observed association between variation in glucosinolate content, herbivore resistance, and fitness suggests that glucosinolate content is in part responsible for the observed variation in herbivore resistance. However, as shown by the percent of variation explained, it is not the only source of variation and other potential sources remain to be identified. For instance, variation in other herbivory resistance mechanisms, such as protease inhibitors, glucosinolate hydrolysis rate and specificity, other secondary metabolites, or inducibility, may influence herbivore variation in resistance and fitness. More field studies are needed to elucidate all the potential factors that control herbivore

resistance of *A. thaliana* in the field as well as to ascertain whether glucosinolate–insect herbivore relationships should be considered herbivore species specific, or to what extent they are dependent upon the degree of ecological specialization of the associated herbivore community.

Acknowledgements We thank the Arabidopsis Biological Resource Center for supplying seeds for this experiment. We also thank four anonymous reviewers for comments, which greatly helped to improve this manuscript. This study was funded by Bowling Green State University and an NSF grant DBI 0408406 (MGBB).

be of importance for seed development (Vogel-Mikuš et al. 2007). Nevertheless, the possible role of differing GS profiles in AM formation during the life cycle of *T. praecox* or other AM-host plant species is not yet understood.

Several Brassicaceae species are hyperaccumulators that take up exceptionally high metal concentrations in their above-ground biomass without visible toxicity symptoms (Brooks et al. 1977). *T. praecox* is a recently reported Cd-hyperaccumulating species (Vogel-Mikuš et al. 2005), with the highest concentrations found during the vegetative phase of development (Pongrac et al. 2007). An evolutionary advantage of metal hyperaccumulation has been proposed. It may be an effective plant defense against pathogen and herbivore attack, with possibly no additional expensive organic defense compound formation being necessary (Boyd and Martens 1998; Poschenrieder et al. 2006b). However, a Cd-induced increase of total GS concentration (especially of sinalbin) observed in hydroponics of *T. praecox* has somewhat questioned the idea that metal accumulation leads to a decrease of investment in organic defense compound biosynthesis (Tolrà et al. 2006).

The relationships between metal and organic defenses in plants are complex (Hartl and Baldwin 2006; Poschenrieder et al. 2006a) and rarely have been studied simultaneously under field conditions (Noret et al. 2007). In the present study, three relationships were investigated in field-collected *T. praecox*: (1) the dynamics of total and individual GS in relation to plant developmental phases, (2) GS profiles in relation to AM formation in plant roots, and (3) GS and Cd concentrations in rosette leaves and their possible relation to plant defense.

Methods and Materials

Sampling and Plant Material Preparation Plants were collected from April to September 2005 in Žerjav, Northern Slovenia on a plot that is located on the rim of the valley, about 500 m from the main source of pollution, with closed vegetation and *Sesleria caerulea* L. and *T. praecox* as dominant plant species. The location is heavily polluted with Cd, Zn, and Pb, a result of centuries of Pb mining and smelting activities (Regvar et al. 2006). The rhizosphere soil of *T. praecox* was highly enriched in total Cd (84.3±7.6 mg kg^{-1}), with on average 28% Cd in available metal fractions in soil (Pongrac et al. 2007).

Five developmental phases during *T. praecox* life cycle were distinguished: (1) vegetative phase (VP) collected in April, (2) flower induction phase (FI) collected in April, (3) flowering phase (FP) collected in May, (4) seeding phase (SP) collected in June, and (5) senescence phase (SC) collected in September. Five plants per plot were collected and analyzed in each phase, with the exception of the vegetative and flower induction phase. During these latter phases, plants were very small. Therefore, three (VP) and two (FI) plants had to be pooled to provide a single sample; three sample pools per plot were collected in these phases. On average, 748±45 mg Cd kg^{-1} were found in roots, 738±103 mg Cd kg^{-1} in shoots, 496±76 mg Cd kg^{-1} in stalks (Pongrac et al. 2007), and 623±78 mg Cd kg^{-1} in seeds (Vogel-Mikuš et al. 2007) of the collected *T. praecox* plants.

Estimation of Arbuscular Mycorrhizal Colonization AM colonization was determined by vital staining of fresh root fragments by using the nitro blue tetrazolium chloride succinate method, with deposition of formazan as the viability indicator and counterstaining with acid fuchsin (Schaffer and Peterson 1993). Roots were mounted in lactoglycerol and immediately examined. The portions of vital AM colonization were estimated on 30 root fragments per plant according to Trouvelot et al. (1986): Mycorrhizal frequency (F%) describes frequency of root fragments colonized with fungus, global mycorrhizal intensity (M%) is the intensity of colonization in the root system, and mycorrhizal intensity in colonized fragments (m%) is the intensity of colonization in the fragments. Vital colonization represents only the colonization in which formazan deposition was observed.

Analysis of Plant Material Plant material was freeze-dried after a careful wash in tap and distilled water. Total GS were extracted from all plant samples (from roots N=21, rosette leaves N=21, flowering/seeding stalks N=10, and seeds N=1) with 70% (v/v) aqueous methanol in a boiling water bath for 5 min. After cooling and centrifugation, the pellet was re-extracted. The joint liquid phases were loaded onto a DEAE-Sephadex A-25 column and treated with myrosinase (thioglucoside glucohydrolase, EC 3.2.1.147; Sigma, St. Louis, MO, USA). The released D-glucose was quantified by using an enzyme-based analytical kit (Boehringer, Mannheim, Germany). The effectiveness of the extraction method was validated by using certified reference rapeseeds (CRM 367) from the European Community Bureau of Reference (BCR, Brussels, Belgium).

Extraction of individual GS was done as previously described (Tolrà et al. 2000) from two samples per developmental phase and plant tissue. Separation and quantification was performed with a liquid chromatograph equipped with a diode array detector Model HP 1090 (Hewlett Packard, CA, USA). Samples of 50 µl were injected onto a Lichospher 60RP Select B column. The mobile phases used for elution were acetonitrile and water containing 0.5% acetic acid. The gradient elution was from 0% to 60% acetonitrile for 74 min at a flow rate of 1 ml min^{-1}, at 30°C and the diode array set at 230 nm. Sinigrin

(2-propenyl-GS) from horseradish (Sigma-Aldrich, Quimica SA, Madrid) was used as an internal standard. Gluconapin (3-butenyl-GS) and glucotropaeolin (benzyl-GS; both from Merck) were used as external standards.

Statistical Analyses To test the overall effect of developmental phases on the total and individual GS concentrations and mycorrhizal colonization, the non-parametric Kruskal–Wallis test was applied, and when significant, Mann–Whitney *U* test with a Bonferroni correction was used to determine the significance of differences among developmental phases at $P<0.05$ (means±standard error). Spearman's correlation coefficient (r_s) was used when calculating correlation between AM colonization parameters and individual GS at $P<0.05$. Statistical tests were performed with Statistica Statsoft® (version 6.0) software.

Results

Total Glucosinolates in Different Organs The highest average total GS concentrations (μmol g^{-1} dry weight) were found in roots (64±9.1), followed by rosette leaves (36.6±6.8), flowering/seeding stalks (16.6±2.04), and seeds (14.3). There was a statistically significant influence of developmental phases on total GS in roots and shoots (Table 1). In roots, a significant decline occurred after the flower induction phase, while it increased again during senescence phase (Fig. 1a). The highest total GS concentrations in rosette leaves were found in the vegetative phase, with a decrease during the flowering, seeding, and senescence phases (Fig. 1a).

Individual Glucosinolates in Different Organs The highest number of individual GS with different aliphatic-, aromatic-, and indolyl-side chains in field collected samples of *T. praecox* was found in roots (eight), followed by seeds (seven), rosette leaves, and stalks (five) (Table 2). The prominent GS in roots and shoots was dependent on the developmental phase (Table 1). Glucobrassicanapin and sinalbin were prominent in rosette leaves (Fig. 1b). The proportion of indolyl-GS in rosette leaves declined with age until the flowering phase and resulted in predominance of aliphatic GS (Fig. 2a). On average, 10% of the total GS in rosette leaves was represented by aromatic GS, and this remained constant during development. Glucobrassicanapin, sinalbin, and 4-OH-glucobrassicin in rosette leaves were found in all developmental phases (Table 2).

The highest proportion of GS type in flowering/seeding stalks belonged to indolyl GS (Fig. 2b). Glucobrassicanapin, sinalbin, and 4-OH-glucobrassicin were found in flowering and seeding stalks, whereas sinigrin and traces of 4-methoxy-glucobrassicin were found only in seeding stalks (Table 2). The GS profile in *T. praecox* seeds was characterized by a higher proportion of aliphatic GS (Fig. 2b) than in stalks and by the presence of the aliphatic-GS, progoitrin, that was not found in other plant parts.

In roots, glucobrassicanapin was not found in the flower induction or flowering phases, whereas glucotropaeolin was found only in these two phases (Fig. 1c; Table 3). A decrease in the relative content of indolyl GS and a simultaneous increase of aliphatic- and aromatic GS after the vegetative phase was observed in roots, with aromatic GS being the highest in the flowering and seeding phase (Fig. 2c). Of the individual GS found in roots, sinigrin, gluconapin, and sinalbin were present in all phases (Table 2).

Mycorrhizal Colonization Significant variation in vital mycorrhizal colonization frequency (F%), global intensity (M%), and intensity in the colonized fragments (m%) was observed during the life cycle of *T. praecox* (Table 3), with peaks during flowering. A positive correlation between AM parameters and root glucotropaeolin concentration was found (Table 3). No other correlation was found between AM parameters and root individual GS.

Table 1 Significance levels of *h-test* (*Kruskal–Wallis*) for developmental phase effects on total and prominent individual glucosinolates in the life cycle of field collected *Thlaspi praecox*

Discussion

Organic defense compounds in plants can be influenced by several external factors and also by intrinsic signals (e.g., leaf age), as has been observed for glucosinolates (GS; Rosa et al. 1996; Petersen et al. 2002; Rangkadilok et al. 2002; Brown et al. 2003). The highest total GS concentrations in *Arabidopsis thaliana* have been reported in seeds, followed by flowers and fruits, leaves, and the lowest in roots (Petersen et al. 2002; Brown et al. 2003). Reproductive organs are expected to have the highest concentrations of defense compounds, as they contribute most to survival and fitness of the offspring, as described

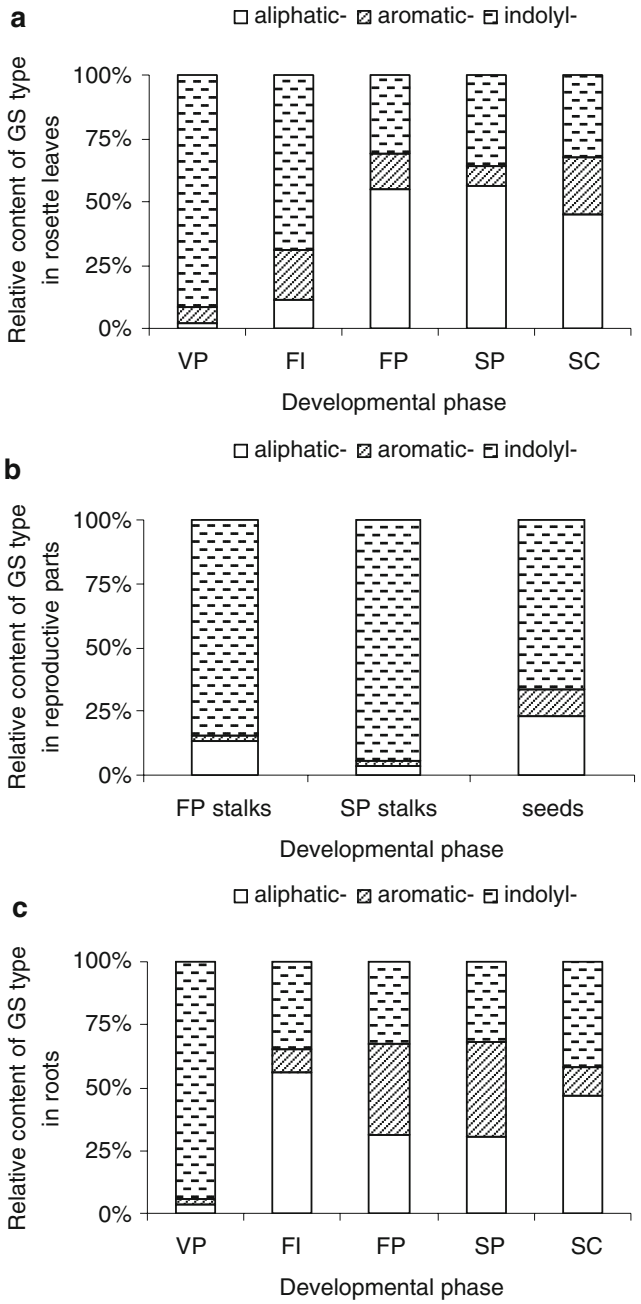

Fig. 2 Relative content of glucosinolate (*GS*) type (aliphatic-, aromatic- and indolyl-) in the life cycle of field collected *Thlaspi praecox* in **a** rosette leaves, **b** stalks and seeds and **c** roots (N=2; 100% presents the sum of total glucosinolate fractions). *VP* Vegetative, *FI* flower induction, *FP* flowering, *SP* seeding, *SC* senescence phase

by optimal defense theory (Wallace and Eigenbrode 2002). In contrast, the lowest GS concentrations were found in seeds of field collected metal-hyperaccumulating *T. praecox* (compared to other plant parts), with indolyl GS as the major GS type and the addition of a GS (progoitrin) that was not detected in any other plant parts. It seems likely that specific enzymes for the biosynthesis of this GS may be present only in seeds and that some of the seed GS were synthesized de novo in the silique as previously reported (Petersen et al. 2002).

An increase in the relative content of aliphatic GS at the expense of indolyl GS in rosette leaves was observed up to the flowering phase in field collected *T. praecox*. In contrast, the proportion of indolyl GS in leaves increased with age at the expense of aliphatic GS in *A. thaliana* (Brown et al. 2003). The concentration of the aliphatic GS, sinigrin, the major GS in *Brassica nigra*, decreased from seedling to early flowering phase, but increased in the late flowering phase, and decreased again during seed maturation (Rangkadilok et al. 2002). The observed differences in GS metabolism may be due to differences in genetics, differences in life cycle length (annuals *A. thaliana* and *B. nigra* vs. perennial *T. praecox*), and/or different growth conditions.

Root indolyl GS of *T. praecox* were found to prevail only in the vegetative phase, whereas in the other phases, they comprised a constant proportion averaging 33% of the total GS. Indolyl GS produce isothiocyanates that are unstable and decompose spontaneously (Fahey et al. 2001). They are, therefore, believed to be less effective deterrents or toxins. The restoration of high root total GS concentrations and aliphatic GS, particularly glucobrassicanapin, in the senescence phase compared to the flowering and seeding phases suggests involvement in root protection of the perennial *T. praecox* during overwintering. However, a targeted study is needed to examine defensive roles during specific developmental phases.

The presence of novel GS (progoitrin, glucotropaeolin, and glucobrassicin) in field collected *T. praecox* compared to hydroponically grown plants that were analyzed only in the vegetative phase (Tolrà et al. 2006) was related to specific developmental phases, mainly to flowering and

Table 3 Minimal–maximal values of vital arbuscular mycorrhizal (AM) colonization parameters In the life cycle of field collected *Thlaspi praecox* and Spearman's correlation coefficient (r_s) between AM colonization parameters and root glucotropaeolin concentration

Developmental phase	Vital AM root colonization

seed production. In addition, among all detected individual GS, sinalbin was the only one present in all plant organs and in all developmental phases of field collected *T. praecox*. Its highest concentrations in rosette leaves were, however, measured in the vegetative phase, which also contained the highest Cd concentrations (Fig. 1) as previously reported by Pongrac et al. (2007). The presence of sinalbin also increased in hyperaccumulating *T. praecox* after Cd treatment in hydroponics, whereas it was not detected in the Cd-sensitive non-hyperaccumulator *Thlaspi arvense* (Tolrà et al. 2006). Thus, the synthesis of sinalbin may be linked with Cd metabolism in *T. praecox*. Additionally, the simultaneous presence of the highest Cd and total GS concentration in rosette leaves in the vegetative phase does not support the "trade-off" hypothesis as proposed by Boyd and Martens (1998) and Poschenrieder et al. (2006b) in this hyperaccumulating species. Rather, plants in the vegetative phase may profit by being protected by both high metal and high GS concentration.

The non-mycorrhizal status of plants is attributed to in situ root GS hydrolysis products, the presence or absence of lectins, and/or the structural-chemical properties of the root cell wall that hinder or inhibit fungal growth (Glenn et al. 1988). Increase of GS concentration and a distinct change of GS profile after inoculation have been observed in several GS-containing plant species regardless of whether colonization occurred or not (Vierheilig et al. 2000). Similarly, in *Tropaeolum majus* and *Carica papaya*, reduced AM colonization could not be correlated with induced concentrations of GS (Ludwig-Müller et al. 2002). As most of the non-AM colonizing plants contained gluconasturtiin (2-phenylethyl GS) in roots, this GS, but not others, has been proposed to act as a general AM inhibitory factor (Vierheilig et al. 2000). In our study, no gluconasturtiin was found, consistent with other GS-containing plants susceptible to AM colonization. However, a distinct change of GS profile and a decrease of total GS concentration in roots coincided with the highest AM colonization in *T. praecox*. The presence of glucotropaeolin and absence of glucobrassicanapin was observed during the reproductive phases of *T. praecox*. Quantities of glucotropaeolin, the main GS of the AM-host *T. majus*, have been shown to increase during AM colonization (Vierheilig et al. 2000; Ludwig-Müller et al. 2002). Glucotropaeolin is an important metabolite for root growth regulation and a potential precursor of phenylacetic acid. Similarly, indol-3-acetic acid is formed from indolyl GS in species of Brassicaceae (Ludwig-Müller 1999; Ludwig-Müller and Cohen 2002). Glucobrassicanapin, on the other hand, has been found only in AM non-host *Brassica napus* (Vierheilig et al. 2000). Thus, the pattern of GS in *T. praecox* roots, i.e., the presence and absence of specific GS, is likely to affect AM formation, as some GS may inhibit while others may contribute to or are of little consequence in AM formation. In addition to GS profiles and/or content, plant mineral demand, seasonal dynamics of mycorrhization (Pongrac et al. 2007), and/or diverse signaling molecules (Akiyama et al. 2005) may all contribute to AM colonization in *T. praecox*.

In summary, this study showed that GS concentrations and profiles change considerably in the life cycle of Cd/Zn hyperaccumulating *T. praecox*. The highest Cd and GS concentrations in rosette leaves are found in the vegetative phase, with indolyl GS the predominate form, presumably providing protection of young, palatable leaves. The presence of glucotropaeolin and absence of glucobrassicanapin in *T. praecox* roots during flower induction and the flowering phases coincide with the highest AM colonization levels during plant development. AM formation is accompanied by an overall absence of gluconasturtiin. In addition, the increase of total GS in roots in the senescence phase may contribute to effective protection of roots during overwintering and in early spring, with the aliphatic and indolyl GS as predominant GS forms.

Acknowledgments The work was supported by the following projects: MSZS P1-0212 Biology of Plants research program, "Young researchers", EU COST 859, Spanish and Catalonian Governments (DGICYT, BFU 2004-02237-CO2-01, Group de Recerca 2005GR 0078) and Spanish Ministry of Education and Science (BFU 2007-60332/BFI). The grant by COST Action 859 to P. Pongrac for her research stay at the Autonomous University of Barcelona is gratefully acknowledged.

Ca. P. mali by grafting shoots of already infected apple trees (from the previous years experiments) or left untreated as uninfected controls. All trees were checked for apple proliferation prior to experiments by extracting deoxyribonucleic acid (DNA) of the rootstock's phloem followed by PCR with specific primers (fAT/rAS) as described below. Trees were transferred from a cooling chamber to a greenhouse chamber 5 wk before the headspace sampling was started. The trees were maintained under natural light and temperature conditions (day/night: 16/8 hr, 20/15°C, 60% relative humidity [RH]) until flowering was completed (phenology stage 68). Subsequently, trees were transferred into a climate chamber (day/night: 12/12 hr, 20°C constant, 60% RH) for headspace sampling (phenology stages 69–79).

Rearing of Insects for Bioassays Mature adults of *C. picta* were collected from apple trees (*M. domestica*) in early spring after having returned from their overwintering host plants. In rearing cages (60×60×90 cm), they were maintained on uninfected or *Ca.* P. mali-infected apple plants where they could feed and oviposit. The rearing cages were located in a tempered greenhouse chamber under natural light conditions and a day/night temperature program (20/15°C). For behavioral trials, test insects were collected from the boxes 1 d before testing in groups of ten in Eppendorf vials at 4°C. All insects were tested within 2 wk after emergence.

Behavioral Bioassays Behavioral tests were carried out by using a dynamic olfactometer consisting of a Y-shaped glass tube (entrance arm: 12.5 cm, test arms=21.0 cm, inner diameter=0.6 cm) mounted on an angular board. Charcoal cleaned air (granulated 4–8 mm, Applichem GmbH, Darmstadt, Germany) was pumped (75 ml/min) through two glass jars (vol=2 l) containing the volatile sources. A twig of uninfected or phytoplasma infected apple plants (length 10–15 cm, phenology stage 69–71) was placed in a water-filled glass vial in each jar. The odors of infected and uninfected twigs were offered simultaneously. According to the method of Soroker et al. (2004), for each test, ten females were put together into the entrance arm. Every individual that passed a final marking (10.0 cm after the branching) on one of the test arms within 15 min was counted and placed into separate vials filled with ethanol (70%) for later determination of their infection status (see below). Both experiments were repeated 29 times. The numbers of psyllids were analyzed statistically after log (x+0.5) transformation by dependent paired t test using Statistica 5.5.

DNA Extraction: Plant Material Phloem tissue from cut roots was abraded. Between 1.0 and 1.5 g of phloem tissue was subjected to DNA extraction following the procedure described by Doyle and Doyle (1990). Instead of 0.2% β-mercaptoethanol, 2% sodium metabisulfide was used. The resulting DNA pellet was resuspended in 50 µl of sterile water and stored at −20°C.

Insect Material Psyllids that were used in bioassays (see above) were subjected to DNA extraction by using the same protocol as described above for plant material. Single insects were homogenized with a conical pestle (polypropylene, 1.5 ml, Eppendorf, Hamburg, Germany) in a 1.5-ml tube containing 150 µl extraction buffer and a pinch of silicon carbide (carborundum, Sigma-Aldrich, Munich, Germany) as grinding additive. The resulting DNA pellet was resuspended in 20 µl sterile water and stored at −20°C.

PCR Analysis DNA was purified by using the primer pair fAT/rAS specific for *Ca.* P. mali (Smart et al. 1996) and amplifying a 400-bp sequence in the 16S–23S ribosomal ribonucleic acid spacer region. PCR reactions were performed in a thermal cycler (Robocycler 96, Stratagene, La Jolla, CA, USA) with a reaction volume of 25 µl containing 2.5 µl extracted DNA, 0.5 pM of each primer, 250 µM of each nucleotide, 0.5 U polymerase, and 1× polymerase buffer (Invitrogen, Karlsruhe, Germany). Samples were subjected to 35 cycles that consisted of 1 min denaturation at 95°C, 1 min annealing at 51°C, and 1.5 min at 70°C. The products of each PCR were electrophoresed on a 1% agarose gel containing ethidium bromide (0.3 µg/ml) in 1× TAE buffer (40 mM Tris, 20 mM acetic acid, 1 mM EDTA, pH 8.0). DNA was visualized and photographed while exposed to UV light (302 nm).

Headspace Sampling Single branches of apple plants (see above) were carefully wrapped in polyethylene terephthalate bags (20 cm diameter, Melitta, Minden, Germany). A stream of purified air (250 ml/min; controlled by a flowmeter) was pumped through the bag for 4 hr. For each treatment, two trees were sampled every second or third day over a period of 45 d. Volatiles from plant headspace were trapped in collection filters (charcoal 5 mg, Gränicher+Quartero, Daumazan, France) and eluted by rinsing the filter with 25 µl of dichloromethane containing 50 ng/µl of tridecane (Sigma-Aldrich, Munich, Germany) as internal standard (IS).

Analysis of Headspace Samples by GC/MS Each sample (0.5 µl) was injected splitless into a gas chromatograph (Shimadzu GC 17A, injector temperature 300°C) equipped with a 30 m×0.32 mm×0.25 µm HP-5 column (J & W, Santa Clara, CA, USA). The temperature program started at 40°C, was held for 3 min, and then

raised by 10°C/min to 250°C. The final temperature was held for 6 min. Helium (Air Liquide, Germany) was used as carrier gas (inlet pressure 3.2 kPa). The gas chromatograph was coupled to a quadrupole mass spectrometer (Shimadzu QP 5000). Electron ionization mass spectra were recorded at 70 eV with scanning from mass 35 to 500 at 0.5 scan/sec. Solvent delay was adjusted to 5 min. Identification of volatiles was determined by comparing retention times with commercially available standards (Sigma-Aldrich, Munich, Germany) and by comparison with the NIST 02 mass spectral database and NIST MS search 2.0 (National Institute of Standards and Technology, USA). The relative amounts of volatiles compared to IS were calculated as previously described by Gross et al. (2008).

Results and Discussion

Phytoplasmas infecting apple trees alter the odor of this host plant that lures their vector. *C. picta*, reared on uninfected plants without any contact with the phytoplasma during their ontogenesis (inexperienced), was attracted by the odor of infected plants (AP^+; Fig. 1a; dependent paired *t* test, $P<0.05$). By contrast, *C. picta* that were reared on infected plants (experienced) showed the opposite behavior depending on their infection status when exposed to the different odor sources. The odor of infected apple was highly attractive for psyllids that had been infected by phytoplasma ($P<0.001$), while adults of *C. picta* that had not been infected were attracted by the odor of uninfected plants or repelled by the odor of infected plants, respectively ($P<0.05$). The motivation of *C. picta* females to enter an olfactometer arm was 51% for experienced and 67% for inexperienced individuals. These are high activities for psyllids in olfactometer bioassays (Soroker et al. 2004). Interestingly, breeding of *C. picta* on infected apple trees resulted only in 29% infection of the potential vectors by phytoplasmas, as shown by PCR analysis of whole-body extracts, using specific primers for detection of *Ca.* P. mali. As all infected trees used for conducting experiments and rearing purposes showed apple proliferation symptoms, we assume that the phytoplasmas were present in the tissue of all parts of these plants. Thus, a much higher infection rate of *C. picta* reared on these trees is expected. Why some females of *C. picta* are susceptible to phytoplasma infection while others are not remains to be elucidated. The psyllids that apparently were not able to transmit the disease (experienced, but uninfected) were attracted by the odor of uninfected apple trees.

Analysis of the plants' headspace by GC/MS revealed about 25 different volatile compounds during a sampling period of 45 d. While there were no significant differences among all other volatiles emitted by uninfected and infected plants (data not shown), only apple plants infected by *Ca.* P. mali emitted the sesquiterpene β-caryophyllene in higher amounts (Fig. 1b). Emission was highest from the beginning of headspace sampling (phenology stage 69; BBCH scale) and decreased during 29 d to 0 (phenology stage 72). After this time, nearly no β-caryophyllene was emitted until the end of the sampling time (45th day, phenology stage 79).

C. picta spends only a short period of its life (2–3 mo) exclusively on apple for reproduction (phenology stages 53–59) and juvenile development (reproduction host). Soon after hatching (phenology stages 69–71), newly emerged adults migrate onto conifers, spending the next 8–9 mo including winter time there (overwintering host). During the relatively short period on apple, the newly hatched adults of *C. picta* are able to ingest *Ca.* P. mali from infected plant phloem (acquisition feeding). Following a latent period, ingested phytoplasmas leave the intestinal tract of their vector, invade the hemolymph, multiply, and infect further tissues of the insect (Christensen et al. 2005). Finally, they intrude into the salivary glands, from which they can infect a new host plant (transmission feeding). Interestingly, the phytoplasma induces emission of β-caryophyllene from apple plants exactly between hatching and migration of its vector (Fig. 1b). According to our behavioral studies, vector insects that developed on uninfected plants were attracted by the odor of infected plants. The phytoplasma-induced change in odor composition may be the attracting signal for its vector to change orientation from uninfected to infected plants, and promote the uptake of phytoplasmas from the phloem. Additionally, infected psyllids are also attracted by infected plants, and that may ensure a longer insect feeding period from these plants, thus acquiring a higher titer of *Ca*. P. mali before shifting to their overwintering host.

In summary, the presented results support our hypothesis that the apple proliferation phytoplasma manipulates both odor of infected plants and behavior of vector insects to promote its propagation. Because experienced but uninfected psyllids show the opposite behavior to infected psyllids, the phytoplasma within the insect may affect behavior as well. These abilities are certainly of epidemiological relevance and will be studied further to understand the complex interactions between pathogens reproducing in distinct hosts. Thus, both laboratory and field experiments are in progress in order to confirm a direct attraction of β-caryophyllene to *C. picta*.

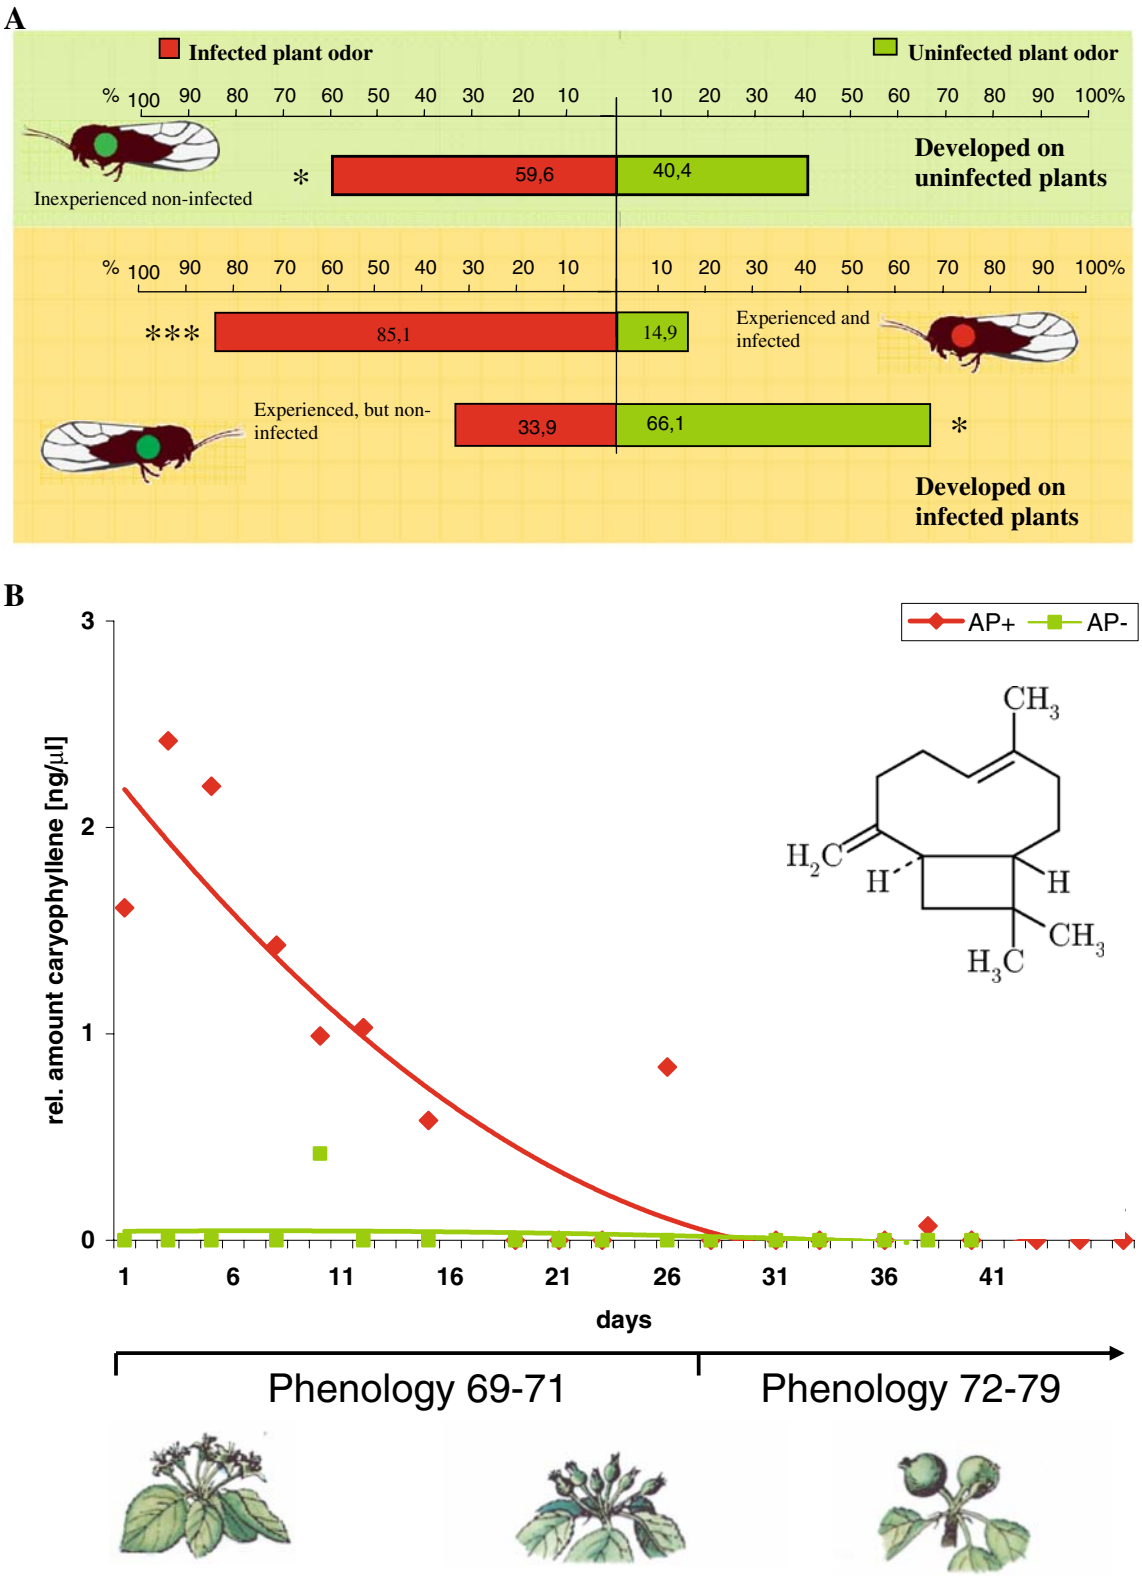

Fig. 1 **a** Olfactory preferences (%) of young adult females of *C. picta* to odors of phytoplasma infected apple vs. odors of uninfected apple. All preferences are statistically significant (dependent paired *t* test, *triple asterisk*, $P<0.001$; *asterisk*, $P<0.05$). **b** Means of relative amounts of β-caryophyllene emitted by infected plants (*red rhombs–darker gray*) compared to uninfected plants (*green squares—lighter gray*). The main emission occurs during the phenology stages 69–71 (BBCH scale: end of blooming [stage 69] until fruit diameter is about 10 mm [stage 71]) until day 28. *AP+* Apple infected by *Ca.* P. mali, *AP−* uninfected apple plant

plant species (Lesica and Miles 2004). Whereas beaver-caused mortality to poplar was extensive in this study (as high as 80% at some sites), beaver use of tamarisk was not observed at any of the ten study sites.

Tamarisk is considered undesirable forage because of low nutritive content and the presence of numerous polyphenolic compounds, including flavonoids, hydrolyzable and condensed tannins (Sharma and Parmar 1998). In addition, deciduous leaves of *Tamarix* species have elevated levels of sodium and salts of other alkali and alkaline earth metals present on the surface of the leaves in specialized glands (Kleinkopf and Wallace 1974). Sodium is one of many micronutrients required by herbivores. However, these nutrients are avoided when they are in excess (Villalba and Provenza 1996).

Mammalian species limit tannin intake when they lack the salivary proteins to bind tannins and render them innocuous (Hagerman and Robbins 1993). Beavers produce a single protein that binds to linear condensed tannins found in plants common to their diet (such as willow and poplar species) but not to branched condensed tannins (quebracho) or hydrolyzable tannins (Hagerman and Robbins 1993). Despite the presence of polyphenolics and highly elevated sodium chloride (NaCl) concentrations, a few mammalian herbivores are known to consume tamarisk. For example, goats can be enticed to consume tamarisk plants, and thus may represent a component of an integrated management plan for tamarisk removal (Richards and Whitesides 2006). Valley pocket gophers (*Thomomys bottae*) have been observed to forage tamarisk roots (Manning et al. 1996), and there have been anecdotal reports of beaver feeding on localized populations of tamarisk (Bergman, personal communication).

Diet preferences are strongly impacted by the post-ingestive consequences of food consumption (Provenza 1995). Phytochemicals that act on the sensory and gut systems of herbivores influence what plants or plant parts are eaten, when they are eaten, and how they are eaten. The poor palatability of tamarisk may be related, in part, to the nutritional status of the animal, hedonic qualities of the plant, and postingestive consequences that result from tannin binding of beneficial proteins. Supplements, analgesics, and masking agents can be used to minimize the antifeedant effects of tamarisk phytochemicals. For example, in humans, salty taste is reduced by addition of equimolar sucrose to salt solutions (Bartoshuk 1975). Astringency and postingestive effects of tannins can be reduced with polyethylene glycol (PEG), which irreversibly binds tannins and promotes intake of high tannin-containing plants by goats (Titus et al. 2001) and lambs (Titus et al. 2000). Accordingly, by alleviating or masking the negative attributes of tamarisk, one could promote its consumption by beavers.

Diet selection is influenced by the availability of food alternatives. The mere presence of multiple sources of the same food can drastically impact what foods are consumed and how much (Tordoff and Bachmanov 2003). Availability and nutritive quality of alternative foods influence the persistence of learned preferences (Kimball et al. 2002). Conversely, the limiting of foraging alternatives can be used to promote consumption of targeted food sources. In managed ecosystems, availability of desirable resources can be limited by exclusion (e.g., fences) and/or deterrent application (Nolte 1999). Thus, the application of an herbivore deterrent to desirable forage plants such as willow and poplar could promote tamarisk consumption by beavers.

A series of experiments was conducted with captive beavers to assess the feasibility of promoting consumption of tamarisk by altering its palatability with topical application of PEG and sugar and/or treatment of native plants with a deterrent.

Methods and Materials

Subjects Beavers were trapped in watersheds located near Olympia, WA, USA, and maintained in individual 3×5 m pens. The 1.5-m tall pen walls were clad with sheet metal. Each pen contained a 1,000-l corrugated steel water tank and insulated den box. Fresh water and a pelleted ration (Lab Diet 5012; PMI Nutrition International, Richmond, IN, USA) were provided in stainless steel food bowls. Diet enrichment consisted of apples, carrots, and dried corn on the cob. Animal procedures were approved by the National Wildlife Research Center (NWRC) Institutional Animal Care and Use Committee. All experiments were conducted during the period of June–August 2007.

Test diets Test and control diets were prepared commercially by Dyets (Bethlehem, PA, USA) with Purina Prolab RMH-1000, a commercial rat/mouse/hamster diet made from wheat, corn, and bone meal (as well as many other minor constituents, vitamins, and minerals). Maltodextrin and gum Arabic were added to both diets to confer integrity to the pellets in the wet environment anticipated in the pens. The control pellet was prepared with 15% cellulose (Dyets) (Table 1). All test pellets (approximately 45×12 mm diameter) were offered to the captive subjects in stainless steel food bowls.

Tamarisk leaves are high in tannins (Bailey et al. 2001), and sodium concentrations can far exceed 10% in plants growing in highly saline conditions (Kleinkopf and Wallace 1974). Leaf litter tannin content from *T. ramosissima* collected in Nevada, USA, was greater than 10% (Kennedy and Hobbie 2004). Thus, the tamarisk diet pellets contained

Table 1 Pelleted test diets used in two-choice tests with beavers

Ingredient	Control diet (%)	Tamarisk diet (%)
Purina RMH-1000	81	81
Cellulose	15	–
Sodium chloride (NaCl)	–	5
Quebracho tannin	–	10
Maltodextrin	2	2
Gum Arabic	2	2

10% quebracho tannin (Tannin, Peabody, MA, USA) and 5% NaCl (Aldrich Chemical, Milwaukee, WI, USA). Quebracho tannin was used in the formulation of the test diet for this study because beavers are physiologically incapable of binding branched condensed tannins with salivary proteins (Hagerman and Robbins 1993).

Plant cuttings Cuttings of black poplar (*Populus nigra*) and Scouler's willow (*Salix scouleriana*) were obtained locally near the Olympia, WA, USA, pen facilities. Tamarisk (*Tamarix ramosissima*) cuttings were collected from an invasive population located on the Saddle Mountain National Wildlife Refuge in Central Washington (USA). One meter cuttings were made from lateral branches such that the diameter at the base of the branch did not exceed 10 mm.

Cuttings were offered to captive beavers by placing them in specially constructed racks attached to the sides of each test pen. Each rack consisted of two galvanized fence top-rail tubes (5 cm diameter). The base rail was mounted 20 cm from the floor of the pen, and the upper rail 80 cm above the base rail. Twelve holes were drilled in both rails at identical locations such that the holes were spaced every 40 cm. Short lengths (7 cm) of 20 mm conduit were tack welded in the holes. One end of each cutting was placed into the conduit in the lower rail and threaded through the conduit in the upper rail. Wood dowels (15 mm diameter) were wedged into the conduit of the top rails to hold the cuttings securely in place.

Treatments Polyethylene glycol 3350 (VWR International, West Chester, PA, USA), fructose (Aldrich Chemical), and casein hydrolysate (HCA-411, American Casein, Burlington, NJ, USA) were used to treat pellets in multiple experiments. Pellets were soaked briefly in a 1.0% (*v*/*v*) solution of a latex sticker (Tactic®; Loveland Industries, Greeley, CO, USA), drained of excess sticker solution, and dusted with either casein hydrolysate (deterrent treatment) or 1:1 PEG/fructose (tamarisk treatment) at an application rate of 120 g treatment per kg pellet. Treated pellets were allowed to dry before offering to the test subjects. Plant cuttings were treated by spraying the leaves with the sticker solution and dusting with casein hydrolysate powder by hand.

Bioassay procedures Acclimation to the bioassay procedures was achieved by offering all subjects the training diet (Purina 5012 pellets) in single-choice tests commencing at 0800 hours daily. At the end of the 24-hr test period, test diets were removed and weighed to determine intake by difference and replacement made with fresh diets. Ten subjects (of 15 initially captured) that successfully acclimated to captive conditions and readily consumed the training diet for at least four consecutive days were retained for experiments 1–4. Two additional subjects were subsequently added for experiment 5.

Experiments 1–4 were each conducted for four consecutive days with position of diets (right, left) randomly assigned and alternated daily. Water was provided *ad libitum.* During intermission periods between experiments, subjects were provided *ad libitum* access to the basal diet (Lab Diets 5012) supplemented with apple, carrot, and/or dried corn. Experiments were conducted sequentially with the same test subjects.

In experiment 1, all subjects were offered the control (cellulose) and tamarisk (tannin and NaCl) diets in separate containers, whereas all subjects in experiment 2 were offered control and treated tamarisk (PEG and fructose treatment) diets in a similar two-choice test (Table 2). Daily intake (24-hr) of each diet was recorded, and preference scores were calculated to describe the proportion of tamarisk diet consumed in the two-choice tests (tamarisk diet intake divided by total intake).

All subjects in experiment 3 were offered control and deterrent-treated control (casein hydrolysate) diets while experiment 4 consisted of tamarisk (untreated) and deterrent-treated control (casein hydrolysate) diets in two-choice tests (Table 2). Preference scores were calculated from the intake data to describe the proportion of deterrent-treated control diet consumed. Mean tamarisk diet intake (g) in experiments 1, 2, and 4 was also calculated for graphical evaluation.

In experiment 5, subjects were assigned to one of two treatment groups such that training diet intake was similar between treatment groups. Two naïve subjects were included in experiment 5 (one per treatment group) for a total of 12 beavers. Subjects in the control group were

Table 2 Test diets and treatments offered to captive beavers in two-choice experiments

Experiment	Diet A	Diet B
1	Tamarisk diet	Control diet
2	PEG/fructose-treated tamarisk diet	Control diet
3	Deterrent-treated control diet	Control diet
4	Deterrent-treated control diet	Tamarisk diet

PEG: polyethylene glycol, *deterrent*: casein hydrolysate

offered four cuttings each of black poplar, Scouler's willow, and tamarisk. The 12 cuttings were randomly placed in the 12 rack locations. Subjects in the treatment group were similarly offered cuttings of the three plant species except that the black poplar and Scouler's willow cuttings were treated with casein hydrolysate. Consumption of plant cuttings was scored according to the following ordinal scale: 1, no evidence of browse; 2, sampled; 3, moderate browse; 4, completely browsed. Plant cuttings were offered for 24 hr on four consecutive days. Cuttings were replaced at the end of each 24-hr period regardless of browse activity, and new random positions were assigned daily.

Statistical analyses For each of the two-choice tests, preference scores were rank transformed within subjects so that day and diet position (right or left position of the diet referred as the proportion) were analyzed as fixed effects by analysis of variance (ANOVA). Mean preference scores for each subject were compared to values of 0.5 (indifference) for each experiment by *t*-test according to the procedures described by Willink (2005) for skewed data.

Browse scores from experiment 5 were subjected to a three-way ANOVA with treatment (control or deterrent treatment), species (willow, poplar, or tamarisk), and day considered fixed effects. Multiple comparisons of least-square means were made by controlling false discovery rate (Benjamini and Hochberg 1995). All statistical analyses were performed with SAS (Cary, NC, USA).

Results

ANOVA results from all two-choice tests indicated that neither test day nor diet position impacted diet preferences. Therefore, mean preference scores were examined to determine preferences for the test diets in experiments 1–4.

In experiment 1, the mean proportion of tamarisk diet consumed by the ten beavers was 0.46, indicating that tamarisk diet intake did not significantly differ from the control (P=0.38; Fig. 1). Treatment of the tamarisk diet with fructose and PEG did not increase the proportion of tamarisk diet consumed in experiment 2. The proportion (relative to the control diet) of treated tamarisk diet consumed was 0.39 (P=0.21; Fig. 1).

Avoidance of casein hydrolysate was demonstrated in experiment 3. The proportion (relative to the untreated control alternative) of casein hydrolysate-treated control diet was 0.024, which was significantly less than 0.5 (P< 0.001; Fig. 1). However, when the alternative food choice was tamarisk diet in experiment 4, the proportion of deterrent-treated diet consumption increased to 0.44, indicating that tamarisk diet intake did not significantly differ from the casein hydrolysate diet (P=0.19; Fig. 1). The tamarisk diet intake data from experiments 1, 2, and 4 suggest a maximum intake that could be tolerated in a 24-hr feeding period, regardless of treatment or the alternative food choice (Fig. 2).

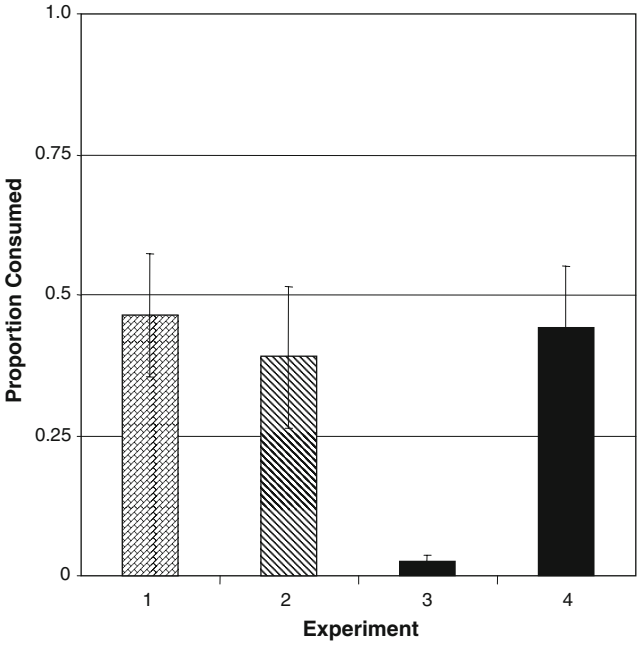

Fig. 1 Preference scores (mean+SE; N=10) for experiments 1–4 describing the proportion of test diet consumed (*crosshatched bars* untreated tamarisk diet, *diagonally hatched bars* sugar/PEG-treated tamarisk diet, *black bars* deterrent-treated control diet) in two-choice tests. The alternative diet for experiments 1–3 was untreated control. The alternative for experiment 4 was untreated tamarisk diet. A preference score of 0.5 indicates indifference. Results of *t*-tests indicated that only the casein hydrolysate preference score in experiment 3 was significantly less than 0.5 (P<0.001)

ANOVA results from experiment 5 demonstrated that browse score (i.e., preference for plant cuttings) was a function of test day (P=0.018), plant species (P<0.0001), and the species×treatment interaction (P=0.001). Browse scores were lower on day 4 of the test vs. days 1 or 3. Among the control group, foraging preference for the plants followed the order: willow>poplar>tamarisk (Fig. 3). However, deterrent treatment of willow and poplar promoted increased browsing of tamarisk and resulted in no significant preferences among the three species (Fig. 3).

Discussion

Herbivore preferences for various plant species are a function of maximizing nutritional benefits while at the same time limiting intake of plant secondary metabolites. For example, beavers strongly preferred aspen (*Populus tremuloides*) over red maple (*Acer rubrum*) in cafeteria tests despite having similar energy, protein, and fiber values (Doucet and Fryxell 1993). Differences in the palatability

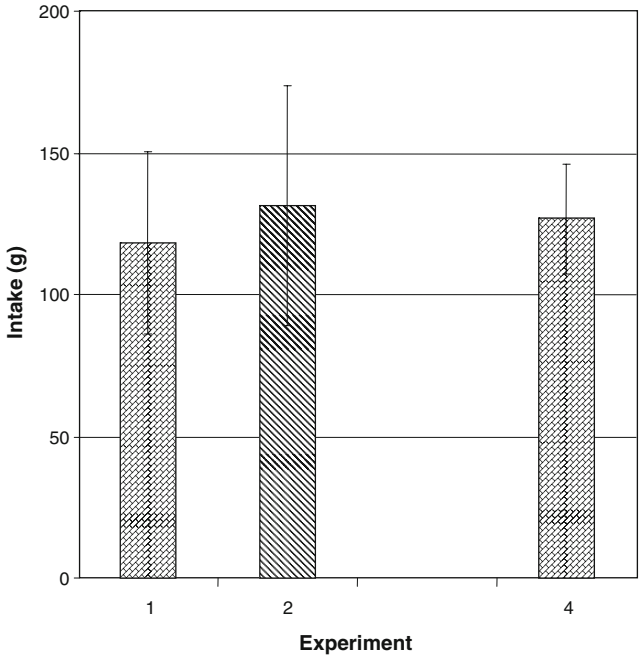

Fig. 2 Tamarisk diet intake (g) from experiments 1, 2, and 4 (mean+SE; N=10). The alternative diet for experiments 1 and 2 was untreated control diet. The alternative diet in experiment 4 was deterrent (casein hydrolysate)-treated control diet (*crosshatched bars* untreated tamarisk diet, *diagonally hatched bars* sugar/PEG-treated tamarisk diet)

of these species were a consequence of phenolic content, not absolute nutritional quality (Muller-Schwarze et al. 1994). Tamarisk can contribute to the nutritional needs of herbivores capable of tolerating the phenolics and NaCl present in the foliage. On a dry matter basis, tamarisk foliage contains approximately 13 kJ/g digestible energy, 21% crude protein, and 16% crude fiber (Kimball, unpublished data).

Tamarisk diet constituted one-half of the total consumption by beavers in experiment 1. Treatment with fructose (to suppress salt flavor) and PEG (to bind tannins) did not promote greater consumption of tamarisk diet in experiment 2. The lack of day effect in these experiments indicates that tamarisk diet intake limitation was not a function of conditioned aversion. It is possible that the high osmolality of the tamarisk diet contributed to fixing a maximum allowable intake (Fig. 2). Although mammals are well-equipped to excrete excess sodium with sufficient water consumption, NaCl satiety can result from hyperosmolality and/or dehydration (Stricker and Verbalis 1991).

It is unclear why treatment with PEG in experiment 2 did not promote greater consumption of the tamarisk diet via tannin binding. It is possible that the PEG concentration was not sufficient for the tannin content of the tamarisk diet. Beavers demonstrated the ability to consume significant quantities of tamarisk diet in the absence of PEG treatment despite lacking salivary proteins to bind quebracho tannin (Hagerman and Robbins 1993). Similarly, goats (also incapable of binding quebracho tannins) consumed significant quantities of tannin-containing foods when given experience with the food (Distel and Provenza 1991). In another study, the alteration of exposure to tannin-containing foods with nontannin foods on an every-other-day basis permitted goats to consume greater quantities of tannin diets vs. subjects offered tannin diet exclusively (Kimball and Nolte 2005). Thus, the presence of a tannin-free alternative food in the two-choice tests may have allowed beavers to maximize tannin intake.

In addition to physiological processes for tolerating phytochemicals (e.g., salivary proteins for tannin binding), herbivores can employ a variety of behavioral approaches to manipulate forage palatability. For example, beavers have been observed to soak branches in water, thus leaching phenolics that contribute to poor palatability (Muller-Schwarze et al. 2001). Diet mixing is another method herbivores employ that minimizes consumption of specific plant toxins and antifeedants (Freeland and Janzen 1974). This is a particularly efficient strategy when the various phytochemicals encountered are complimentary (Burritt and Provenza 2000). Toxic phytochemicals are considered complimentary when they act on different physiological systems in the herbivore—allowing the animal to consume greater quantities of the different foods in total than they could of any individual food item. Limiting intake of a

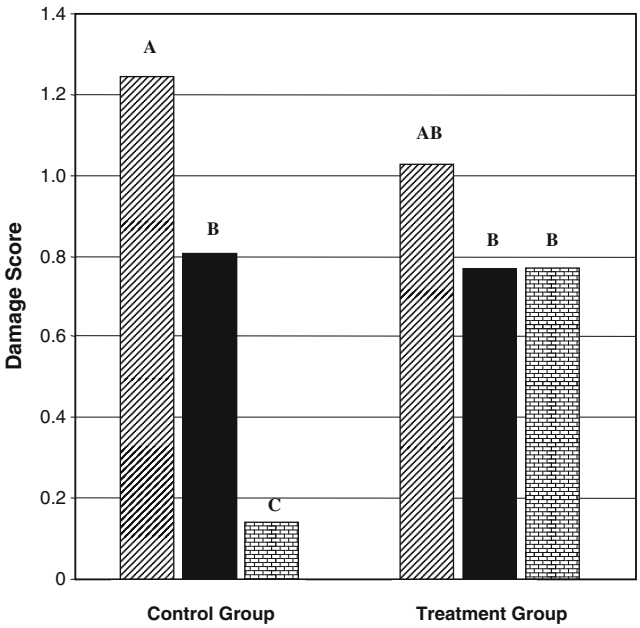

Fig. 3 Species×treatment interaction from the three-way ANOVA of browse scores demonstrates treatment effect on preferences of beavers (N=12) for plant cuttings in cafeteria tests (P=0.001). Casein hydrolysate was applied topically to willow and poplar cuttings in the treatment group. *Different letters* indicate significant differences among damage scores (multiple comparisons) made according to the method of Benjamini and Hochberg 1995) (*diagonally hatched bars S. scouleriana*, *black bars P. nigra*, *crosshatched bars T. ramosissima*)

particular food or phytochemical is not the only regulatory process used by herbivores while foraging. Although few studies have specifically monitored meal patterns, a recent study with ringtail possum demonstrated that intake rate and feeding time are altered in addition to total intake, thus regulating the consumption of deleterious phytochemicals (Wiggins et al. 2006).

Beavers strongly avoided the casein hydrolysate treatment when the control diet was the alternative food (experiment 3; Fig. 1). Avoidance of casein hydrolysate is predictable for most herbivores. Deer (Kimball et al. 2005), mountain beavers, pocket gophers (Figueroa et al. 2008), and guinea pigs (Field, personal communication) have shown strong avoidance responses to casein hydrolysate in single-choice tests. Beavers also avoid plants treated with commercial herbivore deterrents that contain egg or blood products (DuBow 2000).

When tamarisk diet was the alternative food, beavers no longer avoided the casein hydrolysate treatment (experiment 4, Fig. 1). Ironically, protein binding may have contributed to the reduction of casein hydrolysate repellency via diet mixing. Although PEG–tannin binding had no influence on tamarisk diet palatability in experiment 2, tannin–protein binding may have rendered casein hydrolysate more palatable in experiment 4. Self-medicating behavior (in this case, consumption of tannin-containing tamarisk diet that renders the deterrent-treated control diet more palatable) is common among herbivores. In fact, self-regulated PEG intake is the mechanism that makes its use practical in arid rangelands to promote consumption of high-tannin forages (Titus et al. 2000, 2001).

The cafeteria test with plant cuttings (experiment 5) demonstrated that willow was the preferred tree species tested (Fig. 3). In the absence of a deterrent treatment, there was little damage recorded to tamarisk cuttings. Because plant cuttings were not available *ad libitum*, use of tamarisk by the control group was likely influenced by unavailability of the preferred plants as they were exhausted. Deterrent treatment of willow and cottonwood with casein hydrolysate similarly reduced the availability of preferred plants, resulting in a significant increase of tamarisk use (Fig. 3).

Results of this study suggest that deterrent treatment of desirable plant species in wetland areas will facilitate foraging of invasive plants by beavers, including tamarisk. However, maximum intake of tamarisk may be regulated by processes that cannot be circumvented by PEG treatment or supplementation. It is important to emphasize that increased tamarisk consumption by beavers in natural areas holds no promise of tamarisk eradication. Rather, significant use of tamarisk by beavers may decrease the removal of native species and allow natural resources managers to meet management goals in the presence of these efficient ecosystem engineers.

Acknowledgements Mention of specific products does not constitute endorsement by the United States Department of Agriculture. This research was made possible by funding from the City of Phoenix (AZ) Tres Rios Demonstration Wetlands project. Drs. Alexander Bachmanov and Glen Golden provided useful reviews of early drafts of this manuscript. The assistance of Sean Lamb with the bioassays was greatly appreciated. Access to tamarisk plants at the Saddle Mountain National Wildlife Refuge was made possible by the cooperation of the US Fish and Wildlife Service. We are specifically grateful for the assistance of Heidi Newsome (USFWS).

led to the discovery of sex attractants for more than 90 species in highly evolved families (Ando 2008; El-Sayed 2008).

In Type II pheromone components, further structural modification of the dietary fatty acids is expected because of the species diversity in the families such as the Arctiidae and Geometridae. The 6,9-dienes, 3,6,9-trienes, and their epoxy derivatives might be insufficient to produce blends for the many species in these families. In fact, the first pheromone identified from a geometrid species was a 1,3,6,9-tetraene (Bestmann et al. 1982; Roelofs et al. 1982). In addition, hydrocarbons unsaturated at the 11-position and their epoxy derivatives have been characterized as pheromone components in some species (Ando et al. 2004). Since the pheromone content in a gland is quite low, it is not easy to determine the structure of these compounds even when modern analytical instruments are used. In pheromone studies, synthetic pheromone candidates generally play an important role; for example, they are used as the authentic standard in gas chromatography-mass spectrometry (GC-MS) analyses. Identification can be accomplished by comparing the retention time (Rt) values as well as the mass spectra of natural and synthetic compounds. If the synthetic standard is unavailable and a direct comparison is impossible, the published diagnostic ions would contribute to the analysis of a natural pheromone.

We have studied Type II pheromones by utilizing synthetic 6,9-dienes and 3,6,9-trienes (Ando et al. 2004). However, because the chemical data of other polyunsaturated hydrocarbons are still limited, in this study we synthesized the compounds with a 6,9,11-, 3,6,9,11-, or 1,3,6,9-polyene system in a C_{17}–C_{21} chain and report on their spectroscopic data. For the former two polyenes, we targeted geometrical isomers with an (*E*)-double bond at the 11-positon, since preparation was easily accomplished by a Wittig reaction utilizing (*E*)-2-alkenals. Furthermore, we carried out random screening tests of synthetic polyenes in the field to find new sex attractants for the Lepidoptera.

Methods and Materials

Analytical Instruments ^{1}H and ^{13}C NMR spectra were recorded by a Jeol Alpha 500 Fourier transform spectrometer (JEOL Ltd., Tokyo, Japan) at 500.2 and 125.7 MHz, respectively, for $CDCl_3$ solutions containing tetramethylsilane (TMS) as an internal standard. ^{1}H–^{1}H COSY, HSQC, and HMBC spectra were also measured with the same spectrometer with the usual pulse sequences and parameters. GC-MS was conducted in the EI mode with an HP 5973 mass spectrometer (Hewlett-Packard, Wilmington, DE, USA) equipped with a DB-23 capillary column (0.25 mm ID×30 m, 0.25 μm film thickness, J & W Scientific, Folsom, CA, USA). The column temperature program was 50°C for 2 min, 10°C/min to 160°C, and 4°C/min to 220°C. A split/splitless injector was used in the splitless mode for 1 min and kept at 220°C. The ionization voltage was 70 eV, and the flow rate of the carrier gas (He) was 1.0 ml/min. IR spectra were recorded as a thin film (neat liquid) with a Jasco FT/IR-350 (JASCO Corporation).

Chemicals The chemical structures of polyunsaturated hydrocarbons are abbreviated as follows: Z = (*Z*)-double bond, *E* = (*E*)-double bond, number before the hyphen = position of the double bond, number after the hyphen = carbon number of the straight chain, and H = compound without a terminal functional group. The trienes and tetraenes with a C_{17}–C_{21} chain were prepared by the following procedures (Fig. 1).

*1-Iodo-(Z)-3-nonene (***2a***)* Solutions of triphenylphosphine (4.5 g, 17 mmol) and imidazole (1.2 g, 17 mmol) with dry

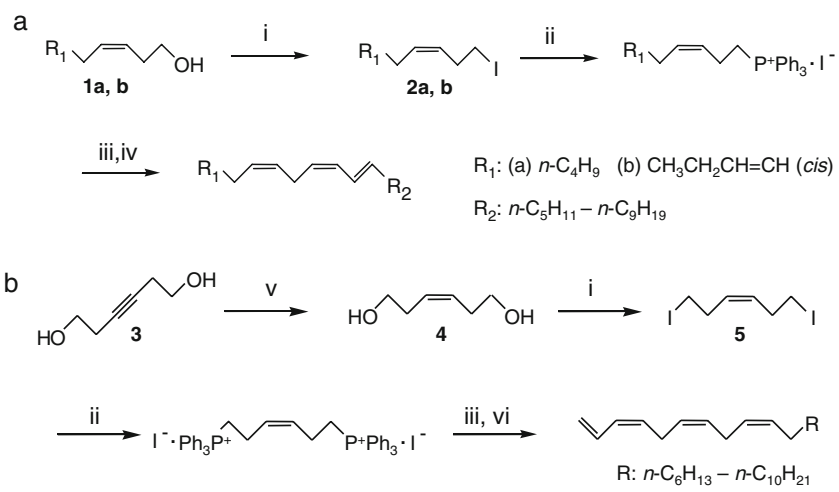

Fig. 1 Synthesis of polyunsaturated hydrocarbons with a C_{17}–C_{21} straight chain. (**a**) (*Z,Z,E*)-6,9,11-trienes and (*Z,Z,Z,E*)-3,6,9,11-tetraenes, and (**b**) (*Z,Z,Z*)-1,3,6,9-tetraenes. *i*, I_2-PPh_3/imidazole; *ii*, PPh_3/benzene; *iii*, $NaN(SiMe_3)_3$/THF; *iv*, R_2CH=CHCHO (*E*); *v*, H_2/Pd-$BaSO_4$/quinoline; and *vi*, acrolein and RCH_2CHO

ether (45 ml) and CH_3CN (15 ml), I_2 (4.4 g, 17 mmol) were mixed by stirring at 0°C under N_2 gas, and the mixture was warmed to room temperature. After 15 min of stirring, the solution was cooled again to 0°C and added dropwise to (*Z*)-3-nonen-1-ol (**1a**, 2.0 g, 14 mmol) dissolved in dry ether (3 ml). After 2 hr of stirring at room temperature, the precipitates were filtered. The eluent was poured into water, and crude products were extracted with hexane, washed with an aqueous solution of $Na_2S_2O_3$, and dried with Na_2SO_4. After evaporation of the extract, the residue was chromatographed on a silica gel column to give **2a** (3.2 g, 12 mmol) in 86% yield. ^{1}H NMR (δ, ppm): 0.89 (3H, t, *J*= 7 Hz), ~1.3 (6H, m), 2.02 (2H, td, *J*=7, 7 Hz), 2.63 (2H, td, *J*=7, 7 Hz), 3.13 (2H, t, *J*=7 Hz), 5.31 (1H, dtt, *J*=11, 7, 1.5 Hz), 5.53 (1H, dtt, *J*=11, 7, 1.5 Hz). ^{13}C NMR (*δ*, ppm): 5.5, 14.1, 22.5, 27.4, 29.2, 31.49, 31.53, 127.7, 132.7. IR (λ_{max} cm^{-1}): 3008, 2955, 2925, 2855, 1464, 1241, 1168, 725.

*1-Iodo-(3Z,6Z)-3,6-nonadiene (***2b***)* By the same procedure for **2a**, dienyl iodide (**2b**) was synthesized from (*Z,Z*)-3,6-nonadien-1-ol (**1b**) in 88% yield. ^{1}H NMR (*δ*, ppm): 0.98 (3H, t, *J*=7.5 Hz), 2.07 (2H, td, *J*=7.5, 7.5 Hz), 2.66 (2H, td, *J*=7.5, 7.5 Hz), 2.78 (2H, dd, *J*=7.5, 7.5 Hz), 3.14 (2H, t, *J*=7.5 Hz), 5.30 (1H, dtt, *J*=11, 7.5, 1.5 Hz), 5.35 (1H, dtt, *J*=11, 7.5, 1.5 Hz), 5.40 (1H, dtt, *J*=11, 7.5, 1.5 Hz), 5.52 (1H, dtt, *J*=11, 7.5, 1.5 Hz). ^{13}C NMR (*δ*, ppm): 5.2, 14.2, 20.6, 25.7, 31.4, 126.3, 127.8, 130.6, 132.1. IR (λ_{max} cm^{-1}): 3053, 3010, 2962, 2929, 1655, 1433, 1240, 1169, 742, 696, 501.

(E)-2-Alkenals (*E*)-2-Octenal and (*E*)-2-nonenal were purchased from Sigma-Aldrich Co. (Milwaukee, WI, USA). (*E*)-2-Decenal, (*E*)-2-undecenal, and (*E*)-2-dodecenal were synthesized from octanal, nonanal, and decanal, respectively, by an established method including the following three steps (Nishida et al. 2003); a coupling reaction with methoxycarbonylmethylenetriphenylphosphorane, reduction with $LiAl(OC_2H_5)_2H_2$, and oxidation with pyridinium chlorochromate. The following nuclear magnetic resonance (NMR) data were commonly obtained for the (*E*)-2-alkenals. ^{1}H NMR (*δ*, ppm): 9.50 (1H, d, *J*=8 Hz, C-1), 6.12 (1H, dd, *J*=15.5, 8 Hz, C-2), 6.86 (1H, dt, *J*=15.5, 7 Hz, C-3), 2.33 (2H, dt, *J*=7, 7 Hz, C-4). ^{13}C NMR (*δ*, ppm): 194.2 (C-1), 133.0 (C-2), 159.0 (C-3), 32.7 (C-4).

(6Z,9Z,11E)-6,9,11-Trienes and (3Z,6Z,9Z,11E)-3,6,9,11-Tetraenes A mixture of **2a** (250 mg, 1.0 mmol), triphenylphosphine (260 mg, 1.0 mmol), and dry benzene (10 ml) was heated under refluxing for 12 hr. After cooling, phosphonium salt was washed with benzene. The salt dissolved in dry tetrahydrofuran (THF, 5 ml) and hexamethylphosphoramide (HMPA, 0.2 ml) was stirred at −35°C under Ar gas, and then $NaN(SiMe_3)_2$ (1 M in THF, 1.0 ml) was added dropwise to the solution to make an ylide. After stirring at room temperature for 30 min, the ylide solution was cooled to −35°C again, and (*E*)-2-octenal (150 mg, 1.2 mmol) in THF (2.0 ml) was added dropwise to it to couple with the ylide. The mixture was further stirred at room temperature for 1 hr and poured into water. Crude products were extracted with hexane, washed successively with 1 N HCl and a saturated aqueous solution of $NaHCO_3$, and then chromatographed on a silica gel column impregnated with $AgNO_3$ with hexane and mixtures of hexane and benzene as eluents. Z6,Z9,E11-17:H (180 mg, 0.77 mmol, >95% purity) was obtained in 76% yield. Other 6,9,11-trienes (>95% purity) with a C_{18}–C_{21} chain were prepared with (*E*)-2-alkenal with a C_9–C_{12} chain in the same manner and more than 60% yield. The 3,6,9,11-tetraenes (>95% purity) were synthesized by the same coupling reaction between the ylide derived from dienyl iodide (**2b**) and (*E*)-2-alkenal with an appropriate carbon chain in the similar yield.

*(Z)-3-Hexene-1,6-diol (***4***)* Pb-$BaSO_4$ (200 mg) and quinoline (10 mg) were added to 3-hexyne-1,6-diol (**3**, 2.5 g, 22 mmol) dissolved in methanol (20 ml). The mixture was stirred at room temperature under positive pressure of H_2 gas for 1 hr. The reaction mixture was filtered, and the eluent was concentrated *in vacuo* to give the olefinic compound (**4**, 2.3 g, 20 mmol) in 91% yield. ^{1}H NMR (*δ*, ppm): 2.31 (4H, td, *J*=7, 4.5 Hz), 3.56 (4H, t, *J*=7 Hz), 5.49 (2H, t, *J*=4.5 Hz). ^{13}C NMR (*δ*, ppm): 31.6, 62.5, 129.8. IR (λ_{max} cm^{-1}): 3338, 3012, 2952, 2879, 1707, 1425, 1049, 723.

*1,6-Diiodo-(Z)-3-hexene (***5***)* The diol (**4**, 2.3 g, 20 mmol) was transferred to diiodide (**5**) by the same procedure for **2a** with two equivalent amounts of the reagents and solvents. The crude products were chromatographed on a silica gel column to give **5** (5.4 g, 16 mmol) in 80% yield. ^{1}H NMR (*δ*, ppm): 2.64 (4H, td, *J*=7, 4.5 Hz), 3.17 (4H, t, *J*=7 Hz), 5.50 (2H, t, *J*=4.5 Hz). ^{13}C NMR (*δ*, ppm): 4.9, 31.5, 130.4. IR (λ_{max} cm^{-1}): 3008, 2954, 1421, 1240, 1169, 717.

(3Z,6Z,9Z)-1,3,6,9-Tetraenes Phosphonium salt of diiodide (**5**) was prepared in the same manner as the salt of **2a**. The salt of **5** (1.3 g, 1.5 mmol) in dry THF (10 ml) and HMPA (1.0 ml) was mixed with $NaN(SiMe_3)_2$ (1 M in THF, 3.0 ml) at −80°C under Ar gas to make bis(ylide), which was further treated with a mixture of acrolein (84 mg, 1.5 mmol) and octanal (190 mg, 1.5 mmol) dissolved in THF (2.0 ml). After stirring at room temperature for 3 hr, the crude products were extracted with hexane, cleaned by the usual workup, and chromatographed on a silica gel column impregnated with $AgNO_3$ using hexane and mixtures of

hexane and benzene as eluents. 1,Z3,Z6,Z9-17:H (74 mg, 0.32 mmol, >95% purity) was obtained in 21% yield. Using the phosphonium salt of **5**, other 1,3,6,9-tetraenes with a C_{18}–C_{21} chain (>95% purity) were prepared by treatment with a mixture of acrolein and an aldehyde with a C_9–C_{12} chain in about 20% yield.

Field Tests In 2004 and 2005, synthetic polyenes were tested for behavioral activity at a mixed forest area in the suburbs of Tokyo (Rolling Land Laboratory, Tokyo University of Agriculture and Technology, Hachioji-shi, Tokyo) and on the Iriomote Islands. Rubber septa (white rubber, o.d. 8 mm, Sigma-Aldrich, St. Louis, MO, USA) were used as dispensers, and 1 mg of each compound dissolved in hexane (100 μl) was applied to them. Each lure was placed at the center of a sticky board trap (30×27 cm bottom plate with a roof, Takeda Chem. Co., Tokyo, Japan), which was set separately by at least 10 m at about 1.5 m above the ground. Two traps were used for each synthetic polyene, and two other traps included septa treated with 100 μl hexane as controls. Field evaluation of each lure was carried out for at least 12 mo. The lures were renewed every 3 mo, and the number of captured males was counted every 2 wk.

Results

Synthesis (*Z,Z,E*)-6,9,11-Trienes and (*Z,Z,Z,E*)-3,6,9,11-tetraenes were synthesized starting from (*Z*)-3-nonen-1-ol (**1a**) and (*Z,Z*)-3,6-nonadien-1-ol (**1b**), respectively, (Fig. 1a). After conversion of these alcohols into iodides (**2a** and **b**), their phosphonium salts were prepared. The ylide derived from each salt was treated with (*E*)-2-alkenal with a C_8–C_{12} chain to yield the objective C_{17}–C_{21} polyunsaturated hydrocarbons. Since HMPA was used as a co-solvent for the Wittig reaction, the production of the undesired (*Z,E,E*)- or (*Z,Z,E,E*)-isomers was restrained under 10%. Finally, column chromatography with silica gel impregnated with $AgNO_3$ gave the pure polyenes. (*Z,Z,Z*)-1,3,6,9-Tetraenes were synthesized by modifying the method reported by Pohnert and Boland (2000) (Fig. 1b). Restricted hydrogenation of 3-hexyn-1,6-diol (**3**) (Eya et al. 1990) gave (*Z*)-3-hexen-1,6-diol (**4**), which was halogenated to 1,6-diiodo-(*Z*)-3-hexene (**5**). Bis(ylide) was prepared from **5** after preparation of the phosphonium salt and coupled with acrolein and an alkanal with a C_8–C_{12} chain to yield the objective tetraenes with a C_{17}–C_{21} chain. In addition to targeting the (*Z*)-tetraenes, this one-pot double-Wittig reaction produced undesired geometrical isomers with an *E* configuration and symmetric products that included two molecules of acrolein or alkanal. The pure tetraenes were obtained after the chromatography of silica gel impregnated with $AgNO_3$.

NMR Analysis The structures of synthetic polyunsaturated hydrocarbons were confirmed by NMR analysis. The ^1H and ^{13}C signal assignments of the polyenes with a C_{19} chain were achieved by two-dimensional experiments (Table 1). The configurations at the conjugated dienyl part of each compound were revealed by coupling constants between two vicinal olefinic protons, i.e., $J_{9,10}$ (11 Hz) and $J_{11,12}$ (15–15.5 Hz) of Z6,Z9,E11-19:H and Z3,Z6,Z9,E11-19:H, and $J_{3,4}$ (11 Hz) of 1,Z3Z6,Z9-19:H. The *J* values of the (*E*)-double bonds were larger than those of the (*Z*)-double bonds. The (*Z*)-double bond at the 6-position of Z6,Z9,E11-19:H and Z3,Z6,Z9,E11-19:H was also confirmed by $J_{6,7}$ (10.5–11 Hz). The configurations of the other double bonds at the 3-position of Z3,Z6,Z9,E11-19:H and the 6- and 9-positions of 1,Z3Z6,Z9-19:H were not determined by the ^1H NMR analysis because the signals of these olefinic protons overlapped with each other; however, the chemical shifts of their allylic carbons indicated their Z configurations. The allylic carbons of a (*Z*)-double bond resonate in a higher field (about 5 ppm) than those of an (*E*)-double bond (Ando et al. 1983), and the carbon signal at the 2-position of (*Z,Z,Z*)-3,6,9-trienes appeared at 20.6 ppm, whereas those at the doubly allylic 5- and 8-positions appeared at 25.6 ppm (Ando et al. 1993). The chemical shifts of the allylic carbons (Table 1) indicate that all of the unconjugated double bonds have Z configurations. Furthermore, the dienyl parts in the ^{13}C spectra of the (*Z,Z,E*)-6,9,11-trienes and (*Z,Z,Z,E*)-3,6,9,11-tetraenes are similar to a (*Z,E*)-isomer of conjugated dienes and those of the (*Z,Z,Z*)-1,3,6,9-tetraenes are similar to a (*Z*)-isomer of terminal conjugated dienes, reflecting the characteristic common structures (Ando et al. 1983).

GC-MS Analysis Analysis of each synthetic polyene (GC-MS equipped with a DB-23 column) yielded retention times (Rt) and Kovat's retention indices (RI) of the polyenes with a C_{17}, C_{19}, or C_{21} chain (Table 2). The effluent from the polar column is regularly delayed as the number of double bonds increases. The RI values of the (*Z,Z*)-6,9-dienes increase by about 55 with the introduction of one unconjugated (*Z*)-double bond and by about 130 with that of one conjugated (*E*)-double bond. In the case of (*Z,Z,Z*)-3,6,9-trienes, an increment of 120–130 was observed by desaturation to the tetraenes. The introduction of one conjugated double bond at the 11-position affected the effluent more strongly than that of one at the 1-position. The intensity of M^+ of the 6,9,11-trienes was remarkably larger than that of the 3,6,9,11- and 1,3,6,9-tetraenes (Table 3). A series of spectra measured with the polyenes with a different carbon chain was analyzed in reference to published spectral data of the 6,9-dienes and 3,6,9-trienes (Ando et al. 1993; Millar 2000), and some diagnostic fragment ions were proposed for each polyene (Fig. 2).

Table 1 ^{1}H and ^{13}C NMR assignments for C_{19} polyenes

While the polyenes synthesized in this study universally showed a base peak at *m/z* 79, the structure of each compound was estimated by different diagnostic ions at the following values: *m/z* 110, 163, and M-85 of the 6,9,11-trienes, *m/z* 108 and M-82 of the 3,6,9,11-tetraenes, and *m/z* 91, 106, and M-54 of the 1,3,6,9-tetraenes. These ions would help to identify natural components in a pheromone extract.

Attraction of Lepidopteran Males In field screening tests of the synthetic polyenes, the compounds were presented as single component lures. Four species in the family of Geometridae were attracted in a forest in Tokyo: *Culpinia diffusa* Walker by Z6,Z9,E11-17:H, *Wilemania nitobei* Nitobe by Z3,Z6,Z9,E11-19:H, *Inurois fletcheri* Inoue by Z3,Z6,Z9,E11-20:H, and *Operophtera rectipostmediana* Inoue by 1,Z3,Z6,Z9-19:H (Table 4). In the Iriomote

Islands, one species in the family of Noctuidae was attracted by 1,Z3,Z6,Z9-19:H, but the taxon was not determined to species. Furthermore, in the case of 1,Z3, Z6,Z9-19:H, its binary mixture with Z3,Z6,Z9-19:H was examined. The response of males of the two species to the tetraene was decreased by including the triene in the lure (data not shown).

Discussion

In our previous random screening tests, the specific attraction of male moths was observed for three species by 6,9-dienes with a C_{17}–C_{21} chain and seven species by 3,6,9-trienes with a C_{18}–C_{21} chain (Ando et al. 1993, 1995). In addition, the field evaluation of 6,9,11-trienes and 3,6,9,11- and 1,3,6,9-tetraenes with a C_{17}–C_{21} chain, which were systematically synthesized by two routes in this study (Fig. 1), revealed the attraction of five other lepidopteran species (Table 4). Four of them belong to the family of Geometridae. To date, female-produced sex pheromones of 43 species and male attractants of 76 species have been reported in the Geometridae (Ando 2008). In this family, however, the chemical communication of the insects in the genera *Culpinia* and *Wilemania* has not been reported (Ando 2008; El-Sayed 2008). The male attractants of *C. diffusa* and *W. nitobei* are the first ones in these genera, indicating the significance of devising a screening test for the study of lepidopteran sex pheromones. Moreover, this study evaluated 6,9,11-trienes as a new pheromone candidate. While *trans*-11,12-epoxy-(*Z,Z*)-6,9-henicosadiene (posticlure), which is expected to be biosynthesized *via* Z6,Z9,E11-21:H, has been identified from *Orgyia postica* (Lymantriidae) (Wakamura et al. 2001, 2005), no 6,9,11-trienes have been identified as a pheromone component. The field attraction of the *C. diffusa* males by Z6,Z9,E11-17:H suggests that the 6,9,11-trienes are utilized as a cue for the mating communication of some species in highly evolved lepidopteran families.

The *W. nitobei* males were attracted by Z3,Z6,Z9,E11-19:H, which has been identified from *Alsophila pometaria* (Geometridae: Oenochrominae) (Wong et al. 1984). Among the 3,6,9,11-tetraenes, the C_{20} compound attracted another geometrid species, i.e., *Inuroi fletcheri* males were attracted by Z3,Z6,Z9,E11-20:H, which has not been identified from any insects. The genus *Inuroi* is one of the groups of winter moths, whose females are wingless or have degraded wings. This genus includes nine species in Japan, and our previous study determined the male attraction of two other *Inuroi* species, *I. fumosa* and *I. membranaria*, by *cis*-3,4-epoxy-(*Z,Z*)-6,9-henicosadiene (Ando et al. 1993).

The 1,3,6,9-tetraenes have been more widely studied. 1, Z3,Z6,Z9-19:H is a pheromone component of *Operophtera* spp. (Geometridae: Larentiinae), *O. brumata* (Bestmann et al. 1982; Roelofs et al. 1982), *O. bruceata* (Underhill et al. 1987), and *O. fagata* (Szöcs et al. 2004), and 1,Z3,Z6,Z9-21:H is a component of *Epirrita autumnata* (Geometridae: Larentiinae) (Zhu et al. 1995) and three species in the Arctiidae, *Utetheisa ornatrix* (Jain et al. 1983), *Arctia villica* (Einhorn et al. 1984), and *Pareuchaetes pseudoinsulata* (Frérot et al. 1993). The genus *Operophtera* is another group of winter moths. The above three species, whose sex pheromones have been identified, do not inhabit Japan. *Operophtera brumata* had been recognized as a species inhabiting Japan, but the taxon identified as *O. brumata* in Japan is now defined to be *O. brunnea* or *O. variabilis*. These two species were not attracted in our field tests with 1,Z3,Z6,Z9-19:H, the sex pheromone of *O. brumata*. Rather, *O. rectipostmediana* males were captured by this tetraene in our study. Seven *Operophtera* species inhabit Japan, and our previous experiment revealed the male attraction of *O. relegata* by *cis*-9,10-epoxy-(*Z,Z*)-3,6-nonadecadiene (Qin et al. 1997).

Our field evaluation was carried out in a limited number of places. To clarify the diversity of lepidopteran Type II

pheromones further, it is necessary to conduct screening tests in many different areas and environments and observe the male attraction of many species. Moreover, this study dealt with only polyunsaturated hydrocarbons. Since their epoxy derivatives are also expected to be the pheromone components of some species in highly evolved families, such as Geometridae, we intend to systematically prepare them and examine their activity in the field. In addition to knowledge of the attractants, this study also accumulated chemical data of Type II pheromones and the candidates including a further modified structure (Tables 1, 2, and 3 and Fig. 2). The Rt values and mass spectra of the synthetic compounds are useful, particularly, for structural determination conducted with a trace amount of a natural pheromone. Utilizing these GC-MS data, the analysis of a pheromone gland extract can be accomplished without significant effort.

Acknowledgments The authors are grateful to Drs F. Mochizuki and T. Fukumoto of Shin-etsu Chemical Co., Ltd. for supplying (*Z*,*Z*)-3,6-nonadien-1-ol and 3-hexyn-1,6-diol and Dr S. Hashimoto for the identification of geometrid species.

Recently, the calling pheromone of *P. transgariepinus* was identified as 1-tridecene (Geiselhardt et al. 2008). This compound is well-known from pygidial defensive secretions of numerous tenebrionids (Tschinkel 1975a) and is also part of this secretion in *P. transgariepinus*. Nevertheless, the pheromone is not produced in the pygidial glands but is secreted from the aedeagal glands. These glands are part of the internal male reproductive system (Brits 1982) and are found only in *Parastizopus* and the sister genus *Ennychiatus* (Geiselhardt, unpublished). In *P. armaticeps*, these glands are 2.0 mm in length and 0.4 mm in diameter, and are connected with the ectodermal sac around the aedeagus by a muscle-controlled opening. Brits (1982) mentioned that the secretion of the glands flows over the aedeagus during evagination and postulated a possible function as a pheromone.

In the present study, we collected the volatiles emitted from the exposed aedeagus of *P. armaticeps* by using solid phase microextraction (SPME) and compared the composition with that of the aedeagal gland secretion. To obtain information about the biologically active compounds and their sex-specificty, we performed chemo-orientation experiments on a servosphere.

Methods and Materials

Beetles Insects were wild-caught *P. armaticeps* from Twee Rivieren, Kalahari Gemsbok National Park, South Africa, and their F1 offspring. They were separated according to sex and kept at 30°C and 40% relative humidity under a 14:10 L/D regime in terraria containing Kalahari sand, hiding places, and a water source. The beetles were fed with oat flakes or dried twigs of *Lebeckia linearifolia* (Fabaceae), their natural food plant.

Collection of Volatiles with SPME Groups of three males were kept in small open terraria (30×20×20 cm) with 1 cm moist Kalahari sand on the floor under the environmental conditions described above. To stimulate the beetles, they were sprayed with water simulating rainfall. When a male did a 'headstand' and exposed its aedeagus, the volatiles emitted were sampled by SPME, holding a polydimethylsiloxane fiber (100 μm, Supelco) for at most 5 s at 1–2 mm distance from the aedeagus.

Composition of the Aedeagal Gland Secretion The male genitalia were dissected in water (Brits 1982), and the aedeagal glands were removed and extracted in 100 μl of *n*-pentane. For quantification, 10 μl of 1,4-benzoquinone (1 mg/ml in *n*-pentane) were added to the samples as an internal standard.

Chemical Analysis Samples were analyzed on a coupled gas chromatography–mass spectrometer system (HP 6890 series GC–HP 5973 MSD) equipped with a split/splitless injector (300°C) and an autosampler (injection volume, 1 μl). Desorption time of SPME fibers was 2 min. A fused silica column (DB-1, 30 m×0.25 mm ID, 0.25 μm, J & W Scientific, Folsom, CA, USA) was used with a helium carrier gas flow of 1 ml/min. The oven temperature was programmed 2 min at 35°C, 20°C/min to 100°C, then 6°C/min to 300°C. Mass spectra were obtained by electron impact ionization at 70 eV.

All volatiles were identified by comparison of mass spectra and retention times with those of authentic standards. Fragmentation patterns of fatty acid esters were compared with those in the Wiley mass spectra library (John Wiley & Sons, Ltd.), and double-bond positions were determined after derivatization with dimethyl disulfide (Scribe et al. 1988). The identification of the hydrocarbons was based on their fragmentation patterns (Nelson and Sukkestad 1970; Nelson et al. 1972; Pomonis et al. 1980) and corroborated by their retention indices (Carlson et al. 1998).

Chemo-Orientation Experiments were performed with the servosphere TrackSphere LC300 (Syntech, Hilversum, The Netherlands). Walking movements of the beetles were recorded as *x*, *y* coordinates at a rate of ten data points per second and displayed in real time by the TrackSphere 2.2 software. Bioassays were conducted in the dark at 25–30°C during the first 3 h of the scotophase. The air stream (0.3 m/s) passed through a glass tube (ID, 5 mm), with its opening located 25 cm from the top of the sphere. Beetles were allowed to acclimate for a few minutes on the servosphere before the trials started. A test consisted of two 3-min periods, i.e., before an odor was applied and during odor presentation. The test criterion for a responding female was a posture in which the beetle elevated the front part of its body and raised the antennae to a vertical position. If the ternary test mixture triggered this reaction in a female, the beetle was subsequently tested with all odor combinations. Males also were tested, if they showed calling behavior. Each series was started and finished with the ternary mixture.

Synthetic Compounds Tested on the Servosphere The concentrations of 3-methylphenol (>99%, Fluka), ethyl-1,4-benzoquinone (>99%, synthesized according to Peschke and Metzler 1982), and 3-ethylphenol (>99.4%, Riedel de Haen) were 52, 46, and 2 μg/ml, respectively, regardless of their use as single components or in binary and ternary mixtures. All components were dissolved in *n*-pentane, which had no behavioral effect on the beetles. Ten microliters of the test mixtures or single components were applied to a piece of filter paper (0.5 cm^2), which was

inserted in the air-stream glass tube. The amounts applied corresponded approximately to the amounts extracted from one aedeagal gland.

Statistics Before the data from the servosphere bioassays were analyzed, the basic track recording intervals of 0.1 s were merged to provide intervals of 1 s to smooth the data. Stops were assumed when the walking speed fell below 5 mm/s because the sphere made small random movements even when the beetles were not moving. All displacements slower than this were discarded. From these modified track recordings, we calculated mean walking speed (without stops), stop number, and stop duration. For each period, we then calculated the mean vector m (length r_{pop}; direction Φ) and the path straightness (r). Values of r range from 0 (ends at the origin) to +1 (straight). Differences in walking speed, stop number, stop duration, and path straightness between the periods before and during odor presentation were compared by using the two-tailed Wilcoxon test for matched pairs. Walking parameters of males and females under clean air conditions were compared with the Mann–Whitney U test. Directional data were subject to the modified Rayleigh V test (Batschelet 1981).

Results

Chemical Composition of the Pheromone and the Aedeagal Glands Extract The volatiles collected with SPME from the air close to the aedeagus of a calling male *P. armaticeps* were identified as 3-methylphenol, ethyl-1,4-benzoquinone, and 3-ethylphenol (N=14; Fig. 1). The proportions of 3-methylphenol and ethyl-1,4-benzoquinone were nearly equal (51.8% and 46.4%, respectively), whereas 3-ethylphenol was only a minor component (1.8%).

In extracts of the aedeagal glands, all three volatile components were present but only as minor components [Table 1 and Fig. 2, 3-ethylphenol (0.03%) is not listed]. The main fraction consisted of several fatty acid esters (23.6%, dominated by ethyl 11-eicosenoate 10.8%) and of *n*-alkanes, and mono- and dimethylalkanes, mainly with carbon backbones from 29 to 33 (69.1%). *n*-Alkanes were minor components (1.9%), whereas mono- and dimethylalkanes amounted to 29.0% and 33.8%, respectively. Although esters and hydrocarbons made up more than 95% of the gland extracts, they were never detected in the airspace around the aedeagus during calling. The total amount (mean ± SD) of volatiles extracted from the aedeagal gland reservoirs was 0.92±0.83 μg per beetle (N=10).

Behavior in the Clean Air Stream Neither males nor females of *P. armaticeps* showed a preferred direction with respect to the direction of the air stream (males' mean vector: N=15, r_{pop}=0.14, Φ=+57°, P>0.05; females' mean vector$_{initial\ trial}$: N=11, r_{pop}=0.08, Φ=+30°, P>0.05; modified Rayleigh V test; Fig. 3, Table 2). Furthermore, males and females did not differ in their walking performance parameters such as speed (median, 22 mm/s vs. 24 mm/s; Mann–Whitney U test, U=79, z=0.18, P>0.05), stop number (median 2 vs. 7; U=41, z=1.93, P>0.05), stop duration (median 1% vs. 17% of the trial duration; U=49, z=−1.74, P>0.05) or path straightness (median 0.24 vs. 0.48; U=57, z=−1.32, P>0.05).

Response to Pheromone Mixtures and Single Components Male *P. armaticeps* did not respond to the complete pheromone blend (mean vector: r_{pop}=0.21, Φ=−10°, P>0.05, modified Rayleigh V test; Fig. 3a and Table 2), whereas females were strongly attracted to this ternary mixture (mean vector$_{initial\ trial}$: r_{pop}=0.88, Φ=−4°, P<0.001; mean vector$_{final\ trial}$: r_{pop}=0.85, Φ=−7°; P<0.001; Fig. 3b,c and Table 2). Although females were attracted to the ternary mixture in the initial and final trial, they were not attracted in any of the trials with binary mixtures or single components alone (Table 2).

With respect to walking performance, males did not differ in any of the measured parameters compared to the clean air condition (Table 2). When stimulated with the ternary mixture, females stopped more often (median, 7_{air} vs. $16_{initial\ trial}$ and 6_{air} vs. $10_{final\ trial}$; P<0.05 in both cases, Wilcoxon test for matched pairs) and longer than in clean air (median, $17\%_{air}$ vs. $35\%_{initial\ trial}$ and $7\%_{air}$ vs. $32\%_{final\ trial}$; P<0.05 in both cases). When ethyl-1,4-benzoquinone was part of the stimulus blend, a similar response was observed as well (Table 2). Among treatments, the number and

duration of stops differed, as did the behavior during the stops. Females often lifted the front part of their bodies, raised the antennae to a vertical position, and turned slowly on their own axis, a behavior that was not seen in clean air. In the initial trial as well as in the trial with ethyl-1,4-benzoquinone, the walking speed of females was significantly lower than in the controls (median, 24 mm/s_{air} vs. 18 mm/$s_{initial\ trial}$ and 32 mm/s_{air} vs. 27 mm/s_{EtBQ}; $P<0.01$ and $P<0.05$, respectively). This seemed to be a result of increased and decreased locomotion associated with more frequent stops rather than of average walking speed itself. None of the chemical stimuli tested affected the path straightness of the beetles' walks in any way (Table 2).

Discussion

Our study demonstrated that the male sex pheromone of *P. armaticeps* consists of 3-methylphenol, ethyl-1,4-benzoquinone, and 3-ethylphenol. In a previous study, Geiselhardt et al. (2008) showed that males of the sister species *Parastizopus transgariepinus* emit 1-tridecene during calling. Although the chemical compositions of the pheromones are entirely different for the two species, the constituent compounds are well-known from defensive secretions of many arthropods (Blum 1981). Most tenebrionids, including *Parastizopus*, possess pygidial defensive glands, which secrete mixtures of 1,4-benzoquinones and 1-alkenes (Brown

The *asterisks* indicate significant preference for the wind direction (modified Rayleigh V test, ***P<0.001)

et al. 1992; Tschinkel 1975a, b), but *Parastizopus* additionally produces appreciable amounts of monoterpene hydrocarbons in the defensive glands (Geiselhardt et al. 2006). The defensive secretions of *P. armaticeps* and *P. transgariepinus* are very similar, comprising the same set of compounds in similar ratios (Geiselhardt et al. 2006, 2008).

Although some pheromone compounds are found in the pygidial glands, such as 1-tridecene in *P. transgariepinus*

(Geiselhardt et al. 2008) and ethyl-1,4-benzoquinone in *P. armaticeps*, respectively, the pheromone is not produced in these glands but in the aedeagal glands that are connected to the aedeagal pouch. The occurrence of the same compounds in different glands has been reported for the flour beetle *Tribolium castaneum*, whose pygidial and prothoracic defensive gland secretions have identical compositions of 1,4-benzoquinones (Loconti and Roth 1953). In the tenebrionid *Zophobas rugipes*, the pygidial glands secrete 1,4-benzoquinones, whereas the prothoracic glands produce phenols (Tschinkel 1969). The author suggested that the biosynthesis of 1,4-benzoquinones proceeds through phenolic precursors. Although the pygidial glands of *Parastizopus* did not secrete phenols, 3-methyl- and 3-ethylphenol are part of the defensive secretions of some closely related Stizopina species (Geiselhardt, unpublished).

The evolution of allomones to function also as sex pheromones has been reported from several insects, including ants (Walter 1993) and beetles (Keville and Kannowski 1975; Peschke 1983). This seems to be a widespread phenomenon especially in melolonthine scarab beetles (Leal 1997), including examples of the incorporation of 1,4-benzoquinones or phenols in the female mate attraction system, such as 1,4-benzoquinone in the cockchafer *Melolontha hippocastani* (Ruther et al. 2001), methyl-1,4-benzoquinone in *M. melolontha* (Reinecke et al. 2002), and phenol in both species (Ruther et al. 2002). In these examples, one gland produces a bifunctional secretion that serves as pheromone and allomone, whereas *Parastizopus* allocates these functions to different glands. As the composition of the pygidial defensive secretions is uniform in the genus *Parastizopus* and the subtribe Stizopina in general (Geiselhardt et al. 2006, 2008), the shift of only a subset of compounds from the pygidial glands to the aedeagal glands opens up the possibility to formulate a species-specific sex pheromone. However, this scenario is still speculative, and further studies are needed to show whether the newly evolved aedeagal glands have adopted the biosynthetic pathways from the phylogenetically older pygidial glands or whether both glands have evolved independently.

The orientation bioassays demonstrated that the emitted pheromone is primarily a sex pheromone rather than an aggregation pheromone, although Rasa et al. (1998) observed more than one male per courtship group and inferred that the pheromone attracts both sexes. However, males in our study showed neither a preference for the upwind direction nor any other observable change in their behavior when exposed to the ternary blend. In contrast, females showed a strong reaction when they perceived the pheromone. They stopped walking and adopted an antennae-raised posture, resembling that of other walking insects that respond to olfactory cues, such as the dermestid beetle *Trogoderma variabile* (Tobin and Bell 1986) or the triatomine bug *Rhodnius prolixus* (Otálora-Luna et al. 2004). During the stops, the females turned slowly on their own axis and sampled the air stream before staring to walk upwind. Therefore, the stops may be important for course control during orientation, as proposed for triatomine bugs that orientate to olfactory cues (Otálora-Luna et al. 2004) and cockroaches (Willis and Avondet 2005). Furthermore, this sampling behavior, in addition to a high stop frequency and duration, may be an adaptation to the male pheromone-emitting behavior, with short calling and long inter-calling periods. Thus, females may perceive the pheromone only for a few seconds before they lose the chemostimulus for about 1 min. The best way for a female to locate a calling male may be a stop-and-go strategy or saltatory search (O'Brien et al. 1990), walking upwind in contact with the pheromone and stopping at loss of the stimulus, waiting for the next pheromone pulse.

Acknowledgment We thank Stefanie Geiselhardt and two anonymous reviewers for helpful comments on the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft, Bonn (Pe 231/13-1,2).

[a] The number of individuals analyzed (N) and number of colonies sampled (in parentheses) are given; error is represented by SD.

to the precise context, differences in the overall CHC profiles among individuals, castes, or colonies inevitably occur. Although the underlying causes of these differences are not known, researchers have attempted to discriminate signals by using sensitive multivariate statistical methods (principal component and discriminate analysis). These methods provide limited insight into what biological processes underlie the often very small differences detected, as they combine rather than separate out the various signals (Howard and Blomquist 2005). It is normally assumed that each peak or compound in a profile is an independent variable potentially containing information. However, what has long been known (Lockey 1988) but often overlooked is that the vast majority of CHCs (alkanes, alkenes, and monomethylalkanes) within any profile are structurally related, belonging to a homologous series in which the chain length increases by two carbons (e.g., C_{25}, C_{27}, and C_{29}), but the position of double bonds or methyl groups remains constant (e.g., 3-MeC_{25}, 3-MeC_{27}, and 3-MeC_{29}). In some insects, CHCs are produced with only one chain length or in highly limited homologous series; often, such CHCs are dominated by dimethylalkanes. Odd chain-length homologous series dominate the CHCs of most insects (Lockey 1988), and even-chain compounds, if present, are always in smaller proportions. However, if the ratios (relative amounts) of the compounds within a homologous series are constant [i.e., highly correlated (r^2>0.9)] within a colony, population, or species, then that series can be treated as a single variable, greatly reducing the apparent complexity of the profile for multivariate analysis.

In order to decode the information contained within the CHC profile, we first investigated the CHC profiles of 13 species of *Formica* ants from geographically and ecologically different populations (Martin et al. 2008b). This allowed us to distinguish between species-specific cues, that must be common to all members of that species, and any potential colony-specific cues, that must vary between colonies but be consistent among colony members (nest mates). This work revealed two species, *F. fusca* and *F. exsecta*, that had characteristics in their CHC profiles and behavioral traits that made them particularly suitable for further study. These characteristics were that (1) both species possess a strong colony identity as demonstrated by inter-colonial aggression (Wallis 1962; Czechowski 1990); (2) *F. fusca* has the most diverse CHC profile, with respect to dimethylalkanes, of any known *Formica* species (Martin et al. 2008b), and profiles of these compounds appeared to vary between colonies; and (3) *F. exsecta* has a simple CHC profile but retains a strong colony identity.

By studying the relationships of compounds within each homologous series and how these series form the CHC profile, from a large number of *F. fusca* and *F. exsecta* colonies, we provide evidence that only part of the CHC profile contains colony-specific information. Furthermore, this information is encoded in two quite different ways despite the two species belonging to the same genus.

Methods and Materials

Ant Samples

Groups of up to ten adult workers were randomly sampled from 30 *F. fusca* and 20 *F. exsecta* colonies at different

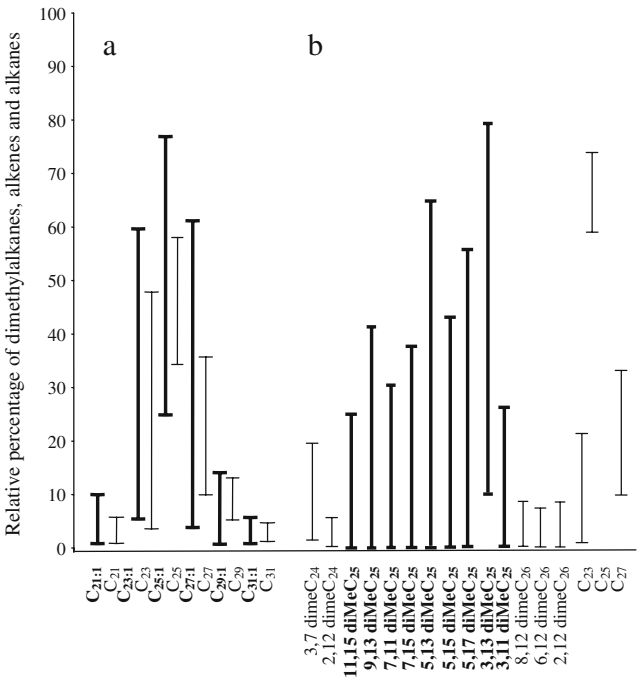

Fig. 1 Variation in relative percentages of the major compounds (alkanes, alkenes, and dimethylalkanes) found in *Formica exsecta* (*a*) and *F. fusca* (*b*) at the species level. The variation for each compound was calculated within each chemical group; e.g., when only the alkanes were considered, C_{25} represents 60–75% of the alkanes in *F. fusca*. The compounds selected for further statistical analysis are shown in *bold*

locations in Finland during 2005 and 2006. All ants were sampled from ten locations within 30km of the Tvärminne Zoological Station in Hanko, south-western Finland. At all collection sites, both species occurred sympatrically in forest clearings created by logging. In total, 111 *F. fusca* and 97 *F. exsecta* workers were sampled. Ants were killed by freezing and stored individually in glass vials at −5°C until extraction. *F. exsecta* colonies in this region are monogynous (Sundström et al. 1996), and only *F. fusca* colonies in which a single queen was found were used in this study, although workers may have been produced by more than one queen (Sundström et al. 2005).

Chemical Analysis

Individual ants were placed in glass vials, 50 µl of high-performance liquid chromatography-grade hexane were added and extracted for 10 min. After this, ants were removed, the hexane allowed to evaporate, and the vials sealed and stored at 5°C. Just before analysis, 30 µl of hexane were added to the vials. Samples were analyzed on an HP 6890 gas chromatograph (GC) connected to an HP5973 MSD (quadrupole) mass spectrometer (MS; −70 eV, electron impact ionization). The GC was equipped with an HP-5MS column (length, 30 m; ID, 0.25 mm; film thickness, 0.25 µm), and the oven temperature was programmed from 70°C to 200°C at 40°C min^{-1} and then from 200°C to 320°C at 25°C min^{-1}. Samples were injected in splitless mode, with helium as carrier gas, at a constant flow rate of 1.0 ml min^{-1}. CHCs were characterized by using standard MS databases, diagnostic ions, and Kovats indices. In *F. exsecta*, the double-bond positions of the alkenes were determined by dimethyl disulfide (DMDS) derivatization (Carlson et al. 1989) of four pooled extracts of ten adults that contained two ants from each colony chosen at random from the 20 colonies. In the few cases in which isomers of methyl-branched hydrocarbons overlapped, a characteristic ion of a compound was used to

delineate the area of the total ion chromatogram for integration. This method introduced some margin of error, but this was expected to be equal across all samples analyzed. In cases in which isomers overlapped completely (e.g., 3,11-diMeC$_{25}$ and 3,13-diMeC$_{25}$), peak area was divided according to the ratio in which the diagnostic ions were present.

Method Used to Search for Colony-Specific Signals

All CHC profiles were of two types. Those with limited diversity, comprising hydrocarbons of only one chain length or a short homologous series of hydrocarbons, which were usually dimethylalkanes, and those comprising long homologous series (alkanes, alkenes, and monomethylalkanes) of hydrocarbons. We assumed that the amount of information contained within a homologous series depended on whether or not the ratios (relative amounts) of the individual compounds were highly correlated (r^2>0.9) to each other. For a highly correlated homologous series, we assumed that the information encoded within the entire series was effectively the same as the information encoded in a single compound. We also assumed that a colony signal should be contained only within a homologous series that is highly correlated at the colony and not at the species level. A similar logic can also be applied to isolated compounds. That is, their occurrence and ratio of abundance to each other should be constant within a colony but vary among colonies. Therefore, correlation levels of major CHCs in each homologous series or among isolated compounds were determined at the species and colony level.

Once a group of compounds had been identified as containing potential colony signatures (referred to as signature CHCs), their ability to encode colony-specific information was tested by using two methods. First, one ant was

The black dots indicate the blind samples that matched a particular colony based on the rule that the proportions of each C_{25}-dimethylalkane in the blind sample was within ±5% of the proportion in the colony.

randomly chosen from each colony, and the proportions of each signature CHC were calculated based on the total relative amount of CHCs in the profile. This was the blind sample. Then, the average proportion of each signature CHC for each colony was calculated from the remaining individuals of a colony. Each blind sample was assigned to the colony or colonies that possessed the same profile (±5%) with respect to the signature CHCs. A greater amount of inter-colony variation in signature CHCs was observed in *F. fusca* than in *F. exsecta*, and, therefore, there was greater ambiguity in assigning blind samples to a colony for this species. Second, we used hierarchical cluster analysis (Ward's method; SPPS v.14) to assign individual ants to a pre-defined number of clusters (colonies) by using the signature proportional data.

Subsequently, the proportions of the signature CHCs were recalculated by ignoring the rest of the profile so that the signature CHCs accounted for 100% of the profile. Although this did not change the overall result, it made the graphical comparisons clearer and may be more biologically relevant, as different groups of hydrocarbons (e.g., alkanes vs. alkenes) are perceived differently (Sachse et al. 1999; Chaline et al. 2005).

Results

Formica exsecta

The CHC profile of *F. exsecta* was dominated (>95%) by a group of (*Z*)-9-alkenes and a homologous series of alkanes. In *F. exsecta*, the alkenes were poorly correlated at the species level but were highly correlated (r^2>0.95) at the colony level (Table 1), thus making them prime candidates for encoding colony-specific signals. The variation of the six signature (*Z*)-9-alkenes across *F. exsecta* colonies was large (Fig. 1a), especially considering that the average intra-colony variation (SD) in the 20 colonies for all alkenes was small (2±1%). By using only the proportions of the six signature (*Z*)-9-alkenes (9-$C_{21:1}$ to 9-$C_{31:1}$), all 20 blind samples were correctly assigned to their colonies (Table 2), although two ants could also each be assigned to another colony that had a similar profile (Table 2). By using the hierarchical cluster analysis, we also correctly assigned 94 of the 97 individuals into the 20 clusters (colonies), with the three incorrectly assigned ants mixed between colonies D and I. Using only the alkanes, 52% (50 out of 97) of the individuals were assigned to their correct colonies. These data support the unique distributions of the (*Z*)-9-alkenes containing colony-/nest mate-specific information. Although colonies from the various populations may possess similar traits (e.g., the presence of $C_{21:1}$ in the Byvägen population), the amount of variation between colonies within each population was striking (Fig. 2).

Formica fusca

The CHC profile of 111 *F. fusca* workers was composed of homologous series of alkanes, monomethylalkanes, and, unusually, a relatively large number of positional isomers of C_{25}–dimethylalkanes. All the compounds within each homologous series of alkanes or monomethylalkanes were highly correlated at both the species ($r^2>0.9$) and colony level ($r^2>0.9$), indicating that these compounds probably do not contain colony-specific information. Of the 14 different dimethylalkanes detected in the Finnish population, nine exhibited large amounts of variation when compared to other CHCs (Fig. 2b). The nine positional isomers of dimethyl pentacosane contributed 15–37% of the total CHC profile. Each of the 30 colonies possessed two to seven of these nine compounds in a variety of combinations and proportions. By using only the proportions of these nine signature CHCs, all 30 blind samples were assigned to their correct colonies (Table 3). However, there was some ambiguity in assigning two of these ants due to similarity of profiles with other colonies (Table 3). The hierarchical cluster analysis supported the rule-based analysis by correctly assigning 107 of the 111 individuals into 30 clusters (colonies). The variation of these nine signature C_{25}–dimethylalkanes among the 30 *F. fusca* colonies was clearer when their proportions were analyzed independently from the rest of the CHCs in the profiles (Fig. 3). Despite the large variation (range=0–94%) of these signature CHCs among colonies (Fig. 3), the intra-colony variation was low within each of the 30 colonies, with the SD averaging only 3±2% across all signature compounds.

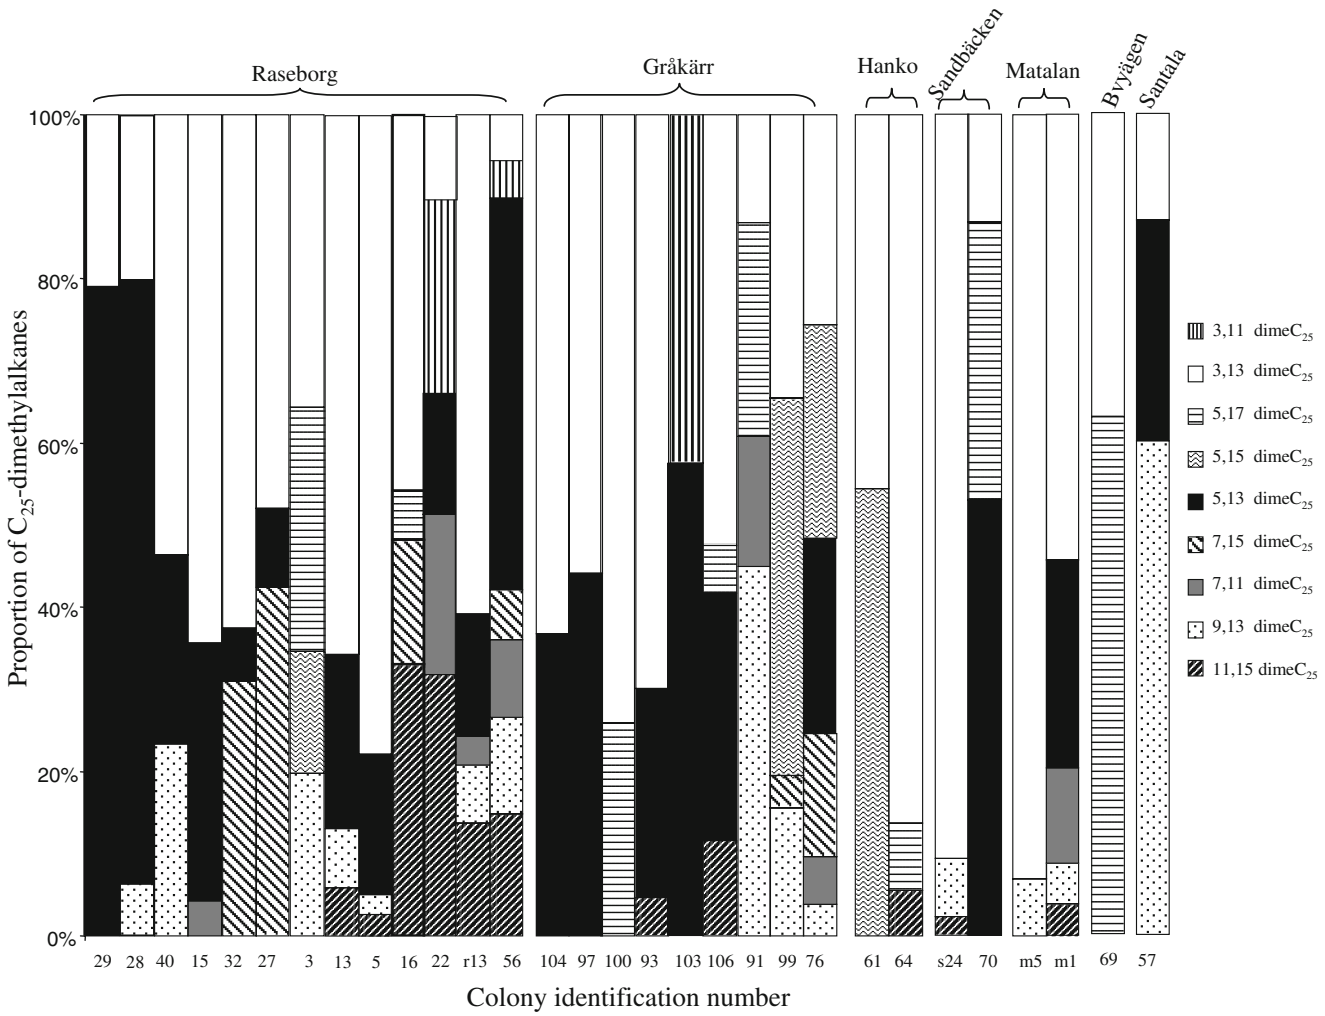

Fig. 3 The relative proportions of nine colony-specific C_{25}–dimethylalkanes from 30 Finish *Formica fusca* colonies collected at seven locations. The colonies are grouped within each population according to the number of C_{25}–dimethylalkanes present. The variation is not shown for the sake of clarity, but the SD averaged 3±2% for all compounds across all the colonies

Discussion

It has been suggested recently that the information encoded within CHC profiles, which social insects use to discriminate between nest mates and non-nest mates, resembles a blurred barcode (Boomsma and Franks 2006). However, we have shown in this study that colony-specific information can be encoded in the CHC profile in two distinct ways, both of which are clear and distinct once identified from the rest of the CHC profile.

Mechanism 1: Altering the Proportions of a Single Type of Hydrocarbon (*F. exsecta*)

Despite *F. exsecta* possessing one of the most basic CHC profiles among the *Formica* ants, it encodes colony-specific information in the proportions of individual hydrocarbons within a single homologous series (of 9-alkenes). Such encoding presumably requires precise control during each step of the chain-lengthening process or in the lipophorin transport system (Schal et al. 2001; Lucas et al. 2004). The encoding of information in a single homologous series of hydrocarbons limits the number of possible unique signatures across colonies. Despite this, *F. exsecta* populations are able to produce a wide variety of distinct colony-specific distributions of alkenes (Fig. 3). Recent experimental evidence (Martin et al. 2008a) with synthetic CHCs has shown that *F. exsecta* uses (*Z*)-9-alkenes to encode nest-mate recognition signals. Our interpretation is supported by data on *F. japonica* in Japan (Akino et al. 2004), which has a similar CHC profile to *F. exsecta*. When synthetic CHCs (9-alkenes and alkanes) were placed on a glass dummy in proportions that mimic a particular colony, *F. japonica* nest mates were not aggressive and non-nest mates were aggressive toward the dummy in the two colonies tested.

Mechanism 2: Synthesis of Colony-specific Compounds (*F. fusca*)

A review of the CHC literature shows that dimethylalkanes in a given species are synthesized principally in one-carbon chain length, as found in *F. fusca* or in limited homologous series (Howard and Blomquist 2005). If only the presence or absence of the nine C_{25}–dimethylalkanes found in *F. fusca* encoded a colony signature, then 512 (2^9) unique colony signatures could exist. Among the 30 colonies studied, 24 unique profiles were found based on combinations of presence or absence of specific compounds, thus illustrating the diverse production of CHC profiles within this species. However, the proportions of each C_{25}–dimethylalkane also varied between colonies, potentially increasing the number of unique colony profiles (e.g., up to 10^9 if a 10% discrimination window is used) dramatically. Behavioral work is needed to determine what differences in a given CHC profile are allowable before it is no longer recognized as that of a nest mate.

The role of methyl-branched hydrocarbons in nest-mate recognition has been implicated in *Polistes* wasps (Dani et al. 2001) and the ants *Camponotus vagus* (Clement et al. 1987), *Messor barbarus* (Provost et al. 1994), possibly *Cataglyphis* spp (Dahbi et al. 1996), and now *F. fusca* (this study). However, in all these studies, including this one, bioassays that use synthetic methyl-branched hydrocarbons have yet to be conducted. This work needs to be carried out to confirm that these compounds are indeed used in nest-mate recognition. From an evolutionary perspective, dimethylalkanes are ideally suited to function as communication molecules because there are numerous isomers for a given chain length, and a relatively minor chemical change, such as in position of a methyl group, can have a profound effect on the conformation of the molecule. This may explain why dimethylalkanes are by far the most diverse type of hydrocarbon found among the ants (Dahbi et al. 1996).

The two systems described here or variations of them may be expected to occur in many species of social insects that have strong colony identity. We believe that the addressing of the roles of chain length, detection thresholds, and biosynthesis in social insect CHCs will provide insight into the world of insect communication and the role of nest-mate recognition in the evolution of sociality.

Acknowledgment Many thanks go to Liselotte Sundström of Helsinki University for assistance with the field work, Jennifer Aldworth of Keele University in helping with the DMDS reactions, Duncan Jackson of Sheffield University for his critical reading of earlier drafts, and many colleagues for their constructive comments, especially David Morgan of Keele University. Funding for this research was provided by NERC (NE/C512310/1) and Academy of Finland grants (213821 and 206505).

of species of several major groups of glandulate oribatids have been investigated, including representatives of Parhyposomata (Sakata and Norton 2001), a few species of Mixonomata and Desmonomata (Sakata et al. 1995, 2003; Raspotnig et al. 2001, 2005a, b; Shimano et al. 2002; Sakata and Norton 2003), and also examples of Brachypylina (Takada et al. 2005; Saporito et al. 2007). While Parhyposomata produce phenols and naphthols, the so-called astigmatid compounds (sensu Sakata and Norton 2001) evolved within ancient mixonomatans, and hence, are possibly found in all the above groups. These astigmatid compounds comprise a set of terpenes and aromatics, namely neral, geranial, neryl formate, 2-hydroxy-6-methyl-benzaldehyde, and γ-acaridial. The distribution of astigmatid compounds in oribatids is of special interest since these compounds not only provide chemical support for the evolutionary origin of astigmatid mites within ancient Oribatida (Norton 1998), but also define a presumably monophyletic subunit within glandulate Oribatida, the "astigmatid compounds-bearing" oribatids (Raspotnig 2006).

Several chemotaxonomic studies that examined these presumptive astigmatid compound-bearing groups have been undertaken and have yielded a fragmented picture of the distribution of astigmatid compounds. These compounds are difficult to detect in the more derived groups of Desmonomata (apart from Trhypochthoniidae) and generally in Brachypylina, suggesting that, in these groups, astigmatid compounds have been prone to evolutionary reduction and replacement. In some cases, desmonomatan and brachypyline species are chemically "dimorphic", with astigmatid compounds present only in juveniles and completely replaced in adults by novel compounds such as toxic alkaloids (Takada et al. 2005; Saporito et al. 2007). In contrast, the full (or nearly full) set of astigmatid compounds seems to characterize highly derived mixonomatans, low to moderately derived representatives of Desmonomata, and Astigmata. Specifically, these compounds have been detected in opisthonotal gland secretions of *Collohmannia gigantea* (Raspotnig et al. 2001), in all Trhypochthoniidae so far investigated (e.g., Sakata et al. 1995, 2003), and in astigmatid mites (e.g., Kuwahara 2004). However, there are large gaps in our knowledge of the distribution of astigmatid compounds: the most conspicuous gap being in the Euphthiracaroidea, a speciose group of box mites whose opisthonotal gland chemistry has yet to be investigated. Euphthiracaroids are considered a group of highly derived mixonomatans that, together with phthiracaroids, constitute a possible sister group of *Collohmannia*. Thus, euphthiracaroids are likely candidates for producing astigmatid compounds. The study of the chemistry of opisthonotal glands in euphthiracaroids is important not only to further our understanding of the evolution of astigmatid compounds, but also because this group is a crucial link for tracing a possible evolutionary lineage from Oribatida to Astigmata. With respect to the latter, some (not all!) recent molecular studies (e.g., Murell et al. 2005; Domes et al. 2007) conflict with morphological data. Therefore, studying the opisthonotal gland chemistry may resolve this problem.

In the present paper, we provide the first chemical analysis of the opisthonotal gland secretion of *Oribotritia berlesei*, a large-sized oribatid mite from the near-basal euphthiracaroid family Oribotritiidae.

Methods and Materials

Mites and Mite Extracts Specimens of *O. berlesei* (Michael 1898) (mixonomatan Oribatida: Euphthiracaroidea, Oribotritiidae) were collected from the litter and fermentation layer of a mixed forest near Ferlach (Carinthia, Austria). Individuals were collected by hand or extracted from soil samples by using Berlese-Tullgren funnels. In all, 35 adults (all in the course of one collection in September 2006) were used for chemical analyses, five adults were used for scanning electron microscopy, and 30 adults were transferred to Petri dishes (equipped with Plaster of Paris and dead wood) and kept in the dark for a period of about 12 months either at room temperature (one Petri dish) or at 10°C (second Petri dish), respectively. Individuals of both Petri dishes laid eggs, and the offspring were reared to deutonymphal and tritonymphal instars. Since immatures are burrowers in dead wood, pieces of dead wood (provided in the rearing dishes) were checked for immatures at weekly intervals. Ten deutonymphs and eight tritonymphs were used in the chemical studies.

Extracts (containing opisthonotal gland secretions) of adults were prepared by immersing freshly collected, living, individuals in hexane (one individual per 100 μl) for 30 min (Raspotnig et al. 2001, 2005a, b). For juveniles, individual and pooled extracts (containing two to six individuals) were prepared similarly. The extracts were used without further cleanup.

Chemical Analysis: Gas Chromatography—Mass Spectrometry A trace gas chromatograph (GC) coupled to a Voyager mass spectrometer (MS; both from Thermo, Vienna, Austria) and equipped with a ZB-5MS fused silica capillary column (30 m×0.25 mm i.d., 0.25 μm film thickness, Phenomenex, Germany) was used for the analyses. Injection was splitless with helium (at a constant flow rate of 1.5 ml min^{-1}) as a carrier gas. The column temperature was programmed from 50°C (held for 1 min) to 200°C at 10°C min^{-1}, and then to 300°C at 15°C min^{-1}. The ion source of the mass spectrometer and the transfer line were kept at 150°C and 310°C, respectively. Electron impact (EI) spectra were recorded at 70 eV.

Derivatization, Syntheses, Reference Compounds, and Other Chemicals Tri-, penta-, and heptadecane, as well as citral (60% geranial, 40% neral) and selenium dioxide for the preparation of oxocitral (see Bellesia et al. 1986), were purchased from Aldrich (Vienna, Austria). For determination of double bonds in the heptadecadiene, dimethyl-disulfide (DMDS) adducts were generated according to the method described by Vincenti et al. (1987). The opisthonotal gland secretion of *Platynothrus peltifer* (Raspotnig et al. 2005b) was used as a natural source for 6,9-heptadecadiene and 8-heptadecene for chromatographic comparisons. In order to clarify further the structure of chrysomelidial, the *O*-methyl-oxime derivatives were prepared with methoxylamine hydrochloride (MOX.HCl; 2% in pyridine): 200 µl of MOX was added to 50 µl of extract and left at 70°C for 1 h. Products were cleaned in H_2O, extracted with hexane, and analyzed. Stereoisomers of chrysomelidial and dehydroiridodial were synthesized according to Bellesia et al. (1986). Secretions from eversible defense glands of larvae of the chrysomelid beetles, *Gastrophya viridula* and *Plagiodera versicolora* (collected in the surroundings of Graz, Austria), known to contain natural (3*S*,8*S*)-chrysomelidial (e.g., Pasteels et al. 1982), were collected on small filter paper pieces, extracted in hexane (one individual in 100 µl), and used as sources for authentic reference compounds. Hexane extracts of fresh leaves of *Actinidia polygama* (obtained from the botanical garden in Tübingen, Germany) were taken as a natural source for (3*R*,8*S*)-dehydroiridodial (Yoshihara et al. 1978).

Scanning Electron Microscopy Air-dried mites were mounted on aluminum stubs, sputtercoated (AGAR sputtercoater, Gröpl, Tulln, Austria), and examined with a Philips XL30 ESEM (Philips/FEI, Vienna, Austria) at high vacuum mode and 20 kV accelerating voltage.

Results

Extracts of Adult O. berlesei A total of ten components (peaks a–j) were detected in extracts of adult *O. berlesei* (Fig. 1a). The main component in extracts, component c (RT=13.36 min; ca. 45% of the total extract, based on peak areas) had an EI fragmentation pattern resembling a methyl-cyclopentene monoterpene (Fig. 2a), with a molecular ion at *m*/*z* 166 (7) and characteristic fragments at *m*/*z* 151 (6), 148 (46), 138 (25), 133 (9), 123 (15), 120 (12), 119 (10), 109 (49), 108 (40), 105 (30), 95 (19), 91 (27), 81 (100), 79 (78), and 77 (38). The spectrum was consistent with that of chrysomelidial from the literature (e.g., Blum et al. 1978; Oldham et al. 1996) and with a compound from the NIST library ("2-formyl-α,3-dimethyl-2-cyclopentene-1-acetaldehyde"; CAS no. 75332-42-2: "2-methyl-5(1-methyl-2-oxoethyl)-1-cyclopentene-1-carbaldehyde"). In order to prove the dialdehyde structure, we generated *O*-methyl-oxime derivatives, resulting in the elimination of peak c and the formation of two new peaks, c′ and c″, with longer retention times (RT=14.92 and 15.11 min). The two compounds had identical mass spectra, with molecular ions at *m*/*z* 224 (4), and fragment ions at *m*/*z* 193 (13), 178 (22), 146 (25), 138 (100), 107 (38), 106 (95), 91 (18), 87 (21), 79 (47), and 77 (29). This pattern indicated *O*-methyl-oximation of compound c, forming two isomeric dimethyloximes, which confirmed the proposed dialdehydic structure (addition of two *O*-methyl-oxime groups to compound c= 166 plus 2×29=new molecular ion at *m*/*z* 224).

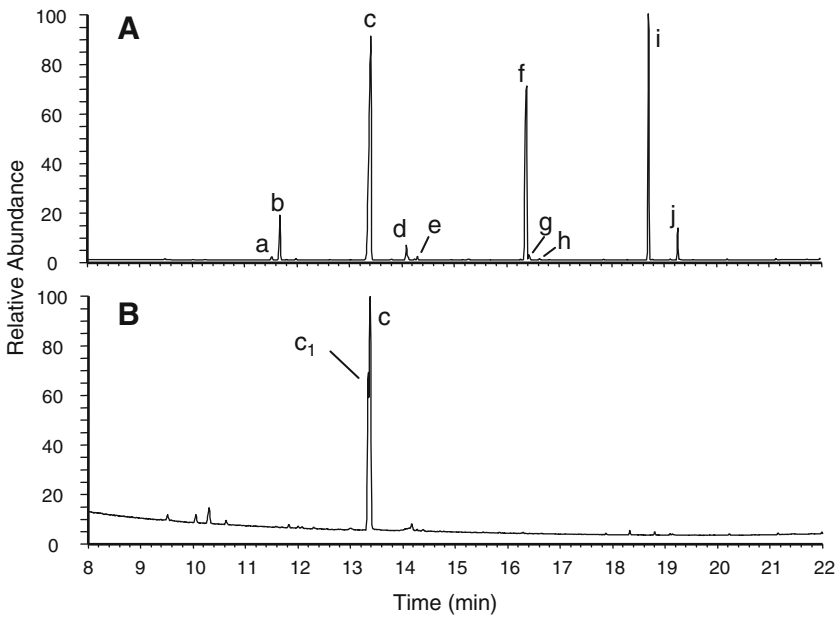

Fig. 1 Typical mass chromatograms of extracts of *Oribotritia berlesei*: **a** adult individual. **b** Deutonymph. Peaks *a* (tridecene), *b* (tridecane), c_1 ("epi-chrysomelidial" = 3*S*,8*R*-chrysomelidial), *c* ("chrysomelidial" = 3*S*,8*S*-chrysomelidial), *d* (pentadecene), *e* (pentadecane), *f* (6,9-heptadecadiene), *g* (8-heptadecene), *h* (heptadecane), *i* (tentatively, β-springene), *j* (tentatively, 9,17-octadecadienal)

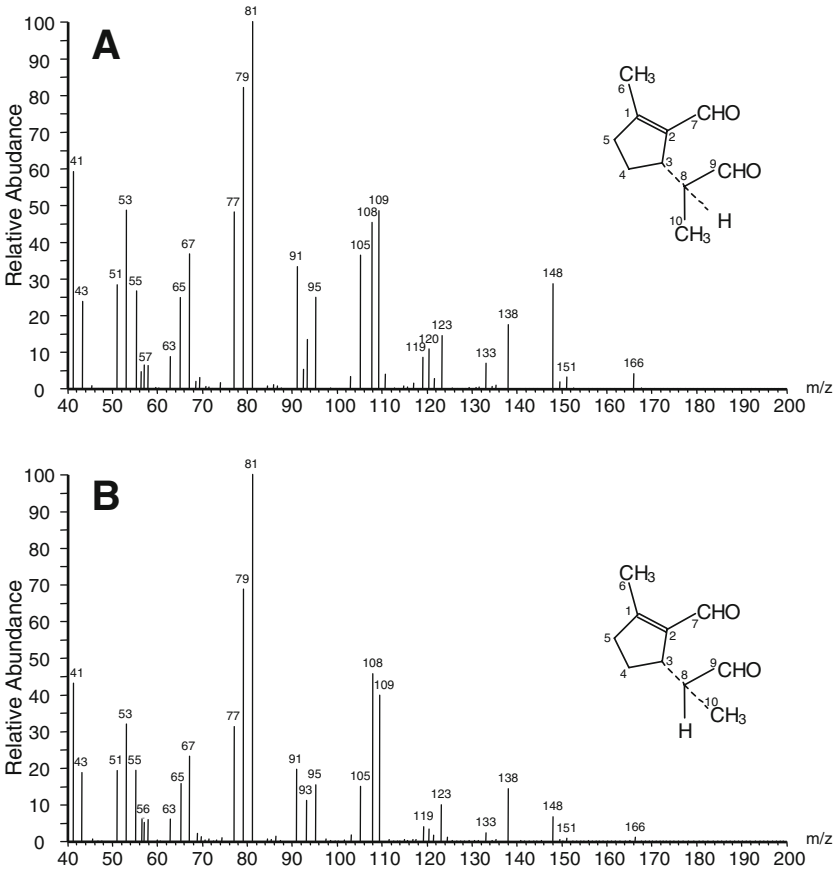

Fig. 2 Electron impact mass spectra of chrysomelidials in extracts of *Oribotria berlesei*. **a** Compound c, tentatively identified as (3*S*,8*S*)-chrysomelidial. **b** Compound c_1, tentatively identified as epi-chrysomelidial = (3*S*,8*R*)-chrysomelidial. Note the differences in relative intensities of ions at *m*/*z* 148 (M^+–H_2O) and *m*/*z* 138 (M^+–CO). Further diagnostic fragments are assigned to: M^+–H_2O–CO (*m*/*z* 120); $C_7H_9O^+$ (*m*/*z* 109), $C_7H_7^+$ (*m*/*z* 91), and $C_6H_9^+$ (*m*/*z* 81: base peak = the methyl-cyclopentene moiety)

For a comparison of compound c to authentic chrysomelidial and its characterization, we used (1) a synthetic mixture of chrysomelidial-stereoisomers, and (2) naturally occurring (3*S*,8*S*)-chrysomelidial. The synthetic mixture was assumed to contain four stereoisomers of chrysomelidial and dehydroiridodial (according to Bellesia et al. 1986), namely two diastereomeric pairs of enantiomers, i.e., (3*S*,8*S*)-chrysomelidial, (3*R*,8*R*)-dehydroiridodial, and (3*S*,8*R*)-chrysomelidial (= epi-chrysomelidial), (3*R*,8*S*)-dehydroiridodial. However, the mixture exhibited only two, poorly separable peaks at RT=13.32 and 13.36 min, each peak corresponding to one pair of enantiomers, with single enantiomers not separable under the chromatographic conditions. The later-eluting peak of the mixture corresponded to compound c from the *Oribotritia* extract, with respect to both retention time and EI fragmentation pattern. Larval secretions of the leaf beetle *Gastrophysa viridula* (see "Methods and Materials"), contain mainly (3*S*,8*S*)-chrysomelidial ("original chrysomelidial"). Analysis of this secretion showed only one abundant component that eluted at RT=13.36 min, corresponding to the later-eluting peak of the synthetic mixture and to compound c of the mite extracts. Thus, the later-eluting peak of the synthetic mixture was assigned as either (3*S*,8*S*)-chrysomelidial or its enantiomer, (3*R*,8*R*)-dehydroiridodial. Since dehydroiridodials are considered of plant origin only (see "Discussion"), compound c was tentatively identified as (3*S*,8*S*)-chrysomelidial.

The mass spectrum of peak *f* (RT=16.36 min), the second most abundant compound in extracts (about 25% of total), suggested a doubly unsaturated C17-hydrocarbon, based on a molecular ion at *m*/*z* 236 and a series of unsaturated hydrocarbon fragments. The DMDS adduct of the heptadecadiene showed a molecular ion at *m*/*z* 362 and diagnostic ions at *m*/*z* 231, 203, 183, 159, 155 (base peak), and 131, consistent with 6,9-heptadecadiene (see Raspotnig et al. 2005b). Compound i (RT=18.70 min; ca. 20% of the total) showed a terpene fragmentation pattern with a molecular ion at *m*/*z* 272 (4) and further *m*/*z* of 257 (3), 229 (4), 203 (5), 187 (10), 161 (17), 133 (31), 120 (15), 119 (17), 107 (20), 93 (50), 81 (37), 69 (100), 55 (16), 53 (17), and 41 (59). The compound was tentatively identified as β-springene on the basis of mass spectral comparison to β-springene spectra from literature and from the NIST library. The remaining peaks a, b, d, e, g, and h, all of them minor components, appeared to be a series of hydrocarbons, with compounds b (RT=11.69), e (RT=14.32 min), and h (RT=16.65 min) exhibiting the spectra of saturated *n*-alkanes with molecular ions at *m*/*z* 184, 212, and 240, respectively. The compounds were identified as tri-, penta-, and heptadecane by comparison of retention times to authentic

standards. Compounds a (RT=11.54), d (RT=14.10 min), and g (RT=16.44 min) had mass spectra of mono-unsaturated analogs, with molecular ions at *m*/*z* 182, 210, and 238, corresponding to tri-, penta-, and heptadecene. The position of the double bonds was not determined because, due to their low amounts, the compounds were not recovered after DMDS derivatization. The retention time of compound g was the same as that of 8-heptadecene (from extracts of *P. peltifer*, see "Methods and Materials"). Compound j (RT=19.27 min), also a minor component, had the following mass spectrum: *m*/*z* 264 (11), 235 (3), 221 (4), 207 (4), 165 (4), 151 (7), 137 (10), 123 (10), 109 (22), 95 (61), 81 (16), 79 (52), 67 (100), 55 (38), 54 (32), 44 (32), and 41 (69). The compound was tentatively identified as 9,17-octadecadienal on the basis of these mass spectral data.

The pattern of the ten compounds was consistently detected in 30 of the 35 individuals of adult *O. berlesei* (Fig. 1a), with relatively low inter-individual variation with respect to the relative abundance of components (data not shown). The other five extracts did not contain any of the components.

Extracts of Juvenile O. berlesei Extracts of juveniles (exclusively deuto- and tritonymphs) contained only two compounds in a 1:2 ratio (peak c_1 and c in Fig. 1b): The major component c corresponded to tentatively identified (3*S*,8*S*)-chrysomelidial from the adult extracts, based on identical retention time and mass spectrum. The minor component c_1 eluted earlier (RT=13.32 min) but was not fully separable from (3*S*,8*S*)-chrysomelidial. The mass spectrum of compound c_1 appeared to be similar to that of (3*S*,8*S*)-chrysomelidial (Fig. 2); one difference, however, was the greater intensity of the ion at *m*/*z* 138 in relation to the ion at *m*/*z* 148 [c.f., in (3*S*,8*S*)-chryomelidial the ion at *m*/*z* 148 is more intense]. These data suggested the compound to be one of the other possible stereoisomers of chrysomelidial, most likely an epimeric diastereomer of (3*S*,8*S*)-chrysomelidial. Moreover, the retention time and mass spectrum of compound c_1 fully corresponded with those of the earlier-eluting peak of the synthetic chrysomelidial mixture, limiting the possibilities to epi-chrysomelidial (3*S*,8*R*-chrysomelidial) and its enantiomer, (*3R*,*8S*)-dehydroiridodial. In addition, its retention time and mass spectrum matched those of plant-derived (*3R*,*8S*)-dehydroiridodial. Thus, again assuming that dehydroiridodials are exclusively plant-derived compounds, compound c_1 was tentatively identified as epi-chrysomelidial (3*S*,8*R*-chrysomelidial).

From a total of eight extracts of juvenile *O. berlesei* investigated (derived from 18 individuals), seven extracts consistently showed these two stereoisomers only; the other extract (an extract of a single individual) apparently did not contain any compounds at all.

Potential Secretory Glands The most conspicuous exocrine gland system of *O. berlesei* is the paired opisthonotal glands that, in light microscopic observations, are visible through the cuticle of the notogaster as kidney-shaped sacs of considerable size (maximal diameter about 0.5 mm: i.e., ca. 1/3 of body length; see Fig. 3b). The glands open to the notogastral surface via one single flap-provided pore orifice on either side of the body (Fig. 3a,c,d). The flap,

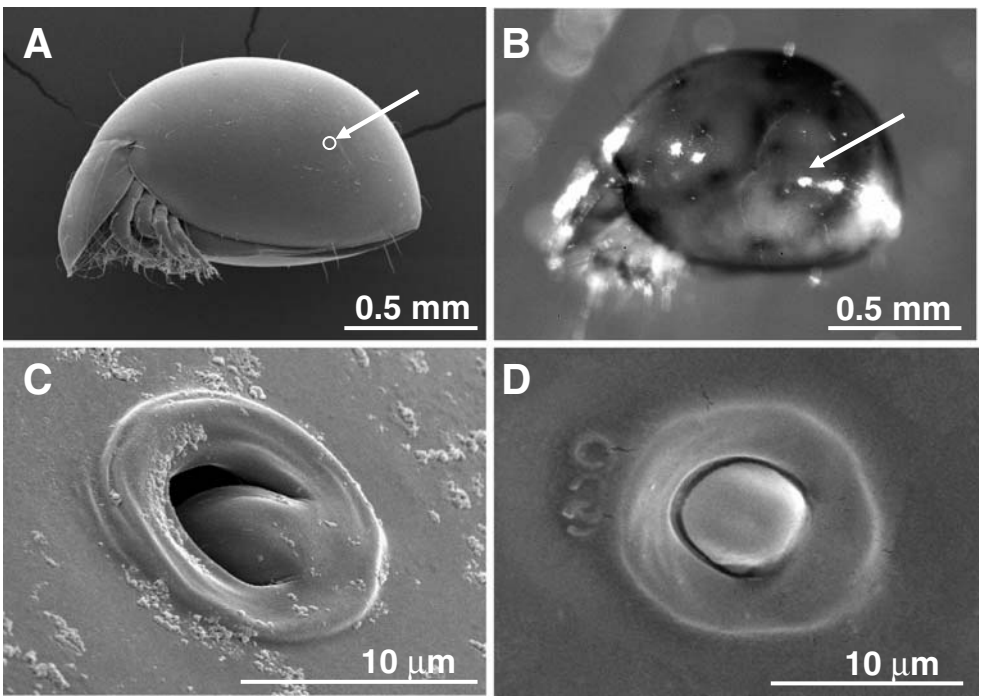

Fig. 3 Topography and external morphology of opisthonotal glands in *Oribotritia berlesei*. **a** Scanning electron micrograph (SEM) of an adult individual, *lateral view*. The *arrow marks* the orifice of the left opisthonotal gland. **b** Opisthonotal glands are visible through the integument under light microscopy. **c** SEM of an opisthonotal gland pore with flap open. **d** SEM of the pore of another individual, orifice closed

presumably an external closing mechanism, was found either in an opened (Fig. 3c) or a closed position (Fig. 3d) in different individuals. No other comparably large glands or pore orifices are present in this species. Opisthonotal glands are present in adults and in all juvenile stages.

Discussion

Occurrence of Chrysomelidial Even though iridoid monoterpenes are widely distributed in exocrine secretions of a diverse range of arthropods, chrysomelidial, so far, has only been reported from leaf beetle larvae (Chrysomelidae) and from certain rove beetles (e.g., Pasteels et al. 1982; Weibel et al. 2001). Originally, chrysomelidial was found as a major constituent of the larval eversible glands of the chrysomelids, *Gastrophysa cyanea* (Blum et al. 1978) and *Plagiodera versicolora* (Meinwald et al. 1977), and its stereochemistry later elucidated by Meinwald and Jones (1978). According to these studies, and to current knowledge, chrysomelidial in leaf beetles is a mixture of two diastereomers, (3*S*,8*S*-chrysomelidial (= the original chrysomelidial) and (3*S*,8*R*)-chrysomelidial (= epi-chysomelidial), with the former being the predominant isomer in the majority of chrysomelidial-producing species (e.g., Sugawara et al. 1979; Pasteels et al. 1982). In contrast, the remaining two possible stereoisomers (there are four stereoisomers due to the two asymmetric carbon atoms at C_3 and C_8) are termed "dehydroiridodials" and are considered of plant origin only (Yoshihara et al. 1978; Sugawara et al. 1979). Under the conditions used in this study, we were able to separate the diastereomers but not the respective enantiomers of chrysomelidial and dehydroiridodial. Assignments of chrysomelidials and dehydroiridodials are often misinterpreted in the literature. For instance, Bellesia et al. (1986) described the chrysomelidials as a pair of enantiomers, whereas they are in fact diastereomers. In the present paper, we use the classification of Sugawara et al. (1979) for these compounds, but also use the more common nomenclature of Bellesia et al. (1986). Thus, assuming dehydroiridodials are found exclusively in plants, the compounds in *O. berlesei* extracts are (3*S*,8*S*)-chrysomelidial and (3*S*,8*R*)-chrysomelidial (epi-chrysomelidial).

Our analysis of *O. berlesei* is not only the first example of the chemistry of exocrine glands of Euphthiracaroidea but also the only report of chrysomelidials found outside the Coleoptera. In *O. berlesei*, chrysomelidials most likely originate from the opisthonotal glands: these glands are quite large in *O. berlesei*, and thus probably capable of producing compounds in the amount detected. Furthermore, some of the components, especially 6,9-heptadecadiene and some other hydrocarbons, found in the extract are characteristic constituents of opisthonotal glands of many oribatid (and astigmatid) mite species (Kuwahara 2004; Raspotnig 2006). Functionally, at least in Chrysomelidae, iridoid monoterpenes such as chrysomelidials are considered defensive or for microbial protection; these functions are also generally attributed to opisthonotal glands of Oribatida (Raspotnig et al. 2003).

Chemosystematic Impact With respect to chemosystematic studies that use opisthonotal gland profiles of Oribatida, the finding of chrysomelidials in *O. berlesei* is significant. In preliminary investigations, chrysomelidials have been found also in other species of Euphthiracaroidea (data unpublished), suggesting that this chemical class may be characteristic for species of Oribotritiidae, possibly representing an important chemical "synapomorphy" of this family. Also, two further compounds in extracts of *O. berlesei*, if our tentative identifications are correct, would be novel for oribatid and astigmatid mite opisthonotal gland secretions. The diterpene, β-springene, which we tentatively identified as one of the three main components of the secretion, was originally found in secretions of springboks (Burger et al. 1978), and has also been detected in exocrine secretions of further vertebrates, especially mammals and reptiles (e.g., Waterhouse et al. 1996; Schulz et al. 2003), and invertebrates such as certain hymenopterans (e.g., Howard et al. 2003; Cruz-Lopez et al. 2005), but not in arachnids. The other novel compound (for oribatid and astigmatid mite opisthonotal gland secretions) is the tentatively identified 9,17-octadecadienal, a minor constituent of the *O. berlesei* extract. Both tentatively identified compounds, β-springene and 9,17-octadecadienal, may be of chemosystematic value in Oribatida. Their unequivocal identification and possible distribution across other species of Euphthiracaroidea remain to be studied.

Astigmatid Compounds Perhaps the most surprising result of our study is the lack of "astigmatid compounds" in the opisthonotal gland extract of *O. berlesei*. These compounds are common secretion constituents in Mixonomata–Desmonomata and Astigmata, and are regarded as characteristic of all groups above middle-derived mixonomatans. In Collohmanniidae (proposed close relatives of euphthiracaroids), astigmatid compounds dominate opisthonotal gland secretions. Astigmatid compounds, at least in some higher-derived desmonomatans and in brachypylines, may be reduced and replaced by other (novel) compounds in adult secretions of certain groups as in, for example, *Hermannia convexa* (Raspotnig et al. 2005a) and *Scheloribates* ssp. (Takada et al. 2005). Thus, there is a chemical dimorphism between juveniles and adults, with juvenile secretions being distinguished by the plesiomorphic, astigmatid compounds-rich condition. This chemical dimorphism was tested in *O. berlesei*; however, neither adults nor juveniles contained any astigmatid compounds.

Even though the lack of astigmatid compounds in *O. berlesei* may be explained by complete evolutionary reduction, this situation may suggest a possible polyphyletic origin of astigmatid compounds in opisthonotal glands in general. The lack of astigmatid compounds is even more surprising in light of the classification system proposed by Haumann (1991), in which oribotritiids are regarded as basal euphthiracaroids. Astigmatid compounds-free opisthonotal gland secretions in adults and juveniles also occur in several groups of brachypylines (Raspotnig, unpublished data), but these groups are considered highly derived. The lack of astigmatid compounds in Oribotritiidae could be reconciled by a systematic replacement of euphthiracaroids below the Collohmanniidae, corresponding to a possible split from the oribatid stem-line before astigmatid compounds evolved. However, this is not supported by morphological characters (Grandjean 1969). The lack of astigmatid compounds may not necessarily be true for all Oribotritiidae, and any extrapolation from data for *O. berlesei* remains speculative. Our major aim for future studies is the search for astigmatid compounds in other representatives of euphthiracaroid families.

Acknowledgments This work was supported by a grant from the Austrian Science Fund (FWF), project number P18486. We thank Dr. Günther Krisper (Institute of Zoology, Karl-Franzens-University, Graz, Austria) for his help in the determination and discrimination of *Oribotritia* species.

of hand-applied rope dispensers for season-long control of this pest by grape growers has been low, and no companies currently produce sprayable pheromones for *P. viteana* control. Among the reasons for the low adoption of this technology is the 2- to 3-week duration of pheromone release by sprayable formulations (R. Isaacs, unpublished data) and the labor required to apply rope dispensers to the crop.

Recently, a paraffin wax emulsion has been developed, into which insect sex pheromones can be mixed at the required concentration (Atterholt 1996; Atterholt et al. 1998; de Lame 2003). This wax is a viscous homogenate that hardens once applied to crop foliage or branches and it can act as a long-lasting discrete source of pheromone emission. The wax can be applied into crop systems by using manual methods that are more rapid than manual application of twist ties (de Lame 2003; Stelinski et al. 2005; Epstein et al. 2006), or it can be applied by mechanical methods (Stelinski et al. 2005) that enable application to large orchards or vineyards from motorized vehicles (Stelinski et al. 2006).

The optimization of mating disruption requires that the density and size of droplets, as well as the pheromone release rate and duration, are appropriate for the biology of the targeted pest (Miller et al. 2006a, b). Because the size, density, and distribution of wax droplets can be easily manipulated, this delivery system also provides researchers with a flexible tool to aid investigations of how moths can be optimally disrupted. For example, Stelinski et al. (2005) documented increased mating disruption of male oriental fruit moth, *Grapholitha molesta*, in apple orchards as droplet density increased, thus leading to increased suppression of mating in virgin female moths. The authors compared mating disruption in plots treated with wax droplets or the standard twist-tie dispenser, and found superior performance when wax was used. This suggests that the typical deployment density of pheromone twist ties may not provide sufficient point sources of pheromone for optimal disruption of *G. molesta*. More recent studies that evaluated mating disruption of the codling moth, *Cydia pomonella*, in apple orchards treated with the codlemone sex pheromone in wax droplets provide further evidence that higher densities of pheromone release sources improve disruption of mating (Epstein et al. 2006). The success of these studies and others in cotton, pear, and walnut crops has led to the development of a commercial product called SPLAT™ (Specialized Pheromone and Lure Application Technology) that acts as the carrier for sex pheromones or other semiochemicals.

To ascertain the potential for wax-based formulations for mating disruption of *P. viteana*, we determined the duration and efficacy of pheromone disruption of *P. viteana* in Michigan vineyards over two growing seasons by using the GBM-SPLAT™ commercial formulation of the wax matrix. We also tested the hypotheses that orientation of *P. viteana* to droplets would decrease with increasing pheromone release, and that mating disruption would be improved by increasing the density of droplets.

Methods and Materials

Study Sites All studies were conducted in mature *Vitis labrusca* var. 'Concord' vineyards in Van Buren Co., Michigan. These vineyards received standard fungicide and insecticide programs applied by the growers, but low crop levels due to a late spring freeze in 2006 led to a reduced pesticide program and higher activity of *P. viteana* in the second year.

Large-scale Mating Disruption Study This study was conducted during 2005 and 2006 in four vineyards at the same farm, each of which was split into two equal-sized plots [ca. 1.3 ha (100×130 m)]. The plots were assigned to be treated with pheromone in wax, or not treated, in a randomized complete block design with four replicates. Plant spacing in these plots was 2.7 m between vines and 3 m between rows, with posts distributed every three vines, resulting in 1200 vines and 400 posts per hectare. In both years, 1-ml droplets of GBM-SPLAT™ (ISCA Technologies, Inc., Riverside, CA, USA) were deployed by hand on the north side of each wooden post in the treated plots with a 30-ml syringe. The applications were made on 9 May in 2005 and 1 May in 2006, with the same plots treated in both years with wax containing 3% (*v*/*v*) of *P. viteana* pheromone (12 ml AI/ha) at a 10:1 ratio of (*Z*)-9 dodecenyl acetate: (*Z*)-11 tetradecenyl acetate (Shin-Etsu Chemical Co., Tokyo, Japan). In 2005, the formulation also contained 3% (*v*/*v*) cypermethrin, but no moths were trapped near these droplets when placed on sticky traps, suggesting that *P. viteana* moths did not contact the droplets (R. Isaacs, unpublished data).

Adult male *P. viteana* were monitored in each plot with large plastic delta traps (Suterra LLC, Bend, OR, USA) baited with rubber septa that contained female sex pheromone (90:10 ratio of (*Z*)-9–12Ac and (*Z*)-11–14Ac) (Suterra LLC, Bend, OR). Two traps were suspended from the top trellis wire at a height of 1.5 m at both the border and the interior of each vineyard, with at least 33 m between traps. Those in the interior were 65 m from the border, in the same rows as the border traps. The number of male *P. viteana* captured was monitored weekly, and moths were removed or sticky inserts were replaced. Pheromone lures were replaced every 4 wk, with lures from the same lot throughout each season.

Infestation by *P. viteana* was quantified by visually examining 50 clusters (25 clusters at two sampling sites) at

the border and interior of each plot. Both the number of clusters, and the number of berries infested were recorded in the first generation of GBM on 29 June 2005 and 6 July 2006, and during the second generation on 15 August 2005 and 4 August 2006.

Droplet Release Rates To determine the release of pheromone from wax droplets, five 1-ml droplets of GBM-SPLAT™ were applied to each of five 30.5×2.9 cm untreated wood garden stakes (Dayton Garden Labels, Dayton, OH, USA) and deployed on 24 May 2006 at one corner of each of the four pheromone-treated plots described above. Garden stakes were scored every 3.8 cm with a utility knife to allow for ease of individual drop collection. Each stake was nailed to the north face of a post located farthest from monitoring traps. One drop was collected from a randomly selected stake in each of the four treated plots each week until the termination of the experiment. Each sample was placed into a 60-ml glass bottle (Qorpak, Bridgeville, PA, USA) and stored at −20°C until it was extracted using the procedure of Stelinski et al. (2005), which was modified from Meissner et al. (2000). Fifty milliliters of an internal standard solution of 232 m1/l methyl myristate (99%, Acros Organics, Geel, Belgium) in acetonitrile (HPLC grade, EMD Chemicals Inc., Gibbstown, NJ, USA), were added to each sample. The bottles were placed into a water bath shaker (model 406015, AO Scientific Instruments, Keene, NH) at 70–75°C without shaking for 10 min, followed by 10 min of shaking, then briskly agitated by hand for 10 sec, before an additional 3 min of shaking in the water bath. Samples were then hand-agitated for 10 sec and frozen at −20°C to precipitate the wax. After 20 hr, samples were thawed, vortexed, and 1 ml of the solution was removed and filtered into a 2-ml GC vial (Agilent Technologies, Santa Clara, CA, USA) through a disposable glass Pasteur pipette fitted with a paper plug (Kimberly-Clark Corp., Roswell, GA, USA) at the tapered end. The pheromone in each sample was quantified by gas chromatography (GC) (HP-6890, Hewlett-Packard, Palo Alto, CA, USA) by using a 30-m HP DB-23 polar column (model 122-2332, J&W Scientific, Folsom, CA, USA) with the internal standard method (McNair and Miller 1998).

Droplet Density Study This study was conducted during 2006 within one large vineyard to determine the effect of droplet density on disruption of male *P. viteana* flight to pheromone traps. The experiment consisted of a randomized complete block design replicated six times. Treatment plots were 15.2×16.5 m with 80 m between plots and between blocks. Plots received either 0, 1, 3, 10, or 30 0.2 ml droplets of wax containing 3% (*v*/*v*) *P. viteana* pheromone per vine, applied by hand with a 1-ml syringe, or Isomate GBM Plus rope dispensers (Shin-Etsu Chemical Co., Tokyo, Japan) at a density of 450/ha. Treatments were applied on 1 and 3 June 2006. A large plastic delta trap (Suterra LLC, Bend, OR, USA), baited with rubber septa that contained *P. viteana* sex pheromone (Suterra LLC, Bend, OR) was placed in the middle of each plot. Traps were monitored weekly until 24 August 2006 to record the number of male *P. viteana* captured, at which time the moths were removed or sticky inserts replaced. Pheromone lures were replaced every 4 wk with lures from the same lot.

Droplet Size Study This experiment used the same protocol as the droplet density study, but in this case the traps were baited with 0-, 0.2-, 0.5-, or 1.0-ml wax droplets (approximately 6, 15.9, and 30 mg *P. viteana* sex pheromone, respectively) applied to aluminum foil suspended inside the traps, or a rubber septum loaded with 0.1 mg *P. viteana* sex pheromone. All treatments were applied on 24 May 2006, and the traps were monitored weekly until 24 August 2006. To help minimize the effect of pest pressure within experimental blocks, treatments were rotated within each block every week, and droplets were changed every 4 wk.

Statistical Analyses In the mating disruption study, the significance of treatment effect on the number of moths captured for 13 and 15 wk after application in 2005 and 2006, respectively, was compared among treatments for both locations (plot interior and border) by using ANOVA (SAS/STAT 2003). For each sample date, the average number of moths per trap was compared among treatments within each vineyard position by using ANOVA (SAS/STAT 2003). All data were log-transformed ($n+1$) for normality prior to analysis, and Tukey's HSD test was used to determine differences between means at $\alpha=0.05$. Percent disruption values were calculated as the proportional reduction in the number of moths caught in the treated plots compared to the untreated plots. Infestation data were arcsine squareroot transformed prior to analysis and compared between treatments at the border and at the interior positions by using ANOVA for each sampling date (SAS/STAT 2003).

To determine the relationship between time after application and the amount of pheromone released, residual concentration of pheromone droplets in the release rate study was analyzed by regression analysis (SAS/STAT 2003). These values also were compared to the percent disruption values calculated from moth captures, to determine a critical release rate for disruption of *P. viteana*.

The significance of treatment effect on total moths captured in the droplet density and droplet size study was compared among treatments by using analysis of variance (ANOVA) (SAS/STAT 2003). Data were log-transformed ($n+1$) prior to analysis and Tukey's HSD test was used to determine differences between means at $\alpha=0.05$.

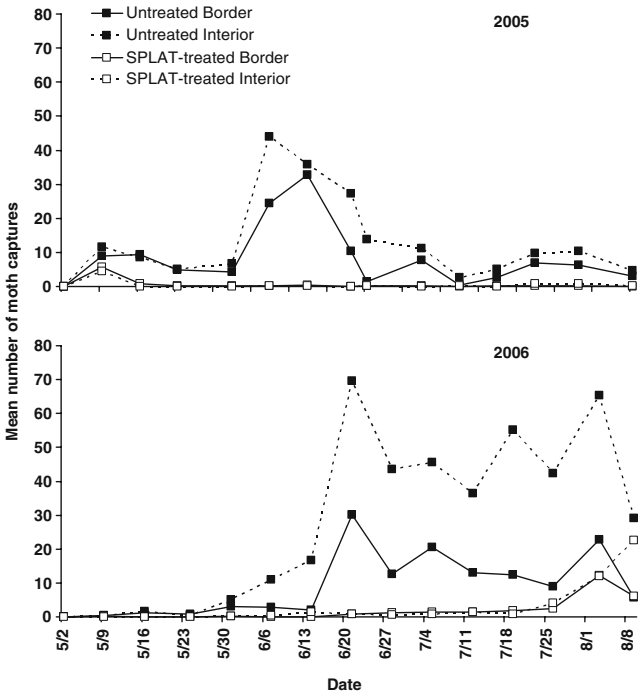

Fig. 1 Average number of adult male *Paralobesia viteana* captured in pheromone traps at the vineyard border or vineyard interior of vineyard plots that were either untreated or treated with 1-ml droplets of SPLAT-GBM™ containing 3% pheromone

Results

Large-scale Mating Disruption Study Before application of treatments in 2005, there was no significant difference in the number of moths trapped between treatments (F=3.67; df=1, 2; P=0.20) or positions (F=0.05; df=1, 8; P=0.83), indicating that pest pressure was similar across vineyards (Fig. 1). However, following the SPLAT-GBM™ treatments, the seasonal total number of moths per trap was lower in treated (2.6±0.7) than untreated (148.9±28.1) plots (F=96.76; df=1, 3; P=0.002) (Fig. 1), a pattern observed both within (F=126.6; df=1, 3; P=0.002) and at the borders (F=37.55; df=1, 3; P=0.009) of plots (Fig. 1).

In 2006, *P. viteana* were not trapped before treatment applications (moths had been trapped at nearby vineyards), but post-treatment the captures of *P. viteana* were significantly lower in the SPLAT-treated (36.5±9.3) than the untreated (279.6±47.2) vineyards (F=39.82; df=1, 3; P=0.008). Most moth captures in the treated plots occurred in the last 2 wk of the trial as the disruption efficiency of the formulations declined (Fig. 1). In contrast to 2005, in 2006 more male *P. viteana* were captured at the interior compared to the border (F=35.4; df=1, 12; P<0.001) within plots. However, similar to 2005, fewer moths were captured at the interior (F=33.97; df=1, 3; P=0.01) and the border (F=21.22; df=1, 3; P=0.019) of treated plots compared to untreated plots.

Percent disruption exceeded 90% at the vineyard interior for approximately 12 wk in 2005 and 11 weeks in 2006. In 2006, when there were no insecticide applications to the vineyards, the level of disruption had declined to 22.7% after 13 wk. In both years, disruption was greater at the interior traps than in traps placed at the borders.

In 2005, neither the total number of larvae found in each sample (F≤0.53; df=1, 3; P≥0.52) nor the proportion of clusters infested with *P. viteana* larvae (F≤3.71; df=1, 3; P≥0.15) varied significantly between treatments or vineyard positions for either sampling date (Table 1). During the first generation samples of 2006, there was no significant difference between treatments in the proportion of clusters infested or the number of larvae in cluster samples at the border (F=2.32; df=1, 3; P=0.23) or interior (F=6.91; df=1,3; P=0.078) of the vineyard (Table 1). However, during the second generation, there were differences in these parameters between the SPLAT-treated and untreated borders (F=12.76; df=1, 3; P=0.038).

Droplet Release Rates Droplets of SPLAT-GBM™ released pheromone as a first-order exponential decay function

Table 1 Average number of *Paralobesia viteana* larval berry infestations and the percentage of clusters infested with *P. viteana* (±S.E.) at the borders and interiors of vineyard plots that were untreated or treated with SPLAT-GBM™ during 2005 and 2006

Date	Position	No. of infestations per 25 clusters			Percent of clusters infested		
		Untreated	SPLAT	*P* value	Untreated	SPLAT	*P* value
6/29/2005	Border	6.1±1.3	7.4±2.2	0.62	7.8±1.0	10.0±1.8	0.15
	Interior	1.9±0.7	1.4±0.9	0.52	2.8±0.9	2.0±1.1	0.48
8/15/2005	Border	_	_	_	20.0±2.0	21.5±3.2	0.64
	Interior	_	_	_	5.8±3.4	3.5±1.6	0.33
6/27/2006	Border	11.1±2.5	7.5±1.4	0.23	15.8±4.5	9.5±1.3	0.23
	Interior	6.8±0.6	3.4±1.1	0.078	9.3±1.0	6.5±2.2	0.27
8/4/2006	Border	22.5±1.9	18.4±1.5	0.038	35.5±3.5	25.8±2.4	0.004
	Interior	11.8±3.9	8.6±1.2	0.43	18.0±5.9	15.3±2.2	0.70

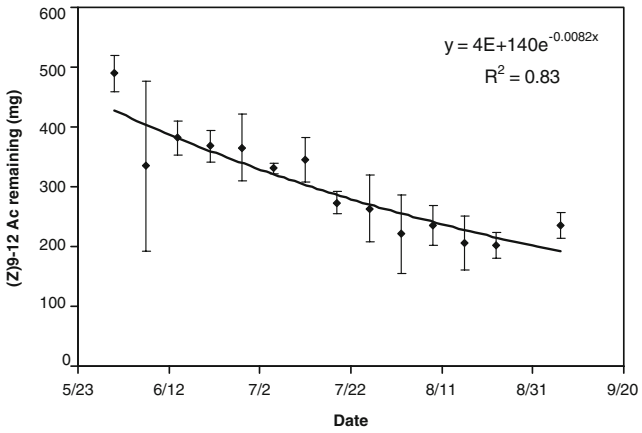

Fig. 2 Release of pheromone from 1-ml droplets of SPLAT-GBM™ during 2006. The release profile best fits an exponential decay function, and the best-fit curve and equation are presented on the graph

(Fig. 2), although the high variability among replicates (shown by the high standard error values), resulted in a relatively low predictive power of the exponential equation. The release function suggests that almost 50% of the pheromone in the wax droplets was still bound in the wax in late July when captures of *P. viteana* were first observed in the SPLAT-treated plots.

Droplet Density Study Significantly more moths were captured in the untreated control plots compared to all other treatments, but the one and three drops per vine treatments had higher moth captures than the 10 drops per vine, 30 drops per vine, and Isomate treatments (F=27.06; df=5, 25; P<0.001) (Fig. 3).

Droplet Size Study The size of each droplet affected how many moths were trapped (F=66.1; df=4, 20; P<0.001) (Fig. 4). The 0.2- and 0.5-ml droplets trapped low numbers

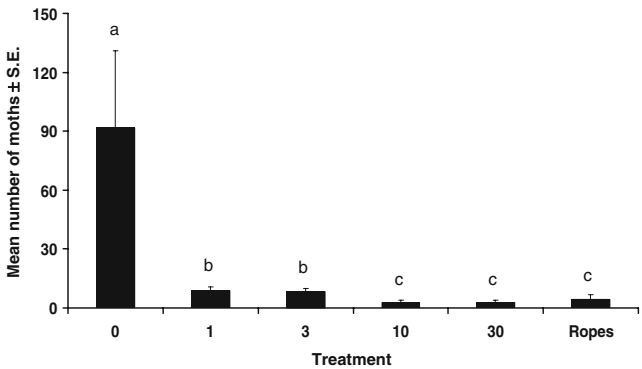

Fig. 3 Average (+SE) number of adult male *Paralobesia viteana* captured in pheromone traps in vineyard plots treated with varying densities of 0.2-ml droplets of SPLAT-GBM™ wax that contained 3% sex pheromone, or pheromone ropes. Bars with the same letter are not significantly different at α=0.05

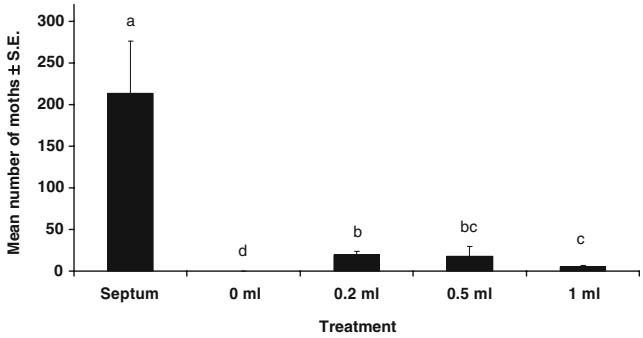

Fig. 4 Average (+SE) number of adult male *Paralobesia viteana* captured in pheromone traps baited with different sizes of SPLAT-GBM™ wax droplets that contained 3% sex pheromone, or a commercial pheromone lure containing 0.1 mg of sex pheromone. Bars with the same letter are not significantly different at α=0.05

of moths, and increasing the droplet size to 1.0 ml caused a slight decrease in the number of moths trapped (Fig. 4). The greatest captures of moths were in traps baited with the lure that contained the standard 0.1 mg of sex pheromone, an amount much lower than that in any of the applied droplets (approximately 6 mg or greater). No moths were caught when the traps were unbaited.

Discussion

Application of 1-ml droplets of SPLAT-GBM™ that contained 3% pheromone to vineyards before the first generation flight of *P. viteana* resulted in high levels of disruption of male moth orientation to monitoring traps during two growing seasons, with reduced crop infestation in treated plots in the second growing season. This first report of using a wax formulation for pheromone deployment in vineyards provides evidence for the potential of this formulation to control *P. viteana*.

Wooden vineyard posts provided a practical target for application of the wax, and droplets applied on the north side of these structures in early May each year remained in place throughout the growing season. These droplets were easy to apply by hand with a 30-ml syringe, and their application was faster than that of Isomate twist ties at 450/ha (Isaacs, unpublished data). The large droplets used in this study released pheromone until late July. The longevity of these droplets is lower compared with those used for mating disruption of *G. molesta* (Stelinski et al. 2006, 2007).

Pheromone dispenser density affects the distribution of pheromone that permeates the crop habitat, thus influencing the degree of mating disruption achieved (Rothschild 1975; Flint and Merkle 1983; Lawson et al. 1996; Stelinski et al. 2005; Miller et al. 2006a, b). A similar pattern was found in this study, as trap catches in untreated plots were greater than one or three droplets per vine (0.2-ml volume) >10 and 30 droplets per vine. The higher doses gave similar results

as Isomate GBM ropes applied once every 0.4 vine. Overall, our results are similar to those observed for *G. molesta* (Stelinski et al. 2005), although they reported higher densities of droplets outperformed twist ties and completely prevented mating of tethered female moths. A profile analysis of variation in moth catch with dispenser density, similar to that conducted by Miller et al. (2006a), was not possible in our study because of an insufficient range of pheromone point-source densities.

A pheromone formulation lasting >20 wk, as achieved with Isomate-GBM twist ties, is necessary to cover the full activity period of *P. viteana* in the Great Lakes region of the US and Canada. Our results suggest that this cannot be currently achieved by using SPLAT-GBM™, so one approach to would be to re-treat vineyards in late July. Alternatively, one could apply an appropriate Lepidoptera-specific insecticide for control of first-generation *P. viteana*, followed by application of SPLAT-GBM™ in early July to provide protection against this pest until harvest. Another promising line of research would be the development of a wax formulation that provides a pheromone release system lasting >20 wk.

Development of formulations that slowly release the pheromone is an important goal for mating disruption, not only to provide a long period of activity but also to ensure that expensive pheromone is not wasted by remaining bound in the wax matrix (de Lame 2003). Residual analysis of wax revealed that approximately 50% of the *P. viteana* pheromone was still bound in the drops when disruption performance declined in late July. The 1-ml droplets used in this study are larger than those deployed in many recent studies (Stelinski et al. 2005, 2006, 2007), so the use of more, smaller-sized droplets should result in a greater proportion of the pheromone being released (Stelinski et al. 2005). This is currently under investigation, especially as the amount of pheromone released per hectare in the 10-drops-per-vine treatment (58.1 mg/Ha) was lower than the Isomate treatment (99.8 mg/Ha).

Evaluations of sex pheromone formulations for control of *P. viteana* have shown that mating disruption can help control this pest (Dennehy et al. 1990; Trimble 1993), yet there has been relatively low adoption of this approach in vineyard IPM programs in eastern North America where vineyards are infested by *P. viteana*. Primary impediments to adoption are the perception that pheromone formulations have lower efficacy, and the cost of pheromone products and their application is greater when compared with insecticides. An additional challenge to controlling infestation of *P. viteana* is that this insect typically causes higher levels of crop infestation at the vineyard borders than in the interiors (Hoffman and Dennehy 1989; Botero-Garcés and Isaacs 2003). Our results showed that while application of SPLAT-GBM™ caused an immediate shutdown of traps, a significant reduction in cluster infestation at the vineyard borders was observed only in the second year of treatment, suggesting that multiyear application of pheromone may be required for mating disruption of GBM.

Acknowledgments We thank Agenor Mafra-Neto and Reg Coler at ISCA Technologies, Inc. for supplying the SPLAT-GBM™ used in these trials. Piera Siegert and Zsofia Szendrei provided technical assistance, and we thank Lukasz Stelinski, Larry Gut, and Jim Miller for input. We also thank the anonymous reviewers for constructive comments on the previous version of this manuscript. This research was funded in part by the National Grape Cooperative, the USDA Viticulture Consortium East, and the Michigan Agricultural Experiment Station.

better understanding of how they initially disrupt communication could provide important insights for optimizing this flexible technology (Knight and Larson 2004; Stelinski et al. 2005).

The major mechanisms of mating disruption, as postulated by Bartell (1982) and discussed by Cardé (1990), fall into two discrete categories, competitive vs. non-competitive (sensu Miller et al. 2006a). Competitive attraction, or false-plume following, occurs when males spend a portion of the female calling period orienting to and following attractive synthetic pheromone plumes from dispensers, thereby reducing the odds of successful mate location (Miller et al. 2006a). Major non-competitive mechanisms include: (1) camouflage of the female-produced pheromone plume by relatively constant atmospheric levels of synthetic pheromone; (2) adaptation of the male peripheral nervous system due to a reduction in the sensitivity of antennal receptors; (3) habituation at any level of the male central nervous system resulting from exposure to pheromone, which leads to a decrease or cessation of appropriate sexual response; and (4) sensory imbalance of the signal processed by males as a result of one or more synthetic pheromone components (Bartell 1982; Cardé 1990) being released in a ratio that differs from the female-produced blend (Flint and Merkle 1983; Judd et al. 1995).

Despite precise definitions of each mechanism, it is often difficult to demonstrate clearly the importance of one mechanism over another, as several are probably involved under most mating disruption regimes (Sanders and Lucuik 1996; Cardé et al. 1998; Miller et al. 2006a, b). Under certain circumstances, however, one can eliminate the importance of competitive mechanisms a priori. For example, MEC formulations that release an unattractive pheromone blend and are applied uniformly to crop foliage over large areas should not result in significant competitive attraction, as a relatively diffuse cloud of unattractive pheromone may be produced (Weatherston 1990; Doane 1999). In such cases, disruption of male mate-finding behavior should stem solely from non-competitive mechanisms that are concentration dependent (Miller et al. 2006a) and can be individually examined under experimental conditions.

MEC formulations characteristically have high initial pheromone release rates that quickly decline, and it is this rapid drop that is thought to reduce formulation efficacy over time (Hall and Marrs 1989; Polavarapu et al. 2001; Albajes et al. 2002). This has led to the conclusion that MEC pheromone technology fails to achieve significant disruption because it does not produce the sustained atmospheric concentrations of pheromone necessary to camouflage natural female plumes or invoke significant sensory effects. However, insects alighting or resting on foliage treated with MEC pheromone may be in continuous contact with undiluted pheromone at the leaf surface–air interface, exposing them to far greater pheromone concentrations than the average atmospheric concentration (Judd et al. 2005a). Despite this possibility, the degree to which surface contact exposure to pheromone might induce various non-competitive mechanisms of disruption has received almost no attention.

This study used *C. rosaceana*, a significant lepidopteran pest of pome fruit in North America (Knight et al. 1998; Lawson et al. 1996), to achieve two objectives. The first was to use behavioral and electrophysiological assays to examine the non-competitive mechanisms of communication disruption involved when male *C. rosaceana* were exposed through direct contact to formulations of MEC (*Z*)-11-tetradecenyl acetate (Z11-14:OAc). Z11-14:OAc is the major pheromone component in the four-component blend of *C. rosaceana* (El-Sayed et al. 2003). The second objective was to examine whether the addition of horticultural oil as an adjuvant to a MEC formulation affected its efficacy and any communication disruption mechanisms involved. This idea arose from earlier work that showed that the addition of horticultural oil stabilized the release rate of Z11-14:OAc from microcapsules over several weeks (Judd et al. 2006), potentially increasing formulation longevity. Specifically, we tested the hypothesis that the formulation of a MEC pheromone with a 2% horticultural oil adjuvant would result in stronger and more sustained disruption of male mate-finding behavior over time than the formulation of a MEC pheromone in water.

Methods and Materials

Insects *C. rosaceana* used in assays came from a 10-year-old colony originally collected in the Okanagan and Similkameen valleys (British Columbia, Canada) and periodically restocked with wild insects. Larvae were reared individually in 25-ml Solo® cups on a modified pinto bean diet (Shorey and Hale 1965) at 23°C under a 16:8 h (L:D) photoregime (scotophase began at 1400 hours). Pupae were collected weekly, separated by sex, and 190 of each sex were returned to the colony. The remaining pupae were placed in separate 10-l buckets for each sex. Eclosed adults were collected each day, transferred to a different 10-l bucket, and held under the same conditions in separate chambers until assays were conducted. Care was taken to ensure that males were not exposed to pheromone before assays.

Treatment Formulations 3M MEC-LR® containing 20% microencapsulated Z11-14:OAc by weight was obtained from 3M Canada (London, ON, Canada) and stored at 4°C between experiments. This formulation of pheromone is no

longer commercially available. Purespray Green® horticultural oil (batch # 655-0602, Petro-Canada, Mississauga, ON, Canada) is a highly purified, *n*C23 mineral oil, with a molecular weight of 325, and an average boiling point of 223.9°C (ASTM D 1160; Petro-Canada, technical data sheet). This oil is prepared with a proprietary emulsifier and approved for use by organic producers in the USA (Organic Materials Review Institute, Eugene, OR, USA). Purespray Green® was held at room temperature before use in formulations.

Treatment Application and Ageing For behavioral and electrophysiological assays, male moths were exposed to treatment formulations while resting on 8.5 cm (diam.)-treated galvanized sheet metal disks (Fehling's Sheet Metal, Penticton, BC, Canada). Each disk received spray applications of one of the following four treatments: (1) distilled water control; (2) 2% (*v*/*v*) Purespray Green® in distilled water; (3) MEC-LR® mixed in distilled water and applied at 1 μg a.i. cm^{-2}; and (4) MEC-LR® applied at 1 μg a.i. cm^{-2} in a 2% (*v*/*v*) Purespray Green® plus distilled water mixture. Hereafter, these treatments are referred to as: water, oil, MEC, and MEC + oil, respectively. One hundred milliliter of each solution was dispensed into 160 ml glass bottles attached to hand-held, pressurized, disposable spray guns (Preval® Sprayer, Precision Valve Corporation, Yonkers, NY, USA). Metal disks were placed on a disposable plastic sheet within a 40×50-cm marked area. The area was sprayed with 20 ml of solution at a distance of 30 cm in successive horizontal and vertical transects. The resulting application rate of 1 μg a.i. cm^{-2} per disk for MEC-LR® best approximated both label-recommended field application rates of 100 g a.i. Z11-14:OAc ha^{-1} for MEC-LR® and 1,000 l water ha^{-1} for Purespray Green®. Disks were air-dried and stored in a fume hood where the sprayed formulations were allowed to age for different time periods before use.

Flight Tunnel Bioassay Protocol Flights were conducted in a flight tunnel described in detail by Evenden et al. (1999, 2000). Air was pushed through the 2.45-m-long×1-m-high tunnel by a variable speed fan and exhausted out of the building by a centrally located exhaust fan. The tunnel was illuminated from above by six 25-W incandescent bulbs that produced uniform, diffuse white light (1 lux). The wind speed was maintained at 0.3–0.4 m s^{-1}, the tunnel temperature was 22–24°C, and all flight experiments started at 1400 hours.

In each replicate of each flight tunnel experiment, a single, calling virgin female (4–48 h old) served as the pheromone source. Female *C. rosaceana* in this age group are similarly attractive to males (Delisle 1992) and have similar pheromone titer (Delisle and Royer 1994). The female was presented in a wire mesh cage (3 cm^3), positioned on a small metal platform 45 cm above the tunnel floor and 20 cm from the upwind end. A cylindrical trap (13 cm long×11 cm diam.) constructed from clear, 1-mm thick polyester (GE Polymershapes, Coquitlam, BC, Canada), was suspended from a ring stand directly downwind of the female's cage so that its long axis was parallel to the tunnel floor, and the pheromone plume traveled directly through the center of the cylinder. The trap was coated internally with STP Oil (First Brands Corporation, Scarborough, ON, Canada) to capture males that flew upwind in close proximity to the female.

Male moths used were aged 24–96 h old, an age range shown to have consistent mating success (Delisle 1995). Males were briefly chilled at 2°C, randomly divided into groups of ten, and each group was lightly dusted with a uniquely colored Day-Glo® Daylight Fluorescent Powder to identify each of the four different treatments (Switzer Brothers Inc., Cleveland, OH, USA). One hour before the start of flights, a group of ten males was placed on a treated disk in a wire mesh release cage (9 cm diam.×2 cm height) with a removable wire mesh lid. Males initially placed on the treated disks often moved onto the sides and inner mesh lid of the release cage; however, individuals were always at a distance of <2 cm from the disk. Males on treated disks were transferred immediately into the bioassay room, placed in a small fume hood adjacent to the tunnel, and held under test conditions. This process was repeated every 15 min until all treatments were established. Clear plastic dividers within the fume hood separated males in different treatments to ensure no pheromone cross contamination among treatments. Flights were staggered at 15 min intervals to maintain a 1-h treatment exposure period for each group. After each flight day, the flight tunnel was wiped down with ethanol, and the wire mesh release devices, female holding cages, and release platform were rinsed with acetone and heated for ca. 12 h at 200°C.

Experiment 1: Disruption of Mate-finding Behavior Through Continuous Exposure with a Pheromone-treated Surface In this experiment, we tested the hypothesis that continuous contact with MEC- and MEC + oil-treated surfaces would disrupt male orientation to a calling female. This experiment also tested the hypothesis that the disruptive efficacy of the MEC treatment would decrease more rapidly over time than the MEC + oil treatment. Disks were sprayed with the four treatments as described above, and aged in the fume hood for 1, 6, or 13 days prior to use in the bioassay. Following the 1-h treatment exposure, the wire mesh release cage that contained the first test group of ten males on the treated disk was introduced into the downwind end of the tunnel on a sliding cart. An externally operated line was used to lift the lid off the release device

5 s after cage introduction. Each group of males was left to respond to the calling female for 5 min, after which the release device and trap were removed. Males caught in each trap were examined under UV light to identify from which group they originated, to ensure that only males caught from the appropriate group were used in subsequent analyses. A fresh trap was inserted after each group flight, with subsequent flights initiated every 15 min. Forty males (four groups of ten) were tested at each treatment and disk age combination (Table 1).

Experiments 2 and 3: Disruption of Mate-finding Behavior After Exposure to Pheromone-treated Disks Experiments 2 and 3 eliminated the effect of camouflage and tested the hypothesis that prolonged sensory effects from pheromone exposure caused disruption in males. In experiment 2, males in groups of ten were exposed for 1 h to disk treatments as above. Disks were aged in the fume hood for increasing lengths of time (1, 6, 13, 20, 33, and 47 days) to further test the hypothesis that the disruptive efficacy of the MEC treatment would decrease more rapidly over time than the MEC + oil treatment (Table 1). After the 1-h exposure, males were chilled briefly in a cooler of ice and quickly transferred to a clean release device before introduction into the flight tunnel exactly 75 s after removal from the treated disk. A preliminary experiment showed no effect of the brief cooling protocol on pheromone responses of naive males, and the 75-s recovery period was chosen to correspond with the electroantennogram (EAG) measurements (experiments 5 and 6). Sixty to 70 males (six to seven groups of ten) were tested at each treatment and disk age combination (Table 1).

Experiment 3 tested the effect of a 60-min clean air recovery period after exposure to treated disks. Experiments 3–6 only used disks aged in the fume hood for 6 days (Table 1). Flight protocol for experiment 3 was identical to experiment 2 except that after the 1-h exposure period, chilled males were transferred to a clean release device and placed in a clear Plexiglas® box equipped with a fan that blew charcoal-filtered air over males under bioassay conditions for 1 h before flights. Seven groups of ten males were tested per treatment.

Experiment 4: Disruption of Mate-finding Behavior at Increasing Times After Exposure to Pheromone-treated Disks In this experiment, we flew individual males to

Table 1 Bioassay descriptions for flight tunnel and electroantennogram (EAG) assays conducted on male *Choristoneura rosaceana*

Experiment	Assay	Treatment[a]	Formulation age[b] (days)	Males tested per treatment × age combination	Exposure time[c]	Recovery time[d]
1	Group flights	Water	1, 6, 13	40	60 min	None
		Oil	1, 6, 13	40	60 min	None
		MEC	1, 6, 13	40	60 min	None
		MEC + oil	1, 6, 13	40	60 min	None
2	Group flights	Water	1, 6, 13, 20, 33, 47	60–70	60 min	75 s
		Oil	1, 6, 13, 20, 33, 47	60–70	60 min	75 s
		MEC	1, 6, 13, 20, 33, 47	60–70	60 min	75 s
		MEC + oil	1, 6, 13, 20, 33, 47	60–70	60 min	75 s
3	Group flights	Water	6	70	60 min	60 min
		Oil	6	70	60 min	60 min
		MEC	6	70	60 min	60 min
		MEC + oil	6	70	60 min	60 min

[d] Time spent by each group of male moths in clean air after removal from treated disks prior to the initiation of the bioassay

examine the impact of exposure to MEC formulations on mate-finding behavior at increasing times (between 1 and 50 min) after exposure. The oil treatment was excluded from this experiment (Table 1) as earlier group flight assays (experiments 1–3) indicated no differences in behavior of males exposed on oil-treated disks compared to males exposed on water-treated disks. Each replicate consisted of males (24–96 h old) exposed for 1 h on a metal disk treated with either water, MEC, or MEC + oil. After the 1-h exposure, the wire mesh release cages that contained males on treated disks were briefly chilled in a cooler of ice, and males were transferred into clean, individual wire mesh release cages (3.5 cm diam.×1.5 cm height) with a sheet metal lid. Individual release cages were positioned in the clear Plexiglas® box adjacent to the flight tunnel, where charcoal-filtered air was continually blown over them until use in the bioassay. Individual flights were initiated every 2 min, alternating males from the three treatments, so that males were assayed at various times between 1 and 50 min after removal from treated disks. The sequence of treatments was re-randomized each day. Males were flown individually to the calling female by inserting the individual release cage into the center of the pheromone plume on the sliding cart at the downwind end of the tunnel. Female handling and placement was identical to that of experiments 1–3, except no cylindrical trap was used. Males were given 5 s in the plume before release. Male responses were scored as positive (+) or negative (−) for contact with the cage housing the female (source contact). Males were quickly aspirated out of the tunnel after each flight.

Experiments 5 and 6: Electrophysiological Effects After Exposure to Pheromone-treated Disks We used EAGs to measure directly and compare potential adaptation of antennal receptors following exposure to MEC- and MEC + oil-treated disks. The effect of 1- and 24-h exposure periods to the four treatment formulations aged for 6 days in the fume hood on subsequent antennal sensitivity to Z11-14:OAc was tested in experiments 5 and 6, respectively. Our EAG system consisted of an IDAC-02 data acquisition interface board, an INR-02 EAG-SSR system, and EAG 2000 software from Syntech (Hilversum, The Netherlands). Each antenna was attached to a gold-plated Syntech PRG-2 probe with a small quantity of Spectra 360 conductive gel (Parker Laboratories Inc., Orange, NJ, USA). Pheromone-loading doses consisted of neat Z11-14:OAc (99% purity, Pherobank, Wageningen, The Netherlands) serially diluted in HPLC-grade hexane to obtain decade solutions between 0.2 ng and 20 μg Z11-14:OAc μl^{-1} hexane. Fifty microliters of each solution, and 50 μl of a hexane control, were pipetted individually onto 1×2-cm strips of folded Whatman no. 1 filter paper and allowed to evaporate in a fume hood for 5 min. As a standard, 10 μl of the plant volatile (*E*)-2-hexenal (1 μg/μl paraffin oil) also were pipetted onto filter paper and allowed to evaporate. Treated strips were inserted into disposable Pasteur pipettes and allowed to equilibrate for 30 min before use. Two-seconds stimulus puffs were generated with a Syntech CS-05 pulse generator at a flow rate of 10 ml/s. EAG responses were measured as the maximum amplitude of depolarization elicited by the stimulus applied. An initial dose-response experiment on naive male *C. rosaceana* antennae determined an optimal range of responsiveness to stimulus puffs between 10 and 1,000 μg Z11-14:OAc in 50 μl hexane; therefore, this stimulus range was used in subsequent experiments.

Male moths (24–96 h old) were exposed individually on metal disks sprayed with one of the four treatments as above. Exposure occurred in standard release devices placed in a fume hood where air was continuously drawn over them for either 1 or 24 h (Table 1). After exposure, a male was removed from a treated disk, and one antenna excised and mounted on the EAG. A stimulus puff of 10 μg Z11-14:OAc was administered to the antenna exactly 75 s after removal from the treated disk, and each antenna received a series of puffs delivered every 30 s in the following order: 10 μg Z11-14:OAc, 10 μg (*E*)-2-hexenal, 100 μg Z11-14:OAc, 10 μg (*E*)-2-hexenal, 1,000 μg Z11-14:OAc, 10 μg (*E*)-2-hexenal, hexane control, and 10 μg (*E*)-2-hexenal. The plant volatile was used to normalize antennal response over one dose series by dividing mV response to each Z11-14:OAc stimulus by the average mV response for (*E*)-2-hexenal for one antenna (Karg et al. 1994; Judd et al. 2005b). We used ten and nine male antennae per treatment for the 1 and 24 h exposure experiments, respectively.

Experiment 7: Microcapsule Density Microcapsules on MEC- and MEC + oil-sprayed disks were counted to determine the rates of microcapsule deposition from each formulation. The disk spraying protocol was identical to experiments 1–6, however, formulations included 0.2% Rose Bengal dye (Aldrich Inc., Milwaukee, WI, USA) to increase microcapsule visibility. After disks had dried, microcapsules were counted with an Olympus SZX12 stereo microscope (×72 magnification; 9.1 mm^2 field of view). Six fields of view were examined per disk, with N= 16 disks/treatment.

Statistical Analyses For both experiments 1 and 2, mean proportion of males captured in group flights was analyzed with a two-way analysis of variance (ANOVA) with formulation treatment and disk age as factors. Significant treatment differences were separated by using the Student–Newman–Keuls (SNK) multiple comparison procedure. In experiment 3, mean proportion trap catch of males was analyzed with a one-way ANOVA followed by a SNK test

to separate significant treatment differences. Experiments 1–3 were analyzed in Sigmastat® 3.0.1 (SYSTAT Software Inc., San Jose, CA, USA). For individual flights (experiment 4), the relationship between time post-exposure and male ability to make source contact was analyzed separately for each treatment by using logistic regression due to the binomial nature of the data (i.e., males scored as (+) or (−) for contacting the female). As both MEC-exposed and MEC + oil-exposed males showed a significant effect of time after exposure on ability to contact the female, a logistic regression model with treatment as a categorical variable and time post-exposure as a continuous variable was used to test the effect of treatment on male ability to contact the female. For experiments 5 and 6, differences in normalized mV antennal response between treatments at each stimulus dose were compared by using a one-way ANOVA. The number of microcapsules deposited on metal disks by application of MEC and MEC + oil in Exp. 7 was compared by using a one-way nested ANOVA with the number of microcapsules within each sampled field of view nested within each sampled disk. Experiments 4–7 were analyzed with SYSTAT 11 (SYSTAT Software Inc., San Jose, CA, USA). All proportion data were arcsine square-root-transformed prior to analysis, and significance set at α=0.05 for all tests.

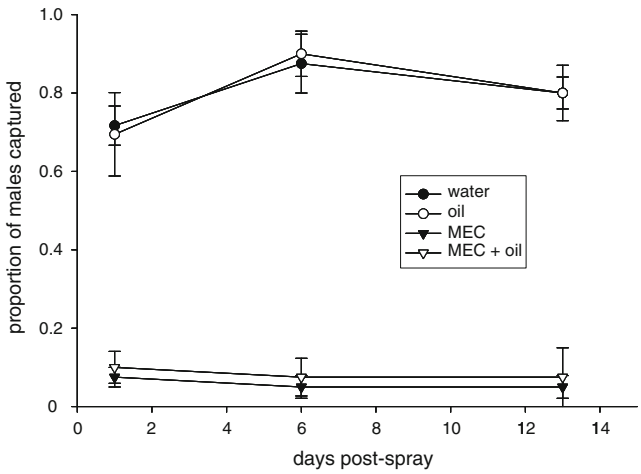

Fig. 1 Mean (±SE) proportion of male *Choristoneura rosaceana* caught in female-baited traps in a flight tunnel following a 1-h exposure on a metal disk sprayed with either water, 2% Purespray Green® (oil), MEC-LR® applied at 1 μg a.i.$^{-1}$ cm^{-2} (MEC), or MEC-LR® at 1 μg a.i.$^{-1}$ cm^{-2} + 2% Purespray Green® (MEC + oil). Groups of ten males were introduced into a female-produced pheromone plume while resting on treated disks, with formulations aged on disks for 1, 6, or 13 days (N=4 groups of ten males/treatment). The effect of treatment was significant ($F_{3,\ 36}$=74.73, P<0.001) while the effect of formulation age was not significant ($F_{2,\ 36}$=1.36, P=0.268) by two-way analysis of variance (ANOVA). Treatment means were further separated by Student–Newman–Keuls multiple comparison test: water and oil treatments were equal, and significantly greater than MEC and MEC + oil treatments, which were equal

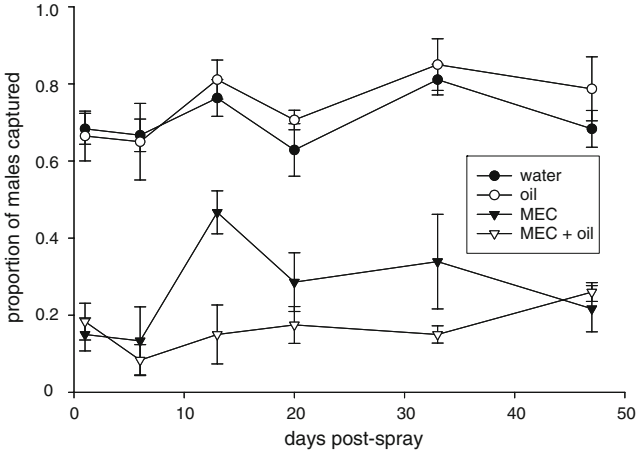

Fig. 2 Mean (±SE) proportion of male *Choristoneura rosaceana* caught in female-baited traps when males were released 75 s after a 1-h treatment exposure on a metal disk sprayed with either water, 2% Purespray Green® (oil), MEC-LR® applied at 1 μg a.i.$^{-1}$ cm^{-2} (MEC), or MEC LR® at 1 μg a.i.$^{-1}$ cm^{-2} + 2% Purespray Green® (MEC + oil). Formulations were aged on disks for 1, 6, 13, 20, 33, or 47 days (N=6–7 groups of ten males/treatment). The effect of both treatment ($F_{3,\ 124}$=95.69, P<0.001) and formulation age ($F_{5,\ 124}$=4.35, P=0.001) were significant by two-way analysis of variance (ANOVA). Treatment means were further separated by Student–Newman–Keuls multiple comparison test: water and oil treatments were equal, and significantly greater than the MEC treatment, which was significantly greater than the MEC + oil treatment

Results

Experiment 1: Disruption of Mate-finding Behavior Through Continuous Exposure with a Pheromone-treated Surface The proportion of males captured in female-baited traps was reduced when males were continuously exposed to pheromone while resting on MEC- or MEC + oil-treated disks as compared to control disks ($F_{3,\ 36}$=74.73, P< 0.001). The proportion of males captured was unaffected ($F_{2,\ 36}$=1.36, P=0.268) by formulation aging up to 13 days after application (Fig. 1). Mate finding was equally disrupted by exposure to MEC alone and MEC + oil treatments (Fig. 1).

Experiments 2 and 3: Disruption of Mate-finding Behavior After Exposure to Pheromone-treated Disks In experiment 2, the effect of a 1-h exposure treatment was significant ($F_{3,\ 124}$=95.69, P<0.001; Fig. 2). The proportion of males captured over the 47-day period was not significantly different between the water (70.4±2.2%) and oil (74.4± 2.8%) treatments. However, exposure to the MEC and MEC + oil treatments caused a significant reduction in trap catch compared to control treatments. In addition, the mean proportion of MEC + oil-exposed males captured (16.8± 1.9%) was significantly lower than MEC-exposed males (26.6±3.5%; Fig. 2). There was an effect of formulation age ($F_{5,\ 124}$=4.35, P=0.001), but there was no significant

interaction between treatment and formulation age ($F_{15, 124}$= 1.29, P=0.215). Although pheromone release rates should have dropped as formulations aged, the effect of exposure to both MEC and MEC + oil treatments on mate finding was still strong on day 47 (Fig. 2).

Even when males were given a 1-h recovery period following exposure to 6-day-old formulations (Fig. 3), there was a significant difference in male trap catch among treatments ($F_{3, 18}$=4.5, P=0.016). The proportion of males captured was significantly reduced in the MEC + oil treatment compared to either control treatment. However, while MEC was similar to MEC + oil, there was no difference between MEC and control treatments (Fig. 3).

Experiment 4: Disruption of Mate-finding Behavior at Increasing Times After Exposure to Pheromone-treated Disks For males exposed to water-treated disks, there was no relationship between flight time post-exposure (1–50 min) and the probability of source contact (N=98, slope=0.012, P=0.545). In contrast, there was a positive relationship between the length of the recovery period and the proportion of males that reached the calling female for both MEC (N=103, slope=0.04, P=0.006) and MEC + oil treatments (N=95, slope=0.04, P=0.010). However, eight of 20 MEC- and nine of 21 MEC + oil-exposed males flown within 5 min of removal from treated disks made contact with the female. When MEC- and MEC + oil-exposed males were included in a pooled model, there was no difference in male recovery time between the two treatments (N=198, P=0.349).

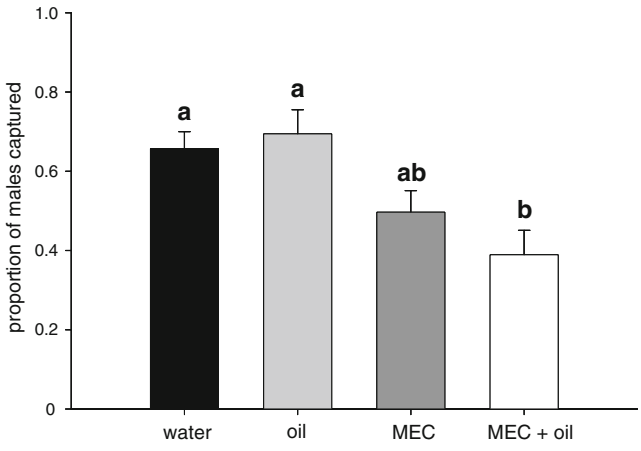

Fig. 3 Mean (+SE) proportion of male *Choristoneura rosaceana* caught in female-baited traps tested 1 h after a 1-h exposure on a metal disk sprayed with either water, 2% Purespray Green® (oil), MEC-LR® applied at 1 μg a.i.$^{-1}$ cm^{-2} (MEC), or MEC-LR® at 1 μg a.i.$^{-1}$ cm^{-2} + 2% Purespray Green® (MEC + oil). Formulations were aged on disks for 6 days (N=7 groups of ten males/treatment). Means with a *different letter* are significantly different by Student–Newman–Keuls multiple comparison test following significant ANOVA (P<0.05)

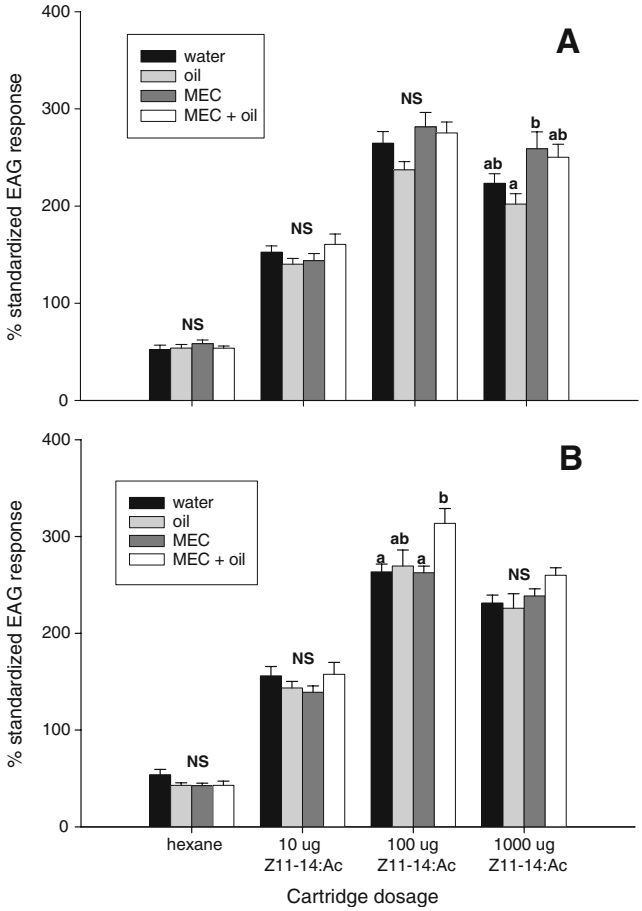

Fig. 4 Mean (+SE) standardized EAG responses generated from excised antenna of male *Choristoneura rosaceana* assayed 75 s after a 1-h (**a**) or 24-h (**b**) exposure on a metal disk sprayed with either water, 2% Purespray Green® (oil), MEC-LR® applied at 1 μg a.i.$^{-1}$ cm^{-2} (MEC), or MEC-LR® at 1 μg a.i.$^{-1}$ cm^{-2} + 2% Purespray Green® (MEC + oil) treatments. Formulations were aged on disks for 6 days before male exposure treatments, N=9–10 antennae/treatment. Means with a *different letter* are significantly different by Student–Newman–Keuls multiple comparison test following significant ANOVA (P< 0.05)

Experiments 5 and 6: Electrophysiological Effects After Exposure to Pheromone-treated Disks Neither 1- nor 24-h exposure periods to formulations of MEC and MEC + oil reduced male antennal response to Z11-14:OAc compared to controls (Fig. 4a, b). Interestingly, after a 1-h exposure, MEC-exposed males showed a small but significantly greater antennal response to the 1,000-μg Z11-14:OAc stimulus ($F_{3, 36}$=3.92, P=0.016) than did oil-exposed males (Fig. 4a), and after a 24-h exposure (Fig. 4b) MEC + oil-exposed males showed enhanced response to the 100-μg Z11-14:OAc stimulus ($F_{3, 32}$=3.66, P=0.018).

Experiment 7: Microcapsule Density Direct counts of microcapsules showed that MEC-treated disks had fewer microcapsules deposited on them compared to MEC + oil-

treated ones (64.8±5.1 microcapsules cm^{-2} vs. 95.1±8.2 microcapsules cm^{-2}: $F_{1, 30}$=4.45, P=0.04).

Discussion

Our data demonstrate that surface exposure to formulations of MEC pheromones in water or oil has a strong effect on mate-finding behavior in *C. rosaceana*, but causes no reduction of antennal response to Z11-14:OAc tested immediately after exposure. Taken collectively, our behavioral and electrophysiological results suggest that habituation of the male central nervous system may be a major mechanism of disruption in this study, and that the disruptive effect of MEC formulations may be moderately enhanced by the addition of 2% oil.

Experiments 1 and 2 showed that exposure to MEC-LR® formulated in oil or water disrupts mate-finding behavior compared to controls up to 47 days after application. Males placed on pheromone-treated disks were generally more quiescent before the flight assays than those placed on control disks, which eliminates exhaustion as a possible explanation for our results. Experiments 2–4 provided behavioral evidence that habituation may be an important mating disruption mechanism because the experimental protocol eliminated any possibility of camouflage of the female plume as a potential mechanism. When males were assayed in the flight tunnel 75 s after removal from the treated surface in experiment 2, a similar reduction in trap catch to experiment 1 was observed. This indicates that the role of physical camouflage of the pheromone plume (Judd et al. 2005a) may be less important once significant habituation has been induced. In experiment 2, there was no significant interaction between treatment and formulation age, which indicates that the relative efficacy of treatments did not change as they aged in the fume hood.

Our finding that pheromone exposure resulted in a significant reduction in subsequent mate-finding behavior up to 1 h after exposure is consistent with previous studies on other moth species such as *G. molesta* (Figueredo and Baker 1992; Rumbo and Vickers 1997), *Trichoplusia ni* Hübner (Kuenen and Baker 1981; Liu and Haynes 1993), and *Heliothis virescens* Fabricius (Daly and Figueredo 2000). However, our results contrast with those of Evenden et al. (2000), in which a 1-h exposure to atmospheric pheromone caused no reduction in male *C. rosaceana* response to a calling female 10–30 min after exposure. It is possible that the atmospheric concentration produced from a pheromone-treated septa (Evenden et al. 2000) was insufficient to induce habituation as compared to males resting directly on a MEC-treated disk.

In experiment 4, both MEC- and MEC + oil-exposed males exhibited a significant positive relationship between the recovery time after exposure and probability of contacting the female. However, this relationship was not as strong as expected given the results from experiments 2 and 3. This suggests considerable phenotypic variability among individual male *C. rosaceana*, which is supported by the fact that 17 of 40 males (42.5%) were able to locate the calling female within 5 min of being removed from the MEC- and MEC + oil-treated disks. Alternatively, it is possible that all males were not exposed identically to pheromone. Males that spent more time on the cage that housed the treated disk may have received lower pheromone exposure than males that consistently remained on the disk surface.

The results of the electrophysiological experiments also indicate that central nervous system habituation is the important mechanism of mating disruption in our experiments, as no significant antennal adaptation was found when EAG assays were performed 75 s after removal of males from treated disks. It is possible that males experienced some transient antennal adaptation within the 75 s immediately following removal from the treated disk. However, release rates of Z11-14:OAc from MEC-LR® in water and oil at 6 days post-spray were ≈8 pg Z11-14:OAc cm^{-2} min^{-1} (Judd et al. 2006), which are well below the threshold concentration of 500 pg Z11-14:OAc ml^{-1} air necessary to induce significant "long-lasting" antennal adaptation in male *C. rosaceana* (Stelinski et al. 2003a, b). Interestingly, in two instances, our EAG experiments showed a marginal increase in antennal response to a stimulus of Z11-14:OAc following exposure to MEC-LR® formulations, possibly a result of antennal sensitization similar to that described by Stelinski et al. (2003c).

The addition of oil to the MEC formulation moderately enhanced disruption over time (Fig. 2). One possible reason is that MEC + oil maintains an elevated release rate (≈8 pg cm^{-2} min^{-1} between 13 and 30 days after application) compared to MEC alone, which maintains a release rate of ≈2 pg cm^{-2} min^{-1} between day 13 and 30 after application (Judd et al. 2006). The greater efficacy of the MEC + oil treatment also could be related to the increased number of microcapsules deposited on the disks compared with MEC. Although the reasons for this remain unclear, the oil may increase the deposition of spray droplets by affecting the surface tension properties and spreading coefficient of the spray (Anderson et al. 1987; Streibig and Kudsk 1992). When these same treatments were applied to apple foliage in the field, an equal level of disruption of mate-finding behavior in *C. rosaceana* was found between MEC and MEC + oil treatments up to 42 days after treatment (Wins-Purdy et al. 2007).

After a 1-h recovery period, the mate-finding ability of MEC-exposed males was no different from control males,

while the mate-finding ability of MEC + oil-exposed males was still significantly reduced (Fig. 3). If pheromone release rates were nearly equal from MEC and MEC + oil disks aged 6 days (Judd et al. 2006), then the difference may be related to small amounts of pheromone adsorbed or absorbed by the male. Pheromone and oil could have been picked up by the male tarsi as a result of direct contact with the treated disks, and potentially transferred to the antennae through preening. Since horticultural oils can penetrate insect tissues (Taverner et al. 2001), the oil could increase the physical adsorption or absorption of pheromone by the male (Krupke et al. 2002; Evenden et al. 2005).

The 47-day period of sustained treatment efficacy in this study is in sharp contrast to the results of Judd et al. (2005a), who found that MEC-LR® applied as an atmospheric treatment was an effective disruptant of mate finding in *C. rosaceana* for <55 h. The degree of formulation longevity in our study highlights the possible importance of male proximity to the treated surface in maintaining a significant disruptive effect, even when pheromone release rates from microcapsules drop to low levels. Atmospheric pheromone concentration declines with the inverse square root of the distance from the pheromone source (Karg et al. 1994). Therefore, pheromone concentrations in the boundary layer (e.g., <1 cm from the treated surface), where an insect may alight or rest, may be many times greater than the average atmospheric concentration throughout a treated area. However, the amount of time that male *C. rosaceana* rest on MEC-treated foliage in the field, where they could be exposed to these higher pheromone concentrations, needs to be determined experimentally.

We applied the same amount of MEC and MEC + oil per unit area to metal disks that would be applied per unit area to an orchard, using the label-recommended application rate for MEC-LR® and Purespray Green®. However, the rate of deposition of microcapsules on metal disks may not equal that on plant tissues under field conditions (Knight and Larson 2004), and we were unable to develop a reliable method for counting microcapsules applied to apple foliage (Wins-Purdy et al. 2007). It is also likely that release rates of Z11-14:OAc from the surface differ between these substrates. Despite these differences, there is a consistency between the results of the current study and our previous findings that used apple foliage over a 21-day period (Wins-Purdy et al. 2007). This suggests that the use of metal disks as a treatment surface is appropriate for an examination of mechanisms of mating disruption with MEC formulations. Wins-Purdy et al. (2007) found that both MEC and MEC + oil treatments lost efficacy after 21 days when foliage was treated and aged in the field, thus suggesting environmental factors such as UV light, high temperatures, and rainfall (Waldstein and Gut 2004) may play a significant role in reducing the efficacy of MEC and MEC + oil formulations over time.

C. rosaceana is a difficult pest to control successfully through mating disruption alone, although the reasons for this remain unclear (Agnello et al. 1996; Lawson et al. 1996; Knight et al. 1998; Stelinski et al. 2003a; Trimble and Appleby 2004). Evenden et al. (2000) concluded that habituation did not occur in this species as a result of exposure to their atmospheric pheromone treatment, and Stelinski et al. (2004) demonstrated an increase in male responsiveness to pheromone 24 h after pheromone exposure. The current study is the first to demonstrate significant nervous system habituation in *C. rosaceana*, although in no trial did pheromone exposure completely eliminate response of all males to calling virgin females. Stelinski et al. (2003a) suggested that significant long-lasting antennal adaptation found in *C. rosaceana* could act to shield the central nervous system from the effects of habituation and allow some males to overcome mating disruption. While this seems an unlikely explanation for our results given the lack of any significant antennal adaptation after exposure, it is possible that transient adaptation of antennal receptors occurred while males rested on the MEC-treated surface. Transient antennal adaptation was demonstrated in *T. ni* (Kuenen and Baker 1981), and would allow for a rapid recovery of sexual behavior once the male leaves an area of high pheromone concentration. Other authors have demonstrated that the time male moths are exposed to pheromone influences the duration of habituation and the subsequent disruption to mate-finding behavior (Rumbo and Vickers 1997; Stelinski et al. 2003a). Further study is necessary to determine how long male *C. rosaceana* need to be exposed to MEC-treated surfaces to achieve significant disruption.

The lack of efficacy and longevity of MEC formulations remains a significant barrier to their widespread adoption. However, the fact that physical contact with MEC- and MEC + oil-treated surfaces in this study induced significant habituation but not adaptation in *C. rosaceana* suggests that the central nervous system of males was not shielded (sensu Stelinski et al. 2003a). As central nervous system habituation should be a more effective mechanism of disruption than antennal adaptation (Kuenen and Baker 1981), this could represent an important benefit of MEC formulations over attractive, high-dosage dispensers, where males may be exposed to much greater concentrations of pheromone that could induce a protective antennal adaptation.

Acknowledgments We wish to thank Caroline Whitehouse and Sarah Cockburn for insect rearing and assistance with flight tunnel work, Mark Gardiner for technical assistance and ideas, and Michael Fefer of Petro-Canada for supplying Purespray Green® oil. This research was funded in part by NSERC PGS M (to A.H. Wins-Purdy), the Department of Biological Sciences at the University of Alberta, and an Agriculture and Agri-Food Canada IFSP grant to G.J.R. Judd.

ing citrus, is of greater importance than its impact as an herbivore. Infection by *X. axonopodis* results in defoliation, premature fruit drop, and general decline in tree quality (Graham et al. 2004). Although this disease is spread primarily by wind-driven rain, the serpentine-feeding galleries of *P. citrella* are easily colonized by the bacterium, and the resulting canker lesions generally are larger and more infectious than those formed without the benefit of *P. citrella* leaf injury (Graham et al. 2004; Gottwald et al. 2007).

In Japan, (*Z*,*Z*)-7,11-hexadecadienal (*Z*7*Z*11-16Ald) was reported as the behaviorally active sex pheromone (Mafi et al. 2005). Brazilian and US populations of *P. citrella* produce a 30:10:1 mixture of (*Z*,*Z*,*E*)-7,11,13-hexadecatrienal (*Z*7*Z*11*E*13-16Ald), *Z*7*Z*11-16Ald, and (*Z*)-7-hexadecenal (Leal et al. 2006; Moreira et al. 2006). However, a 3:1 blend of *Z*7*Z*11*E*13-16Ald/*Z*7*Z*11-16Ald is sufficient for eliciting the full complement of male sexual behaviors (Leal et al. 2006; Moreira et al. 2006) and is now being exploited in management programs for this pest (Lapointe et al. 2006; Stelinski and Rogers 2008).

Recently, two mathematical transformations of moth catch *versus* dispenser density data were developed to differentiate between competitive and noncompetitive mechanisms of mating disruption (Miller et al. 2006a,b). Competitive disruption occurs when males are attracted to the source of synthetic pheromone, while noncompetitive mechanisms, such as camouflage or sensory desensitization, by definition, do not require attraction to the synthetic pheromone source (Miller et al. 2006a). If competitive attraction occurs, then plotting 1 over male visitation rate to a given attractant source against dispenser density (on the *Y*- and *X*-axes, respectively, Miller–Gut plot) yields a straight line with a positive slope, while plotting male visitation rate to a given attractant source against dispenser density×visitation rate (Miller–de Lame plot) results in a straight line with a negative slope (Miller et al. 2006a). In contrast, noncompetitive attraction predicts a characteristically concave Miller–Gut plot, as well as a recurved Miller–de Lame plot (Miller et al. 2006a). Post hoc analyses of 13 published mating disruption trials across a range of moth species were consistent with the hypothesis that competitive attraction is the mechanism that explains the majority of cases (Miller et al. 2006b).

The first objective of the current investigation was to evaluate the potential of using mating disruption as a management tactic for *P. citrella* in Florida citrus. The second was to gain insight into the behavioral mechanisms that underlie disruption of this species, which may help facilitate development of robust and economical management of *P. citrella* with pheromones. In addition, the current study was designed to test directly the predictions recently outlined by Miller et al. (2006a) by developing moth catch *versus* dispenser density profiles while concurrently observing moth behavior in the field.

Methods and Materials

Field plots The experiment was conducted in an 8-yr-old 10.2-ha orange grove (*Citus sinensis* [L.] var. "Valencia") in Clermont, FL, USA. Trees were planted on a 3×6-m spacing, and the average canopy height was 4 m. The grove was managed by the University of Florida according to commercial pruning, irrigation, herbicide, and fungicide management practices but without the input of insecticides.

Dispenser Density Treatments and Experimental Design Disruption trials were conducted by comparing four application densities of red rubber septa (The West Company, Lionville, PA, USA): 0 (0/ha, 0.0 g active ingredient [AI]/ha), 0.2 (one every fifth tree or 35/ha, 0.05 g AI/ha), 1 (215/ha, 0.29 g AI/ha), and 5 (1,100/ha, 1.5 g AI/ha) per tree loaded with 1.0 mg of *Z*7*Z*11*E*13-16Ald and 0.33 mg of *Z*7*Z*11-16Ald (ISCA Technologies, Riverside, CA, USA). Pheromone components were greater than or equal to 98% pure by gas chromatographic analysis. The experiment was arranged as a randomized complete block design with five replicates, each consisted of a 30-tree (0.14 ha) plot of five rows of six trees. Replicate plots were separated by 40 m, and blocks of treatments were separated by 50 m. Rubber septum dispensers were affixed to foliage via metal paper clips on the edge of tree canopies approximately 2.0 m above ground level, which is the location of greatest male *P. citrella* activity within trees approximately 4 m tall (Stelinski and Rogers 2008). Treatments were applied on 4 April 2007 and renewed on 15 June 2007 so that the experiment could be conducted throughout the *P. citrella* seasonal flight.

Orientational Disruption Measurements Disruption of male *P. citrella* orientation was quantified by using two pheromone traps (LPD Scenturion Guardpost, Suterra, Bend, OR, USA) deployed within each replicate plot. One trap was placed in the central tree of each plot and the second on the inside border row two trees from the plot edge. All traps were baited with a single red rubber septum lure loaded with 0.1 mg of *Z*7*Z*11*E*13-16Ald and 0.03 mg of *Z*7*Z*11-16Ald as this has been shown to be highly effective for trapping male *P. citrella* in Florida (Stelinski and Rogers 2008). Monitoring traps were hung at least 1.0 m from the nearest mating disruption dispenser, at approximately 1.5–2 m above ground level in the midcanopy (Stelinski and Rogers 2008). Pheromone lures were replaced a total of four times or approximately every 7.5 wk throughout the season based on known longevity of attractiveness (Lapointe and Leal 2007). Moths captured in traps were counted and removed weekly.

Flush Infestation Damage to newly flushed leaves was assessed weekly 15 April through 28 October, 2007, except during the weeks of 16 July, 6 and 13 August, 10 and 17

September, and 15 October because of insufficient new flush on those dates. Twenty shoots, ten from the midcanopy (2.5 m) and ten from the lower canopy (1.0 m), were inspected at random from 20 trees per replicate block (2,000 flush samples per treatment), and the number of shoots per tree containing live mining *P. citrella* larvae was recorded.

Field Observations Male *P. citrella* behavior was studied in the field to test the prediction that male moths approach mating disruption dispensers in pheromone-treated plots, as other studies have reported male moths of various species orienting to, closely approaching, and even touching pheromone dispensers of a wide range of release rates in the field (Stelinski et al. 2004; Epstein et al. 2006). Observations of dispensers in tree canopies were conducted for approximately 2 hr each night between 21:00 and 23:00 hours, the period of greatest male *P. citrella* response (Stelinski and Rogers 2008), on eight nights between 24 August and 13 September and on five subsequent nights between 27 September and October 11. An observer rotated among plots conducting 20 min observational bouts per treatment such that multiple treatments were observed on a given night. The order of observations across treatments was randomized nightly.

In addition, male moth orientation to pheromone traps (as described above) was observed for 2-hr periods on four separate nights (14–22 September 2007) in control plots to verify that male *P. citrella* could be observed orienting to an attractive point source in the field. The number of moths observed orienting to such traps, as well as the number caught in traps under observation, was assessed. During the observations of both dispensers and traps, data were dictated into a hand-held microcassette audio recorder by an investigator standing 0.75 m from the pheromone source under observation. Observations after dusk employed night-vision goggles (Rigel, Model 3250, DeWitt, IA, USA) as described by Stelinski et al. (2004).

Profile Analyses Moth catch vs. dispenser density data were analyzed according to the profile analyses developed by Miller et al. (2006a,b). In addition to examining the untransformed data, two types of transformations were performed on male catch vs. dispenser density data: (1) 1 over male catch per trap per night on the *y*-axis was plotted against dispenser density on the *x*-axis (Miller–Gut plot), and (2) male catch per trap per night on the *y*-axis was plotted against dispenser density×visitation rate on the *x*-axis (Miller–de Lame plot).

Trapping Evaluation of Pheromone Dispensers An experiment was conducted to compare the lure dose used to monitor the effect of disruption treatments (0.1 mg of *Z7Z11E*13-16Ald and 0.03 mg of *Z7Z*11-16Ald) with the dose used to induce mating disruption (1.0 mg of *Z7Z11E*13-16Ald and 0.33 mg of *Z7Z*11-16Ald). The objective was to determine whether the release rate of the pheromone from the mating disruption dispensers was attractive to *P. citrella* in pheromone-free air over the course of the mating disruption study. This test was conducted on 13 April through 1 November, 2007 in 4.0 ha of untreated plots of "Valencia" oranges. Fresh lures were installed every 7.5 wk into plastic delta traps. Unbaited delta traps were included as a negative control treatment. The experiment was arranged in a randomized complete block with five replicates. Traps, hung approximately 1.5–2 m above ground level in the upper third of the tree canopy, were spaced approximately 40 m apart within replicates, and replicate blocks were spaced by 60–70 m. Moths captured in traps were counted and removed weekly, at which time the position of traps was rotated.

Statistical Analyses For orientational disruption and trapping studies, data were transformed to $\ln(x+1)$ (which normalized the distributions) and then subjected to analysis of variance (ANOVA). Flush injury data were arcsine transformed prior to ANOVA. When significant ANOVAs were identified, differences among means were separated by using the least significant difference (LSD) test (SAS Institute 2000). In all cases, the significance level was $\alpha<0.05$. Percent disruption was calculated as $1-[(\text{mean moth catch per trap in the pheromone-treated block/mean moth catch per trap in the control block})]\times 100$.

Results

Moth Catches and Leaf Infestation Preliminary analysis revealed no significant difference in moth catch between traps placed at the centers and borders of plots. Thus, data from the two traps per plot were combined for subsequent analyses. Fewer ($F=29.3$, $df=3, 16$, $P<0.001$) male *P. citrella* were captured in traps in plots treated with 1,100 dispensers per hectare (five dispensers per tree) than in any other treatment (Fig. 1a). This highest dispenser density treatment resulted in 98% disruption of moth catch in traps relative to untreated control plots over the season. There also was a significant reduction in male catch in traps placed in plots treated with 215 dispensers per hectare (69% disruption) compared with plots treated with 35 dispensers per hectare and untreated control plots; however, there was no difference in male catch between the latter two treatments (Fig 1a).

There was a trend of declining infestation with increasing dispenser density with a significant reduction ($F=12.1$, $df=3, 16$, $P<0.01$) in infestation of flush by both the 1,100- and 215-dispensers-per-hectare treatments relative to untreated plots (Fig. 1b), and the lowest infestation occurred

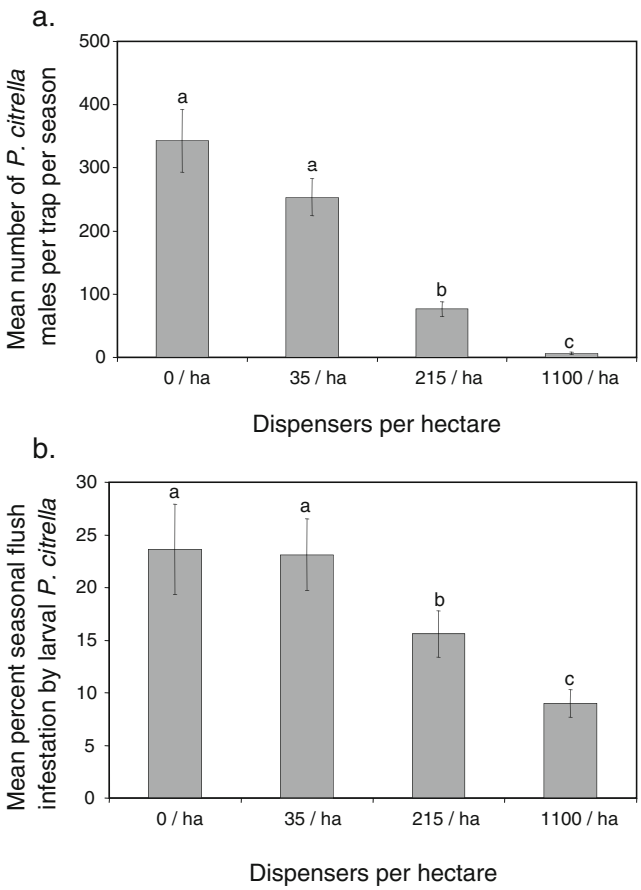

Fig. 1 Mean captures of male *Phyllocnistis citrella* in lure-baited delta traps in plots containing various densities of red septum dispensers of a 3:1 blend of *Z*7*Z*11*E*13-16Ald and *Z*7*Z*11-16Ald (**a**), Mean percent flush infestation by *P. citrella* larvae (**b**). Means followed by the same letter are not significantly different (AVOVA followed by LSD test at $\alpha<0.05$)

in plots treated with 1,100 dispensers per hectare. Flush infestation in plots treated with 35 dispensers per hectare was not significantly different from control plots.

Field Observations No male *P. citrella* were observed orienting to rubber septum disruption dispensers in any of the treatments during 26 hr of observation. In contrast, in control plots, 17.0±2.1 (mean±SE) males per night (N=4 nights) were observed orienting to baited monitoring traps, and 11.6±0.9 males were captured.

Profile Analysis The untransformed plots of dispenser density (Fig. 2a), as well as both secondary transformation plots (Fig. 2b,c), were consistent with the predictions of mating disruption by a noncompetitive mechanism. The untransformed plot was initially linear (Fig. 2a), the Miller–Gut plot was concave (Fig. 2b), and the Miller–de Lame plot was recurved (Fig. 2c). This set of traits is diagnostic of a noncompetitive mating disruption mechanism (Miller et al. 2006a).

Trapping Evaluation of Pheromone Dispensers In plots not under pheromone disruption, the number of male *P. citrella* captured per night in traps baited with the lower-loading monitoring lures (261.4±18.2, X±SEM) was significantly greater (F=15.7, df=2, 8, $P<0.01$) than the number captured with those baited with higher-dose mating disruption dispensers (179.3±16.9). Traps baited with both lure dosages captured significantly more moths over the course of the season than blank negative control traps (0.03±0.01).

Discussion

Nearly complete disruption of *P. citrella* orientation to female-proxy-monitoring traps was achieved for 221 d with only two deployments of just 1.5 g AI/ha each. This would be sufficient for the season-long disruption of *P. citrella* males in Florida. Furthermore, nearly 70% disruption was achieved with only a 0.25-g/ha rate. The pheromone rate per hectare required for the disruption of *P. citrella* was well below 75–300 g of pheromone per hectare required for effective disruption of other species such as the Oriental fruit moth, *Grapholita molesta* (Rice and Kirsch 1990), the European grape moth, *Eupoecilia ambiguella* (Charmillot et al. 1987), the grape berry moth, *Paralobesia viteana* (Trimble et al. 1991), and the codling moth, *Cydia pomonella* (Howell et al. 1992). Ten grams of pheromone per hectare is one of the lowest effective rates for disruption of pink bollworm, *Pectinophora gossypiella*, when applied every 23 weeks as a microencapsulated sprayable formulation (Critchley et al. 1984). Short (2–3 wk) residual activity is characteristic of sprayable formulations in general (Gut et al. 2004). Effective disruption at a relatively low deployment rate (10 g of pheromone per hectare) was also achieved for a different leafmining species, the tomato pinworm (*Keiferia lycopersicella*; Jenkins et al. 1990). Thus, the low amount of pheromone required for effective season-long disruption of *P. citrella* is unique among moth species investigated to date and may be characteristic of Gracillariids and Gelechiids.

One of the objectives of this investigation was to test directly the predictions of Miller et al. (2006a,b) by conducting a disruption experiment where male moth catch in pheromone monitoring traps was quantified in plots with varying dispenser densities to differentiate between competitive and noncompetitive attraction. Furthermore, the outcomes of the theoretical predictions were compared with behavioral data collected directly in the field, thus providing evidence for a noncompetitive mechanism of disruption for *P. citrella* (Fig. 2a–c). As predicted, males did not approach mating disruption dispensers in any of the dispenser density treatments. Furthermore, we confirmed that male *P. citrella* could be observed orienting to attractive pheromone dispensers in plots not treated with pheromone. In addition, our trapping study confirmed that the dosage of pheromone loaded into the dispensers used as the mating disruption treatment attracts male *P. citrella* in control plots. These findings present a dilemma—how does a noncompetitive disruption profile arise from deployment of dispensers that, in a trapping study, were attractive? We speculate that the release rate of pheromone from the "disruptive dispensers" was well above normal but insufficient to preclude brief attraction events when such dispensers were sparse and hence rarely encountered. However, when these higher-dosage dispensers were packed together promoting numerous plume encounters, males enveloped in them for prolonged periods became desensitized and ceased plume following, or discrete plumes were enveloped within a miasma of background pheromone precluding orientation to an individual point source. Cessation of attraction under high dispenser density was supported both by the profile analysis and the failure to observe males arriving at dispensers in the disruption trials. Had attraction been a required first step mediating disruption of all males under these conditions, some males should have been observed approaching dispensers in pheromone-treated plots, and the profiles should have reflected competitive attraction. It appears that the disruption in this study was occurring mainly at some distance from the dispensers.

This reasoning raises the question of over what area each dispenser exerted a given effect. An examination of Fig. 2a reveals that approximately 100 dispensers per hectare were required to reduce male catch by 50% (11.5 to 5.7 males per trap per night). Since 1 ha=10,000 m^2, each dispenser can be calculated to have halved catch across approximately 100 m^2 of citrus grove (10,000 m^2 per 100 dispensers). If each dispenser had released all of its 1.33 mg of pheromone over the 14 weeks it was deployed, the average release rate per dispenser per hour would be 0.6 μg/hr, and the corresponding specific area for 1/2 trap suppression per microgram pheromone per hour would be 167 m^2. We suspect that this value underestimates pheromone specific activity for this study, because it is likely that pheromone load was not completely exhausted over the 14 wk of deployment, given that catch in traps was still being suppressed when the dispensers were replaced on 15 June. Nevertheless, this specific activity value for *P. citrella* pheromone is 40-fold higher than the 4 m/ μg pheromone/hr calculated to halve male catch of Oriental fruit moth based on the noncompetitive disruption profiles reported by Miller et al. (2006b).

Mating disruption could be an important contribution to *P. citrella* management programs in the USA and elsewhere. Spray programs for leafminers in citrus are often ineffective, require biweekly application given continual growth of new flush, and are detrimental to natural enemy populations of *P. citrella* and other citrus pests (Peña et al. 2002). In the current study, new flush infestation by larval *P. citrella* was reduced by more than half in the highest pheromone rate treatment, despite the small size of study plots (0.14 ha). It is well known that disruption outcomes are better in larger plots (see reviews by Gut et al. 2004; Witzgall et al. 2008), and thus, the current data suggest that the disruption of *P. citrella* should be effective on a larger scale. Furthermore, the control of this species by mating disruption should be density independent given the noncompetitive mechanism (Miller et al. 2006a,b). This bodes well for the development of commercial formulations that are economically feasible in the face of high *P. citrella* populations in Florida (Lapointe et al. 2006; Stelinski and Rogers 2008).

The primary challenge to developing a commercially viable mating disruption formulation for *P. citrella* is the complexity of the pheromone chemistry (Leal et al. 2006; Moreira et al. 2006), which currently renders the cost of synthesis economically prohibitive from a management perspective. Fortunately, little pheromone is required for effective disruption, and even lower rates of pheromone may prove effective for integrated programs that combine pheromone and reduced insecticide input. However, opportunities also exist to improve the economic feasibility of this pheromone technology if a less expensive synthesis protocol could be developed. In addition, even though it has been proven that a 3:1 blend of *Z*7*Z*11*E*13-16Ald/*Z*7*Z*11-16Ald is required for the attraction of *P. citrella* to traps (Leal et al. 2006; Moreira et al. 2006), the evidence for a noncompetitive mechanism of disruption, such as desensitization or camouflage, suggests that the diene or triene components alone might yield effective disruption. Indeed, *Z*7*Z*11-16Ald alone has been shown to effectively disrupt communication of *P. citrella* in Japan (Mafi et al. 2005). Finally, the large acreage of citrus in Florida will demand mechanical application for economic feasibility; therefore, long-lasting formulations amendable to mechanical application should be explored (Stelinski et al. 2007).

Acknowledgments Ian Jackson, Angel Hoyte, and Wendy Meyer are gratefully acknowledged for assistance with trap deployment and maintenance. We thank ISCA Technologies for providing lures and pheromone to conduct the studies herein. A previous version of the manuscript was improved by Paul Jenkins, Rufus Isaacs, and Steve Lapointe. We also thank two anonymous reviewers for helpful comments.

Adults of *H. burnsi* are similar in size to those of *H. electra* but are different in appearance. The forewings of *H. electra* are white, with black borders and markings, and the hind wings are a brilliant red, with black borders. *H. burnsi* more closely resembles *H. neumogeni*, being nearly completely white with two narrow black lines across the wings and a black spot on each wing. Eggs and larvae of the three species appear similar and the host range of *H. burnsi* overlaps with those of the other two species, with *H. neumogeni* feeding on *Rhus trilobata* (Nuttal) and *Prunus fasciculata* (Torrey) Gray, *H. electra* using solely *Eriogonum fasciculatum* Bentham, and *H. burnsi* using several hosts including *P. fasciculata*, *Tetradymia axillaris* A. Nelson, *Dalea spp*. Jussieu and, in the last instar, *E. fasciculatum* (Tuskes 1984; Tuskes et al. 1996). All three species are gregarious in the early instars and disperse after the third instar (Tuskes 1984; Tuskes et al. 1996). In the last instar, both *H. burnsi* and *H. electra* can be found together feeding on *E. fasciculatum*, after the primary hosts of *H. burnsi* have been defoliated.

In a study comparing the attraction of males of *H. electra mojavensis* to conspecific females or females of the allopatric *H. electra electra*, it was found that male *H. electra mojavensis* flew predominantly in the morning hours, usually from 0800 hours to as late as 1300 hours (JSM, unpublished data). In contrast, *H. burnsi* tends to fly later in the day, from 1530 hours to dusk (Tuskes et al. 1996). Despite this, males of both species exhibit pheromone-mediated flight beyond their normal flight times (JSM, unpublished observations). For example, males of *H. burnsi* have been collected in flight as early as 0900 hours, and males of *H. electra* have been attracted to a calling female as late as sunset (JSM, personal observations). Females of both species fly and oviposit after sunset (Tuskes et al. 1996).

Studies on the sex pheromones of the two subspecies of *H. electra* identified three differences between the subspecies, even though they are separated by a relatively short distance (100 km; McElfresh and Millar 1999d): (1) the ratio of sex pheromone components in pheromone gland extracts, (2) responses of male antennae to the pheromone components in coupled gas chromatography–electroantennogram detection (GC–EAD) analyses, and (3) behavioral responses of males to reconstructed synthetic pheromone blends in the field. Based on these results, we hypothesized that the differences between the two populations of *H. electra* might be due to interference in the pheromone channel from *H. burnsi* in the western Mojave Desert, which appeared to use a similar or, at least, overlapping pheromone blend to those used by the respective *H. electra* subspecies (McElfresh and Millar 1999d). That is, *H. electra mojavensis* might have altered its pheromone blend, thus minimizing cross-attraction of males to *H. burnsi* females. The objective of the study reported here was to identify the sex pheromone blend of *H. burnsi* fully, in order to assess the degree of similarity, and therefore the potential for interactions, between the sex pheromone blends of the two species.

Methods and Materials

Insects Last-instar *H. burnsi* were collected on host plants at Oro Grande Wash, 10 miles east of Phelan, or at Rock Corral, both in San Bernardino County, CA, USA. The principal host for the moth at Oro Grande Wash was *T. axillaris*, whereas larvae were collected from *Dalea spp*. at Rock Corral. Larval development was completed on *E. fasciculatum* for both populations, with larvae held inside 3.2-mm mesh screen cylinders (45 cm high × 60 cm diameter). The screen cylinders were wrapped around an *E. fasciculatum* plant and anchored with a wooden stake, driven into the ground, to which the screen was stapled. Loose sand was piled along the base of the screen enclosure to prevent escape, and fiberglass window screen mesh was placed over the top and stapled into position. To prevent ants from killing the larvae or prepupae, a barrier of granular Dursban® insecticide was placed around the outside of the enclosure. Pupae and prepupae were removed from cocoons in the leaf litter at the base of the plant once sufficient insects had completed larval development. Pupae were kept in screened cages (30 cm^2) outdoors to coordinate emergence; adults were removed prior to mating and either used immediately or placed in labeled glassine envelopes, in plastic bags with damp tissue, and held at 10–15°C until needed. Females were placed in 6×8-cm screen cages and allowed to call for at least 1 h prior to removal of the sex pheromone gland. Males were allowed to warm to room temperature for at least 1 h prior to use in coupled GC–EAD experiments.

For the GC–EAD experiments (see below), adult male *H. burnsi* were collected at the Oro Grande Wash field site using a lure containing five components: [(10*E*,12*Z*)-hexadecadienyl acetate (*E*10,*Z*12-16:Ac), (10*E*,12*Z*)-hexadecadienol (*E*10,*Z*12-16:OH), (10*E*,12*Z*)-hexadecadienal (*E*10,*Z*12-16:Ald), (10*E*,12*E*)-hexadecadienyl acetate (*E*10,*E*12-16:Ac), and hexadecyl acetate (16:Ac)] optimized for that species (in a ratio of, respectively, 100:10:1:50:350 μg, *E*10,*Z*12-16:Ac: *E*10,*Z*12-16:OH: *E*10,*Z*12-16:Ald: *E*10,*E*12-16:Ac:16:Ac). *H. electra mojavensis* males were caught after attraction to an optimized three-component blend (100:10:33 μg, *E*10,*Z*12-16:Ac: *E*10,*Z*12-16:OH: *E*10,*Z*12-16:Ald) at a site east of Hesperia, CA, USA, along the base of Ord Mountain, where field trials for that species had been conducted previously (McElfresh and Millar 1999d). *H. electra electra* males were captured after being attracted to a lure with an optimized four-component blend (100:10:1:0:333 μg, *E*10,*Z*12-16:Ac: *E*10,*Z*12-16:OH: *E*10,*Z*12-

16:Ald: *E*10,*E*12-16:Ac:16:Ac), west of Anza, Riverside County, where field trials had been conducted previously (McElfresh and Millar 1999d).

Preparation of Extracts The sex pheromone gland was removed from virgin, 1–2-day-old calling females by applying gentle pressure to the lateral sides of the abdomen, everting the ovipositor and sex pheromone gland, and excising the terminal segments of the abdomen with microscissors. The gland was placed in approximately 30 μl pentane and extracted for up to 60 min before the extract was decanted to a clean conical insert; to ensure complete transfer of the extract, the original tube was rinsed with two 10–20 μl aliquots of pentane. The sample was stored at −20°C and concentrated by passive evaporation, as needed, prior to analysis.

Gas Chromatography and Coupled GC–EAD Synthetic standards and aliquots of female extract were analyzed by using Hewlett-Packard 5890A or 5890 series II gas chromatographs (Hewlett-Packard, Palo Alto, CA, USA) with helium as carrier gas, splitless injection, and an injector temperature of 250°C. Columns (J&W Scientific, Folsom, CA, USA) and temperature programs used for the analyses were a DB-5 (30 m×0.32 mm ID, 0.25-μm film; temperature program 100°C for 0 or 1 min, increased by 10°C or 15°C min^{-1} to 275°C, and held for up to 33 min) and a DB-Wax (30 m×0.32 mm ID, 0.25-μm film; temperature program 100°C for 1 min, increased by 10°C min^{-1} to 240°C and held for up to 60 min, or 130°C to 240°C at 10°C min^{-1}, and held for 5 min). Aliquots of single and composite extracts of pheromone glands and synthetic standards were analyzed by coupled GC–EAD with methods and equipment as described previously (McElfresh and Millar 1999d). Tentative identifications of compounds were based upon retention time matches and responses of antennae of male moths in GC–EAD studies that used the two different columns described above. Identifications were confirmed by gas chromatography–mass spectrometry (GC–MS) with synthetic standards available from previous work (e.g., McElfresh and Millar 1999d).

Antennal response profiles of *H. burnsi*, *H. electra mojavensis*, and *H. electra electra* were generated by stimulating antennae of male moths with a mixture of the five components in the blend found to elicit behavioral responses from *H. burnsi*. The GC–EAD standards consisted of 10 ng/μl each of 10*E*,12*Z*-16:Ac, 10*E*,12*E*-16:Ac, 10*E*,12*Z*-16:Ald, 10*E*,12*Z*-16:OH, and 16:Ac in heptane. Each antennal preparation was stimulated with 1 μl of the mix, and antennal responses to each compound were recorded with PeakSimple software (version 2.83, SRI Instruments, CA, USA).

Gas Chromatography–Mass Spectrometry Electron impact mass spectra (70 eV) were recorded with an HP 6890 gas chromatograph interfaced to an HP 5973 mass selective detector. Injection was splitless; helium was the carrier gas, and injector and transfer line temperatures were 275°C and 280°C, respectively. An HP5-MS column (30 m×0.25 mm ID), programmed from 50°C (held for 1 min) to 250°C at 10°C min^{-1} (held for 20 min), was used for the analyses. Compounds from a composite pheromone gland extract were identified by comparison of their retention times and mass spectra with those of authentic standards.

Formation of Adducts with 4-Methyl-1,2,4-triazoline-3,5-dione Determination of double-bond positions in the diene acetates was accomplished by reaction with the powerful dienophile 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) to form Diels-Alder cycloadducts (Young et al. 1990). Thus, an extract of two females was evaporated just to dryness, and approximately 5 μl of MTAD in methylene chloride (2 mg/ml) was added at room temperature. The solution was analyzed immediately by GC–MS, with injector and detector temperatures set at 300°C and an oven temperature program of 100°C for 0 min, increased by 15°C min^{-1} to 300°C and held for 20 min.

Chemicals Synthetic compounds used in this study were prepared as previously described (McElfresh and Millar 1999a), with the exception of hexadecyl acetate and hexadecanol, which were purchased from Sigma Chemical Co. (St. Louis, MO, USA) and Avocado Research Chemicals (Hassham, UK), respectively. All compounds used were at least 98% chemically and isomerically pure. GC standards of all four isomers of the 10,12-16 acetates, aldehydes, and alcohols were also obtained from Darwin Reed, Plant Biotechnology Institute, National Research Council of Canada, Saskatoon, Saskatchewan, Canada.

Field Trials Field trials were conducted at Oro Grande Wash, 16 km east of Phelan, CA, USA. A single field trial consisted of three to four replicate blocks, at least 100 m apart, with a maximum of 12 treatments per block. Custom-made cylindrical screen traps were as previously described (McElfresh and Millar 1999d). Compounds were loaded on 11-mm rubber septa (Wheaton Scientific, Millville, NJ, USA) in hexane solutions (doses and ratios are listed in figure captions). For the final trial, the traps were modified by the addition of clips and rubber bands to hold the top, inward-pointing funnel more securely. Securing the top funnel was necessary because, in the trapping area, high winds occasionally overturned traps and, on several occasions, roadrunners, *Geococcyx californianus* (Lesson), dismantled traps to get at the trapped moths. Consequently, it was not possible to leave the traps unattended for more

Table 1 Relative amounts of compounds identified in single female extracts and relative responses elicited from antennae of male moths by these compounds

Compound	Amount in single female extracts (% relative to *E*10,*Z*12-16:Ac)			Male antennal responses[a]	
	Mean±SD	*N*	Range	Mean±SD	*N*
*E*10,*Z*12-16:Ac	100	45	–	100	19
*E*10,*Z*12-16:Ald	0.37±0.03	3	0.34–0.42	17.8±11.9	8
16:OH	60±81	44	10–395	0	0
*E*10,*Z*12-16:OH	14±13	33	1.8–55	21.3±13.3	16
*E/Z*11-16:Ac	9.1±7.3	38	2.5–44	20.2±7.9	18
16:Ac	232±256	45	76–480	17.4±7.5	15
*E*10,*E*12-16:Ac	23±11	43	6–58	38.0±13.1	16

All extracts were analyzed on a DB-5 column (30 m×0.32, 25-μm film).
E10,Z12-16:Ac (10*E*,12*Z*)-hexadecadienyl acetate, *E10,Z12-16:Ald* (10*E*,12*Z*)-hexadecadienal, *16:OH* hexadecanol, *E10,Z12-16:OH* (10*E*,12*Z*)-hexadecadienol, *E/Z11-16:Ac* (*E*)- and (*Z*)-11-hexadecenyl acetate, *16:Ac* hexadecyl acetate, *E10,E12-16:Ac* (10*E*,12*E*)-hexadecadienyl acetate
[a] Responses from antennae of male moths, expressed as a percent of the response to *E*10,*Z*12-16:Ac, calculated from EAD peak height, with antennae stimulated with equal amounts of each compound.

than 2 h. Thus, blocks of traps were set up in the early afternoon (1200–1400 hours) and taken down just before dusk (1630–1700 hours). Catches were counted from one to three times a day (during which the traps were emptied) and the traps rerandomized after each count. Because of fluctuations in the populations of the moths over the relatively short flight season (4 to 5 weeks), and from year to year, field trials were conducted over several years.

Statistical Analyses For statistical analyses of field trials, possible day and time effects were eliminated by pooling counts for a particular treatment within a block. This sum was then transformed ($\sqrt{x}+0.5$) prior to conducting a two-way analysis of variance (ANOVA), followed by Student–Neuman–Keuls tests (SNK), as required for separation of means (SigmaStat 1.0, Jandel Scientific Corporation, 1992–1994). Any treatments that failed to attract males were not included in the statistical analysis to avoid violating assumptions of ANOVA (i.e., zero values have no variance).

For statistical comparisons of antennal responses to synthetic standards, the antennal response peak heights of a given antenna, to each of the five compounds in the blend, were converted to the proportion of the combined responses for all five compounds. This was then √arcsin-transformed prior to a one-way ANOVA, followed by SNK tests as described above ($\alpha=0.5$). If the assumptions for ANOVA were not met, Kruskal–Wallis ANOVA of ranks was used, followed by Dunn's method to separate means ($\alpha=0.5$).

Results

Analysis of Pheromone Gland Extracts The pheromone gland component that elicited the largest and most consistent responses from antennae of male *H. burnsi* was identified as *E*10,*Z*12-16:Ac (Table 1; Fig. 1, peak 6). The mass spectrum had a molecular ion at *m/z* 280 (23% of base peak at *m/z* 67), consistent with a 16-carbon diunsaturated acetate. The relatively strong molecular ion in the mass spectrum and longer retention time than 16:Ac, on the DB-

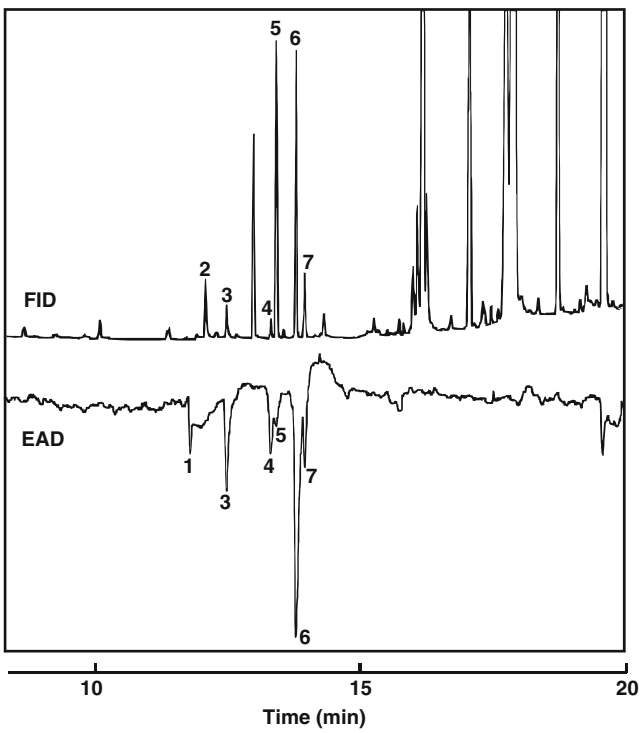

Fig. 1 Representative coupled gas chromatogram–electroantennogram of extract of female *H. burnsi* (Watson) pheromone gland (three female equiv) using a DB-5 column. *Top trace*: flame ionization detector (*FID*) response; *bottom*, *inverted trace* (*EAD*): response elicited from antenna of a male *H. burnsi* moth. Identification of peaks: *1*, (10*E*,12*Z*)-hexadecadienal; *2*, hexadecanol; *3*, (10*E*,12*Z*)-hexadecadienol; *4*, (*E*)- and (*Z*)-11-hexadecenyl acetate; *5*, hexadecyl acetate; *6*, (10*E*,12*Z*)-hexadecadienyl acetate; *7*, (10*E*,12*E*)-hexadecadienyl acetate

5 column, suggested a conjugated diene. Conjugation of the double bonds was confirmed by formation of the MTAD adduct, which showed a molecular ion at *m/z* 393 (5%) and diagnostic ions at *m/z* 208 (100%) and 350 (22%), indicating a 10,12 position for the double bonds. The *E*10,*Z*12 geometry was determined by exact retention time matches to a synthetic standard on both DB-5 and DB-Wax columns, which resolve all four isomers (McElfresh and Millar 1999a). In addition to the *EZ* isomer, a small amount of *E*10,*E*12-16:Ac was identified; based upon its mass spectrum (molecular ion at *m/z* 280, 27% of base peak at *m/z* 67), retention time matches to synthetic standards on both columns, and similar responses are elicited from male antennae in GC–EAD analyses (Table 1; Fig. 1, peak 7).

The identification of *E*10,*Z*12-16:OH was similarly based upon retention time matches on polar and nonpolar columns, matching of the mass spectrum with that of a standard, and similar GC–EAD responses elicited by the insect-produced compound and the standard (Table 1; Fig. 1, peak 3). The mass spectrum showed a comparatively strong molecular ion at *m/z* 238 (19% of base peak at *m/z* 67), suggesting a 16-carbon conjugated dienol. There was insufficient material in the extract to detect the MTAD adducts, but the other analytical data in support of this structure, its close similarity to the corresponding acetate, and its biological activity in field trials (see below) support its identity.

Two saturated 16-carbon compounds, 16:Ac and 16:OH, were also identified from pheromone gland extracts by tentative matches with database spectra. These identifications were confirmed by mass spectral and retention time matches with those of standards (Table 1; Fig. 1, peaks 5 and 2, respectively). Of the two, only 16:Ac elicited responses from antennae of male moths in GC–EAD analyses.

Trace quantities of *E*11- and *Z*11:16:Ac were identified, based upon retention time matches, during GC–EAD analyses (Table 1; Fig. 1, peak 4). These assignments were corroborated by GC–MS analysis (*m/z* 222, 22%, M^+–AcOH; significant ions at *m/z* 82, 96, 110, 124, 138, 152, 166 179/180, 196). The isomers were identified by comparison of retention indices to those of all possible C_{16} monounsaturated acetates, as described in McElfresh and Millar (1999a).

*E*10,*Z*12-16:Ald could not be conclusively identified in the extracts due to the very small amounts present. However, in GC–EAD analyses, responses were elicited from male moth antennae by a trace component eluting at the retention time of *E*10,*Z*12-16:Ald, and antennae of males also responded strongly when stimulated with synthetic *E*10,*Z*12-16:Ald (Table 1; Fig. 1, peak 1). Taken together, these data suggest that traces of this compound were present in the pheromone gland extract.

Because of the large response elicited from male antennae by *E*10,*Z*12-16:Ac from pheromone gland extracts, this component was considered to be the major component in the blend. The average ratio of the various components in pheromone gland extracts from individual females was 100:232:23:9:14:60:0.4 (*E*10,*Z*12-16:Ac: 16:Ac: *E*10,*E*12-16:Ac: *E/Z*12-16:Ac: *E*10,*Z*12-16:OH:16:OH: *E*10,*Z*12-16:Ald; Table 1).

Responses of Antennae of Male Moths to Synthetic Standards The profiles of antennal responses to the five compounds tested were remarkably consistent within populations, but there was considerable variation between species and populations (Fig. 2). In general, *E*10,*Z*12-16:Ac and *E*10,*Z*12-16:OH elicited the largest responses and, together, constituted over 50% of the summed total responses for each population. For *E*10,*Z*12-16:Ac, responses from antennae of *H. electra electra* were intermediate between those of *H. burnsi*, which had the largest proportional responses to this compound, and *H. e. mojavensis*, which had the smallest. For *E*10,*Z*12-16:OH, antennae of *H. burnsi* showed the smallest proportional responses, whereas antennae of *H. e. mojavensis* showed the largest, with *H. electra electra* once again being intermediate. Responses of *H. burnsi* to *E*10,*Z*12-16:Ald

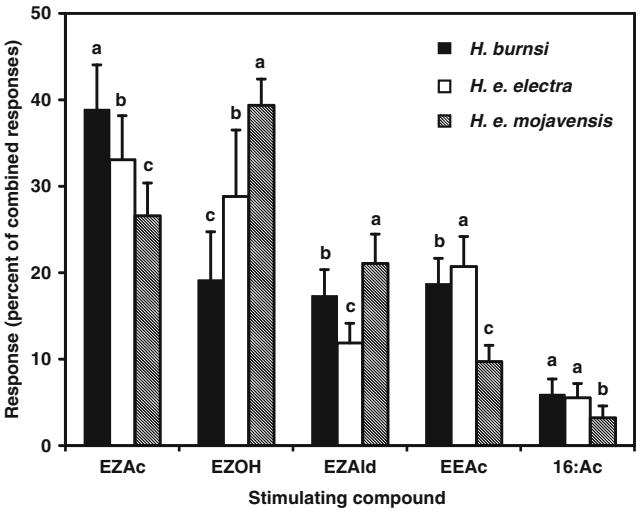

Fig. 2 Mean relative magnitudes (as a proportion of all responses) of antennal responses to synthetic standards [*EZAc*=(10*E*,12*Z*)-hexadecadienyl acetate, *EZOH*=(10*E*,12*Z*)-hexadecadienol, *EZAld*=(10*E*,12*Z*)-hexadecadienal, *EEAc*=(10*E*,12*E*)-hexadecadienyl acetate, *16:Ac*=hexadecyl acetate] of male *H. burnsi* (*N*=30), *H. electra electra* (*N*=23), and *H. electra mojavensis* (*N*=15). For each compound, *bars* surmounted with different *letters* are significantly different (SNK, α=0.05 or Dunn's method, α=0.05). For EZAc, one-way ANOVA, F=33.2; df=2, 67; P<0.001; for EZOH, Kruskal–Wallis ANOVA on ranks, H=41.1; df=2; P<0.001; for EZAld, one-way ANOVA, F=53.0; df=2, 67; P<0.001; for EEAc, one-way ANOVA, F=81.4; df=2, 67; P<0.001; and for 16:Ac, one-way ANOVA, F=17.24; df=2, 67; P<0.001

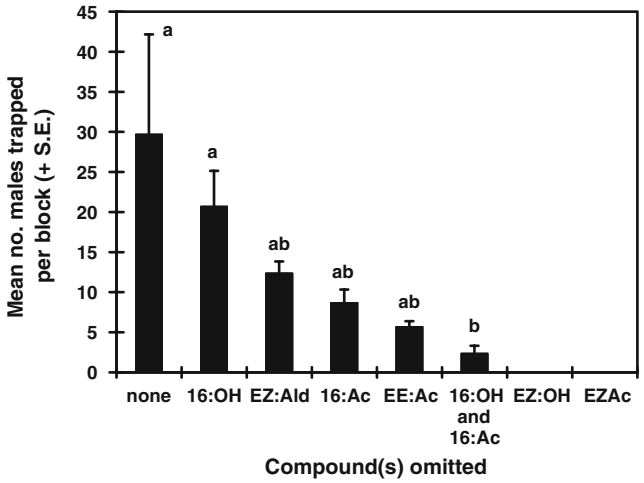

Fig. 3 Mean numbers of male *H. burnsi* caught in traps baited with a blend based upon ratios of compounds found in female *H. burnsi* extracts or deletions from that blend. Compounds and amounts (microgram per septum) used in the base blend were: hexadecanol (*16:OH*), 60; (10*E*,12*Z*)-hexadecadienal (*EZAld*), 1; hexadecyl acetate (*16:Ac*), 350; (10*E*,12*E*)-hexadecadienyl acetate (*EEAc*), 50; (10*E*,12*Z*)-hexadecadienol (*EZOH*), 10; and (10*E*,12*Z*)-hexadecadienyl acetate (*EZAc*), 100. Field trial was conducted on September 25 (three readings for blocks A and B, two for C) and 26 (two readings each block), 1994. Total moths trapped: 238. Treatments with different *letters* are significantly different (SNK, α=0.05). Two-way ANOVA for treatment effect, F=4.85; df=5, 17; P=0.016; for block effect F=2.14; df=2, 17; P=0.17

were intermediate between those of *H. e. mojavensis* (largest) and *H. electra electra* (smallest). Conversely, responses to *E*10,*E*12-16:Ac were largest for *H. electra electra* and smallest for *H. e. mojavensis*, with *H. burnsi* once again in the middle. Finally, antennae of both *H. burnsi* and *H. electra electra* exhibited small and similarly sized responses to 16:Ac, whereas *H. e. mojavensis* responses were smaller still.

Field Trials with Synthetic Compounds A preliminary field trial that used single components, binary blends, and a ternary blend (which attracted male *H. electra electra*) failed to attract *H. burnsi* males (data not shown). Consequently, a more complete reconstruction of the blend of compounds identified from pheromone gland extracts was tested. This six-component blend consisted of *E*10,*Z*12-16:Ac, *E*10,*E*12-16:Ac, *E*10,*Z*12-16:OH, 16:Ac, 16:OH, and *E*10,*Z*12-16:Ald in a ratio of 100:50:10:350:60:1 μg per septum, respectively. The *E*10,*Z*12-16:Ald dose used was an estimate because the actual amount in pheromone gland extracts could not be determined due to the small amounts present. Blends tested included the complete six-component blend, all blends with a deletion of one single component, and a blend in which the two saturated components were not present. There were no significant differences in the attractiveness of the complete blend or the blends lacking 16:OH, *E*10,*Z*12-16:Ald, 16:Ac, or *E*10,*E*12-16:Ac (Fig. 3). Blends lacking either *E*10,*Z*12-16:Ac or *E*10,*Z*12-16:OH caught no moths.

With this trial as a baseline, further studies were carried out to test the effects of different ratios of the various compounds and to verify the role of each compound as part of the attractant blend for male *H. burnsi*. Thus, a field trial testing different amounts of *E*10,*Z*12-16:OH (0, 3, 10, 33, and 100 μg per septum) showed a strong dose effect, with the 10 μg per septum treatment attracting the most males (Fig. 4). An increase to 33 μg or decrease to 3 μg per septum resulted in significantly fewer males being attracted than to the 10-μg treatment. Elimination of *E*10,*Z*12-16:OH from the base blend rendered the blend unattractive (three of 150 males trapped). These results confirmed the importance of both the presence and the ratio of *E*10,*Z*12-16:OH in the blend.

When *E*10,*E*12-16:Ac was varied over the same range of doses (0, 3, 10, 33, and 100 μg per septum), holding the ratio of the other components constant, trap catches increased with increasing amounts of *E*10,*E*12-16:Ac (Fig. 5), with the lowest dose attracting only nine males (out of 222 total), whereas the highest dose attracted 85 males. These results confirmed that *E*10,*E*12-16:Ac was necessary for maximum attraction of male *H. burnsi* and that the ratio again was important.

A broader range of doses was tested for 16:Ac (0, 1, 10, 100, 1,000 μg per lure) because this compound was the most abundant of the six compounds found in analyses of pheromone gland extracts (see above). Increasing amounts of 16:Ac resulted in greater numbers of males trapped

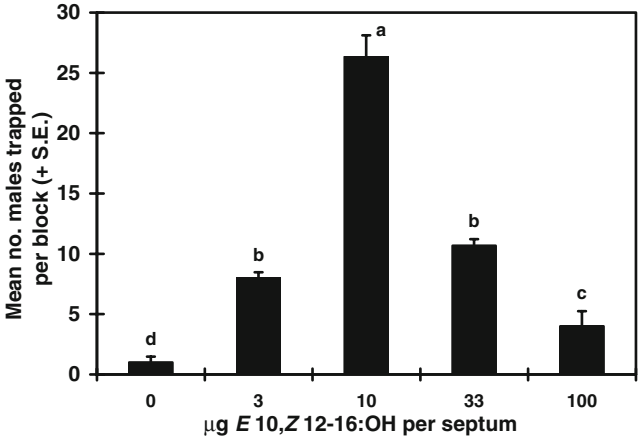

Fig. 4 Mean numbers of male *H. burnsi* caught in traps baited with 60 μg hexadecanol, 1 μg (10*E*,12*Z*)-hexadecadienal, 350 μg hexadecyl acetate, 50 μg (10*E*,12*E*)-hexadecadienyl acetate, 100 μg (10*E*,12*Z*)-hexadecadienyl acetate, and varying amounts of (10*E*,12*Z*)-hexadecadienol (*E*10,*Z*12-16:OH). Field trial conducted September 28 and 30, 1994, with two counts for blocks A and B and a single count for block C on each day. Total males trapped: 150. Treatments with different *letters* are significantly different (SNK, α=0.05). Two-way ANOVA for treatment effect, F=45.46; df=4, 14; P<0.001; for block effect F=2.01; df=2, 14; P=0.20

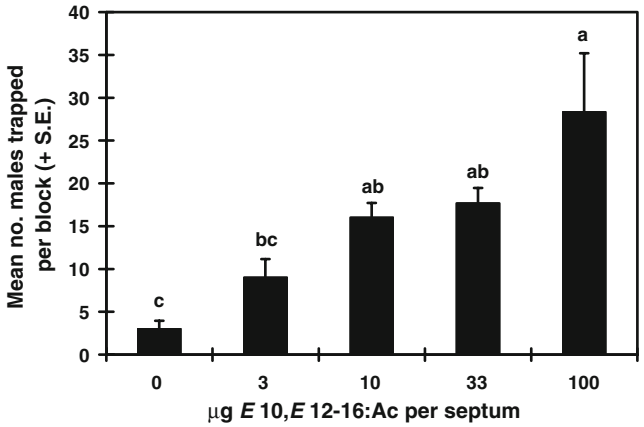

Fig. 5 Mean numbers of male *H. burnsi* caught in traps baited with 60 μg hexadecanol, 1 μg (10*E*,12*Z*)-hexadecadienal, 350 μg hexadecyl acetate, 10 μg (10*E*,12*Z*)-hexadecadienol, 100 μg (10*E*,12*Z*)-hexadecadienyl acetate, and varying amounts of (10*E*,12*E*)-hexadecadienyl acetate (*E*10,*E*12-16:Ac). Field trial conducted September 28 and 30, 1994, with two counts for blocks A and B and a single count for block C on each day. Total number males trapped: 222. Treatments with different *letters* are significantly different (SNK, α=0.05). Two-way ANOVA for treatment effect, F=8.05; df=4, 14; P=0.007; for block effect F=0.73; df=2, 14; P=0.51

(Fig. 6), but even blends that contained little or no 16:Ac still caught moths; traps baited with lures containing no 16:Ac captured approximately one fifth as many moths as those baited with the highest dose. Thus, the data suggested that this compound is an important, but not essential, component for attraction of male *H. burnsi*.

A field trial was conducted to assess further the possible role of *E*10,*Z*12-16:Ald in the pheromone blend, using *E*10,*Z*12-16:Ald doses of 0, 0.001, 0.01, 0.1, 1, 10, and 100 μg per lure. The data indicated that a 1 μg per septum dose of *E*10,*Z*12-16:Ald, in a base blend with the other components, was optimal (Fig. 7). Nevertheless, all of the other blends also attracted some moths, indicating that *E*10,*Z*12-16:Ald is a part of the attractive blend, but its presence is not essential for attraction.

Having investigated the roles of the various minor components, a dose response trial was conducted by varying the dose of the major component, *E*10,*Z*12-16:Ac, from 3.3 to 333 μg per lure, while holding the other components constant at 60 μg 16:OH, 1 μg *E*10,*Z*12-16:Ald, 50 μg *E*10,*E*12-16:Ac, 10 μg *E*10,*Z*12-16:OH, and 350 μg 16:Ac. Traps baited with lures that contained less than 10 μg per septum of *E*10,*Z*12-16:Ac failed to catch any males. However, the trap catch increased sharply as the dose of *E*10,*Z*12-16:Ac increased above 10 μg (Fig. 8). This confirmed the role of *E*10,*Z*12-16:Ac as an essential part of the pheromone blend, with higher doses giving greater trap catches.

Addition of 16:OH over a broad range of doses (0, 1, 10, 100, and 1,000 μg per septum) had no effect on the attractiveness of the basic blend (100:50:10:350:1 μg per septum, *E*10,*Z*12-16:Ac: *E*10,*E*12-16:Ac: *E*10,*Z*12-16:OH: 16:Ac: *E*10,*Z*12-16:Ald) in a field trial conducted between September 22 and 29, 1999 (189 males trapped; data not shown; two-way ANOVA for treatment effect, F=0.022;

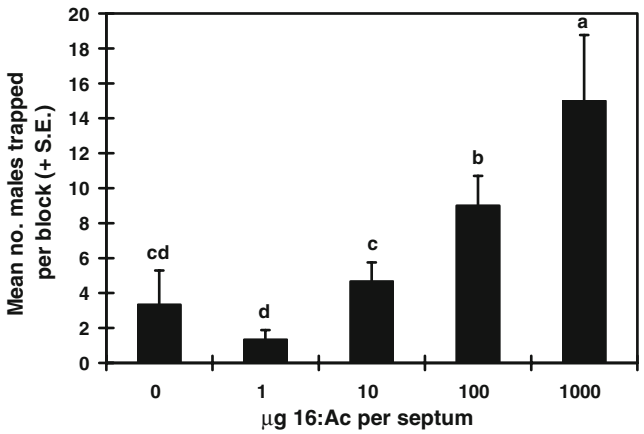

Fig. 6 Mean numbers of male *H. burnsi* caught in traps baited with 60 μg hexadecanol, 1 μg (10*E*,12*Z*)-hexadecadienal, 50 μg (10*E*,12*E*)-hexadecadienyl acetate, 10 μg (10*E*,12*Z*)-hexadecadienol, 100 μg (10*E*,12*Z*)-hexadecadienyl acetate, and varying amounts of hexadecyl acetate (16:Ac). Field trial conducted October 1, 2, and 8, 1994, with a total of four counts for each block over the 3-day period. Total number of males trapped: 100. Treatments with different *letters* are significantly different (SNK, α=0.05). Two-way ANOVA for treatment effect, F=22.00; df=4, 14; P<0.001; for block effect F=18.8; df=2, 14; P=0.001

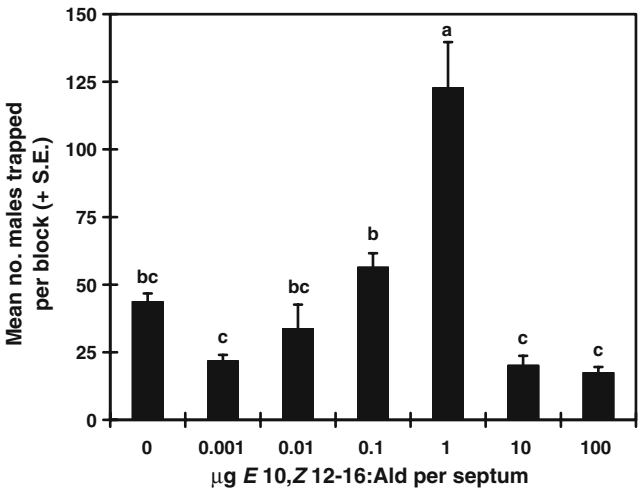

Fig. 7 Mean numbers of male *H. burnsi* caught in traps baited with 1,000 μg hexadecyl acetate, 60 μg hexadecanol, 100 μg (10*E*,12*E*)-hexadecadienyl acetate, 10 μg (10*E*,12*Z*)-hexadecadienol, and 100 μg (10*E*,12*Z*)-hexadecadienyl acetate per septum, and varying amounts of (10*E*,12*Z*)-hexadecadienal (*E*10,*Z*12-16:Ald). Field trials conducted October 7–8 and 14–15, 1995 for a total of four counts. Total males trapped: 946. Two-way ANOVA for treatment effect, F=19.09; df=6, 20; P<0.001; for block effect F=2.49; df=2, 20; P=0.125

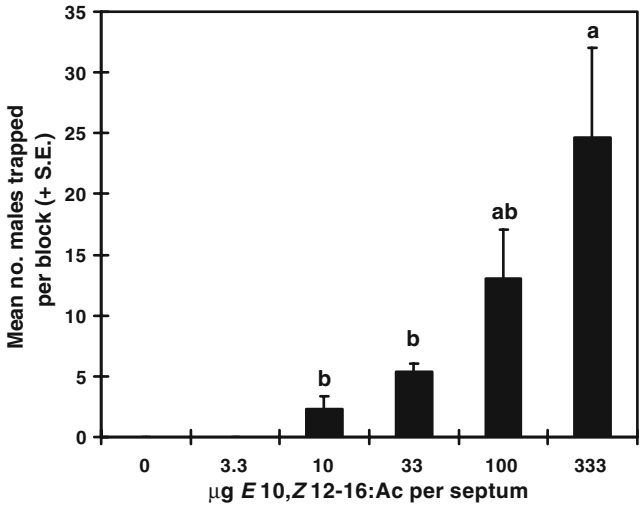

Fig. 8 Mean numbers of male *H. burnsi* caught in traps baited with 60 μg hexadecanol, 1 μg (10*E*,12*Z*)-hexadecadienal, 50 μg (10*E*,12*E*)-hexadecadienyl acetate, 10 μg (10*E*,12*Z*)-hexadecadienol, 350 μg hexadecyl acetate, and varying amounts of (10*E*,12*Z*)-hexadecadienyl acetate (*E*10,*Z*12-16:Ac). Field trial conducted September 22 and 28, 1999, with one count per block per day. Total males trapped: 136. Treatments with different *letters* are significantly different (SNK, α=0.05). Two-way ANOVA for treatment effect, F=6.83; df=3, 11; P=0.023; for block effect F=2.16; df=2, 11; P=0.20

df=4, 14; P=0.99; for block effect F=1.71; df=2, 14; P=0.24). Addition of *Z*- and *E*12-16:Ac at doses determined from a composite extract from nine pheromone glands (1.5 and 1.25 μg per septum, respectively) to a base blend (consisting of 100:100:10:1,000:60:1 μg per septum, *E*10,*Z*12-16:Ac: *E*10,*E*12-16:Ac: *E*10,*Z*12-16:OH: 16:Ac: 16:OH: *E*10,*Z*12-16:Ald) also had no affect on catches compared to the base blend (two-way ANOVA for treatment effect, F=0.65; df=3, 11; P=0.62; for block effect F=1.36; df=2, 11; P=0.33; 235 males trapped, data not shown).

A final field trial (Fig. 9) was conducted to compare the attractiveness of the basic five-component blend (100:50:10:350:1 μg per septum, *E*10,*Z*12-16:Ac: *E*10,*E*12-16:Ac: *E*10,*Z*12-16:OH: 16:Ac: *E*10,*Z*12-16:Ald, respectively) to single and multiple deletions from that blend and to a five-component blend with the optimal doses of *E*10,*E*12-16:Ac and 16:Ac (100 and 1,000 μg per septum, respectively), as determined from the field trials described above. The results confirmed that the blend of the two essential components alone (*E*10,*Z*12-16:Ac and *E*10,*Z*12-16:OH) was not attractive. Addition of any one, or any two, of the other three components to this two-component blend resulted in weak to moderate attraction. All five components were required for maximum trap catches. Somewhat surprisingly, the blend containing "optimized" ratios of *E*10,*E*12-16:Ac and 16:Ac caught similar numbers of moths as the nonoptimized blend.

Discussion

The five-component sex pheromone blend we have identified for *H. burnsi* is the most complex blend yet described for a hemileucine moth. None of the components are unique to *H. burnsi*; all have been identified from at least one other species of *Hemileuca* or its sister genus, *Coloradia*. Two components were found to be essential (*E*10,*Z*12-16:Ac and *E*10,*Z*12-16:OH), in that traps baited with blends missing either of these components caught no moths. *E*10,*Z*12-16:Ac has now been found to be a crucial pheromone component for all *Hemileuca* and *Coloradia* species examined to date, including *Hemileuca eglanterina*, *Hemileuca nuttalli*, and *H. electra*, *Coloradia velda* (McElfresh and Millar 1999a, b, c, d) and *Coloradia pandora* (McElfresh et al. 2000). However, although isomers of 10,12-16:Ac constitute the major pheromone component for at least one population of most of the *Hemileuca* and *Coloradia* species examined to date, this may be an artifact of sampling because we have been specifically studying species that may interact (Tuskes et al. 1996). *E*10,*Z*12-16:Ald is the major pheromone constituent of two of these species (McElfresh et al. 2000, 2001a, b) and has been found in others as a minor component (JSM, unpublished data).

*E*10,*Z*12-16:OH also has been found in all of the *Hemileuca* and *Coloradia* species examined to date and is

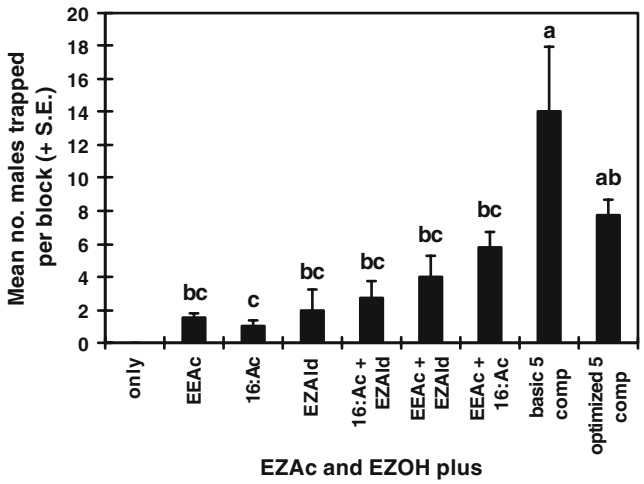

Fig. 9 Mean numbers of male *H. burnsi* caught in traps baited with 100 μg (10*E*,12*Z*)-hexadecadienyl acetate (EZAc) and 10 μg (10*E*,12*Z*)-hexadecadienol (EZOH) alone ("only") and in various combinations with 350 μg hexadecyl acetate (16:Ac), 50 μg (10*E*,12*E*)-hexadecadienyl acetate (EEAc), and 1 μg (10*E*,12*Z*)-hexadecadienal (EZAld) per septum. The "basic five-comp" blend included all five components in the amounts above. The "optimized five-comp" blend differed in that it contained 1,000 and 100 μg per septum of 16:Ac and EEAc, respectively. Field trial conducted October 2 and 7, 1999. Total males trapped: 155. Treatments with different *letters* are significantly different (SNK, α=0.05). Two-way ANOVA for treatment effect, F=6.81; df=7, 31; P<0.001; for block effect F=1.39; df=3, 31; P=0.27

an essential component of the sex pheromone blends of *H. electra*, *H. eglanterina*, and *Hemileuca maia*. It is less important for *C. velda* and not required at all by *H. nuttalli* or *C. pandora*. Thus, despite being present in pheromone gland extracts, it does not appear to be part of the attractive blend for some species and may even be antagonistic to other species at levels found in glands in *H. nuttalli* (McElfresh and Millar 1999b). In some cases, it may be present primarily as a biosynthetic intermediate–by-product, rather than a required pheromone component. Only one population of *H. eglanterina* has been shown to use *E*10, *Z*12-16:OH as a major pheromone component (McElfresh and Millar 2001).

Although *E*10,*E*12-16:Ac is frequently present in extracts of pheromone glands of hemileucine moth species, to date, only *H. nuttalli* appears to require this isomer as a component of its blend (McElfresh and Millar 1999b). It also appears to be a minor, but not essential, component for both species of *Coloradia* studied (McElfresh and Millar 1999c; McElfresh et al. 2000). Similarly, 16:Ac is a pheromone component in the blends of only two species studied, *H. burnsi* and the allopatric *H. electra electra* (McElfresh and Millar 1999d). *H. electra mojavensis*, which is sympatric with *H. burnsi*, does not use 16:Ac, either as an attractant or as an antagonist. For both species, inclusion of 16:Ac in synthetic pheromone blends is not essential. Nevertheless, addition of this compound, even at very high doses, consistently enhanced attraction (McElfresh and Millar 1999d).

It was not possible to prove conclusively the presence of *E*10,*Z*12-16:Ald in pheromone gland extracts of *H. burnsi* due to the trace amounts of the putative compound in extracts. Nevertheless, in toto, the available data make a strong case for its presence. In GC–EAD analyses of extracts, antennae of males showed strong responses to a trace component at the retention time of this compound and, when 1 μg of this compound was added to a six-component blend, trap catches increased significantly. It is interesting to note the degree of similarity between *H. burnsi* and *H. electra electra* in terms of their preferred doses–ratios of this aldehyde as compared to that of *H. electra mojavensis*. Specifically, *H. electra electra* and *H. burnsi* were more attracted to blends with low does of this compound (around 1% or less), whereas male *H. electra mojavensis* were more attracted to much higher levels (McElfresh and Millar 1999d). This alone could provide a strong reproductive isolation barrier between sympatric *H. burnsi* and *H. e. mojavensis*.

The response profiles of antennae of male moths to synthetic standards of the sex pheromone components showed that the antennae of the various species were differentially tuned to the various compounds. The relative antennal responses were consistent when expressed as a proportion of the combined responses to all five compounds. Antennae of male *H. burnsi* and *H. electra electra* showed large responses to *E*10,*Z*12-16:Ac, the major component in their respective blends. In contrast, antennae of male *H. electra mojavensis* responded less to *E*10,*Z*12-16:Ac and more to *E*10,*Z*12-16:Ald, mirroring the relative importance of these components in field bioassays (McElfresh and Millar 1999d). Antennae of both *H. burnsi* and *H. electra electra* responded similarly to 16:Ac, whereas antennae of *H. electra mojavensis*, which does not use this compound, showed relatively weak responses to this compound. Although the results from the GC–EAD comparisons appear clear-cut, one qualification is that the moths used in this study were collected in the field by using blends of synthetic pheromone components optimized for each population. This may have created a bias in the males collected and hence their EAD responses. This collection method was necessary because of the problems and time constraints (on average a 2-year life cycle) involved in rearing these insects. Nevertheless, such comparisons of antennal response profiles to a suite of possible pheromone components could provide a useful method of assessing differences in pheromone blends of populations.

Populations of *H. burnsi* and *H. electra mojavensis* co-occur throughout much of the Mojave Desert. Their distributions reflect the results of natural forces acting over millennia and have been minimally affected by human activities. We had previously hypothesized that the observed differences in the pheromone systems of *H. electra electra* and *H. electra mojavensis* were the result of the latter subspecies being sympatric with *H. burnsi* in the Mojave Desert, whereas the former subspecies had no apparent competition for its pheromone channel (McElfresh and Millar 1999d). The data presented here have allowed a more rigorous test of this hypothesis. The potential for interference was demonstrated by artificially placing females of the allopatric subspecies *H. electra electra* to attract wild males of both *H. burnsi* and *H. electra mojavensis* (McElfresh and Millar 1999d). This cross-attraction suggested that the pheromone blends of the latter two species–subspecies must be similar to that of *H. electra electra*, and this has now been verified. Specifically, both *H. burnsi* and *H. electra electra* use *E*10,*Z*12-16:Ac as their major component; both require *E*10,*Z*12-16:OH; both utilize 16:Ac as a minor component, and both prefer low doses of *E*10,*Z*12-16:Ald. In contrast, *H. electra mojavensis* is more divergent, using both *E*10,*Z*12-16:Ald and *E*10, *Z*12-16:Ac as major components and a specific ratio of *E*10,*Z*12-16:OH, with apparently no additional compounds. The new data reported here support our original hypothesis that the divergence between the two *H. electra* subspecies is a result of competition for, and interference with, a shared pheromone channel. This suggests that reproductive

character displacement has occurred with one subspecies, thus maximizing prezygotic mating barriers, thereby minimizing costly and unproductive interspecific mating.

Introduction

The Australian gum leaf skeletonizer, *Uraba lugens* (Walker 1863) (Lepidoptera, Nolinae, Nolidae), arrived recently in New Zealand. In New Zealand, this insect has few natural enemies present (Mansfield et al. 2005) and is a significant threat to New Zealand eucalyptus forestry and amenity plantings (Kriticos et al. 2007). The larvae of *U. lugens* feed gregariously on *Eucalyptus* and allied Myrtaceae, skeletonizing the leaves and, at times, causing considerable damage (Common 1990; Allen and Keller 1991; Potter and Stephens 2005. Outbreaks of *U. lugens* in urban trees and school playground shade trees in Auckland have led to medical complaints about the urticating hairs of the larvae (Derraik 2006). A classical biological control program for this species has commenced, with testing of host range of parasitoids with respect to native New Zealand species (Bernt 2006; Berry and Mansfield 2006). In Australia, *U. lugens* occurs from Cooktown to the Atherton Tableland and from southern Queensland to Victoria, South and south-western Australia, and Tasmania (Common 1990). Outbreaks of *U. lugens* have been reported from Queensland (Brimblecombe 1962), New South Wales (Campbell 1962), Victoria (Harris et al. 1977), and Western Australia (Strelein 1988; Farr 2002; Farr et al. 2004). Between 1997 and 2001, infestations of *U. lugens* were discovered in New Zealand on three separate occasions at localities in the northern part of the North Island (Hoare 2001).

The most recent biosecurity incursions, centered in the south-west suburbs of Auckland city, have been ongoing since late 2001 (Ross 2001, 2003). While the first two incursions were localized and apparently eradicated at the time, the New Zealand Ministry of Agriculture and Forestry (MAF) considered that *U. lugens* had the potential, if it established, to spread widely and cause major damage to New Zealand's *Eucalyptus* timber plantations. MAF's response was to commission a team to identify the sex pheromone. The development of a synthetic sex pheromone attractant for male *U. lugens* moths was considered to be a high priority to detect any further incursions and to undertake delimitation surveys of infestations (Suckling et al. 2005).

While several authors have published on the biology of *U. lugens* (Campbell 1962; Morgan and Cobbinah 1977; Farr 2002), there has been no research on female calling behavior, pheromone identity, pheromone production, or longevity of the adults. Campbell (1962) noted that "Both emergence and copulation take place during the early hours of darkness."

In Australia, *U. lugens* exists in univoltine and bivoltine forms, and these are said to differ in the arrangement of their deposited eggs. Morgan and Cobbinah (1977) suggested that any biomorph differences were temperature induced, rather than representing separate taxa. Farr (2002) observed the ability of "the univoltine form to change to a bivoltine cycle following two consecutive warm winters" in the southern jarrah forest of Western Australia, but this was apparently not correlated with a change in egg deposition pattern. The population in Auckland is bivoltine (Suckling et al. 2005).

Our objectives in this study were to: (1) characterize the sex pheromone of *U. lugens* so as to provide a monitoring tool for cost-effective detection of populations; (2) measure any quantitative and/or qualitative differences in sex pheromone between a univoltine population of *U. lugens* from Hobart, Tasmania, Australia, and a bivoltine population from Auckland, New Zealand; and (3) investigate female calling behavior and temporal pheromone production in the bivoltine population.

Methods and Materials

Insects Egg batches of *U. lugens*, adhering to *Eucalyptus* leaves, were collected from *E. nicholi* trees in Walter Massey Park, Mangere East, Auckland, New Zealand, and air-freighted in doubly contained, sealed packaging to HortResearch, Lincoln for emergence in containment facilities [approximately 22°C and approximately 60% relative humidity (RH)]. Larvae were reared in 680-ml plastic containers (Huhtamaki Henderson Ltd., Auckland, New Zealand) and supplied with fresh leaves of *Eucalyptus viminalis*, as required. Groups of about 10 fifth instars were transferred to additional plastic containers to avoid cannibalism. Pupae were placed individually in 50-cm plastic Petri dishes for emergence. In addition, two shipments of female pupae from a Tasmanian population of *U. lugens* were imported and held in quarantine facilities at Landcare Research, Lincoln. The Tasmanian larvae originated from *E. viminalis* trees at Government Hills, Risdon, Hobart and were reared on *E. viminalis*, initially, and then *E. nitens*, in a similar fashion to the Auckland population.

Females from the Auckland and Tasmanian populations had their pheromone glands excised and extracted for qualitative and quantitative analyses by gas chromatography (GC) and gas chromatography–mass spectrometry

(GC-MS). Males from the Auckland population were used for coupled gas chromatography electroantennographic detection (GC-EAD) studies.

Chemicals Authentic samples of (10*Z*,12*E*)-hexadecadienal (*Z*10,*E*12–16:Ald) (91% isomerically pure), (10*E*,12*Z*)-hexadecadien-1-ol (*E*10,*Z*12–16:OH) (86% isomerically pure; 1%, 3%, and 9% of the *Z*,*E*-, *Z*,*Z*-, and *E*,*E*- isomers, respectively), and (10*E*,12*E*)-hexadecadien-1-ol (*E*10,*E*12–16:OH) (>98% isomerically pure) were obtained from D. R. Hall, Natural Resources Institute, University of Greenwich, Chatham Maritime, Kent, UK. Larger amounts of *E*10,*Z*12–16:OH (>95% isomerically pure), (*Z*)-11-hexadecen-1-yl acetate (*Z*11–16:Ac), and (*Z*)-9-tetradecen-1-yl acetate (*Z*9–14:Ac) (both >98% isomerically pure), for trapping trials, as well as (*E*)-11-hexadecen-1-yl acetate (*E*11–16:Ac) and (*Z*)-10-pentadecen-1-yl acetate (*Z*10–15:Ac) (>98% isomerically pure), were purchased from Pherobank, Wageningen, The Netherlands. (10*Z,*12*E*)-Hexadecadien-1-ol (*Z*10,*E*12–16:OH), (10*Z,*12*E*)-hexadecadien-1-yl acetate (*Z*10,*E*12–16:Ac), (10*E,*12*Z*)-hexadecadien-1-yl acetate (*E*10,*Z*12–16:Ac), and (10*E,*12*E*)-hexadecadien-1-yl acetate (*E*10,*E*12–16:Ac) were all synthesized at HortResearch, Palmerston North. Dimethyldisulfide (DMDS) was obtained from Merck, Darmstadt, Germany and octadecan-1-ol and 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) from Sigma-Aldrich, Sydney, Australia.

Syntheses of (10E,12Z)-Hexadecadien-1-yl Acetate and (10E,12E)-Hexadecadien-1-yl Acetate Vinyl acetate (5.35 g, 62.2 mmol, Sigma-Aldrich, Sydney, Australia) and 1.0 g of lipase PS-C "Amano" II (Amano Enzyme Inc., Nagoya, Japan) were added to a solution of an authentic sample of either *E*10,*Z*12–16:OH or *E*10,*E*12–16:OH (0.92 g, 3.86 mmol) contained in dry, freshly distilled pentane (100 ml, from P_2O_5) under dry nitrogen. The slurry was shaken for 18 hr at room temperature, and the disappearance of either *E*10,*Z*12–16:OH or *E*10,*E*12–16:OH was monitored by thin layer chromatography on silica gel plates [Merck 1.05554; eluted with hexane/ethyl acetate 10:1; visualized under UV (234 nm) and developed with acidified ethanolic vanillin and heat]. The reaction mixture was filtered through a short pad of celite (10 mm) and rinsed with additional freshly distilled pentane (2×30 ml). Finally, the resulting colorless solution was concentrated under reduced pressure to give either *E*10,*Z*12–16:Ac or *E*10,*E*12–16:Ac as a pale, yellow oil. The identity and purity of the compounds was confirmed by GC-MS.

Syntheses of (10Z,12E)-Hexadecadien-1-ol and (10Z,12E)-Hexadecadien-1-yl Acetate The authentic sample of *Z*10,*E*12–16:Ald was converted to *Z*10,*E*12–16:OH by reduction with $NaBH_4$ (2 mg, 0.053 mmol) in ethanol (1 ml). Approximately 0.75 mg of the *Z*10,*E*12–16:OH were then converted to *Z*10,*E*12–16:Ac using the lipase PS-C "Amano" II method, as described previously for *E*10,*Z*12–16:Ac and *E*10,*E*12–16:Ac. The identity and purity of the compounds was confirmed by GC-MS.

Pheromone Gland Extracts All pheromone gland extracts were harvested from calling females held under a 12L/12D reverse-phase photoperiod in a room maintained at 22°C and 60% RH. Female moths were kept in 40-ml humidified polycarbonate plastic boxes and provided with 10% sugar solution to feed on *ad libitum*. Excised pheromone glands were placed into liquid nitrogen-cooled 0.5-ml V-vials (Wheaton, Millville, NJ, USA), containing 20–30 μl of *n*-hexane. After glands had been excised, the vial and its contents were brought to room temperature and the glands extracted for 5 min. The extract was transferred to a 1.1-ml conical glass vial and concentrated under a stream of argon to ca 10 μl, and stored at −20°C until analysis. To quantify pheromone titer per female, pheromone glands were extracted in 50-μl of *n*-hexane containing 50 ng of (*Z*)-10-pentadecen-1-yl acetate as internal standard.

To determine double-bond positions of the EAD-active compounds, two pheromone gland extracts were derivatized and analyzed by GC-MS. For the DMDS derivatizations of a 13-female gland extract and *Z*11–16:Ac and *E*11–16:Ac standards, we followed the procedure described by Buser et al. (1983). For details, see Gibb et al. (2006). For the MTAD derivatizations of a six-female gland extract and *E*10,*Z*12–16:Ac and *E*10,*Z*12–16:OH standards, we followed the procedure of McElfresh and Millar (1999).

Female Calling Behavior Experiments and Pheromone Titer Analysis over Time In an experiment to determine the most appropriate time for extracting pheromone glands, the calling behavior of female *U. lugens* (five replicate groups of 10 females, all from the Auckland Population) was observed and recorded every hour on the hour over a 12-h period, from the beginning to the end of each of the first four scotophases following female emergence. Female mortality at the end of each activity period was also noted. In a subsequent, related experiment, we extracted the pheromone glands of groups of 10 freshly emerged females for quantitative analysis at the beginning of their first scotophase (T0) and thereafter at 2, 4, 7, 24, and 48 hr (T2, T4, T7, T24, and T48). There were three replicate groups for each sample of 10 females.

Comparison of Auckland, New Zealand, and Tasmania U. lugens Gland Extracts The pheromone titers of the Auckland bivoltine and Tasmanian univoltine populations were compared by excising and extracting glands of 14 actively calling female moths (N=3) from each population

during the sixth hour of the first scotophase following emergence.

Gas Chromatography Electroantennographic Detection Pheromone gland extracts of *U. lugens* females were analyzed by GC-EAD using a Varian 3800 gas chromatograph, coupled to an EAD Recording Unit (Syntech Research and Equipment, Hilversum, The Netherlands). Extracts were run on ZB-5 (30 m×0.25 mm i.d.×0.5 μm film; Phenomenex, Torrance, CA, USA) and ZB-Wax (30 m×0.25 mm i.d.× 0.5 μm film; Phenomenex) columns, with a 1:1 split between the flame ionization detector and the EAD. Nitrogen was the carrier gas (1 ml min^{-1}), and the injections were splitless. Injector and detector temperatures were set at 250°C and 300°C, respectively, and the GC oven program was 80°C for 1 min, increasing at 20°C min^{-1} to 230°C, and held for 30 min. For details of the preparation of moth antennae and our setup of associated equipment for GC-EAD analyses, see Gibb et al. (2006). Kováts retention indices (KIs; Kováts 1965; Marques et al. 2000) were calculated for the EAD-active compounds.

Quantitative Analysis of Pheromone Glands For quantitative analysis of pheromone gland extracts, we used a Varian 3800 gas chromatograph fitted with a DB-5 column (30 m× 0.25 mm i.d.×0.5 μm film; Agilent Technologies, Palo Alto, CA, USA). Helium was the carrier gas (1 ml min^{-1}), and injections were splitless. Injector and detector temperatures were set at 220°C and 300°C, respectively, and the GC oven program was 100°C for 1 min, 10°C min^{-1} to 210°C, held for 16 min, then increased at 20°C min^{-1} to 240°C, and held for 20 min.

Gas Chromatography–Mass Spectrometry Gland extracts of insects from the Auckland and Tasmanian populations were analyzed by GC-MS using a Varian 3800 GC coupled to a Varian 2200 MS. Helium was used as carrier gas (1 ml min^{-1}) and injections were splitless. Injector, transfer line, and ion trap temperatures were 220°C, 250°C, and 200°C, respectively. The machine was fitted with a VF-5ms column (30 m×0.25 mm i.d.×0.25 μm film; Varian Inc., Walnut Creek, CA, USA), and the following temperature program was used: 100°C for 1 min, 10°C min^{-1} to 210°C, and held for 30 min. The DMDS- and MTAD-derivatized pheromone gland extracts, and standards were also analyzed using the VF-5ms column (injector temperature, 250°C), using a temperature program of: 80°C to 240°C at 10°C min^{-1} (DMDS) or 100°C to 300°C at 15°C min^{-1} (MTAD).

Trapping Bioassays Field trials were conducted in Queensland, Australia in 2002 (trial A) and in Auckland from 2003 to 2007 (trials B-D). Green delta traps (Clare et al. 2000) were attached to individual eucalypt trees at a height of approximately 2.5 m, with at least 5-m spacing between traps and at least 20-m spacing between replicates. Trap positions within each replicate were re-randomized between readings, and sticky inserts were replaced at each check for capture of male *U. lugens*. Test compounds, based on ratios from GC analyses of *U. lugens* gland extracts, were loaded onto red rubber septa (Thomas Scientific Inc., Philadelphia, PA, USA). All bioassays included a blank control.

In trial A (April to June 2002), the attraction of *U. lugens* males to various combinations of the three candidate EAD-active compounds was tested at a rural site near Goomeri (26°11′ S; 152°07′ E), 3 hr north of Brisbane (one replicate), where there had been previous outbreaks of *U. lugens*, and at Brisbane Forest Park (three replicates). An additional compound, Z9–14:Ac, was also included in trial A because a review of the literature (Arn et al. 1992) had revealed that Z9–14:Ac occurred frequently as a sex pheromone component in the superfamily Noctuoidea. Traps were checked three times at intervals of 4–8 d. Treatments comprised the following ratios (in microgram loadings) of *E*10,*Z*12–16:OH, *E*10,*Z*12–16:Ac, *Z*11–16:Ac, and *Z*9–14:Ac: (1) 26:70:3:3, (2) 0:100:0:0, (3) 100:0:0:0, (4) 25:75:0:0, (5) 24:72:3:0, (6) 24:72:0:3, (7) 0:95:0:5, (8) 0:95:5:0, (9) 0:92:4:4, (10) 88:0:12:0, (11) 88:0:0:12, and (12) 80:0:10:10.

Trial B (March 18 to May 10, 2003) examined the attraction of *U. lugens* males to various combinations of the two major candidate EAD-active compounds with and without *Z*11–16:Ac, a minor gland component. Replicates of the trial were placed in 10 locations in the greater Auckland area that were considered likely to be sites of infestation by *U. lugens*. Traps were checked weekly. Treatments were (1) 0:300:0, (2) 30:270:0, (3) 75:225:0, (4) 150:150:0, (5) 225:75:0, (6) 270:30:0, (7) 300:0:0, (8) 30:270:9, (9) 75:225:9, (10) 150:150:9, (11) 225:75:9, and (12) 270:30:9 μg loadings of *E*10,*Z*12–16:OH, *E*10,*Z*12–16:Ac, and *Z*11–16:Ac (n=3).

Trial C (March 14 to May 9 2004) was a dose–response trial based on results derived from earlier trials and a test of two minor components that had been identified in the gland extract. Treatments were (1) 40:60:0:0, (2) 400:600:0:0, (3) 1200:1800:0:0, (4) 250:750:30:0, (5) 225:75:0, and (6) 400:600:30:50 μg loadings of *E*10,*Z*12–16:OH, *E*10,*Z*12–16:Ac, *Z*11–16:Ac and octadecan-1-ol (18:OH). The last component had been found in the gland extract but due, to its relatively lower volatility, was considered more likely to be a pheromone precursor than an actual component but was included in the trial to test attraction. Ten replicates were used and traps were checked weekly.

Trial D (6 Nov to 13 Dec 2007) investigated the effect of the second minor component, *E*10,*E*12–16:Ac, on catch. Treatments were (1) 250:750:0:0, (2) 250:750:50:30, (3)

250:750:0:30 μg loadings of *E*10,*Z*12–16:OH, *E*10,*Z*12–16:Ac, and *Z*11–16:Ac. Ten replicates were used and traps were checked weekly.

Statistical Analyses Only treatments that trapped moths were included in the statistical analyses. For each trial, the sum of moths captured per trap was analyzed for treatment effects using one-way analysis of variance (ANOVA; SAS Institute Inc. 1998). Residual plots were used to check the validity of the ANOVA assumptions, with $\log_{10}(x+1)$ transformations of the summed captures, when necessary, to remove variance heterogeneity. Means were compared by Fisher's protected least significant differences test (P=0.05; SAS Institute Inc. 1998).

Results and Discussion

Identification of Pheromone Components Analyses of *U. lugens* gland extracts by GC-EAD revealed the presence of two major EAD-active compounds (compounds **1** and **2**) and one minor EAD-active compound (compound **3**) that consistently elicited responses from male antennae (Fig. 1). Two other compounds (compounds **4** and **5**) were also present in gland extracts, but EAD responses to these compounds were small and inconsistent.

The retention times of compound **1** on ZB-5 and ZB-wax columns were consistent with that of a conjugated C_{16} dienol-1-ol and were the same as those of the *E*10*Z*12–16:OH standard. The analysis of the MTAD-derivatized pheromone gland extract by GC-MS revealed an adduct with a molecular ion at *m/z* (relative intensity) 351 (3) and diagnostic ions at *m/z* 308 (18) ($[C_{16}H_{26}N_3O_3]^+$), and 208 (46), ($[C_{10}H_{14}N_3O_2]^+$), indicative of a C_{16} dien-1-ol with conjugation at the 10,12 position. Moreover, comparison of the mass spectrum [*m/z* (rel. int.) 238 (1, M^+), 220 (5), 149 (3), 135 (5), 121 (16), 109 (15), 95 (38), 81 (68), 67 (100), 55 (24), 41 (32)] and KI of compound **1** with those of all four possible 10,12-hexadecadien-1-ol stereoisomers confirmed compound **1** unambiguously as *E*10*Z*12–16:OH (KI of 1,924 on the VF-5ms column; KIs of the *Z*,*E*, *Z*,*Z*, and *E*, *E* isomers were 1,917, 1,936, and 1,940, respectively).

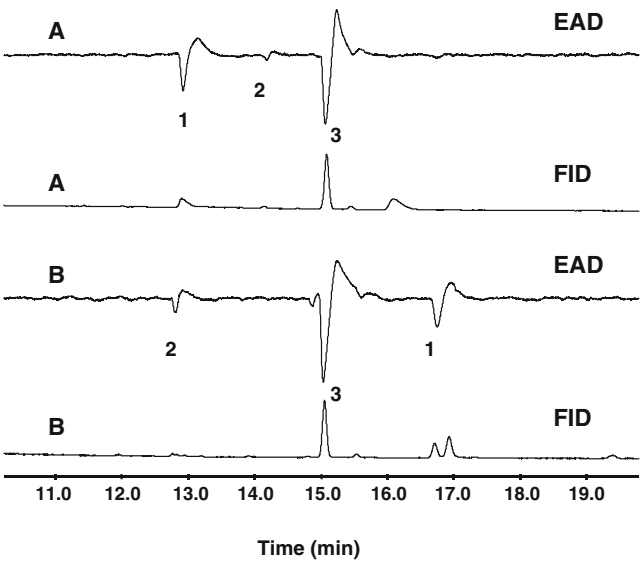

Fig. 1 Coupled gas chromatography electroantennogram analysis of pheromone gland extract of female *Uraba lugens*, using a conspecific male antenna, on ZB-5 (**a**) and ZB-Wax (**b**) capillary columns. *1* (*E*10, *Z*12)-hexadecadien-1-ol; *2* (*Z*)-11-hexadecenyl acetate; and *3* (*E*10, *Z*12)-hexadecadienyl acetate. *FID* Flame ionization detector response, *EAD* electroantennogram detector response

Similarly, the retention times of compound **2** on ZB-5 and ZB-wax columns suggested a conjugated C_{16} dien-1-yl acetate and were the same as those of authentic *E*10*Z*12–16:Ac. Analysis of the MTAD-derivatized pheromone gland extract revealed an adduct with a molecular ion at *m/z* (rel. int.) 393 (2) and diagnostic ions at *m/z* (rel. int.) 350 (32), $[C_{18}H_{28}N_3O_4]^+$, and 208 (100), $[C_{10}H_{14}N_3O_2]^+$, indicative of a C_{16} dien-1-yl acetate with conjugation at the 10,12 position. Moreover, comparison of the mass spectrum [*m/z* (rel. int.) 280 (1, M^+), 220 (5), 177 (3), 163 (4), 149 (8), 135 (19), 121 (33), 107 (18), 95 (35), 81 (70), 67 (100), 61 (3), 55 (17), 43 (48)] and retention time of compound **2** in pheromone gland extracts, with all four possible C_{16} dien-1-yl acetate stereoisomers for the 10,12 position, confirmed compound **2** unambiguously as *E*10*Z*12–16:Ac (KI=2,046 on the VF-5ms column; *Z*,*E*, *Z*,*Z*, and *E*,*E* stereoisomers of 10,12 hexadecadien-1-yl acetate had KIs of 2,037, 2,058, and 2,064, respectively). A small amount (approxiamtely 5% compared with the *E*,*Z*-isomer) of *E*10*E*12–16:Ac (compound **3**) was also present in gland extracts, based on its KI and mass spectrum.

Compound **4** had KIs of 2,001 and 2,364, respectively, on the ZB-5 and ZB-Wax columns, the same as those of *Z*11–16:Ac standard. In addition, the mass spectrum of compound **4** [*m/z* (rel. int.) 222 (5), 166 (3), 137 (8), 123 (11), 109 (33), 95 (56), 81 (100), 67 (96), 61 (6), and 55 (42)] and its retention time on the VF-5ms column was the same as that of authentic *Z*11–16:Ac. Finally, compound **4** was unequivocally confirmed to be *Z*11–16:Ac, rather than *E*11–16:Ac, by comparing the retention times of the DMDS adducts of the two standards, with the adduct formed in the DMDS derivatized gland extract. Both hexadecen-1-yl acetate-DMDS adducts had a molecular ion at *m/z* (rel. int.) 376 (7) and diagnostic ions at *m/z* (rel. int.) 117 (20, $[C_5H_{10}SCH_3]^+$) and 259 (100, $[O_2C_{13}H_{24}SCH_3]^+$), corresponding to the addition of DMDS to a double bond at position 11.

The spectrum of compound **5** suggested an aliphatic primary alcohol (Pretsch et al. 2000) and was confirmed as

octadecan-1-ol by comparing its KI (2,088) on the VF-5 ms column and mass spectrum [*m/z* (rel. int.) 270 (1, M^+), 138 (3), 125 (8), 111 (39), 97 (88), 83 (89), 69 (91), 55 (100), and 41 (46)] with that of the authentic standard.

Qualitative and Quantitative Comparison of Auckland and Tasmania U. lugens Gland Extracts Gland extracts from the Auckland and Tasmanian populations contained four main compounds (Fig. 2), with two components dominant. Neither the quantities nor ratios of the four compounds varied significantly between these populations.

Female U. lugens Calling Behavior and Sex Pheromone Analysis Female *U. lugens* moths emerged during late photophase and early dusk. Characteristic lepidopteran calling behavior by females was first observed 2 hr into the scotophase and continued until dawn, with a peak at 7 hr into the scotophase (Fig. 3). A similar calling pattern was observed for 24-, 48-, and 72-hr-old females, although the proportion of females calling decreased significantly after the third scotophase.

Consistent with the calling behavior, pheromone titer reached a peak 7 hr into the first scotophase (Fig. 4) and

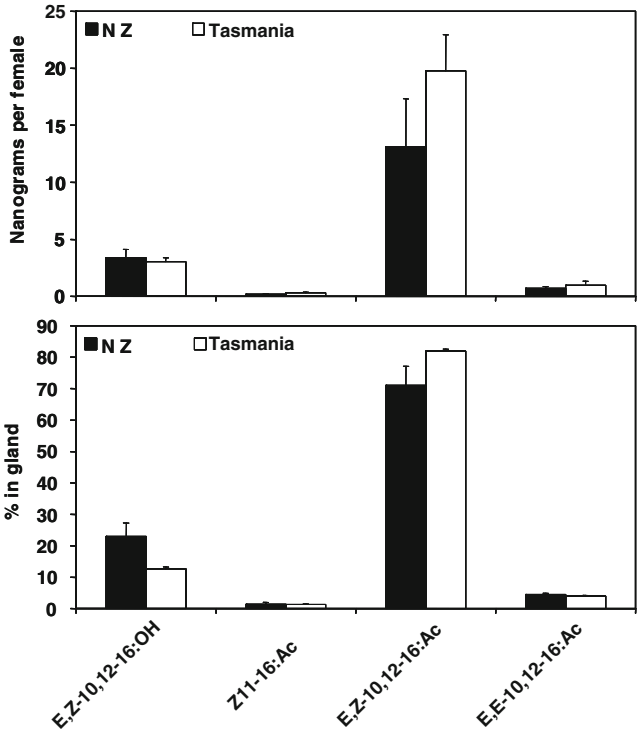

Fig. 2 Pheromone gland extract of *Uraba lugens* from Auckland (New Zealand) and Tasmania showing titers of (*E*10,*Z*12)-hexadecadien-1-ol (E,Z-10,12–16:OH), (*Z*)-11-hexadecenyl acetate (Z11–16:Ac), (*E*10,*Z*12)-hexadecadienyl acetate (E,Z10,12–16:Ac), and (*E*10,*E*12)-hexadecadienyl acetate (E,E-10,12–16:Ac). *Bars* indicate one standard error

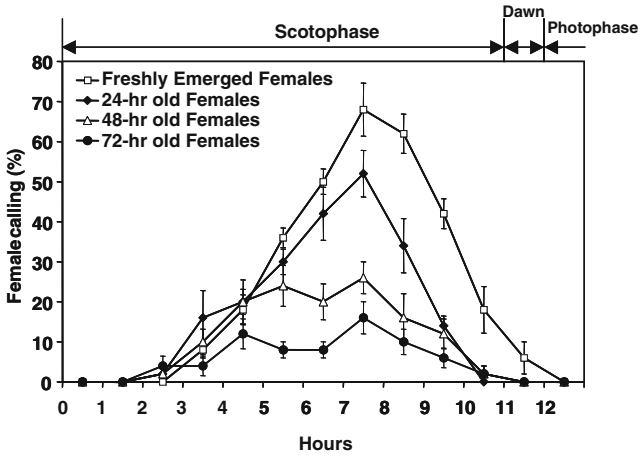

Fig. 3 Percentage of *Uraba lugens* females observed calling over a 12-h period from the first to the fourth scotophases. Age of females given is at start of the scotophase. *Bars* indicate one standard error

was at a comparable level during the scotophase on the next day and the day after that. Except at the beginning of the first scotophase (0 hr), when the amount was barely detectable, there was no significant difference in the amount of 18:OH in the gland at any of the time periods (i.e., from 2–48 hr) analyzed (Fig. 4). By the fourth scotophase, mortality of females was 35% and, after 96 hr, was 80% (Fig. 4).

Trapping Bioassays Trap tests in Australia were comparatively unsuccessful, catching a total of only 14 *U. lugens* to synthetic blends (Fig. 5a), which precluded meaningful statistical analysis. However, a second species (*Nola* spp.), visually distinct from *U. lugens* by the lack of a dark band across the wings, was caught in traps. We were unable to identify this species beyond the genus level. The catches of this insect to the blends tested are included in Fig. 5b for future reference.

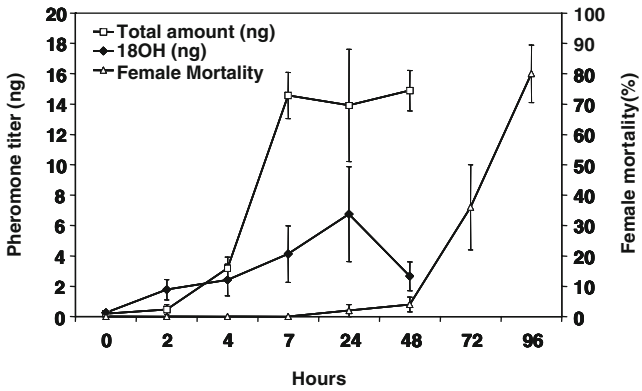

Fig. 4 Titer of pheromone (total amount of four compounds in Fig. 1) and octadecanol (18:OH) in the gland of *Uraba lugens* females and mortality over time. *0* Beginning of first scotophase. *Bars* indicate one standard error

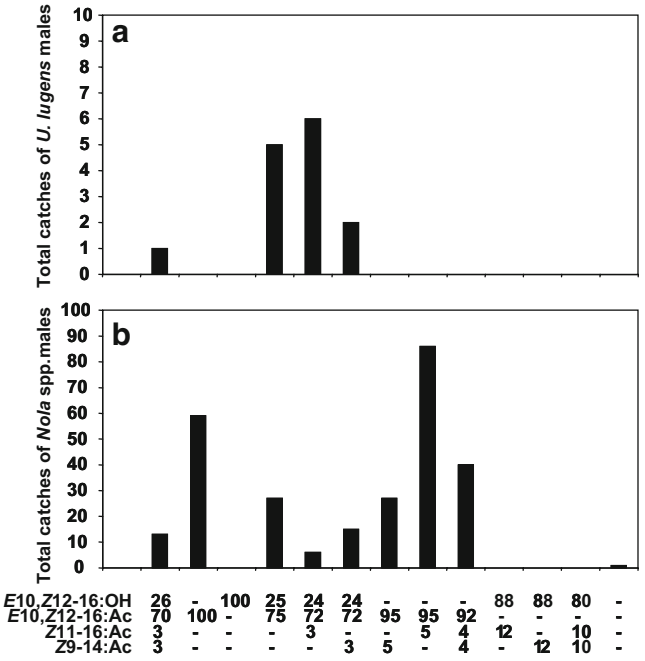

Fig. 5 Trap catch of *Uraba lugens* males (**a**) and *Nola* spp. males (**b**) in pheromone traps, baited with 100-μg total loadings of various combinations of candidate pheromone components, at a rural site near Goomeri, north of Brisbane (trial A). E,Z-10,12–16:OH=(*E*10,*Z*12)-hexadecadien-1-ol; Z11–16:Ac=(*Z*)-11-hexadecenyl acetate; E,Z10,12–16:Ac=(*E*10,*Z*12)-hexadecadienyl acetate; and Z9–14:Ac=(*Z*)-9-tetradecenyl acetate

Trapping assays in New Zealand confirmed that the binary combination of *E*10*Z*12–16:Ac and *E*10*Z*12–16:OH was necessary and sufficient for trap catch of male *U. lugens*. Treatment effects were significant on log-transformed counts ($F_{12,91}$=2.21, P<0.05) in trial B (Fig. 6) and on untransformed counts in trial C ($F_{5,48}$=14.21, P<0.001; Fig. 7a) and trial D ($F_{3,36}$=33.59, P<0.001; Fig. 7b). None of the tested compounds identified from female *U. lugens* pheromone glands was attractive by itself. Furthermore, the addition of the minor gland components *Z*11–16:Ac, *E*10*E*12–16:Ac, and octadecan-1-ol to the binary mix of *E*10*Z*12–16:Ac and *E*10*Z*12–16:OH did not result in increased trap catches relative to the binary mix alone. Except at very low ratios (1:9, Fig. 6) of *E*10*Z*12–16:Ac: *E*10*Z*12–16:OH, trap catches did not differ significantly over the ratios of these two compounds tested. Trap catch at a constant ratio of 2:3 (*E*10*Z*12–16:Ac: *E*10*Z*12–16:OH) increased from the lowest dosage tested (100 μg total of the two components) to the intermediate dosage (1,000 μg) but did not increase further to the highest dosage (3,000 μg) (Fig. 7a).

Unless an invasive moth is a major pest in another country, it is unlikely that its pheromone has been identified previously. Moreover, it is difficult to anticipate problematic invasive moths, since it is difficult to predict risk of a species arriving and its potential impact in a new

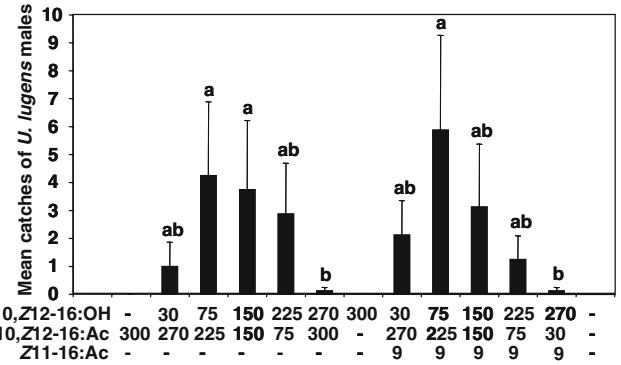

Fig. 6 Trap catch of *Uraba lugens* males in Auckland using lures containing a range of ratios of one, two, or three components at 300 μg (total components) (trial B). *Differences in letters* indicate differences between treatments at the P<0.05 level. E,Z-10,12–16:OH=(*E*10,*Z*12)-hexadecadien-1-ol; Z11–16:Ac=(*Z*)-11-hexadecenyl acetate; E,Z10,12–16:Ac=(*E*10,*Z*12)-hexadecadienyl acetate. *Bars* indicate one standard error

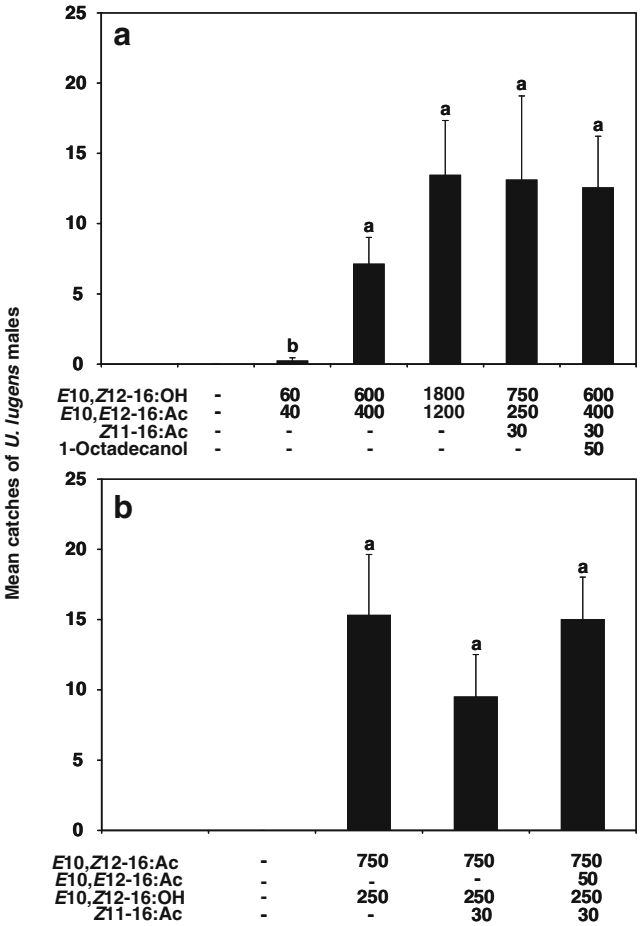

Fig. 7 Trap catch of *Uraba lugens* males in Auckland to **a** different doses (μg) and blends (trial C), and **b** addition of minor gland components to the two component blend (trial D). E,Z-10,12–16:OH=(*E*10,*Z*12)-hexadecadien-1-ol; Z11–16:Ac=(*Z*)-11-hexadecenyl acetate; E,Z10,12–16:Ac=(*E*10,*Z*12)-hexadecadienyl acetate. *Differences in letters* indicate differences between treatments at the P<0.05 level. *Bars* indicate one standard error

ecosystem. Therefore, pheromone identifications of such moth pests are likely to occur only after the insect has arrived and established. The gum leaf skeletonizer is not considered a major pest in its native Australia. A parasitoid complex (Brimblecombe 1962; Austin and Allen 1989; Allen 1990; Farr 2002), microbial diseases (Strelein 1988; Farr 2002), and periods of protracted drought help keep population levels relatively low, although occasional outbreaks of populations do occur (Brimblecombe 1962; Farr et al. 2004).

We commenced our study on the gum skeletonizer after it had been found in New Zealand, but to the knowledge at the time, it had yet to establish a permanent population. We were able to supply attractive lures to the official quarantine delimitation program in New Zealand (Suckling et al. 2005) within 3 mo of commencing the study, in part due to the initial field trial we conducted in Australia. Lures containing a 1-mg dose of a 75:25:3 mix of *E*10,*Z*12–16:Ac, *E*10, *Z*12–16:OH and *Z*11–16:Ac have since been used widely to collect phenological data, conduct delimitation surveys in the Auckland area (Suckling et al. 2005), conduct a survey in Tasmania in 2005 to determine the distribution of native Australian populations, and also to develop a model to determine the potential spread of this invasive pest (Kriticos et al. 2007). The surveys in New Zealand have shown that the insect has spread quite rapidly. An interactive map of the distribution of *U. lugens* in New Zealand, based on pheromone trapping data, is available (http://gis.scionresearch.com/maful/viewer.htm).

Acknowledgments We thank John Allen (HortResearch) for initial GC-MS analysis, AgriQuality personnel, Andréa Stephens, and Asha Chagan (HortResearch) for technical assistance in the field in Auckland, and John Bain (Ensis) for supplying the initial egg batches. Luke Rapley and Anthony Rice from the Cooperative Research Centre for Sustainable Production Forestry in Hobart, Tasmania reared the Tasmanian *U. lugens* pupae. Robert Hoare (Landcare Research) and Ian Common (retired, formerly CSIRO) confirmed the identity of the specimens. Funding was provided by the New Zealand Ministry of Agriculture and Forestry (MAF) and the New Zealand Foundation for Research, Science and Technology (FRST), under "Better Border Biosecurity" (www.b3.org) and previous programs.

potheses, and act as standards for comparison. Models of mating disruption and mass trapping may need to consider parameters such as (a) odor dispersion (e.g., plume structure, emission rates, meteorology, and densities of chemical dispensers), (b) behavior (e.g., orientation mechanisms, sensitivity to components, mating, and dispersal), and (c) population ecology (e.g., duration, percentage mating or trapped, densities of males and females).

One parameter that could be used in models described above is the active space, defined by Elkinton and Cardé (1984) as the volume of air inside in which the odor concentration is above the threshold that elicits a behavioral reaction in the receiving organism (Sower et al. 1971; Nakamura and Kawasaki 1977; Baker and Roelofs 1981). This concept is based on various Gaussian equations that calculate the odor concentrations in still and moving air (Sutton 1953; Bossert and Wilson 1963; Fares et al. 1980). The active space has been investigated in several studies by observing wing-fanning of male moths in cages at various points within a pheromone plume (Elkinton and Cardé 1984; Elkinton et al. 1984). The fine structure of pheromone plumes on a small time scale is extremely complicated but thought to comprise filaments of higher concentrations due to turbulent eddies of air (Mankin et al. 1980; Elkinton and Cardé 1984; Baker et al. 1998).

While plumes and active spaces are three-dimensional in nature, they can be simplified further to two dimensions for practical purposes. This is because mate- and host-seeking insects disperse and orient over hundreds of meters within a relatively thin layer of air a few meters thick, as shown in many studies (e.g., Meyerdirk and Moreno 1984; Meyerdirk and Oldfield 1985; Chandler 1985; Meyer and Colvin 1985; Stone 1986; Byers et al. 1989; Stewart and Gaylor 1991; Isaacs and Byrne 1998; Pearsall and Myers 2001; Weber et al. 2005). Thinking in a two-dimensional way (Fig. 1a), the active space can be thought of as an instantaneous snapshot or as a time-averaged area (Sutton 1953; Bossert and Wilson 1963; Elkinton and Cardé 1984; Elkinton et al. 1984; Byers 1987). Elkinton and Cardé (1984) reviewed reports that suggested that the plume's active space is affected by wind speed, turbulence, temperature, topography, vegetation, and time scale. Thus, under field conditions, the active space might be at least as chaotic as suggested in Fig. 1a.

Another concept connected to the active space is the capture probability (CP). There is likely a specific CP at any position in the active space that depends on the semiochemical concentration and orientation ability of the insect species (McClendon et al. 1976; Wall and Perry 1987; Branco et al. 2006). It is well known from theoretical and experimental studies above and others that concentrations of odor decline with distance from the source. In addition, it is known that at lower release rates, insects are less attracted. This is probably due to a combination of individual variation in response threshold, less receptor firing frequency, and lower plume filament flux frequency at these low concentrations (Baker et al. 1998). Therefore, we expect that insects that enter the active space of a plume at a position far from the source would have a lower probability of finding the source than an insect that enters much nearer the source. For example, McClendon et al. (1976) presented a capture probability response surface based on catch of marked boll weevils, *Anthonomus grandis* Boheman, released at various distances from a synthetic pheromone source. The probabilities ranged from 5% at about 150 m from the source to about 45% near the source. Branco et al. (2006) proposed a declining logistic function to predict capture probability with distance for scale insects that respond to sex pheromone.

The CP does not depend solely on pheromone concentration since even if the concentration is the same at two points downwind, one further than the other from the source, the insect entering farther from the source will likely have a lower CP due to more time needed to fly to the source and more possibilities of becoming disoriented. Thus, the CP depends on where the insect enters the active space (Fig. 1b). If the semiochemical release rate is increased, it is apparent that the active space increases in area as well as the varied CP values, all of which would be impractical to measure. The semiochemical release rate can be increased to a point that adaptation or confusion occurs with little catch (Bartell and Roelofs 1973; Baker and Roelofs 1981; Kuenen and Baker 1981; Baker et al. 1989; Rumbo and Vickers 1997; Judd et al. 2005). In this case, the active space should move a distance downwind from

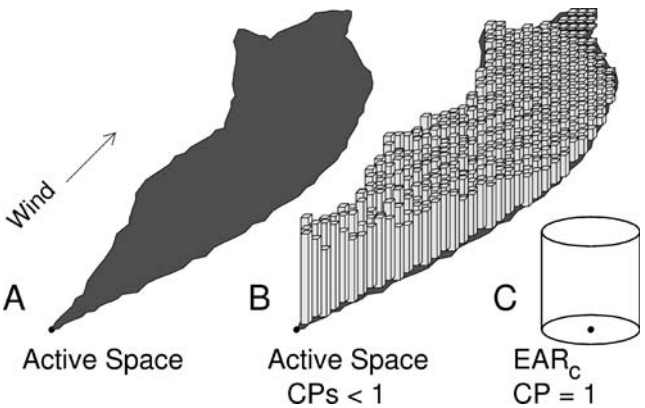

Fig. 1 **a** Representation of a pheromone plume as an active space in which semiochemical concentration is above a behavioral threshold eliciting orientation; **b** the same plume represented with CP<1 indicating the probability of an insect reaching the pheromone source upon initial observation at a particular position; **c** the capture finding probability surface compressed into an effective attraction radius with the same effect on catch by reducing the diameter but maximizing the CP at a probability of 1

the source, although it may be of similar size, while CP values would be drastically reduced.

The *effective attraction radius* (EAR) was proposed by Byers et al. (1989) as the radius of a passive sphere that would intercept the same number of insects as does a specific attractive trap baited with semiochemicals. A similar concept used in models of mate finding, mass trapping, and host-tree finding (Byers 1991, 1993a, b, 1996a, 1999) is here termed the EAR_c (c for circle) to distinguish it from the spherical EAR. As discussed below, the EAR_c concept is more useful in developing practical control with mating disruption and mass trapping than the better-known active space concept. The two ideas are related. In the EAR_c used in models, the CP response volume within the active space is compressed into a cylindrical volume with CP equal to 1 so that insects entering will find the source and be trapped (Fig. 1c). The cylinder can be further compressed to two dimensions so that the EAR_c is a circular area. The time-averaged active space and its various CPs are extremely difficult to determine in nature but are hypothesized to attract an equivalent number of insects under the same population conditions as would a corresponding EAR_c. Fortunately, the spherical EAR is easily determined by a time-averaged catch ratio of active and unbaited traps in the field as well as the interception area of the unbaited trap. Once this EAR is established, it is advantageous to transform it to an EAR_c for use in encounter rate models of mass trapping and mating disruption (Byers 1993a, b, 1999; El-Sayed et al. 2006; Byers 2007, and unpublished). Of particular importance is that measurement of the EAR at different population densities should give the same value because it is derived from a ratio of active and passive catches (Byers et al. 1989).

No algorithms have been developed to transform the spherical EAR to a circular EAR_c. In addition, the assumption that the EAR_c can simulate encounter rates (catches) that are equivalent to that for plumes with more complex CP-active space has not been investigated. In contrast to molecular diffusion that is random, animals disperse in a correlated random walk (CRW) of forward direction because the direction of each step is correlated to some degree with their previous step direction (Turchin 1998; Byers 2001). My objective was to design graphical simulations of insects that move in a CRW while sometimes entering elongated active space plumes that have an inverse linear CP relationship with distance in order to calculate catch at various constant insect densities and flight speeds. This was to demonstrate merely that changes in CP and/or active space dimensions in this model would result in corresponding changes in catch. Then, for a particular catch obtained in the CP-active space model, I wanted to vary the EAR_c circle of CP=1 to iteratively solve for the same catch. This would demonstrate there is an EAR_c that is equivalent to any complex interaction of active space and varying CP, of which the CP-active space is virtually impossible to obtain experimentally. In this case, the EAR_c would provide a simple but effective alternative to a model that uses the active space and its spatially complex probabilities of attraction. The goal is then to determine the EAR in the field and convert it to an EAR_c for use in models of mating disruption and mass trapping in order to develop cost-effective control programs with these methods (Miller et al. 2006a, b; El-Sayed et al. 2006; Byers 2007).

Methods and Materials

Simulation of Insect Catch with Capture Probabilities in the Active Space of Plumes Insects were simulated in a two-dimensional area with *x*-axis (xa) and *y*-axis (ya) that can be adjusted but was held at 1,000×1,000 m in which a pheromone source was placed at (xa/2, ya/2) and an active space plume extended as an angular sector of 15° with a radial length of 100 m (Byers 1996b). Insects were simulated at a constant density in the area outside of the plume (usually $0.001/m^2$ or 997 insects for the plume above). Any insect that left the simulation area was replaced by another that was taking a half step from the perimeter at random into the area. Also, any insects that reached the source (i.e., caught) were counted and replaced outside the active space at random. Insects flew in the area according to a CRW and entered active space plumes as in earlier models (Byers 1996a, b, 1999, 2001). Each insect was given an initial direction and position outside the active space at random. Thereafter, each male followed a CRW made of a series of steps with a distance covered per second (speed), each step calculated as a polar vector from the former position. The vector length was the average distance traveled per second (usually 1 m/s speed), and the direction was the former direction plus a turning angle chosen at random from a normal distribution, usually an SD° (angular standard deviation) of 5° centered on the former direction (Byers 2001).

Insects that entered the plume active space of length L were assumed to reach the source with a probability that depended on their initial entry distance, d, from the source. Thus, to obtain CP as a function of distance from the source, a linear function beginning with P=0.05 at L= 100 m and rising to a CP=1 at the source was used:

$$\mathrm{CP} = \frac{L - d + P \cdot d}{L} \tag{1}$$

However, other values of L, $d \le L$, and $0 \le P \le 1$ can be used. This equation generally accounts for the expectation, based on general knowledge of dosage–response relationships and mark–recapture studies (e.g., Zolubas and Byers

1995), that catch is higher when entering the active space nearer the source than when entering farther downwind. However, the exact nature of the relationship is known poorly due to little information about variation in odor concentration, behavioral responses, and orientation time while approaching the source. In the model, an insect reaches the source (is caught) if a random number (0 to 1) is ≤CP at the point where the insect enters the active space (Eq. 1). If not caught, then the insect moves in the opposite direction away from the plume so only one test is made at that point in time. This algorithm merely approximates the effect of the plume CPs because only the edges of the plume are encountered.

The model was programmed in QuickBASIC 4.5 (Microsoft, Redmond, WA, USA) for use in simulations as well as Java 1.4.2_10 or later (Sun Microsystems, Santa Clara, CA, USA) for general demonstration on the Internet with a web browser and Java runtime installed (http://www.chemical-ecology.net/java2/act-ear.htm).

Simulation of Equivalent Insect Catch by the Effective Attraction Radius The same model parameters and algorithms as above were used except there was no plume but rather a circle representing the EAR_c placed at (xa/2, ya/2). Insects that entered the EAR_c were captured with a probability of 1. Since insects could be allowed steps that jump over the circular EAR_c, the algorithm for encountering the circle was that shown in Byers (1991, his Fig. 3). The goal was to find an EAR_c in simulations with a catch that was approximately the same as for the assumed active space and CP relationship with the same CRW model parameters. This goal was facilitated by the functional response type I equation of Holling (1959). His equation defines the number of prey found (y) by a predator as:

$$y = a \cdot T_s \cdot x \tag{2}$$

where T_s is the total foraging time, x is the prey density, and a is the instantaneous attack rate. The attack rate is equal to the area covered by the predator each time unit and is, thus, the size of the predator or prey ($2\times EAR_c$) times the speed of prey or predator (depending on which is moving). This equation assumes one trap (i.e., predator) does not appreciably deplete insect densities and that predators/prey do not revisit previous areas.

In regard to an EAR_c of a pheromone plume (or trap), substitution of the relevant variables into Eq. 2 and solution for the radius (EAR_c) gives the equation:

$$EAR_c = \frac{C \cdot xa \cdot ya}{T \cdot S \cdot 2 \cdot N} \tag{3}$$

where T is the test duration (same as T_s above), S is the insect speed, C is the number caught, and N is the number of insects in the area (xa·ya) or prey density (x). In the simulations, N is known but would not be measured easily in nature. Thus, the catch obtained in the CP-active space model (mean of ten simulations) was used in Eq. 3 to predict an equivalent EAR_c. Simulations were then performed to bracket the predicted EAR_c by incrementing in 3-m steps the simulated EAR_c from 1 to twice the predicted (each increment had ten simulations). Linear regression was used to solve for the EAR_c that caught the equivalent catch as that in the CP-active space response area.

To gain insight about effects of various model parameters used in both the CP-active space and EAR_c in models, simulation results were compared to predicted results of Eq. 3. Both EAR_c (1, 2, 5, 10, and 20 m) and number of insects (100, 200, 500, 1,000, and 2,000) were varied in simulations of ten replicates each for all combinations of these parameters. The standard deviation of turning angle distribution (SD°) was varied similarly (0, 2, 5, 10, 15, 20, 25, and 30°) in simulations to test for effects on catch.

Relationship Between EAR of Sphere and EAR_c of Circle Used in Models The original EAR (Byers et al. 1989) was the radius of a sphere as calculated by the equation:

$$EAR = \sqrt{\frac{A_c \cdot 2 \cdot r \cdot h}{P_c \cdot \pi}} \tag{4}$$

where A_c is the catch on the active trap (semiochemical), P_c is the catch on the passive (unbaited) trap, and r is the radius and h is the height of the passive trap cylinder. For hanging flat panel traps of width × height, $2{\cdot}r{\cdot}h$ in Eq. 4 can be substituted with ($0.637{\cdot}width{\cdot}height$) for the average interceptive trap area, TA (Byers et al. 1989). In simulation models, the EAR is better described in a new way:

$$EAR_c = \frac{A_c \cdot TA/2}{P_c \cdot F_L} \tag{5}$$

where F_L is the thickness of the air layer in which insects search primarily while flying. Regressions were done by enlarging r from 0.1 to 2 m with various h, A_c, and P_c in F_L from 1 to 10 m thickness in order to determine the relationships between Eqs. 4 and 5. The goal was to try and convert EAR of Eq. 4, measured conveniently with two trap catches, to corresponding EAR_c of Eq. 5, which is most useful in simulation models.

The scientific literature was searched (BIOSIS Previews) for articles on flight heights of insects caught by traps to estimate the effective flight layer of search, F_L, as well as catches on attractant and passive sticky traps to estimate EAR from Eq. 4 or EAR_c from Eq. 5. The F_L was estimated from published catches at various heights by calculating the mean height of catch and standard deviation (SD) by using standard statistical formulas (McCall 1970). In some

reports, actual catch was not given but rather the total catch proportion at each trapping height. It was assumed that at least 100 insects were caught among all trap heights. Effects of this assumption were tested on simulated data of either 20, 100, or 2,000 catches at five trap levels (1, 2, 3, 4, and 5) assuming catch proportions of 0.1, 0.3, 0.3, 0.2, 0.1, respectively. The F_L was then calculated from $SD \cdot \sqrt{2 \cdot \pi}$. This gives a probability area equal to the height of the normal distribution ($1/(SD \cdot \sqrt{2 \cdot \pi})$; McCall 1970) times the layer's thickness that would equal the area under the normal curve (Byers, unpublished).

Results

Simulation of Insect Catch with Capture Probabilities in the Active Space of Plumes The simulation of the 15°-sector× 100-m long CP-active space response plume in the square kilometer arena caught an average of 121.4±6.9 (±95% confidence limits (C.L.) N=10) insects when a constant density of 1,000 in the area each took 3,600 steps of 1 m each and turned with an SD° of 5°. By assuming the same simulation conditions and using Eq. 3, an equivalent number of insects should be caught by a predicted EAR_c of 16.86 m. An increase of the plume length (X) from 50 to 200 m increased the catch (Y) as expected as a linear function (Y= 5.5+1.145X, R^2=1.0, N=7). Other CP-response surfaces in the active space altered the simulated catch depending on the values. For example, assuming an exponential decline in probability with distance from the source (Mason et al. 1990; Zolubas and Byers 1995), CP = $P/\exp(d)^{5/L}$ with P=1, gave a mean catch of 43.6±6.08 with the parameters above. This predicts an EAR_c of 6.06 m by using Eq. 3. Simulations also showed that the CRW parameter of the SD° of angular turns affected catch, as is presented below.

Simulation of Equivalent Insect Catch by the Effective Attraction Radius An increase in the number of insects in the arena (density) caused a linear increase in catch (Table 1) in accordance with that predicted from solving catch (C) in Eq. 3. Also, an increase in the EAR_c caused a linear increase in catch (Table 1) that was close to that predicted. Other simulations in which the SD° of turning angles was increased from straight at 0° to sinusoidal at 30° gave results that were surprising (Table 2). At an SD° of 0°, the catch was 60.3±5.9, which was less than 72 predicted from Eq. 3, while as the SD° was increased to 5°, the catch increased to 71.3±6.4 and was indistinguishable from predicted. Further increases in SD° to 10° (65.7±4.1), 15° (56±4.8), 20° (42.2±4.2), 25° (33.5±2.6), and 30° (27.9± 4.4) caused the catch to decline well below predicted. The general reasons for this will be discussed below.

The EAR_c was increased incrementally in simulations from 1 m to about twice the predicted EAR_c in order to find the catch that was equivalent to the catch by the CP-active space model. The results fit a linear function, Y=7.209X+ 0.26 (R^2=1.0, N=11, Fig. 2). By using a catch of 121.4 for Y above in the CP-active space plume, an equivalent EAR_c is found by solving for X=(Y−0.26)/7.209=16.80 m, which is close to 16.86 m predicted from Eq. 3. Another random seed gave an equivalent EAR_c of 16.85 m. This shows in principle that any CP-active space response surface can be transformed into an equivalent EAR_c. While the CP-active space response surface is exceedingly difficult to measure, the EAR can be found experimentally in the field (see below).

Relationship between EAR of Sphere and EAR_c of Circle Used in Models There is a positive linear relationship between radius of the passive trap and the EAR of the sphere, while the EAR_c increases as a function of the square of the trap radius (Fig. 3). The exact relationships depend on the ratio of catch (active/passive), the interception area of the passive trap, and in the case of the EAR_c, the effective flight layer thickness. When the EAR_c (Y) is plotted against EAR (X), the EAR_c increases as the square of the EAR (Y=aX^2, Fig. 4). This relationship does not depend on the catch ratio or the dimensions of the passive trap; however, the proportion of the passive trap height that intercepts the flight layer (F_L) does influence the power curves. For example, if the F_L=10 m then Y=0.157X^2,

Table 1 Effect of EAR_c and number of insects on catch when each insect moved 3,600 steps of 1 m (1 m/s) with an SD° of turning angles of 5° in an area of 1,000×1,000 m (catches are means±95 C.L. of ten simulations)

while if F_L=3 m, then $Y=0.524X^2$. Plotting of the regression coefficient a above against F_L gives an inverse power relationship $a=1.571/F_L$. This a used in $Y=aX^2$ above can be used with an effective flight layer thickness to convert any spherical EAR to the corresponding model EAR_c with the equation:

$$EAR_c = \frac{1.571 \cdot EAR^2}{F_L} \quad (6)$$

It turns out that 1.571 is $\pi/2$.

Over 100 articles were found on insect flight heights of which some were suitable to estimate the flight layer of search, F_L (Table 3). Most insects, while searching for mates and/or food, fly within a few meters above the ground (Table 3). Insects that are of agricultural importance fly within an even thinner layer just above the canopy. In some studies, only proportions of catch at each trap height were reported, so N=100 or 1,000 insects were assumed when calculating mean height of catch and SD. However, there was little possible error from this assumption since calculation with 20, 100, or 2,000 catch on specific proportions (see "Methods and Materials") gave the same mean height of catch (2.9 m), while the SD also was similar at 1.165, 1.142, or 1.136, respectively.

A few studies were found on catches of attractant and passive sticky traps of various insects and used to calculate EAR from Eq. 4, which was then used with an estimated F_L to determine an EAR_c by Eq. 6 (Table 4). The EAR_c is directly proportional to the ratio of catch, so the radius of its circle catches in direct proportion to its size in simulations as expected.

Discussion

The active space concept is readily understood as the plume area where male moths detect female moth pheromone (Sower et al. 1971; Nakamura and Kawasaki 1977; Baker and Roelofs 1981; Elkinton and Cardé 1984). It is time-

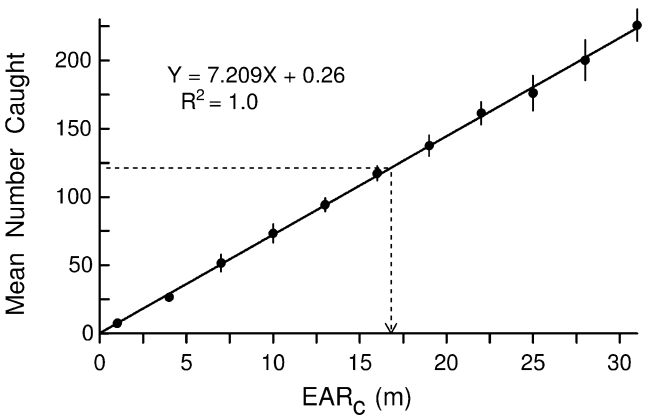

Fig. 2 Mean number of insects caught in an area of 1,000×1,000 m with a constant density of 1,000 insects, each taking 3,600 steps of 1 m with a 5° SD of turning angle distribution as a function of EAR_c in meters (*bars* represent 95% C.L., ten simulations each point)

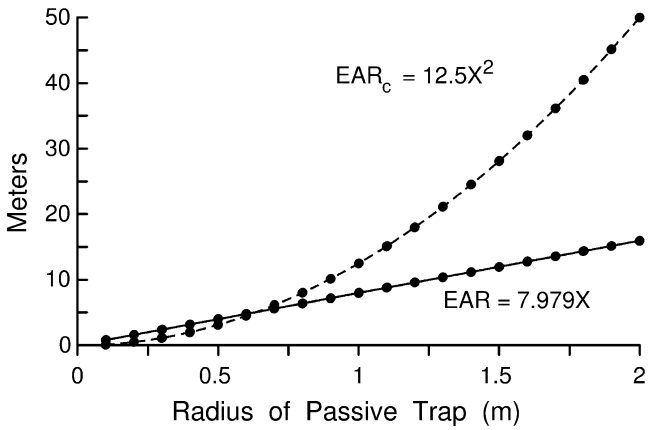

Fig. 3 EAR from Eq. 4 and EAR_c from Eq. 5 as a function of the passive cylinder trap radius when the pheromone trap caught 50 times more than the passive trap (height of passive trap was twice the radius and F_L=8 m)

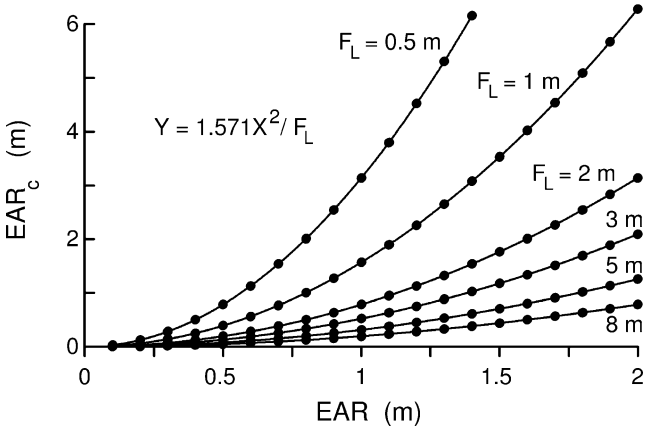

Fig. 4 EAR$_c$ as a function of EAR in various flight layers

consuming and tedious to measure the general dimensions of the active space for a particular pheromone release rate and moth species by observing male wing-fanning in cages at many distances downwind from the source (Elkinton and Cardé 1984; Elkinton et al. 1984). Knowledge of the active space would be useful in mass-trapping programs if moths entering the space have a constant probability of being caught by a trap. Unfortunately, a constant probability is unlikely and not consistent with our knowledge of moth orientation behavior in wind tunnels or in the field. It is likely that males entering the active space far from the pheromone source have lower CP than males entering the active space nearer the source (McClendon et al. 1976; Branco et al. 2006). However, the difficulties of determining the many CPs in the active space are enormous, and as such, no studies have attempted precise measurements. Still, knowledge of the CP-active space dimensions could be useful in modeling of mate- and host-finding as well as mating disruption and mass trapping with synthetic pheromone dispensers (Byers 2007).

The simulations demonstrated that males encountering CP-active space plumes of a specific dimension reach the pheromone source at a rate that depends on the model parameters chosen. The equivalent attraction rate of a CP-active space plume of any arbitrary complexity was obtained by adjusting the circular EAR$_c$ in size until this caught an equivalent number during the same period. In modeling insect encounters with semiochemical lures, the use of highly complex CP-active space plumes is less desirable than the simple-to-measure-and-use EAR$_c$.

The EAR, as used originally (Byers et al. 1989) in Eq. 4, is calculated from the passive trap interception area as seen from any particular direction multiplied by the ratio of catch on the pheromone trap (A_c) and passive trap (P_c). This interception area is solved for a circular area of radius EAR (also the radius of a sphere of this size). The EAR (or EAR$_c$) is useful to compare the relative strengths of semiochemical attractants of various blends and release rates among insect species and studies. Catches alone are not sufficient for such comparisons because catch depends on trap dimensions as well as on population density, both of which vary between locations and times. In contrast to simple catch comparisons, the EAR is not affected significantly by flight density variations, as Eq. 4 uses a ratio of attractive to passive catches that, in principle, would not vary with flight density. It is relatively simple to obtain an average catch on passive sticky traps as well as one on attractive pheromone traps. The size of the passive trap then determines the EAR as long as there is some catch on both trap types (division by zero is undefined).

An insect species with a larger EAR than a second species generally means that individuals of the first species are attracted from a longer distance, assuming the CP gradients in the two active spaces are about the same. However, if the CP-active spaces are different, it is possible that the second species could, on average, be attracted from further away. Because we have little or no knowledge of the CP-active space, it is assumed that the larger the EAR, the longer the average distance of attraction. In the simulations, insects did not reach the inner areas of the plume, so the response surface actually applied only on the periphery, while in nature, CP could be observed anywhere in the plume. If simulated insects were allowed to continue into the plume, they would have a new chance of being caught according to the CP at each step, which would incorrectly cause nearly all to be caught. The EAR with CP=1 does not exist in nature, as does a plume, but merely acts as a convenient method of comparison of attractive bait strengths or as a convenient substitute for plumes (as EAR$_c$) in encounter rate models. The attractive trap must catch more than the passive trap, the passive trap should catch some insects, and higher catches on many passive traps will improve the accuracy of the EAR measurement. The attractive trap should be placed far enough from the passive trap as to hardly influence the latter's catch, but both kinds of traps should be within the same area of flight density. The EAR is usually up to only a few meters and, thus, considerably smaller than the attraction range (maximum orientation distance), the sampling range (maximum distance over which an insect can reach a trap in a given time; Wall and Perry 1987), or the average distance of attraction. A related concept is the effective sampling area (trap catch divided by the population density; Turchin and Odendaal 1996), which, for European pine sawflies *Neodiprion sertifer* Geoffroy, released away from a pheromone trap, was estimated to have a radius of 125 m (Östrand and Anderbrant 2003), much larger than any expected EAR.

The EAR calculation is convenient to measure in the field with sticky traps that sample a small portion of the flight layer (usually within meters of the ground for most agricultural insects). The trouble in modeling with the EAR as measured

in the field is that its radius is a sphere and extends vertically and horizontally in three dimensions and often would not fill the flight layer or could theoretically protrude above the flight layer. Byers (2007) used a circular EAR in simulation models of mating disruption and mass trapping and implied that field-measured EAR could be used to predict catch rates. However, in the present work, I found that the spherical EAR must be transformed into the circular EAR_c for appropriate prediction due to the effect of the effective flight layer, F_L, which varies among species. It is simpler to model insect search in two dimensions because they fly over wide areas in essentially a two-dimensional layer of a few meters thickness. However, if the passive trap is a tall cylinder that extends vertically through the flight layer, then the EAR_c of Eq. 5 can be measured in nature. In this case, the interception is proportional to the radius of the cylinder in simulations with CP=1 (Fig. 1c) or as a circle of EAR_c.

Byers et al. (1989) measured EAR_c in the field with several 12-m columns of sticky cylinder traps baited or not with attractants for insects. In this study, the flight layer was sampled throughout by the sticky traps whose catch was multiplied by 4 to account for gaps in coverage. Therefore, the EAR_c of the aggregation pheromone baits of the bark beetle *Ips typographus* (L.) is simply the ratio of catches times the passive trap radius (0.7 m, Table 4). These ten baits were released at one point in another study (Schlyter et al. 1987) that gave an EAR of 1.9 m, which, assuming an F_L of 8 m, gives an identical EAR_c of 0.7 m (Eq. 6). Other F_L estimates would alter the calculated EAR_c. For example, the estimate of F_L for *I. typographus* from flight height data (Table 3) was 6.9 m, giving an EAR_c of 0.82 m. Equation 6 can be used to convert the EAR to EAR_c if a flight layer is estimated from observations or trap catches at various heights. By using data from Byers et al. (1989) for two species of bark beetle caught on baits of host tree monoterpenes or aggregation pheromone components, the two types of EAR calculations are compared (Table 4). In these cases, the EAR_c was smaller than the spherical EAR because of the size of the

Table 4 EAR and EAR_c of monoterpene or aggregation pheromone component release rates attractive to bark beetles, *Tomicus piniperda* and *Ips typographus*, respectively, based on passive and active catches on cylindrical sticky trap screens and effective flight layer estimate (from Table 3)

EAR and estimated F_L. However, the EAR_c can be larger than the EAR (Fig. 4), where both the F_L and the size of the EAR as a function of EAR^2 affect the EAR_c.

The SD° of turning angles usually does not affect encounter rates of insects with mates, host plants, or pheromone traps because the distances of insect search are far greater than distances to these objects at natural densities (Byers 1991, 2007). However, the SD° does influence the encounter rate of insects that must travel relatively far in proportion to their allotted search distance to encounter an object at low density (Table 2). Surprisingly, a straight path (SD°=0°) caused insects to less often encounter an object than slightly more sinuous tracks (SD°=5°), while highly sinuous tracks (e.g., SD°=30°) caused significantly fewer encounters. Short travel distances did not cause many encounters when insects began anywhere at random. This was because many insects could simply not reach the single object no matter how they traveled, as their search distance was less than their initial distance from the object. At larger search distances, insects could intercept the object by going straight but would have only one chance that was proportional to the object's diameter and initial distance because usually the insect could not return once it "missed" the object (only if meeting area's boundary). However, with a slightly more sinuous path, the insect had the same probability of intercepting the object, but there was an additional small probability that it could miss and then return to find the object due to the ability to turn (SD°>0°). At still higher SD°, many turns would tend to prevent many insects placed relatively far from the object from reaching the object, even though a few placed nearer the object could turn back and have one or more chances of interception. This means that predators and parasitoids that land on a leaf and search for insect hosts would benefit if they evolved a small but sufficient SD° of about 5° to cause more frequent host encounters than if they used a straight path or a highly sinuous path.

Estimation of the mean flight height and SD is done easily from either proportions or numbers caught on trap heights, although rarely are they calculated. Appropriate calculation of the SD assumes that the distribution is approximately normal and that catch does not continue to increase with height. The number of trap levels increases the accuracy and confidence of the calculated values. The type of traps used to monitor flight height should not matter as long as they are the same and catch a correct proportion of flying insects at the respective heights. However, many previous studies (Table 3) have not used passive traps but rather attractive traps (yellow color, ultraviolet lights, and sex/aggregation pheromone) that might alter the natural flight patterns. For example, Byers et al. (1989) found that sticky traps baited with aggregation pheromone or host plant monoterpenes altered the pattern of catch with height for two

species of bark beetle compared to passive sticky traps. The mean flight height for *I. typographus* on passive traps was 4.63±2.75 (±SD) and F_L=6.89, while for the pine shoot beetle, *Tomicus piniperda* (L.), mean height was 5.98±3.00 and F_L=7.52. However, when aggregation pheromone was released at each height, *I. typographus* had a mean flight height of only 1.50±1.63 and F_L=4.08 (N=740), while *T. piniperda* attraction to host tree monoterpenes altered its mean flight height to 2.90±2.77 and F_L=6.95 (N=48). An estimation of the EAR from published results is usually not possible because (a) few studies have used unattractive sticky traps to intercept flying insects in comparison with attractive traps, or (b) the blank traps did not catch insects. For example, most moth pheromone studies (Pherobase: El-Sayed 2007) have used traps where moths must enter to be caught (e.g., Delta traps), and so few were caught on blank traps (causing the EAR to be undefined).

The EAR_c can be used to predict mating disruption and mass trapping with competitive attraction and camouflage by modeling male moth search, female calling, moth and dispenser densities, and EAR_c of females and dispensers (Byers 2007, unpublished). However, many of these parameters are difficult to quantify in nature, such as moth density and male search distance. Other parameters, although usually not measured, can be estimated more easily such as EAR of females and dispensers by using catch ratios on sticky traps and converting to EAR_c with F_L estimated from sticky trap catches at fixed heights. The estimated EAR_c of 0.82 m discussed above for a standard *I. typographus* trap can be used in the model of Byers (2007) with no competition (female EAR=0) to determine the catch of these bark beetles. For example, if five of these traps are placed in a 200×200 m Norway spruce forest with 360 beetles (Byers et al. 1989) flying at 2 m/s for up to 6 km, then 99% are expected to be caught. This assumes there are no pheromone sources of competitive attraction such as might occur shortly after flight initiation in the spring. Models can predict mass trapping and mating disruption outcomes correctly only when the relevant parameters are known with good precision. Otherwise, models are still useful to gain better understanding of the effects of the parameters on decisions regarding control and the likely efficacy of deploying pheromone dispensers of various numbers and EAR_c.

Acknowledgments In addition to the editors, I thank Ashraf El-Sayed, Steve Naranjo, and two anonymous reviewers for their reviews of the manuscript.

In a recent study, we found that juvenile aphids reared in social isolation on artificial diet release less EβF than those reared in a colony or in isolation but exposed to colony odors (Verheggen et al., unpublished). We suggested that aphid volatiles may stimulate other aphids to produce EβF. In this study, we tested this by stimulating release of EβF from aphids and measuring whether additional EβF is released by individuals that perceive these volatiles. Such a contagious phenomenon could be adaptive if there are benefits to disseminating the alarm farther than would be achieved by the release of EβF by an individual.

Methods and Materials

Insects and Plants Pea aphids were reared on broad beans, *Vicia faba*, in an environmentally controlled greenhouse (L16:D8, RH 35±5%, 25±2°C) for several months prior to the experiments. Plants were grown in 9×9 cm plastic pots, filled with a peat-based, general-purpose potting soil (Metro Mix 200 Series, SunGrow Agriculture Distribution Inc., Bellevue, WA, USA).

Push–pull Headspace Collection System The push–pull headspace collection system consisted of two cylindrical chambers (12 cm diam.×30 cm) made of glass and Teflon®. Chambers were connected to one another with Teflon® tubing. To maintain ambient humidity and normal atmospheric pressure within the chambers, activated-carbon-filtered air was pumped into the system at the same rate that air was removed via air-entrainment filters, in a manner consistent with push–pull headspace collection setups described elsewhere (e.g., Tholl et al. 2006).

To generate natural EβF emissions, we crushed 50 third instar aphids inside the collection chambers with a glass pestle, which along with the aphids was left inside the chamber after crushing. To quantify EβF produced by the crushed (lead) and undisturbed (downstream) aphids, an adsorbent filter, containing 40 mg of SuperQ® (Alltech, Deerfield, IL, USA), was connected to each chamber. Clean air was pushed into the system at a rate of 1.5 L min^{-1} and sampled air was pulled through the filters from both the lead and downstream chambers at a rate of 0.75 L min^{-1} per chamber. Five experiments were conducted; each of 1 h with nine replicates (Table 1). The first experiment (crushed–empty) was a positive control designed to document the distribution of EβF, released upwind, in the two chambers. The second experiment (empty–infested) measured the amount of EβF released by a colony of 50 *A. pisum* under the laboratory conditions. The third (empty–non-infested) and fifth (crushed–non-infested) experiments were, respectively, controls devoted to the evaluation of the potential amount of EβF that could be released from an uninfested broad bean plant unexposed or exposed to EβF. The fourth experiment (crushed–infested) was conducted to show whether downstream aphids emit additional alarm signal when exposed to an alarm signal from upstream conspecifics.

Volatile Analysis Filters were eluted with 150 μl of dichloromethane and nonyl acetate (320 ng) was added to each sample as an internal standard. Extracts were analyzed by gas chromatography with flame ionization detection with a Hewlett–Packard 6890 series gas chromatograph equipped with a splitless injector (260°C). The column (Equity-1, Supelco, Bellefonte, PA, USA, 30 m×0.25 mm i.d.) was held at 40°C for 1 min before being heated to 260°C at 15°C min^{-1}. Quantification of compounds was carried out by comparing individual peak areas to that of the internal standard. Identification of EβF was made by comparison of its retention time with that of synthetic EβF (Bedoukian Research, Inc., Danbury, CT, USA) and confirmed by gas chromatography-mass spectrometry.

Table 1 Mean (*E*)-β-farnesene (EβF) emission amounts released by *Acyrthosiphon pisum* and detected in lead and downstream chambers, as well as average lead/downstream EβF ratios (±SE), in different experiments

Number	Lead chamber	Downstream chamber	Average EβF amounts (ng±SE)[d]		Average downstream/lead EβF ratios (±SE)[d]
			Lead chamber	Downstream chamber	
1	Crushed aphids[a]	Empty	1,295.74±261.43	1,130.25±148.87	1.056±0.190
2	Empty	Infested plant[b]	–	–	–
3	Empty	Non-infested plant[c]	–	–	–
4	Crushed aphids	Infested plant	1,585.06±288.37	957.69±153.83	0.769±0.094
5	Crushed aphids	Non-infested plant	1,384.22±275.00	1,048.26±133.65	0.859±0.113

[a] 50 crushed third Instar larvae *A. pisum*
[b] Single 20-cm-high *Vicia faba* infested with 50 third Instar *A. pisum*
[c] Single 20-cm-high non-infested *V. faba*
[d] Nine replicates were performed for each experiment

Results and Discussion

EβF was the only volatile released by *A. pisum* detected in our experiments, which is consistent with previous findings (Francis et al. 2005). In experiment one (crushed–empty), third instar *A. pisum* released an average (sum of upstream and downstream collections) of 48.5 ng of EβF per individual. The higher EβF levels observed in our study, compared to those found by Mondor et al. (2000) and Schwartzberg et al. (2008), may be explained by differences in eliciting EβF release (crushed vs. probed or natural attack). These EβF amounts are larger than what we might expect to see in a natural condition. However, within a colony, signaling and receiving aphids are much closer to each other than in our experiment and, therefore, the higher release rate in our experiment may compensate for this. Moreover, a higher release rate should be advantageous for testing our hypothesis.

The ratio of downstream aphid to lead aphid emission should be 1.0 if no additional EβF were produced from aphids in the downstream chamber. A ratio greater than 1.0 should, therefore, reflect emission of EβF from aphid/host plant complexes subjected to the alarm signal. No EβF was emitted from downstream plant and plant/aphid complexes in experiments with empty lead chambers (Table 1, experiment 2 [empty–infested] and 3 [empty–non-infested]). These data confirm that undisturbed aphids under the conditions of this experiment do not produce a detectable alarm signal. EβF was detected in experiments 1 (crushed–empty), 4 (crushed–infested), and 5 (crushed–non-infested). However, there was no difference in EβF ratios among these experiments (ANOVA, $F_{2,24}$=1.12, P=0.342). Although not significant, the small reduction in ratio in experiment 1 compared to experiments 4 and 5, may have been due to absorption of some EβF by the downstream plants used in the latter experiments. Interestingly, in experiment 4, the downstream aphids appeared to perceive EβF as 14% of these aphids dropped from their host plant.

These results indicate that the EβF alarm signal is not contagious. This conclusion is consistent with further observations that the amount of EβF released by a single aphid under attack is similar to the average amount of alarm pheromone released per consumed aphid in a colony (Schwartzberg et al., unpublished).

An understanding of how alarm pheromone is emitted in a natural setting may be important when studying the effects of alarm signaling among aphids, since a single alarm signal can influence aphid ecology through both inter- and intra-specific signaling. The way that such signals convey information in an aphid colony may be important for the effectiveness of a signaling alarm, as well as in reducing the costs of signal production in an environment in which signal eavesdropping by predators can add a fitness cost to signal production.

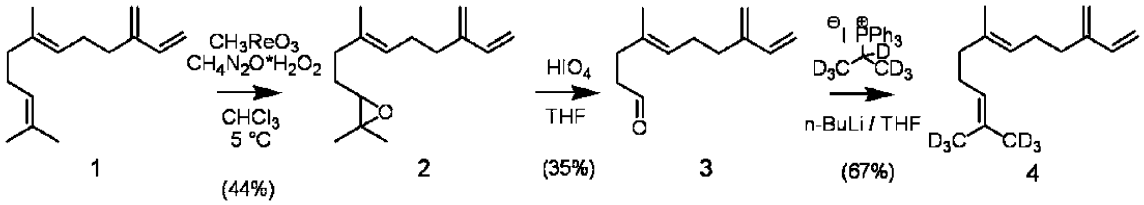

Fig. 1 Synthesis of [12,12,12,13,13,13]-$^2H_6$-(*E*)-β-farnesene

(DEBF), labeled on the geminal dimethyl group, to investigate signal reinforcement in the pea aphid.

Methods and Materials

Synthesis of Deuterated EBF Following Cravotto et al. (2004) (Fig. 1), epoxidation of (*E*)-β-farnesene (**1**) (408.70 mg, 2 mmol), employing methyltrioxorhenium (VII) and urea-hydrogen peroxide adduct in $CHCl_3$ at 5°C, gave a mixture of mono- and di-oxiranes. The 10,11-epoxy-(*E*)-β-farnesene (**2**) (180.3 mg, 44%, R_f 0.48) was separated on Florisil 100–200 (petroleum ether 40–60/ether 40:1 *v*/*v*). As specified by Fielder and Rowan (1994) (Fig. 1), the epoxide **2** was cleaved with periodic acid to give (*E*)-4-methyl-8-methylenedeca-4,9-dienal (**3**) (49.1 mg, 35%, R_f 0.27), which was purified on silica 60 (petroleum ether 40–60/ether 40:1 *v*/*v*). Wittig reaction of **3** with d_7-isopropyltriphenylphosphonium iodide produced the d_6-(*E*)-β-farnesene (**4**) ([12,12,12,13,13,13]-$^2H_6$-(*E*)-β-farnesene; DEBF) (221.60 µg, 67%, R_f 0.60). Purification of **4** was carried out by flash chromatography on silica gel (silica 60, Merck, Darmstadt, Germany) with pentane. The chemical purity of DEBF after chromatographic purification was 97% as determined by gas chromatography-mass spectrometry (GC-MS).

NMR Data of Deuterated EBF ^{1}H NMR (500 MHz, $CDCl_3$): δ (ppm)=1.53 (s, 3H), 1.89–1.94 (m, 2H), 1.97–2.03 (m, 2H), 2.08–2.19 (m, 4H), 4.92 (d, *J*=1.3 Hz, 1H), 4.94 (d, *J*=1.3 Hz, 1H), 4.98 (d, *J*=10.8 Hz, 1H), 5.03 (t, *J*=6.8 Hz, 1H), 5.09 (tq, *J*=6.8, 1.0 Hz, 1H), 5.17 (d, *J*=17.7 Hz, 1H), 6.31 (dd, *J*=17.7, 10.8 Hz, 1H).

Aphid Lines We used a red clone (BP) of the pea aphid, *A. pisum*, maintained on *Vicia faba* plants in controlled conditions at 20°C, 16L/8D photoperiod, and approximately 75% RH. For experiments, aphid lines descended from a single founder were established (Kunert et al. 2005).

Experiment 1: DEBF and Aphid Behavior Three groups of 15 apterous adults of the same line were transferred to three plants and covered with cellophane bags (18.8×39 cm, *N*=12 lines). A piece of filter paper, to which DEBF, EBF (both 1 µg in 3 µl hexane), or hexane (3 µl) was applied, was placed inside the bags. The solutions were applied three times per day over 5 d. After the first application of each solution, the number of pea aphids walking was counted for 5 min. At the end of the experiment, mothers were counted and removed, and nymphs left for four more days on plants. Nymphs were then frozen and scored as winged or apterous morphs.

Experiment 2: DEBF and EBF Release For volatile collection, two groups of 15 third/fourth instars, of the same line, were transferred to two plants (*N*=13 lines) and placed in glass chambers (modified 1-L beaker). Teflon plates were placed around the base of the plant, keeping the soil out of

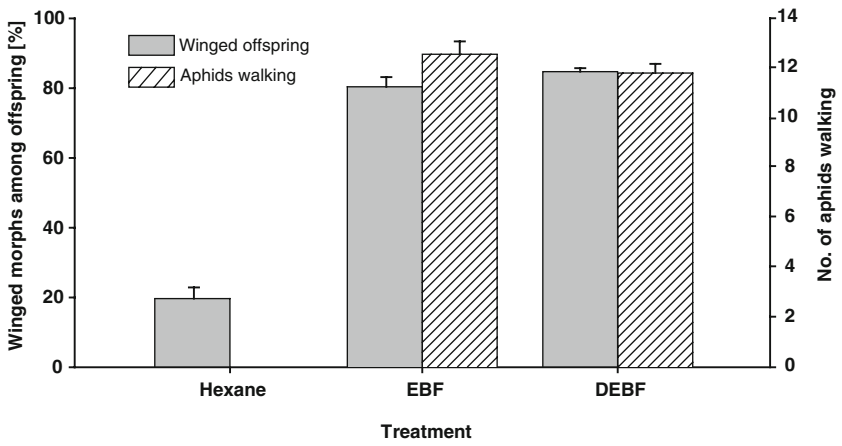

Fig. 2 Percentage of winged offspring produced by adult pea aphids and number of pea aphid mothers walking after exposure to hexane, (*E*)-β-farnesene (*EBF*) or deuterated (*E*)-β-farnesene (*DEBF*). The bars show the mean value±SE

the collection system. Two openings (Ø=1 cm) were present on top of the chamber: one provided air (2 L min^{-1}) filtered through active charcoal, and the other held a filter paper to which either DEBF (1 μg in 3 μl hexane) or hexane (3 μl) was applied. The chambers had an additional opening 3 cm from the rim holding a Super-Q filter (80/100 mesh; Alltech, Deerfield, IL, USA) connected to an air pump (1 L min^{-1}). With this set-up, six plants (three lines) could be tested simultaneously.

Volatile Analysis Super Q filters were eluted with 140 μl of dichloromethane and analyzed by GC-MS on a DB-5MS (J&W) column. For analysis, the column oven was kept at 60°C for 2 min., increased to 180°C at 5°C min^{-1}, and then increased at 60°C L min^{-1} until 300°C. Mass spectra from each peak were compared to those in the NIST and Wiley libraries for tentative peak identification. An internal standard of (*E*)-β-caryophyllene (400 ng in 30 μl of CH_2Cl_2) was added to all samples as an internal standard.

Statistical Analyses The number of aphids walking was analyzed by analysis of variance (ANOVA). Wing induction was analyzed by a generalized linear model (glm) with a quasi-binomial error structure. The aphid lines and number of nymphs produced in each replicate were included in the model, which was then simplified by removing non-significant variables or interactions, and accepted after an ANOVA ($P>0.05$; Crawley 2007). The survival of the mothers was analyzed with a glm using a Poisson error structure and simplified as described above. Data were analyzed with R software 2.6.0 (2007) and are presented as mean±SE.

Results and Discussion

In experiment 1, there was no significant difference among treatments in the mean number of adult pea aphids that survived (hexane=13.75±0.52; EBF=17.83±0.44; DEBF=13.58±0.47; $t=1.317$; $P=0.197$; $N=36$). In both EBF and DEBF treatments, the proportion of winged morphs among aphid offspring was higher than in the hexane treatment (Fig. 2; $t=15.075$; $P<0.001$, $N=36$). The number of aphids that responded to treatment by walking did not differ between EBF and DEBF (Fig. 2, $t=-1.542$, $P=0.152$, $N=36$); no walking responses were observed in the hexane treatment (Fig. 2, $t=27.211$, $P<0.001$, $N=36$).

In experiment 2, aphids started dispersing after DEBF application, but there was no measurable emission of endogenous alarm pheromone, suggesting that only attacked aphids emit EBF. Given the amounts of DEBF applied and re-collected, we estimated that the minimum amount of EBF detected by our experimental system was about 30 ng, an amount equivalent to that typically released by two to three third/fourth instars (Schwartzberg et al. 2008). Therefore, because we used colonies of 30 aphids, no more than 10% of the individuals tested, if any, could have responded by emitting their own EBF.

While signal amplification would have the advantage of alerting more aphids in the colony, it also has disadvantages. For example, it is thought that aphids may use the frequency of alarm pheromone perception as a measure of danger. Experiments with predators that induce alarm pheromone release and synthetic EBF, respectively, have shown that the proportion of winged offspring is related to the number of aphids consumed and the frequency of application of EBF (Kunert et al. 2005). Signal amplification would preclude aphids from employing the frequency of alarm pheromone release as a measure of the severity of an attack. Additionally, some natural enemies use EBF to detect their prey (Acar et al. 2001; Beale et al. 2006), and amplification of the signal would increase the danger of predator attraction.

Acknowledgments We are grateful to Ingrid Jakobi for rearing the aphids, Michael Reichelt for assisting with the GC-MS, Doreen Schachtschabel for helping with the synthesis of DEBF, Efthymia Kazantzidou for assisting with volatile collection, Emily Wheeler for valuable editorial comments, and the Max-Planck-Gesellschaft, International Max Planck Research School (IMPRS) for financial support.

SCHWARTZBERG, E. G., KUNERT, G., STEPHAN, C., DAVID, A., RÖSE, U. S. R., GERSHENZON, J., BOLAND, W., and WEISSER, W. W. 2008. Real-time analysis of alarm pheromone emission by the pea aphid (*Acyrthosiphon pisum*) under predation. *J. Chem. Ecol.* 34:76–81.

At a distance, aphids are able to use visual cues to recognize their hosts (David and Hardie 1988; Gish and Inbar 2006), with gustatory cues playing a role in acceptance or rejection of a plant after landing (Powell et al. 1999). Olfaction plays a prominent role in both the pre- and post-alighting stages of host selection and has been widely demonstrated in a variety of aphid species (Pickett et al. 1992; Powell and Hardie 2001). Aphids possess a sophisticated ability to recognize a wide variety of plant-volatile compounds by using olfactory receptor neurons housed in sensilla located on the antennae (Visser et al. 1996). Two types of olfactory sensilla exist, the primary and secondary rhinaria (Bromley et al. 1979, 1980). Distal and proximal primary rhinaria are found on the sixth and fifth antennal segments, respectively, and are used in the detection of plant volatiles (Hardie et al. 1994b; Park and Hardie 2002). As well as housing olfactory receptor neurons used to recognize host volatiles, the primary rhinaria also house olfactory receptor neurons used in the detection of non-host volatiles that may act as deterrents (Nottingham et al. 1991; Isaacs et al. 1993). Olfactory-mediated host location in aphids is thus a combination of host recognition and non-host avoidance.

An improved understanding of aphid olfaction could facilitate the development of novel crop protection strategies that rely on semiochemicals to reduce aphid populations in the field (Bruce et al. 2003, 2005a; Ninkovic et al. 2003). Semiochemicals used in host location could be used to help predict outbreaks by incorporation into traps used for monitoring populations. Semiochemicals can also be used within "push–pull" or stimulo-deterrent diversionary strategies (SDDS) (Miller and Cowles 1990; Cook et al. 2007). This involves protecting a main crop with repellents or masking compounds (the 'push' away from crops) and using a trap crop to lure insects away from the main crop (the 'pull'). Attractive semiochemicals could potentially be incorporated into the 'pull' element, and manipulation of the host odor to deter pest insects could constitute the 'push'.

There is already evidence that winged virginoparous *A. fabae* use olfaction to locate their summer host plant, *V. faba* (Nottingham et al. 1991; Pickett et al. 1992), but the volatile compounds used in host location have not yet been identified. The work carried out here sought to identify the semiochemicals released by *V. faba* that *A. fabae* uses to identify its host.

Methods and Materials

Insect Rearing The Kennedy and Booth clone of *Aphis fabae* (Kennedy and Booth 1950) was reared on tick beans (*Vicia faba* var. minor) in a Perspex rearing cabinet under controlled conditions (22±1°C, L:D, 16:8 hr). Winged aphids were induced by allowing the colony to become crowded. Prior to behavioral bioassays, aphids were starved for 24 hr.

Chemicals Authentic chemical standards used in electro-antennogram and laboratory behavioral studies were (*E*)-2-hexenal, benzaldehyde, 6-methyl-5-hepten-2-one, decanal, 1-hexanol (all 99% purity, Sigma Aldrich, St. Louis, MO, USA), (1*R*,5*S*)-myrtenal (98% purity, Sigma Aldrich), undecanal (97% purity, Sigma Aldrich), (*R*)-linalool and (*S*)-linalool (98% purity, Sigma Aldrich), octanal, methyl salicylate, (*Z*)-3-hexen-1-ol, and (*Z*)-3-hexen-1-yl acetate (all 98% purity, Avocado Research Chemicals, Lancs., UK), (*Z*)-3-hexen-1-yl acetate (99% purity, Avocado Research Chemicals), and (*E*)-caryophyllene (85% purity, Pfaltz & Bauer inc., Stamford, CT, USA). (*E*)-β-Farnesene (98% purity) was synthesized from (*E*)-farnesyl chloride (Kang et al. 1987). (*S*)-(−)-Germacrene D and (*R*)-(+)-germacrene D (both 98% purity) were obtained by incubation of farnesyl pyrophosphate with purified, expressed (R)-(+) or (S)-(−)-germacrene-D synthase and subsequent hexane extraction and purification through a short column of silica gel (BDH, 40–63 μm)/$MgSO_4$ (10:1) (Prosser et al. 2004). (*E*,*E*)-4,8,12-Trimethyl-1,3,7,11-tridecatetraene was synthesized from (*E*,*E*)-farnesol by oxidation to its aldehyde followed by Wittig methylenation (Leopold 1990).

Air Entrainment of Plants All equipment was washed with Teepol detergent (Herts County Supplies, Herts, UK), rinsed with acetone and distilled water, and baked overnight at 160°C. Porapak Q tubes were eluted with redistilled diethyl ether and heated at 132°C for 2 hr to remove contaminants. *Vicia faba* (var. Sutton dwarf) plants were grown individually in 7.5-cm pots in a glasshouse maintained at 20°C. Three-week-old plants at the vegetative growth stage were enclosed individually in glass vessels (190 mm high × 100 mm wide), open at the bottom and closed at the top except for an inlet and outlet port. The bottom was closed without pressure around the plant stem by using two semicircular aluminum plates with a hole in the center to accommodate the stem. Charcoal filtered air was pumped in at 400 ml min^{-1} and drawn out at 300 ml min^{-1} through a Porapak Q adsorbent tube (Alltech Associates, Lancashire, UK) in a 5-mm diam glass tube (Alltech Associates, Carnforth, Lancashire, UK; 50 mg Porapak Q in 5-mm diam glass tube). The difference in flow rates created a slight positive pressure to ensure that unfiltered air did not enter the system, thus removing the need for an airtight seal around the stem. All connections were made with PTFE tubing (Alltech Associates, Lancashire, UK) with brass ferules and fittings (North London Valve, London, UK) and sealed with PTFE tape (Gibbs & Dandy, Luton,

UK). Plants were entrained for 7 d, and the Porapak Q filter was eluted with 0.5 ml of redistilled diethyl ether, providing a solution that contained the isolated volatile compounds. Four plants were entrained. Gas chromatography (GC) analysis of each entrainment sample revealed similar GC traces, and these samples were combined to give a bulk air entrainment sample.

Gas Chromatography Analysis Volatiles were analyzed on a Hewlett-Packard 6890 GC equipped with a cold on-column injector, a flame ionization detector (FID), a non-polar HP-1 bonded-phase fused silica capillary column (50 m × 0.32 mm i.d., film thickness 0.52 μm) and a polar DB-WAX column (30 m × 0.32 mm i.d., film thickness 0.82 μm). The oven temperature was maintained at 30°C for 1 min, and programmed at 5°C min^{-1} to 150°C and held for 0.1 min, then 10°C min^{-1} to 230°C. The carrier gas was hydrogen. Stereochemistry of linalool and germacrene D was determined by using an HP5890 GC (Agilent Technologies, UK) equipped with a cool on-column injector and a FID, fitted with a *β*-cyclodextrin chiral capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness). The GC oven was maintained at 40°C for 1 min and then raised by 5°C min^{-1} to 150°C where it was held for 30 min. The carrier gas was hydrogen. A 1-μl aliquot solution that contained equal quantities of both enantiomers of the compounds in redistilled hexane was injected onto the chiral GC to establish that successful separation of enantiomers took place. This was followed by co-injections of the air entrainment sample, first with an authentic standard of one enantiomer and then with the second enantiomer. Peak enhancement with either enantiomer confirmed the presence of that enantiomer in the air entrainment sample.

Coupled Gas Chromatography–Electroantennography (GC-EAG) Electroantennogram (EAG) recordings were made with Ag-AgCl glass microelectrodes filled with Ringer solution (7.55 g l^{-1} sodium chloride, 0.64 g l^{-1} potassium chloride, 0.22 g l^{-1} calcium chloride, 1.73 g l^{-1} magnesium chloride, 0.86 g l^{-1} sodium bicarbonate, 0.61 g l^{-1} sodium orthophosphate). The head of an *A. fabae* winged virginopara was separated from the body with a scalpel, and the tips of the antennae were removed to ensure good contact with the electrode. The head was placed into the tip of the indifferent electrode, and the tips of the antennae were positioned in the end of the recording electrode. The coupled GC–EAG system, in which the effluent from the GC column was simultaneously directed to the antennal preparation and the GC detector, has been described previously (Wadhams 1990). Separation of the volatiles was achieved on a Hewlett-Packard 6890 gas chromatograph equipped with a cold on-column injector and a FID. The column used was 50 m × 0.32-mm i.d. HP-1. The oven temperature was maintained at 30°C for 2 min and then programmed at 5°C min^{-1} to 100°C and then at 10°C min^{-1} to 250°C. The carrier gas was hydrogen. Electroantennogram signals were passed through a high-impedance amplifier (UN-06; Syntech, the Netherlands), and simultaneous recordings of the EAG and FID responses were obtained with specialized software (EAD version 2.3; Syntech, the Netherlands). Six coupled runs were completed. Only FID peaks that corresponded to an EAG peak in three or more replicates were considered electrophysiologically active.

Coupled Gas Chromatography–Mass Spectrometry (GC-MS) Tentative identification of electrophysiologically active FID peaks was achieved by GC-MS. A 1-μl aliquot of the air entrainment sample was injected onto a capillary GC column (50 m × 0.32 mm i.d. HP1) directly coupled to a mass spectrometer (Thermo-Finnigan, MAT95, Bremen, Germany). Ionization was achieved by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min and then programmed at 5°C min^{-1} to 250°C. Tentative identifications of electrophysiologically active FID peaks were made by comparison of spectra with those of authentic samples in a database (NIST 2005). Tentative identifications by GC-MS were confirmed by co-injection of the air entrainment sample with authentic standards on both HP-1 and DB-WAX columns, with peak enhancement indicating co-elution. Quantification of identified compounds was achieved by injecting authentic standards at three known concentrations onto the HP 1 GC column and recording the peak area. Each standard was injected three times, and a calibration curve was plotted for each compound, and used to determine quantities of each compound in the air entrainment sample.

Electrophysiological Responses of Aphids to Identified Compounds Electrophysiological activity of identified compounds was confirmed by EAG. The stimulus delivery system, which employed a piece of filter paper in a disposable Pasteur pipette cartridge, has been described previously (Wadhams 1982). Authentic standards of each test compound were applied to a strip of filter paper at a dose of 10 μg in 10 μl redistilled hexane, and responses were compared to a solvent control. For compounds where there was no significant response to 10 μg, a dose of 100 μg in 10-μl redistilled hexane also was tested. The stimulus (2 sec duration) was delivered into a purified air stream (1 l min^{-1}) that flowed continuously through a glass tube (i.d. 8 mm) and over the preparation. Electrophysiological responses were recorded by using specialized software (EAD version 2.3; Syntech, the Netherlands). A standard stimulus of (1*R*,5*S*)-myrtenal, previously demonstrated to be electrophysiologically active for *A. fabae*

(Hardie et al. 1994a), was tested at the start and end of each replicate to ensure that insect preparations were functional throughout the experiment. The hexane control was tested at the start and end of each experiment, and an average was taken. Responses to test compounds were compared to the average of the two hexane control stimuli for each replicate. All comparisons were made by using a paired *t*-test (Genstat).

Olfactometer Bioassays A Perspex four-arm olfactometer (Pettersson 1970) was used to determine behavioral responses of *A. fabae* winged virginoparae to intact *V. faba* (var. Sutton dwarf) plants, an air entrainment sample of *V. faba* (var. Sutton dwarf) plants, and a synthetic volatile blend that comprised all identified electrophysiologically active compounds at the same concentrations and ratio as in the air entrainment sample. Prior to each experiment, all glassware was washed with Teepol detergent, rinsed with acetone and distilled water, and baked in an oven overnight at 160°C. Perspex components were washed with Teepol solution, rinsed with 80% ethanol solution and distilled water, and left to air dry. The olfactometer was fitted with a filter-paper base to provide traction for the walking insect, and was illuminated from above by diffuse uniform lighting from two 18W/35 white fluorescent light bulbs screened with greaseproof paper. It was surrounded by black paper to remove any external visual stimuli. For bioassays with plant material, a 2-l glass vessel that contained a single 3-wk-old plant was connected to the treatment inlet of the olfactometer by PTFE tubing. Three identical glass vessels that contained 110-mm filter paper saturated with distilled water were connected to the three control inlets. When the air entrainment sample and synthetic blend were used as test stimuli, the glass vessels were replaced with glass arms. Ten microliters of the air entrainment sample/synthetic blend were placed onto a piece of filter paper, 30 sec was allowed for the solvent to evaporate, and then it was placed in the treated arm. In these experiments, the three control arms contained a piece of filter paper with 10 μl of redistilled diethyl ether or redistilled hexane (for tests with the air entrainment sample and synthetic blend, respectively).

A single aphid was introduced through a hole in the top of the olfactometer with a fine paintbrush. Air was drawn through the central hole at a rate of 400 ml min^{-1} and subsequently exhausted from the room. Each aphid was given 2 min to acclimatize in the olfactometer after which the experiment was run for 16 min. The olfactometer was rotated 90 degrees every 2 min to control for any directional bias in the room. It was divided into four regions that correspond to each of the four glass vessels/arms, and time spent in each region was recorded with Olfa software (F. Nazzi, Udine, Italy). If an aphid remained motionless continuously for 2 min, it was considered inactive, and the replicate was repeated by using a new aphid (Pettersson 1970). Twelve replicates were carried out for each odor source tested. Time spent in the treated region was converted to a percentage of total time and transformed by using a logit transformation. The transformed data were normally distributed and compared to a test mean of −1.099 (logit transformation of 25%) by using a one-sample *t*-test (Genstat v. 10).

A choice test between 10 μl synthetic blend and 10 μl air entrainment sample was carried out. These two treatments were assigned randomly to different glass arms in each replicate. The other two arms contained filter paper with 10 μl solvent and were used as controls. Time spent in each region was recorded for 16 min. Twenty-four replicates were carried out. To determine if more time was spent in either of the treated regions, the difference between the time spent in each was calculated. The data were normally distributed and compared to a test mean of zero by using a one-sample *t*-test.

Results

Identification of Electrophysiologically Active Compounds in Air Entrainment Sample Coupled GC-EAG revealed 16 electrophysiologically active compounds in the air entrainment sample (Fig. 1). By using coupled GC-MS and GC peak enhancement on two GC columns of different polarity, 15 of these compounds were identified as (*Z*)-3-hexen-1-ol, 1-hexanol, (*E*)-2-hexenal, benzaldehyde, 6-methyl-5-hepten-2-one, octanal, (*Z*)-3-hexen-1-yl acetate, (*R*)-linalool, methyl salicylate, decanal, undecanal, (*E*)-caryophyllene, (*E*)-β-farnesene, (*S*)-(−)-germacrene D, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT). The quantities and ratio of all identified compounds are listed in Table 1. One compound, with a retention index of 1377 on an HP-1 column, could not be identified.

Electrophysiological Responses of Aphids to Identified Compounds All compounds elicited statistically significant electrophysiological responses when tested at 10 μg, with the exception of (Z)-3-hexen-1-ol, 6-methyl-5-hepten-2-one and benzaldehyde. These three compounds, however, did yield a statistically significant electrophysiological response when tested at 100 μg (Table 2).

Behavioral Responses to Plant Material, Air Entrainment Sample and Synthetic Blend In the olfactometer bioassays, the aphids spent significantly more time in the treated region of the olfactometer than the controls when a *V. faba* plant was used as an odor source ($P<0.001$), and also when a 10-μl aliquot of the *V. faba* air entrainment sample was

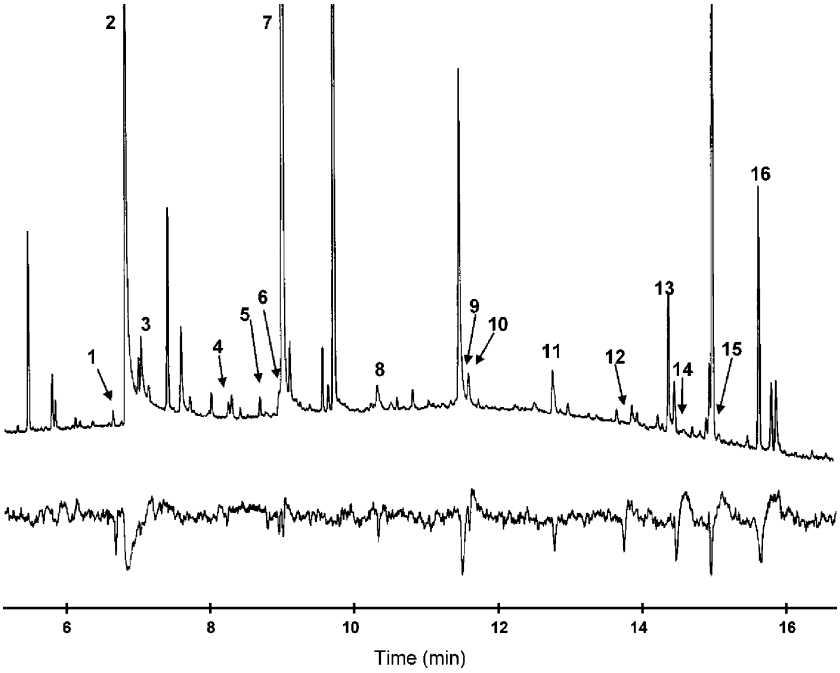

Fig. 1 Amalgamation of coupled GC-EAG traces showing electrophysiologically active peaks. 1 = (*E*)-2-hexenal, 2 = (*Z*)-3-hexen-1-ol, 3 = 1-hexanol, 4 = benzaldehyde, 5 = 6-methyl-5-hepten-2-one, 6 = octanal, 7 = (*Z*)-3-hexen-1-yl acetate, 8 = (*R*)-linalool, 9 = methyl salicylate, 10 = decanal, 11 = undecanal, 12 = unknown, 13 = (*E*)-caryophyllene, 14 = (*E*)-β-farnesene, 15 = (*S*)-(−)-germacrene D, 16 = (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

used (P=0.048). A similar response was observed when the 15-component synthetic blend was used as an odor source, with the aphids spending more time in the treated region of the olfactometer than the controls (P=0.018) (Fig. 2).

When the synthetic blend and air entrainment samples were tested in a choice test, the total time spent in the two olfactometer treatment arms was greater than the total time spent in the two control arms (P=0.012). The aphids did not show any preference for either of the two treatments (P=0.844) (Fig. 3), thus demonstrating that the synthetic blend had activity similar to the natural sample.

Discussion

Aphis fabae has been found previously to move toward the odor of its host plant, *V. faba* (var. Sutton dwarf), in olfactometer studies (Nottingham et al. 1991), but the volatile compounds responsible were not identified. In this study, a synthetic kairomone blend that comprised all identified volatile compounds in the headspace of *V. faba* (var. Sutton dwarf) plants that were electrophysiologically active at physiologically relevant levels to *A. fabae* was tested. This blend elicited a similar behavioral response to

Table 1 Names, quantities and ratio of compounds

Compound no.	Compound name	Quantity in 10 µl of *Vicia faba* air entrainment sample (ng)	Ratio
1	(*E*)-2-hexenal	0.36	9
2	1-hexanol	14.2	355
3	(*Z*)-3-hexen-1-ol	85.8	2145
4	benzaldehyde	0.04	1
5	6-methyl-5-hepten-2-one	0.58	14.5

11	undecanal	0.52	13
12	unknown	–	–
13	(*E*)-caryophyllene	4.6	115
14	(*E*)-β-farnesene	0.44	11
15	(*S*)-(-)-germacrene D	0.36	9
16	(*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene	4.96	124

Table 2 Corrected EAG responses of winged virginoparae *Aphis fabae* to compounds identified in headspace of *Vicia faba*

Compound name	Corrected EAG response (±SE) [-μV] at 10 μg dose	Corrected EAG response (±SE) [-μV] at 100 μg dose
(*E*)-2-hexenal	56 (±3)**	Not tested
1-hexanol	48 (±1)***	Not tested
(*Z*)-3-hexen-1-ol	7 (±1)	50 (±2)**
Benzaldehyde	60 (±2)	36 (±2)**
6-methyl-5-hepten-2-one	45 (±3)	59 (±3)*
Octanal	85 (±2)***	Not tested
(*Z*)-3-hexen-1-yl acetate	22 (±2)*	Not tested
(*R*)-linalool	43 (±2)**	Not tested
Methyl salicylate	36 (±2)**	Not tested
Decanal	82 (±4)**	Not tested
Undecanal	60 (±3)***	Not tested
(*E*)-caryophyllene	110 (±2)***	Not tested
(*E*)-β-farnesene	36 (±2)*	Not tested
(*S*)-(-)-germacrene D	111 (±4)**	Not tested
(*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene	75 (±4)**	Not tested

Only those compounds which did not elicit a significant EAG response at a dose of 10 μg were tested at a dose of 100 μg. EAG responses were corrected by subtracting the response to the hexane solvent control. *Significantly different from control ($P<0.05$); **Significantly different from control ($P<0.01$); *** Significantly different from control ($P<0.001$).

the odor of a *V. faba* (var. Sutton dwarf) plant and also to the air entrainment sample, suggesting that the volatile compounds used in host location have successfully been identified. This was confirmed by the fact that aphids did not show any preference for the air entrainment sample over the synthetic blend when offered the choice. One compound could not be identified and so could not be included in the synthetic blend. However, since the aphids showed no preference for the air entrainment sample over the synthetic blend, it is unlikely that this unidentified compound is essential in host location.

Several of the compounds reported here have been identified previously in the headspace of undamaged *V. faba* plants, namely (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, benzaldehyde, (*Z*)-3-hexen-1-yl acetate, linalool, (*E*)-caryophyllene, and 4,8,12-trimethyl-1,3,7,11-tridecatetraene (Blight et al. 1984; Griffiths et al. 1999; Colazza et al. 2004). Methyl salicylate has not been found previously in the headspace of undamaged *V. faba* plants but is known to be released by bean upon damage by chewing insects (Blight and Pickett, unpublished data) and by other plants in the Fabaceae family (Dicke et al. 1999; Mithofer et al. 2005;

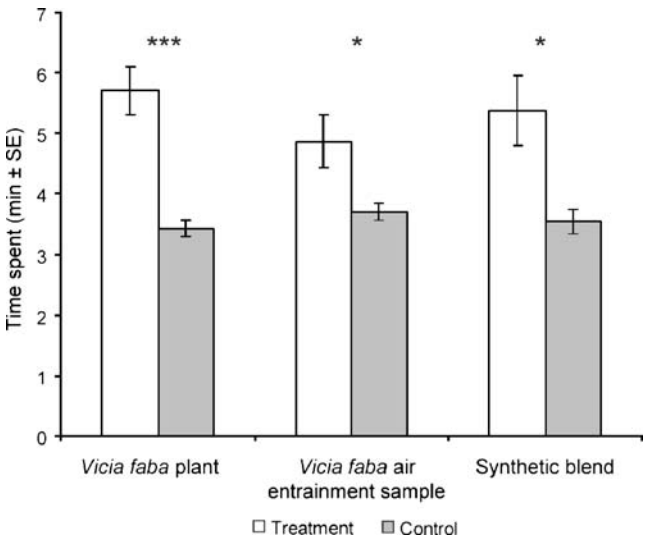

Fig. 2 Behavioral responses of winged virginoparae *Aphis fabae* to different odor sources in four-arm olfactometer ($N=12$). *Single asterisk* Treatment significantly different from control ($P<0.05$) *Triple asterisk* Treatment significantly different from control ($P<0.001$). Time spent in treated arm was converted to percentage, logit transformed, and then compared to a test mean of −1.099 (logit transformation of 25%) by using a one-sample *t*-test

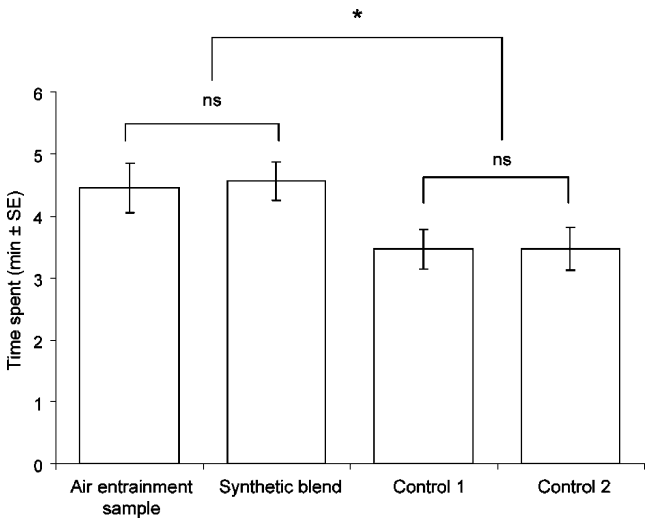

Fig. 3 Behavioral response of winged virginoparae *Aphis fabae* to *Vicia faba* air entrainment sample and synthetic blend when both odor sources present together in the same olfactometer ($N=24$). *Single asterisk* Significantly different ($P<0.05$). The difference between time spent in each treated arm was calculated and compared to a test mean of zero by using a one-sample *t*-test

Ishiwari et al. 2007). Its presence in a relatively small quantity (0.7 ng in 10 μl of air entrainment sample tested) suggests that this compound may be produced constitutively but only in small amounts that may not have been detected in previous work. Hardie et al. (1994a) observed that *A. fabae* made oriented movement away from methyl salicylate in a linear-track olfactometer at release rates at and above 50 μg hr^{-1}. The relatively small quantity of methyl salicylate in the air entrainment sample is likely to be below the threshold for which a repellent effect normally would be observed; hence, the aphids responded to the air entrainment sample and synthetic blend despite the presence of this compound. (*E*)-β-Farnesene is used by aphids as an alarm pheromone, released by aphids under attack from predators or parasitoids and causing nearby aphids to disperse (Nault et al. 1973; Pickett et al. 1992; Bruce et al. 2005a). It is also a widely occurring plant volatile (Knudsen et al. 1993), and aphids distinguish between plant- and aphid-originating (*E*)-β-farnesene by the presence of certain other plant volatiles that inhibit the behavioral response to the alarm pheromone (Dawson et al. 1984). *Aphis fabae* uses linalool as an alarm pheromone inhibitor (Bruce, unpublished data), which explains why the aphids orientate toward the air entrainment sample and synthetic blend despite the presence of (*E*)-β-farnesene.

The work carried out here has resulted in considerable progress in identifying which volatiles *A. fabae* could use in host location. However, a behavioral response to a blend of 15 volatile compounds does not necessarily mean that all 15 compounds are necessary to elicit that behavioral response. There are many examples in the literature that demonstrate host location can be mediated by only a small fraction of the electrophysiologically active volatiles identified in the headspace of an insect's host plant, the other compounds being redundant (Blight et al. 1997; Nojima et al. 2003; Birkett et al. 2004; Tasin et al. 2007). Other examples show that host location can be mediated by a single compound (Guerin et al. 1983; Hern and Dorn 2004), although such cases usually involve taxonomically specific volatile compounds that are not found in unrelated plant species (Bruce et al. 2005b). All of the electrophysiologically active volatile compounds identified in the headspace of *V. faba* are found in a diverse range of taxonomic plant groups and not specific to this species (Knudsen et al. 1993; Pare and Tumlinson 1997; Buttery et al. 2000; Blackmer et al. 2004; Williams et al. 2005), making it unlikely that a single volatile compound is used in host location. Visser (1986) suggested that host recognition by using ubiquitous rather than host-specific volatile compounds must be achieved by recognizing host-specific ratios of these compounds. Since none of the compounds identified here are specific to *V. faba*, it is likely that host location is meditated by a blend of several in a particular ratio.

Aphis fabae has a broad host range, and by using ratios of commonly occurring plant volatiles, it has the ability to recognize a large number of host plants. If an insect with a broad host range used host-specific volatile compounds, it would require specialized olfactory receptor neurons for volatile compounds associated with each host. By recognizing species-specific ratios of commonly occurring plant volatiles, the ability to recognize a larger range of plants with a much smaller number of receptor neurons is possible. The use of commonly occurring plant volatiles to recognize a large range of plant species could also facilitate learning behavior and preference for whichever host is more abundant in the habitat. *A. fabae* exists as a number of 'host races', each race specialized on a particular host (Douglas 1997). Host recognition by using ratios of commonly occurring plant volatiles could partly explain the abundance of these host races, as a change in integration in the central nervous system, rather than the need to evolve new receptor neurons when a new host race forms, could possibly facilitate more rapid evolution. The determination of how *A. fabae* responds to blends of volatile compounds in different ratios, and how this is used in host location will form the basis of future work.

2007). Like other bark beetle species belonging to the genus *Tomicus* Latreille, *T. destruens* has two dispersal phases per generation: mature adults seek recently cut or dying pines for reproduction, whereas newly emerged callow adults fly toward healthy trees and tunnel into vigorous shoots to become sexually mature (Chararas 1962). Maturation feeding continues for several months, making trees susceptible to stem attacks the following year. Host selection by bark beetles is governed mainly by volatile attractive signals (Wood 1982). In many cases, individuals of only one sex (pioneers) find suitable hosts, begin the attack, and then release a species-specific aggregation pheromone (Byers 1989). Individuals of the nonhost-searching sex join the pioneers, simply by orienting to the pheromone. Although a sexual attractant has been reported in *T. destruens* (Carle 1974, 1978; Carle et al. 1978), an effective aggregation pheromone has never been found, and adult aggregations appear to be mediated only by host volatiles (Guerrero et al. 1997). However, depending on their degree of maturation, adults appear to be attracted to volatiles emitted by either dying or healthy pines, and thus, flying adults need effective cues to find suitable breeding or feeding material (Guerrero et al. 1997). In some cases, efforts to trap *T. destruens* have been made with commercially available lures for *Tomicus piniperda*, a closely related species that lives mainly on Scots pine (*Pinus sylvestris*) and often considered synonymous with *T. destruens* until a recent systematic revision (Faccoli et al. 2005c; Faccoli 2006). The bait contains a synergistic blend of the host-volatile α-pinene and ethanol (Czokajlo and Teale 1999), with or without 3-carene and α-terpinolene (Byers et al. 1985; Schröeder and Eidmann 1987; Poland et al. 2004). α-Pinene is one of the main monoterpenes released by conifers, and ethanol is a product of the anaerobic fermentation of phloematic sugars in weakened and dying trees (Kimmemer and Kozlowski 1982). However, the number of *T. destruens* adults captured in traps baited only with α-pinene and ethanol is always very low (Sabbatini Peverieri et al. 2004; Vasconcelos et al. 2005) when compared with catches of other bark beetles. Thus, *T. destruens* adults probably follow more specific chemical cues than α-pinene and ethanol, as they are able to recognize the right host species, its physiological state (healthy or dying), as well as specific parts of the host tree (shoots or bark).

Few studies have focused on maturation feeding of *Tomicus* species (Långström 1980, 1983; Ye 1996; Ye and Lieutier 1997; Poland and Haack 2000). Långström et al. (2002) suggest that, if aggregation occurs during the shoot-feeding phase, it could be mediated by visual and/or chemical cues. Eidmann (1977) reported that callow adults are guided from brood logs toward pine shoots by visual stimuli, and Långström et al. (2002) noted that Yunnan pines (*Pinus yunnanensis*) with a high level of shoot infestation tended to have a canopy larger than trees with little damage. Borg-Karlson et al. (1999) found that β-pinene contents were higher in more severely rather than only slightly damaged Yunnan pines. Nevertheless, it was not clear if trees that released more (−)β-pinene were preferred by callow adults or if the observed differences among monoterpene profiles were the result of the attack. However, these studies were performed on *T. piniperda*, and there is no information on the chemical and/or physical stimuli that govern shoot selection by callow adults of *T. destruens*. The identification of semiochemicals attractive to both callow and mature adults of *T. destruens* should allow the development of effective control programs, based on traps baited with different lures in relation to season and degree of maturation of the insects. The aims of the present study were: (1) to identify the volatiles released by the shoots and bark of stone pine (*Pinus pinea*) that are behaviorally and electrophysiologically active on *T. destruens* and (2) to verify if the blends and concentrations of such volatiles effect callow and mature males and females differently, during the two host search phases (breeding and feeding) of the insect's biology.

Methods and Materials

Sample Collection and Handling Callow adults of *T. destruens* were obtained under laboratory conditions [21 ± 1°C, 70% R.H., 16:8 h (L:D) photoperiod] from naturally infested logs of stone pine (10 cm in diameter, 30 cm long). Emerging callow adults were removed daily from the cages and starved at room temperature for 24 h before the beginning of the trials. Mature adults were collected during winter 2006 in a stone pine forest growing in NE Italy (Caorle (VE), 45° 54′ N; 12° 36′ E) from attacked pine shoots on the litter. Both callow and mature adults were sexed by using acoustical and morphological features (Faccoli 2006). Host material used for chemical and behavioral studies, including logs and shoots of healthy pine, was collected from the same stand as the insects.

Odor Collection Headspace collections were made from fresh shoots and bark of stone pine over 24 h in a climatic chamber at 25 ± 2°C, 60 ± 10% R.H., 16:8 h (L:D) photoperiod, 1,000 lx during the light period. Five shoots (approximately 150 g) or one freshly cut log (approximately 800 g, length 20 cm, diameter 10 cm), with the cut ends sealed with paraffin, were placed into 2,000-ml glass jars (Tasin et al. 2005) and charcoal-filtered air was pumped through the system at 150 ml/min and over a Porapak Q cartridge that contained 50 mg of adsorbent (Sigma-Aldrich, Milan, Italy). Volatiles were desorbed by eluting the cartridge with 500 µl

of redistilled hexane. Additional extracts (N=5) of both shoots and bark were prepared for chemical quantification, and 0.5 μg of heptyl acetate (purity≥99%) were added as an internal standard (Bengtsson et al. 2001). Sample volumes were reduced to 50 μl at room temperature, sealed in glass vials, and stored at −18°C until used.

Chemical Analysis Five samples of both extracts were analyzed with a Hewlett-Packard 5890 gas chromatograph (GC), with a polar Innowax column (30 m×0.32 mm; J & W Scientific, Folsom, CA, USA) programmed from 60°C (hold 3 min) at 8°C min^{-1} to 220°C (hold 7 min) and interfaced with a Hewlett-Packard 5970B MS with electron impact ionization (70 eV). The identity of most compounds from the volatile collections was verified by comparison with synthetic compounds purchased from Sigma-Aldrich and Fluka Chemie (Buchs, Switzerland). Compounds that did not elicit antennal responses, and for which no standards were available, were tentatively identified by using the Wiley mass spectral database. Identified compounds were quantified by comparing their peak areas with that of the internal standard (Zhang et al. 2007).

Gas Chromatography and Electroantennographic Detection Two microliters of each extract were injected onto the same GC setup mentioned above, interfaced with an electroantennogram apparatus (Arn et al. 1975). The outlet of the GC column was split in a 1:1 ratio between the flame ionization detector (FID) and an antenna of *T. destruens*. A glass capillary indifferent electrode filled with Kaissling solution (Kaissling 1987) added with 5 g l^{-1} polyvinylpyrrolidone K90 (Fluka Chemie) was inserted into the severed head of the beetle, while the different electrode in a similar pipette was brought into contact with the distal end of the antennal club. Compounds that eluted from the capillary column were delivered to the antenna through a glass tube (12 cm × 8 mm) by a charcoal-filtered and humidified airstream. The antennal and FID signals were amplified and recorded simultaneously by Syntech software (Hilversum, The Netherlands). Samples from both stone pine shoot and bark extracts were tested on ten males and ten females of *T. destruens*, five callow and five mature individuals for each sex. A compound was considered electrophysiologically active when it elicited antennal responses at least three times greater than background noise (Zhang et al. 2001). The absolute EAD amplitudes were calculated.

Behavioral Responses A four-arm olfactometer (from Pettersson 1970, modified by Vet et al. 1983) was used to test the behavioral responses of walking callow and mature adults to various sources of volatiles. Incoming air passed through an activated carbon filter (Whatman Carbon-Cap 75), before passing into separate but identical lines leading to each corner of the olfactometer. The air passed through a flowmeter (0–2 l/min, Gapmeter Type GT), allowing the fine adjustment of the flow, into a 300-ml glass jar that contained the odor source. Air was then drawn directly to the corners of the exposure chamber and exited through a tube placed in the center of the olfactometer floor, leading to a Plexiglas vial containing a test insect. The clearest boundaries of the flows, with no intermingling, occurred at a rate of 800 ml/min. Fluorescent tubes were attached to all the sides of the olfactometer, providing homogeneous, diffuse illumination. Only one arm of the olfactometer contained a test odor (Arm 1); the other arms were empty. To prevent possible disturbing effects of movement around the apparatus (Vet et al. 1983), the olfactometer was kept in a box with walls covered by white sheets, and a digital camera, positioned centrally above the chamber, was linked to a recording video monitor. Digital records were analyzed later, as described below. With this system, we tested 50 g of either fresh shoots or bark, 10 ml of collected volatiles, two blends of synthetic compounds α-pinene and β-myrcene (blend A) and α-pinene, β-myrcene, and α-terpinolene (blend B), and a blank (empty olfactometer). The synthetic blends were chosen based on EAG results and the known attraction of the compounds to other species of bark beetles. The blends were prepared at α-pinene, β-myrcene, and α-terpinolene ratios of 79:21:0 (blend A) and 18:80:2 (blend B) based on the ratios found from shoots and bark, respectively. The two blends were then tested at five concentrations, ranging from 10^{-2} to 10^{2} of the amounts collected from 150 g of fresh shoots and 800 g of a cut branch (Table 1). For each source, ten adults were tested according to sex (male–female) and maturation (callow–mature), except for the synthetic blends where sex was not considered as a variable. For every five insects tested, the whole apparatus was washed and Arm 1 randomly reassigned. Experiments were carried out under constant laboratory conditions (21 ± 1°C, 70% R.H.), assuming that samples kept at the same temperature and having the same size and similar physiological conditions release a similar concentration of volatiles. Each insect and each sample tissue was used only once.

Analysis of Data The digital record of the activity of each insect over 10 min in the olfactometer was analyzed by the Micro Measure program (Wye College Programs). A video-mixing desk was used to lay a computer-generated map of the olfactometer on the video image. The borders of the odor fields were drawn on the computer image and labeled as zones. All the tracks of the insect were traced from the video image by a cursor. For each insect tested, and for each arm of the olfactometer, the program measured time spent walking (second), time spent stationary (second), and

total time spent (second) in each arm. Data were analyzed by multiway analysis of variance to find statistical differences in time spent by adults in Arm 1, in relation to their degree of maturation, sex, and tested odor source. Possible interactions among the three variables were also analyzed. Homogeneity of variance was tested by Cochran's test (test C) and normality by Kolmogor Smirnov's test (test D); when necessary, data were log-transformed ($X'=\log(x+1)$) or arcsine-transformed ($X'=\arcsin\sqrt{x}$) to obtain homogeneous data and normal variance. Whenever significant differences occurred, Tukey's honestly significant difference multiple comparison test was applied for separation of means (Zar 1999). Differences at the 0.05 level of confidence, adjusted by Bonferroni correction for mass comparison, were considered significant. For each compound, differences in the absolute EAD responses (millivolt) of males and females, either mature or callow, were evaluated by using Student's *t* test. Analyses were performed by STATISTICA® 3.1 for WINDOWS® software (Statistica®, Tulsa, OK, USA).

Results

Chemical Analysis Monoterpenes and sesquiterpenes were identified from both shoot and bark samples. (*Z*)-3-hexenol and 3 hydrocarbons were collected only from shoot samples, while among the terpenes, α-terpinolene, limonene oxide, (*Z*)-limonene oxide, and α-longipinene were found only in bark, whereas (*E*)-furanic-linalool oxide, (*Z*)-furanic-linalool oxide, and germacrene-D were found only in shoots (Table 1). Furthermore, shoots and bark also differed in the proportion of α-pinene and β-myrcene, with shoots having higher amounts of α-pinene (78.58:21.42, respectively) while bark had more β-myrcene (17.78:80; Table 1). Limonene represented more than 80% of the total blend of both shoots and bark (Table 1).

Gas Chromatography and Electroantennographic Detection GC–electroantennography (EAD) analyses of headspace collections detected six active compounds (Table 1), of which the monoterpenes α- pinene, β-myrcene, and

[a] Average amounts collected from 150 g of fresh shoots and 800 g of a cut branch were 92.3 ± 13.8 μg/h and 16.9 ± 4.4 μg/h, respectively.
[b] Reported percentages are relative to limonene (100).
[c] Asterisks: compounds eliciting responses in *T. destruens* antennae during GC–EAD experiments (see Table 2).
[d] Compound identified with Wiley mass spectral database.

α-terpinolene were the most active (Table 2). These were subsequently tested in the olfactometer in synthetic blends with and without α-terpinolene (see "Methods and Materials"). Four active compounds were common to both mature and callow adults (Table 1), but only mature individuals detected α-terpinolene released from bark, while (*Z*)-3-hexen-1-ol released by shoots was detected only by callow individuals (Table 1). Both sexes of callow and mature individuals showed similar EAD responses for all the tested sources (Table 2).

Behavioral Responses Because in both callow ($F1, 98 = 0.79$, $P=0.38$; Fig. 1, a) and mature adults ($F1, 98=1.52$, $P=0.24$; Fig. 1, b), males and females showed similar responses when exposed to the same source, data for the sexes were pooled. Callow insects were most attracted to shoots and their extracts ($F4, 96=7.83$, $P<0.01$; Fig. 1, a), while mature insects were more attracted to bark and its extracts ($F4, 96=8.29$, $P<0.01$; Fig. 1, b). The responses of callow adults to bark, and mature insects to shoots, did not differ from controls (Fig. 1). With increased concentrations of blends A and B, both callow and mature adults showed an increased response (Fig. 2), which became significantly higher than controls with concentrations equal to or higher than 1 ($F5, 58=6.22$, $P<0.05$ and $F5, 58=3.46$, $P<0.001$, respectively; Fig. 2).

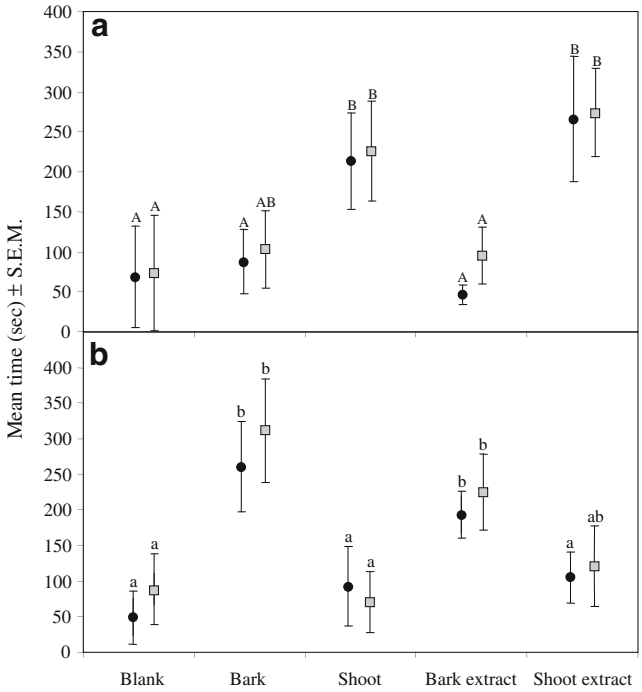

Fig. 1 Mean time spent by males and females of callow (*a*) and mature (*b*) *T. destruens* in the olfactometer test arm containing different odors (arm 1; ten insects per sex, degree of maturation, and odor, for a total of 200 insects). *Black dots*: females; *gray squares*: males. Differences analyzed by two-way ANOVA on odors and sexes, separately for callow and mature adults. Different *letters*: statistical differences by Tukey test ($P<0.05$)

Discussion

Maturation feeding in bark beetles often has been neglected, except in a few species that vector diseases, such as *Scolytus* spp. associated with Dutch Elm Disease and *Phloeosinus* spp. associated with Cypress Canker Disease (Webber and Brasier 1984; Webber and Gibbs 1989). Even in these cases, studies have focused mainly on the role of insects as vectors rather than on the semiochemical interactions between host tree and callow adults. Our results indicate that the behavior of *T. destruens* is governed by specific volatile cues and affected by adult maturation, with callows showing higher responses to shoot extracts and matures to bark volatiles. It has been demonstrated that the behavior of many insects may be affected by previously encountered odors, but the clear

Table 2 Antennal responses of *T. destruens* males and females to volatile compounds emitted from *P. pinea* as determined by GC–EAD with headspace collections from bark and shoots on both callow and mature adults

GC–EAD active compounds	EAD responses (mV) ± SD							
	Mature adults				Callow adults

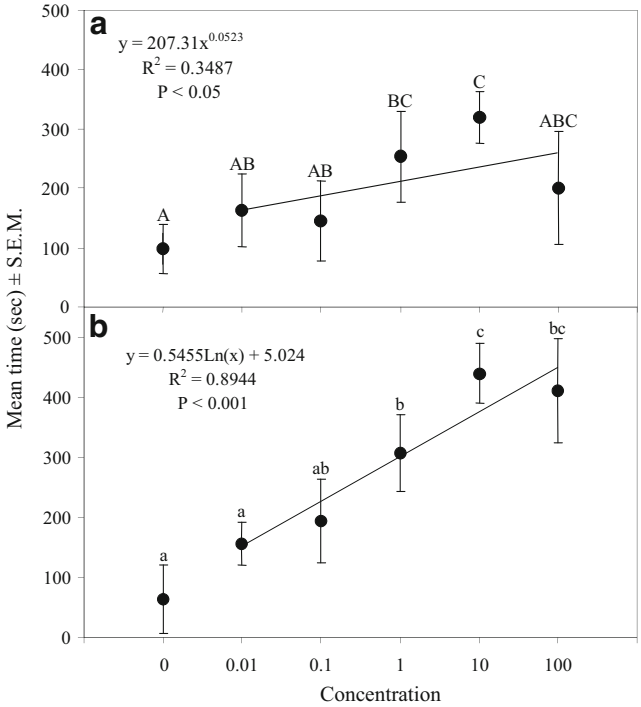

Fig. 2 Mean time spent by callow *T. destruens* in the arm containing the "blend A" (α-pinene and β-myrcene; *a*) and mature individuals in the arm with the "blend B" (α-pinene, β-myrcene, and α-terpinolene; *b*; ten insects per degree of maturation, blend, and concentration, for a total of 120 insects). 0 is the blank (empty olfactometer), whereas 1 is the concentration of volatiles collected from 150 g of fresh shoots and 800 g of a cut branch (Table 1). Values followed by different *letters* are statistically different (Tukey test; $P<0.05$)

responses shown by naive newly emerged callow adults excludes a similar mechanism in this species. Also the intensity of the odor can affect its activity, and several species fail to respond to either low or high concentrations of a kairomone (Jones et al. 1971). However, in our study, concentrations equal to or higher than those naturally released by bark and shoots caused significant alterations in behavior compared with control (clean air). The responses were always positive, although high concentrations of the monoterpenes tested in the blend B may have a repellent effect, as observed in other bark beetle species (Faccoli et al. 2005b).

In many species of scolytids, the host selecting sex (pioneer) tend to be the most sensitive to host volatiles. For example, the males of *Ips typographus* responded more than females (Schlyter et al. 1989; Zhang and Schlyter 2004; Faccoli et al. 2005b, c), and females, which have fewer α-pinene receptors, locate host plant by following male pheromones (Dickens 1981). Similar results were found also in *Scolytus rugulosus* (Ascher et al. 1975) and *Pityogenes* species (Byers et al. 1998, 2004). However, the system is different in *Tomicus* species. Both sexes of *T. piniperda* are equally attracted to pine logs or shoots and host monoterpenes (Långström 1980, 1983; Byers et al. 1985; Lanne et al. 1987), and our results suggest this is also true for *T. destruens*.

An aggregation pheromone has not been found for *T. destruens* or in the more frequently studied species *T. piniperda* (Perttunen et al. 1970; Byers et al. 1985; Lanne et al. 1987). In our experiments, the only compounds that elicited antennal responses in *T. destruens* were four monoterpenes (a-pinene, β-myrcene, a-terpinolene, limonene), one sesquiterpene (β- caryophyllene), and one alcohol ((*Z*)-3-hexen-1-ol). These are common plant volatiles and, depending on the species of bark beetle, may act as attractants (Byers 1995; Poland et al. 2004) or repellents (Poland and Haack 2000; Wallin and Raffa 2000; Byers et al. 2004). Our results suggest that α-pinene, α-terpinolene, and β-myrcene are compounds that modulate host location in *T. destruens* but that the specific responses are different for callow and mature beetles. We propose that this discrimination is based on the presence of α-terpinolene only in bark and on the different ratios of α-pinene and β-myrcene released from needles and bark (see Table 1). In particular, β-myrcene, inducing responses in both mature and callow adults, may have a major role in host selection, as it is one of the most common components of oleoresins of Mediterranean pines (Macchioni et al. 2003) but only occurs in small amounts in continental pine species (Idzojtic et al. 2005). In addition, β-myrcene is not attractive to *T. piniperda* (Byers et al. 1985), and although recent papers reported positive responses of some Chinese populations of *T. piniperda* to β-myrcene released by *P. yunnanensis* (Borg-Karlson et al. 1999; Zhao et al. 2002), these populations were later ascribed to a new species (*Tomicus yunnanensis*; Duan et al. 2004; Kirkendall et al. 2008). It is possible that visual cues also play a role in the location of specific sites on the host plant (Långström et al. 2002), but this was not a parameter considered in our study. Additional studies to examine this possibility, as well as the role of ethanol released by weakened trees and known to attract the congeneric *T. piniperda* (Schröeder and Lindelöw 1989) need to be performed.

In summary, mature adults of *T. piniperda* and *T. destruens* respond to similar blends, but for *T. piniperda* β-myrcene is replaced by 3-carene (Byers et al. 1985; Schröeder and Eidmann 1987), a monoterpene common on continental pines (Idzojtic et al. 2005). This, together with different climatic requirements, may explain the preference of *T. destruens* for Mediterranean pines and *T. piniperda* for the continental ones. Our results show promising possibilities for the use of infochemicals in the protection of Mediterranean pine forests from bark beetle attacks, but additional research on the odor signals that mediate host location by *T. destruens* is still necessary.

Acknowledgments We are grateful to Silvia Carlin and Francesco Nazzi for providing technical assistance and laboratory facilities. Special thanks go to Fredrik Schlyter, Francesco Loreto, Andrea Lucchi, and Andrea Battisti for helpful comments on earlier versions of the manuscript and to Gabriel Walton for linguistic proofreading. The research was partially funded by the Autonomous Province of Trento (SafeCrop Project).

often longer. An effective portable insect trap baited with a semiochemical attractant that could provide earlier detection of infestations has not yet been developed. Although large-panel, sticky traps that make use of the color purple as a visual cue and are baited with ash logs are attractive to emerald ash borer (Francese et al. 2005); they are not sufficiently sensitive or easy to use for this purpose.

Adult beetles feed on ash leaves for a week or more before mating (Lyons et al. 2007). Studies by Otis et al. (2005) and Lelito et al. (2007) revealed that males use visual cues to locate females, and that they actively search for females on ash leaflets in the tree canopy. To date, there is no evidence that the emerald ash borer uses long-range pheromones to locate mates (Rodriguez-Saona et al. 2006; Lelito et al. 2007), but the borer is attracted by host volatiles (Rodriguez-Saona et al. 2006; Crook et al. 2008). Manuka oil, which contains high amounts of several antennally active sesquiterpenes found in ash bark, is attractive to emerald ash borer and shows promise in baited traps (Crook et al. 2008). Rodriguez-Saona et al. (2006) demonstrated that at least 16 compounds emitted by Manchurian ash (*F. mandshurica* Rupr.) were antennally active to both sexes of emerald ash borer, which feeds on Manchurian ash in northeast Asia (Yu 1992). The compounds that elicited the strongest and most consistent antennal activity in coupled gas chromatography-electroantennogram detection (GC-EAD) bioassays were the green leaf volatiles (GLVs). These C_6 aldehydes, alcohols, and acetates are produced in large amounts by angiosperm trees (Zhang and Schlyter 2004). Their release rates are elevated by various stress factors, including damage caused by insect feeding (Ruther et al. 2000; Cossé et al. 2006; Rodriguez-Saona et al. 2006). Our preliminary chemical analysis of leaf volatiles from green ash and white ash hosts by using the solid phase micro-extraction (SPME) sampling technique, and analysis of homogenated foliage extracts, revealed the presence of several GLVs that consistently provided strong GC-EAD responses (unpublished data, Poland et al. 2004, 2006). We hypothesized that the emerald ash borer would show attraction to GLVs emitted by ash trees native to North America. GLVs serve as key components in host attractants, as pheromone synergists or as sexual kairomones for a number of coleopteran folivores (Dickens et al. 1990; Dickens 2000; Ruther et al. 2000, 2002; Ruther 2004; Reinecke et al. 2002, 2006; Cossé et al. 2006; Fernandez et al. 2007). The antennal chemoreceptors of some species are tuned specifically to individual GLVs and respond to them with very high, pheromone-like sensitivity (Hansson et al. 1999; Larsson et al. 2001).

In this study, we examined the antennal and behavioral responses of male and female emerald ash borer to GLVs in leaf volatiles from green and white ash trees. We collected volatiles on Super-Q® by aeration of trees, used GC-EAD and GC-MS (gas chromatography-mass spectrometry) to screen and identify candidate compounds, and conducted a series of field experiments over 3 years to evaluate their attractiveness.

Methods and Materials

Aeration of Leaf Volatiles and Chemical Analysis Leaf volatiles were collected from four healthy green ash trees in Sault Ste. Marie, ON on 2, 5, and 23 August 2005, and from a single healthy white ash tree on 8 August and 1 September 2005. Sampling of volatiles took place between 12:30 and 16:30 h; sampling dates were chosen when the weather was warm and sunny. Green ash was received as nursery stock (35 mm diam) from Winkelmolen Nursery Ltd. (Lynden, ON) on 29 April 2005 and out-planted on 5 May 2005. The white ash tree was about 18 years old and located on a residential property.

Foliage was enclosed in bags (approximately 45×25 cm) made from Tedlar® (Richmond Aircraft Products, Norwalk, CA, USA). Two holes were cut at opposite ends of the bag, one fitted with an activated carbon filter for air intake and one fitted with a Super-Q volatile collection trap (VCT) (Analytical Research Systems, Inc., Gainesville, FL, USA), containing 30 mg Alltech Super-Q® adsorbent material. The traps were held tightly inside 1/4 inch Teflon® tubing that was secured to the Tedlar bag with twist-ties and/or hose-clamps. Foliar headspace was sampled at 0.5 l/min with the aid of a Gilair-5 Personal Air Sampler (Sensidyne, Inc., Clearwater, FL, USA). Sampling periods varied from 0.5 to 2 h. Empty Tedlar bags placed in close proximity to the trees were sampled as controls.

The Super-Q VCTs were extracted with 3×50 µl of hexane (>99% purity, Acros) and analyzed by GC-MS on an HP5890 Series II GC fitted with a DB-1 column (25 m× 0.2 mm, with a 0.33-µm film thickness; J&W Scientific), and equipped with an HP5989A mass spectrometer. The GC temperature program started at 40°C held for 1 min, increased to 80°C at 8°C/min, and then to 260°C at 10°C/min, and finally to 325°C at 15°C/min, held for 5 min. The helium flow rate was 1 ml/min. GLVs were identified by comparing EI mass spectra with those from commercially available standards and against Wiley and National Institute of Standards and Technology libraries (Wiley275.L and Nist98.l), and by comparison of retention times with authentic standards. Extracts and GLV standards were also analyzed on a Varian 3500 GC fitted with a SPI injector and a DB-17 column (30 m×0.25 mm with a 0.25-µm film thickness, J&W Scientific) with helium as the carrier gas (2.4 ml/min) for further confirmation of the identity of the GLV compounds. The temperature program started at 40°C

for 1 min, increased at 2°C/min to 70°C, and then increased to 250°C at 15°C/min and held for 1 min. The following GLV standards were used for chemical and GC-EAD analysis: hexanal (98% purity), (*E*)-2-hexenal (98%), hexanol (99%), (*Z*)-2-hexenol (95%), (*Z*)-3-hexenol (98%), (*E*)-3-hexenol (98%), (*E*)-2-hexenyl acetate (98%), (*Z*)-3-hexenyl acetate (98%), and hexyl acetate (99%), obtained from Sigma-Aldrich Canada, and (*Z*)-3-hexenal (92% with 1–2% *E* isomer); (*E*)-2-hexenol (95%); and (*E*)-3-hexenyl acetate (98%) obtained from Bedoukian Research Inc (Danbury, CT, USA).

GC-EAD Detection Green and white ash extracts were analyzed by GC-EAD bioassay to identify GLVs that elicited electrophysiological responses from antennae of 10–40 days-old virgin male and female adults. Newly emerged adults were segregated by sex to provide virgin beetles, which do not mate until a week or more old.

GC-EAD bioassays were performed as previously described (Rodriguez-Saona et al. 2006; Grant et al. 2007). Two microliter of an extract were injected into a Varian 3400 GC fitted with a nonpolar HP-1 capillary column (25 m×0.20 mm with a 0.33-μm film thickness, Hewlett-Packard) with helium as the carrier gas. The GC temperature program started at 60°C for 1 min, increased at 10°C/min to 190°C, and then increased to 265°C at 35°C/min and held for 4 min. The column effluent was split 1:1, with one part going to the flame ionization detector of the GC and the other through a heated (225°C) transfer line (Syntech, Hilversum, Netherlands) into a humidified airstream (800 ml/min) directed at an excised emerald ash borer antenna. The cut ends of the antenna were inserted into small droplets of electrode gel (Signa Gel, Parker Labs, NJ, USA) held in small loops at the ends of gold wire electrodes connected to a Syntech portable INR-2 amplifier.

To compare the relative stimulatory effectiveness of the GLVs identified in the extracts, a synthetic mixture, which included hexanal, (*E*)-2-hexenal, (*Z*)-3-hexenol, (*E*)-2-hexenol, hexanol, (*Z*)-3-hexenyl acetate, and hexyl acetate, was prepared in methylene chloride at a concentration of 7 ng/μl for each component. Two microliter of the mixture were injected into the GC operated with a temperature program that started at 60°C for 1 min, increased at 7°C/min to 80°C, and then increased to 120°C at 25°C/min and held for 1 min. Recordings were obtained from each of five male and female antennae from virgin adults. EAD responses were subjected to a two-way analysis of variance (ANOVA) with GLVs and sex as factors after square root transformation of data to meet the assumptions of normality and equality of variance. Significantly different ($P<0.05$) means were identified with the Holm-Sidak test (SigmaStat for Windows, version 3.5).

Field Studies Based on continuing results from our chemical and GC-EAD analyses, we conducted a series of six factorial, randomized, complete block design experiments to investigate the attractiveness of various GLVs. From 2004 to 2006, experiments 1–5 were conducted in Essex County near Windsor, Ontario, and experiment 6 was undertaken in Livingston County, Michigan. All experiments were conducted in open areas within or along natural woodlots containing green ash (*Fraxinus pennsylvanica* Marsh), also known as red ash in Canada.

Prior to these experiments, we had conducted a preliminary field trial in 2003 (Poland et al. 2004) that indicated 12-unit funnel traps (Phero Tech Inc., Delta, BC, CA, USA) or Japanese beetle traps (Great Lakes IPM Inc., Vestaburg, MI, USA) hung in the canopies of trees were ineffective in capturing emerald ash borer. As previously noted, research conducted in 2003 by Francese et al. (2005) on trap color revealed that glue-coated purple corrugated plastic panels were attractive to emerald ash borer. Thus, in all of our field experiments we used 4.0-mm-thick purple corrugated plastic (Champion Box Company, Inc, Cedaredge, CO, USA; same material and source as Francese et al. (2005)) that was coated in the field with Pestick™ insect trapping glue (Phytotronics Inc, Earth City, MO, USA) just before the installation of the various semiochemical treatments. Traps were hung from 2-m-tall free-standing vertical metal poles (with a 90° bend 45 cm from the top) constructed from 1-cm-diameter concrete-reinforcing bar and inserted 50–60 cm into the ground. Traps were placed 15–20 m apart and 2–4 m clear of the forested edges of woodlots or plantations infested with emerald ash borer.

In Experiment 1, we compared three traps of different design (flat, triangular, or cross-vane) that were unbaited (control) or baited with three GLVs ((*Z*)-3-hexenol, hexanal, and (*E*)-2-hexenal). These were the intial GC-EAD active GLVs we identified. Flat traps were constructed from corrugated plastic panels (30 cm wide×150 cm long) and glued on both sides. Triangular traps were constructed from three 30×150-cm-long panels fastened together with plastic cable ties to form a triangle (prism) and glued on the outside. Cross-vane traps were constructed from two 30×150-cm panels with corresponding slots to allow them to fit together to form a cross-vane, and glued on all exposed surfaces. The traps were baited with the semiochemical lures on 3 June 2004, lures were replaced on 8 July, and the experiment terminated on 28 July when it was evident that most of the beetle flight was over. Treatments were replicated 10 times. Details on the compounds, release device, and release rates are listed in Table 1. As in all experiments, traps were serviced every 10–14 days and the captured emerald ash borers were removed from the traps, washed in Histo-Clear II® (National Diagnostics, Atlanta,

Table 1 Release devices and release rates of compounds used in field experiments as potential attractants for *Agrilus planipennis*

Experiment	Compound (% purity)[a]	Release device	Release rate (mg/24 h)[b]
1	Hexanal (98.1)	1 bubble cap	24
	(E)-2-hexenal (99.1)	1 bubble cap	38
	(*Z*)-3-hexenol (98.0)	1 bubble cap	17
2	Hexanol (99.5)	2 bubble caps	24
	(*E*)-2-hexenol (99.7)	2 bubble caps	32
	(*Z*)-3-hexenol (98.0)	2 bubble caps	34
3	Nonanal (95.6)	2 bubble caps	84
	Hexanal (98.1)	2 bubble caps	48
	(*E*)-2-hexenal (99.1)	2 bubble cap	76
4	(*Z*)-3-hexenol (99.5)	Polyethylene pouch	330
	(*E*)-2-hexenal (99.1)	15-ml polyethylene bottle	110
5	(*Z*)-3-hexenol (99.5)	Polyethylene pouch	330
	(*E*)-2-hexenal (99.1)	Two 15-ml polyethylene bottles	220
6	(*Z*)-3-hexenol (99.5)	Polyethylene pouch	48
	(*Z*)-3-hexenol (99.5)	Polyethylene pouch	330
	(*E*)-2-hexenal (99.1)	15-ml polyethylene bottle	110
	(*E*)-2-hexenal (99.1)	Three 15-ml polyethylene bottles	330

[b] Release rates determined at 30°C in the laboratory by Phero Tech Inc. All compounds released from closed and separate devices

GA, USA) to remove the glue, and preserved in 70% ethanol. All beetles were sexed by examining the internal genitalia.

Experiment 1 had combined (*Z*)-3-hexenol, hexanal, and (*E*)-2-hexenal as one treatment and, in 2005, we conducted two experiments to examine the separate effects of various alcohols (Experiment 2) and aldehydes (Experiment 3). Each of these experiments included a control consisting of an unbaited (blank) sticky trap, as did all remaining experiments. In Experiment 2, we compared binary and tertiary combinations of hexanol, (*E*)-2-hexenol, and (*Z*)-3-hexenol. Thus, the treatments consisted of (1) hexanol+(*E*)-2-hexenol, (2) hexanol+(*Z*)-3-hexenol, (3) hexanol+(*E*)-2-hexenol+(*Z*)-3-hexenol, (4) (*E*)-2-hexenol+(*Z*)-3-hexenol, and (5) unbaited or blank trap. In Experiment 3, we compared binary and tertiary combinations of (*E*)-2-hexenal, nonanal, and hexanal, that is: (1) (*E*)-2-hexenal+nonanal, (2) (*E*)-2-hexenal+hexanal, (3) (*E*)-2-hexenal+nonanal+hexanal, (4) nonanal+hexanal, and (5) blank trap. Nonanal (an aldehyde by product of the GLV biosynthesis pathway) was detected in our early SPME analysis of host volatiles and was GC-EAD active (unpublished data, Poland et al. 2007). In 2005, we used purple traps consisting of two 45×60-cm corrugated purple plastic panels with corresponding slots that allowed them to fit together in a cross-vane shape, and glued on all surfaces. Each trap was fitted with a flat top and bottom (45×45 cm) and was suspended from the cross bar of the metal trap poles by an umbrella rig spreader (Zing Products, Westport MA, USA). The spreader not only provided a means to suspend the trap and keep the trap panels in place, it also allowed the trap to move with the wind and, thus, be less rigid and prone to wind damage. The two field experiments were initiated on 4 June 2005 and were terminated on 20 July 2005. Experiment 2 had five replicates and experiment 3 had 10 replicates of each treatment.

In 2006, the last three experiments were conducted to assess the efficacy of (*Z*)-3-hexenol and (*E*)-2-hexenal, but at higher release rates than used previously. Experiment 4 evaluated traps baited with (*Z*)-3-hexenol (released at 330 mg/day) or (*E*)-2-hexenal (110 mg/day), or the two combined. In Experiment 5, the same volatiles were used as in experiment 4, but the release rate of (*E*)-2-hexenal was increased to 220 mg/day. Experiment 6 examined four single semiochemical treatments consisting of (*Z*)-3-hexenol (released at 48 or 330 mg/day), (*E*)-2-hexenal (released at 110 or 330 mg/day), and the unbaited control. Traps used in 2006 were constructed from a single purple corrugated plastic panel folded into a three-sided prism measuring 40.0-cm wide and 60.0-cm tall on each side, and held together by cable ties. Traps were glued on all exposed surfaces and suspended from the metal trap stand as in 2005. Experiments were conducted from 14 June to 27 June (experiment 4), 28 June to 18 July (experiment 5), and 12 June to 19 July 2006 (experiment 6). Experiments 4 and 5 had six replicates of each treatment and experiment 6 had 12 replicates.

The trap catches of male and female emerald ash borers from each experiment were analyzed independently by using analysis of variance. In each experiment, we had a priori hypotheses about the treatments and they were used to structure orthogonal contrasts for the ANOVA. For example, in the first experiment, our goal was to determine whether or not emerald ash borer trap catch numbers may be influenced by (*a*) an artificial lure, (*b*) sex, and (*c*) trap type, in particular, a triangular-arrayed surface as compared to conventional flat and cross-vane surfaces. As such, the

11 degrees of freedom (*df)* associated with the treatments tested in this experiment [2 lures (baited and unbaited)×2 sexes×3 trap types—1], were broken down into contrasts within the ANOVA to directly address each of these questions:

Contrast	d.f.
Bait	1
Sex	1
Trap	2
Bait×sex	1
Bait×trap	2
Sex×trap	2
Bait ×sex×trap	*2*
Total	11

In the above, the tests for interaction determine whether the levels of one factor behave consistently across the levels of another, such that generalized statements may be made about the individual factors. For example, if the bait×sex interaction term were insignificant ($P>0.10$), then conclusions may be drawn about the effectiveness of the lure, irrespective of sex. The two *df* for trap type was further broken down into a contrast that compared cross-vane and flat traps, and another that compared the average of these two types to the triangular array. With this factorial treatment arrangement, this type of analysis is more powerful and appropriate than multiple comparison procedures, and better suited to specifically address the a priori hypotheses that we posed (Steel and Torrie 1980; Mize and Schultz 1985; Warren 1986).

All of our subsequent experiments focused on lure development and generally followed the treatment arrangement of a 2^2 factorial design (Montgomery 2004). In the simplest cases (experiments 4 and 5), two types of lures were tested (e.g., *a* and *b*), producing four treatment combinations: *a*, *b*, *ab*, and *0* (blank). In a manner parallel to the first experiment, orthogonal contrasts were used to test for interaction between the two lures and then generalized effects associated with the presence of each. Experiments 2 and 3 followed this same form, but involved three compounds, producing the four treatment combinations: *ac*, *bc*, *abc*, and *0*. In these experiments, we contrasted a fifth treatment, *ab*, with *abc* to test for the effect of the third compound *c*. In Experiment 6, two lures were tested, each at three levels (0, 1, and 2×), without combination. In this case, a contrast was used to compare the average effects of the two lures, and polynomial contrasts were used to test for dose responses in each [e.g., response proportional to dose (linear) and disproportional to dose (quadratic)] (Montgomery 2004).

In experiment 1, trap catches were standardized to the same trap surface area as the cross-vane traps (1.8 m^2): all remaining experiments used the same trap size. Residuals from the analyses were examined to verify normality and homogeneity of variance assumptions and, where necessary, trap catch numbers were increased by one to avoid zero counts, and natural log transformed to satisfy these assumptions. Case-by-case, this transformation was identified from the family of power transformations as being the most effective through the procedures developed by Box and Cox (1964). Where data were transformed, we present the untransformed least squares means and the standard errors of the least square means, along with the statistics ($P>F$) from ANOVA of the transformed data. Analyses were conducted by using PROC GLM of the SAS® System (SAS Institute Inc. 2004).

Results

Aeration of Leaf Volatiles and Chemical Analysis Eight GLVs were detected in both white and green ash foliar aeration extracts. (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexenol, (*E*)-2-hexenol, hexanol, (*Z*)-3-hexenyl acetate, and hexyl acetate were identified in the white ash extract by GC-MS. The presence of hexanal was determined by its retention times on the DB-17 and HP-1 columns. Green ash extracts were considerably less concentrated than the white ash extract, possibly due to differences in age and maturity of the sampled trees. Only (*E*)-2-hexenal, (*Z*)-3-hexenol, and (*Z*)-3-hexenyl acetate were identified by GC-MS. (*Z*)-3-hexenal, hexanal, (*E*)-2-hexenol, hexanol, and hexyl acetate were identified by their retention times on the DB-17 and HP-1 columns. In both the green and white ash extracts, (*Z*)-3-hexenol and (*Z*)-3-hexenyl acetate represented over 80% of the GLV volatiles emitted by both tree species. No GLVs were detected in the control extracts.

Gas Chromatography-Electroantennogram Detection All of the GLVs identified in both green and white ash extracts elicited EAD responses from both male and female antennae. However, during the initial bioassays of white ash extracts, which were more concentrated than the green ash extracts, the male antennal responses to the GC peaks corresponding to the GLVs, particularly the (*Z*)-3-hexenol GC peak, were unusually small until the extract was diluted 15-fold. This resulted in the expected higher response levels (Fig. 1 inset). Male EAD responses to the aldehydes and alcohols in extracts of both tree species were typically larger than female responses to these compounds, with the GC peak corresponding to (*Z*)-3-hexenol always eliciting the largest male EAD response (Fig. 1 inset). Similar results were obtained previously with the GLVs occurring in Manchurian ash volatiles (Rodriguez-Saona et al. 2006). In our initial GC-EAD bioassays of the ash extracts, the

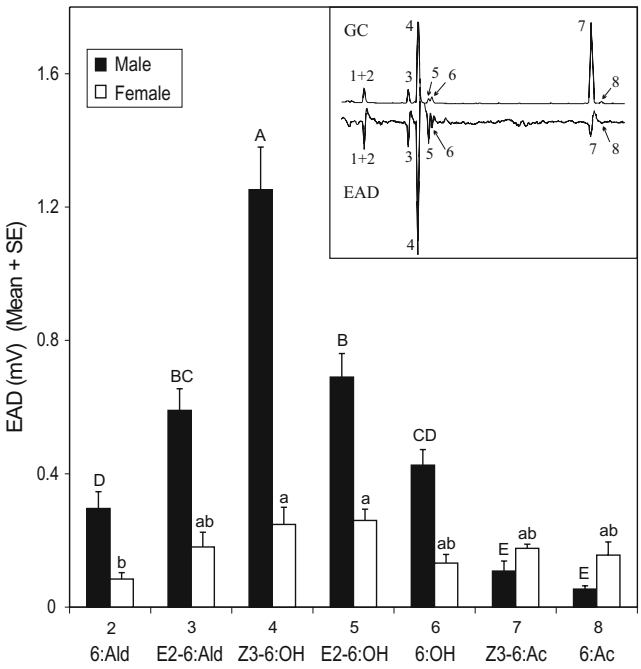

Fig. 1 Mean EAD responses from male and female antennae of *Agrilus planipennis* (N=5 each) to equal quantities (7 ng each) of seven host GLVs (6:Ald=hexanal; E2–6:Ald=(*E*)-2-hexenal; Z3–6:OH=(*Z*)-3-hexenol; E2–6:OH=(*E*)-2-hexenol; 6:OH=hexanol; Z3–6:Ac=(*Z*)-3-hexenyl acetate; 6:Ac=hexyl acetate). *Numbers* above the compound names correspond to the numerically labeled GC and EAD peaks in the *inset figure*. *Male bars* with *different capital letters* are different and *female bars* with *different small case letters* are different (P<0.05, Holm–Sidak test). Differences between male and female responses were significant for all GLVs (P<0.05, Holm–Sidak test) except Z3–6:Ac. Fig. 1 *inset*: GC-EAD recording of male antennal response to GLVs in the diluted white ash aeration extract (1+2, (*Z*)-3-hexenal plus hexanal; 3, (*E*)-2-hexenal; 4, (*Z*)-3-hexenol; 5, (*E*)-2-hexenol; 6, hexanol; 7, (*Z*)-3-hexenyl acetate; 8, hexyl acetate)

male response to the GC peak thought to be only hexanal was larger than expected based on the size of the GC peak and the response to synthetic hexanal. Subsequent closer examination of this peak by using a slower temperature program (40°C to 75°C at 6°C/min) revealed a second peak that was identified as (*Z*)-3-hexenal by GC-MS and its retention time on the HP-1 and DB-17 columns.

Because there were substantial differences in the amounts of GLVs in the ash extracts, we confirmed the relative stimulating effectiveness of the host GLVs by testing a synthetic mixture of GLVs held at a constant concentration of 7 ng/μl. There was a difference between male and female responses (F=101.3, df=1, 6; P<0.001) with male antennae producing larger EAD responses to all of the alcohols and aldehydes than females (P<0.05, Holmes-Sidak test) (Fig. 1). Females were more responsive to hexyl acetate than males, but there was no difference in their respective responses to (*Z*)-3-hexenyl acetate. As with the ash extracts, (*Z*)-3-hexenol was by far the most stimulating compound for males (Fig. 1), often eliciting responses more than twofold larger than either (*E*)-2-hexenal or (*E*)-2-hexenol at the same concentration. Only slight differences were observed among female responses to the GLVs (Fig. 1). The synthetic GLV mixture did not include (*Z*)-3-hexenal because it was discovered late in this study and after the synthetic mixture was bioassayed. However, the EAD response from male antennae to synthetic (*Z*)-3-hexenal was larger than the EAD response to the same concentration of synthetic hexanal, but comparable to that elicited by synthetic (*E*)-2-hexenal.

Field Studies In experiment 1, trap catches for males and females were consistent across both baited and unbaited traps and trap types (two- and three-way interactions, $P\geq$ 0.38). In general, 3.7 times more males were attracted to the traps baited with the three GLVs ((*Z*)-3-hexenol+hexanal+(*E*)-2-hexenal) than females (P<0.01) (Fig. 2a). Also, these traps resulted in an average 76% increase in total catches of both sexes (P<0.01). While there was little difference in the performance of cross-vane and flat traps (P=0.86), triangular traps provided a 40% increase in catches over the other trap types (P=0.07), suggesting the need for further evaluation.

In experiment 2, the combination of hexanol+(*Z*)-3-hexenol (lures 2 and 3) resulted in increased catches of males (P<0.01), but not females (P=0.18) (Fig. 2b). Hexanol+(*E*)-2-hexenol had no effect as an attractant for either sex, either as a binary combination (lure 3) ($P\geq$0.14), or as a tertiary combination with (*Z*)-3-hexenol (lure 4) ($P\geq$ 0.27). Adding hexanol to the combination with (*Z*)-3-hexenol+(*E*)-2-hexenol (lure 3) had no effect on male catches (P=0.30), but appeared to increase female numbers (P=0.06). In general, the presence of (*Z*)-3-hexenol in the various lures resulted in a 3.8-fold increase in males captured with no conclusive effect on females.

In experiment 3, variation in female trap catch was high. The combination of hexanal+nonanal (lures 1 and 3) increased catches of males (P=0.04), but not females (P= 0.08) (Fig. 2c). The combination of (*E*)-2-hexenal+nonanal had no effect as an attractant, either by itself (lure 4) ($P\geq$ 0.35), or in combination with hexanal (lure 3) ($P\geq$0.55) for either sex. Also, adding nonanal to the combination of hexanal+(*E*)-2-hexenal had no effect on catches of either sex ($P\geq$0.58).

In experiment 4, variation in female trap catch was also high. Nonetheless (*Z*)-3-hexenol increased trap catches of both sexes (lures 1 and 3) (P<0.01) (Fig. 2d). In contrast, (*E*)-2-hexenal had no effect as an attractant, either by itself ($P\geq$0.38), or in combination with (*Z*)-3-hexenol ($P\geq$0.22). The presence of (*Z*)-3-hexenol resulted in an average 2.3-fold increase in total catch of beetles. In contrast to the previous experiments, substantially more females were trapped than males in response to (*Z*)-3-hexenol.

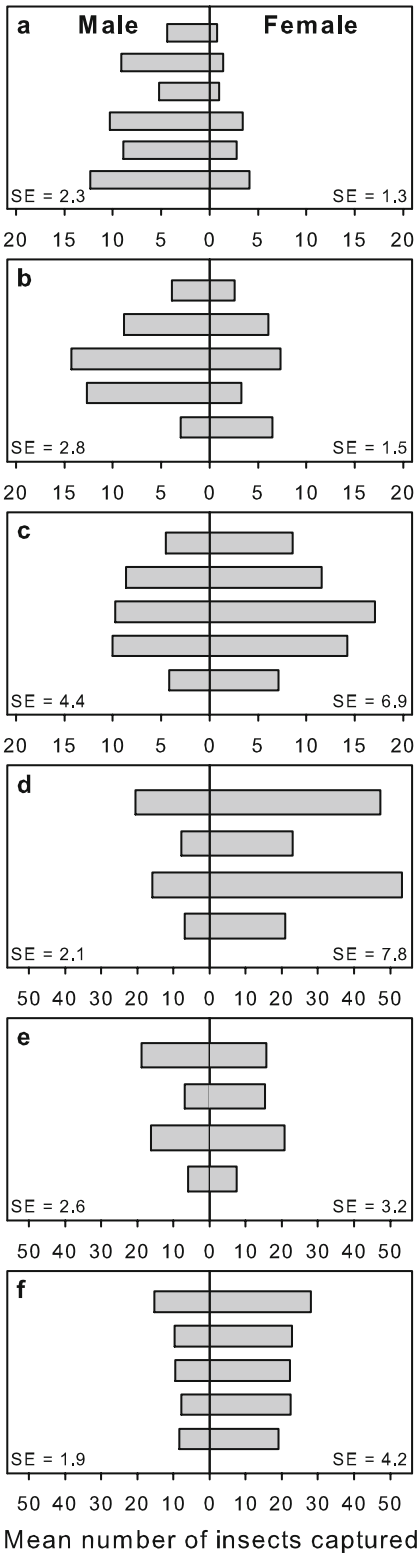

Fig. 2 Response of male and female *Agrilus planipennis* to various combinations of green leaf volatiles in six field experiments. Data were analyzed independently using analysis of variance (ANOVA) followed by orthogonal contrasts. Statistics ($P>F$) are shown for each contrast and those marked with a *dagger* apply to the natural log-transformed data following ANOVA. The standard error (SE) shown is the standard error of the least squares means

In experiment 5, doubling the release rate of (*E*)-2-hexenal used in Experiment 4 had no effect as an attractant for males (lures 2 and 3) ($P=0.73$), but may have had some effect on females ($P=0.06$) (Fig. 2e). (*Z*)-3-Hexenol again resulted in an increased catch of both sexes (lures 1 and 3) ($P\leq0.05$): an average 2.7-fold increase in males and a 1.6-fold increase in females. The presence of (*E*)-2-hexenal did not influence the effects of (*Z*)-3-hexenol ($P\geq 0.52$).

In experiment 6, (*Z*)-3-hexenol resulted in an increased catch of males only, and only at the low release rate (48 mg/day) ($P=0.01$) (Fig. 2f). Female numbers also increased, but not significantly ($P=0.39$). (*E*)-2-hexenal had no effect as an attractant for males or females ($P\geq0.59$). Low dosages of (*Z*)-3-hexenol resulted in total trap catches of beetles that were 50% greater than unbaited traps.

Discussion

The most promising GLV attractant found in this study was (*Z*)-3-hexenol. It was one of the most abundant GLVs in the aeration extracts of both green ash and white ash. In the GC-EAD bioassays, males showed the strongest response to (*Z*)-3-hexenol, whereas for females it was no more stimulating than the other GLVs. In field experiments, males consistently responded positively ($P<0.05$) to the presence of (*Z*)-3-hexenol (experiments 2, 4, 5, and 6), and females responded positively in two (experiments 4 and 5), but not in two other experiments (experiments 2 and 6). In experiment 6 where the two release rates of (*Z*)-3-hexenol were compared directly, males showed a positive ($P<0.05$) response to the low rate (48 mg/day) but not to a rate nearly seven times higher (330 mg/day). This suggests that there is a dose effect, but in experiments 4 and 5 the high release rate lures were attractive. In our GC-EAD bioassays, however, we found that the initial white ash extracts were too concentrated and had to be diluted 15-fold before eliciting full antennal responses from the GLVs, particularly (*Z*)-3-hexenol. Male antennae were sensitive to low dosages (<1 ng) of aldehyde and alcohol GLVs, as observed in other beetle species (Hansson et al. 1999; Larsson et al. 2001), so that excessively high dosages probably saturated the male olfactory receptors which resulted in the reduced EAD responses with the undiluted white ash extracts. Thus high doses of GLVs in traps may well be unattractive or even repellent at close range. In laboratory bioassays involving the Colorado potato beetle, *Leptinotarsa decemlineata* (Say), Dickens (2000) found high dosages of (*Z*)-3-hexenol and (*E*)-2-hexenol in lure blends were repellent but low levels in the same blend were attractive. Further investigation of the effect of lure dosage or release rates of GLVs on emerald ash borer may be worthwhile.

Although hexanol and (*E*)-2-hexenol readily elicited antennal responses from male and female antennae in the GC-EAD bioassays, these compounds were not attractive in the field, when tested at release rates of 24–32 mg/day, within the lower range where (*Z*)-3-hexenol shows activity (17–48 mg/day), nor did they enhance the attractiveness of (*Z*)-3-hexenol. Similarly, the aldehydes (hexanal, (*E*)-2-hexenal, nonanal) were active in GC-EAD bioassays but, with one exception (experiment 2, hexanal+nonanal), they were not attractive to male or female emerald ash borer in the field. We tested (*E*)-2-hexenal in several different experiments. In all cases, it was not attractive to either sex, and did not noticeably increase or decrease trap catch when traps were co-baited with (*Z*)-3-hexenol. The combination of hexanal+nonanal may warrant further attention for its effects on males, either alone or in combination with (*Z*)-3-hexenol.

There are practical and statistical constraints in the number of treatments (chemicals, blends and release rates), layout of traps, and replications possible in field experiments, especially in forests. Consequently, not all host GLVs or their blends were tested, which may account for our failure to detect any behavioral effects for some GLVs, such as (*E*)-2-hexenal. Also, the GLV acetates, which had the weakest EAD activity, were not included in our field tests. Second, it may also be that GLVs are not particularly attractive to females. Aeration extracts from insect damaged Manchurian ash were attractive to female emerald ash borers, but not to males (Rodriguez-Saona et al. 2006). These extracts contained relatively low levels of (*Z*)-3-hexenol and other GLVs and could explain the lack of male behavioral response to these extracts, thus suggesting that females were responding to other induced host compounds. (*Z*)-3-Hexenal was discovered too late in our GC-EAD study for inclusion in the field tests. Further tests are planned to broaden our evaluation of host ash GLVs and to include other EAD active host compounds in combination with them.

Little is known about effective methods to trap buprestids, and this can present difficulties in evaluating attractants. In general, an important component of the development of a trap-based detection program for insects is the design and placement of the trap itself. Attractive chemicals placed in an ineffective trap may result in poor trap catches, and conversely, a well-designed trap, baited with unattractive chemicals or incorrect release rates may also result in poor trap catches. With this in mind, we chose to keep trap color (purple) constant throughout the 3 years of our field tests, and in 2005 and 2006 to keep trap design the same within the year of the experiment. Our results from 2004 showed that flat, cross-vane, and triangular traps were essentially the same in capturing emerald ash borers, although the triangular trap appeared to offer an advantage. In 2005, we chose to use the purple cross-vane trap because of its availability from USDA APHIS. This trap had

tendencies to rotate easily in the wind because of the vanes; therefore, in 2006 we reverted to the triangular (prism), but smaller trap. Further development of the trap silhouette, optimal, but practical positioning of the trap, and perhaps revisiting trap color will no doubt help improve trapping effectiveness for emerald ash borer and buprestids in general.

Green leaf volatiles are well known to be negative olfactory signals used by several species of conifer inhabiting bark beetles to indicate the presence of non-hosts or unsuitable hosts at the tree-species and habitat level (Zhang and Schlyter 2004). On the other hand, several coleopteran folivores feeding on angiosperms use these same GLVs, especially the C_6-alcohols, to help locate hosts, or synergistically enhance their response to pheromones as mentioned in the Introduction. To our knowledge, our results provide the first evidence that buprestids use GLVs as attractants. Because the release of GLVs from plant tissue is elevated by insect feeding damage, we hypothesize that foliage feeding by adult emerald ash borer may increase the apparency and attractiveness of their host trees, *Fraxinus* spp. Because (*Z*)-3-hexenol is most attractive to males and elicits an exceptionally strong male antennal response, it may also serve as an important cue along with other visual and olfactory stimuli for finding females on host foliage. Similar male biased antennal and behavioral responses to (*Z*)-3-hexenol have been reported in other beetle species, particularly chafers (Ruther et al. 2000, 2002; Ruther 2004), where it serves as a sexual kairomone in conjunction with a female pheromone.

In summary, our laboratory and field experiments demonstrate that the GLV (*Z*)-3-hexenol increased trap catch of the emerald ash borer when placed on purple traps in open areas or along the edges of woodlots containing ash. It had greater influence on males than females, and dosage may be a factor determining its effectiveness. This work represents a step towards understanding the role of GLVs for host-plant finding by *A. planipennis*, and for development of an attractant-based trapping systems for early detection of this serious invasive insect pest.

Acknowledgements We thank Gene Jones and Pat Roden for rearing beetles in quarantine for the GC-EAD study, and Dorothy Ambeault, Tim Dalseg, Laura Chouinard, Jordana Fera, Tasha Gauthier, Erin Clark, Tina Kuhn, and Toby Petrice for assistance with the field studies. We appreciate the assistance of Vic Mastro and Joseph Francese, USDA-APHIS, in providing the traps for our 2005 studies. Funding and support were provided by the Canadian Forest Service, Ontario Ministry of Natural Resources, and the USDA Forest Service Special Technology Development Program (Project No. NA-2003-02).

Over the last two decades, an increasing number of studies has reported on the importance of host-plant volatile chemicals in mediating host recognition by herbivores (Visser 1986; Bernays and Chapman 1994; Schoonhoven et al. 1998; Bruce et al. 2005). This volatile-mediated response has been suggested to be more pronounced in specialist than generalist herbivores (Bernays and Chapman 1994), and can occur to very low concentrations of chemicals (Angioy et al. 2003). Several studies have investigated optimal combinations of host volatiles to improve monitoring or trapping of insect pests (e.g., Zhang et al. 1999; Hammack 2003; Blackmer et al. 2004; Leskey et al. 2005; Pinero et al. 2006). Within tortricid moth pests, research on the use of host volatiles has focused on species with moderate to broad diet breadths such as codling moth, Oriental fruit moth, and European grape berry moth. In these cases, a number of relatively common volatile compounds show behavioral activity in the laboratory (Ansebo et al. 2004; Coracini et al. 2004; Hern and Dorn 2004; Natale et al. 2004; Tasin et al. 2005, 2006a, b, 2007). However, lures based on host-plant volatiles have not been successful in the field (e.g., Ansebo et al. 2004; Coracini et al. 2004; Mitchell et al. 2008). One possibility is that the role of odors in location of hosts may be a stronger selective force for specialists than for generalists (Bernays and Chapman 1994). Therefore, the development of a lure based on host-plant volatiles to improve monitoring and management decisions for insect pests may be a more suitable strategy for specialist herbivores such as GBM.

Here, we present results of chemical, electrophysiological, and behavioral experiments that used solid phase microextraction (SPME), gas chromatography–electroantennogram detection (GC-EAD), and flight-tunnel assays, to identify the key volatile chemicals from grape shoots used by female GBM to locate a host. In our previous behavioral study, grape shoots were the most attractive grape tissue to female GBM (Cha et al. 2008). Our goal was to develop a host-plant-based synthetic lure that is as attractive as live grape shoots to female GBM. We also present data from a field trial in which we tested the efficacy of traps baited with synthetic lures.

Methods and Materials

Insects GBM were reared in cages placed in walk-in environmental chambers at 26°C and 60% RH under a 18:6 (L:D) photoperiod. Adult moths were fed with 50% honey and water soaked on cotton. Adults mated freely in rearing cages (45 cm H×77 cm W×45 cm D) and oviposited on seedless grape (*Vitis vinifera*, red flame variety). First and second instars were transferred to a diet cup (30 ml, WinCup Inc.) and reared on semi-synthetic diet (Nagarkatti et al. 2000) that consisted of grapes, pinto beans, and commercially available tobacco hornworm diet (Bio-Serve). To minimize any potential effect of laboratory rearing on the behavior of moths, colonies were re-established once a year with larvae and pupae collected from commercial vineyards in July or August.

Plants We used a native host species of GBM in north-eastern USA, *Vitis riparia*, to identify candidate volatile host compounds for the synthetic lure. Cuttings were made from *V. riparia* growing in a research vineyard at the Cornell University, New York State Agricultural Experiment Station in Geneva, NY, USA in December 2005. Cuttings were dipped in rooting hormone (Green Light Co., San Antonio, TX, USA) and placed in a planting box filled with moistened Perlite® in a cold room (4°C), equipped with a heating pad, to facilitate root growth while retarding development of shoots. Once roots were developed, all plants were transplanted to 1-gal pots filled with a mixture of sand, peat moss, and Vermiculite® and moved to a greenhouse with temperatures maintained between 21–26°C. Supplemental light was provided to extend the day length to 16 h and pots were fertilized weekly with water-soluble fertilizer (Peters 20–20–20, Scotts-Sierra Horticultural Products Co.). For sampling of volatile chemicals and flight-tunnel assays (see below), we used plants that were 2–4 weeks post-bloom, without any flowers or berries, since grape shoots were most attractive to female GBM in our previous flight-tunnel study (Cha et al. 2008).

Adsorbent Sampling We used a push–pull collection system to collect headspace volatiles of live grape shoots. The system was a custom-made, bell-shaped glass chamber (18 cm ID, 10 L) with two air-in adapters (7 mm ID) on the top and four air-out adapters (7 mm ID) equally distributed at the bottom wall of the chamber. To accommodate a whole, live potted plant, the glass chamber was placed on two pieces of Pyrex glass with a hole (2 cm) in the middle so that the vegetative portion of the plant could be sampled. After a plant was set up in the chamber, the chamber was flushed with filtered air (3 L min^{-1}) for an hour to replace air inside the chamber with filtered air and to stabilize volatile emission from the plant, because we noticed that handling of the plant during set up temporarily induced release of green leaf volatiles. During the collection, flow meters were used to insure that more filtered air was pushed into the chamber than pulled out through the charcoal filters so as to eliminate possible contamination from outside air. Filtered clean air from a wall-mounted air filtering system (ARS Inc., Gainesville, FL, USA) was pushed into the chamber at 2.5 L min^{-1} and volatiles from the headspace of grape shoots were drawn by a vacuum pump onto four activated charcoal filters (ORBO32-small, Supelco Inc., Bellefonte,

PA, USA) at 0.5 L/min/filter. Adsorbent samplings were made from four plants, with collections for each grape plant made over 4 days at room temperature with supplemental light (18:6 L:D). The chamber was washed with acetone, and new ORBO filters were used for a new plant. The volatiles were eluted with 1 ml hexane every 24 h and then combined. The combined extract was concentrated to 1 ml under a gentle stream of nitrogen gas and kept in a freezer (−20°C) and subjected to GC-EAD and gas chromatography–mass spectrometry (GC-MS) analyses, and flight-tunnel bioassay.

SPME Sampling We used the same glass chamber that was used for adsorbent sampling to collect headspace volatiles of live grape shoots using SPME. Filtered air was pushed into the chamber at 1 L min^{-1}. Three of the four air outlets were blocked with rubber septa, while one was 70% blocked with Teflon tape allowing the SPME fiber to be inserted into a thin stream of headspace volatiles for increased collection efficiency. After a plant was set up in the chamber, we flushed the chamber with filtered air as described above. We conditioned a carboxen/poly-dimethyl siloxane-coated SPME fiber (film thickness 85 μm; Supelco Inc., Bellefonte, PA, USA) in the GC injector (280°C) for 5 min and then inserted the fiber through a small hole on the air-outlet. The fiber was exposed for up to 24 h to absorb the volatiles, and immediately subjected to GC-EAD or GC-MS analyses. The chamber was washed with acetone before sampling a new plant.

Coupled GC-EAD Analysis Coupled GC-EAD analyses were performed following procedures described previously (Zhang et al. 1999; Nojima et al. 2003). A Hewlett-Packard 5890 Series II gas chromatograph, equipped with a non-polar EC-1 capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; Alltech Associates, Inc., Deerfield, IL, USA) or a polar EC-Wax Econo-Cap capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; Alltech) was used for GC-EAD analyses. The oven temperature was programmed from 40°C for 5 min then increased by 15°C min^{-1} to 250°C. Injector and detector temperatures were set at 280°C and 270°C, respectively. A 0.75-mm ID glass inlet liner (Supelco) was used for SPME sample injection and a 4-mm ID liner (Supelco) for liquid samples. Splitless injection was used with nitrogen as the carrier gas at a flow of 2 ml min^{-1}. The column effluent was split in a ratio of 1:1 in the oven to the flame ionization detector and to the heated (270°C) EAD port.

A whole head was removed from a 3-day-old virgin female GBM and both antennae were positioned between two gold wire electrodes that were immersed in two saline-filled micropipettes in a small acrylic holder. We used an Ephrussi–Beadle insect Ringer as saline (Ephrussi and Beadle 1936). The moth's head was placed into the tip of one micropipette, and the tips of both antennae, which were wetted with saline containing surfactant (0.02% Triton X-100) for easy insertion, were maneuvered to make contact with the saline in the other micropipette tip. The antennal holder was placed inside a humidified cooling condenser maintained at 10°C. To compare relative magnitudes of antennal responses, the millivolt values for EAD-active compounds were calculated from GC-EAD recordings performed with SPME and adsorbent sample runs. A minimum of five different antennal pairs (two to three runs/pair) were used to analyze volatiles from shoots of the same four *V. riparia* plants that were subjected to adsorbent sampling.

Chemical Analysis GC-MS was carried out with a Shimadzu GCMS-QP5050A quadrupole mass spectrometer running in the EI (at 70 eV) scan mode coupled with a Shimadzu GC-17A equipped with a nonpolar DB-1 capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA) or a polar EC-Wax Econo-Cap capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; Alltech Assoc.). Helium was used as the carrier gas at a constant flow of 1.0 ml min^{-1}. GC conditions and temperature program were as for the GC-EAD analyses. Volatile compounds were identified by mass spectral matches to library spectra as well as by retention time matches to available authentic standards. The EAD-active compounds were verified by GC-EAD analysis with authentic standards. Quantification of the relative ratio of the EAD-active compounds was made from the adsorbent collection based on ion abundances from GC-MS analyses.

Chemicals (*Z*)-3-hexen-1-yl acetate, linalool oxide (1:1 mixture of (*E*)- and (*Z*)-isomers), nonanal, linalool, methyl salicylate, decanal, β-caryophyllene, and α-farnesene, were obtained from Sigma-Aldrich Inc. (St. Louis, MO, USA), Alfa Aesar (Ward Hill, MA, USA), Fluka (Buchs, Switzerland) or TCI America (Portland, OR, USA). All, except α-farnesene (a mixture of various isomers) were greater than 97% purity. The 4,8-dimethyl-1,3(*E*),7-nonatriene was synthesized by oxidation of (*E*)-citral (Zhang et al. 2002) and then by Wittig reaction (Greenwald et al. 1963), and was a mixture of 95% (*E*)-isomer and 5% (*Z*)-isomer. Germacrene-D was isolated from golden rod as 91% germacrene-D and 9% β-caryophyllene (by USDA Chemistry Research Unit, Gainesville, FL, USA).

For all flight-tunnel bioassays and field tests, mixtures were prepared in ratios that corresponded to the ratios of compounds found in the collections of *V. riparia* shoots. For flight-tunnel bioassays, the blends with all identified compounds were mixed according to the ratios indicated by live plant samplings and diluted with hexane to 0.108 μg of total compounds in 1 μl of hexane. Preliminary flight-

tunnel experiments showed adequate moth responses to this concentration. All subsets of this blend were mixed at the same concentration as the blend with all identified compounds. For the field trial, the blend of compounds tested was diluted to 0.875 μg μl^{-1}. All the blends were stored in a freezer (−20°C) between tests.

Flight-Tunnel Assays Five-day-old females from a mating cage were used for flight-tunnel bioassays. Each cohort was set up using 10–15 female pupae (near eclosion) in a Plexiglas mating cage (30 cm H×30 cm W×30 cm D) and provided with 50% honey and water. Fifteen to 20 males (one antenna clipped for distinction from females) were added to the cage with a grape cluster. On average, 70% of females were mated by the fifth day, with copulation peaking on the second day (G. Loeb, unpublished data). The responses of female moths from the mating cage to grape shoots and volatile blends were assessed in a flight tunnel as described in Cha et al. (2008). After each flight-tunnel trial, the male and female moths were returned to the colony to maintain a consistent population level. We did not confirm mating status of females in the flight-tunnel experiments. The flight tunnel was 2 m in length by 0.6 m in width and 0.6 m in height, with a fan installed at the upwind end to create a steady airflow into the tunnel and an exhaust hood at the downwind end to evacuate odor from the flight tunnel. Wind speed was set at 0.25 m s^{-1} at the point of release of moths. A pattern made of dark green paper circles (10 cm diameter) was randomly presented both on a white background glass floor and on the glass ceiling below the light source. The upwind and downwind ends of the tunnel consisted of two layers of cheesecloth to prevent escape of moths. Light was provided from above by eight 25-W incandescent bulbs. Light intensity in the tunnel was 25 lx so as to mimic dusk conditions. During the experiments, the temperature and relative humidity of the flight tunnel were 23.3°C (±0.72 SD) and 23.2% (±0.32 SD).

All female moths were flown around dusk for the laboratory colony (over a 2-h period, from 1 h before to 1 h after dark). We tested individual moths in the flight tunnel, recording behavior for 8 min per moth. For each moth, we noted whether it left the release cage and made an upwind flight (more than 50 cm of tight, zigzag flight to within 10 cm of the target) as well as if it landed on (made contact with) the target. For data analysis, we categorized each moth based on the most complete behavior the moth displayed within an 8-min observation period. Thus, the behavioral responses of moths were categorized as 'no upwind flight' (no directed flight toward the target), 'upwind flight' or 'landing'.

We used freshly cut grape shoots and rubber septa (Thomas Scientific, Swedesboro, NJ, USA) loaded with synthetic blends as targets in the flight tunnel. A grape shoot (15 cm) was cut and immediately placed into a water pick just prior to flights as described in Cha et al. (2008). Freshly cut shoots were used because we found no difference in upwind flight or landing responses of females to freshly cut shoots or potted grape plants and because we wanted to minimize target size and eliminate possible contamination from pot or soil. In the flight tunnel, the cut shoot was apparent to female GBM. The target for a particular trial was placed at the upwind end in the center of the tunnel (30 cm from upwind end), affixed on an acetone-washed holder constructed of a glass rod and Teflon tubing. Female moths were introduced in the target plume (determined by using smoke from incense) at about 1.5 m downwind from the target in the center of the tunnel (30 cm from downwind end) in a small metal screen cage.

Field Experiment The field test was conducted during August and September of 2007 in a commercial vineyard near Rushville, NY, USA that had a history of severe GBM damage. We chose a custom-made plastic sheet trap for the field test, based on preliminary flight-tunnel tests of three different trap designs, including the Bio-lure Scenturion delta trap (Suterra LLC, Bend, OR, USA), a red ball trap (Zhang et al. 1999) and our custom plastic sheet trap, and by using the same seven-component blend we used in the field test. The Delta trap and red ball trap baited with the seven-component blend did not catch any upwind flying moths in the flight tunnel, whereas the plastic sheet trap captured 20% of the moths. The plastic sheet trap was constructed by overlaying 11 layers of plastic sheets (30 cm×30 cm; Kittrich Co., La Mirada, CA, USA) coated with STP Oil Treatment as the sticky substance. Each week one layer of plastic sheet was removed from each side, allowing us to monitor GBM for up to 6 weeks without applying additional oil. Each trap had six holes (2.5×2.5 cm) cut in two rows (three holes in top row and three holes in bottom row), with a rubber septum attached at each hole. Each hole was 5 cm apart and 6.25 cm from an edge of the trap. Each septum was loaded with 300 μl of one of the synthetic blends or hexane, and attached to the trap with an insect pin. For each hole, a pin was pressed through the middle plastic layer (2.5 cm below hole) and woven back out again in a manner that left the point of pin in the center of each hole. Rubber septa were replaced every 3 weeks.

We compared attractiveness of two different lures, the seven- and 11-component blends, as well as a hexane control, to female GBM. Each treatment was replicated four times in four blocks, with two traps installed (one trap per block) at the edge of a vineyard planted with *V. labrusca* (variety niagara) and two traps installed (one trap per block) at the edge of a forest contacting the vineyard. Traps were hung approximately 1 m from the ground and spaced at least 10 m apart. Traps were monitored twice weekly from

August 17, 2007 until September 11, 2007, yielding a total of seven assessments over a 25-day period. Each captured GBM was transferred to the laboratory, and its sex was determined under a dissecting microscope. Since the captured moths were usually drenched with oil, we could not determine whether the female moths were mated or not.

Statistical Analysis The attractiveness of different lure mixtures to female GBM was analyzed by using generalized linear models, with upwind flight or landing as dependent variables and different mixtures as a fixed independent variable, with binomial distribution with logit link function and maximum likelihood estimation (Proc Glimmix; SAS Institute 2006). The effect of the different type of lures (hexane control vs. seven-component vs. 11-component) and location of trap (forest edge vs. vineyard edge) on the number of male and female GBM captured over a 25-day period was analyzed by using repeated mixed model analysis of variance with Kenward–Roger degrees of freedom estimation and AR(1) as a covariance structure for repeated measures (Proc Mixed; SAS Institute 2000). Block was a random factor nested in location. Lure type, location, and time were fixed factors.

Results

Identification of Candidate Host Volatiles from V. riparia Shoots A total of four shoot samples were analyzed by SPME and GC-EAD by using at least five female GBM antennae for each sample. SPME sampling consistently revealed the same 11 significant antennal responses (Table 1). The EAD-active compounds were identified by comparison of mass spectra and GC-MS retention times with those of synthetic standards. The adsorbent collection of volatiles was made from four *V. riparia* shoots and the relative ratios of the 11 EAD-active chemicals determined by GC-MS and used in the flight-tunnel tests.

Flight-Tunnel Experiments for Identification of Key Host Volatiles: Negative and Positive Controls Responses of female GBM in the flight tunnel to hexane-loaded rubber septa and grape shoots were used as negative and positive controls, respectively. A total of 42 females were tested individually to a rubber septum loaded with 300 μl of hexane; the majority of these did not leave the cage, and those that did flew to the ceiling, sides, or back screen of the flight tunnel. A total of 144 females were flown to grape shoots and 73.6% (±3.7 SE) of them showed upwind flight. Thus, we used an upwind flight rate of 0% as our negative control and 73.6% as our positive control. Some 55.6% (±11.7 *SE*; $N=51$) of females tested exhibited upwind flight to the shoot extract; this was not significantly different from the responses to the shoots ($t_{24}=1.57$; $P=0.129$).

Flight-Tunnel Experiment 1 Based on the strength of EAD responses (Table 1), we first tested a blend composed of seven compounds, (*Z*)-3-hexenyl acetate, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, methyl salicylate, β-caryophyllene, germacrene-D, and α-farnesene (treatment 1, Fig. 1). This blend elicited 51.6% (±8.9 SE) of females to exhibit upwind flight responses, but this was not as attractive as actual grape shoots ($t_{36}=2.37$; $P=0.023$). Next, we tested whether there were possible deterrents in this blend by sequentially removing each of the components (treatments 2–8, Fig. 1). No deterrent was detected, as no blend with one component removed had significantly greater attraction

Table 1 EAD-active chemicals from shoots of *Vitis riparia* determined by SPME, GC-EAD, and GC-MS

Antennae active compounds	GC-MS (%)	EAD response (mV±SD)	Relative ratio in mix (%)	First seven-compo mix	Second seven-compo mix
(*Z*)-3-hexen-1-yl acetate	14.6	0.23±0.14	10	•	
(*Z*)-Linalool oxide	0.7	0.14±0.07	3		•
(*E*)-Linalool oxide	1.2	0.09±0.06	3		•
Nonanal	2.2	0.06±0.04	6		•
Linalool	1.7	0.50±0.40	6	•

β-caryophyllene	10.4	0.36±0.20	3	•	•
Germacrene-D	10.5	0.26±0.19	11	•	•
α-Farnesene	33.0	0.35±0.21	34	•	

Relative ratio (%) of peak areas of active compounds in the shoot extract and the strength of antennal response (mV±SD) to each of the active compounds are shown. All synthetic blends were mixed based on the relative ratio of compounds shown here. In addition, volatile components in the first seven-component blend (see "Flight-tunnel experiment 1") and second seven-component blend (see Flight-tunnel experiment 2) are shown

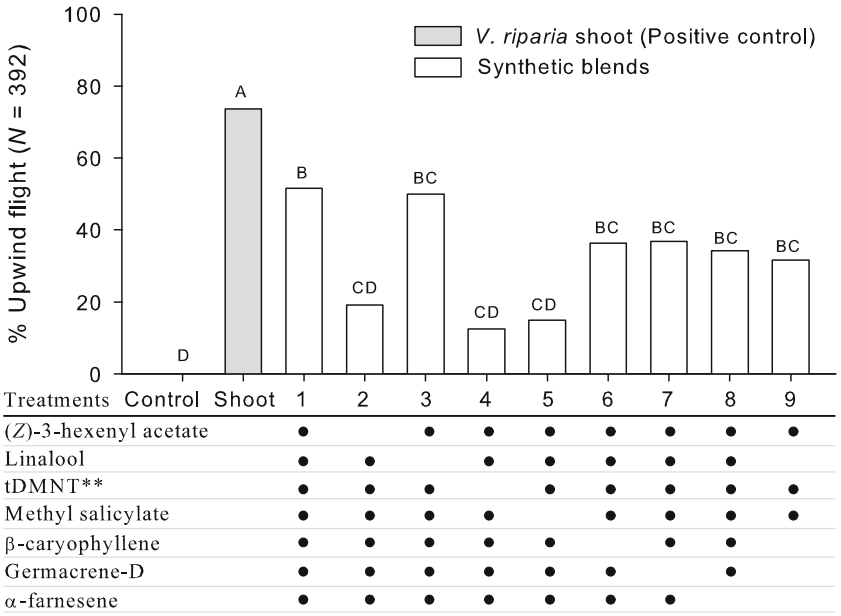

Fig. 1 Upwind flight responses (%) of female grape berry moth (N=392) in flight tunnel to hexane control (0%), *Vitis riparia* shoots (*gray bar*), and various synthetic blends (*white bars*). Treatment 1 was a mixture of seven compounds listed below the graph. Treatments 2–9 were subsets of treatment 1. At least 20 individual moths were flown to each synthetic blend tested. Different *letters on bars* indicate significant differences (P<0.05; *tDMNT: (*E*)-4,8-dimethyl-1,3,7-nonatriene)

compared to the original seven-component blend. However, from this experiment, (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene, and methyl salicylate appeared to be important components, since removing any of these resulted in significantly fewer upwind flights compared to the original blend (Fig. 1). The blend composed only of (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene, and methyl salicylate (treatment 9) elicited GBM flight responses not statistically different from those to the original blend (t_{36}=1.37; P=0.179). Three hundred and ninety two females were tested in this experiment.

Flight-Tunnel Experiment 2 The second set of flight-tunnel trials used all 11 EAD-active compounds listed in Table 1. This full blend elicited 68.6% (±7.8 SE) of females to exhibit upwind flight; this was not statistically different from that to grape shoots (t_{38}=0.60; P=0.55; treatment 10, Fig. 2). The removal from the blend of linalool, β-

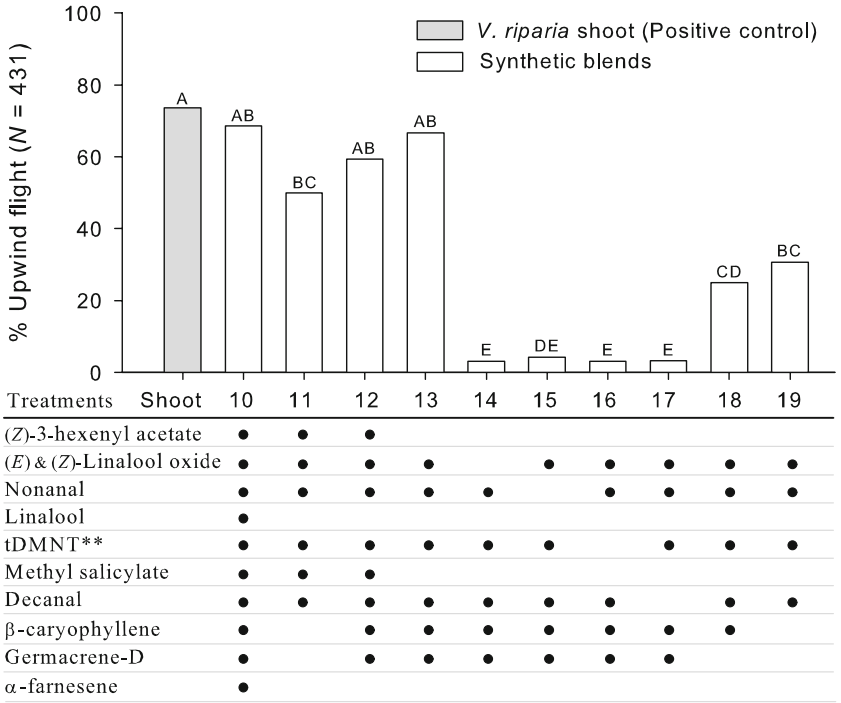

Fig. 2 Upwind flight responses (%) of female grape berry moth (N=431) in flight tunnel to *Vitis riparia* shoots (*gray bar*) and various synthetic blends (*white bars*). Treatment 10 was a mixture of 11 compounds listed below the graph. Treatments 11–19 were various subsets of treatment 10. At least 20 individual moths were flown to each synthetic blend tested. Different *letters on bars* indicate significant differences (P<0.05), except that P=0.051 for both "shoot vs. treatment 11" and "treatment 17 vs. treatment 18" (*tDMNT: (*E*)-4,8-dimethyl-1,3,7-nonatriene)

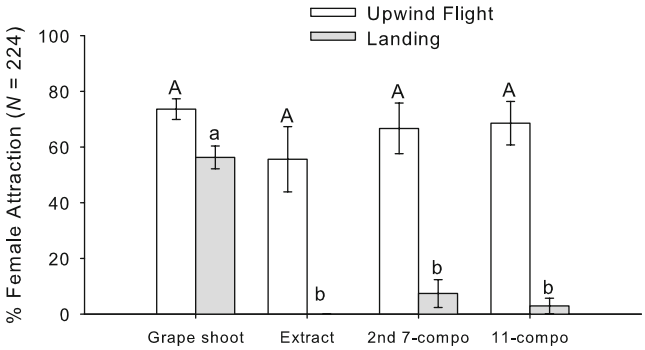

Fig. 3 Comparison of upwind flight (%) and landing (%) responses of female grape berry moth to *Vitis riparia* shoots, shoot extract and two synthetic blends. 11-component blend=(*Z*)-3-hexen-1-yl acetate, (*E*)-linalool oxide, (*Z*)-linalool oxide, nonanal, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, methyl salicylate, decanal, β-caryophyllene, germacrene-D, and α-farnesene; second seven-component blend=11-component blend minus (*Z*)-3-hexen-1-yl acetate, linalool, methyl salicylate and α-farnesene. Different *letters* (*capital letters* for orientation response and *small letters* for landing response) *on bars* indicate significant differences ($P<0.05$). *Error bars*=±1 SE

caryophyllene, germacrene-D, and α-farnesene, the four compounds that appeared not to be important based on the results of the first experiment, resulted in 50% (±11.8 SE) of GBM tested exhibiting upwind flight; this was not statistically different from the responses exhibited to the 11-component blend ($t_{38}=1.31$; $P=0.198$), but was marginally lower than that of the shoots ($t_{38}=2.02$; $P=0.051$). Adding β-caryophyllene and germacrene-D back to the blend (treatment 12) increased attractiveness to the level comparable to shoots.

In a further treatment, (*Z*)-3-hexen-1-yl acetate and methyl salicylate (treatment 13) were removed from the nine-component blend (i.e., 11-component blend minus linalool and α-farnesene) without reducing the attractiveness (66.7%±9.1 SE) of the mixture relative to that of the shoots or the original 11-component blend (Fig. 2). Linalool oxide, nonanal, (*E*)-4,8-dimethyl-1,3,7-nonatriene, and decanal were key components in this second seven-component blend. The removal of linalool oxide (as a 1:1 mixture of (*E*)- and (*Z*)-linalool oxide), nonanal, decanal, or (*E*)-4,8-dimethyl-1,3,7-nonatriene individually resulted in significantly lower (3.1~4.2%; treatments 14–17, Fig. 2) flight responses from females. In contrast, the removal of germacrene-D (treatment 18) or β-caryophyllene and germacrene-D (treatment 19) from the second nine-component blend resulted in only a 41.7% and 36.1% decrease (relative to that to the second seven-component blend), respectively, in upwind flight responses of females. Since the germacrene-D contained 9% of β-caryophyllene, however, we could not conclude that both germacrene-D and β-caryophyllene were essential compounds in the second seven-component blend. Four hundred and thirty one females were tested in this experiment.

Although the upwind flight responses of females to the 11- and second seven-component synthetic blends (treatments 10 and 13 in Fig. 2, respectively) were not significantly different ($F_{3,24}=0.93$; $P=0.442$) from those to grape shoots or shoot extract, there were significant differences among these treatments in terms of landing ($F_{3,24}=8.71$; $P<0.001$). In particular, the extract and synthetic blends elicited significantly lower landings from females in the flight tunnel compared to the shoots (Fig. 3). Two hundred and twenty four females were tested in this experiment.

Field Experiment In a late-season field trial, conducted in a high GBM-pressure commercial vineyard, traps baited with either the 11- or second seven-component blends caught significantly ($F_{2,15}=7.22$; $P=0.006$) higher numbers of female GBM than traps baited with a hexane control (Fig. 4); there was no significant effect of location (i.e., forest edge vs. vineyard) or time on catch of female moths. In contrast, there were no differences among treatments in the numbers of male moths captured ($F_{2,24.9}=0.08$; $P=0.925$). For males, however, we found a significant interaction among time, location, and lure ($F_{12,27}=2.47$; $P=0.025$). Overall, the total number of female and male moths captured was low (0.25 moths per day for best treatment), especially considering that the trial was performed in a high GBM-pressure vineyard. The best blend caught an average of four female moths/trap during the 25-day trapping period.

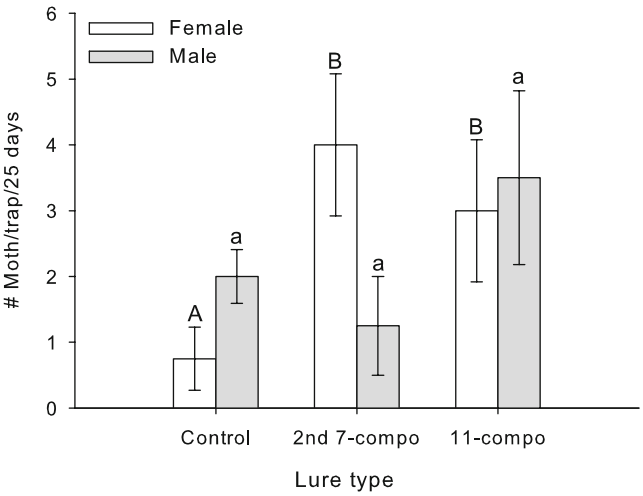

Fig. 4 Number of female and male grape berry moth captured in plastic-sheet traps, each baited with six rubber septa impregnated with a hexane control, the second seven-component blend or an 11-component blend in a commercial vineyard over a 25-day period. Eleven-component blend=(*Z*)-3-hexen-1-yl acetate, (*E*)-linalool oxide, (*Z*)-linalool oxide, nonanal, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, methyl salicylate, decanal, β-caryophyllene, germacrene-D, and α-farnesene; second seven-component blend=11-component blend minus (*Z*)-3-hexen-1-yl acetate, linalool, methyl salicylate and α-farnesene. *Error bars*=±1 SE

Discussion

We identified a blend of 11 volatile compounds [(*Z*)-3-hexen-1-yl acetate, (*E*)-linalool oxide, (*Z*)-linalool oxide, nonanal, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, methyl salicylate, decanal, β-caryophyllene, germacrene-D, and α-farnesene] from the shoots of *V. riparia*, a native host, that elicited an equivalent percentage of upwind flight by female GBM as that by intact shoots. Traps baited with this blend successfully caught female GBM in a vineyard. Subtraction of (*Z*)-3-hexen-1-yl acetate, linalool, methyl salicylate, and α-farnesene from this blend did not affect efficacy of the mixture with respect to eliciting both upwind flight responses of female GBM in a flight tunnel and trap catch in the field.

We originally hypothesized that the magnitude of antennal response in the GC-EAD analysis may indicate the relative importance (i.e., behavioral activity) of each of the compounds. However, this approach resulted in a blend that was not as attractive as grape shoots in our first set of flight-tunnel experiments. Addition of the four compounds that elicited the smallest antennal responses resulted in improved levels of upwind flight, comparable to that to grape shoots in the second set of experiments. This result suggests that the strength of antennal responses should not be assumed to correspond directly to behavioral activity.

Although both the 11- and second seven-component blends elicited upwind flight responses of female GBM comparable to that to grape shoots, the lower level of landing and low trap catches in the field to the synthetic blends suggest that their compositions may not be optimal for trapping female GBM. Several, non-mutually exclusive factors may be responsible for this. GBM could use both olfactory and visual cues for landing. For example, in *Lygus hesperus*, visual cues were shown to enhance the response to host-plant volatiles (Blackmer and Cañas 2005). GBM, a crepuscular species, oviposits dramatically less in the absence of light (Clark and Dennehy 1988), suggesting that females may use visual cues in this behavior. In addition, other chemicals, such as fatty acids, with low volatility present on grape leaf or berry surfaces could also elicit landing. For example, Wallace et al. (2004) reported that mated females of the spruce budworm preferentially oviposited on substrates treated with waxes from the needles of a host plant. Finally, CO_2 and moisture gradients released by grape shoots could affect close-range landing behaviors (references in Thom et al. 2004; Hilker and McNeil 2008).

The low-landing responses we obtained to the synthetic mixtures could also be due to a sub-optimal ratio of components in the blend. It has been suggested that many herbivores and parasitoids perceive a specific mixture of plant volatiles to locate their host reliably (Schoonhoven et al. 1998; Hilker and McNeil 2008). Such specificity can be mediated by species-specific host chemicals. However, the compounds in our two blends are relatively ubiquitous plant volatiles. In such a case, a species-specific ratio of common compounds could be a key to locating hosts within a complex environment of plant volatiles (Bruce et al. 2005; Hilker and McNeil 2008). Although we based the ratio of compounds in the blends on our adsorbent collections from live, potted plants, it is possible that the ratio of components we tested might not correspond exactly to that released by live grape shoots due to the adsorbent characteristics (Tasin et al. 2006b), and also the differential release rate of components from the rubber septa (Butler and McDonough 1979; Heath et al. 1986). The fact that we also observed low levels of landings on septa with the extract supports this contention, although other factors may also be involved.

Headspace volatiles were collected from live potted grapes to ensure that they were consistent in quality and quantity with that released by plants in the field, since physical wounding, such as cutting, could cause changes in volatile emissions both locally and systemically (Davies 1987; Rhodes et al. 1999). In the flight tunnel, however, we found both cut shoots and potted plants were equally attractive to female GBM, suggesting that cut-plant materials did not significantly affect behavior. However, immediately after excision, there was a six-fold increase in (*Z*)-3-hexenyl acetate released by shoots. This chemical, a green leaf volatile, is well recognized as a wound-induced compound (e.g., Engelberth et al. 2004), and also elicited a GC-EAD response from female GBM. Thus, the ratio of at least one GC-EAD-active compound, (*Z*)-3-hexenyl acetate, that was also considered essential in one of our blends (see below), appears to be not critical for female GBM behavior. Our future research will investigate explicitly the role of blend ratio of GC-EAD-active compounds to determine how GBM, a specialist herbivore, recognizes its host by using common, ubiquitous volatile compounds, and, if ratio is important, whether the ratios of all the GC-EAD compounds are important or just that of a subset of the compounds.

The results from the field-trapping experiment showed no significant differences in the number of males captured between traps with synthetic lures based on host-plant volatiles and control traps. This suggests that males may not be responding to the same blend of host-plant volatiles as females, similar to the findings in flight-tunnel trials for the European berry moth (e.g., Masante-Roca et al. 2007). However, definitive conclusions cannot be drawn since our field trial was conducted late in the season, and relatively few moths were captured.

Not all the volatile compounds isolated by GC-EAD were essential for eliciting upwind flight from female

GBM. Moreover, what compounds are essential appears to be context specific (e.g., Mumm and Hilker 2005; Hilker and McNeil 2008). For example, removal of (*Z*)-3-hexen-1-yl acetate, linalool, methyl salicylate, and α-farnesene from the 11-component blend gave equivalent levels of attraction as shoots. Removal of any of the remaining seven compounds, individually, significantly reduced attractiveness of the blend, suggesting that some or all of these seven compounds [(*E*)-linalool oxide, (*Z*)-linalool oxide, nonanal, (*E*)-4,8-dimethyl-1,3,7-nonatriene, decanal, β-caryophyllene, and germacrene-D] are essential for optimal attraction. However, with the first seven-component blend of (*Z*)-3-hexen-1-yl acetate, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, methyl salicylate, β-caryophyllene, germacrene-D and α-farnesene that we tested, we found that (*Z*)-3-hexen-1-yl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene and methyl salicylate were essential components of the blend. Therefore, the finding that some compounds, such as (*Z*)-3-hexen-1-yl acetate and methyl salicylate in this study, acted as essential components in one blend (i.e., the first seven-component blend; treatment 1 in Fig. 1) but not in another (i.e., the second seven-component blend; treatment 13 in Fig. 2) suggests that some plasticity exists in the volatile-based host recognition system of GBM. Such a context dependency may have important implications both for understanding the evolution of volatile-based host recognition of herbivores and for developing a synthetic lure that works in the field. Plasticity in recognition of host plants with different volatile blends could have been selected for to allow host location under seasonal and daily variation in host chemistry (e.g., Vallat and Dorn 2005; Hilker and McNeil 2008).

The long-term goal of our research is to develop a synthetic lure based on host-plant volatiles that can be used to monitor female GBM populations in the field as a way to improve the timing of management decisions. Our late-season field trial provides some reason for optimism that this approach is feasible. However, the low capture of moths indicates that significant hurdles remain. One problem is that synthetic lures may not stand out to females from the background volatile noise produced by the crop plant and the many other plants in the environment. Ultimately, we may need to discover some novel compounds that are uniquely attractive, either temporally or spatially. Furthermore, information on close-range visual and chemosensory cues may help improve the utility of volatile chemical-based lures for pest management.

Acknowledgments We thank Sara Villani, Charles Moser, Eric Smith, Shinyoung Park, Rachel Tucker, Mike Colizzi, Jessica Worden, Arianna Waheed, and Kevin Conley, for support on various aspects of this research, but particularly their efforts in maintaining the GBM colony and setting up mating cohorts. The manuscript was improved by comments from two anonymous reviewers and the subject editor for which we are grateful. We thank Aijun Zhang and Peter Teal for the gift of the (*E*)-4,8-dimethyl-1,3,7-nonatriene and germacrene-D, respectively. Authors also thank Arthur Agnello for plastic sheet trap design. Paul Robbins and Shannon Olsson provided valuable technical insights in the beginning of this study. Special thanks go to David Wise at Cornell University Glass Workshop for constructing volatile collection chamber and Jeff and June Pendleton for permitting us to perform field trial in their commercial vineyard. This research was supported by USDA NRI grant #2005-35302-16154 and USDA Viticultural Consortium.

(HIPVs) have been used to attract and retain beneficial insects into vineyards and hopyards (James 2003a,b, 2005), which has led to a reduction in pest densities (James and Price 2004; James and Grasswitz 2005). To date, however, little is known about practical application of HIPVs in cotton agroecosystems.

Lygus lineolaris and *Lygus hesperus* (Heteroptera: Miridae) are important pests of cotton and other crops in North America (Jackson and Graham 1983; Leigh et al. 1988; Wheeler 2001). The feeding mechanics of *L. hesperus* can be categorized as 'mechanical cell rupture-enhanced maceration' that involves stylet maceration of plant cells, injection of saliva, and ingestion of the saliva-cell content slurry (Backus et al. 2007). Selection of oviposition sites by mirids typically is preceded by probing with the mouthparts (Cobben 1978; Wheeler 2001), and we have observed this behavior by *L. hesperus* (Williams, unpublished data). Rodriguez-Saona et al. (2002) showed that feeding and oviposition by *L. hesperus* females induced emission of significant amounts of volatiles from cotton, and the level of emission was positively associated with the number of eggs laid on a plant. Williams et al. (2005) reported that feeding by virgin females of *L. hesperus* induced 2.6-fold higher emission of cotton volatiles than feeding by mated females, and treatment of maize plants with *L. hesperus* salivary gland extracts and artificial mechanical injury resulted in 2.7-fold higher emission of volatiles than artificial mechanical injury alone.

Anaphes iole (Hymenoptera: Mymaridae) is an egg parasitoid that attacks *Lygus* and other mirids in North America (Huber and Rajakulendran 1988). Parasitism rates can exceed 90%, and thus, this wasp is an important natural enemy of *Lygus* species that has potential for pest suppression (Ruberson and Williams 2000). Conti et al. (1996, 1997) demonstrated that chemical and physical cues were important for host acceptance (i.e., recognition and oviposition) by *A. iole* of *L. hesperus* eggs. Wasps on plants harboring host eggs utilized chemical cues from the host and injured host plant, as well as physical cues associated with eggs and oviposition sites for host acceptance. Oviposition behavior of *A. iole* was also influenced by the experience of female wasps (Conti et al. 1997). Naïve females spent more time examining host eggs than did females preconditioned by exposure to host eggs embedded in plant tissue. Subsequent behavioral studies demonstrated that *A. iole* females were attracted to odors derived from plants infested with *L. hesperus* in a four-arm olfactometer (Manrique et al. 2005). However, wasp perception of individual synthetic plant volatiles and their role in attraction to and parasitism of host eggs by *A. iole* have not been previously investigated.

The goal of the present study was to evaluate the responses of *A. iole* wasps to individual HIPVs by using a combination of electroantennogram (EAG), behavioral, and field studies. Because associative learning often increases the response of parasitoids to host-related volatiles (Vet and Groenewold 1990; Turlings et al. 1991; Steinberg et al. 1992; Conti et al. 1997; Drukker et al. 2000; Santolamazza-Carbone et al. 2004), we investigated the effects of experience on *A. iole* response to HIPVs. Specifically, we asked: (1) Do female and male *A. iole* antennae respond differentially to HIPVs? (2) Does experience influence *A. iole* response to (*Z*)-3-hexenyl acetate, a common green leaf volatile? (3) Does *A. iole* respond to individual HIPVs in a wind tunnel? and (4) Do HIPVs increase field parasitism by *A. iole*?

Methods and Materials

Insects *A. iole* used in this study were originally obtained from a laboratory colony maintained on *L. hesperus* Knight eggs at the US Department of Agriculture-Agricultural Research Service (USDA-ARS) Biological Control and Mass Rearing Research Unit, Mississippi State, MS, USA. After emergence, wasps were provided with distilled water and 1 M sucrose ad libitum. *A. iole* were reared in Plexiglass cages (26×26×20 cm) at 25±1°C, 60–85% relative humidity (RH), and 14:10 L/D photoperiod until experimentation (3-day-old adults).

Electroantennography Concentration Responses The compounds included in this study (Table 1) were tested individually as olfactory stimuli. For the EAG study, serial dilutions (0.1, 1.0, 10, and 100 μM) of each compound were made with paraffin oil (E. Merck, Darmstadt, Germany). Stimulus applicators were prepared by pipetting 25 μl of a test solution onto a 6×0.5 cm strip of Whatman no. 1 filter paper (Whatman International Ltd., Maidstone, Kent, UK), after which the filter paper was placed inside a 14.5-cm long glass Pasteur pipette. Fresh stimulus applicators were prepared after 2 h of use. Three controls were used: (1) an empty pipette, (2) a pipette containing 25 μl paraffin oil only on filter paper, and (3) a pipette containing 25 μl 100 μM octanal in paraffin oil on filter paper (octanal standard). Differences in volatilities (see Kovats indices, Table 1) of the test compounds permitted only relative comparisons between test chemicals, except for closely related compounds.

The EAG apparatus (Syntech Ltd., Hilversum, The Netherlands) was linked to a desktop computer (with IDAC-02 data acquisition interface board) on which recording, storing, and quantifying EAG responses were performed. The recording and indifferent electrodes were silver wires enclosed in drawn glass capillary tubes filled with phosphate-buffered saline (NaCl, 4 g; Na_2HPO_4,

0.57 g; KH_2PO_4, 0.1 g; KCl, 0.1 g in 500 ml distilled water; pH 7.4). Antennal preparations were made by cutting transversely through the mesonotum just anterior to the tegulae with a scalpel and mounting the thorax on the indifferent electrode. Both antennae remained intact, and the recording electrode was placed on the tip of one randomly chosen antenna. The antennal preparation was bathed continuously by a stream of charcoal-filtered and humidified air at a flow rate of 1 l/min. Air temperature and relative humidity was measured approximately 15 cm from the antennal preparation (overall ranges for all trials: 19.2–26.3°C, 28–52% RH).

EAG recording began 6 min after the antennal preparation was mounted. At this time, the following test protocol was used for each recording trial. The controls were tested in the following order: 1, 2, 3, 2, after which six randomly chosen chemical treatments were tested. For each chemical, order of delivery of the four concentrations was random. Delivery of controls (2, 3, 2) was made after each four-concentration series of a chemical treatment. After the final chemical treatment for each recording, controls were presented in the following order: 2, 3, 2, 1. Presentation of controls throughout the recording session permitted standardization of antennal responses. Test compounds and controls were applied (0.5-s pulse) at 30-s intervals separated by a purge of filtered–humidified air via an aluminum tube approximately 5 mm from the antenna. EAGs were measured as maximum amplitude of depolarization (mV). Each chemical was tested on 10 to 35 individuals of each gender.

Short-Range Olfactory Response to HIPVs Short-range walking response of parasitoids to HIPVs was measured with a four-arm olfactometer (Vet et al. 1983). The base of the arena was precision-machined aluminum with a groove for a rubber O-ring, and the top consisted of a circular piece of Plexiglass (30 cm diameter). The Plexiglass top had a hole (5 mm diameter) in the center to facilitate placement of a wasp into the arena. The hole was plugged with a Teflon-wrapped cork. The top of the arena was held securely to the base by spring clamps, and the O-ring seal ensured that the arena did not leak. Each arm of the olfactometer was divided into three regions: release, visit, and selection regions (Manrique et al. 2005). The airflow (25 ml/min per arm) inside the arena was equalized by using one flowmeter (Aalborg, Orangeburg, NY, USA) at each arm and a terminal flowmeter between the olfactometer and the pump (Model 400-3910, Barrant Co., Carrington, IL, USA). Charcoal-filtered and humidified air was passed through four 250 ml Erlenmeyer flasks that contained odor sources. A white 19-l plastic bucket was inverted over the olfactometer. The bottom of the bucket had been removed and covered with a light diffuser upon which a circular light (22 cm diameter) was placed. The outside of the bucket was covered with aluminum foil to ensure that it was opaque.

An observation hole (6×6 cm) was cut in the side of the bucket to facilitate visual recording of data. This hole remained covered except when observations were being made. The use of a white bucket over the olfactometer provided uniform light inside the arena and reduced bias from external visual cues. Smoke tests ensured that the system was working properly (Vet et al. 1983).

In all trials, a single HIPV treatment was compared against an untreated control. (*Z*)-3-hexenyl acetate was chosen because of the high antennal response recorded in the EAG study (Fig. 1). The HIPV stimulus was prepared in the same way that EAG stimuli were prepared (see above). After pipetting 25 μl of the test solution or paraffin oil only (untreated control) onto the strip of filter paper, it was placed inside an Erlenmeyer flask. Two treatment arms were assigned opposite one another, and the other two arms were untreated controls. Individual *A. iole* females were transferred into the center of the arena with a dissecting needle, and the hole in the top of the arena was plugged. Thereafter, the vacuum pump was turned on, and the bucket-light assembly was replaced onto the arena. Wasps not leaving the release site within 2 min of initiating a trial were replaced. Otherwise, each wasp was observed continuously for 5 min, and the time spent in each region of the arena was recorded with a multichannel timer. Individual *A. iole* females were used only once. After each trial, the inside of the arena was wiped with 70% ethanol, the arena was rotated 90° clockwise, and the treatments were randomly reassigned. The HIPV stimulus was replaced after 30 min use. Air temperature was measured inside the chamber (overall range for all trials, 20.8–25.0°C) during the bioassays (April–June; 1000 to 1700 hours CDT).

Trials were conducted to determine the effect of different preconditioning regimes on response of *A. iole* female wasps to a single HIPV. The goal was to partition the preconditioning effects of a single synthetic HIPV, a blend of 11 synthetic HIPVs, a host plant on which *L. lineolaris* had fed and oviposited, and an artificial egg pack of *L. lineolaris* eggs on the response by *A. iole*. Compounds were chosen because their levels increased after *Lygus* feeding (Rodriguez-Saona et al. 2002) and because of the strong concentration response we observed in the EAG trials (see below). *Erigeron annuus* was used because it is an important host of *Lygus* species. *E. annuus* was collected from the vicinity of Stoneville, MS, USA, and stems (6 cm-long) with flowers were caged with mated *L. lineolaris* females for approximately 12 h, thus permitting feeding and oviposition. Artificial egg packs into which *L. lineolaris* had oviposited (<24-h old) were also used as a treatment. For these last two treatments, insects were removed from plants or egg packs prior to

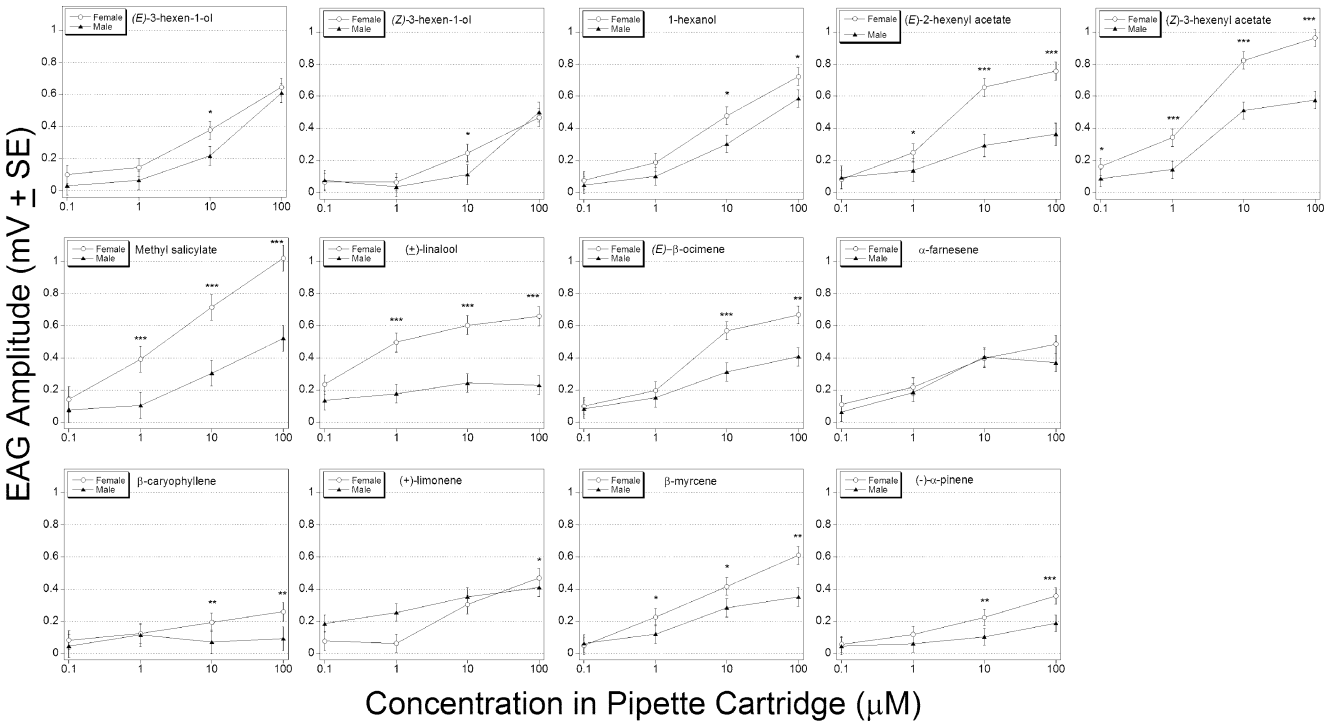

Fig. 1 EAG concentration–response curves of *A. iole* to 13 herbivore-induced plant volatiles. EAG amplitudes are control-adjusted and presented as proportional responses (mean±SE) to the standard, 100 μM octanal. Each compound was tested on 10 to 35 individuals of each gender. Significant differences between genders are noted by asterisks (*single asterisk* P=0.05–0.01, *double asterisk* P=0.01–0.001, *triple asterisk* P<0.001). P values correspond to ANOVA

experiments. Five preconditioning regimes were chosen to represent a range of signals, from simple to complex: (1) 10 μM (*Z*)-3-hexenyl acetate, (2) 1 μM each of 11 HIPVs (refer to Table 1), (3) *E. annuus* with *L. lineolaris* eggs, (4) *E. annuus* with *L. lineolaris* eggs + 10 μM (*Z*)-3-hexenyl acetate, and (5) *E. annuus* with *L. lineolaris* eggs + 1 μM each of 11 HIPVs. The exposure time for all preconditioning regimes was 45 min. For all these trials, wasps were tested with 100 μM (*Z*)-3-hexenyl acetate in the four-arm olfactometer. Different combinations of these four treatments allowed partitioning the effects of different odors on the behavior of *A. iole* wasps.

Long-Range Olfactory Response to HIPVs A horizontal wind tunnel was used to assess the behavioral response of *A. iole* at a larger scale than possible in a four-arm olfactometer. The wind tunnel was constructed of Plexiglass and measured 65 cm long×35 cm high×40 cm wide. It was subdivided into two compartments by a 34-cm-long partition at the upwind end. Each compartment received odors from either a treatment stimulus or untreated control. Charcoal filtered and humidified air was first pushed via pump (Model 400-3910, Barrant Co., Carrington, IL, USA) through 250 ml Erlenmeyer flasks containing either an odor source or blank control, and then into the two upwind wind tunnel compartments. HIPV odor sources were prepared as described for the four-arm olfactometer. Each compartment had four holes (each 5 mm diameter) to allow air flowing from the treatment chambers to enter the cage, and a flowmeter (Aalborg, Orangeburg, NY, USA) was used to regulate the overall airflow at 100 ml/min per hole. At the downwind end of the tunnel, there was a door with a rectangular window (19×15.25 cm) covered with nylon organdy that allowed introduction of wasps. At the downwind end of the tunnel, a piece of Plexiglass (20.3×35 cm) was glued from each side of the window to the side wall of the box, thus helping to funnel air toward the window. A computer muffin fan at the downwind end vented airflow from the tunnel. Smoke tests confirmed that air flowed through the chamber without mixing between treatment compartments. All outside walls of the box were covered with opaque white cardstock to provide uniform lighting and avoid external visual cues. The paper on the top of the wind tunnel had two holes (22 cm diameter) to facilitate illumination provided by two circular lights. The lights were placed parallel to the long axis of the chamber, with the outside edge of each light 10 cm from the edge of the chamber. The wind tunnel was rinsed with 70% ethanol after each bioassay. Temperature and humidity inside the room were measured (overall ranges for all trials, 20.8–24.0°C, 18–49% RH) during the bioassays (1100 to 1700 hours CDT).

In all trials with the horizontal wind tunnel, a single HIPV treatment was compared against an untreated control. (*Z*)-3-hexenyl acetate, methyl salicylate, and α-farnesene were chosen because of the high antennal responses observed in the EAG study (Fig. 1) and the responses in the four-arm olfactometer study. The HIPV stimulus was prepared in the same manner as EAG stimuli (see above); after adding 25 μl test solution or paraffin oil only (untreated control) onto a 6×0.5 cm strip of filter paper, it was placed inside an Erlenmeyer flask. The air pump, muffin fan, and lights were turned on 5 min before each release. Thereafter, 50 naïve *A. iole* females were released from each of four 20-ml glass scintillation vials (Kimble Glass, Inc., Vineland, NJ, USA) on the tunnel floor at the downwind end of the tunnel. The assay was terminated after 2 h, and the number of wasps on all walls of both compartments at the upwind end of the wind tunnel was counted. This procedure was repeated six times for each HIPV treatment, and the stimulus and blank controls were randomly reassigned to the two upwind chamber compartments after each repetition.

Field Parasitism A field investigation was conducted to determine the effect of synthetic HIPVs on parasitism of *L. lineolaris* eggs by *A. iole*. Based on our olfactometry studies and the work of Manrique et al. (2005), we hypothesized that host eggs in proximity to HIPVs would suffer greater parasitism than hosts associated with an untreated control. A cotton field (25 ha, *Gossypium hirsutum* L. var. DPL 215 BG/RR) was selected in Elizabeth, Washington Co., Mississippi (2.8 km E Stoneville; 33°25.4″ N, 90°52.8″ W). Agronomic practices (e.g., pesticide and fertilizer use) were consistent with those used in commercial cotton production, except no foliar insecticides were applied. This field was bordered on two sides by soybean, *Glycine max* (L.) Merr., one side by corn, *Zea mays* L., and on one side by a 12-m wide grass, *Cynodon dactylon* (L.) Pers., alley adjacent to natural vegetation (e.g., *Vitis* spp., *Ampelopsis arborea* (L.) Koehne, *Ambrosia trifida* L., *Quercus nigra* L., *Lonicera japonica* Thunberg, *Sambucus canadensis* L., and *Carya illinoensis* (Wangenheim) K. Koch.

A 6-ha portion of the cotton field was chosen for the study, and the experiment was arranged in a randomized complete block design with ten replicates of each of the following four treatments: (*Z*)-3-hexenyl acetate, α-farnesene, methyl salicylate, and an untreated control. These compounds were chosen because of our previous olfactometry results and previous studies on HIPVs with another mymarid (James 2005; James and Grasswitz 2005). Each plot was approximately 0.04 ha (20×20 m). HIPV bait-host egg stations were used to test the effect of synthetic HIPVs on parasitism of *L. lineolaris* eggs by *A. iole*. Each station consisted of a 45-ml

transparent plastic vial (12 dram crystal, Thornton Plastics, Salt Lake City, UT, USA) with four 1-cm diameter equidistant holes 5 mm from the top of the vial. Nested inside the plastic vial was a 20-ml glass scintillation vial (Kimble Glass, Inc., Vineland, NJ, USA) containing 2 ml of undiluted synthetic HIPV (see above) and a 1×5 cm piece of filter paper (Whatman no. 1, Whatman International, Ltd., Maidstone, England) that acted as a wick and enhanced volatilization of the HIPV. The plastic vial was closed with a white plastic cap to exclude rain and debris, and aluminum foil was wrapped around the vial, taking care not to cover the holes, to reduce ultraviolet light effects on the HIPV. In untreated controls, the scintillation vial contained only the strip of filter paper. The vial assembly was attached to a bamboo garden stake (65 cm long) so that the top of the dispenser was 45 cm above the soil surface. A *L. lineolaris* egg pack (9×9 cm) <2 days old was clipped to the bamboo stake 3 cm above the top of the dispenser.

One HIPV bait-host egg station was established in the center of each plot from 1530 to 1600 hours CST on 9 July 2004. Stations were placed in the furrow such that the top of the HIPV dispenser was 45 cm above the soil surface, and the egg pack was parallel to the row. Plants were removed such that there was no vegetation within 30 cm of the station; the destroyed plants were moved at least 10 m from the station to avoid bias of HIPV production from these plants. Approximately 1,000 naïve mixed gender wasps held in a glass scintillation vial were released 2 h later at each bait-egg station by placing the open vial on the soil beneath the host egg pack. Egg packs were recovered after 2 days and were held in an environmental chamber for 10 days at 25±1°C, 60–85% RH, and 14:10 L/D photoperiod. Egg packs were then observed under a dissecting scope at ×50, and parasitized and unparasitized eggs were counted. Parasitism data were expressed as the proportion of parasitized eggs in each egg pack. There was no difference in total host egg density per pack between HIPV treatments (mean=2,120, SE=101; F=1.73; df=3, 36; P=0.178). Voucher specimens of the wasps that were released are deposited in the National Entomological Collection, National Museum of Natural History, Smithsonian Institution, Washington, D.C., USA.

Data Analysis Maximum EAG responses were control-adjusted with the paraffin oil only control and expressed as proportional responses relative to the octanal standard. These data were then square root-transformed $(0.5(\sqrt{x}+\sqrt{x}+1))$ (Zar 1996), and analysis of variance, PROC MIXED (SAS Institute 2003), was used to compare maximum EAG deflection between gender and HIPV treatment–concentration combinations. Regression analysis was also used to assess the influence of gender and HIPV treatment on EAG amplitude (PROC REG and PROC MIXED; SAS Institute 2003). Due to heteroscedasticity over concentrations, a weighted regression (reciprocal of the variance) was calculated. Data from olfactometry studies were arcsine square root-transformed $(\arcsin(\sqrt{x}+\sqrt{x}+1))$ prior to two-tailed paired t test (selection region in the four-arm olfactometer) or G test for goodness of fit (flight tunnel; SAS Institute 2003). Data on parasitism were arcsine square root-transformed $(\arcsin(\sqrt{x}+\sqrt{x}+1))$ prior to single-factor analysis of variance (ANOVA) followed by mean comparison by using a one-tailed Dunnett's test of each HIPV treatment to the control (SAS Institute 2003). Untransformed values are presented for EAG, behavioral, and parasitism results.

Results

EAG Concentration–Response Curves Overall responses of female *A. iole* were significantly greater than male responses (F=76.52; df=1, 69.7; P<0.001). Female *A. iole* responses to (*E*)-2-hexenyl acetate at 1, 10, and 100 μM (F=2.47, 4.29 and 5.08, respectively; df=1, 1,205; P=0.014, <0.001, and <0.001, respectively) and to (*Z*)-3-hexenyl acetate at 0.1, 1, 10, and 100 μM (F=2.19, 3.41, 3.98, and 4.64, respectively; df=1, 1,200; P=0.029, <0.001, <0.001, and <0.001, respectively) were significantly greater than male responses (Fig. 1). For (*E*)-3-hexen-1-ol, (*Z*)-3-hexen-1-ol, and 1-hexanol, female responses were greater than those of males at 10 μM (F=2.56, 2.32, and 2.46, respectively; df=1, 1,203, 1,203, and 1,202, respectively; P=0.011, 0.021, and 0.014, respectively) and for 1-hexanol at 100 μM (F=2.00; df=1, 1,202; P=0.046). Female responses were greater than those of males at 1, 10, and 100 μM for methyl salicylate (F=3.34, 3.72, and 3.75, respectively; df=1, 1,204; P=<0.001, <0.001, and <0.001, respectively) for (±)-linalool (F=5.11, 5.19, and 6.29, respectively; df=1, 1,204; P<0.001), and for β-ocimene at 10 and 100 μM (F=3.53 and 2.93, respectively; df=1, 1,185 and 1,223, respectively; P=<0.001 and 0.004, respectively; Fig. 1). For β-myrcene, female responses were greater than those of males at 1, 10, and 100 μM (F=2.37, 1.97, and 3.25, respectively; df=1, 1,202; P=0.018, 0.049, and 0.001, respectively). For β-caryophyllene and α-pinene, female responses were greater than those of males at 10 μM (F=2.65 and 2.79, respectively; df=1, 1,205 and 1,199, respectively; P=0.008 and 0.005, respectively) and 100 μM (F=3.01 and 3.92, respectively; df=1, 1,205 and 1,199, respectively; P=0.003 and <0.001, respectively). For (+)-limonene, female response was greater than that of males at 100 μM (F=2.26; df=1, 1,202; P=0.024). For α-farnesene, there was no difference between female and male response at any concentration (Fig. 1).

Regression analysis of the impact of gender and HIPVs on antennal response indicated a linear response between antennal receptiveness (y) and HIPV concentration (log10 x; Table 2). Contrasts of slopes between the genders revealed greater ($P<0.05$) slopes for females for seven of the 13 HIPVs (Table 2). Ranked in order of P values (greatest to least significant), the seven significant compounds were: (*E*)-2-hexenyl acetate < β-myrcene = (±)-linalool < α-pinene = methyl salicylate < β-caryophyllene < β-ocimene (Table 2).

Comparison of slopes across herbivore-induced plant volatiles by gender showed that 42 comparisons were significant ($P<0.05$) for females, and 35 were significant for males (Table 3). For example, in females, responses to (*E*)-2-hexenyl acetate and (*Z*)-3-hexenyl acetate were not significantly different from one another, but each was different from β-caryophyllene, (*Z*)-3-hexen-1-ol, α-farnesene, (±)-linalool, (+)-limonene, and α-pinene. Female response to (*Z*)-3-hexenyl acetate was different from the response to (*E*)-3-hexen-1-ol and β-ocimene. The response of females to β-caryophyllene was significantly different from responses to all HIPVs except (±)-linalool. The matrix layout of Table 3 facilitates additional comparison of slopes for each gender.

EAG analyses clearly revealed that *A. iole* responded to the compounds tested. Although female antennae generally were more responsive than male antennae, both genders responded to most HIPVs. For females, methyl salicylate and (*Z*)-3-hexenyl acetate elicited significantly higher EAG responses than the other compounds tested. Wasps were least responsive to the monoterpenes β-caryophyllene and α-pinene. The two C_6 acetates, (*E*)-2-hexenyl acetate and (*Z*)-3-hexenyl acetate, had similar shapes of concentration–response curves, although wasps were more responsive to (*Z*)-3-hexenyl acetate. Two alcohols, (*E*)-3-hexen-1-ol and (*Z*)-3-hexen-1-ol, had similar-shaped concentration–response curves, but wasps were more responsive to the *E* isomer. At the two lowest concentrations tested, female wasps seemed to be most responsive to linalool and methyl salicylate.

Short-Range Olfactory Response to HIPVs A. iole females spent significantly more time in odor fields (selection regions) containing (*Z*)-3-hexenyl acetate compared to untreated control odor fields for trials using preconditioning regimes 3 (3.08 vs. 1.92 min; $t=2.31$; $df=28$; $P=0.028$), 4 (3.09 vs. 1.91 min; $t=2.24$; $df=25$; $P=0.034$), and 5 (3.29 vs. 1.71 min; $t=3.42$; $df=29$; $P=0.002$; Fig. 2). In contrast, significant responses to (*Z*)-3-hexenyl acetate were not detected for preconditioning regimes 1 (2.40 vs. 2.60 min; $t=-0.47$; $df=46$; $P=0.644$) and 2 (2.87 vs. 2.13 min; $t=1.73$; $df=51$; $P=0.090$).

Generally, responsiveness toward (*Z*)-3-hexenyl acetate increased as complexity of the preconditioning regime increased. For example, preconditioning regimes that included host plant (*E. annuus*) that had been subjected to feeding and oviposition by *L. lineolaris* led to the greatest attraction to (*Z*)-3-hexenyl acetate. The regime with the most complex odor mixture (*E. annuus* with *L. lineolaris* eggs + 1 μM each of 11 HIPVs) led to significantly greater attraction than did *Erigeron* and host eggs alone or 1 μM of

P values for males are in italics.

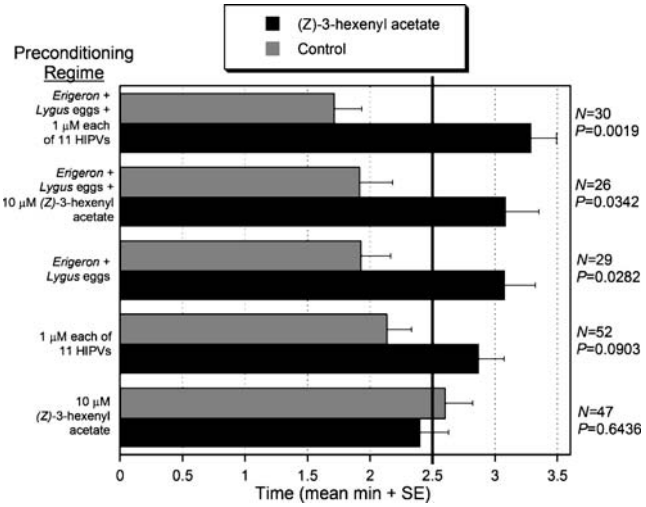

Fig. 2 Mean total time (+SE) that female *A. iole* wasps spent in treatment vs. control fields of four-arm olfactometer after exposure to different preconditioning regimes. Treatment odor was 100 μM (*Z*)-3-hexenyl acetate. *Solid vertical* line at 2.5 min indicates hypothetical value for equal response. *P* values correspond to paired *t* test

11 HIPVs, suggesting an additive or synergistic effect for the combination of *Erigeron* and host eggs alone or 1 μM of 11 HIPVs. In the simplest regime (10 μM (*Z*)-3-hexenyl acetate), the lack of behavioral response contrasted with EAG results that showed that *A. iole* females perceived (*Z*)-3-hexenyl acetate.

Long-Range Olfactory Response to HIPVs More naïve *A. iole* females were recovered from methyl salicylate (G=15.57; df=1; P<0.001) and α-farnesene (G=4.31; df=1; P<0.05) treatment compartments than controls; there was no difference in wasp numbers recovered from the (*Z*)-3-hexenyl acetate treatment and controls (G=3.61; df=1; P>0.05; Fig. 3). For this experiment, approximately 32% of the wasps were recaptured in the treatment and control compartments.

Field Parasitism Single-factor ANOVA revealed a significant HIPV treatment effect on parasitism (F=3.84; df=3, 36; P=0.018). Parasitism was greater in the α-farnesene (q=3.27; df=36; P=0.007) and (*Z*)-3-hexenyl acetate (q=2.42; df=36; P=0.053) treatments than in the untreated control. Mean parasitism ranged from 0.68% in the control to 2.57% in α-farnesene (Fig. 4). Parasitism was numerically but not significantly (P>0.05) greater for host eggs in the methyl salicylate treatment than the control (Fig. 4).

Discussion

An understanding of the chemical ecology of *A. iole* is essential before developing HIPV strategies for enhancing

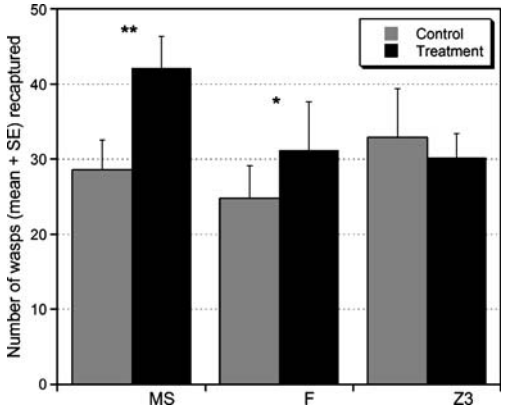

Fig. 3 Mean number (+SE) of female *A. iole* wasps recovered in treatment vs. control compartments of a horizontal wind tunnel. *Empty bars* indicate controls; *solid bars* indicate treatments [*MS* methyl salicylate, *F* α-farnesene, and *Z3* (*Z*)-3-hexenyl acetate]. Significant differences are noted by *asterisks* (*single asterisk* $P<0.05$, *double asterisk* $P<0.001$) using *G* test for goodness of fit. $N=6$ replicates per tested compound

biological control of *Lygus* species. This study used a variety of approaches to study the response of *A. iole* to HIPVs. Our EAG analyses on *A. iole* are the first that we are aware of on a mymarid, and we found that the strongest antennal responses were elicited by (*Z*)-3-hexenyl acetate and methyl salicylate. The greater female antennal responses may be adaptive given that these compounds are associated with the presence of host eggs. Male perception of HIPVs might reflect their use as cues for locating female conspecifics. Behavioral studies revealed that the response to (*Z*)-3-hexenyl acetate was dependent on wasp experience. In further behavioral studies, naïve *A. iole* females were responsive to methyl salicylate and α-farnesene but not to (*Z*)-3-hexenyl acetate. In a field

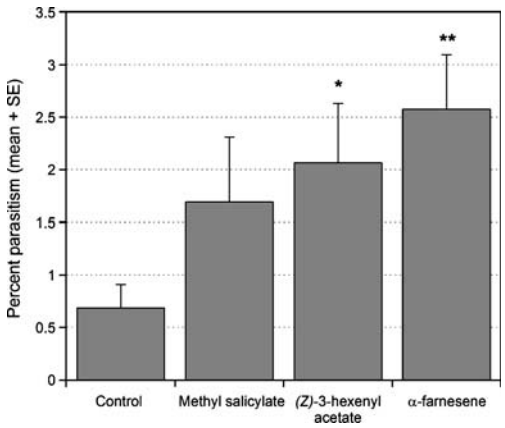

Fig. 4 Percent mean parasitism (+ SE) by *A. iole* of *L. lineolaris* eggs baited with single herbivore-induced plant volatiles in a cotton field. Significant differences for Dunnett's test of each treatment vs. the control are noted by *asterisks* [(*Z*)-3-hexenyl acetate, $P=0.053$; α-farnesene, $P=0.007$). $N=10$ replicates per tested compound and control

experiment, (*Z*)-3-hexenyl acetate and α-farnesene increased egg parasitism by *A. iole*.

Vet and Dicke (1992) proposed a conceptual framework for infochemical use in parasitoid–host and predator–prey interactions. An important issue in this framework is the reliability-detectability problem faced by foraging natural enemies, i.e., that cues from the host or prey are reliable but not easily detectable and, conversely, that signals from plants damaged by the host or prey are more easily detectable but not necessarily reliable. Detection of host-specific cues has important implications for the use of HIPVs in pest management, i.e., HIPVs must be attractive to natural enemies of the herbivore species that cause the injury. Recent studies recognize a growing list of parasitoids that can distinguish between host and non-host HIPVs (Du et al. 1996; Dicke 1999; Meiners et al. 2000; Moraes et al. 2005), including *A. iole*, which is attracted to cotton volatiles emitted after injury by its host, *L. hesperus*, but not by a non-host, *Spodoptera exigua* (Manrique et al. 2005). However, the present study also indicated that a single, relatively ubiquitous HIPV can be attractive to *A. iole* and can lead to increased parasitism. The green-leaf volatile, (*Z*)-3-hexenyl acetate; the sesquiterpene, α-farnesene; and the carboxylate ester, methyl salicylate, are all produced and released by plants in response to injury by *Lygus* species (Rodriguez-Saona et al. 2002; Blackmer et al. 2004; Williams et al. 2005) and by other herbivores (Turlings et al. 1991; Loughrin et al. 1995; Röse et al. 1996; Paré and Tumlinson 1998). Thus, it appears that *A. iole* can use either host-specific or general volatile cues in the process of host habitat location.

Under field conditions, the variation in production and emission of HIPVs by plants likely complicates the signal perceived and utilized by parasitoids for host location. However, associative learning, i.e., association of host-specific volatiles with the presence of hosts, is a possible solution to this problem (Vet and Groenewold 1990; Vet and Dicke 1992; Kaiser et al. 2003; Randlkofer et al. 2007; Schröder et al. 2008). Compared to larval parasitoids, little is known on the learning capabilities of host-plant-derived cues in egg parasitoids. Egg parasitoids are less expected to use plant-derived cues or to learn; instead, they are likely to use host-derived cues (i.e., host adult pheromones) that are highly predictable within and between generations during foraging (Vet et al. 1995). Recent studies have shown that egg parasitoids use not only short-distance (host-associated) cues but also may use long-distance volatiles, such as those associated with the host plant (Meiners and Hilker 1997; Hilker et al. 2002; Hilker and Meiners 2006). Because host-plant volatiles are highly detectable but less reliable than host-associated odors, learning might be critical for egg parasitoids that employ host-plant volatiles in host finding (e.g. Mumm et al. 2005). Schröder et al. (2008) hypothe-

sized a contextual learning sequence by a eulophid that is mediated by both a sugar food source and by the presence of host eggs of a suitable age. The present study and those by Conti et al. (1997) and Manrique et al. (2005) show that *A. iole*, a parasitoid that specializes in *Lygus* spp. eggs, uses host-plant volatiles and that both innate and learned responses are important in host finding. Naïve wasps responded to methyl salicylate and α-farnesene but needed to learn host-plant odors before responding to (*Z*)-3-hexenyl acetate. These three volatile compounds are common in many plant species, and one or more of them are induced in cotton, maize, and alfalfa following herbivory by *L. hesperus* (Rodriguez-Saona et al. 2002; Blackmer et al. 2004; Williams et al. 2005). It is, therefore, not surprising that *A. iole* uses more than one volatile cue to find hosts; still, a single compound was sufficient to attract wasps in both laboratory and field experiments. This was confirmed by the fact that several plant volatile compounds elicited an antennal response from *A. iole*, albeit at different amplitudes. Associative learning, however, was not a requisite for host-habitat location by *A. iole* given that naïve wasps responded to HIPVs under both laboratory and field conditions.

Field studies that address the applicability of using HIPVs for the protection of agricultural crops are limited but promising. Drukker et al. (1995) and Shimoda et al. (1997) reported higher densities of predators in the proximity of host-infested plants than near uninfested plants. Several investigators have applied signal molecules, such as jasmonic acid or methyl jasmonate, to plants and demonstrated increases in oxidative enzymes (Thaler 1999), proteinase inhibitors (Rodriguez-Saona et al. 2005), and HIPVs (Ockroy et al. 2001; Rodriguez-Saona et al. 2001). Thaler (1999) also reported increases in parasitism of *S. exigua* on induced plants versus controls. A series of field studies demonstrated that sachets of individual synthetic HIPVs could be used to attract and retain natural enemies in perennial crop systems (James 2003a,b; James and Price 2004; James and Grasswitz 2005). In particular, these studies showed that (*Z*)-3-hexenyl acetate, farnesene, and methyl salicylate could be used to manipulate behavior of beneficial insects under field conditions. These three compounds were attractive to numerous predators and parasitoids; methyl salicylate attracted the broadest diversity of insects and farnesene the least (James 2005; James and Grasswitz 2005). However, all compounds attracted the mymarid *Anagrus daanei* and other *Anagrus* species, although this effect was inconsistent. In our field study with the mymarid *A. iole*, we found that host eggs baited with (*Z*)-3-hexenyl acetate or α-farnesene suffered greater parasitism than untreated controls. The low overall rate of parasitism (approximately 2.6%) may be due to the unnaturally large number of host eggs present in a single patch and the propensity of *A. iole* to disperse its eggs among host patches. Wasps may also have been more strongly attracted to volatiles emitted by nearby cotton plants.

This study provides evidence that plant volatiles represent key semiochemical signals in the recognition of and attraction to host-associated patches by *A. iole*. Bloem and Yeargan (1982) reported that *Anaphes diana* (=*Patasson lameerei* Debauche) used its antennae to differentiate between volatiles from host-damaged vs. undamaged plants and from host vs. non-host frass. The authors proposed that volatiles from host-damaged plants and from host frass play important roles in the host-finding sequence of *A. diana*. It would be adaptive for host-specific natural enemies of *Lygus* to recognize and walk or fly to host-associated habitats. Prior work by Manrique et al. (2005) found that *A. iole* females can discriminate between plant odors emanating from *Lygus*-damaged vs. non-host damaged plants. Here, we identified several plant-produced compounds that, upon further development, might be useful tools to manipulate *A. iole* behavior to enhance *Lygus* suppression. Future recordings from antennal sensilla might help determine if the structurally similar compounds [(*E*)-3-hexen-1-ol vs. (*Z*)-3-hexen-1-ol] are detected by the same or different types of receptor cells and if specific receptor cells exist for certain compounds. Likewise, further lab and field studies of other plant- and host-associated compounds not included in this study, mixtures of compounds, and identification and behavioral testing of GC-EAG active compounds, would be worthwhile.

Based on our current understanding of *A. iole* host foraging, we propose the following host-finding sequence for this egg parasitoid. The proposed sequence does not exclude the possible roles of other sensory modalities (e.g., vision). This sequence is similar to that proposed for *A. diana* (Bloem and Yeargan 1982) and fits into the conceptual framework of Vet and Dicke (1992): (1) detection of the host habitat via host-specific HIPVs; (2) nonrandom and random searching for host eggs on the plant guided by physical and chemical (volatile and/or tactile) cues from host and plant; (3) recognition and acceptance of host eggs directed by physical and chemical (volatile and/or tactile) cues from host eggs and associated plant tissue.

Acknowledgments We are grateful to D. A. Streett, A. C. Cohen, B. Woods, G. McCain, and D. A. Nordlund (USDA-ARS BCMRRU, Mississippi State, MS, USA) for supplying *A. iole* and *L. lineolaris* egg packs. The authors thank A. A. Faulkner, C. Li, and V. Manrique for technical assistance and J. L. Blackmer, J. M. Patt, L. L. Stelinski, and anonymous reviewers for critical and helpful comments on the manuscript. This article reports the results of research only. butterflies such as *M. cinxia* lay their eggs in clusters, often depositing a single cluster in a day (Wahlberg et al. 2004; Saastamoinen 2007). Butterflies that lay eggs singly must often seek at least 20–50 oviposition sites per day and thus may be more time limited than egg limited (Courtney 1982), whereas for butterflies that lay their eggs in clusters, the costs of prolonged search or host assessments may be beneficial (Singer 2004).

In general, butterflies are attracted to alight on plants through a combination of visual and olfactory stimuli (Rausher 1978; Feeny et al. 1989; Janz and Nylin 1997). A positive response to visual stimuli is to alight and taste a plant. To assess whether a plant is chemically acceptable, a female checkerspot butterfly scratches the surface of a leaf with the first pair of tarsal claws. This scratching damages the leaf surface and facilitates the release of chemical stimuli that are assessed by the female butterfly. If the plant is accepted for oviposition, the butterfly curls her abdomen to the underside of a leaf and oviposits. In checkerspot butterflies, plant acceptance depends on the physical features of the oviposition site such as the size, shape, and orientation of the leaf (Singer 2004).

Most checkerspot species are oligophagous or even monophagous on plant species that produce iridoid glycosides (IGs) as plant secondary compounds (Bowers 1983; Jensen 1991; Wahlberg 2001; Murphy et al. 2004; Reudler Talsma et al. 2008). In this study, we focus on two IGs, aucubin and catalpol, which are found in more than ten Asteridae plant families (El-Naggar and Beal 1980; Olmstead et al. 2000). These IGs are known to be oviposition cues for the specialist butterfly *Junonia coenia* (Pereyra and Bowers 1988) and feeding stimulants for larvae of at least some checkerspot butterflies (Bowers 1983). *M. cinxia* larvae perform better on diets high in iridoid glycosides (Harvey et al. 2005; Saastamoinen et al. 2007).

Nieminen et al. (2003) examined the natural pattern of oviposition by *M. cinxia* on their food plant, *P. lanceolata* in the field. The authors compared plants used for oviposition with neighboring and random plants in the patch. They found that plants used for oviposition contained significantly higher concentrations of aucubin than neighboring and random plants. Additionally, plants selected for oviposition and random plants had higher catalpol concentrations than neighboring plants. This suggests that ovipositing females selected plants with higher IG concentrations, or at least with higher concentrations of aucubin.

An alternative explanation for the positive association between IG concentrations and oviposition in Nieminen et al. (2003) is that the presence of butterfly eggs on leaf tissues leads to an induction of IGs in the plant. Studies of other insects have reported that allelochemicals in plants can be induced through oviposition and the presence of eggs on, or imbedded in, the leaf surface (Agrawal 2000; Colazza et al. 2004; Hilker et al. 2005). Induction of IGs by *M. cinxia* oviposition has not been investigated thus far, but IG production in *P. lanceolata* can be induced both by fungal infection (Marak et al. 2002) and by herbivory (Darrow and Bowers 1999; Stamp and Bowers 2000). Furthermore, Peñuelas et al. (2006) found that the leaves of *Lonicera implexa* (Camprifoliaceae) with egg clusters of *Euphydryas aurinia* (a close relative of *M. cinxia*) had 15-fold higher concentrations of IGs than leaves directly opposite on the same plant.

Plant size as well as chemistry may influence butterfly oviposition choice. Large plants may receive more eggs than small plants simply because they are visually conspicuous and difficult to leave accidentally after alighting. If the butterfly can perceive size, then large plants may also be used because they are more suitable for larval development. For instance, the gregarious *M. cinxia* larvae seldom move to another individual plant during early instars (although this can happen, see "Results"), so they would benefit from a large oviposition plant (Kuussaari et al. 2004). Indeed, Nieminen et al. (2003) found that naturally occurring egg clusters tended to occur on larger than average plants. More generally, the 'plant vigor hypotheses', elaborated by Price (1991), predicts that vigorous pants that reach a larger than average size should be preferred by herbivores. Both plant biomass and nutritional quality may be higher in vigorous plants (Heisswolf et al. 2005; Lastra et al. 2006).

We performed a set of dual- and multiple-choice experiments in cages and in the field to answer the following questions: (1) What is the effect of *P. lanceolata* plant chemistry on the oviposition behavior of *M. cinxia*? (2) Does oviposition cause induction of IGs in the host plant? (3) What is the effect of plant size (measured as number of leaves) on the oviposition behavior of *M. cinxia* butterflies?

Methods and materials

Study Species M. cinxia (Glanville fritillary) butterflies used for these experiments were the offspring of field-caught butterflies from Åland, SW Finland. In Åland, the butterflies fly in June and lay large clusters (150–200 eggs) on the underside of leaves of *P. lanceolata* and *Veronica spicata* L. (Plantaginaceae) (Kuussaari et al. 2000). Larvae hatch after 2–4 weeks depending on the temperature. The larvae spin a communal web on the host plant and feed gregariously throughout the summer. Because of restricted mobility, small larvae usually depend on the host plant the adult female chose for oviposition. Larvae diapause gregariously as L5 in a silk winter nest and become active

again in spring. In the last instar (L7), larvae disperse and feed individually. They pupate within the vegetation in mid May (Kuussaari et al. 2004).

P. lanceolata (ribwort plantain) is a perennial plant with a worldwide distribution (Sagar and Harper 1964). In natural populations, IG levels range from undetectable to ca. 9% of dry weight (Bowers 1991). In the field in Åland, these concentrations range between 0.6% and 2.2% for aucubin and between 0.7% and 2.0% for catalpol (Nieminen et al. 2003). The variation in the constitutive IG amount in *P. lanceolata* is partially genetically determined (Adler et al. 1995; Bowers and Stamp 1992, 1993). Most plants used for oviposition experiments were derived from an artificial selection experiment, in which plants were selected on the basis of high and low concentrations of total leaf iridoid glycosides for four generations (Marak et al. 2000). For experiment 1 (see below), nine plants, each derived from a different half sib family from the low selection line, and six plants, each derived from a different half sib family from the high selection line, were clonally propagated following root cloning (Wu and Antonovics 1975). This resulted in 15 different genotypes. In addition, for experiments 2 and 3, five new crosses were made between pairs of plants of the low selection line and five crosses between pairs of plants of the high selection line. From each of these crosses, a single offspring was raised and clonally propagated. This resulted in five from the low (L1–L5) and five genotypes originating from the high (H1–H5) IG selection line. Since not all genotypes originating from the high selection line have higher IG concentrations than all genotypes originating from the low selection line under all environmental conditions (see "Results"), we use differences in IG between genotypes, rather than selection lines, as the basis of our experiments. In experiment 1, we included 15 more plants that were collected from the field in Åland to extend the range of variation in concentrations of aucubin and catalpol used in the experiment. Although these plants had similar IG concentrations as genotypes from the selection lines (field plants 4.3±0.5% dry weight (dw); plants from the selection lines 4.5±0.5% dw), they had lower average concentrations of aucubin but higher average concentrations of catalpol (see Fig. 4).

Oviposition Experiments Three experiments were carried out to study the oviposition behavior of *M. cinxia* in response to concentrations of iridoid glycosides and plant size of *P. lanceolata.* In experiments 1 and 2, we offered potted plants to butterflies in cages by using dual (exp. 1) or multiple (exp. 2) choice tests. In experiment 3, we transplanted plants and butterflies to a natural field plot. Experiments were carried out in Finland, except for one of the cage experiments (exp. 2) that was carried out in the Netherlands. In the cage experiments, none of the plants flowered, and *M. cinxia* females usually laid a single egg batch per plant.

Experiment 1: Small Cages, Finland In total, 30 pairs of plants were used in dual-choice oviposition tests, using eight small mesh cages (38×38×44 cm) over the course of 13 days in June 2005, when the weather was sunny and warm. Cages were placed outside the Nåtö Biological Station, Åland, Finland. In 18 trials, we used sets of two *P. lanceolata* plants of different genotypes, one randomly selected from the nine genotypes of the low, and one randomly selected from the six genotypes of the high selection line. In 12 other trials, we used sets of two of the Finnish plants from the field. Before the plants were put in the cage, we counted the number of leaves, and the second fully expanded leaf was taken to determine its IG content by using high-performance liquid chromatography (HPLC) analyses. A mated female *M. cinxia* butterfly was put into each cage along with a sponge saturated with honey water (1:3) to provide a source of water and food for the butterfly. At the end of the day, all plants and butterflies were removed from the cages. Plants were then searched for butterfly egg clusters. The following day, the number of eggs in each cluster was counted. This process was repeated with new plants and butterflies without oviposition experience. If a butterfly died in the cage, and there was no oviposition, the same pair of plants was used again with a new butterfly. In total, 44 different female butterflies were used, and 19 of them oviposited.

To see if there was systemic induction of IGs in the plant after oviposition, we determined the IG concentrations in leaves from 28 plants that received eggs (19 from experiment 1 and an additional nine from a similar unpublished experiment). We compared the IG concentration of the second fully expanded leaf, sampled before oviposition, with that of a leaf from the same rosette ring as the one that bore the egg batch. This leaf was sampled the evening after oviposition.

Statistical Analyses Cage trial was used as the experimental unit. In 19 of the cages, oviposition was observed. In 17 cases, butterflies oviposited on only one of the two plants. In two cases, butterflies oviposited on both plants, but laid a "normal-sized" cluster on one plant (overall clutch size ± SE=121±22) and only a few eggs (18 and 23, respectively) on the other plant. Only plants with the "normal-sized" clusters were considered as oviposition plants in the analyses. Paired *t* tests (STATISTICA version 7.1 (StatSoft Inc., Tulsa, OK, USA) were used to test whether within a cage leaf IG concentrations and plant size (number of leaves) differed between plants with and without oviposition. The number of leaves, the number of eggs, and the aucubin concentration were log10-transformed prior to

analyses to meet the assumptions of normality and homogeneity of variances. We used Pearson's correlations to test for associations of egg cluster size with the iridoid concentrations and plant size (number of leaves).

Experiment 2: Large Cages, the Netherlands Ten cages (1×1×1 m) were placed outside near the Netherlands Institute of Ecology at Heteren. In each cage, we placed ten plants, five genotypes originating from the low (L1–L5) and five originating from the high IG selection line (H1–H5; see study species). Each cage represented a single replicate. We counted the number of leaves on each plant and collected the sixth fully expanded leaf for chemical analyses. A male and female of *M. cinxia* were released into each cage. Over the following days, we checked for evidence of oviposition, but if oviposition occurred, we did not remove the plant or the butterflies. We marked the leaves onto which the female butterflies had oviposited, but did not remove the eggs. If a female died without ovipositing, she was replaced by a new female. The experiment was terminated when all of the butterflies had died. In total, we used 13 female butterflies from 25th May until the 16th June 2003, six of these butterflies laid eggs.

Statistical Analyses Cages were used as the experimental unit. Paired *t* tests were used to test whether average IG concentrations and the number of leaves differed between plants with and without oviposition events within a cage. Aucubin was log10-transformed, and catalpol and total IG values were square-root-transformed prior to analyses to meet assumptions of normality and homogeneity of variances. Associations of plant size with iridoid concentration were compared by using Pearson's correlations.

Experiment 3: Uncaged Field Experiment, Finland We used the same ten genotypes of *P. lanceolata* as in the above experiment, L1–L5 and H1–H5. In the fall of 2001, we made 40 clonal replicates of each genotype by using the root-cloning method from Wu and Antonovics (1975). Plants were maintained over the winter in 11 cm pots filled with potting soil in an unheated greenhouse in Heteren, the Netherlands. In May 2002, roots of the ca. 25-cm tall plants were washed to remove adhering potting soil, put in moist bags, shipped to Finland, and stored at 4°C until transplantation. A small field was selected as transplantation site, in an open, dry rocky area on peat soil with sparse shrubs and trees near Tvärminne Zoological Station, SW Finland (59° 50′35 N, 23°14′54 E). This site represents a suitable habitat within the distribution range of *P. lanceolata* and *M. cinxia*, but neither of the species was present. On May 11, 2002, plants were planted in 40 patches of ten plants, with each patch containing one individual of each genotype. Roots were gently placed in small slits in the soil to minimize disturbance of the natural vegetation. Plants within the patches were planted 10 cm apart, and the patches were at least 2 m apart. They were watered as required.

M. cinxia larvae were collected from Åland in 2001, overwintered as fifth instar in the lab at Nåtö Biological Station, Finland, and pupated in the spring of 2002. From the 300 reared pupae, 269 adult butterflies (134 ♂ and 135 ♀) emerged, and were introduced in the field site the morning after they had emerged. This occurred between June 6 and 9, 2002, when the experimental plants had regrown new leaves under the prevailing conditions.

We harvested the two youngest fully expanded leaves of each plant from seven patches and air-dried them for HPLC analysis of IGs to estimate the average concentration of IGs for each genotype in the field. Starting when the first butterflies were released on June 6, plants were checked daily for the presence of egg clusters. Egg clusters were left in place and we recorded whether eggs hatched and whether caterpillars managed to produce a winter nest. As some caterpillars moved from the oviposition plant to nearby plants, the number of damaged plants exceeded the number of plants on which oviposition occurred, and some winter nests occurred on non-oviposition plants. On June 15, we measured the number of leaves and the length and width of the longest leaf of each experimental plant. All plants in the field were of the same age because they were cloned at the same time.

Statistical Analyses Differences in plant size and iridoid glycoside concentrations among genotypes and patches were analyzed by using generalized linear models (Procedure GENMOD, SAS v. 8.2, SAS Institute, Cary, NC, USA) with a normal error distribution. Leaf length, leaf width, leaf number, and the product of these ("plant size index"), as well as the concentrations of aucubin, catalpol, and total IG were square-root-transformed prior to analyses to meet assumptions of normality and homogeneity of variance. Plant size index was used as a covariate in analyses of iridoid glycosides to estimate size-independent genotypic differences in secondary chemistry. Effects of plant size, genotype, and patch on the number of egg clusters, number of hatched clusters, and number of diapausing clusters per plant were analyzed by using a GLM with a Poisson error distribution and a log-link function after $(x+1)$ transformation of the independent variables. Since concentrations of aucubin and catalpol were measured only in a subset of the plants and yielded insufficient data on phenotypic associations between secondary metabolites and oviposition, the effects of aucubin and catalpol on oviposition were assessed by using the mean genotypic concentration. We performed univariate and multiple regression of genotype means for size and secondary metabolite concentrations on genotype

means for oviposition traits (number of egg clusters laid, hatched, and surviving to diapause).

Chemical Analyses The second fully expanded leaf was taken from all the *P. lanceolata* plants used in experiment 1. They were air-dried in open envelopes as were the leaves collected from the field plot in experiment 3. The sixth fully expanded leaf from the plants in the cages in Heteren (exp. 2) were frozen at −80°C and freeze-dried. After the leaf drying step, the procedure for chemical analyses was the same for all experiments. Leaves were ground with a Laboratory Vibration Mill (MM 301, Retsch GmBH & Co, Germany). Fine ground dry material of the leaves (25 mg) was extracted in 10 ml of 70% MeOH and shaken overnight. The crude extract was filtered on a Whatman #4 filter paper and diluted ten times with Milli-Q water. Concentrations of the IGs aucubin and catalpol were analyzed by HPLC with a Bio-Lc (Dionex Corp., Sunnyvale, CA, USA) equipped with a GP40 gradient pump, a Carbopac PA 1 guard (4×50 mm) and analytical column (4×250 mm), and an ED40 electrochemical detector for pulsed amperimetric detection (PAD). NaOH (1 M) and Milli-Q water were used as eluents (10:90, 1 ml/min). Retention times were 3.25 and 4.40 min for aucubin and catalpol, respectively. Concentrations were analyzed with Chromeleon version 6.60 (Dionex Corp. Sunnyvale, CA, USA).

Results

Experiment 1: Small Cages, Finland Oviposition was observed in 19 cages, with a total of 21 egg batches. Plants onto which *M. cinxia* oviposited had a significantly higher level of aucubin (2.56±0.43) than plants without (1.57±0.37) oviposition within the same cage (paired *t* test, $t=2.78$, $df=16$, $P=0.013$; Fig. 1a). In 71% of the cases, females chose the plant with the higher aucubin concentration. By contrast, there were no consistent differences in the concentration of catalpol between plants selected (2.25±0.35) and ignored (2.59±0.35) for oviposition (paired *t* test, $t=-0.72$, $df=16$, $P=0.48$). There was also no significant difference in the total IG concentration between plants with (4.81±0.58) and without (4.16±0.55) oviposition (paired *t* test, $t=0.81$, $df=16$, $P=0.43$).

The number of leaves on the plants ranged from six to 26. There was no association of leaf number with oviposition choice (paired *t* test, $t=0.45$, $df=15$, $P=0.66$; Fig. 1b). In 43% of the cases, the plant onto which the butterfly oviposited had fewer leaves than the alternative plant, whereas in 50% of the cases it had more leaves. For plants on which eggs were laid, there was no correlation between the egg cluster size and the iridoid concentration

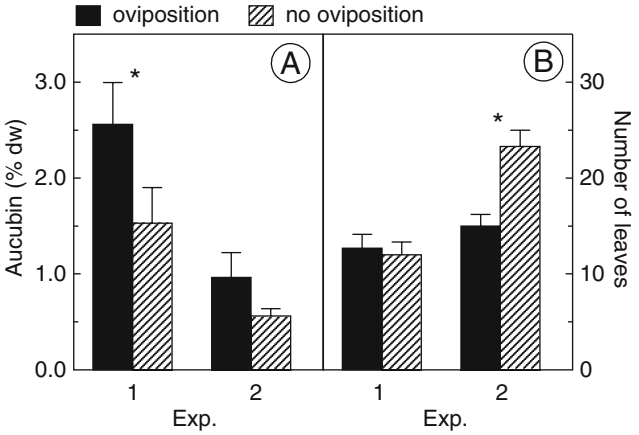

Fig. 1 **a** Average leaf concentration of aucubin (percent of dry weight) and **b** average number of leaves on *Plantago lanceolata* plants with (*black bars*) and without (*hatched bars*) oviposition by *Melitaea cinxia* in experiments 1 and 2. See text for a detailed description of the experiments. *$P<0.05$

or plant size (number of leaves; aucubin: $r=-0.085$, $N=17$, $P=0.75$; catalpol: $r=0.15$, $N=17$, $P=0.56$; total iridoid level: $r=0.19$, $N=17$, $P=0.46$; no. of leaves: $r=0.43$, $N=16$, $P=0.10$).

The observed patterns of associations between plant traits and oviposition did not differ between the cages with plants originating from the field (Finnish plants) and the cages with plants from the cloned Dutch genotypes. Higher concentrations of aucubin in plants chosen for oviposition were observed both for the Finnish (1.8±0.6% vs. 1.0±0.3%) and for the Dutch plants (3.3±0.6% vs. 2.0±0.6%), whereas neither the concentration of catalpol (Finnish: 3.0% vs. 3.4%; Dutch 1.6% vs. 1.7%) nor the number of leaves (Finnish 17.4 vs. 15.3; Dutch 9.4 vs. 9.0) affected oviposition.

We analyzed concentrations of iridoid glycosides in leaves of 28 plants both before and after oviposition. These measures did not differ significantly, suggesting that there was no systemic induction of IGs by the oviposition event within the observed time frame (1 day; paired *t* test, aucubin: $t=-0.15$, $df=27$, $P=0.89$; catalpol: $t=0.22$, $df=27$, $P=0.82$; total iridoid glycosides: $t=1.7$, $df=27$, $P=0.10$).

Experiment 2: Large Cages, the Netherlands Oviposition by *M. cinxia* was observed in six of the ten cages, on one to four plants within a cage, with a total of 15 egg batches on 12 plants. The average iridoid glycoside concentrations of plants with oviposition did not differ from those without oviposition within a cage (paired *t* tests, aucubin: $t=1.35$, $df=5$, $P=0.23$; Fig. 1a; catalpol: $t=1.83$, $df=5$, $P=0.13$; total IG concentration: $t=1.57$, $df=5$, $P=0.18$). Egg batches

were found on plants with significantly fewer leaves than average (t=−3.91, df=5, P<0.05; Fig. 1b). The number of leaves ranged from six to 49 and was negatively correlated with the iridoid concentration (aucubin: r=−0.047, N=59, P<0.001; catalpol: r=−0.045, N=59, P<0.001; total IG level: r=−0.048, N=59, P<0.001).

Experiment 3: Field Site, Finland; Size and Chemistry of Plant Genotypes Plant size differed both among genotypes and patches (Tables 1 and 2). There was a three-fold variation among genotypes. Genotypes also showed a significant, ca. four-fold, variation in their average leaf concentration of iridoid glycosides (Table 1). The range of aucubin concentrations (nine-fold) was larger than the range of catalpol concentrations (four-fold, Table 1). Although genotypes originating from the high IG selection line (H1–H5) on average had higher concentrations of total iridoid glycosides than genotypes originating from the low IG selection line (L1–L5; Table 1), the concentrations of the constituent components aucubin and catalpol varied greatly among genotypes within lines. Part of the variation in total concentrations of iridoid glycosides and catalpol among plants was associated with plant size (Table 2). The total IG concentration of the plant was negatively correlated with both the number of leaves and the size index of the plants (phenotype concentration: no. of leaves: r=−0.55, N=64, P<0.001; size index: r=−0.43, N=64, P<0.001; genotype concentration: no. of leaves: r=−0.77, N=10, P<0.01; size index: r=−0.68, N=10, P<0.05). In other words, larger plants tended to have lower IGs. The concentrations of both aucubin and catalpol were independent of the patch where plants were growing (Table 2).

Experiment 3: Field Site, Finland; Oviposition and Performance of M. cinxia on Different Plant Genotypes Egg clusters of *M. cinxia* were found in 41 (10.3%) plants in the field site. The total number of egg clusters was 63, with a maximum of seven per plant and nine per patch. Forty-eight (76.2%) of the egg clusters hatched, and one-third of them eventually produced winter nests. Of these nests, 13 were on the initial oviposition plant and eight on non-oviposition plants to which the larvae had moved during the season.

The number of egg clusters per plant increased significantly with plant size and differed both among patches and among genotypes (Table 3), ranging from a mean number of 0.025 to 0.50 clusters per plant for different genotypes. Similar effects were found for the number of successful clusters, i.e., clusters that hatched (Table 3). The effects of plant size on the number of egg clusters were mainly due to an increase in oviposition with the number of leaves per plant (Fig. 2a). The association between maximum leaf length and oviposition was non-linear: plants with leaves of an intermediate length of ca. 8 cm were the most often used for oviposition (Fig. 2b), whereas leaf width was not associated with the number of egg clusters on a plant (P> 0.5). Univariate regression analysis (Table 4) showed that at the genotype level, two factors significantly contributed to differences in the number of egg clusters per plant: average concentrations of aucubin and average leaf length (Table 4, Fig. 2b,c). In a multiple regression, the effect of aucubin disappeared (Table 4), indicating that it was partly mediated by genotypic correlations with other factors. In particular, this involved a negative correlation with leaf number (Fig. 3) that tended to have a positive effect on oviposition (Fig. 2a), and a positive correlation with maximum leaf

Values for leaf IG concentrations and plant size are back-transformed least square estimates from GLM with block and genotype effects. Values within columns that do not share a common letter have non-overlapping 95% confidence intervals. Occurrence of *M. cinxia* is summed over the 40 replicate plants per genotype: the observed numbers of plants with egg clusters (P), total numbers of egg clusters (C), hatched clusters (H), and diapausing groups in winter nests (D).

length that had a negative effect on oviposition in the range of values for the genotype means (Fig. 2b).

Comparison of Plant Chemistry Between the Three Experiments The total amount of IGs as well as the ratio of aucubin to catalpol differed among the experiments (Fig. 4). Plants originating from Finnish field sites that were used in the small cages (exp. 1) and cloned genotypes transplanted into natural habitat in Finland (exp. 3) had on average more catalpol than aucubin. By contrast, cloned genotypes grown in potting soil in the small cages in Finland (exp. 1) or large cages in the Netherlands (exp. 2) had on average more aucubin than catalpol. In the large cage experiment (exp. 2), the concentrations of IGs were generally very low. Especially striking is the huge difference between the plants used for the experiment in NL (exp. 2) and the field experiment in Finland (exp. 3) because plants used for these two experiments were of the same genotypes. Although the rank order of the genotypes was consistent across both of these experiments (Fig. 5), the absolute concentrations of IGs were significantly higher in the field experiment in Finland (exp. 3). Concentrations of aucubin in these genotypes were ca. three times higher in Finland ($t=5.44$, $df=9$, $P<0.001$), whereas concentrations of catalpol were on average more than 20 times higher in the field experiment in Finland (4.0%) than in the large cage experiment in the Netherlands (0.16%; $t=8.75$, $df=9$, $P<0.001$).

Discussion

Butterflies that lay eggs in clusters, such as checkerspots, are expected to spend more time discriminating among potentially suitable host plants than solitary egg laying species (Singer 2004). When a searching *M. cinxia* female alights on a plant, it habitually "tastes" it, rests for a while before moving to another part of the plant or to another plant, and tastes again, continuing this process until she finds a plant chemically acceptable and begins to oviposit. The female selects where to oviposit based on cues she obtains from the plant. The results of the cage experiment in Finland (exp. 1) suggest that oviposition choice in female butterflies is related to concentration of aucubin in the plant. This result is in agreement with those of Nieminen et al. (2003) obtained by sampling from natural populations in the field.

We found no difference in IG concentrations of leaves before and after oviposition, suggesting that the butterflies chose plants with higher aucubin, and that the oviposition event itself did not systemically induce further production of IGs. However, since we did not measure IG concentrations before and after oviposition in the leaf that was actually oviposited on, there remains the possibility that local induction in the leaf selected for oviposition occurs (Peñuelas et al. 2006). Also, our post-oviposition sample occurred the evening after oviposition. It is possible that the induction of the IGs took longer than a single day. Unfortunately, although induction of secondary metabolites following herbivory is well studied, the timing of induction that follows oviposition is poorly studied. We do know that induction of IGs in *P. lanceolata* that follows fungal infection has been observed as early as 6 h after inoculation (Marak et al. 2002), while induction after leaf damage by caterpillars of the specialist *J. coenia* was not observed until 6 days after herbivory (Fuchs and Bowers 2004).

The concentration of aucubin is correlated with the total concentration of IGs. Several experiments have shown that the performance of *M. cinxia* larvae is enhanced when the larvae feed on plants with a higher concentration of IGs than on plants with a lower concentration. They have a shorter development time, higher larval weight, and they

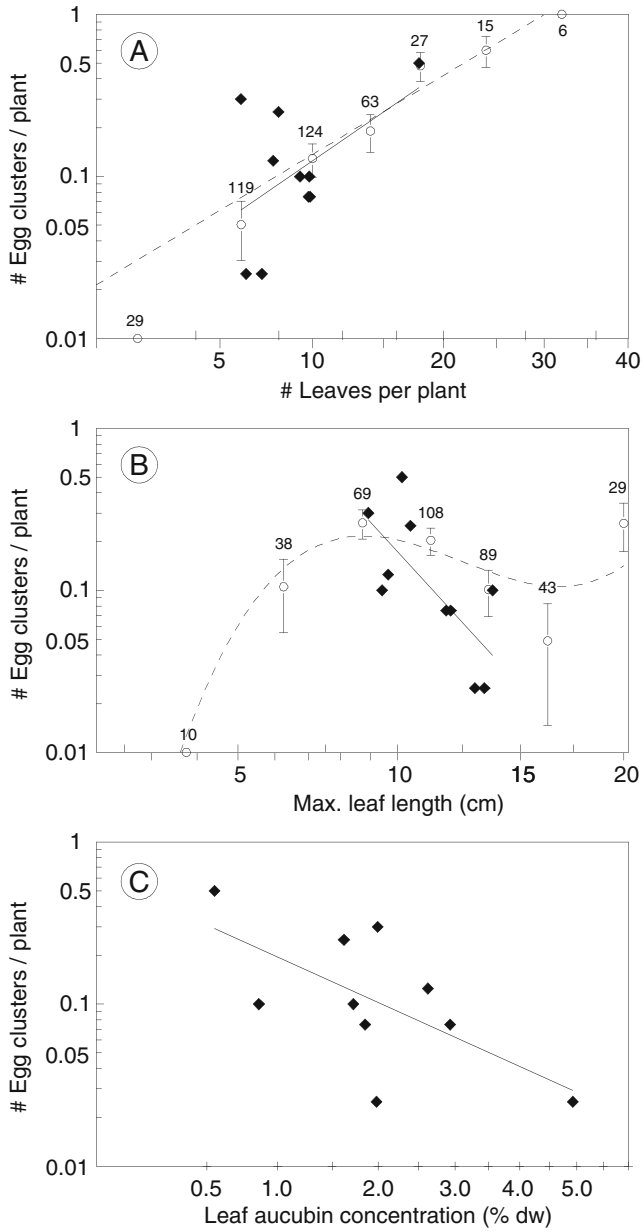

Fig. 2 Number of *Melitaea cinxia* egg clusters (*Y*-axis log scale) per *Plantago lanceolata* plant in experiment 3, as a function of **a** number of leaves per plant, **b** length of the longest leaf per plant, and **c** leaf aucubin concentration (*X*-axis, square root scale). *Black diamonds* represent genotype mean values of traits with corresponding *solid lines* of regression. *Open circles* (sample size on top) represent mean numbers of egg clusters for classes of phenotypic values of leaf number and leaf length ± 1 SE (class limits indicated above the *X*-axis). *Dotted lines* are corresponding polynomial regression lines based on parameter estimates from Poisson regressions of the phenotypic data

tend to have a larger pupal size (Harvey et al. 2005; Saastamoinen et al. 2007). These trait values are usually associated with a higher fitness (Roff 1992). There are many factors that affect larval fitness of *M. cinxia*, but larval size is strongly correlated with overwintering

$^{+}P<0.10$; $*P<0.05$

survival, which can be low (Nieminen et al. 2001; Kuussaari et al. 2004). The shorter development time also may be an advantage for *M. cinxia* because of the short growing season (Kuussaari et al. 2004). Furthermore, fast development decreases the period of time the caterpillar will be vulnerable to its natural enemies (Benrey and Denno 1997; van Nouhuys and Lei 2004).

Another advantage of feeding on plants with a high concentration of iridoid glycosides may be chemical defense against predators and parasitoids. Specialized larvae feeding on iridoid-producing plants are able to sequester these iridoids and become distasteful or noxious to their natural enemies (Bowers 1980, 1981, 1990; Bowers and Puttick 1986; Gardner and Stermitz 1988; L'Empereur and Stermitz 1990; Stermitz et al. 1994; Camara 1997; Nieminen et al. 2003).

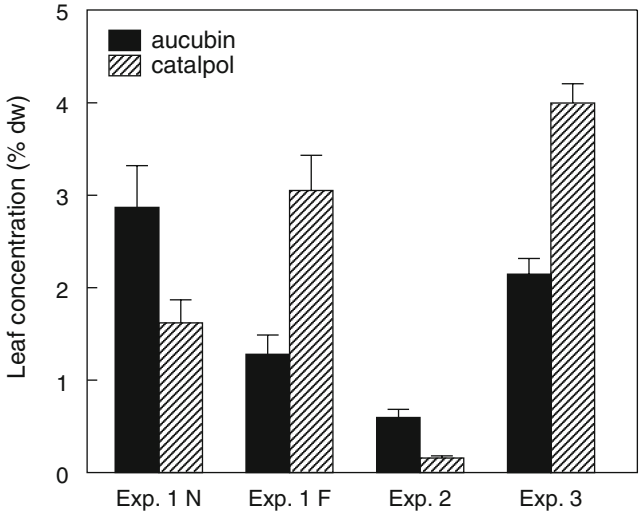

Fig. 4 Mean aucubin and catalpol concentration of *Plantago lanceolata* plants used in the three experiments. *Black bars* indicate the mean aucubin concentration, *hatched bars* the mean catalpol concentration. Exp. 1 N: small cages, Finland (Dutch genotypes); exp. 1 F: small cages, Finland (Finnish plants); exp. 2: large cage, the Netherlands; exp. 3: field site, Finland. See text for a detailed description of the different experiments

The fact that we did not observe an association of oviposition choice with IGs in experiment 2 (large cages NL) could be because of the overall low concentration of IGs in these plants. Perhaps, the female *M. cinxia* is not able to discriminate at such low absolute amounts of IGs (on average lower than 1% of the dry weight). This would suggest a threshold concentration below which these secondary metabolites are no longer used as a suitable cue for oviposition decisions although the small sample size of six females also could have contributed to the lack of a significant relationship.

The results of the field experiment (exp. 3) differed from the results of the cage studies. Perhaps, this is not surprising. In the field, *M.* cinxia and other checkerspots visit many possible plants without ovipositing, and the ranking of plants can depend on time and context (Schöps and Hanski 2001; Singer 2004). Thus, the plants used in the field should probably be considered a more absolute choice than in the cages where the butterflies may have selected plants that they would reject in other circumstances. Notably, the size of the plant (mainly the number of leaves per plant) had a positive effect on the oviposition preference of the females in the field, while in the cage experiment there was no association (exp. 1) or a significantly negative association (exp. 2) between these parameters. As mentioned, the higher oviposition rates of *M. cinxia* on larger plants in the field are in agreement with observations in natural populations by Nieminen et al. (2003). This is not unexpected given the limited mobility of early instar gregarious caterpillars (Kuussaari et al. 2004).

A further possible explanation for the stronger impact of plant size on oviposition in the field than in cage experiments is the different range of plant sizes between the field and cage studies. In the field, the difference in leaf number between the smallest and largest plant was 78; in the cage study in Finland, the mean difference in leaf number between the plants between which *M. cinxia* could choose was only 3.3. Because of this smaller variation in plant size in the cage experiments, the oviposition choice of the female in the cages could be based to a greater extent on chemical rather than visual stimuli. In addition, the use of visual cues may manifest more clearly in the field experiment where butterflies may encounter plants at a distance, whereas in the cages they are constrained in close proximity to each plant.

Future studies are needed to disentangle the relative importance of plant size and IG concentrations of individual plants for oviposition in the field. In the cage experiments, IGs were measured for each individual plant. Associations between oviposition and traits including IGs could be studied at the individual plant level. However, in the field experiment (exp. 3), IG concentrations were measured for a subset of plants only. Based on these measurements, genotype mean IG concentrations were used to assess associations between oviposition and IGs. This resulted in a loss of power to detect associations and reduced our ability do distinguish effects of morphological traits from IGs on oviposition.

In summary, our results show that ovipositing *M. cinxia* discriminate between host plants based at least on factors associated with plant chemistry and size. For females in the field experiment, the size of the plant was a positive stimulus, whereas in the cages, where plants were more

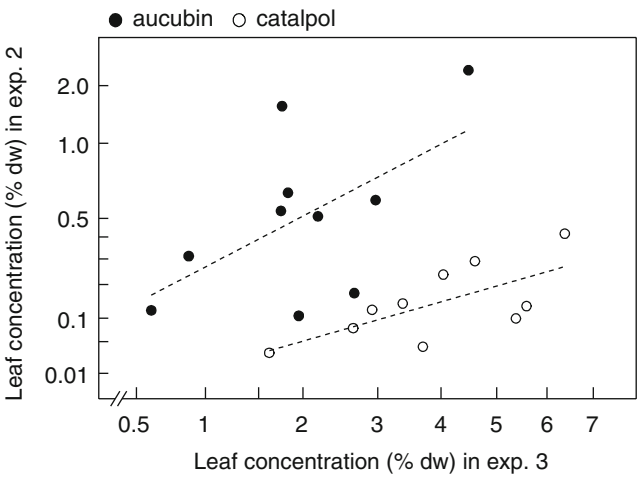

Fig. 5 Average leaf concentrations of aucubin (*black dots*) and catalpol (*open dots*) of ten *Plantago lanceolata* genotypes used in experiment 2 vs. the average IG concentrations of the same genotypes in experiment 3. See text for a detailed description of the experiments

similar in size and appearance, chemical stimuli were apparently more important. In particular, oviposition tended to increase with constitutive concentration of aucubin.

Acknowledgments We thank two anonymous reviewers for helpful comments on this manuscript, and H. Paulomaki, K. Linqvist, K. Luodekari, and K. Valosaari for field and laboratory assistance. The Tvärminne Zoological Station and Nåtö Biological Station provided facilities in Finland. and subtemperate regions, mostly for consumption as leafy vegetable and herb. Because of the pungent flavor, it is traditionally used to flavor beans and other South American dishes. Its extract or EO has medicinal (Boiteau 1986; Kishore et al. 1996; Lall and Meyer 1999; Noumi and Yomi 2001), acaricidal, and insecticidal properties (Malik and Mujtaba-Naqvi 1984; Su 1991; Chiasson et al. 2004a,b). However, investigations of its antifungal properties are rare (Dubey et al. 1983).

The chemical composition and yield of epazote EO shows wide variation in composition, which may be related to the herbal source, chemotype of the plant species, and/or the analytical methods used (Guenther 1952; Bauer and Brasil 1973; Onocha et al. 1999; Tapondjou et al. 2002; Gupta et al. 2002; Huang and Kong 2002; Pino et al. 2003; Cavalli et al. 2004; Kasali et al. 2006). Although there are a few reports regarding the fungicidal properties of epazote extracts, fungicidal properties have not been linked to specific EO component(s). Use of EO to protect agricultural commodities requires consistency of results, which can only be obtained if the EO is standardized against the most active component of the oil. Identification of such components helps in understanding the EO mode of action and can lead to discovery of new antifungal compounds.

In this study, we report the chemical composition and antifungal activity of Brazilian epazote EO and identify the major constituents responsible for this activity.

Methods and Materials

Plant Material and Hydrodistillation Epazote leaves were harvested from shrubs in Viçosa, Minas Gerais, Brazil, and mixed with water (1:5 *w*/*v*) for hydrodistillation. The distillate was extracted twice with dichloromethane (1:1 *v*/*v*). The organic phase was collected and dried with anhydrous sodium sulfate; dichloromethane was evaporated in a rotatory evaporator at 30°C under reduced pressure and weighed.

Identification of EO Components The compounds in the crude EO and its fungitoxic component were tentatively identified by gas chromatography (GC) using Kováts retention indices (RIs) and gas chromatography combined with mass spectrometry (GC-MS). The peaks were first identified by GC-MS library system based on similarity indices (SI). Also, RIs were obtained for all the major GC peaks. The final identification was based on the best SI and RI fits (Adams 1995).

Data were obtained on two instruments. For RIs, data were obtained on a gas chromatograph with a flame ionization detector (Shimadzu, Kyoto, Japan, model GC 17 A), an auto sampler, and workstation. Mass spectral data were obtained on a gas chromatograph-mass spectrometer (Shimadzu, Kyoto, Japan, model QP 5000 and software program-Classs-5000, version.1.2) fitted with an auto sampler, workstation, and a database (Wiley 229) with about 350,000 entries. Fused capillary columns (30 m× 0.25 mm; film thickness of 0.25 μm) coated with the DB-5 stationary phase were purchased from Supelco (Bellefonte, PA, USA). In all cases, the GC oven temperature was programmed from 60°C (1 min hold) to 240°C (9 min hold) at a rate of 3°C/min. One microliter of the sample dissolved in hexane (10%) was injected by the split mode (10:1) with the split vent being closed for 30 s. Nitrogen and He were the carrier gases for GC and GC-MS, respectively, at flow rates of 1.33 ml/min. The mass spectrometer was scanned from *m*/*z* 40 to 350 in the electron impact mode (70 eV). To obtain representative data, the mass spectra over the entire GC peaks (~50 scans) of interest were grouped and subtracted from the grouped mass spectra of the region closest (before or after) to where no compound eluted (~50 scans). Only compounds with similarity indexes of 90% (SI=90) were considered as positive identifications.

For RI data, a mixture of linear saturated hydrocarbons was co-injected and the mixture analyzed by GC. RIs were calculated by using the following formula: $KI=100y+100(z-y)\times t_{R(x)}-t_{R(y)}/t_{R(z)}-t_{R(y)}$, where y and z are the carbon numbers in the hydrocarbons eluting before and after a GC peak of interest, respectively; $t_{R(x)}$ is the retention time of the acetate; $t_{R(y)}$ and $t_{R(z)}$ are the retention times of the hydrocarbons eluting before and after a GC peak of interest, respectively.

Antifungal Activity Antifungal activity of the EO was tested with the poison food assay on potato-dextrose agar (PDA; Dhingra and Sinclair 1995). To obtain a uniform dispersal, the EO was dissolved in methanol (1:1 *v*/*v*), and the mixture was added to cool molten PDA to obtain EO concentrations of 0.1% and 0.05%. The active EO fraction was tested at 0.1%, 0.05%, and 0.03% concentrations. Ten milliliter of the medium was poured into 9-cm culture plates. The controls consisted of PDA containing an equivalent amount of methanol. *Aspergillus flavus*, *Aspergillus glaucus*, and *Aspergillus ochraceous* (stored grain and feed deteriorating fungi); *F. semitectum*, *Colletotrichum gloeosporioides*, and *Aspegillus niger* (postharvest rot of tropical fruits and vegetables); *Colletotrichum musae* (banana fruit anthracnose); and *Fusarium oxysporum* were used as test fungi. The medium in each plate was spot-seeded with the conidia of either of the test fungus (Dhingra and Sinclair 1995). Colony diameter was measured at either at fifth or sixth day after incubation at 25°C. All tests were performed in triplicate. Percent growth inhibition was calculated by dividing radial growth in the treatment plates by growth in the control plates and multiplying by 100. The data were

Table 1 Percent composition of the crude essential oil of *C. ambrosioides*

Peak no	Kováts retention index	Compound	Structure	%
1	1018	α-Terpinene		0.9
2	1026	*p*-Cymene		2.0
3	1033	Benzyl alcohol		0.3

Tentative identifications of components based on Kováts retention indices and gas chromatography-mass spectrometry

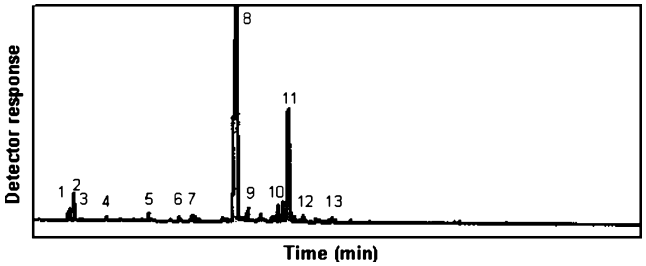

Fig. 1 Reconstructed gas chromatogram of crude *C. ambrosioides* essential oil. Chromatography conditions: oven temperature programmed from 60°C (1 min hold) to 240°C (9 min hold) at 3°C/min; He carrier gas (1.33 mL/min), temperatures of injector, transfer line, and detector 240°C, 240°C, and 250°C, respectively, 70 eV; scanning range (*m*/*z*), 40–350 with a fused silica capillary column coated with the DB-5 stationary phase

analyzed by analysis of variance and the means compared by the Tukey test (P=0.05).

Identification of Fungitoxic Components Preparative thin layer chromatography (TLC) bioautography (Rahalison et al. 1991) was used to separate the major antifungal fraction of the EO. A 200-mg aliquot of the crude EO was applied onto each of the six preparative silica gel TLC plates (20× 20 cm, 1-mm thick, 60GF, Merck) and developed in dichloromethane:ethyl acetate (9:1 *v*/*v*). After evaporation of the solvent at room temperature, cool molten PDA containing 100 mg/l streptomycin sulfate and conidia of the respective fungus (10^3/ml) was spread over each plate and incubated for 6 days at 30°C in a moisture-saturated plastic box. The plate area where the fungus did not grow was delineated, measured, scrapped, and extracted twice by shaking for 2 h with 200 ml of dichloromethane. The mixture was filtered, the filtrate was dehydrated with anhydrous sodium sulfate, and the dichloromethane removed by rotary evaporation. The residue was weighed, collected in vials, and stored at 4°C until use.

Results

Hydrodistillation of the epazote leaves yielded 0.3% EO on a fresh weight basis. Through GC-MS and GC analysis using RI, 13 components were tentatively identified (see Table 1) and represented 90.4% of the crude EO. These included (*Z*)-ascaridole (61.4%), (*E*)-ascaridole (18.6%), carvacol (3.9%), and *p*-cymene (2%), constituting 85.9% of the EO, while the remaining 4.5% was made up by the other nine components having relative concentrations of less than 1% (Fig. 1, Table 1).

The crude EO completely inhibited the mycelial growth of all eight of the test fungi at a concentration of 0.3% (Fig. 2). At a concentration of 0.1%, the growth inhibition

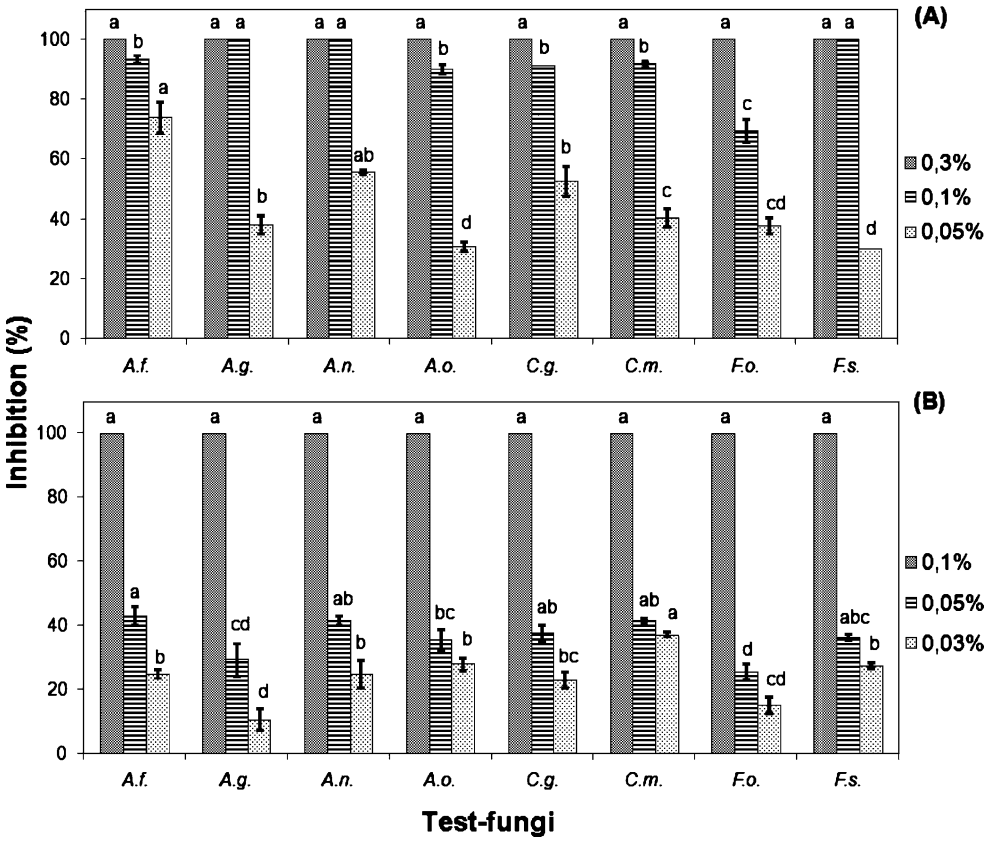

Fig. 2 Percent radial growth inhibited by **a** crude essential oil of *C. ambrosioides* essential oil after 6-day incubation at concentration of 0.05%, 0.1%, or 0.3%, and **b** by the purified fraction at a concentration of 0.1%, 0.05%, and 0.03% after 5-day incubation at 25°C. Mean of three replications ±SD within each treatment. For each concentration, the histograms of different fungi, headed by the same letter, do not differ at P=0.05. *A.f. Aspergillus flavus*, *A. g. A. glaucus*, *A.n. A. niger*, *A.o. A. ochraceous*, *C.g. C. gloesporioides*, *C.m. C. musae*, *F.o. F. oxysporum*, and *F.s. F. semitectum*

of fungi varied from 90% to 100%, except *F. oxysporum* whose growth was inhibited by about 70%.

Fractionation of crude EO to isolate and identify the most active antifungal constituent yielded only one band without fungal growth on the autobiographic TLC (R_f= 0.89, longitudinal width 5 cm). The GC and GC-MS analysis of this fraction revealed the presence of only *Z*-ascaridole (44.4%), *E*-ascaridole (30.2%), and *p*-cymene (25.4%). This fraction at 0.1% completely inhibited growth of all test fungi, but at 0.05% the inhibition of *A. flavus*, *A. niger*, and *Colletotrichum gloesporioides* was lower, and that of other fungi was similar to the crude EO at the same concentration.

Discussion

The yield of crude oil was within the range of 0.06% reported from Nigeria (Onocha et al. 1999) to 0.8% from Cameroon (Tapondjou et al. 2002). Yields between 0.2% and 0.3% have been reported (Bauer and Brasil 1973; Muhayimana Uhayimana et al. 1998; Gupta et al. 2002), but higher yields (1–2%) have also been noted (Guenther 1952). The yield of plant EO is affected by several factors such as genotype and environment (Guenther 1952; Wink 1993).

This composition of the epazote EO is substantially different from that reported from southern Brazil plants (Bauer and Brasil 1973), where limonene (29.6%), mycrene (19%), and β-pinene (3.6%) constituted the major portion of the EO. These compounds were not detected in the present study. Moreover, the results from the two studies may not be comparable, since in the previous study, GC with a thermal conductivity detector was used to determine relative concentrations of the compounds without specifying the identification procedure. In addition, 30.6% of the components could not be identified. In this study, we identified 90.4% of the volatile oil by using a widely employed methodology for EO identification (Adams 1995).

The chemical composition of the epazote EO was quite different from that reported in other studies. Ascaridoles (*Z* and *E*) were the major components (80%) in the present study, while *p*-cymene (2%) and α-terpinene (0.9%) were minor components. On the other hand, *p*-cymene and α-terpinene were the major components in EO, with respective concentrations of 15.5% and 56% from Nigeria (Onocha et al. 1999), 19.5% and 63.6% from India (Gupta et al. 2002), and 50% and 37.6% from Cameroon, (Tapondjou et al. 2002), while (*Z*)- and (*E*)-ascaridole were the minor components. Cavalli et al. (2004) reported α-terpinene (9.7%), *p*-cymene (16.2%), and ascaridole (41.8%) in a commercial EO available in France. Thus, in all cases, the ascaridoles, considered to be quality indicators of *C. ambrosioides* EO (Guenther 1952), were much lower than those obtained in Brazil.

Dubey et al. (1983) reported a minimum concentration of 0.1% for complete inhibition of *Rhizoctonia solani*. However, even at 0.05%, the growth of the many important postharvest fungi was inhibited by over 50% in this study, with that of *A. flavus* being inhibited by 70%. The higher sensitivity of *A. flavus* to epazote EO is of particular interest, since this fungus produces potentially carcinogenic alfatoxins in grain and feeds colonized by it. This EO might be a good candidate for use with such commodities.

Although higher concentrations are required to inhibit the growth of other postharvest deteriorating fungi, under certain circumstances, crude EO might be useful for retarding fungal growth. The toxicity of EO to *A. flavus* in this study is much higher than that reported for the dichloromethane extract, where fungal growth was inhibited by 13% at a 0.05% concentration (Arispuro et al. 1997), and *Tilletia indica* by 40% (Castaneda et al. 2001). However, the chemical profile of that extract was not reported.

These data, along with the fact that the percentage of ascaridoles was only slightly lower in comparison to the crude EO (74.6% vs. 80%), suggest that they are the major fungitoxic components. However, total fungitoxcity may involve other minor components that have additive or synergistic effects. The high proportion of *p*-cymene in the active fraction, with no increase in the fungitoxicity, suggests that it may not be involved.

Despite little evidence, insecticidal activity of epazote EO has been attributed to ascaridoles (Pollack et al. 1990; Tapondjou et al. 2002). There is no study that reports the antifungal component(s) of epazote EO. This study shows, for the first time, the wide spectrum antifungal activity of this EO and indicates that ascaridoles are the major antifungal components, which may be used as markers for standardizing the product for use in postharvest protection of agricultural commodities. Identification of fungicidal properties of ascaridole opens the possibility of developing new fungicides by using it as the lead compound.

et al. 2007a, b), pollinators (Caissard et al. 2004), herbivores, viruses, bacteria, and fungi (Panizzi et al. 1993; Pasqua et al. 2002; Lahlou and Berrada 2003; Giordani et al. 2004). Plant terpenes may also be sensitive to abiotic factors such as ultraviolet B radiation (Zavala and Ravetta 2002), severe conditions of water stress (Delfine et al. 2005), high temperatures and light intensity (Flesh et al. 1992; Wassner and Ravetta 2005), and ozone (Kainulainen et al. 2000). The numerous factors affecting terpene production represent a significant obstacle for developing a model capable of predicting the quantities of plant secondary metabolites, such as terpenes, under differing environmental conditions. Hence, the construction of such models is still one of the most challenging issues related to plant secondary metabolism.

Numerous studies have covered the impact of climatic conditions on terpene content in the Mediterranean area, whereas only a few advances have been made in understanding the effect of other abiotic factors such as soil type on terpene accumulation within plant tissues. Studies focused on elucidating soil contributions to terpene accumulation in plants mostly have been performed by considering different fertilizing doses (Muzika et al. 1989; McCullough and Kulman 1991; Heyworth et al. 1998). Other studies have dealt with terpene content variation in different geographical areas (*Rosmarinus officinalis*—Diab et al. 2002; *Pinus halepensis*—Ghanmi et al. 2005), but little is known about the effect of the type of natural soil, such as calcareous and siliceous soils, on terpene production by plants.

The Mediterranean region and particularly the Provence-Alpes-Côtes-d'Azur (PACA) region (southern France) features predominantly calcareous and siliceous soils (also called alkaline and acid soils, respectively), which are geographically well separated. These soils could affect terpene production since they are known to differ in pH, which may affect nutrient availability. These soils also vary in temperature (Gorenflot 1998); species needing warmer and low acidity soils prefer calcareous soils (Gorenflot 1998).

A few studies, all performed in the Mediterranean area, have investigated terpene content of plants growing in calcareous and siliceous soils. These reported that species growing in these two soil types show: (i) qualitative differences in terpene production (Robles and Garzino 2000; Flamini et al. 2004), suggesting the existence of different chemotypes and (ii) quantitative differences (Robles and Garzino 1998), indicating that properties of these soils affect plant terpene production.

The main goals of the present study were: (i) to explore the chemical diversity of monoterpenes and sesquiterpenes stored in leaves of woody Mediterranean species, *P. halepensis*, *R. officinalis*, and *Cistus albidus*, on calcareous and siliceous soils. In contrast to isoprene (hemiterpene with five carbons), monoterpenes and sesquiterpenes may be stored in leaves before being volatilized into the atmosphere; (ii) to assess quantitative differences in terpene production among plants growing in calcareous and siliceous soils; and (iii) to investigate whether nitrogen (N) and extractable phosphorus (P_E) from these soils affect leaf terpene content. This was of particular interest since leaf terpene emissions vary when they grow in calcareous or siliceous soils owing to different nutrient concentrations in these soils (Ormeño et al. 2007c). In addition to leaf terpene content, mean annual radial growth of each species was calculated allowing us to verify any preference for calcareous soils.

Methods and Materials

Species, Sites, and Sampling Three Mediterranean species that prefer calcareous rather than siliceous soils were chosen: the evergreen tree *P. halepensis* Mill. (Pinales, Pinaceae), the sclerophyllous shrub *R. officinalis* L. (Lamiales, Lamiaceae), and the semideciduous shrub *C. albidus* L. (Malvales, Cistaceae). All are terpene-accumulating species that store terpenes in specialized structures. *C. albidus* and *R. officinalis* store terpenes in glands (Gulz et al. 1996; Bottega and Corsi 2000), while in *P. halepensis*, they are contained in resin or secretory ducts, typical of conifers species. These species store different terpene mixtures: *C. albidus* stores sesquiterpenes alone, *P. halepensis* needles contain both monoterpenes and sesquiterpenes, and leaves of *R. officinalis* mainly posses monoterpenes (Ormeño et al. 2007a).

This study took place in southeastern France, in PACA region, from 19 to 24 March 2004 and between 1100 and 1530 hours (solar time). All sites were placed in open garrigue habitats, since terpene content of the selected species vary quantitatively between closed and open habitats (with and without a canopy structure, respectively; Ormeño 2006). The study area consisted of three open calcareous sites (C1, C2, C3; 43°28′ N–5°26′ E; 43°29′ N–5°18′ E; 43°15′ N–5°37′ E, respectively) and three open siliceous sites (S1, S2, S3; 43° 13′ N–6°10′ E; 43°12′ N–6°9′ E; 43°30′ N–6°39′ E, respectively) per species. Since *R. officinalis* was absent from one siliceous site (S3), a supplementary siliceous site was chosen (S4; 43°20′ N–6°30′ E), where only this species was sampled. All sites were located at similar altitudes (between 150–300 m) with negligible slopes. Geographical limits between these soils are known to be clearly marked in the study area. Distance between calcareous and siliceous sites is approximately ~150–200 km but climatic conditions are similar. Thus, mean precipitation (±standard error (SE)) and mean temperatures (±SE) recorded for the last 5 years in March were 30.1±4.4 mm and 11.1±0.17°C for calcareous sites and 37.7±6.7 mm and 12.1±0.3°C for siliceous sites (Meteo France Data). During the sampling period, similar temperatures (mean temperature, 23.5°C), relative air humidity (<30%; psychrometer, Jules Richard), and horizontal

wind speed (<7 m s^{-1}; Wind Speed Meter, WSC, 888H, Huger®) were recorded, and no precipitation occurred. Moreover, during sampling hours, atmospheric O_3 concentrations were not significantly different (Student's test, P=0.35) in calcareous (hourly average=80.9 and maximum=100 ppb) and in siliceous sites (hourly average=90.5 and maximum=103 ppb; AIRMARAIX Data).

To study physical and chemical properties of soils from calcareous and siliceous sites, four 200 g soil samples from the A1 horizon were collected at each site and then analyzed in different laboratories (Laboratoire de Chimie et Environnement, Laboratoire de Chimie et Agriculture). Properties analyzed following standard methods (Table 1) were pH, total organic carbon (TOC), nitrogen, total and extractable phosphorus, Mg^{2+}, Ca^{2+}, K^{+}, and texture.

Sampling was carried out on mature individuals of similar age (see below mean annual radial growth measurement). Because light conditions (Flesh et al. 1992) or stress factors such as herbivores or pathogens (Keeling and Bohlmann 2006) may alter or induce terpene production, only sun exposed individuals that showed apparent healthy leaves and that were free of pests were sampled. Health of leaves was checked visually (Llusià and Peñuelas 2000; Peñuelas and Llusià 2002). Four individuals per site were studied. For each plant, a single branch containing current and mature leaves was used to extract terpenes.

Terpene Extraction and Analysis Sampled leaves collected per plant were stored in a portable refrigerator at +4°C until being stored at −20°C in the laboratory within a period not longer than 2 h. Prior to terpene extraction, leaves were lyophilized for 48 h in a lyophilizer/freeze drier (Liovac-GT-2E Sterys®), in order to express results as leaf dry mass (DM; in sampled leaves, water content was on average 50% of total leaf mass). Lyophilization did not induce terpene losses (Ormeño et al. 2007a). Leaves were mechanically ground with a grinder to obtain powder. As previously tested in the laboratory, this mechanical procedure is preferred over the manual procedure often reported, in which a pestle is used to grind leaves in a chilled mortar. The latter procedure results in leaf terpene concentrations that are on average 37±0.6% lower in comparison to those obtained if the mechanical grinding technique is employed. This probably occurs because finer powder leads to a high contact between the leaf surface and the solvent. The extraction method consisted of dissolving 1 g of leaf DM in cyclohexane, for 20 min, under constant shaking at room temperature (Ormeño et al. 2007c). Well-filled, tightly closed glass vials wrapped in aluminum foil were used to avoid exposure to light and oxygen (Guenther 1949). A nonisoprenoid volatile internal standard (Undecane) was added to quantify measurements. Extracts were immediately analyzed or stored at −20°C until analysis (within 24–72 h).

Analyses were performed with a gas chromatography (Hewlett Packard GC6890®) coupled to a mass selective detector (MSD; HP 5973N). The system is described in Ormeño et al. (2007a). Briefly, the system was fitted with a dual column. One of them, the HP-5MS capillary column, in constant flow mode, was connected directly to MSD for qualitative analysis. The other, HP5 capillary column, was connected directly to the flame ionization detector for quantitative analyses. Sampled volumes (2 μl) were injected

Table 1 Soil properties of calcareous and siliceous soils

Values are mean±SE (in parentheses). N=4 per site and N=12 if all calcareous and siliceous sites are lumped together, respectively. Intracalcareous and intrasiliceous differences tested through post hoc Tukey test are denoted by different letters (a<b<c). Letters are not shown when no significant differences were detected. Significant intersoil differences (P<0.05) tested through Student's test, appear in bold type
TOC Total organic carbon, *N* nitrogen, *P* total phosphorus, P_E extractable phosphorus

through an automatic injector (ALS 7683). Helium (99.995%) was used as carrier gas. The oven temperature was initially set at 50°C and then increased to 160°C at a rate of 2°C min^{-1}. It then remained constant for 5 min.

Identity of most leaf stored terpenes was established by comparison of the retention time and the mass spectrum of detected compounds with those of authentic reference samples (Aldrich–Firmenich). Terpene identity was further confirmed by comparing the experimental Kovats index of each compound with that of bibliography (Jennings and Shibamoto 1980; Adams 1989; Table 2). When terpene standards were not available (shyobunone, γ-cadinene, and α-eudesmol), their identity was tentatively achieved using this second approach. To determine terpene concentrations, the integrated area of each peak was multiplied by the appropriate response factor and divided by the sample volume. Response factors were determined from high-concentration standards.

Mean Annual Radial Growth Measurements Mean annual radial growth (mm $year^{-1}$) was measured by dividing the radius of the main stem at the collar level of each sampled plant by their age. For shrub species, age and radius were calculated at the main branch of each plant, which was cut off in order to collect cross sections (N=4, for each species). Meticulous sanding of cross-sections was necessary in order to evidence ring limits, since ring boundaries were difficult to detect. For each cross-section, rings were counted along two radii. The radius of a shrub plant was measured with a vernier calliper (graduated from 0–17 cm, 2/100 mm precision). For *P. halepensis*, age and radius were calculated from cores collected as low as possible. Age was calculated by following classical dendrometric methods (Schweingruber 1988). Mean age was calculated by counting rings on cross-sections of cores with pith.

Data Analyses Statistical analyses of variance by one-way analysis of variance (ANOVA), followed by post hoc Tukey tests, were used to detect differences in: (i) leaf terpene content of each species; and (ii) soil properties, within calcareous and siliceous sites (intracalcareous and intrasiliceous differences). Before applying the ANOVA test, both normality and homocedasticity of data were checked. Then, Student's t test was applied to test differences in: (i) foliar terpene content; (ii) soil properties; (iii) plant age; and (iv) plant annual radial growth, between calcareous and siliceous sites (intersoil differences). Quantitative differences in leaf terpene content between calcareous and siliceous soils were tested separately: (i) total monoterpenes and sesquiterpenes, and (ii) each major and minor compound. Main compounds were considered as major or minor when they contributed to at least 15% or 3% of total foliar terpene content, respectively. To study whether soil nutrients selected (N and P_E) were correlated to terpene content, linear and nonlinear regression analysis were performed. All results presented throughout the text represent the mean±SE. Statistical analyses were carried out with Statistical Graphics Plus®, version 4.1.

Results and Discussion

Calcareous and Siliceous Soil Properties Significant heterogeneity was found between soils of the same type (ANOVA, $P<0.05$, Table 1). For calcareous soils: (1) Cal2 appeared to be the poorest soil in terms of TOC, N, P, and Ca^{2+} (Table 1, Tukey test) and (2) Cal1 showed a loam texture, such as some siliceous soils (Sil1, Sil2). For siliceous soils: (1) S4 had the highest N and P concentrations, and (2) Sil2 contained the lowest Mg^{2+} and K^+ concentrations.

The analyses of intersoil differences indicated that pH and most nutrients concentrations (N, total and P_E, Ca^{2+}, and K^+) except Mg^{2+}, were significantly greater in calcareous than in siliceous soils ($P<0.05$, Student's t test, Table 1). Calcareous soils consisted of loamy and silty loam textures, whereas siliceous soils were loamy and sandy loam. However, some calcareous and siliceous soils showed similar textures as described above (Table 1). These results suggest that these calcareous and siliceous soils differ mainly in their pH and nutrient status and to a lesser degree in textures.

The low overall fertility found for siliceous soils has been described in other studies performed in the Mediterranean area (Canadell and Vila 1992; Castells and Peñuelas 2003). However, in high alkaline calcareous soils in the Mediterranean region (pH~8.5), lower concentrations of extractable phosphorus have been reported compared to siliceous soils (Sardans et al. 2004). This is attributed to excessive basic conditions that cause excessive calcium in soil solution that can precipitate with P, thus decreasing P availability (Haynes 1982). Differences in pH conditions may be due to the existence of different parent rocks. Consequently, some heterogeneity may appear between calcareous and siliceous soils.

Growth of Study Species in Calcareous and Siliceous Soils All study species showed similar ages in calcareous and siliceous soils (Student's test, $P>0.05$). Their mean age (years± SE) was 7.5±0.5 and 9.4±0.7 for *R. officinalis*, 44.0±3.7 and 55.1±3.3 for *P. halepensis*, and 6.0±0.7 and 6.4±1.2 for *C. albidus* in calcareous and siliceous soils, respectively.

Mean annual growth rate was higher in calcareous than in siliceous soils for all species (Student's t test, $P<0.05$). This was 0.73±0.03 mm $year^{-1}$ and 0.61±0.05 mm $year^{-1}$ for *R. officinalis*, 0.52±0.27 mm $year^{-1}$ and 0.38±0.13 mm $year^{-1}$ for *P. halepensis*, and 3.15±0.06 mm $year^{-1}$ and 2.0± 0.04 mm $year^{-1}$ for *C. albidus* in calcareous and siliceous soils, respectively. This was the expected result not only

[a] Tentatively identified compound

because calcareous soils showed a higher level of fertility but also because the naturally occurring selected species prefer calcareous soils (*C. albidus*—Passama 1970; *R. officinalis*, *P. halepensis*—Trabaud 2001).

Terpene Content Diversity of Study Species in Calcareous and Siliceous Soils All species appeared to contain numerous terpenes in leaves. For *P. halepensis*, 20 terpenes were identified (three of them in trace amounts; Table 2). Most of them were monoterpenes, but similar concentrations of sesquiterpenes were found (4.05±0.37 and 5.03±0.25 mg g_{DM}^{-1}, respectively; Fig. 1). β-caryophyllene and α-pinene were the most abundant compounds in both types of soils. β-caryophyllene represented 41±2% and 46±2% of total content for plants growing in calcareous and siliceous soils, respectively, and α-pinene accounted for 18±2% of total content in both types of soils (Table 2). Terpene constituents in needles of *P. halepensis* vary in other Mediterranean areas: Algeria, β-caryophyllene>α-humulene (Dob et al. 2005) and Spain, α-pinene>myrcene (Llusià and Peñuelas 2000), indicating that, in our study, *P. halepensis* showed a different chemotype. Important concentrations (higher than 0.25 mg g_{DM}^{-1}) of α-humulene, myrcene, δ-terpinene, sabinene, and δ3-carene also were found in needles of *P. halepensis* (Table 2). These minor terpenes contributed to 29±5% and 27±5% of total content for plants growing in calcareous and siliceous soils, respectively.

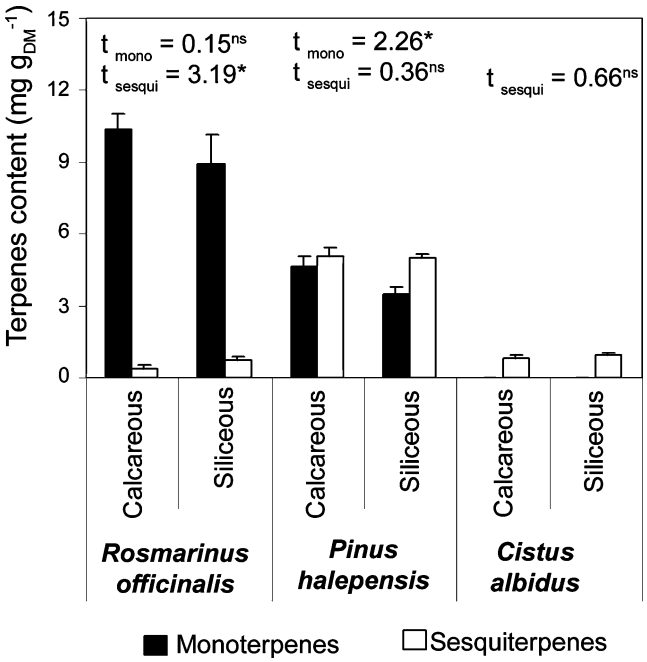

Fig. 1 Mean monoterpene and sesquiterpene concentration in leaves of *R. officinalis*, *P. halepensis*, and *C. albidus* in calcareous and siliceous soils (*bars* indicate SE; N=12). Statistical differences through Student's t test are also shown. t_{mono}, t_{sesqui}—Student's test value for monoterpene and sesquiterpene content, respectively. *P< 0.05; **P<0.01. *ns* Not significant at 95% of confidence

Twenty-one terpenes (six of them in trace concentrations) were identified in leaves of *R. officinalis* (Table 2). Most of them belonged to the monoterpene group. Mean monoterpene concentration was 9.64±0.93 mg g_{DM}^{-1} for both calcareous and siliceous soils. The major compound in leaves of *R. officinalis* was camphor, followed by α-pinene and eucalyptol (Table 2). These compounds showed similar relative amounts (percentage in respect to total content) in calcareous and siliceous soils. Camphor represented 30±5% and 23±6%, α-pinene accounted for 14±1% and 21±3%, and eucalyptol constituted 17±2% and 18±2% of total content in plants from calcareous and siliceous sites, respectively. These findings contrast with those of Peñuelas and Llusià (1997), where α-pinene was the major compound. This difference is probably due to *R. officinalis*, which generally exhibits numerous chemotypes, such as camphor, α-pinene, or eucalyptol chemotypes (Elamrani et al. 2000). High concentrations of myrcene, camphene, limonene, β-pinene, borneol, and verbenone were also extracted. These compounds represented 32±4% of total content in *R. officinalis*, for both calcareous and siliceous soils, and are, thus, minor major compounds. *R. officinalis* contained low concentrations of sesquiterpenes (0.55±0.12 mg g_{DM}^{-1}), which were mostly represented by β-caryophyllene (Table 2).

For *C. albidus* leaves, 21 terpenes were identified (five of them in trace concentration; Table 2). All of them were sesquiterpenes. Leaf terpene concentration (0.85±0.12 mg g_{DM}^{-1}) was tenfold lower than that of *P. halepensis* and *R. officinalis*. α-Zingiberene was the main compound (Table 2), in agreement with results of Robles and Garzino (1998), but unlike Llusià and Peñuelas (2000) who did not report this compound in extracts of this species. This compound represented 15% and 10% of total content in plants growing in calcareous and siliceous soils, respectively. Alloaromadendrene, D-germacrene, ar-curcumene, δ-cadinene, γ-cadinene, β-caryophyllene, and α-bisabolol were present in leaves in similar concentrations (<0.1 mg g_{DM}^{-1} both soils; Table 2). These minor compounds represented 49±8% and 50±7% of total content in calcareous and siliceous soils, respectively.

No qualitative differences in terpene diversity were observed between soil types and major compounds appeared in similar percentages in species located in both soils, indicating that sampled plants did not belong to different chemotypes; different chemotypes are recognized by the presence of distinct secondary metabolites, such as terpenes, and their relative concentrations (e.g., *P. halepensis*, Petrakis et al. 2000; *R. officinalis*, Lahlou and Berrada 2003).

These findings provide evidence that terpene diversity is species specific as expected since terpene mixtures are mainly genetically defined (Loreto 2002). Moreover, the terpene diversity (also called the terpene mixture) of all species studied appeared to be remarkable. Why plants allocate resources for synthesizing a wide variety of terpenes, is a question often debated by ecologists. The screening hypoth-

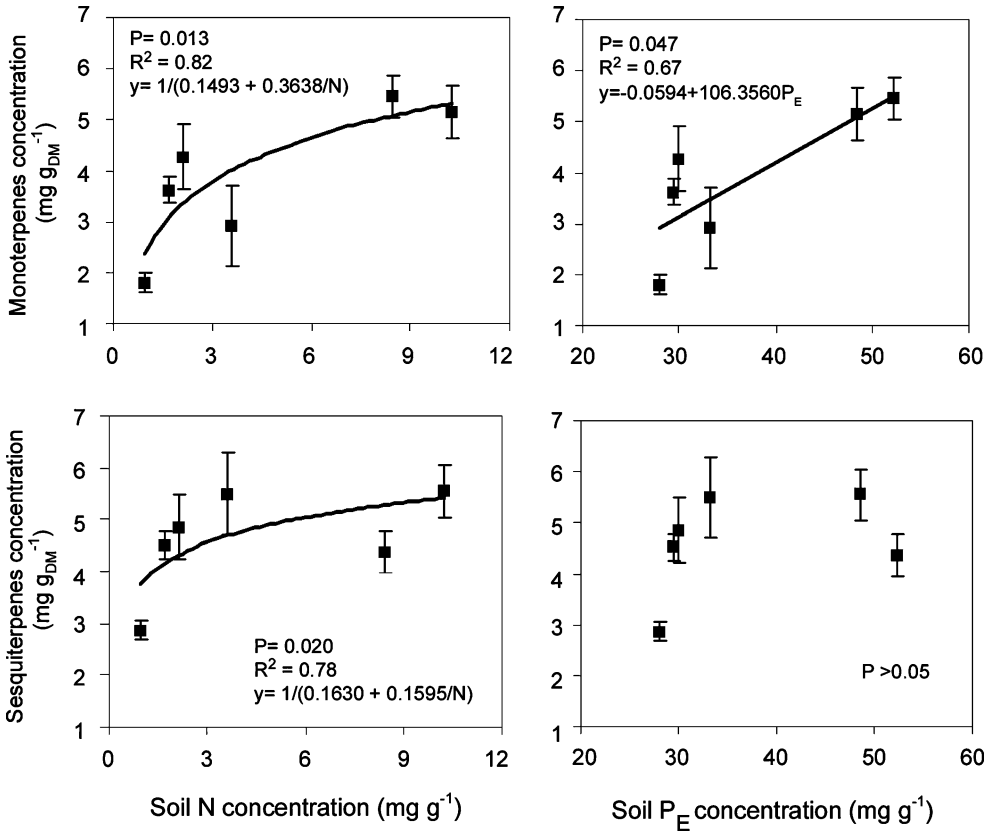

Fig. 2 Relationship between monoterpene and sesquiterpene concentration of *P. halepensis* and soil nitrogen (*N*; *left graphics*) and extractable phosphorus (P_E) concentration (*right graphics*). *Bars* shown are SE (*N*=4). Best fitting relationship is shown

esis formulated by Jones and Firn (1991) stresses that terpene mixtures would have ecological advantages over single substances, since most secondary metabolites do not have functions because their concentrations in plant tissues are too low. Hence, by synthesizing mixtures, the likelihood that some compounds are functional or active is improved, since the chemical diversity increases the chances of synthesizing an appropriate defensive product. This hypothesis is based "on a simple and single proposition: potent biological activity is a rare property for any molecule to possess" (Firn and Jones 2003).

Soil Type Effect on Terpene Content: Importance of Nutrients No previous study, except for *C. albidus*, has analyzed terpene content of the selected species in calcareous and siliceous soils (Robles and Garzino 1998). In that case, content was examined during the dormancy period. In the present study, it was tested when plants grew either in calcareous or siliceous soils and under nutrient differences (N and P_E).

For *P. halepensis*, total monoterpenes were higher when growing in calcareous soils (Student's *t* test, $P<0.05$; Fig. 1). Sabinene, δ3-carene, and δ-terpinene were more highly concentrated when *P. halepensis* grew in calcareous soils (Student's *t* test, $P<0.05$; Table 2). Total monoterpenes were significantly and positively correlated to both soil N and soil P_E ($P<0.05$; Fig. 2), indicating that high monoterpene content in calcareous soils is partly explained by the high N and P_E of these soils. This is consistent with previous findings (Ormeño et al. 2007c), where it was noted that higher concentrations of these nutrients in soil produce larger terpene emissions of *P. halepensis*. Unlike monoterpenes, total sesquiterpenes (i) were not significantly different when *P. halepensis* grew in the different soils (Student's *t* test, $P>0.05$; Fig. 1) and (ii) were not significantly correlated to soil P_E ($P>0.05$; Fig. 2). However, as for monoterpenes, overall sesquiterpene content was significantly and positively correlated to soil N concentration ($P<0.05$; Fig. 2).

P. halepensis showed high terpene content when growing in soils that contained high N and P_E presumably because increasing nutrient concentrations (mainly N) favor resin duct formation (Bjorkman et al. 1991; Kainulainen et al. 1996; Schindler et al. 1998), and in turn allow the storage of high terpene concentrations in needles of conifer species (e.g., *P. sylvestris* L., Bjorkman et al. 1998). In light of those results, it has been suggested that under an environment characterized by chronic increasing nitrogen deposition (Lu et al. 2007), *P. halepensis* might respond by allocating carbon resources to the synthesis of terpene metabolites, without detrimental effects on growth. Consequently, *P. halepensis* fitness might benefit from this scenario, since constitutive terpenes may act as defenses that allow plant species to cope with natural enemies (pathogens, virus, bacteria, fungi, herbivores; Rizvi and Rizvi 1992).

No consensus has been achieved to date regarding the way soil nutrients influence leaf terpene storage in woody species. Under varying nitrogen, terpene concentrations in mature needles of *P. sylvestris* have shown variable responses: enhancement (Kainulainen et al. 2000), reduction (Kainulainen et al. 1996), or no change (Heyworth et al. 1998). Leaf terpenes of *Eucalyptus* species are also variable: increase under nursery high fertilizer (Close et al. 2004) and remain invariable in field conditions (Close et al. 2004; King et al. 2004), when nutrients are supplied. Barnola and Cedeño (2000) showed high concentrations of most terpenes produced by *P. caribea* Morelet, in soils poor in P and N.

Total monoterpenes of *R. officinalis* were homogeneous within calcareous and siliceous soils (ANOVA, $P>0.05$; Table 3). They were not influenced by soil type (Student's *t* test, $P>0.05$; Fig. 1), although some major compounds were more highly concentrated in leaves growing in calcareous soils (β-pinene, myrcene, limonene and camphor, β-caryophyllene) or in siliceous soils (α-pinene; Student's *t* test, $P<0.05$; Table 2). In contrast, total sesquiterpene content (Fig. 1) was higher when *R. officinalis* grew in siliceous soils (Student's *t* test, $P<0.05$). The higher sesquiterpene concentration was due

Table 3 Terpene content of plants growing on calcareous and siliceous soils

Values are mean ($mg_{DM} \cdot g^{-1}$)±SE ($N=4$). Intrasoil differences are tested through ANOVAs analysis (*F*—ANOVA value). Results of the comparison are given by letters: values that differ at the 0.05 level are noted with different letters (a<b; i.e., ab=a, ab=b; Tukey test)

*$P<0.05$

ns Non significant

mainly to β-caryophyllene, which had twofold higher concentrations in plants in siliceous soils (Table 2). These results emphasize that monoterpene and sesquiterpene compounds may respond similarly to soil type.

In the case of *C. albidus*, total sesquiterpene content was similar within calcareous and siliceous soils (ANOVA, $P>0.05$; Table 3) and did not vary significantly between calcareous (0.8 mg g_{DM}^{-1}) and siliceous soils (0.9 mg g_{DM}^{-1}; Student's t test, $P>0.05$; Fig. 1). However, alloaromadendrene and δ-cadinene had significantly higher concentrations in leaves when *C. albidus* grew in siliceous soils (Table 2). Together, they contributed 20% on average to the total content. In contrast to results reported here, Robles and Garzino (1998) found high amounts of many terpenes (e.g., alloaromadendrene, β-caryophyllene) in plants growing in calcareous soils and high amounts of some other terpenes (e.g., β-bourbonene) in siliceous soils.

Contrary to *P. halepensis*, terpene content of *R. officinalis* and *C. albidus* showed no significant relationship with either N or P_E ($P>0.05$, $-0.46<r<0.54$), indicating that soil nutrients do not cause changes in terpene content of these species. This diverges from results reported by Ormeño et al. (2007c) who showed a positive effect of these nutrients on some terpene emissions of *R. officinalis* and a negative effect of the same nutrients on some terpene emissions of *C. albidus*. This disparity suggests that terpene content and emissions may respond differently to environmental changes as demonstrated previously by Ormeño et al. (2007a) for both *R. officinalis* and *C. albidus* and by Peñuelas and Llusià (1997) for *R. officinalis*.

It was earlier argued that differing results for *R. officinalis* and *C. albidus* could be due to the fact that calcareous and siliceous soils derive from different parent materials. Possibly, stands located in these soils show different adaptive differentiation (Canadell and Vila 1992) that lead to differences in secondary metabolism.

It was suggested also that leaf content of some terpenes of *C. albidus* and *R. officinalis* increased in siliceous soils because plants have been submitted to a greater stress in those soils. In the study area, the preference for calcareous soils is accentuated in the case of *C. albidus* and in *R. officinalis* to a lesser degree (Albert and Jahandiez 1985), compared to *P. halepensis*. This hypothesis is supported by previous results reported for *Quercus coccifera* L. by Ormeño et al. (2007a) under controlled conditions and during the same season. In that study, terpenes synthesized by potted seedlings of *Q. coccifera*, which is almost absent from siliceous soils in southern France, were strongly favored in siliceous soils. The stress generated in siliceous soils for species that prefer calcareous soils is probably due to soil acidity (Gorenflot 1998).

It is well known that plants produce a bouquet of volatile terpenes that mediate interactions between plants and other organisms (D'Alessandro and Turlings 2006), thus playing a central role in mediating interactions at different trophic levels, between plants and herbivores, between herbivores and their natural enemies, between plants and microorganisms, and also among plants themselves (Baldwin et al. 2002; Dicke et al. 2003). The chemical production of these compounds depends on both abiotic (humidity, temperature, light, soil nutrients) and biotic factors (plant cultivar, growth stage, and attacking pathogen and herbivore species; Vuorinen et al. 2007) and can provide information on plant physiological status and the stresses they are being subjected to (D'Alessandro and Turlings 2006).

Hence, the observed quantitative variation in terpene production of *R. officinalis* and *C. albidus* as a response to soil-induced stress might mediate interaction among plants and arthropods, leading to an ecological advantage. High leaf concentration of some terpenes when plants grow in siliceous soils might protect them against biotic attack and, thus, produce a fitness benefit. Thus, it would not simply account for a response to a soil-induced stress that entails extra synthesis costs for producing a high terpene concentrations without functional advantage. This could account for a strategy that allows species to grow in soils where their growth is not optimal.

Acknowledgements This research was primarily funded by the French Agriculture Minister (DERF), the Environmental Agency (ADEME), and the Provence-Alpes-Côtes d'Azur (PACA) region. Authors wish Sylvie Dupouyet and Dr. Christiane Rolando for their collaboration in measurement campaigns, Laboratory of Chemistry and Environment (LCE, University of Provence, FRE 2704) for soil analysis, and Stephane Greff for his help using analytical methods. We thank Mr. Michael Paul for improvements to the English. All experiments conducted in this study comply with the French laws.

root elongation, reduces rates of photosynthesis, and inhibits nutrient uptake. At the cellular level, the allelochemical induces lipid peroxidation, affects certain enzymatic activities, and rapidly depolarizes the root cell membrane causing a generalized increase in membrane permeability, thus blocking plant nutrient uptake (Weir et al. 2004). At the same time, ferulic acid may be esterified with cell wall polysaccharides, incorporated into the lignin structure, or form bridges that connect lignin with wall polysaccharides, thus making cell walls rigid and restricting cell growth (Iiyama et al. 1990; Sánchez et al. 1996; Lam et al. 2001).

More recently, dos Santos et al. (2004) reported that ferulic acid reduction of soybean growth might be due to premature lignification of root tissues associated with increases in enzyme activities of the phenylpropanoid pathway, such as phenylalanine ammonia lyase (PAL) and POD. The aim of the present report was to investigate what the mode of action of ferulic acid is on the lignification process. For this, light and electron microscopy studies and determinations of CAD and POD activities, H_2O_2 level, and lignin content and composition were carried out after treatment of soybean roots with ferulic acid and inhibitors of the phenylpropanoid pathway.

Methods and Materials

General Procedures Soybean (*Glycine max* L. Merrill) seeds, surface-sterilized with 2% sodium hypochlorite for 5 min and rinsed extensively with deionized water, were dark-germinated (at 25°C) on two sheets of moistened filter paper. Twenty-five 3-d-old seedlings of uniform size were supported on an adjustable acrylic plate and transferred into a glass container (10×16 cm) filled with 200 ml of half-strength Hoagland's solution (pH 6.0), with or without 1.0 mM ferulic acid. Additional experiments with 0.1 mM of piperonylic acid (PIP) or 2.0 mM of 3,4-(methylenedioxy) cinnamic acid (MDCA) were made as indicated in the figure legends. The container was kept in a growth chamber (25°C, 12/12 hr L/D photoperiod, irradiance of 280 μmol m^{-2} s^{-1}). Roots were measured at the beginning and at the end of experiments (24 or 48 hr). When indicated, the fresh root weight was determined immediately after incubation, and the dry weight was estimated after oven-drying at 80°C until it reached a constant weight. CAD and POD activities and lignin contents were determined after the incubation period of 24 hr, while light and electron microscopy analyzes were carried out after 48 hr of incubation. Ferulic acid, PIP, and MDCA were purchased from Sigma-Aldrich Chemical Co (St. Louis, MO, USA), and all other reagents used were of the purest grade available or chromatographic grade.

Light Microscopy Studies Samples of material for morphological and anatomical studies were fixed in FAA 50 (Johansen 1940). The material was conserved in ethanol 70% (Jensen 1962). The anatomical description was made from the analysis of permanent slides obtained of longitudinal and transversal sections of the roots. In the preparation of permanent slides, plant material was embedded in glycol methacrylate according to the technique described by Gerrits (1991). These slides were stained with toluidine blue O (O'Brien et al. 1964) and mounted in Permount. Additionally, fresh transverse cross-sections of roots were immersed in a freshly prepared solution of phloroglucinol-HCl (Berlyn and Miksche 1976). Micrographs were photographed with an Olympus® photomicroscope. Scales were calculated using a decimal ruler and a micrometer under the same optical conditions used for each case.

Electron Microscopy Studies For scanning electron microscopy, fresh root segments were fixed in 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer, pH 7.2. Tissues were postfixed in a solution containing 1% osmium tetroxide, 0.8% potassium ferrocyanide, and 5 mM calcium chloride in 0.1 M cacodylate buffer, and then in a 1% tannic acid solution. Further, the samples were dehydrated in graded ethanol solutions, critical-point-dried in CO_2, sputter-coated with gold, and examined on a Jeol-JSM-5310® field emission scanning electron microscope. For transmission electron microscopy, fresh root segments were washed in 0.01 M phosphate-buffered saline and fixed in 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer. Tissues were postfixed in a solution containing 1% osmium tetroxide and 0.8% potassium ferrocyanide in 0.1 M cacodylate buffer, washed in the same buffer, dehydrated in acetone, and embedded in Spurr resin. Ultrathin sections obtained in a Reichert Ultracut E ultramicrotome were stained with uranyl acetate and lead citrate, and examined in a Zeiss EM900® transmission electron microscope.

Cinnamyl Alcohol Dehydrogenase Assay Cinnamyl alcohol dehydrogenase was extracted from fresh roots (2 g) with 3 ml of an extraction medium containing 40 mM of β-mercaptoethanol and 100 mM potassium phosphate buffer (pH 7.3). The homogenate was centrifuged at 2,200×*g* for 15 min, and the supernatant was used as enzyme preparation (dos Santos et al. 2006). CAD was assayed chromatographically by the reaction of reduction of sinapaldehyde to sinapyl alcohol. The assay was carried out, at 30°C, in 1.0 ml of reaction mixture containing 200 μl of crude enzyme preparation (≤0.35 mg of protein), 104 nmol NADPH, and 150 nmol Tris–HCl buffer (pH 8.0). At the start, 50 nmol of sinapaldehyde were added, and the reaction was stopped after 3 min of incubation by adding 50 μl of 5 N HCl. Parallel controls with sinapaldehyde added in the reaction mixture (without NADPH) were made. All samples were filtered through a 0.45-μm disposable syringe filter (Hamilton® Co., NV, USA) and analyzed (20 μl) with a Shimadzu® Liquid Chromatograph (Tokyo,

Japan) equipped with an LC-10AD pump, a Rheodyne® injector, an SPD-10A UV detector, a CBM-101 Communications Bus Module, and a Class-CR10 workstation system. A reversed-phase Shimpack® CLC-ODS (M) column (150× 4.6 mm, 5 μm) was used at room temperature together with the same type of pre-column (10×4.6 mm). The mobile phase was methanol/acetic acid 4% in water (20:80, *v*/*v*) with a flow rate of 1.2 ml min^{-1} for an isocratic run of 20 min. Absorption was detected at 345 nm. Data collection and integration were performed with Class-CR10 software (Shimadzu®, Tokyo, Japan). Sinapyl alcohol was identified by comparing its retention time with standard values. CAD activity was expressed as nanomole sinapaldehyde consumed per minute per milligram protein. Protein was determined spectrophotometrically at 595 nm (Bradford 1976), with bovine serum albumin as a standard.

Peroxidase Assay Root (0.8 g) was homogenized in Eppendorf tubes with 0.12 ml of cold extraction medium containing 0.886 M sodium potassium buffer pH 7.0, 1.0 mM EDTA, 1.0 mM sodium metabisulfite, 9.96 mM sodium borate, 5% PVP-40 (polyvinylpyrrolidone), 0.5% β-mercaptoethanol, 10% glycerol, 2% ascorbic acid, and 4% polyethylene glycol (Pereira et al. 2001). The homogenates were centrifuged (21,900 ×*g*, 30 min, 4°C), and the supernatant was used as soluble POD extract. For cell wall-bound POD isolation, fresh roots (5 g) were macerated with 67 mM phosphate buffer (50 ml, pH 7.0) containing 0.5 g PVP (dos Santos et al. 2004). The extract was centrifuged (2,200 ×*g*, 5 min, 4°C). The pellet was washed with deionized water until no soluble POD activity was detected in the supernatant. The pellet was incubated in 10 ml of 1 M NaCl (prepared in 50 mM phosphate buffer, pH 7.0) for 1 hr. The homogenate was centrifuged (2,200 ×*g*, 5 min, 4°C) and the supernatant obtained. Cold acetone (30 ml) was slowly added in the supernatant under constant stirring. After centrifugation (10,000 ×*g*, 30 min, 4°C), the pellet was resuspended with 0.15 ml of 1 M NaCl and considered as cell wall-(ionically)-bound POD.

For polyacrylamide gel electrophoresis (PAGE), samples (50 μl) of the enzyme extract were applied in 12% gel prepared in 0.375 M Tris–HCl pH 8.8 buffer. Electrophoresis was performed for 5 hr at 200 V. The running buffer used was 0.1 M Tris–glycine pH 8.3 (Pereira et al. 2001). This gel was incubated at 37°C for 15 min with 50 ml of 1 M sodium citrate buffer, pH 4.7, adjusted with acetic acid, 50 ml of methanol, and 0.05 g of benzidine. Then, 5 ml of 30% H_2O_2 were added to the staining mixture and the preparation was maintained at 37°C until the time of isozyme detection (Mangolin et al. 1994).

H_2O_2 Quantification Fresh roots (2 g) were homogenized in 3 ml of 50 mM phosphate buffer, pH 6.8 (Hsu and Kao 2007). The homogenate was centrifuged at 2,200 ×*g* for 20 min. Further, 1.5 ml of extracted solution, mixed with 0.5 ml of 0.1% titanium chloride in 20% (*v*/*v*) H_2SO_4, was then centrifuged at 2,200 ×*g* for 15 min. Absorbance was measured at 410 nm, and H_2O_2 was quantified with a calibration curve of known standard concentrations. Whereas the blank consisted of a reaction mixture without tissue extract, its absorbance was subtracted from the mixture with H_2O_2 extract. Results were expressed as nanomole H_2O_2 per gram fresh weight.

Quantification of Lignin Content and Composition After the incubation period, dry roots (0.3 g) were homogenized in 50 mM potassium phosphate buffer (7 ml, pH 7.0) with a mortar and pestle and transferred into a centrifuge tube (Ferrarese et al. 2002). The pellet was centrifuged (1,400 ×*g*, 4 min) and washed by successive stirring and centrifugation as follows: twice with phosphate buffer pH 7.0 (7 ml); 3× with 1% (*v*/*v*) Triton® X-100 in pH 7.0 buffer (7 ml); 2×with 1 M NaCl in pH 7.0 buffer (7 ml); 2×with distilled water (7 ml); and 2×with acetone (5 ml). The pellet was dried in an oven (60°C, 24 hr) and cooled in a vacuum desiccator. The dry matter was defined as a protein-free cell wall fraction. Further, all dry protein-free tissue was placed into a screw-cap centrifuge tube containing the reaction mixture (1.2 ml of thioglycolic acid plus 6 ml of 2 M HCl) and heated (95°C, 4 hr). After cooling at room temperature, the sample was centrifuged (1,400 ×*g*, 5 min), and the supernatant was discarded. The pellet contained the complex lignin–thioglycolic acid (LTGA). The pellet was washed three times with distilled water (7 ml) and the LTGA extracted by shaking (30°C, 18 hr, 115 oscillations per minute) in 0.5 M NaOH (6 ml). After centrifugation (1,400 ×*g*, 5 min), the supernatant was stored. The pellet was washed again with 0.5 M NaOH (3 ml) and mixed with the supernatant obtained earlier. The combined alkali extracts were acidified with concentrated HCl (1.8 ml). After precipitation (0°C, 4 hr), LTGA was recovered by centrifugation (1,400 ×*g*, 5 min) and washed two times with distilled water (7 ml). The pellet was dried at 60°C, dissolved in 0.5 M NaOH, and diluted to yield an appropriate absorbance for spectrophotometric determination at 280 nm. Lignin was expressed as milligram LTGA per gram dry weight.

Alkaline cupric oxidation was used to determine lignin monomer composition (Chen and McClure 2000). Protein-free cell wall fraction (25 mg) was sealed in a Pyrex® ampule containing 1 ml of 2 M NaOH plus 0.2 g of CuO and heated to 170°C for 2 hr, while shaking the sample occasionally during the reaction. After oxidation, the sample was cooled at room temperature, acidified to pH 2 with 2 M HCl, and extracted twice with anhydrous ethyl ether. The organic extracts were combined, dried, and resuspended in methanol/acetic acid 4% in water (20:80, *v*/*v*). All samples were filtered through a 0.45-μm disposable syringe filter (Hamilton® Co., NV, USA) and analyzed by high-performance liquid chroma-

tography (HPLC), as described earlier. The mobile phase was methanol/acetic acid 4% in water (20:80, *v*/*v*), with a flow rate of 0.8 ml min^{-1} for an isocratic run of 20 min. Quantification of *p*-hydroxybenzaldehyde, vanillin, and syringaldehyde was performed at 290 nm by corresponding standards. Results were expressed as microgram monomer per milligram cell wall.

Additionally, cell wall-bound ferulic acid was extracted after alkaline hydrolysis (de Ascensao and Dubery 2003). Dry roots (0.2 g) were homogenized in 4 ml of 50% methanol with a mortar and pestle and transferred into a centrifuge tube, heated to 80°C for 1.5 hr. Supernatant was discarded after centrifugation (2,200 ×*g*, 10 min). The pellet was washed twice with 2 ml of 50% methanol and dried in an oven (60°C, 24 hr). Dry material (0.1 g) was resuspended in 10 ml of 0.5 M NaOH and heated to 96°C for 2 hr. The sample was acidified to pH 2 with HCl, centrifuged (2,200 ×*g*, 10 min), and the supernatant was extracted twice with 10 ml of anhydrous ethyl ether. The organic extracts were combined, dried, and resuspended in methanol/acetic acid 4% in water (30/70, *v*/*v*). All samples were filtered through a 0.45-µm disposable syringe filter (Hamilton® Co., NV, USA) and analyzed by HPLC, as described earlier. The mobile phase was methanol/water (30:70, *v*/*v*) with a flow rate of 0.8 ml min^{-1} for an isocratic run of 20 min. Cell wall-released ferulic acid was identified at 330 nm by co-injection with authentic standard.

Statistical Design The experimental design was completely randomized, and each plot was represented by one glass container with 25 seedlings. Data are expressed as the mean of three to five independent experiments ±S.E. The one-way variance analysis to test the significance of the observed differences was performed by Sisvar® package (Version 4.6, UFLA, Brazil). The difference among parameters was evaluated by the Scott–Knott test, and P values <0.05 were considered as statistically significant.

Results

Effects of Ferulic Acid on Root Growth As may be judged visually, differences in the roots were apparent (Fig. 1). Primary root elongation of treated seedlings was inhibited by the compound. Roots became brown, thicker, and less flexible. After 24 and 48 hr, the allelochemical prompted significant decreases in the root lengths when compared to the control conditions (Table 1).

Light and Electron Microscopy Analyses Subsequent experiments were carried out to evaluate anatomical changes in roots by light microscopy (Table 1). The effects of ferulic acid on diameter (root and vascular cylinder) measures of medial and basal sections were examined after root treatments. After 24 hr, the vascular cylinder diameters increased in both medial (40.9%) and basal (14.3%) sections in comparison to controls. Significant effects of ferulic acid were evident at 48 hr; the root diameter decreased (11.3%) while the vascular cylinder diameter increased (19%) in the medial section. Cross sections of the medial region in untreated roots showed a normal pattern of growth (Fig. 2A,C). Results of the two histochemical methods used to verify lignification gave results that agreed closely. When the ferulic acid-exposed roots (Fig. 2B) were subjected to phloroglucinol-HCl reagent, an intense coloration indicating lignified cell walls developed when compared to control (Fig. 2A). Moreover, the number of differentiated xylem elements formed was greater in ferulic acid-treated roots than in control roots. In ferulic acid-treated roots stained with toluidine blue O (Fig. 2D), the metaxylem also showed lignification when compared to control (Fig. 2C). In addition, longitudinal sections of the transition zone in treated roots indicated initiation of lateral roots and lignification of the primary xylem (Fig. 2E,F). Similar sections revealed a smaller distance between the quiescent center and the differentiated cells in ferulic acid-treated roots when compared to the untreated roots (Fig. 2G,H).

Transmission electron microscopy observations of ferulic acid-treated root caps showed a reduced number of starch granules in comparison to control (Fig. 3A,B). Micrographs of the quiescent center in treated roots revealed that the cells were smaller and compressed, and contained irregular and enlarged nucleoli and many lipid globules in comparison to the untreated roots (Fig. 3C,D). Finally, scanning electron microscopy photomicrographs showed disintegration of the root cap in the ferulic acid treated roots in comparison to control (Fig. 3E,F).

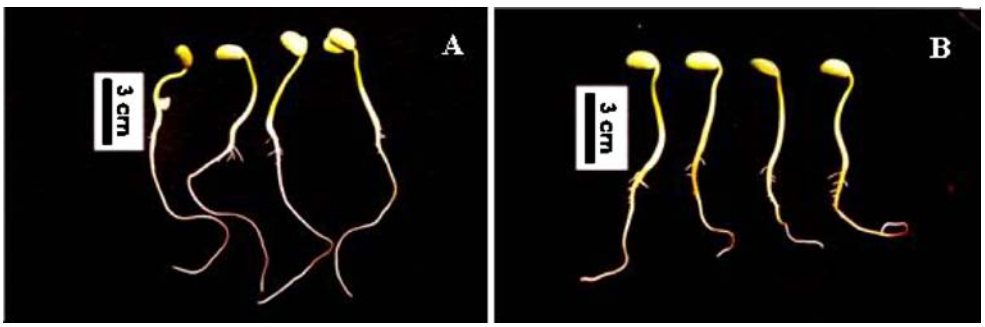

Fig. 1 Effects of ferulic acid on soybean root length. Control (A) and treated (B) roots with 1.0 mM ferulic acid after 48 hr

Table 1 Anatomical characteristics of ferulic acid treated soybean roots after 24 and 48 hr

			Medial region		Basal region	
		Root length (cm)	Root diameter (μm)	Cylinder diameter (μm)	Root diameter (μm)	Cylinder diameter (μm)
24 hr	C	3.3±0.21	5.8±0.37	2.2±0.07	7.7±0.50	2.8±0.10
	T	2.2±0.09[a]	7.5±0.59	3.1±0.06[a]	8.2±0.22	3.2±0.09*
	%	−33.3	ns	+40.9	ns	+14.3
48 hr	C	7.0±0.14	7.1±0.05	2.1±0.02	8.0±0.32	3.0±0.11
	T	2.7±0.16[a]	6.3±0.44[a]	2.5±0.07[a]	7.2±0.26	2.9±0.11
	%	−61.4	−11.3	+19.0	ns	ns

The symbol % represents inhibition (−) or activation (+) of statistically significant means after treatment in comparison to control.
C control, *T* treatment, *ns* not significant.
[a] Means (N=4±SE) significantly ($P \leq 0.05$) smaller than the control experiment (Scott–Knott's test)

Effects of Ferulic Acid on CAD and POD Activities and H_2O_2 Content Ferulic acid-affected CAD activity was significantly different from control (Fig. 4). The allelochemical decreased the enzymatic activity by 42.8% at 1.0 mM treatment. In addition to this earlier finding, electrophoretic patterns of POD isozymes were determined in soybean roots after allelochemical treatment (Fig. 5). PAGE zimograms of POD in ferulic acid treated roots revealed that only the anionic form PODa5 increased compared to the control condition. Moreover, the allelochemical decreased the H_2O_2 content 30% when compared to control (Fig. 6).

Effects of Ferulic Acid on Lignin Content and Composition Lignin content in soybean roots increased following 1.0 mM ferulic acid treatment by about 46% at 24 hr (Figs. 7 and 8). Figure 7 reveals that PIP, a potent quasi-irreversible inhibitor of cinnamate 4-hydroxylase (C4H), reduced lignin content of soybean roots 37.6% compared to control. Similar to ferulic acid, treatment of roots with allelochemical plus PIP increased lignin content 26.5% compared to the control condition. Experiments with MDCA, a competitive inhibitor of 4-coumarate:CoA ligase (4CL), are seen in Fig. 8. Lignin content was not affected by MDCA, alone or jointly with ferulic acid (FA plus MDCA), in comparison with the control experiment. The analysis of alkaline cupric oxidation products (Fig. 9) revealed that lignin monomer content (*p*-hydroxybenzaldehyde+guaiacyl+syringyl; H+G+S) increased 3.8-fold compared to that in untreated roots. The allelochemical mainly increased the guaiacyl (G) monomer. When subjected to alkaline hydrolysis, cell walls of allelochemical-exposed roots released significant amount of ferulic acid identified chromatographically (Fig. 10).

Discussion

Root growth is characterized by high metabolic rates, and for this reason roots are highly susceptible to environmental stresses, such as allelochemicals in soils (Cruz-Ortega et al. 1998). The experimental conditions used in this work were chosen because the net uptake of ferulic acid by the root system is high (Shann and Blum 1987a), and lignification begins during the early stages of seedling growth (dos Santos et al. 2004; Passardi et al. 2005). At the final stages of xylem cell differentiation, lignin is deposited within the carbohydrate matrix of the cell wall by infilling of interlamellar voids and, at the same time, by the formation of chemical bonds with the non-cellulosic carbohydrates (Donaldson 2001). An important fact revealed in the present work is that the reduction of soybean root length (Table 1) by ferulic acid is associated with an increase in the lignin contents (Figs. 7 and 8).

Structural changes of root cells have been associated with root growth inhibition induced by stress (Cruz-Ortega et al. 1998). The increase in root diameter, especially of vessel cylinder, may be attributed to the early differentiation of vessel tissues verified by the lignification of metaxylem (Fig. 2D). As reported earlier, cell walls may be lignified when stressed or when they differentiate to xylem (Christensen et al. 1998). Anatomical observations here showed that the diameter of the vascular cylinder in the medial and basal regions was enhanced after 24 and 48 hr of treatments, compared with controls (Table 1). Ferulic acid-treated roots showed a greater number of differentiated xylem elements and lignification of cell walls (Fig. 2B), induction of lateral roots (Fig. 2F) with lignification of the metaxylem (Fig. 2D), and an increase of the central cylinder (Fig. 2D), all consistent with increased lignin production (Figs. 7 and 8). Furthermore, a smaller distance between the quiescent center and the first differentiated cells together with clustered cells in the longitudinal section of treated roots (Fig. 2H) indicate premature cessation of root growth. There is evidence to corroborate these results (Chon et al. 2002). For example, coumarin-treated alfalfa (*Medicago sativa*) roots revealed a significant increase in diameter due to an expanding of the vascular cylinder and cortex cell layers. Moreover, this allelochemical inhibited root elongation and cell division, indicating that the thickness of roots was enlarged due to inhibition of root longitudinal

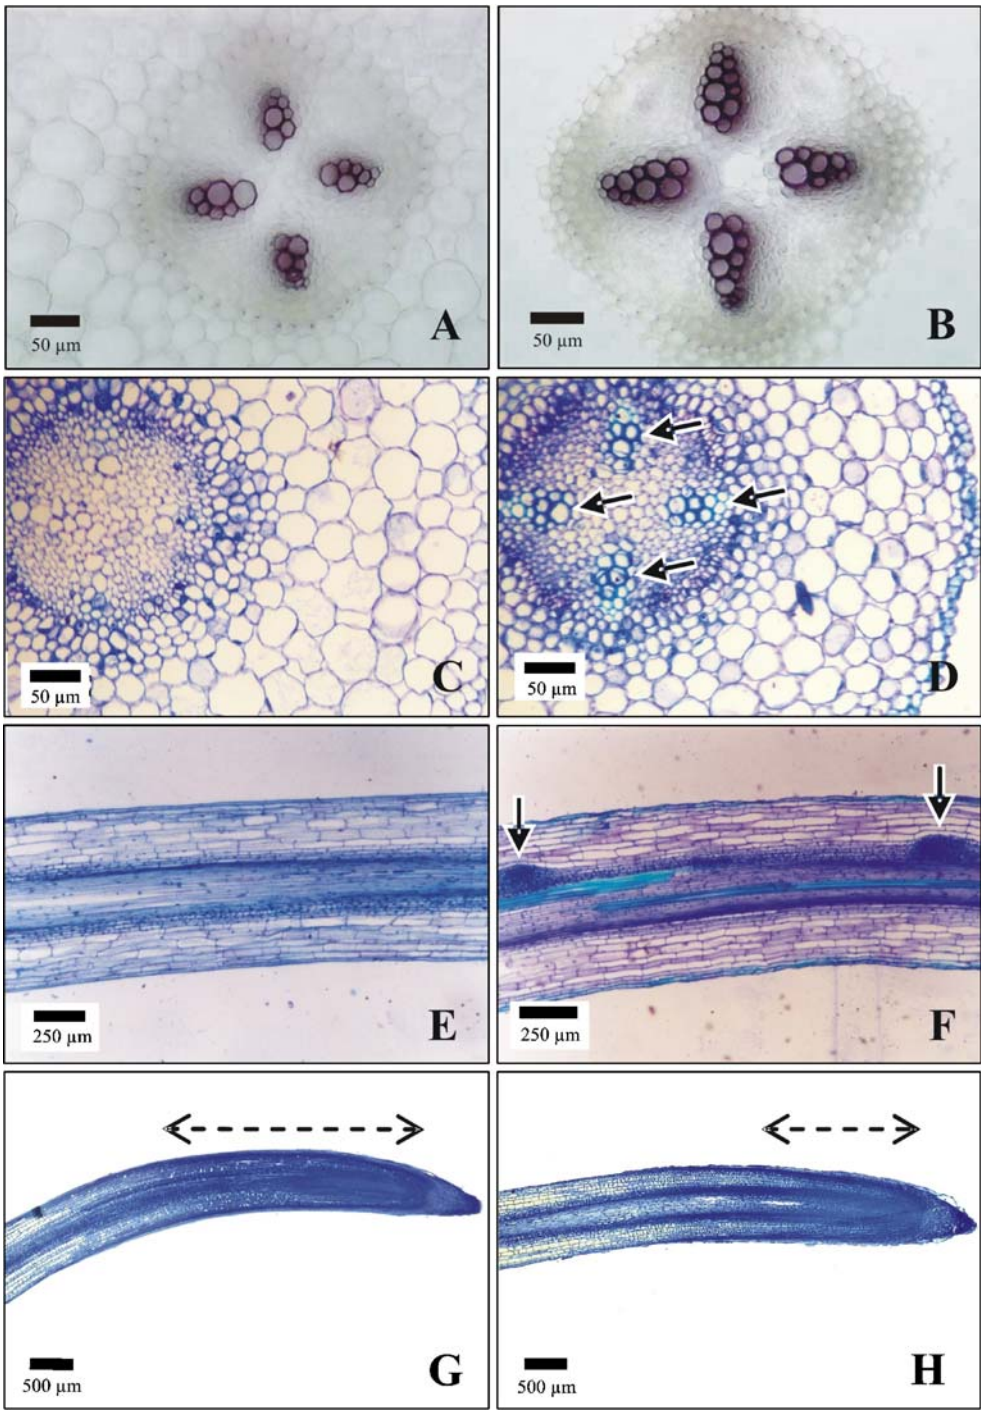

Fig. 2 Light microscopy photomicrographs of control (A, C, E, G) and treated (B, D, F, H) soybean roots with 1.0 mM ferulic acid for 48 hr. A and B: phloroglucinol-HCl staining method indicating lignified cell walls in cross sections of the medial zone. C and D: toluidine blue O staining method in cross sections of the medial zone (*arrows* indicate lignification of metaxylem). E and F: longitudinal sections of the central cylinder in the basal region (*arrows* indicate induction of lateral roots and lignification). G and H: longitudinal sections (*dotted lines* indicate the distance between the quiescent center and first differentiated cells)

growth. The water-soluble extract of alfalfa leaves, which contains mainly ferulic acid among other allelochemicals, showed similar effects (Chon et al. 2002).

At the ultrastructural level, treatment with ferulic acid adversely affected soybean root cells. Electron micrographs showed a reduction in the number of starch granules (Fig. 3B), an increase in lipid globules, and compression of cells with enlarged nucleoli (Fig. 3D) in ferulic acid treated roots. Disintegration of the root cap in treated roots (Fig. 3F) suggests death of cells after direct contact with the allelochemical. In simplest terms, ferulic acid inhibited the root growth and led to cellular ultrastructural abnormalities. Studies have shown that allelochemicals can affect the cellular structure of growing roots. White mustard (*Sinapis alba*) radicle treated with gramine and hordenine showed vacuolation, disorganization of organelles, and damage to cells walls (Liu and Lovett 1993). Root cell ultrastructure of cucumber exposed to 2-benzoxazolinone presented cytoplasmatic vacuolation and

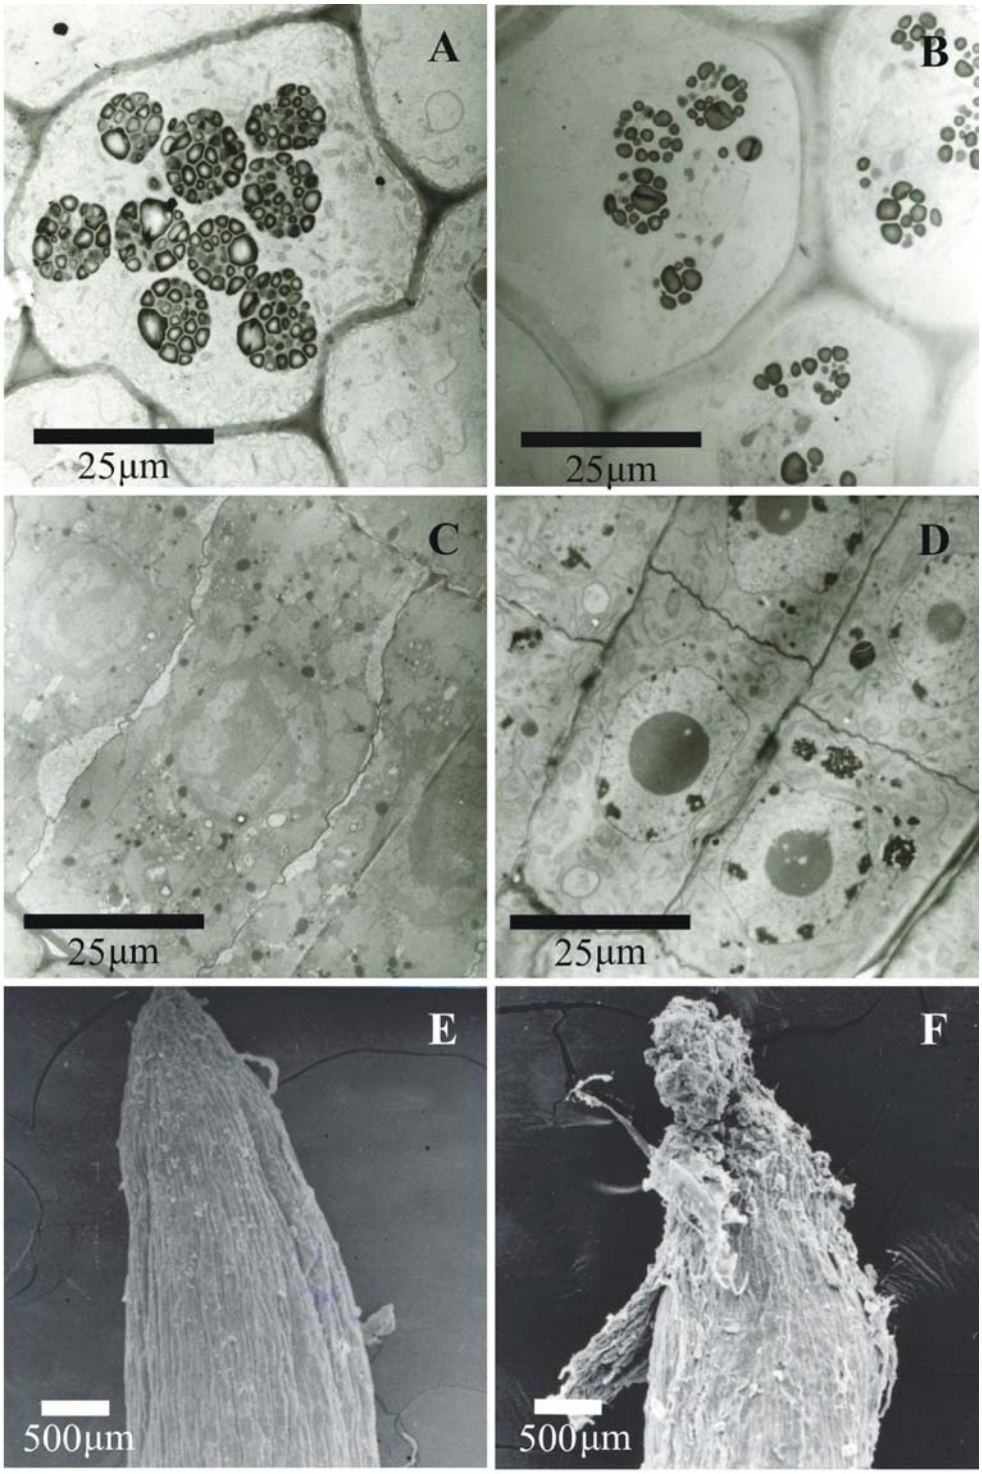

Fig. 3 Electron microscopy photomicrographs of control (A, C, E) and treated (B, D, F) soybean roots with 1.0 mM ferulic acid for 48 hr. C and D: transmission electron microscopy of quiescent center cells showing compression with enlarged nucleoli and lipid globules in treated roots. E and F: scanning electron microscopy of root cap showing epidermic tissue disintegrated in treated roots

reduced number of starch granules (Burgos et al. 2004). Mustard (*Brassica juncea*) seedlings treated with benzoic acid showed cellular disorganization (Kaur et al. 2005). According to these authors, inhibition of root growth was due to reduced lipid catabolism, protein synthesis, and adverse effects on cell division and mineral uptake. In agreement, ferulic acid inhibits protein synthesis, affects membrane permeability, and decreases uptake of nutrients (Politycka 1996; Baziramakenga et al. 1997). Moreover, it reduces lipid mobilization followed by accumulation of unsaturated fatty acids in germinating canola (*Brassica napus*) seeds (Baleroni et al. 2000). It also increases the contents of saturated and unsaturated fatty acids, xylose, fructose, and sucrose in soybean root (Ferrarese et al. 2001). Thus, the cellular structure changes reported here appear to be, at least partially, associated with changes in the lipid and carbohydrate metabolism (Ho 1988).

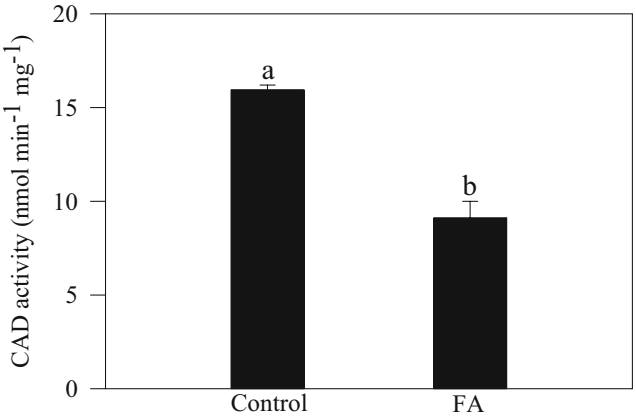

Fig. 4 Effects of ferulic acid (*FA*) on CAD activity in soybean roots. Mean±SE values (*N*=4) followed by the different letter are significantly different according to the Scott–Knott test ($P \leq 0.05$)

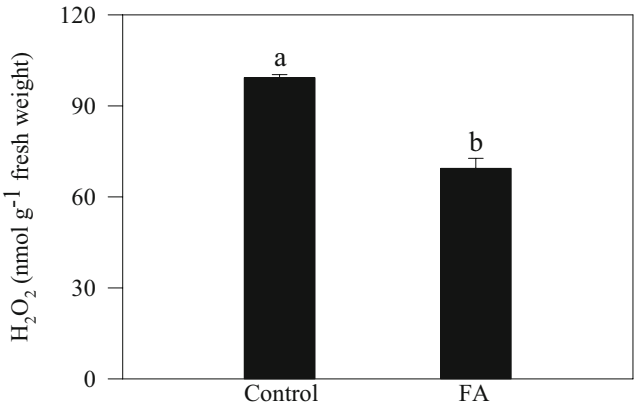

Fig. 6 Effects of ferulic acid (*FA*) on H_2O_2 content in soybean roots. Mean±SE values (*N*=3) followed by the different letter are significantly different according to the Scott–Knott test ($P \leq 0.05$)

There is evidence that the effects of ferulic acid on soybean are related to premature lignification of roots, since enzyme (PAL and POD) activities of the phenylpropanoid pathway increased jointly with lignin production (dos Santos et al. 2004). Direct incorporation of exogenous ferulic acid, independent of phenylpropanoid metabolism, was initially hypothesized. This possibility should not be discounted. The radiotracer [U-ring-^{14}C]ferulic acid] was found in residues of lignin isolated from cucumber seedlings treated with the allelochemical (Shann and Blum 1987b). To test the hypothesis that exogenous ferulic acid induces the lignification process, CAD activity was determined in treated soybean roots. Surprisingly, this showed that CAD activity decreases in ferulic acid treated roots (Fig. 4) despite lignin production (Figs. 7 and 8). Increase in CAD activity would be anticipated, since it is considered to be a lignification marker (Boerjan et al. 2003). Increased lignification under reduced CAD activity might, at least in principle, strengthen the hypothesis of direct incorporation of exogenous ferulic acid into lignin polymer. However, plants are able to circumvent the block in CAD activity by shipping substrates, the cinnamaldehydes, to the cell wall for polymerization (Boerjan et al. 2003). This indicates that the impact of CAD on lignin biosynthesis may not be critical. Cross-coupling of hydroxycinnamyl aldehydes into lignin compensates for the reduced availability of monolignols in CAD-deficient plants (Kim et al. 2000; Li et al. 2001).

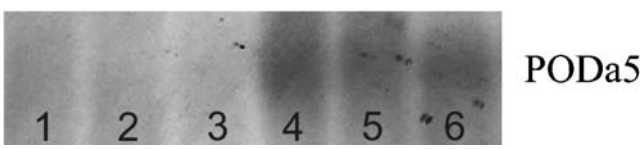

Fig. 5 PAGE isozyme patterns of POD in soybean roots. 4 to 6, ferulic acid-treated roots showing increase of the anionic isoform of soluble enzyme (*PODa5*) in comparison to control (*1* to *3*). POD activity was stained using H_2O_2 as the substrate

Ferulic acid increased the activity of anionic isoform PODa5 in treated roots (Fig. 5). Anionic isoperoxidases are often held to be those most directly involved in lignification of xylem cells (Wallace and Fry 1999; Passardi et al. 2005). POD is able to dehydrogenate monolignols, to induce lignification after addition of H_2O_2 in tissue sections, and to reveal specific colocalization of isoforms in lignifying tissues (Ros Barceló et al. 2004; Passardi et al. 2005). H_2O_2, produced by the pH-dependent POD and NADPH oxidase complex, is a necessary substrate for the cell wall's lignifying process catalyzed by POD, thus causing a rapid cross-linking of cell-wall polymers (Wojtaszek 1997). Ferulic acid exposure reduced the H_2O_2 content of roots (Fig. 6). It is feasible that these facts may, in part, explain the increase in anionic isoform PODa5 in treated roots (Fig. 5), consistent with increased lignin production (Figs. 7 and 8).

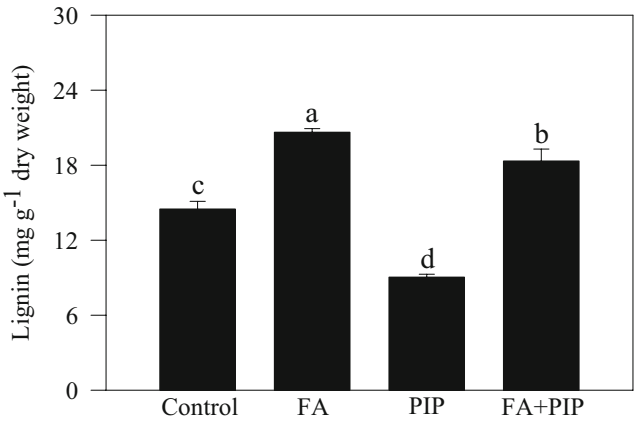

Fig. 7 Changes in the lignin contents of soybean roots untreated (*Control*) or treated with 1.0 mM ferulic acid (*FA*), 0.1 mM piperonylic acid (*PIP*) and 1.0 mM ferulic acid plus 0.1 mM piperonylic acid (*FA+PIP*) for 24 hr. Mean±SE valus (*N*=5) followed by different letters are significantly different according to the Scott–Knott test ($P<0.05$)

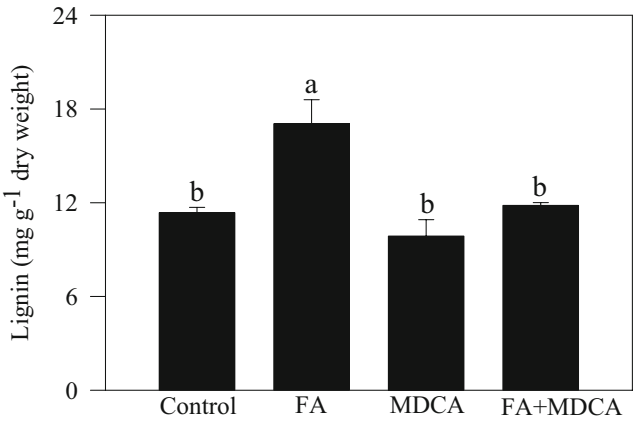

Fig. 8 Changes in the lignin contents of soybean roots untreated (*Control*) or treated with 1.0 mM ferulic acid (*FA*), 2.0 mM methylene dioxocinnamic acid (*MDCA*) and 1.0 mM ferulic acid plus 2.0 mM methylene dioxocinnamic acid (*FA+MDCA*) for 24 hr. Mean±SE values (N=5) followed by same letter are not significantly different according to the Scott–Knott test (P<0.05)

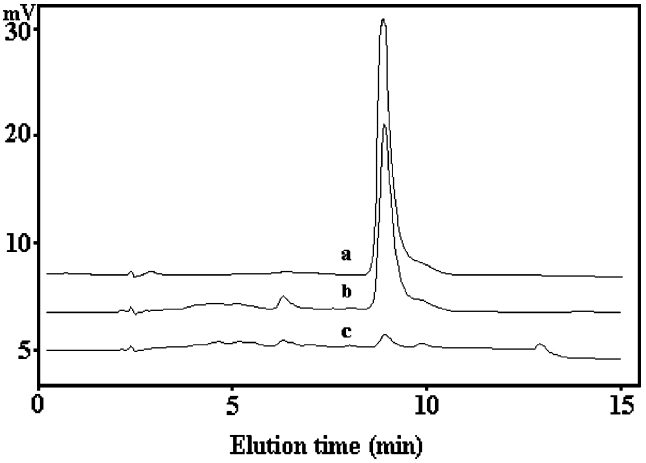

Fig. 10 HPLC elution profiles of ferulic acid standard (*a*, retention time=8.83 min), cell wall-released ferulic acid in the treated roots (*b*, retention time=8.87 min), and cell wall-released ferulic acid in the control roots (*c*, retention time=8.85 min)

Hamada et al. (2003) demonstrated that exogenously supplied ferulic acid was converted to feruloyl and then to coniferyl and sinapyl alcohols, in poplar (*Populus alba*) callus. Since feruloyl CoA is an intermediate of phenylpropanoid metabolism (Fig. 10), a possible entry of free ferulic acid into the pathway, by the 4CL reaction, must be considered. To elucidate, subsequent experiments were made by growing roots with two inhibitors of the pathway enzymes: PIP, a quasi-irreversible inhibitor of cinnamate 4-hydroxylase (C4H), and MDCA, a competitive inhibitor 4-coumarate:CoA ligase (4CL). Figure 7 shows that roots grown under ferulic acid treatment produce more lignin, while PIP-treated roots synthesize less lignin, compared to standard conditions. This is in agreement with the fact that PIP is an effective inhibitor of C4H, and acts before the entry point of ferulic acid in the pathway (Schoch et al. 2002). When applied jointly with PIP, ferulic acid prompted an increase in lignin content, suggesting its entrance into pathway by the 4CL reaction. To strengthen this assumption, roots were incubated with MDCA, an inhibitor of 4CL (Schoch et al. 2002). Lignin content did not change after MDCA or MDCA plus ferulic acid treatments, compared to controls (Fig. 8), thus indicating that the access of exogenous allelochemical has been blocked at this metabolic point.

Since exogenous ferulic acid may be incorporated into lignin structure by means of the phenylpropanoid pathway, changes in the lignin monomer content should not be discounted. In order to ascertain lignin composition, cell walls isolated from ferulic acid exposed roots were subjected to alkaline cupric oxidation. Results shown herein reveal a striking feature. The lignin monomer contents increased in treated roots (Fig. 9). Root lignin from ferulic acid exposed plants was mainly composed of guaiacyl (G) unit in a 18:72:10 (H/G/S) ratio, compared to control plants (40:50:10 ratio). It is well-known that in dicotyledonous angiosperms, lignin is derived from three monomer types; *p*-hydroxyphenyl (H), guaiacyl (G), and syringyl (S) units, derived from *p*-coumaryl, coniferyl, and sinapyl alcohol, respectively (Boerjan et al. 2003). One of the important precursors of *p*-coumaryl alcohol in the phenylpropanoid pathway is ferulic acid (Fig. 11). Moreover, lignin polymerization is regulated by the cell through the supply of available monomers (Boerjan et al. 2003). In robinia (*Robinia pseudoacacia*), labeled ferulic acid was incorporated into guaiacyl (G) and syringyl (S) lignin, and these incorporations increased as cell-wall lignification proceeded (Yamauchi and Fukushima 2004). Based on results reported herein (Figs. 6, 7, 8, 9 and 10), it is

(2006), *(2)* dos Santos et al. (2004), *(3)* Shann and Blum (1987a), *(4)* Baziramakenga et al. (1995), *(5)* Wojtaszek (1997), *(6)* Boerjan et al. (2003)

plausible to suggest that exogenous ferulic acid was channeled into the phenylpropanoid pathway, and later on, caused an increase in lignin. Consistent with these findings, cell walls of allelochemical-exposed roots released significant amount of ferulic acid (Fig. 10).

The focus of the present work was to investigate how the mode of action of ferulic acid is related to the lignification process. Light and electron microscopy studies, combined with biochemical assays, suggest a possible mechanism of soybean response to ferulic acid (Fig. 10). Exogenously applied ferulic acid induces premature cessation of soybean root growth, with disintegration of the root cap, and cellular modifications, such as compression of cells in the quiescent center, early lignification of the metaxylem and cell wall, and increase of the vascular cylinder diameter. At the metabolic level, ferulic acid is channeled into the phenylpropanoid pathway and converted to feruloyl CoA by the 4CL reaction. Catalyzed by subsequent enzymatic reactions, feruloyl CoA is then converted to coniferal- and sinapaldehydes. As an endwise enzyme of the pathway, CAD might not be a limiting step. So, either these metabolites are converted into the respective alcohols by CAD or, eventually circumvent the inhibited CAD reaction (Kim et al. 2000; Li et al. 2001; Boerjan et al. 2003) by polymerizing with lignin in the cell wall. Lignin polymerization requires a sufficient supply of H_2O_2, which is produced by the pH-dependent POD and NADPH oxidase complex, after changes in the membrane permeability (Baziramakenga et al. 1995; Wojtaszek 1997). Whether or not this is the actual process, it seems plausible to assume that ferulic acid induced inhibition in root growth of soybean may be due to excessive production of monolignol from exogenously applied ferulic acid. Monolignol polymerization forms a complex network that solidifies the plant cell wall and restricts plant growth.

(2004). So far, most activated defenses have been discovered in algae. Reported examples in macroalgae include the conversion of halimedatetraacetate to the anti-feeding compound halimedatrial in *Halimeda* spp. (Paul and Van Alstyne 1992), and the wound-activated deacetylation of caulerpenyne in *Caulerpa* spp. (Jung and Pohnert 2001; Jung et al. 2002). Phytoplanktonic diatoms convert polyunsaturated fatty acids to α,β,γ,δ-unsaturated aldehydes as an activated anti-predator defense that negatively affects the reproductive success of copepods (Miralto et al. 1999; Pohnert 2000, 2002). Remarkably, a cell damage-activated conversion of dimethylsulfoniopropionate (DMSP) to acrylic acid and dimethylsulfide (DMS) was found in both macro- and microalgae (Wolfe et al. 1997). In both cases, an ecological relevance as an anti-predator defense was proposed (Van Alstyne et al. 2001; Van Alstyne and Houser 2003).

Many sessile marine invertebrates share numerous ecological features and challenges with plants (e.g., modular body organization, high regenerative capabilities, habitat restriction to exposed sites, structural defenses with low efficiency). Thus, it is not surprising that both groups have evolved similar strategies, including chemical defense. In sessile marine invertebrates, examples of activated chemical defenses have also been reported. In *Tridentata marginata*, tissue damage results in an enzymatic formation of a series of dithiocarbamates, tridentatols A–D, that intensify the chemical protection of the hydroid against fish predators (Lindquist 2002). In sponges of the genus *Aplysina*, isoxazoline alkaloids are cleaved to aeroplysinin-1 and dienone following wounding (Teeyapant and Proksch 1993; Weiss et al. 1996; Ebel et al. 1997; Thoms et al. 2006). Puyana et al. 2003, however, have questioned early studies on activated defenses in the genus *Aplysina*. To our knowledge, these two reactions are the only examples of activated defenses that have been reported in sessile marine invertebrates to date. In a recent review on chemical defense in sponges, the problems and challenges encountered when addressing activated defenses in sponges and the limits of conclusions that can be drawn on ecological relevance of these reactions have been discussed (Thoms and Schupp 2007).

The sponge *Aplysinella rhax* (order Verongida, family Aplysinellidae) is closely related to the sponges of the genus *Aplysina* (order Verongida, family Aplysinidae). The dominant secondary metabolites in *A. rhax* (e.g., psammaplins, aplysinellins, bisaprasin) as well as the isoxazoline alkaloids in *Aplysina* spp., are derived from bromotyrosine, and share pronounced structural similarities (Pham et al. 2000; Shin et al. 2000). Psammaplins, in particular psammaplin A, have gained pharmaceutical interest due to their cytotoxic properties (Kim et al. 1999; Jiang et al. 2004; Newman and Cragg 2004). In past studies on *A. rhax*, psammaplin A was described as one of the dominant compounds in the organic extract of the sponge (Pham et al. 2000; Tabudravu et al. 2002).

In contrast, our experiments have revealed a dominance of psammaplin A sulfate in intact tissue of *A. rhax*, whereas psammaplin A is present in low quantities, only. However, damage to tissue of *A. rhax* results in a pronounced shift in the chemical profile with psammaplin A increasing considerably. In a series of wounding experiments and feeding assays with generalist reef fish and an omnivorous sponge predator, we investigated a possible ecological role of this reaction as an activated chemical defense. For the experimental design and the interpretation of data, we used the following criteria defined by Paul and Van Alstyne (1992) for activated defenses in macroalgae: (1) a less potent stored secondary metabolite is converted into a more potent one. (2) The process is rapid, requiring only seconds to a few minutes. (3) The conversion is catalyzed by one or few enzymes.

Based on our results and other recent observations of potentially enzyme-catalyzed conversions of secondary metabolites in sponges (e.g., a deacetylation of sesterterpenes in the sponge *Luffariella variabilis* (Ettinger-Epstein et al. 2007) and changes in secondary metabolite profiles following wounding in *Suberea* sp. (Schupp et al., unpublished data)), we question whether, in the past, activated defenses may have been overlooked in the phylum Porifera and possibly also in other sessile invertebrate phyla.

Methods and Materials

Sponge Collection A. rhax De Laubenfels, order Verongida, is commonly found in the West–Central Pacific at depths between 5–30 m. Around Guam, the sponge is most abundant on coral patch reefs in Apra Harbor. We collected *A. rhax* at Western Shoals, Apra Harbor, at depths between 15–20 m. The sponges *Hyrtios altum* and *Stylissa massa* were collected in close vicinity. Replicate samples always were taken from sponge colonies at least 5 m apart to minimize collection of clones. We minimized air contact and damage to fresh *A. rhax* by keeping the specimens submerged in seawater during collection and experiments whenever possible and by transporting them in large wide-mouth plastic bottles. While *A. rhax* is usually not overgrown by algae or other invertebrates, we occasionally observed feeding scars on individuals in the field. However, we never observed predators actually feeding on the sponge, and to our knowledge, no predator has yet been reported in the literature.

Preparation of Extracts and Pure Compounds Extractions and isolation of psammaplin A sulfate (**1**) and psammaplin

A (**2**) (Fig. 1) from *A. rhax* were performed according to previously published methods (Pham et al. 2000; Shin et al. 2000). We simplified the protocol by using fresh intact sponge as source material for (**1**) and fresh sponge material that was ground in a mortar for 1 min as source for (**2**). The extraction procedures for both compounds were similar. Sponge tissue was lyophilized, ground to a fine powder, and extracted exhaustively with methanol. The crude extracts were evaporated in vacuo and partitioned between butanol and water. Repetitive partitioning of the water layer with butanol transferred (**1**) and (**2**) entirely into the butanol fraction (both were no longer detectable in the water layer by HPLC). Since large amounts of salt and precipitating sponge pigment were removed by this technique, the butanol fractions appeared better suited for our bioassays than crude extracts. The butanol fraction of extract from intact sponge (in the following referred to as "Ar intact"; Fig. 1) consisted of ~70% wt. of (**1**) and of ~4% wt. of (**2**). The butanol fraction of ground tissue (in the following referred to as "Ar wounded"; see Fig. 1) consisted of ~20% wt. of (**1**) and of ~50%wt. of (**2**).

To obtain pure (**1**) and (**2**), the butanol fractions were subjected to C_{18} reversed-phase vacuum flash chromatography by using gradient mixtures of methanol and water (elution order: 50, 45, 35% methanol). The 50% fraction yielded almost entirely compound (**1**), whereas almost all (**2**) was found in the 35% fraction. Both fractions were further purified by semipreparative and preparative HPLC on a Waters HPLC system coupled to a refraction index detector (column: Alltech Econosil C_{18}, 250×10 mm; eluents (isocratic): 20% aqueous methanol and 100% methanol).

NMR spectra of the purified compounds were recorded in CD_3OD solutions containing Me_4Si as internal standard on a 500-MHz Unity Inova spectrometer. Samples were run in 3-mm tubes at room temperature. Mass spectra were obtained with an Agilent LCMS-ESI-TOF system. Compounds were identified by comparison of our spectral data with literature data (Pham et al. 2000; Shin et al. 2000; Tabudravu et al. 2002).

Wounding Intensity Series To determine correlations between injury to *A. rhax* tissue and changes in its chemical profile, we caused different intensities of wounding to four pieces of identical volume (5 ml) of one sponge individual. Each piece was kept submerged in 15 ml seawater during the experiment. Piece 1 was not further treated; piece 2 was stabbed 60× with a scalpel; piece 3 was ground for 15 s; and piece 4 was ground for 1 min (both pieces, 3 and 4, in a small mortar to keep them submerged in the 15-ml seawater). After a standardized reaction time of 2 min (including treatment), samples were frozen along with the seawater at −80°C. The protocol was repeated with a total of six sponge individuals.

Forceps Experiment To mimic fish bites, we removed small tissue pieces from fresh *A. rhax* with forceps. Two fragments of 50 ml volume were cut from one individual and kept submerged in 150 ml seawater each. Fifty "bite" pieces (10–100 µl volume) were taken randomly from

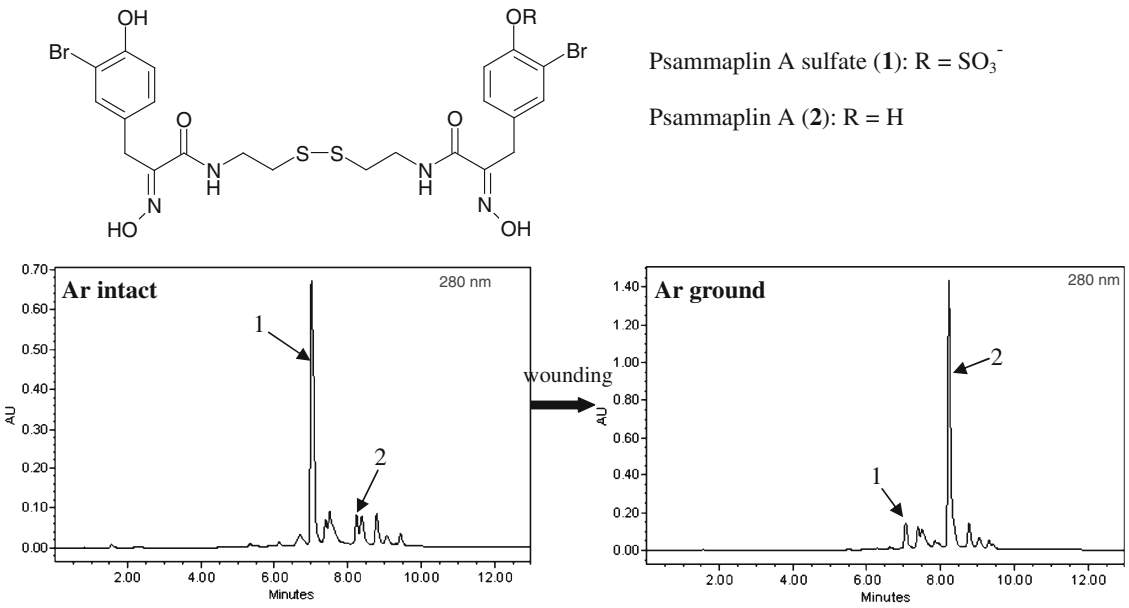

Fig. 1 HPLC chromatograms of the butanol fractions of crude extracts from intact ("Ar intact") and ground ("Ar wounded") *A. rhax* tissue. Tissue wounding resulted in a conversion of psammaplin A sulfate (**1**) to psammaplin A (**2**)

different spots on the sponge surface of one of the pieces and frozen in liquid nitrogen within 2 s. Both 50-ml sponge fragments were frozen at −80°C. The seawater was decanted to remove solid particles and also frozen. The protocol was repeated with a total of four sponge individuals.

Testing for Enzyme-Mediation of the Conversion Reaction Other than grinding of fresh sponge tissue, grinding of lyophilized tissue did not cause any bioconversion, indicating that the conversion enzymes did not function in a water free environment. Two 50-mg subsamples of lyophilized and subsequently ground tissue of *A. rhax* individuals were incubated in 300 µl of distilled water, either at room temperature (25°C) or at 95°C, respectively (2 min incubation time). The suspensions were frozen at −80°C, and the experiment was repeated with tissue powder of three individuals.

Fresh 5-ml pieces of the sponges *A. rhax*, *S. massa*, and *H. altum* were each spiked with 22.8 µmol psammaplin A sulfate dissolved in 75 µl EtOH. Another tissue piece of *A. rhax* was spiked with EtOH only. The tissue pieces were ground vigorously for 4 min and then frozen at −80°C.

Effects of Solvent Exposure In the sponge *Aplysina aerophoba*, reactions similar to those occurring in its activated chemical defense were induced when fresh (wet) tissue contacted organic solvents (Thoms et al. 2006). Preservation of fresh tissue as well as its extraction in organic solvents are common practices in marine chemical ecology. We tested effects of solvent exposure on the metabolite profile in fresh tissue of *A. rhax*.

Five 5-ml pieces of fresh tissue of one *A. rhax* individual were immersed in 10 ml methanol, each. Another piece was frozen immediately at −80°C. In a time series (exposure times 10 min, 30 min, 1 h, 6 h, 24 h), the solvent of each sample was decanted, and the tissue pieces were frozen at −80°C. Solvent samples were dried in a SpeedVac (SPD2010, Thermo Savant). They were re-dissolved in methanol and used to extract the lyophilized and ground sponge pieces as described below. The experiment was repeated with tissue pieces of three sponge individuals.

Chemical Analysis All tissue samples underwent a precisely defined extraction procedure to ensure identical extraction efficiencies. Samples were lyophilized, ground to a fine powder, and homogenized. Fifty milligrams of tissue powder were extracted with 1,500 µl methanol. The samples were vortexed vigorously for 60 s, and after 2 min soaking time, vortexing was repeated for another 30 s. After centrifugation at 13,000 rpm for 2 min, supernatants were analyzed in an HPLC system coupled to a photodiode-array detector (Waters, Milford, Ireland; column: Alltech Rocket Platinum EPS C18, 53×7 mm). Routine detection and quantification of compounds was at 280 nm, but the chromatograms were also inspected with the MaxPlot function of the Waters Empower Pro software that covered wavelengths between 210 and 400 nm.

For quantification, extinction coefficients were determined by repeated analysis of defined amounts of the purified metabolites. Contents in the extracts were calculated based on the detector response at the respective retention times. Seawater samples were lyophilized, redissolved in 50 ml methanol, and an aliquot was analyzed by HPLC as detailed above.

Field Feeding Assay with Generalist Reef Fishes The field assay was conducted based on a method described by Schupp and Paul (1994). In a first set, we tested food treated with psammaplin A sulfate (**1**) against untreated controls. Psammaplin A sulfate (856 mg) dissolved in methanol was added to fish food consisting of 5 g ground catfish pellets, 1.25 g agar, 1.25 g carrageenan, and 80 ml seawater, to match the natural volumetric concentration of (**1**) in *A. rhax* tissue. Controls were prepared by adding the same amount of pure methanol instead. Dissolved extracts and pure compounds always were added to molten food, only after it had cooled down to 60°C in order to avoid compound degeneration due to heat. Mixtures were poured into 1-cm^3 molds containing rubber o-rings. The resulting food cubes were attached with the o-rings and safety pins to ropes. Twenty pairs of ropes, with each rope holding either four treated or four control food cubes, were attached on the reef of Western Shoals, Apra Harbor, Guam. The fish community present was dominated by the species *Abudefduf sexfasciatus*, *A. vaigiensis*, *Amblyglyphidodon curacao*, *Cheilinus fasciatus*, and *Naso vlamingii*. We collected the rope pairs when the fishes had removed half of the cubes. In a second set, we directly compared the repellent activities of psammaplin A sulfate and psammaplin A against generalist reef fish by using the same protocol. In this assay, food treated with natural volumetric concentrations of psammaplin A sulfate was offered together with food treated with an equimolar amount of psammaplin A.

Feeding Assay with a Sponge Predator Feeding experiments were performed with the pufferfish *Canthigaster solandri* based on a laboratory assay described by Schupp et al. (1999). The *A. rhax* extracts "Ar intact" and "Ar wounded" were added in their natural volumetric concentrations to fish food prepared of 2% molten agar and 0.1 g ml^{-1} finely ground catfish food. In a first set, food pieces treated with "Ar intact" and "Ar wounded" were tested separately against controls. Extracts were dissolved in methanol and mixed with the fish food. Control food was prepared similarly, but the same volume of pure methanol was added instead. Treated and control food were poured in

parallel molds backed with fiberglass window screening. When the agar had cooled down, the food was cut into identical strips, each holding a treated and a control food piece (each piece covering 120 squares of the screening). Part of the agar was lyophilized and re-extracted with the same protocol as for extraction of sponge tissue. HPLC comparison with the original extracts revealed no changes in the chemical profile of the extracts after incorporation into the agar.

Food strips were placed in 30-l flow-through tanks and offered to individual pufferfish. Strips were pulled from the tanks, and the number of screening squares where food had been removed was counted when at least 25% of the total food had been eaten. The experiment was terminated after 4 h. In a second set, sponge extracts were compared directly with each other by offering food strips that held two treated food pieces (one with "Ar intact" and the other with "Ar wounded"). Only food strips where no food at all had been removed after 4 h were disregarded in the statistical analysis. A third set of treated food strips was kept in a seawater tank without fish for 4 h. The extract of these strips was compared to extract from strips not exposed to seawater to test for possible diffusion of compounds into the seawater.

Data Analysis Data of the wounding intensity series, the "forceps experiment", and the experiments to test for effects of solvent exposure were analyzed by randomized block analysis of variance. Multiple comparisons were made with the Tukey test (Zar 1999). Levels of significances are given for the treatments. For the field feeding assay, we used Wilcoxon's signed-ranks test for paired comparisons to test for significant differences in the number of cubes eaten. For the feeding assay with the omnivorous sponge predator, we used paired *t*-tests to test for significant differences in the percentage of food squares eaten.

Results

Wounding Intensity Series Mechanical damage to tissue of *A. rhax* resulted in pronounced changes in the concentrations of psammaplin A sulfate (**1**) and psammaplin A (**2**) (Fig. 1). In intact tissue, psammaplin A sulfate (**1**) was present at 52.8±13.4 µmol g^{-1} dry weight (Fig. 2). Upon 1 min grinding, the concentration of (**1**) decreased to 8.2± 3.6 µmol g^{-1}. At the same time, psammaplin A (**2**) concentration increased from 2.1±0.8 to 46.0±8.9 µmol g^{-1} dry weight. Upon gradually increasing the wounding intensity (no wounding<stabbing<grinding for 15 s<grinding for 1 min), (**1**) gradually decreased. This was paralleled by a gradual increase of (**2**) (Fig. 2).

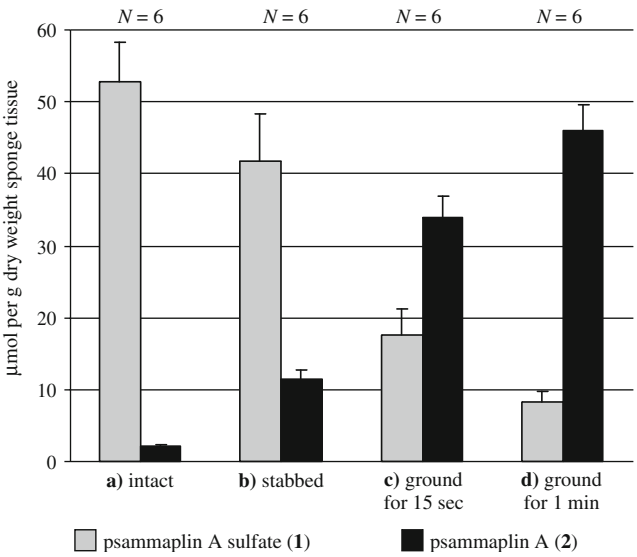

Fig. 2 Changes in psammaplin A sulfate (**1**) and psammaplin A (**2**) concentrations in tissue of *A. rhax* upon different intensities of wounding (overall reaction time was 2 min for all wounding intensities). *Vertical bars* represent SE. Randomized block ANOVA: (**1**) F=36.9, P<0.001; (**2**) F=99.5, P<0.001. Tukey test (significant differences are indicated only): (**1**): $a \neq (c, d)$; $b \neq (c, d)$. (**2**): $a \neq (b, c, d)$; $b \neq (c, d)$; $c \neq d$

Forceps Experiment Tissue pieces that were excised from *A. rhax* with forceps and shock-frozen after 2 s showed a significant decrease in psammaplin A sulfate (**1**) and a concomitant increase in psammaplin A (**2**) when compared to intact sponge tissue (Fig. 3). Similarly, the injured 50-ml sponge fragments (after forceps treatment) showed an increase in psammaplin A concentration, yet to a considerably lesser extent.

Whenever we removed a tissue piece from *A. rhax*, we observed the release of a mucus-like cloud from the wounded sponge area into the ambient seawater. We, therefore, analyzed the seawater and calculated the amounts of (**1**) and (**2**) released per "bite". The amounts, as well as the relative proportions of (**1**) and (**2**) in the seawater came out to be similar to those determined in the removed tissue pieces themselves (Fig. 3).

Testing for Enzyme-Mediation of the Conversion Reaction Following a 2 min incubation of lyophilized and subsequently ground tissue of *A. rhax* in water at room temperature (~25°C), the concentration of psammaplin A sulfate (**1**) decreased from 67.8±2.5 to 1.9±1.6 µmol g^{-1} dry weight sponge tissue. The concentration of psammaplin A (**2**) increased from 2.1±0.4 to 31.1±6.2 µmol g^{-1} dry weight. Upon treatment of another subsample of the same material with hot water (~95°C), instead, the compound concentrations changed to a considerably lesser extent: after a 2-min incubation, psammaplin A sulfate (**1**) amounted for 27.9±7.4 and psammaplin A (**2**) for 4.1±1.1 µmol g^{-1} dry

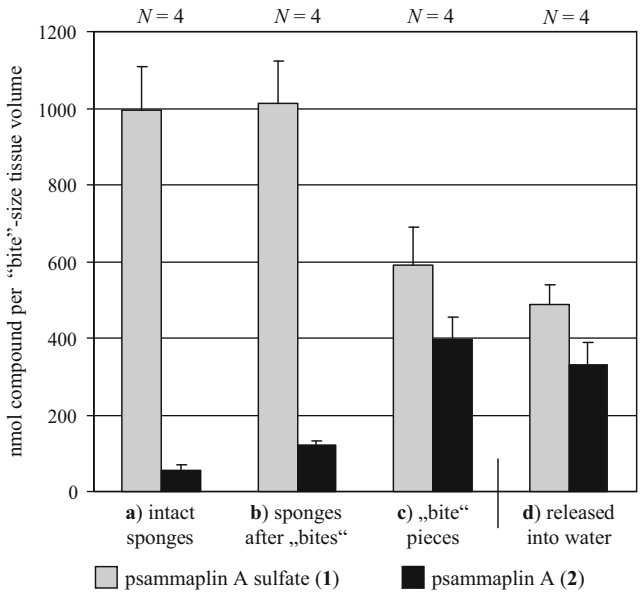

Fig. 3 "Forceps experiment": Contents of psammaplin A sulfate (**1**) and psammaplin A (**2**) in sponge tissue and seawater after mimicked fish bites. "Bite" pieces were shock-frozen within 2 s after removal from the sponges. Concentrations in the sponge tissue samples (*a–c*) are calculated per average "bite" volume (~76 µl). Amounts of compounds released into the water (*d*) are calculated per "bite" caused to the sponge tissue. *Vertical bars* represent SE. Randomized block ANOVA: (**1**) F=12.7, P<0.0025; (**2**) F=15.3, P<0.001. Tukey test (significant differences are indicated, only): (**1**): $a \neq (c, d)$; $b \neq (c, d)$. (**2**): $a \neq (c, d)$; $b \neq (c, d)$

weight. The discrepancy between the total concentrations of psammaplins before and after addition of water (i.e., the apparent loss of compounds) may be explained by the formation of non-UV-detectable side products.

Grinding with additional EtOH-dissolved psammaplin A sulfate (**1**) together with fresh *A. rhax* resulted in an increase of the psammaplin A (**2**) concentration in the sponge tissue to 75.1 µmol g^{-1} dry weight (compared to 50.3 µmol g^{-1} dry weight in sponge tissue ground with EtOH, only). Apparently, artificially added (**1**) was converted to (**2**) when ground together with fresh *A. rhax*. In contrast, no (**2**) was formed when (**1**) was ground together with fresh tissue of the sponges *H. altum* and *S. massa*.

Isolated (**1**) proved stable for at least 6 days when stored at room temperature in seawater or methanol, respectively.

Effects of Solvent Exposure Similar to mechanical damage, solvent exposure had an activating effect on the conversion of psammaplin A sulfate (**1**) to psammaplin A (**2**) in fresh *A. rhax* tissue (Table 1). The concentration of (**1**) dropped quickly—yet much more slowly than upon mechanical damage—within 10 min of exposure, and remained largely constant over the next 24 h. At the same time, (**2**) considerably increased in concentration—likewise mostly within the first 10 min of exposure.

Table 1 Concentration of psammaplin A sulfate (**1**) and psammaplin A (**2**) following methanol exposure of fresh *Aplysinella rhax* tissue

Exposure time	Psammaplin A sulfate (1) µmol g^{-1} dry weight±SE	Psammaplin A (2) µmol g^{-1} dry
a, no exposure	79.7±2.0	6.6±0.6
b, 10 min	28.9±2.8	51.4±1.5
c, 30 min	23.8±3.8	69.4±9.9
d, 1 h	21.2±1.5	76.0±4.7
e, 6 h	25.1±7.9	68.9±7.4
f, 24 h	16.9±1.6	76.1±5.4

N=3 for all time points. Randomized block ANOVA: (**1**) F=48.5, P< 0.001; (**2**) F=41.9, P<0.001. Tukey test (significant differences are indicated, only): (**1**) $a \neq$(b, *c*, *d*, *e*, *f*) and (**2**) $a \neq (b, c, d, e, f)$; $b \neq (d, f)$.

Field Feeding Assay with Generalist Reef Fishes Psammaplin A sulfate (**1**) was strongly deterrent against feeding by generalist reef fish. While control food was readily eaten, food treated with (**1**) was scarcely removed (Fig. 4a). When pairs of ropes, both containing treated food [one with (**1**) and the other with (**2**)] were offered to the fish, they only occasionally took bites; repetitive feeding was rarely observed. Over time, similar amounts of both types of food were removed (Fig. 4b). This indicates a strong repellent effect also by (**2**), but it precludes conclusions on differences in anti-feeding intensity between (**1**) and (**2**), since the occasional choices by the fishes in this assay have to be considered random.

Feeding Assay with a Sponge Predator Both "Ar intact" (butanol fraction of crude extract from intact *A. rhax* tissue) and "Ar wounded" (butanol fraction of crude extract from ground *A. rhax* tissue) had significant repellent effects in

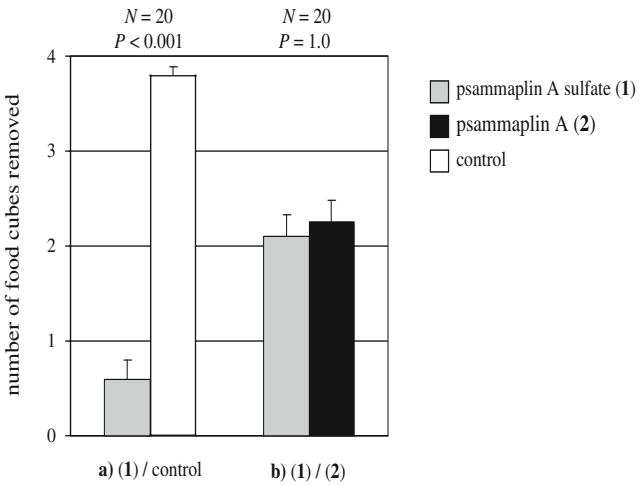

Fig. 4 Results of two field feeding assays testing (*a*) food treated with psammaplin A sulfate against untreated controls and (*b*) food treated with psammaplin A sulfate against food treated with psammaplin A. In each assay, 20 pairs of ropes (each rope holding four food pieces) were offered to generalist reef fish. *Vertical bars* represent SE

choice feeding assays with *C. solandri* when they were tested separately against controls (Fig. 5a and b). When offered in a direct choice without control food, "Ar wounded" proved to be a significantly stronger deterrent than "Ar intact" (Fig. 5c).

Diffusion of compounds from the food strips into the seawater was minimal in the course of the experiment as revealed by HPLC comparison of extracts from strips kept in the seawater tanks (without fish) with food strips not exposed to water. Compound concentrations were >90% compared to the original concentrations after 4 h of seawater exposure.

Discussion

Whereas numerous activated chemical defenses have been documented in terrestrial plants and marine algae (see reviews by Zagrobelny et al. 2004 for terrestrial and Pohnert 2004 for marine-activated defenses), in sessile marine invertebrates, chemical defense is considered largely static. Our study revealed that psammaplin A, a natural product that has been considered constitutive in the marine sponge *A. rhax* (e.g., Shin et al. 2000; Tabudravu et al. 2002), is, in fact, a cleavage product of psammaplin A sulfate. This cleavage reaction is triggered by wounding of the sponge tissue (Figs. 1 and 2).

The conversion of psammaplin A sulfate to psammaplin A occurs within a few seconds following damage of *A. rhax* tissue, as revealed by the "forceps experiment" (Fig. 3). Simulated predator "bites" caused a more than six-fold increase in psammaplin A in the excised tissue compared to undamaged tissue. Psammaplin A was also formed in the remaining damaged sponge, yet to a much lesser extent. Apparently, the conversion reaction was restricted to the wounded tissue area and did not disperse through the sponge. Analogous localized reactions in plants are usually induced by disintegration of compartments that facilitates contact between precursors and enzymes previously stored in separate compartments (Matile 1984; Wittstock and Gershenzon 2002). Storage of secondary metabolites in compartments also has been observed in sponges (Turon et al. 2000; Richelle-Maurer et al. 2003). *Aplysina* sponges, which are closely related to *A. rhax*, contain isoxazoline alkaloids, compounds structurally and biogenetically similar to psammaplin A sulfate (Ciminiello et al. 1994, 1996). These compounds are stored in so-called spherulous cells (Thompson et al. 1983; Turon et al. 2000). By electron microscopy, we found this cell type also to be highly abundant in tissue of *A. rhax* (Thoms et al., unpublished). This suggests that the mechanism that results in the formation of psammaplin A in *A. rhax* is analogous to those that are typically involved in plant activated defenses (i.e., the disruption of compartments to trigger enzymatic compound conversion). We found several further indications that the conversion reaction in *A. rhax* is, indeed, enzyme-mediated. First, the rapidness of the conversion of psammaplin A sulfate, a compound that proved highly stable when isolated from the sponge tissue, indicates enzyme-catalysis. Second, the factor that mediates the conversion appears to be specific to *A. rhax* tissue, since no psammaplin A was formed when psammaplin A sulfate was ground together with tissue of other sponge species. This indicates that *A. rhax* possesses a specific enzyme that catalyzes the cleavage of the sulfate ester group in psammaplin A sulfate. Third, the conversion reaction occurs only in the presence of water. No conversion occurred when lyophilized tissue of *A. rhax* was ground. If, however, water was added to the lyophilized and ground sponge material, psammaplin A was formed at high concentrations. Finally, the conversion reaction was inhibited by heat. In case of a non-enzymatic reaction, the turnover rate should increase with higher reaction temperature. In contrast, the yield of psammaplin A was considerably lower when lyophilized *A. rhax* tissue was treated with hot water compared to water at room temperature. This indicates heat denaturation of the enzyme(s) that catalyzes the cleavage of psammaplin A sulfate in *A. rhax*. In fact, arylsulfatases, enzymes catalyzing reactions such as the cleavage of psammaplin A sulfate in *A. rhax* (i.e., the hydrolysis of a phenolic sulfate ester group) have been described from most organisms, including sponges and marine microorganisms (Mraz and Jatzkewitz 1974; Byun et al. 2004).

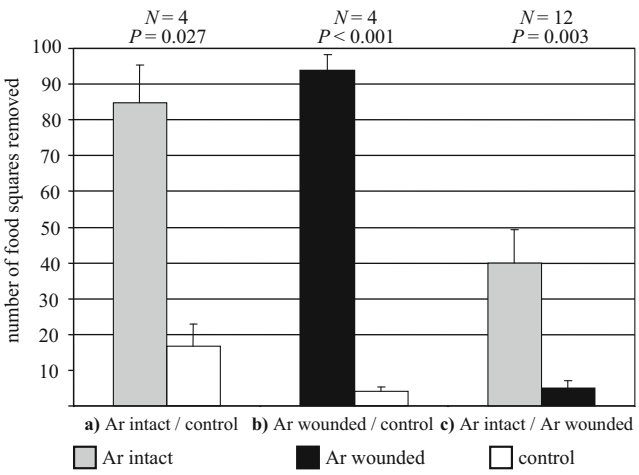

Fig. 5 Results of three choice feeding experiments with the sponge predator *C. solandri*. Fish food was treated with the butanol fractions of extracts from intact ("Ar intact") and ground ("Ar wounded") *A. rhax* tissue. The two fractions were tested separately against controls (*a*+*b*) and in a direct comparison against each other (*c*). *Vertical bars* represent SE

To test for ecological relevance of the observed wound-activated conversion in *A. rhax* as a chemical defense mechanism, we conducted fish-feeding assays comparing the repellent effects of the precursor and the product. When generalist reef fish in the field were offered a choice between food treated with psammaplin A sulfate and controls, they significantly preferred the controls (Fig. 4a). When offered a choice between food treated with psammaplin A sulfate and food treated with psammaplin A (Fig. 4b), the fish only occasionally took bites. By contrast, untreated food—offered to attract the fishes to our experiment—was readily taken. We found that both psammaplin A sulfate and psammaplin A barely leak from the experimental fish food. Thus, their deterrent properties are presumably only perceived by the fish when bites are taken. During the experiment, tasting of both compounds by one individual fish or repetitive feeding were rarely observed, making the occasional fish bites in this experiment rather random. This precludes conclusions on differences in anti-feeding activity between the two compounds. However, the observation that both types of treated food were largely avoided whereas untreated food was readily taken, suggests that both psammaplin A sulfate and psammaplin A had a pronounced feeding deterrent effect against the generalist reef fish.

Despite this pronounced repellence, we observed feeding scars on *A. rhax* in the field, suggesting that there are predators that are able to overcome the strong constitutive chemical defense of the sponge. We, therefore, performed another feeding experiment—this time with a "non-specialist" omnivorous sponge predator, i.e., a predator that is not adapted to the defense compounds of a particular sponge species, but may be less susceptible to sponge chemical defense compared to common reef fish. We selected the pufferfish *C. solandri* for this assay, since it is known to feed on sessile invertebrates such as sponges (Myers 1991). Moreover, this species is highly abundant on the coral reefs around Guam. Similar to the generalist reef fish in the field experiment, *C. solandri* strongly preferred control food over food treated with the *A. rhax* compounds (Fig. 5a and b). However, when no control but only a choice between the two *A. rhax* compounds was offered, *C. solandri* was significantly more deterred by the bioconversion product psammaplin A (Fig. 5c). Thus, the wound-activated conversion reaction in *A. rhax* resulted in an enhanced chemical protection against the potential predator *C. solandri*.

Taken together, we found a rapid, most likely enzyme-mediated bioconversion in *A. rhax* that was activated by tissue wounding and enhanced protection of the sponge against a known sponge predator. Thus, all criteria for an activated chemical defense as defined by Paul and Van Alstyne (1992) are fulfilled. Apparently, *A. rhax* is sufficiently protected against generalist reef fish by its constitutive chemical defense (i.e., the storage of psammaplin A sulfate). However, if despite this defense *A. rhax* is wounded—for instance by a sponge predator that is less susceptible to defensive chemicals than the average reef fish—the sponge's protection against predators is rapidly boosted by the wound-activated formation of psammaplin A.

When simulating fish grazing by picking tissue pieces from *A. rhax*, we observed the release of mucus-like clouds from the wounded tissue. We quantified the psammaplin A sulfate and psammaplin A concentrations released with these clouds and found that they were similarly high as the concentrations in the removed tissue bits (Fig. 3). The latter had proven sufficient to efficiently repel fishes. The mucus clouds may facilitate a rapid transport of the rather lipophilic defense compounds psammaplin A sulfate and psammaplin A to the olfactory organs of the predator, thus accelerating and intensifying their repellent effect.

To our knowledge, the bioconversion in *A. rhax* is so far only the second reported example of an activated chemical defense in sponges—the third among sessile marine invertebrates. Interestingly, all compounds in the sponges *A. rhax* and *Aplysina* spp., as well as in the hydroid *Tridentata marginata*, were initially considered constitutive (Fattorusso et al. 1970; Lindquist et al. 1996; Pham et al. 2000; Shin et al. 2000). In all cases, it was only later discovered that they are, in fact, products of wound-activated conversions (Teeyapant and Proksch 1993; Lindquist 2002; this study). Recently, a cleavage of acetylated sesterterpenes in the sponge *L. variabilis* was reported to occur when fresh tissue of the sponge is frozen and subsequently thawed (Ettinger-Epstein et al. 2007). Here, again, the cleavage products had originally been considered constitutive (de Silva and Scheuer 1981; Kernan et al. 1987). Ettinger-Eppstein et al. proposed an enzyme-mediated cleavage reaction and speculated about its relevance as an activated defense. We have lately observed pronounced changes in the chemical profiles of yet unidentified deep-water sponges collected off the coast of Guam that occurred upon damage to their tissue (Thoms C. and Schupp P.J., unpublished data). More detailed investigations on these preliminary findings need to be done. Based on all these recent observations, however, we deem it reasonable to address the question whether more activated defenses in sponges—and perhaps also in other sessile marine invertebrate phyla—may have been overlooked in the past. In fact, this would be analogous to the development in research on marine algae. Here, it took almost a decade from the first discovery of activated defenses, until it was realized that this strategy is, in fact, widespread among both micro- and macroalgal species (Pohnert 2004). Even for algae, it was recently proposed that the prevalence

of this strategy may still be underestimated due to a "restricted methodological approach by marine chemical ecologists that focuses on constitutive chemical defense" (Pohnert 2004).

In this context, it is interesting to note that the reaction mechanisms of the bioconversions in *A. rhax* and in the *Aplysina* spp. (the genus that accommodates the only other wound-activated defense reported in sponges as yet) are dissimilar. In the latter, isoxazoline alkaloids are cleaved between the isoxazoline moiety and the carbonyl function common to all these molecules (Fig. 6a; Ebel et al. 1997; Thoms et al. 2006). The cleavage is catalyzed by a yet unknown enzyme and results in the formation of the antimicrobially active compounds aeroplysinin-1 and dienone. In contrast, the activated defense reaction in the hydroid *Tridentata marginata* shares many similarities with the conversion reaction we report in this study. In *T. marginata*, as well, a phenolic sulfate ester is enzymatically hydrolyzed and a fish-feeding-deterrent phenol is formed (Fig. 6b; Lindquist 2002). Interestingly, the precursors of all three reactions (in *Aplysina* spp., *A. rhax*, and *T. marginata*) are structurally similar tyrosine-derivatives (Figs. 1 and 6). This may indicate a predisposition of this class of compounds for being converted in activated defenses. An alternative explanation for the repeated discovery of activated defenses that involve tyrosine-derivatives may be found in the fact that these compounds are accumulated in extraordinarily high concentrations in the sponges and the hydroid (Lindquist et al. 1996; Pham et al. 2000; Thoms et al. 2006). Consequently, conversion reactions in these invertebrates may simply be more conspicuous than analogous processes in other species with lower compound yields and more complex chemical profiles. Moreover, if the conversion reactions involve a high number of different precursors, intermediates, or products, this may additionally conceal activated defense reactions.

We recently reviewed the various difficulties involved in studies investigating wound-activated reactions in chemical profiles of sponges in regard to both methodological constraints and limitations of conclusions that can be drawn on the ecological relevance of these reactions (Thoms and Schupp 2007). One of our conclusions is that, in order to clarify the true prevalence of activated defenses in sponges (and in other sessile marine invertebrate phyla), studies are required that systematically compare chemical profiles of these organisms before and after tissue wounding at the

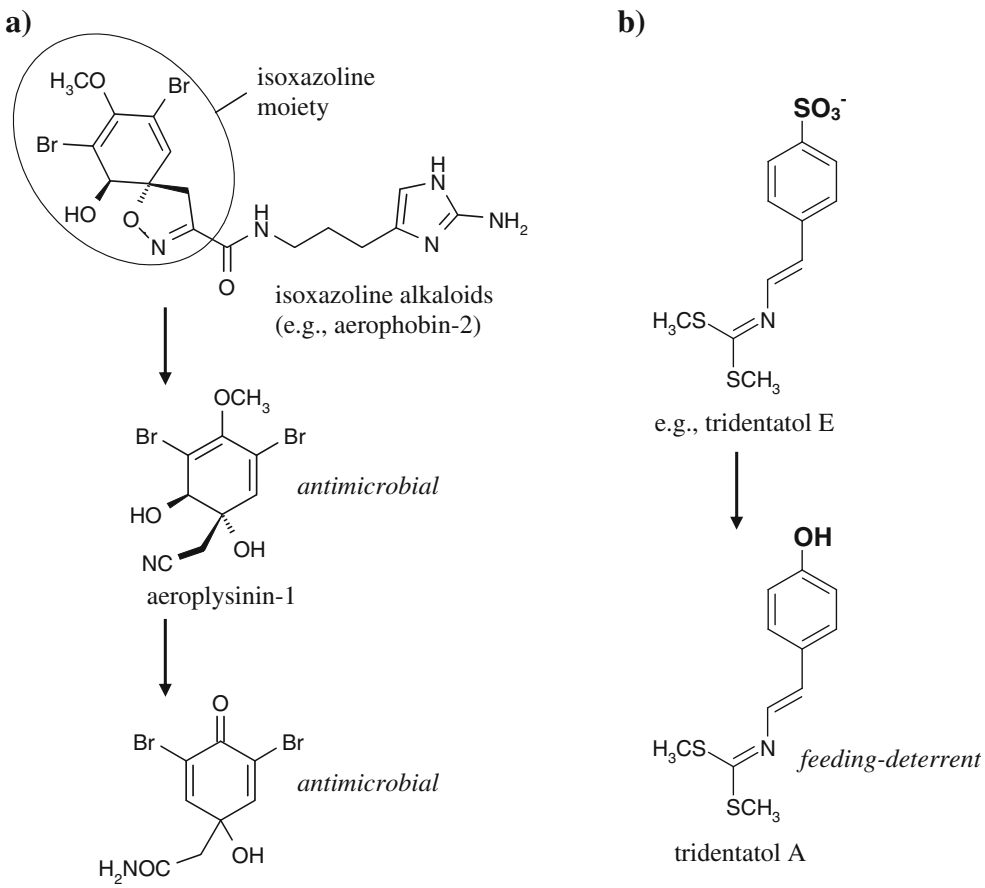

Fig. 6 Activated chemical defenses in sessile marine invertebrates: **a** wound-activated cleavage of the isoxazoline moiety of isoxazoline alkaloids in sponges of the genus *Aplysina* (Thoms et al. 2006). **b** Wound-activated hydrolysis of the sulfate ester groups of tridentatols in the hydroid *Tridentata marginata* (Lindquist 2002)

species level. An important issue that needs to be considered in this context is the methodology for preservation and extraction of invertebrate tissue that is employed in such studies. Preservation and extraction of fresh (wet) tissue in organic solvents are common practices in marine natural product chemistry and ecology. We observed that conversion reactions similar to those activated in *A. rhax* upon tissue wounding also occurred when fresh sponge tissue was stored in methanol. This finding parallels earlier observations in *Aplysina* spp. where storage of fresh sponge tissue in organic solvents elicited the cleavage of isoxazoline alkaloids to an extent similar to that of mechanical injury (Teeyapant and Proksch 1993; Thoms et al. 2006). The activation of enzymatic reactions in invertebrate tissue may be explained by the lacerating effect of organic solvents on biomembranes (Jones 1989; Weber and DeBont 1996). Similar to mechanical damage, this likely results in decompartmentalization and, thus, facilitates contact between enzymes and precursors. If the solvent concentration increases gradually (as occurs if fresh invertebrate tissue is soaked by solvents), enzymes can still sustain their activity and catalyze compound conversions (see Klibanov 2001 and references cited therein).

Another possible trigger for enzyme-mediated reactions in invertebrate tissue after sampling is freezing and thawing for preservation and subsequent extraction (see for example Ettinger-Epstein et al. 2007). Here, the formation of intracellular ice crystals may result in disruption of compartments (Gahan 1981; Hällgren and Öquist 1990). Thawing of the tissue may then re-activate the enzymes. Last but not least, mechanical damage caused during sampling and handling has to be taken into account as a potential elicitor of wound-activated defenses.

Taken together, various factors could potentially have led to the oversight of activated chemical defenses, and, in consequence, to the misinterpretation of products of these defense mechanisms as constitutive chemical profile components. If future systematic investigations on activated defenses in sessile marine invertebrates reveal additional examples of this strategy, this could add another interesting aspect to the chemical ecology of this group of animals.

Acknowledgments NMR and LC/MS analyses were conducted by T. Hemscheidt from the Department of Chemistry, University of Hawaii. D. Taitano and B. Antolin helped with the feeding assays and the compound extraction. L. Goldman and N. Pioppi assisted in sponge collection. We thank C. Kohlert-Schupp for interesting discussions, A. Kerr for critical proofreading of the manuscript and advice in statistical matters, as well as two anonymous reviewers whose comments greatly improved this manuscript. (4 mm inner diameter) 15-ml glass vial (Sigma-Aldrich, Dorset, UK) by piercing the septum in the cap with the SPME needle. The vial was kept under the armpit by an individual; this sampling device is the subject of UK Patent Application WO/2006/111748. To standardize environmental effects on odor profiles, the volunteers followed an established hygiene regime (Roberts et al. 2005). After 50 min of axillary sampling at room temperature, the fiber was introduced into the gas chromatograph for sample desorption. The air in the sampling room was monitored for background volatiles using the same absorbent material.

Gas Chromatography–Mass Spectrometry Analysis Separation and analysis of the odor compounds was performed by using an Agilent 6890N gas chromatograph. The gas chromatograph injection port liner used was a SPME injection sleeve of 0.75 mm inner diameter (Supelco). SPME desorption was at 230°C, in pulsed splitless mode for 2 min at 25 psi. The gas chromatograph was coupled to an Agilent 5973 mass-selective detector (EI+, electron voltage 70 eV, full scan mode in a range of *m*/*z* 35–400 amu, interface temperature of 300°C; Agilent Technology, Stockport, Cheshire, UK). Separation of compounds was performed on a Zebron, ZB-Wax (30 m× 0.25 mm×0.25 μm film thickness) capillary column coated with 100% polyethylene glycol (Phenomenex, Cheshire, UK). The carrier gas used was helium at a flow rate of 1 ml min^{-1}. The oven temperature program was 40°C (held for 5 min), then raised to 100°C at 3°C/min (5 min), followed by 5°C/min to 150°C (5 min), and reaching 230°C at 5°C/min (8 min).

Culturing of Axillary Microflora A sterile swab, pretreated in 0.8% NaCl, was applied for 10 sec to the left axilla to harvest its microbial flora. The swab was transferred into 20 ml of the glucose-enriched medium (glucose 1%, ammonium chloride 0.5%, sodium dihydrogen orthophosphate 0.2% with final pH adjusted to 7.2) (Sigma-Aldrich) prepared in a screw-cap bottle. The bottle was kept in an orbital shaker at 37°C, 160 rpm, for 12 hr. One milliliter of the culture was then transferred into a sterile 1.8-ml Eppendorf centrifuge tube that was spun for 10 min at 11,500×*g*. The supernatant was removed, and the pellet was washed eight times with sterile distilled water. The pellet was resuspended in the sterile distilled water, and a total microbial count was equated to McFarland turbidity standard 10 (6×10^7cfu/ml).

Preparation of Substrate Solution The LRGYYNQSED and GSHSMRYFST HLA decapeptides (97% purity) were synthesized by Sigma Genosys (Pampisford, Cambridge, UK). To prepare a substrate solution, 1.5 mg of each HLA peptide were dissolved in 1 ml filtered (0.25 mm) sterile distilled water. Each substrate solution also contained 4.4 mg KH_2PO_4, 4.8 mg Na_2HPO_4, 1.0 mg NH_4Cl, and 0.5 mg $MgSO_47H_2O$.

Headspace Analysis of Medium An aliquot (20 μl) of the resuspended pellet and 115 μl of the final substrate solution were added to a 2-ml gas chromatography–mass spectrometry (GC-MS) glass vial containing 2.5 μl of vitamin solution, made of 0.05% thiamine (aneurine) hydrochloride, 0.05% riboflavin, 0.05% niacin, 0.05% pyridine hydrochloride, 0.05% inositol, 0.05%, calcium pantothenate, 0.05% *p*-aminobenzoic acid, and 0.025% biotin (Sigma-Aldrich). The vial was capped, and the mixture was incubated in an orbital shaker (160 rpm) at 37°C for 48 hr. The cap septum was then pierced with the protective needle covering the SPME fiber, and the fiber was extruded to sample the headspace over the medium. The sampling was carried out for 30 min over a heating block set at 50°C. After sampling, the fiber was immediately introduced into the gas chromatograph for sample desorption. In all cases, a negative control of the headspace of the microbial culture without added peptide was analyzed. Each sample was analyzed in duplicate.

Data Analysis Ion 41 (*m*/*z* 41) was selected as one of the main diagnostic ions of 3-methylbutanal (3-MB) from the GC-MS profile of an individual, and its abundance was recorded. Six other compounds that also contained *m*/*z* 41 were selected from the same profile of the individual, their *m*/*z* 41 abundances were also measured, and the mean abundance across all six compounds was calculated. The abundance of *m*/*z* 41 for 3-MB was divided by this mean to obtain a standardized value of *m*/*z* 41 for 3-MB. The standardized value was calculated for every individual profile

Table 1 Standardized abundance of *m*/*z* 41 of 3-methylbutanal from axillary samples from 18 human subjects sampled over 3 wk[a]

[a] ANOVA ($F_{1,\ 17}$=40.125, P<0.001) showed significant variation in abundance of 3-methylbutanal among 18 individuals.

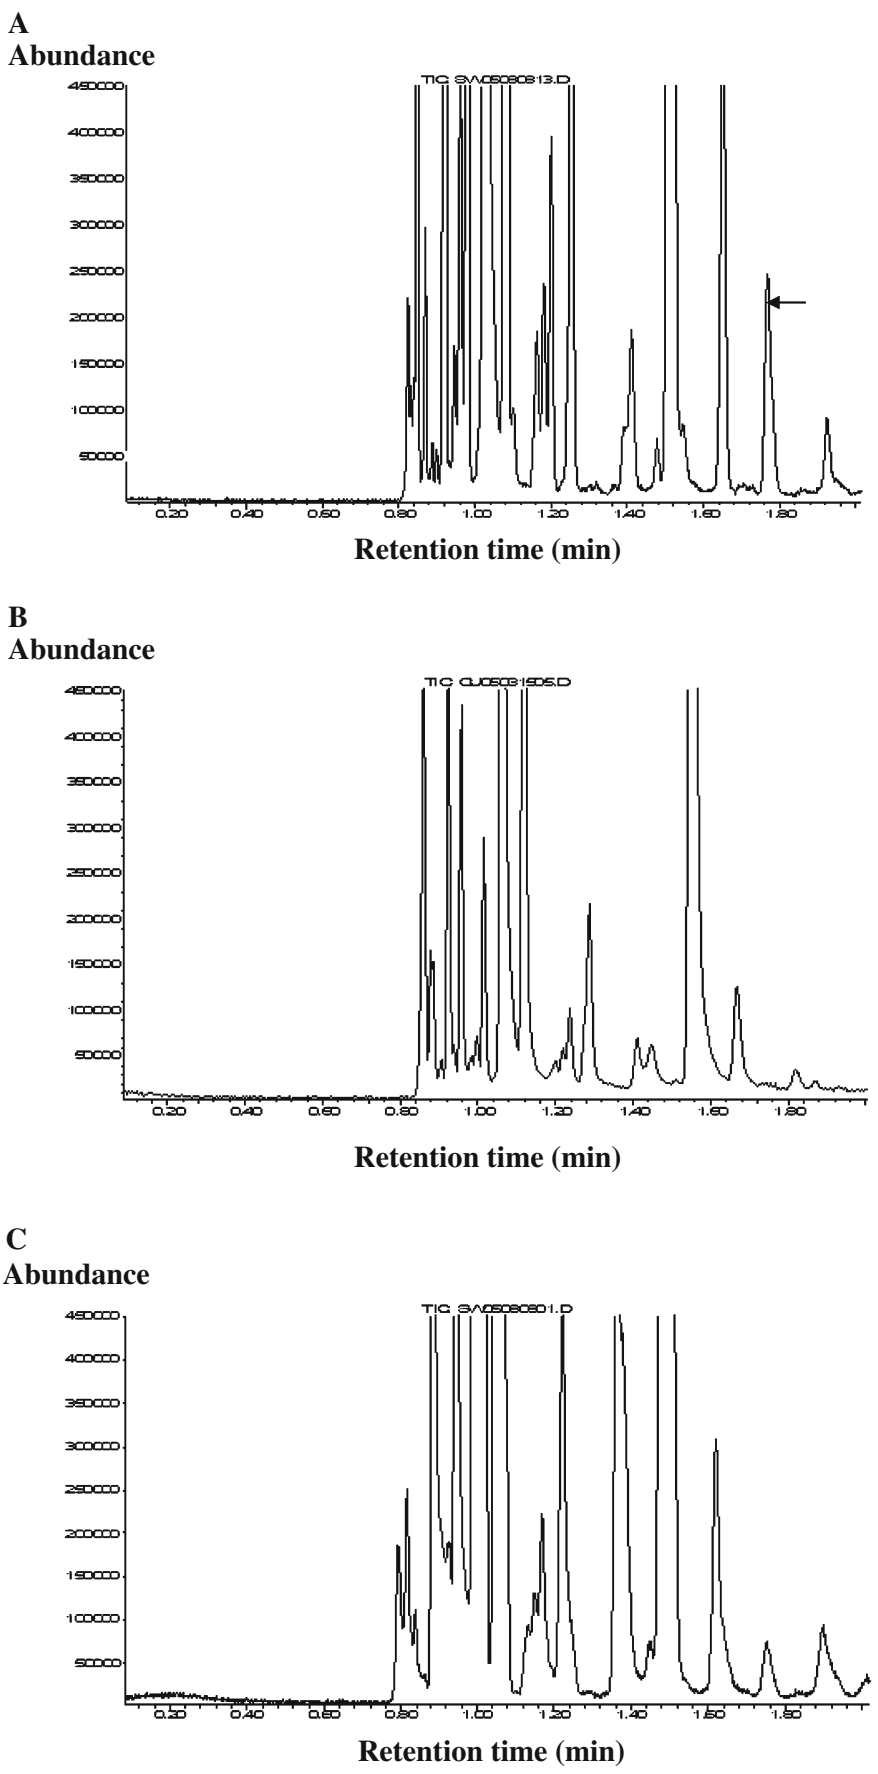

Fig. 1 GC-MS profiles of volatiles trapped above three incubation media including **a** medium containing LRGYYNQSED and microflora cultured from an individual (ORE_2), who consistently emitted 3-MB *in vivo* (*arrow* indicates 3-MB, which eluted at 1.75 min and was verified with the authentic standard from Sigma-Aldrich), **b** medium as in **a** except that the decapeptide GSHSMRYFST was used as the substrate (3-MB was not detected *in vitro*), and **c** medium containing LRGYYNQSED and microflora cultured from an individual (ORE_5), who did not emit detectable 3-MB *in vivo* (3-MB was not detected *in vitro*)

(Table 1). Comparisons of the standardized abundances of 3-MB among individuals were performed by using repeated-measures analysis of variance (ANOVA) with α=0.05 as the threshold for significance (SPSS statistical software).

Results and Discussion

The GC-MS analysis of the axillary odor of 18 volunteers revealed a number of compounds among which 3-MB was noted as a potential link to HLA (Montag et al. 2001). The signal was not reported by Curran et al. (2005), who also used SPME for the analysis of the axillary odor. This discrepancy may be attributed to differences in sampling methodologies between the two studies. The abundance of 3-MB among individuals varied during 3 wk of sampling (Table 1) without a discernable general pattern. Five of 18 subjects yielded at least one zero measurement for 3-MB, and since zero values do not represent a confirmed absence of the chemosignal, abundance measurements from these individuals were excluded initially from the statistical analysis of the significance of the variation in emission of 3-MB among individuals. ANOVA revealed significant variation in the signal among the 13 subjects ($F_{1,\ 12}$=22.9, P<0.001), whereas variation among weeks was not significant ($F_{2,\ 24}$=1.9, P>0.05). There were also significant disparities in the signal among all 18 subjects when zero values were included in the analysis ($F_{1,\ 17}$=40.125, P< 0.001; data were square root-transformed prior to analysis due to significant departures from normality). In this instance, there was also no significant variation in the signal across weeks ($F_{2,\ 34}$=3.07, P>0.05). These statistical analyses may indicate a possible genetic origin of 3-MB, especially after taking into account the observation of Montag et al. (2001) that strains of environmentally controlled congenic mice that differ only in the major histocompatibility complex (MHC or HLA in humans) expression can be distinguished on the basis of differences in the ratio of their urine volatile signals, including 3-MB.

An *in vitro* experiment was carried out to determine whether 3-MB may be formed from the interaction between HLA peptides and dermal microflora. Two decapeptides, whose sequences are expressed in the α1 domain of the HLA class 1 region (Mason and Parham 1998), namely LRGYYNQSED and GSHSMRYFST, were synthesized. The first sequence was selected because it was shown previously that leucine and arginine substitutions in congenic mutant mice, differing only in three amino acids in the MHC region (Schulze et al. 1983), allowed olfactory distinction between the strains (Yamazaki et al. 1983) and that these two amino acids, L and R, were neighbors in the MHC sequence. The other peptide was chosen for the lack of L and L–R linkage in its sequence.

In the first instance, microflora cultured from individual ORE_2, whose axillary odor contained a relatively large abundance of 3-MB during all three weekly samplings (Table 1), was incubated in two separate media. One medium contained LRGYYNQSED, whereas the other contained GSHSMRYFST. The headspace above the surface of each medium was sampled and analyzed for 3-MB. The target compound was detected in the headspace above the LRGYYNQSED incubate (Fig. 1a) but not in the headspace above the GSHSMRYFST incubate (Fig. 1b). If the cutaneous microbial population is affected by an individual's genotype and possibly phenotype, we would predict that the sampled microflora from individual ORE_5, who was not associated with a positive 3-MB signal (Table 1), would not yield the signal when incubated with LRGYYNQSED. Subsequent analysis did not detect 3-MB in the headspace of the medium containing LRGYYNQSED or microflora from this individual (Fig. 1c). The results of the *in vitro* experiment were reproduced by using the microflora cultured from ORE_8 and ORE_7; that is, abundances of 3-MB were 123,560 and 0 (undetected), respectively. The negative controls provided evidence that different HLA peptides can alter production of the signal and that individuals possess differences in microbial populations that influence production of the signal. Based on Leyden et al. (1981), we speculate that aerobic diptheroids, *Corynebacterium*, were involved in the interaction with the HLA peptides. These findings are in agreement with the hypothesis that genes and microflora may influence formation of the odor (Penn and Potts 1998), although it remains unclear whether the production of the chemosignal: (1) is HLA sequence specific, (2) depends on the L–R linkage, or (3) is entirely due to the encoded presence of leucine in the peptide. A further study on the substitutions of the amino acids in the LRGYYNQSED may reveal the extent of HLA contribution to the production of the chemosignal.

Acknowledgments We thank Paul Miller and Daniel Farrelly for assistance with the *in vivo* experiment, Dr. Catherine Dreanno and Yashawant Kumar for assistance with the *in vitro* experiment, and Dr. George Wake for comments. by larval sea lampreys (Haslewood and Tokes 1969; Polkinghorne et al. 2001). A series of experiments demonstrated that PS is released by larvae, detected by adults at picomolar concentrations, and is behaviorally attractive to adult lampreys (Li et al. 1995; Polkinghorne et al. 2001; Vrieze and Sorensen 2001; Fine and Sorensen 2005). However, the behavioral activity of PS was considerably less than whole larval odor, suggesting that PS was part of a multi-component pheromone (Vrieze and Sorensen 2001). By using bioassay-guided fractionation, two novel sulfated steroids, petromyzonamine disulfate (PADS) and petromyzosterol disulfate (PSDS), were identified in larval water (Sorensen et al. 2005).

Methodological details of this isolation and identification, as well as biological tests with highly purified natural and synthetic compounds, have not previously been reported. In this paper, the isolation of PADS, PSDS, and PS is described for the first time, along with the results of new, confirmatory tests of the biological activity of both purified natural and synthetic compounds. This is the first complete account of the isolation and biological activity of a multi-component migratory pheromone in a fish. This manuscript has four goals: (1) to provide a path that others may follow to identify multi-component aquatic pheromones; (2) to provide key details not included in our initial report; (3) to provide new data on the specificity with which these components are discerned; and (4) to prove that this important pheromone has been correctly identified by providing descriptions of tests of highly purified and synthetic compounds.

Methods and Materials

Experimental Design and Rationale Pheromone isolation and purification proceeded in three phases: (I) extraction of the pheromone from larval sea lamprey holding water; (II) isolation of compounds from larval holding water extract; and (III) establishment of the olfactory and behavioral activity of the isolated compounds. The overarching goal was to isolate and identify the active compounds (see Hoye et al. 2007) and then to test these compounds to ascertain biological activity. Protocols were approved by the Animal Care and Use Committee of the University of Minnesota.

Phase I: Extraction of Pheromone from Larval Lamprey Holding Water A method to extract the complete pheromone from larval holding water was developed. Initial tests employed reversed-phase C18 resin (RP-C18) to extract compounds of interest from larval water (Fine et al. 2006). Larval water was collected following established protocols in which groups of 500 larval sea lampreys were maintained in 200-l flow-through tanks with the water turned off for 12 h after feeding (see Polkinghorne et al. 2001). Ten liter aliquots of this water (a quantity known to activate approximately 100,000 l of water and to represent a biologically relevant concentration; Vrieze and Sorensen 2001) were filtered through paper and passed through methanol-activated RP-C18 sep-paks (1 l/sep-pak, Waters Corp., MA, USA; Polkinghorne et al. 2001). Columns were washed with 5 ml 20% methanol (to remove unwanted highly polar compounds) followed by 5 ml hexane (to remove non-polar compounds) and then eluted with 5 ml of methanol.

Column eluates and other odors were tested for ability to attract migratory sea lampreys in 9-m-long preference mazes that had two side channels through which a mixture of Lake Huron water and river water lacking lampreys (1:100) was pumped (see Fine et al. 2004 for details). For tests, groups of four recently caught lampreys were placed into upstream cages and then released one cage at a time after sunset (when lampreys typically migrate) while experimental and control odors were added to the side channels. Time spent by the lampreys in each side was monitored for 15 min using overhead cameras and infrared lighting and later compared to an expected 50% (i.e., no preference) value using two-tailed t tests after a Zar transformation. Experiments employed 12–14 groups of lampreys. Calculations of pheromone concentration were based on concentration of larval holding water extract (number of larvae held in static holding water multiplied by the time they were held divided by final dilution in the maze).

Initial tests compared the activity of 10 l aliquots of larval water extract (0.018 larval hours per liter) to methanol (carrier) control passed through the columns. Next, extract potency was tested against 10 l of whole (unmodified) larval odor to ascertain whether all activity had been extracted. Behavioral experiments occurred during the lamprey migratory season (May–June) over 5 years (2001–2005).

Phase II: Isolation of Pheromonal Compounds from Larval Water using Bioassay-Guided Fractionation RP-C18 resin appeared to extract all pheromone compounds so a bioassay-guided fractionation scheme based on this extraction was designed. This scheme had seven steps and concluded with a test designed to determine if the isolated component(s) was as active as whole larval odor. The scheme was designed so that steps could be repeated to isolate additional components if/as needed.

II-1. Fractionation Larval holding water was extracted (as described above), dried under nitrogen, reconstituted in 60% methanol (110 μl), injected onto a RP-C18 column (Nova-pak, 4 μm column, Waters Chromatography, Milford, MA, USA) and eluted with a gradient of methanol and water (1 ml/min; 15% methanol for the first 4 min., followed by a

linear increase from 15% to 100% methanol from 4 to 60 min.) Twenty fractions (3 min/fraction) were collected during the course of each high-performance liquid chromatography (HPLC; Gilson HPLC system equipped with 305 and 306 pumps and a FC203 fraction collector) run. This step was repeated twice. The first used extract collected from 280 l of larval water, while the second used extract from 360 l of larval water to which ^{14}C-chenodeoxycholic acid (^{14}C-CDCA) was added as a tracer so as to monitor retention times by using an in-line radiation detector (INUS Systems, FL, USA).

II-2. Identification of Promising Fractions by Olfactory Activity Fractions were tested using electro-olfactogram (EOG) recording to identify those with the greatest promise. Briefly, migratory sea lampreys were anesthetized, immobilized, and positioned on a stand, while odors were pulsed across their olfactory epithelia and DC voltage transients, believed to reflect receptor binding activity, measured (see: Li et al. 1995). One-thousand-fold dilutions of each fraction (0.03 larval hour per liter), similar to that used in the behavioral assay, were tested.

II-3. Identification of Fractions with Strong Behavioral Activity Fractions were tested for behavioral activity using two-choice mazes (described above). First, mixtures of the EOG-active (with adjacent fractions) and the EOG-inactive fractions were tested to confirm that the EOG assay was correctly isolating all compounds with potential behavioral activity. Next, the activity of each EOG-active fraction was tested on its own to identify those with greatest promise. Aliquots of these fractions (representing 10 l of larval water, which produced a final maze concentration of 0.018 larval hours per liter) were tested against methanol control or whole extract.

II-4. LC/MS Sub-Fractionation of Active Fractions As a first step in isolating compounds with pheromonal activity, behaviorally active fractions (representing 20 l of larval holding water) were fractionated and analyzed by mass spectrometry (MS). These fractions were injected onto an RP-C18 column and eluted with a gradient of methanol and water (40% methanol for 4 min and increased to 65% methanol for 52 min and then to 100% methanol for 8 min; 1 ml/min). The eluate was routed to a splitter with 90% collected, and the remainder was passed to an ion trap mass spectrometer equipped with an ESI source (LCQ Classic, Thermo Electron Corporation, Waltham, MA, USA) using a spray voltage of 5 kV and sheath gas of 99% pure nitrogen at 60 psi.

II-5. Isolation of Individual Compounds with Olfactory Activity The fractions were fractionated into 20 sub-fractions (3 min/fraction), each of which was tested with EOG at a 1,000-fold dilution (0.6 larval hour per liter) on three fish. After EOG-active sub-fractions were identified, another three 20 l aliquots of that fraction were re-fractionated in the same manner using liquid chromatography (LC)/MS, except this time, compounds of interest were collected and tested for EOG activity (1,000-fold dilution).

II-6. Verification that Isolated Compounds Had Behavioral Activity Compound(s) isolated in step II-5 were tested in mazes against methanol control (0.018 larval hours per liter).

II-7. Determination of Whether Isolated Compounds Had a Majority of Pheromonal Activity The mixture of all known active compound(s) was tested in the maze against whole extract at equivalent concentrations (0.018 larval hours per liter). If the behavioral activity of the isolated compounds was less than the whole extract, step II-1 was repeated to obtain additional fractions/compounds and the basic procedure repeated with appropriate modifications using new combinations of isolated compounds before testing once again against the whole extract.

Phase III: Olfactory and Behavioral Activity of Compounds Isolated from Larval Water As a final step, the olfactory and behavioral activities of the compounds isolated in phase II were extensively tested for behavioral and olfactory (EOG) potency across a range of concentrations. In this experiment, three candidate pheromonal compounds (PS, PSDS, and PADS) were isolated and identified, one of which (PS) was commercially available and purchased (Toronto Research Chemicals, Canada). The other two compounds (PSDS and PADS) were novel and had to be collected and isolated from larval holding waters in mg quantities. To collect these quantities, 8,000 l of larval holding water was passed though XAD7HP resin, which was found to be more efficient than RP-C18 for extracting large volumes of water (Fine et al. 2006), and the extract fractionated following procedures described above. In addition, approximately 1 mg of PADS was synthesized from chenodeoxycholic acid (Hoye et al. 2007). While Sorensen et al. (2005) reported EOG data collected from PSDS and PADS that were ~65% pure, in this study, we tested new samples that were approximately 85% pure.

The sensitivity of the lamprey olfactory system to each compound was determined with EOG recording. Log molar dilutions ranging from 10^{-14} to 10^{-8} M of PS, PSDS, and PADS were tested on four lampreys, and responses were compared using *t* tests with 10^{-5} M L-arginine (a non-pheromonal odorant) as a standard. Following established protocols, EOG responses were calculated relative to the standard after subtracting responses (typically, zero) to blank water control. To determine whether PADS, PSDS, and PS were discerned by independent olfactory receptor

sites/mechanisms, cross-adaptation tests were conducted. This procedure exposes the olfactory epithelium to a compound (saturating olfactory receptors) before adding other stimuli into the background; if a response is measured, it is assumed that a different receptor mechanism is activated (see, Li and Sorensen 1997). In addition to PADS, PSDS, and PS, the sea lamprey sex pheromone component, 3-keto petromyzonol sulfate (3k-PZS; Li et al. 2002; Toronto Research Chemicals), was tested as a positive control. Each compound was tested at a concentration that elicited responses of about 25–30% of the standard (at 10^{-10} M). Results are expressed as percent unadapted response (PUR). A high PUR with a value close to 100% implies independent receptor sites, while a low PUR denotes shared receptor sites.

Finally, the behavioral activities of purified PADS, PSDS, and PS were tested at a range of concentrations in the maze as described above. Behavioral activity of synthesized PADS was tested alone and then against authentic PADS at concentrations of 10^{-12} M to confirm that the synthesized compound was correct (had full activity).

Results

Phase I: Extraction of Pheromone from Larval Holding Water When tested against methanol control, adults were strongly attracted to RP-C18-extracted larval water (average relative time in extract=67%±8% [95% CI] vs. expected value of 50%; $P<0.05$). Further, adults did not distinguish between larval water and RP-C18 extract (average time in extract vs. control=52%±7%; $P>0.05$).

Phase II: Isolation of Pheromonal Compounds Two HPLC fractionations (Fig. 1) were required for the isolation of all the active compounds. In the first fractionation, the strongest olfactory responses were, on average, elicited by fractions 1, 7, 9, 10, and 11 (Fig. 2a) with some variation among injected samples. Pooled fractions 1–20 from the first fractionation were attractive ($P<0.05$; Fig. 3a) to lampreys in the behavioral bioassay, while groups of EOG-inactive fractions were not ($P>0.05$). The group of EOG-active fractions was highly attractive ($P<0.05$) in the behavioral bioassay, and when tested against all 20 fractions, no difference was noted ($P>0.05$; Fig. 3a). This suggested that all key components were in these fractions. When fractions were tested individually in the behavioral bioassay (step II-3; Fig. 1), only fraction 10 was attractive ($P<0.05$; Fig. 3b). This fraction was fractionated by LC/MS (step II-4), with only sub-fraction 3 possessing EOG activity (step II-5a, Fig. 1; data not shown). Seven compounds were subsequently isolated from sub-fraction 3 using LC/MS, two of which elicited significant EOG responses. One elicited an average relative response of 49±

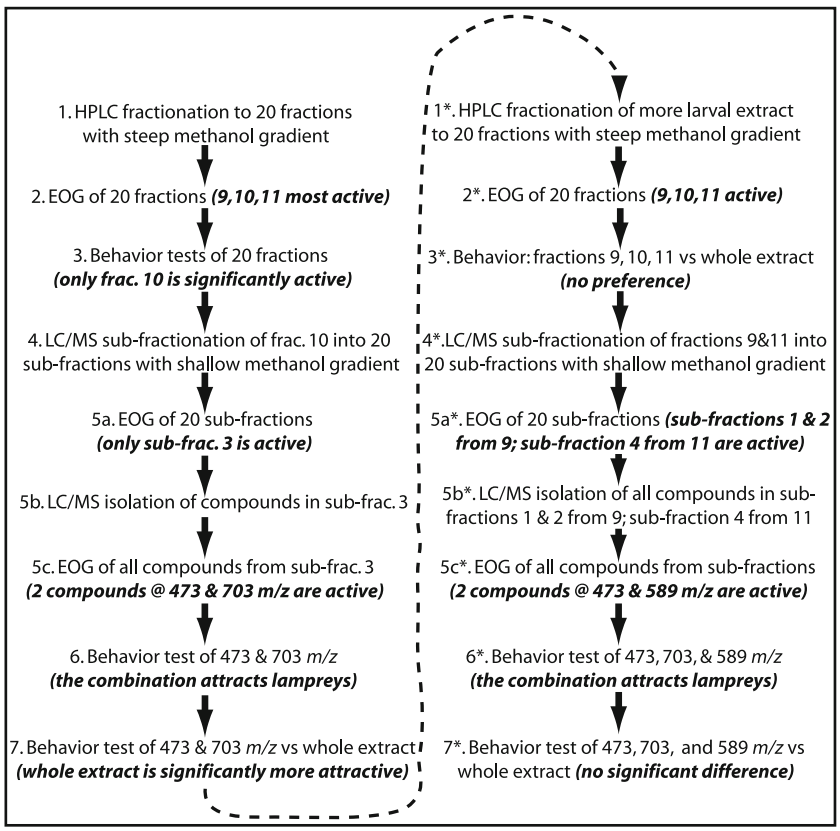

Fig. 1 Stepwise scheme of the specific methods and results employed in this study. Results are in *parentheses*, *bold* and *italics*. Note that two fractionations were employed; steps associated with the second have an *asterisk* and differ slightly from those associated with the first because of our findings

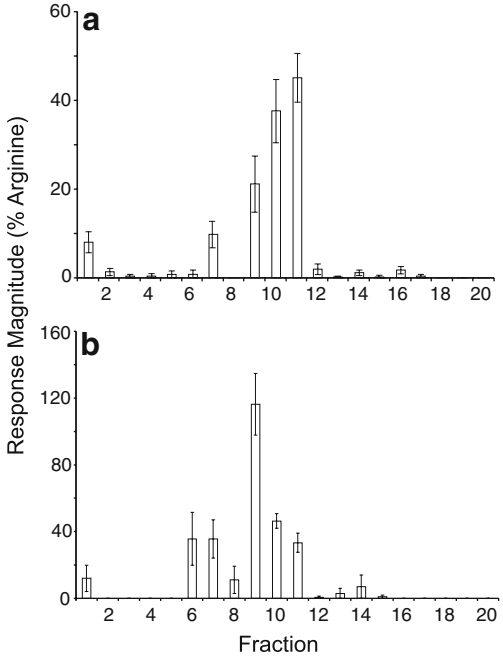

Fig. 2 Average electro-olfactogram (*EOG*) responses (±SE) recorded from migratory adult sea lamprey to fractionated larval extract (N=3). Results are expressed relative to the standard, 10^{-5} M L-arginine. Odors are RP-C18 extracts of 1 l of larval sea lamprey holding water that had been fractionated and diluted 1,000-fold to a concentration of 0.03 larval hour per liter. Two fractionations were conducted: **a** EOG responses to the first fractionation (shown in Sorensen et al. 2005); **b** EOG responses to fractions from the second fractionation which was used to confirm petromyzonamine disulfate and petromyzonol sulfate and isolate petromyzosterol disulfate

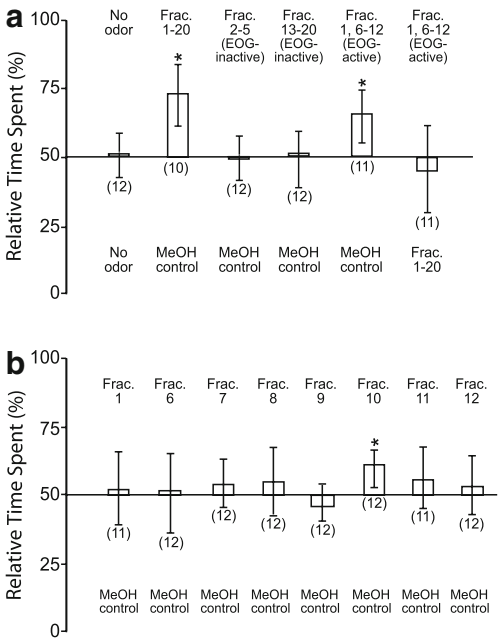

Fig. 3 Mean percent time (±95% CI) spent by adult sea lampreys in fractions of larval sea lamprey holding water in the maze (fractionation 1). Tests employed groups of fractions (**a**) and individual fractions (**b**). Test odor concentration was 0.018 larval hour per liter. *Numbers in parentheses* represent the number of trials (groups of four lampreys). Means were compared to a no-preference value of 50% by t test; *P<0.05. The first, second, fifth, and sixth tests (from *left*) in **a** are also shown in Sorensen et al. (2005)

7% (N=3) and had a negative ion at m/z 473.4, while the other elicited a relative average response of 81±18% and had negative ions at m/z 703.3 and 351.4. Closer inspection of m/z 351.4 showed an isotopic distribution pattern of 0.5, demonstrating that it was the dianion of m/z 703.3 and, therefore, the same compound. These compounds were combined and tested in the behavioral bioassay against whole extract (step II-7; Fig. 1); the mixture had significantly less activity than the extract (Fig. 4a).

Because the mixture of the two compounds did not fully explain the activity of larval extract, a second aliquot of larval extract was collected, extracted, fractionated (step II-1*, Fig. 1), and tested by EOG (step II-2*, Fig. 1). Fractions 6, 7, 8, 9, 10, and 11 had the greatest olfactory activity (Fig. 2b). The retention time of ^{14}C-CDCA in this set of fractionations suggested that on average, individual compounds ran about 1 min more quickly. Nevertheless, in both fractionations, fractions 9–11 explained the bulk of the activity. MS of a subsample of fraction 10 confirmed that it contained both compounds with respective m/z 473.4 and 703.3/351.4 m/z.

To check whether fractions 9 and 11 contained other components, these fractions were added to fraction 10 and tested against whole extract in the behavior maze (step 3*, Fig. 1). Lamprey did not discriminate between these two odors (Fig. 4b). Fractions 9 and 11 were further fractionated and the resulting sub-fractions tested by EOG (steps 4* and

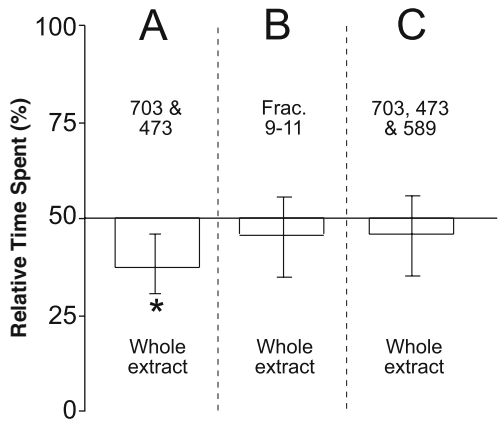

Fig. 4 Mean percent time (±95% CI) spent by adult sea lampreys in various fractionated odors tested against each other in the maze to confirm the complete presence of the pheromone. Three experiments were conducted: **a** The electro-olfactogram-active compounds from fraction 10 vs. whole extract (first fractionation); **b** fractions 9–11 vs. whole extract (second fractionation); **c** the three isolated compounds vs. whole extract (second fractionation). Concentration was 0.018 larval hours per liter. N=14 groups of four lampreys. Means were compared to a no-preference value of 50% using a t test; *P<0.05

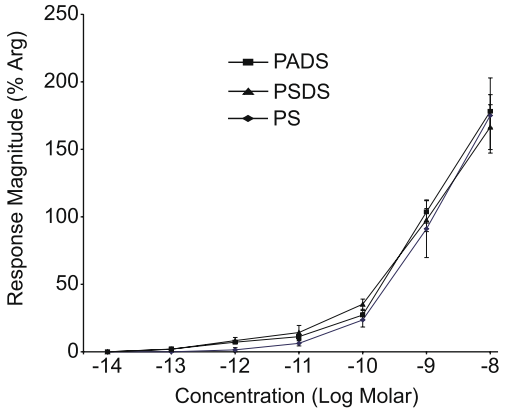

Fig. 5 Average electro-olfactogram responses (±SE) of adult sea lampreys (N=6) to natural, highly purified petromyzonamine disulfate (*PADS*), petromyzosterol disulfate (*PSDS*), and petromyzonol sulfate (*PS*) at a range of concentrations presented as a percentage of that elicited by the standard odorant, 10^{-5} M L-arginine

5a*, Fig. 1). Sub-fractions 1 and 2 from fraction 9 had EOG activity. Seven compounds were isolated from these sub-fractions, with one compound having EOG activity (data not shown). This compound had *m/z* 589.1/294.2 and elicited an EOG response of 99±9%. Closer inspection of *m/z* 294.2 *m/z* showed an isotopic distribution pattern of 0.5, demonstrating that it was the dianion of *m/z* 589.1. Sub-fractions 3 and 4 from fraction 11 both had EOG activity, but this was attributable to a single compound (*m/z* 473.3) which appeared to be the same compound as that found in fraction 10 previously; it had moderate olfactory activity (52±10%). When a sample of the compound with *m/z* 589.1 was added to a mixture (at natural ratios) of compounds with *m/z* 473.3 and 703.3 and tested against control water in the maze, the resulting three-component mixture was highly attractive (data not shown). Finally, there was no difference (P>0.05; Fig. 4c) in lamprey responses in the behavioral bioassay to this mixture and whole extract (step 6*, Fig. 1). Therefore, the respective compounds with *m/z* 473.3, 589.1, and 703.3 appear to elicit the majority of pheromonal activity.

Phase III: Biological Activity of the Pheromonal Compounds The three compounds isolated in phase II were identified (see, Sorensen et al. 2005; Hoye et al. 2007): *m/z* 473.4 was the negative molecular ion of PS, *m/z* 589.1 was the negative molecular ion of PSDS, and *m/z* 703.3 was the negative molecular ion of PADS. Preliminary tests using semi-purified samples of these compounds also found them to be attractive (Sorensen et al. 2005), but the biologically activity of purified samples has not been reported. Here we report the results of these studies using new samples. Approximately 85% pure PADS elicited strong EOG responses at 10^{-8} M and significant (P<0.05) responses at concentrations down to 10^{-13} M, but not at 10^{-14} M (N=6; P>0.05; Fig. 5). As measured by EOG, the detection thresholds of PSDS and PS were approximately 10^{-13} and 10^{-12} M, respectively (P<0.05; Fig. 5). When used as adapting stimuli, each compound suppressed EOG responsiveness to itself (Fig. 6a–d). Further, when the lamprey olfactory epithelium was adapted to PADS, the other three compounds (3k-PZS,

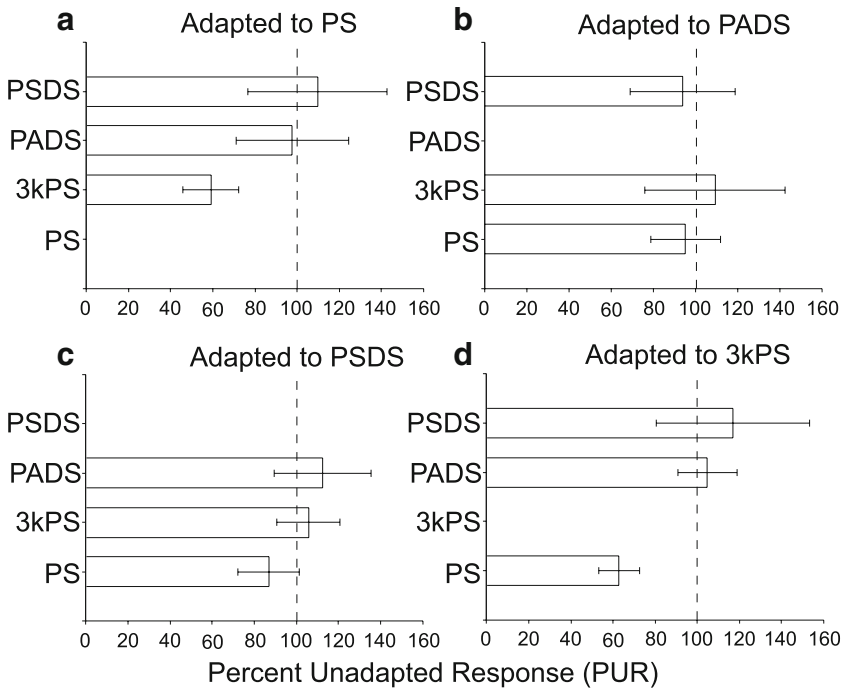

Fig. 6 Average electro-olfactogram responses (±SE) of adult sea lampreys (N=4) to petromyzonamine disulfate (*PADS*), petromyzosterol disulfate (*PSDS*), 3-keto petromyzonol sulfate (*3k-PZS*), and petromyzonol sulfate (*PS*) when adapted to one of these four compounds: **a** PS, **b** PADS, **c** PSDS, and **d** 3k-PZS. *Bars* (±SD) are the average percent unadapted response (*PUR*)

PSDS, and PS) elicited PURs of ~100% (Fig. 6b). The result was the same when the lamprey nose was adapted to PSDS (Fig. 6c). When adapted to PS and 3k-PZS, PURs for PADS and PSDS were ~100%. However, when adapted to PS, the PUR for 3k-PZS was only ~60% ($P<0.05$; Fig. 6a). Conversely, when the lamprey olfactory epithelium was adapted to 3k-PZS, the PUR for PS was 63% (Fig. 6d).

Pure natural PADS elicited behavioral responses at 10^{-13} M ($P<0.05$), but not at 10^{-14} M (Fig. 7a). Synthetic PADS elicited identical behavioral activity as natural PADS (Fig. 7b). Both PSDS and PS were attractive at 10^{-11} M ($P<0.05$), but not at 10^{-12} M (Fig. 7c,d). When natural and synthetic PADS were tested against each other in the maze at 10^{-12} M, the lampreys did not distinguish between them (avg=50.5%; $P=0.88$).

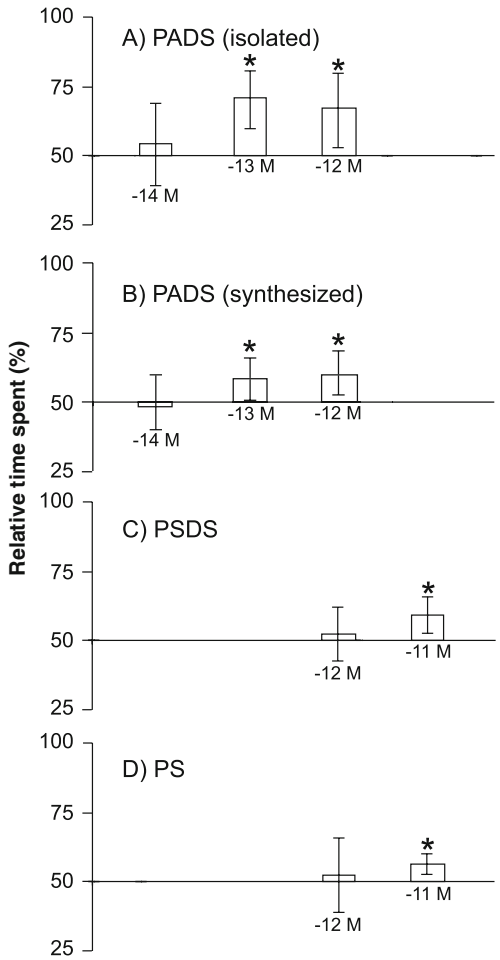

Fig. 7 Mean percent time (±95% CI) spent by adult sea lampreys in various concentrations of: **a** authentic petromyzonamine disulfate (*PADS*); **b** synthesized PADS; **c** petromyzosterol disulfate (*PSDS*); and **d** petromyzonol sulfate (*PS*) tested vs. methanol in the maze. $N=14$ trials for each experiment. Means were compared to a no-preference value of 50% using a *t* test; *$P<0.05$. The data used in **a**, **c**, and **d** is also described by Sorensen et al. (2005) who tested components with lower purity

Discussion

This study describes the isolation of pheromone components from larval lamprey holding water and the testing of their olfactory and behavioral activity and complements details already reported in Sorensen et al. (2005). First, and most importantly, the present dataset demonstrates for the first time that synthesized PADS, the most active component of the pheromone, is as biologically active as PADS isolated from larval holding water. Second, this study demonstrates for the first time that a mixture of the three compounds (not just the fractions that contain them) is as behaviorally attractive as whole larval odor when tested in our maze, demonstrating that these are the principal components of the pheromone. Third, cross-adaptation tests showed that each of the isolated compounds is detected with independent olfactory receptors. Fourth, we describe how to isolate multiple components from a pheromonal mixture—a tricky task in the case of the lamprey pheromone whose components synergize each other's activity (Fine 2006). Especially valuable is the ability of our assay to isolate key individual components one/several at a time and test their effects in a pheromonal mixture in an iterative fashion. Finally, this study confirms (through new behavior and EOG dose–response data) the potency of the pheromone, which is the first migratory pheromone identified in a vertebrate. Similar protocols could be used for structural elucidation of other complex aquatic pheromones.

Because the mixture of PADS, PSDS, and PS was not significantly different from the whole extract in the behavior maze, it seems reasonable to conclude that these compounds do indeed constitute the key components of the pheromone (Sorensen et al. 2005). Notably, the present data confirm our earlier preliminary study that used HPLC fractions (Sorensen et al. 2005) and olfactory studies of semi-purified components. However, the fact that the extract was consistently, albeit not significantly, more potent than the mixture of the three components as well as the mixture of fractions 9, 10, and 11 suggests that there may be other minor components which a more powerful/sensitive assay or larger sample size may discern. Such minor components could nevertheless be important in natural settings where background odors exist (Sorensen et al. 2003). The high potency of the RP-C18 extracts of larval holding water and the ability of XAD extracts of larval water to attract lampreys in the field (Wagner et al. 2006) suggest that if there are missing components, they are present in the extract and could be isolated by using the scheme presented here. The consistent olfactory activity of fractions 6 and 7 suggests a place to look. Allocholic acid, another minor bile acid released by sea lampreys (Li and Sorensen 1997), is probably not an important part of the

pheromone since it was found in fraction 16. Similarly, it is unlikely that 3k-PZS is a component of this pheromone, although it was occasionally found in low concentrations in fraction 9 (two of seven samples we examined over the course of several years; data not shown).

The behavioral detection thresholds for the pheromone components are very low: 10^{-13} M for PADS, and 10^{-11} M for both PSDS and PS. Recent EOG studies of synthesized PADS have also confirmed a 10^{-13} M threshold (Jeffrey and Sorensen, unpublished results). Our EOG cross-adaptation study showed that these compounds have independent olfactory receptor sites from each other and from the receptor for the lamprey sex pheromone component, 3k-PZS (Li et al. 2002). Similar scenarios have been described for insects (Roelefs 1995). Interestingly, and without obvious explanation, the cross-adaptation tests showed some overlap between receptor sites for PS and 3k-PZS, as seen in the study by Siefkes and Li (2004).

Why and how the sea lamprey evolved a multi-component pheromone is an interesting question, especially because it does not appear to be related to species specificity (Fine et al. 2004). Perhaps lampreys evolved a multi-component pheromone because it (or portions of it) might be easier to discern at greater distances/lower concentrations in the complex and variable natural environments that this creature has experienced over the past several hundred million years.

The results of this study are important for practical reasons. Complete identification of the pheromone now allows it to be developed for sea lamprey control in the Great Lakes (Sorensen and Hoye 2007). Similarly, this pheromone could be used to help restore threatened or endangered lamprey species around the world (Close et al. 2002; Yun et al. 2003) because unlike most pheromones identified in teleost fish (Stacey and Sorensen 2005; Sisler and Sorensen 2008), it seems to lack species specificity (Fine et al. 2004; Fine 2006). Research on the evolution and use of lamprey pheromones may now proceed with confidence that the three unique sulfated steroids we have isolated and identified constitute the key components of the migratory cue.

Acknowledgments We thank the staff of the Hammond Bay Biological Station (U.S. Geological Survey) who provided assistance, access to their facilities, and larval lampreys. Adult lampreys were supplied by the Marquette Biological Station (US Fish and Wildlife Service) and the Department of Fisheries and Oceans (Canada). We also thank Lance Vrieze, Sean Sisler, Melanie Burton, Chad Nordstrom, Elizabeth Fine, and Daniel Kurkeiwicz for assistance with behavioral studies. Tom Krick and Leeann Higgins of the Mass Spectrometry Consortium for the Life Sciences at the University of Minnesota provided assistance and access to their facility. We are grateful to Tom Hoye and Vadims Dvornikovs for advice, insight, synthesized PADS, and reviewing early versions of this manuscript. Chris Jeffrey and Andy Graves also reviewed earlier versions of this manuscript. Funding was provided by the Great Lakes Fishery Commission and the Minnesota Agricultural Experiment Station.

sis, *B. griseocollis*, *B. morrisoni*, and *B. rufocinctus* in North America. In many of these species, scent marking of the perching site has been observed (Haas 1949; Alcock and Alcock 1983; O'Neill et al. 1991; Williams 1991; Kindl et al. 1999). Male labial gland secretions of only a few species with perching behavior have been investigated chemically (Hovorka et al. 1998; Bertsch et al. 2004; Rasmont et al. 2005). In this paper, we investigated the cephalic labial glands of males of the North American bumblebees *B. morrisoni* and *B. rufocinctus*.

Methods and Materials

Materials Males of *B. morrisoni* Cresson and *B. rufocinctus* Cresson were collected at 40°22′41″ N, 120°19′42″ W near Litchfield (about 30 km east of Susanville, CA, USA) where these species are abundant. Males of both species are low in numbers, shy, and fast in flight. Ten individuals of each species were caught when they were feeding at *Chrysothamnus* in late afternoon. Individual gland contents may be variable and change quantitatively and qualitatively (a) during a lifetime (see Sobotnik et al. 2008 for *B. terrestris*) and (b) during daytime (when secretions are used for scent marking in the morning, glands may be depleted later in the day; see Bergman 1997 for *B. lapidarius*). In our field collections, old males were recognized by their frayed wings and were discarded. The borders of the wings of all males used for gland preparation were smooth, indicating active males. Males were transported alive to the laboratory and fed with a honey solution for 2 days in flight cages so that they could refill their glands. Then, they were frozen after a short flight activity very early in the morning. The cephalic part of the labial glands was dissected from the head of frozen males and placed in vials (glands from five males per vial) containing 0.2-ml pentane. As the aim of this investigation was not to study the variability of gland content but to elucidate the complexity of a composition of bumblebee male labial glands, we pooled the glands of five males into a single vial. This method allowed us to detect even minor compounds present in the glands.

Gas Chromatography/Mass Spectrometry A Finnigan MAT TSQ700 gas chromatograph (GC)/tandem mass spectrometer (MS) was employed. GC was carried out on a Hewlett-Packard Ultra 1 column (50 m, 0.2 mm i.d., 0.11 μm film thickness) in a splitless mode with helium as carrier gas at an inlet pressure of 300 kPa. The split valve was opened for 1 min. Initial temperature of 120°C was held for 1 min, then increased at 8°C/min to 280°C, at 3°C/min to 310°C, and at 1°C/min to 320°C. This temperature was held for 10 min. Mass spectrometer conditions were interface temperature 300°C, source temperature 130°C, electron energy 70 eV, emission current 0.2 mA, and electron multiplier 1,400 V. When using the positive ion chemical ionization (CI) mode, ammonia CI gas pressure was 70 Pa. Compounds were identified by comparing their mass spectra with those of the NIST'02 Library (National Institute of Standards and Technology, USA) and by retention times and molecular ions from CI spectra. To determine the position of double bonds, derivatization with dimethyl disulfide was used as described by Buser et al. (1983).

Results

The labial glands of both *B. morrisoni* and *B. rufocinctus* males contained a mixture of acyclic diterpenes (alcohols, acetates, and hydrocarbons), two cyclic terpenes, and various straight-chain fatty acid derivates (alcohols, esters, and both saturated and unsaturated hydrocarbons with C21–C31). Typical chromatograms of the male cephalic labial gland secretions of *B. rufocinctus* and *B. morrisoni* are shown in Fig. 1. The compounds are summarized in Table 1.

In labial glands of male *B. morrisoni*, the major compound was 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate (Fig. 1, 82% of total peak area, peak 20). In addition, considerable amounts of (6*E*, 10*E*)-3,7,15-trimethyl-3-methylene-hexadeca-1,6,10,14-tetraene (peak 6), 3,7,11,15-tetramethyl-hexadeca-1,3,6,10,14-pentaene (peak 9), 3,7,11,15-tetramethyl-6,10,14-hexadecatrien-1-ol (peak 18), and hexadecyl dodecanoate (peak 30) were detected. Traces of 3,7,11-trimethyl-2,6,10-dodecatrien-1-ol (peak 3), two more isomers of 3,7,11,15-tetramethyl-hexadeca-1,3,6,10,14-pentaene (peak 7 and 11), two unidentified cyclic diterpenes (peak 13a and 14), 9-hexadecenyl 9-tetradecenoate (peak 31), 9-octadecenyl 9-tetradecenoate (peak 33), and eicosenyl 9-tetradecenoate (peak 34) complete the pattern of substances found. Small amounts of 9-hexadecenol (peak 4) and hexadecanol (peak 5) were identified. The peak area of hexadecyl dodecanoate (30) with about 4.5% of the total peak area shows that considerable amounts of hexadecanol may be used by this species to form esters.

In labial glands of male *B. rufocinctus*, the major compound was 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate (Fig. 1, 79% of total peak area, peak 20). Furthermore, considerable amounts of 9-hexadecenol (peak 4), (6*E*, 10*E*)-3,7,15-trimethyl-3-methylene-hexadeca-1,6,10,14-tetraene (peak 6), and 3,7,11,15-tetramethyl-hexadeca-1,3,6,10,14-pentaene (peak 9) were detected. Minor amounts of two more isomers of 3,7,11,15-tetramethyl-hexadeca-1,3,6,10,14-pentaene (peak 7 and 11) and 3,7,11,15-tetramethyl-6,10,14-hexadecatrien-1-ol (peak 18)

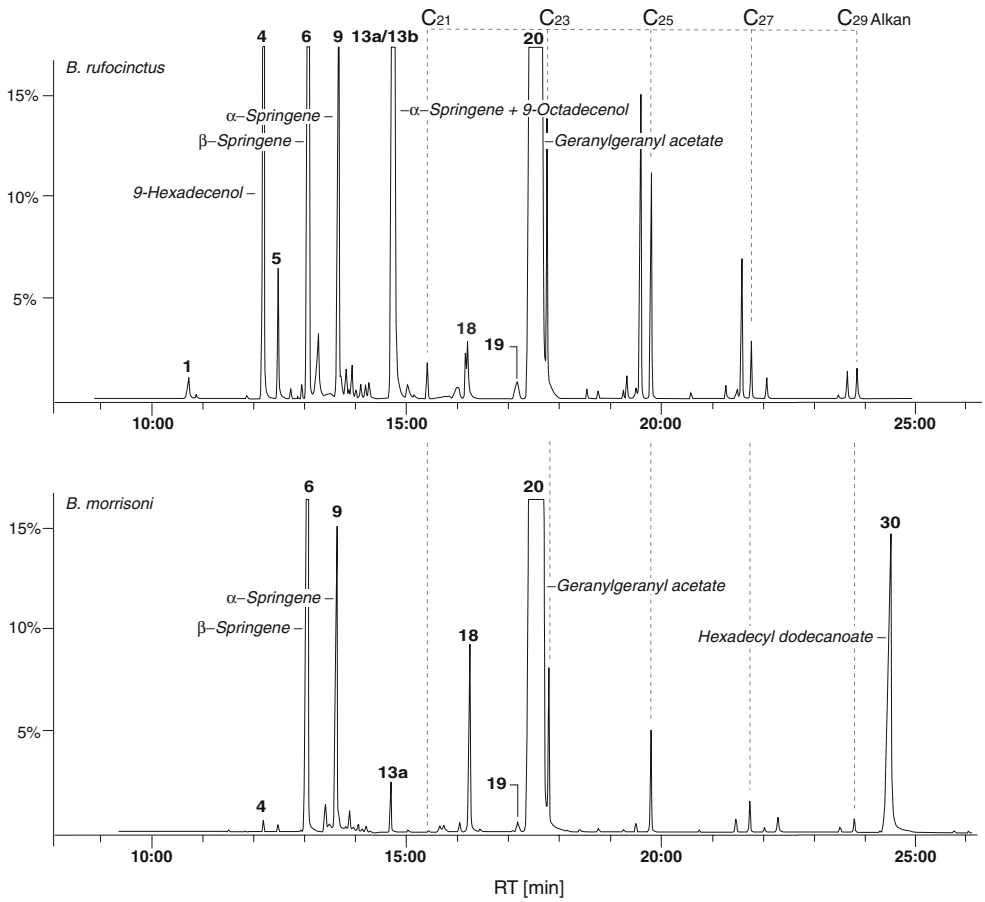

Fig. 1 Total ion chromatograms of the pentane extract of the cephalic labial gland from *B. morrisoni* and *B. rufocinctus*. *Numbers* correspond to the numbers in the peak list (Table 1). Some compounds listed in Table 1 were present in quantities too low to be visible in these chromatograms

were found. 9-Octadecenol (peak 13b) was also present in considerable amounts co-eluting with the unidentified cyclic diterpene detected in the GC of *B. morrisoni* (peak 13a). Small amounts of an isomer of this unidentified cyclic diterpene (peak 14), 9-tetradecenoic acid (peak 1), tetradecanoic acid (peak 2), hexadecanoic acid (peak 8), 9-octadecenoic acid (peak 17), 9-hexadecenyl acetate (peak 10), hexadecyl acetate (peak 12), and 9-octadecenyl acetate (peak 17) were detected.

Compared to the chemistry of labial glands of other male bumblebee species, the proportion of hydrocarbons and esters was low in the species studied here. Only few wax-type esters were found (Table 1). Typical GCs of the species studied here also contained four diterpenes, i.e., isomers of springene. Their molecular ion was *m*/*z*=272. Their mass spectra were identical with those of (6*E*, 10*E*)-7,11,15-trimethyl-3-methylene-hexadeca-1,6,10,14-tetraene [β-springene] (peak 6) and α-springene (peaks 7, 9, 10). The relative retention times of (6*E*, 10*E*)-7,11,15-trimethyl-3-methylene-hexadeca-1,6,10,14-tetraene [β-springene], (3*Z*,6*E*,10*E*)-3,7,11,15-tetramethyl-hexadeca-1,3,6,10,14-pentaene, and (3*E*,6*E*,10*E*)-3,7,11,15-tetramethyl-hexadeca-1,3,6,10,14-pentaene [the α-springenes] were as reported by Burger et al. (1981). As expected, the mass spectra of the three isomers of 3,7,11,15-tetramethyl-hexadeca-1,3,6,10,14-pentaene [α-springene] were nearly identical.

Peaks 13a and 14 in the secretions could not be identified. The mass spectra of both compounds exhibited molecular ions at *m*/*z*=272, indicative of a hydrocarbon of the molecular formula $C_{20}H_{32}$. The molecular mass was confirmed by CI (NH_3) and the pseudo molecular ion *m*/*z* 273 ($[M+H]^{+\cdot}$), whereas the pseudo molecular ion *m*/*z* 290 ($[M+NH_4]^+$) could not be detected. The mass spectrum of peak 13a was characterized by the following fragment ion *m*/*z* (%) values: 272 (19, M^+), 135 (100), 120 (11), 119 (10), 107 (90), 105 (36), 93 (43), 91 (33), 79 (11), 77 (13), 69 (46), 53 (13), 41 (33). The mass spectrum of peak 14 was nearly identical. The most intense fragment ions *m*/*z* 135 ($[C_{10}H_{15}]^+$) and *m*/*z* 107 ($[C_8H_{11}]^+$) were observed in cyclic and polycyclic hydrocarbons indicating peak 13a and peak 14 to be isomers of a cyclic terpene.

Discussion

The labial glands of most bumblebee males with the *patrolling* premating behavior contain a pattern of straight chain primary alcohols [C12–C26] (Bergström et al. 1981,

Valterová and Urbanová 1997). The corresponding acetates are often found only in minor amounts or as traces. Indeed, sometimes they are completely absent and occur only because of an aging process of the prepared glands. Our study and other previous studies show that the secretions of male bumblebees with the *perching* premating behavior differ from bumblebees with *patrolling* premating behavior in the occurrence of acetates as the leading components (Table 2).

In *B.* (*Cullumanobombus*) *rufocinctus*, 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate [geranylgeranyl acetate] and 9-octadecenol contributed 84% to the total peak area. In *B.* (*Separatobombus*) *morrisoni*, 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate [geranylgeranyl acetate] and 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraen-1-ol [geranylgeraniol] contributed 84% to the total peak area. In *B.* (*Separatobombus*) *griseocollis*, tetradecyl acetate and 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate [geranylgeranyl acetate] contributed 97% to the total peak area (Bertsch et al. 2004). In *B.* (*Confusibombus) confusus, (Z)*-9-octadecenyl acetate and 3,7,11,15-tetramethyl-6,10,14-hexadecatrien-1-ol [geranylcitronellol] contributed 77% to the total peak area (Hovorka et al. 1998), and in *B.* (*Sibiricobombus*) *vorticosus*, 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate [geranylgeranyl acetate] and 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraen-1-ol [geranylgeraniol] contributed 87% to the total peak area (Rasmont et al. 2005). In all labial gland secretions of males with perching behavior, two compounds dominate the marking secretions, with an acetate being the dominant compound.

A mixture of substances with high and lower volatility is characteristic of the scent glands in male bumblebees. Bergman and Bergström (1997) detected the main component, farnesol, of the labial glands of *B.* (*Pyrobombus*) *pratorum* in headspace samples from marked leaves, but they could not detect 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate [geranylgeranyl acetate], also produced by the glands, in these samples. Kindl et al. (1999) showed that 3,7,11,15-tetramethyl-6,10,14-hexadecatrienyl acetate [geranylcitronellyl acetate], though present only in minor amounts in the labial glands of *B.* (*Confusibombus*) *confusus*, could be detected in headspace samples of the male-marked perch (dry flower head of *Centaurea stoebe*). O'Neill et al. (1991) studied marking behavior and labial glands of male *B. rufocinctus*. Their results suggest that males of this species mark leaves of *Symphoricarpus* and *Ribes* with at least three components of labial gland secretion. Even though these compounds were not identified, the retention times given for them indicate that they might be hexadecenol (O'Neill et al., Fig. 4, peak 12.31), octadecenol (peak 14.29), and 3,7,11,15-tetramethyl-2,6,10,14-hexadecatetraenyl acetate (peak 16.37). Less volatile compounds left on leaves may remain detectable until the next day, helping the bumblebees to find and reconstruct the activity, of the previous day. Evaporation of alcohols and acetates is a first-order process (release rate is proportional to the amount of pheromone present) with long half-lives (Butler and McDonough 1981; McDonough et al. 1989) strongly depending on size, weight, and polarity of the compound molecule.

In labial gland secretions of *B.* (*Pyrobombus*) *pratorum*, two isomers of 3,7,11-trimethyl-2,6,10-dodecatriene [farnesene] were identified, the only isoprenoid hydrocarbons detected in bumblebee labial glands so far (Valterová et al. 1997). (3*E*, 6*E*, 10*E*)-3,7,11,15-Tetramethyl-hexadeca-1,3,6,10,14-pentaene and 7,11,15-trimethyl-3-methylene-hexadeca-1,6,10,14-tetraene [α- and β-springene, respectively] detected in the labial glands of *B.* (*Separatobombus*) *griseocollis* were newly identified isoprenoid hydrocarbons in bumble bee secretions (Bertsch et al. 2004). Meanwhile, these substances also have been detected in *B.* (*Sibiricobombus) vorticusus* (Rasmont et al. 2005), a male bumblebee with perching habit. (6*E*, 10*E*)-β-Springene has been isolated from a diversity of organisms, including the paracloacal gland of reptiles [the American alligator (Ibrahim

et al. 1998) and the smooth-fronted caiman (Avery et al. 1993)], the dorsal secretions of mammals [collared peccary (Waterhouse et al. 1996), white-lipped peccary (Waterhouse et al. 2001), and springbok (Burger et al. 1978, 1981)], the Dufour glands of insects [Australian ant *Nothomyrmecia macrops* (Billen et al. 1988), the Old World army ant *Aenictus rotundatus* (Oldham et al. 1994), the ectoparasitoid *Habrocon hebetor* (Fukushima et al. 1990; Howard et al. 2003), and as a trace component in the stingless bee *Nannotrigona testaceicornis* (Cruz-Lopez et al. 2001)]. Additional isomers of α-springene described so far are 3,7,11,15-tetramethyl-hexadeca-1,4,6,10,14-pentaene (Waterhouse et al. 1996; *Tayassu tajacu*, Mammalia) and 2,6,11,15-tetramethyl hexadeca-2,6,8,10,14-pentaene (Burger et al. 1981; see Table 1; *Antidorcas marsupialis*, Mammalia, and Zhou et al. 2006; *Citrus grandis*, Spermatophyta).

Studies of the perching behavior of bumblebees have revealed that no activity of virgin females (gynes) is detected near perches that have been marked by males with labial glandular secretion. This effect of male labial glandular secretion in male–female interactions has been shown in *B.* (*Separatobombus*) *griseocollis* (Alcock and Alcock 1983), in *B.* (*Cullumanobombus*) *rufocinctus* (O'Neill et al. 1991), and in *B.* (*Confusibombus*) *confusus* (Kindl et al. 1999). The question whether male labial glandular secretions mark small territories or individual perches and thus, mediate male–male interactions, need to be addressed in future studies.

than males produced by their mother (r=0.25). Although worker reproduction may be favored due to relatedness, other factors such as maintaining colony efficiency and conflict over sex allocation favor reproductively restrained workers (Cole 1986; Ratnieks 1988). Under queenright conditions, workers usually either behaviorally inhibit (police) the reproductive efforts of other workers or are selected to exhibit reproductive self-restraint (Ratnieks 1988; Wenseleers et al. 2004).

The two most common policing behaviors in ant societies are physical policing of potential egg layers and egg policing (Monnin and Ratnieks 2001; Ratnieks et al. 2006). The reproductive efforts of individuals that are physically policed are inhibited by nestmates attacking the policed individual (Hölldobler and Carlin 1989; Dietemann et al. 2003; Hartmann et al. 2003). Egg policing occurs when worker-laid eggs are destroyed by nestmates (Kikuta and Tsuji 1999; D'Ettorre et al. 2004; Endler et al. 2004). In order for either one of these policing behaviors to be carried out effectively the policing individuals must have reliable information that indicates which workers should be policed or which eggs should be destroyed. Hydrocarbon blends present on the cuticle of workers and queens, and on the surface of eggs, are thought to contain these signals.

Cuticular hydrocarbons provide resistance to desiccation (Lockey 1988) and have the potential for holding information through recognizable quantitative and qualitative blend differences (Monnin 2006; Le Conte and Hefetz 2008). Changes in cuticular hydrocarbons in numerous ant species reliably correlate with changes in reproductive ability (e.g., Liebig et al. 2000; Dietemann et al. 2003, 2005; Cuvillier-Hot et al. 2004; Lommelen et al. 2006). This potentially allows the effective policing of individuals that change their hydrocarbon blends while becoming reproductively active. However, experimental data to prove a causal relationship has not yet been presented. Similar correlative evidence exists for egg policing. Policing occurs where eggs can be identified according to the reproductive caste of the egg-laying worker (Monnin and Peeters 1997; D'Ettorre et al. 2004; Endler et al. 2004). A causal relationship between surface hydrocarbons and egg policing has been shown in the ant *Camponotus floridanus* (Endler et al. 2004). In this species, workers destroy significantly fewer worker-produced eggs when the eggs are given a queen-derived profile. This indicates that egg surface hydrocarbons are the signal that provides the information necessary for effective egg policing.

In the current study, we examined behavioral regulation of reproduction and fertility signaling within the worker caste of the desert-ant *Aphaenogaster cockerelli*. The derived status of this species is indicated by a distinct worker–queen dimorphism and large-size colonies with a single queen. Workers of this species have highly active ovaries that produce trophic eggs in the presence of a queen and viable male eggs in as few as 2 weeks after the removal of the queen (Hölldobler and Carlin 1989). In the presence of a queen, workers have been shown to police reproductive nestmates physically (Hölldobler and Carlin 1989), thus limiting workers to trophic egg production in queenright colonies. However, egg policing has not yet been examined in this species. Furthermore, the hydrocarbon signals that potentially underlie both of these behaviors have yet to be identified. Herein, we study egg policing and identify the hydrocarbon signals available for both egg and physical policing behaviors.

Studies of fertility signaling and policing in ants have mostly focused on more primitive species with low to non-existent worker–queen reproductive dimorphism. Our findings on the signaling and policing behavior of *A. cockerelli* provide new insights into the evolution of fertility signals. We conclude that the policing behaviors performed in this species are a direct result of the signals available to the policing workers. In comparison to other ant species, our results provide the first insights into the physiological adaptations that may influence patterns of reproductive signaling.

Methods and Materials

Study Species Mature colonies of *A. cockerelli* were collected from the Chihuahuan desert between Portal, Arizona, and Rodeo, New Mexico, from the end of August through the beginning of October 2006 and in August 2007. Colonies were collected by triggering nest evacuation using army ants (*Neivamyrmex nigrescens*; Smith and Haight 2008). Collected colonies averaged 1,500 workers; all had a single queen. Mature colonies consist of a nest with a single queen and one to four distinct satellite nests containing workers and brood (Hölldobler and Carlin 1989). The colonies used for this experiment consisted primarily of workers collected from the nest containing the queen. Previous work based on 31 colonies and 487 workers genotyped for two microsatellites has shown that queens are singly mated (Mösl and Gadau, unpublished data).

Laboratory Conditions In the laboratory, ants were housed in a dental-plaster nest with molded chambers, darkened inside by red acetate over glass. The nests were attached to a foraging arena in which they received a constant supply of water, sugar–water, and pieces of cricket (*Acheta*

domestica) and beetle larvae (*Zophobas morio*). For this study, temperature was maintained at 25°C, and the foraging arenas were kept in constant light.

Egg Policing To determine whether or not workers selectively destroy viable eggs produced by sister workers, we measured egg acceptance by using discriminator worker groups (a method used to show egg policing; Endler et al. 2004, 2006). These worker groups consisted of 50 randomly chosen nest workers. Each group was placed into a nest connected to a foraging arena similar in construction to the queenright colonies from which they originated. These workers were given food (as mentioned above), water, sugar–water, and 24 h to acclimate to their new nests. There were three discriminator worker groups from each colony (N=9) in this experiment. Each group simultaneously received one of three egg treatments, introduced into the nest area. One group received 20 mother-queen-produced eggs, another received 20 sister-worker produced eggs, and the final group received a mixture of ten mother-queen eggs and ten sister-worker eggs. Sister-worker-produced eggs were taken from isolated worker groups that had become reproductive, exhibiting an egg-carrying behavior indicative of tending viable eggs rather than trophic eggs (Hölldobler and Carlin 1989). This setup allowed us to test if workers would police worker-produced eggs in the presence and absence of queen-produced eggs. *A. cockerelli* workers are often separated from the queen due to polydomous colony nest structure (mentioned above). Therefore, the short-term absence of a queen present in these discriminator groups should not have affected the outcome of our egg-policing tests.

The number of eggs remaining after 24 h was recorded in all treatments. This period of time has proven to be suitable for egg policing to occur (Endler et al. 2004; Dietemann et al. 2005; Helanterä and Sundström 2007). Egg survival in the experimental groups was analyzed by using a non-parametric Friedman's ANOVA.

Hydrocarbon Profiles Queen (N=16), non-reproductive worker (N=14), and reproductive worker (N=10) cuticular hydrocarbon profiles were collected from our laboratory colonies. Note that the sample size (above) represents ants from independent colonies, except the reproductive worker group in which two workers from the same colony were sampled, thus making colony sample size actually N=9. Queen profiles were taken from live queens that were reproductively active, as indicated by the presence of eggs. Non-reproductive workers consisted of non-callow workers that were randomly picked off of the brood pile of a queenright colony; therefore, these ants were likely to be trophic-egg producing, brood-tending workers. Reproductive workers were taken from reproductive groups of workers (100–200 individuals) that had been isolated from their queen and brood for an extended time span (3 weeks to 6 months). Workers were classified only as reproductive (1) when they had been observed laying an egg that was then deposited onto the pre-existing egg pile (to ensure that the worker was producing viable eggs, not trophic eggs, as the latter are immediately fed to brood or eaten by other workers; Hölldobler and Carlin 1989), and (2) when subsequent dissection of these workers confirmed ovarian activity and the condition or type of yolky oocytes indicated the development of viable eggs.

Eggs used for gathering egg profiles were taken directly from the egg piles of both queenright colonies and isolated worker groups (mentioned above) that had started to reproduce.

Chemical Analysis Cuticular hydrocarbon profiles were gathered from live queens and workers by using solid-phase microextraction (Arthur and Pawliszyn 1990). A fiber (Supelco Inc., coated with a 30-μm polydimethylsiloxane film) was rubbed on the gaster surface for 5 min (Monnin et al. 1998). The fiber was inserted into the injection port of an Agilent 6980N series gas chromatograph (GC) equipped with a DB-1MS (J&W Scientific) non-polar capillary column (30 m×0.25 mm×0.25 μm), connected to an Agilent 5975 series mass selective detector. The GC injection port was set to 260°C and the transfer line to 300°C. The column temperature was held at 60°C for 2 min before increasing to 200°C at 40°C min^{-1}, and then to 320°C at 5°C min^{-1}. Helium was used as carrier gas at 1 ml min^{-1}, and samples were injected in the splitless mode. Electron impact mass spectra were measured at 70 eV with a source temperature of 230°C. Identification of the compounds was tentatively based on a comparison of their mass spectra with published spectra, synthetic alkane standards, and retention indices.

Egg-surface hydrocarbon profiles were gathered by extracting groups of 20 eggs in 20 μl of hexane for 5 min. The extract was evaporated and suspended in 2 μl of hexane from which 1 μl was injected into the GC.

Compounds were included in the statistical analysis if they occurred in ≥70% of the sampled individuals within at least one of the classes (queen, reproductive worker, nest worker, worker-produced egg, and queen-produced egg). We performed non-parametric multi-dimensional scaling to analyze the similarity of cuticular and egg profiles by using Primer 6. Chord distances were used to calculate the distance matrices.

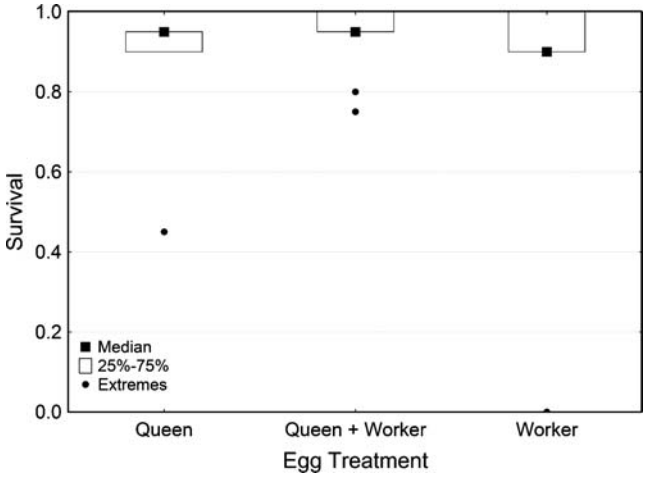

Fig. 1 Bioassay of egg survival over 24 h. Survival of 20 queen eggs is compared to ten queen eggs mixed with ten worker eggs and to 20 worker eggs. There was no statistical difference among treatments, Friedman's ANOVA, n_{groups}=9, P=0.875

Results

Egg Policing There was no significant difference in the survival of eggs among the different treatments (Fig. 1). Median survival of queen eggs and a mix of worker and queen eggs was 0.95, while median survival of worker eggs was 0.9. If workers effectively police worker-produced eggs, survival of the queen and worker mixed egg group would have been 0.5, while worker egg survival would have been zero.

Egg Surface Hydrocarbon Profiles The two classes of eggs (worker-produced and queen-produced) were not qualitatively different in their hydrocarbon profiles. Only small relative abundance differences were distinguishable (Fig. 2, Table 1), which was confirmed by the lack of a clear separation of the two classes of eggs in the non-parametric multi-dimensional scaling (Fig. 3). The stress value of 0.09 indicates a good graphical representation of the data structure.

Cuticular Hydrocarbon Profiles Quantitative and qualitative differences separated the classes of individuals (queen, nest worker, and reproductive worker; Fig. 2, Table 1). For instance, compounds 1–9 (Fig. 2) were unique to reproductive individuals. There were only three of these compounds that occurred in all reproductive workers sampled (peaks 3, 7, and 8; Table 1). In two of these three compounds, quantitative differences separated reproductive workers and queens; e.g., median relative abundance of pentacosane (peak 3; Table 1), queen = 25.2 and reproductive worker = 6.8.

Non-parametric multi-dimensional scaling separated queens and non-reproductive workers well, with a large gap between the two groups (Fig. 4). The reproductive workers were between the two groups as expected, including profiles that were relatively similar to those of queens and those of non-reproductive workers. The stress value of 0.07 indicates a good graphical representation of the data structure.

Discussion

The crucial requirement for effective reproductive policing is the ability to identify which workers or which eggs should be policed. Our findings suggest that the policing behaviors of *A. cockerelli* can be explained by discriminatory information present in hydrocarbon blends on the worker cuticle and the surface of eggs. Workers of *A. cockerelli* do not police worker-produced eggs; viable worker egg survival was not different from that of queen eggs in the egg policing experiment. Correspondingly, workers produce eggs with a surface hydrocarbon blend nearly identical to that of queen-produced eggs (Table 1, Fig. 2). In contrast, the cuticular profiles of non-reproductive workers showed strong qualitative differences from queens. Reproductive egg-laying workers fall between the two groups. This difference provides potential to identify reproductive workers, while eggs cannot be distinguished.

A. cockerelli is a species with workers that have active ovaries used for trophic egg production within a queenright nest. There are striking parallels between *A. cockerelli* and another trophic egg-producing ant, *Myrmecia gulosa*, in which policing and hydrocarbon signaling has been studied. Like *A. cockerelli*, *M. gulosa* do not police worker-produced viable eggs. Instead, reproductive workers are singled out and policed. Correspondingly, reproductive workers develop a distinct cuticular hydrocarbon profile, and their eggs are covered with a suite of hydrocarbons similar to queen eggs (Dietemann et al. 2003, 2005). In both phylogenetically distant systems (*Aphaenogaster*, Myrmicinae; *Myrmecia*, Myrmeciinae), workers can distinguish only reproductive castes and not their eggs. Thus, policing is limited to physical attacks and immobilization of reproductive workers.

In contrast to the mode of policing seen in *M. gulosa* and *A. cockerelli* is that of the ant *Camponotus floridanus* (subfamily Formicinae). When workers become reproductive, their cuticular hydrocarbon profile does not change.

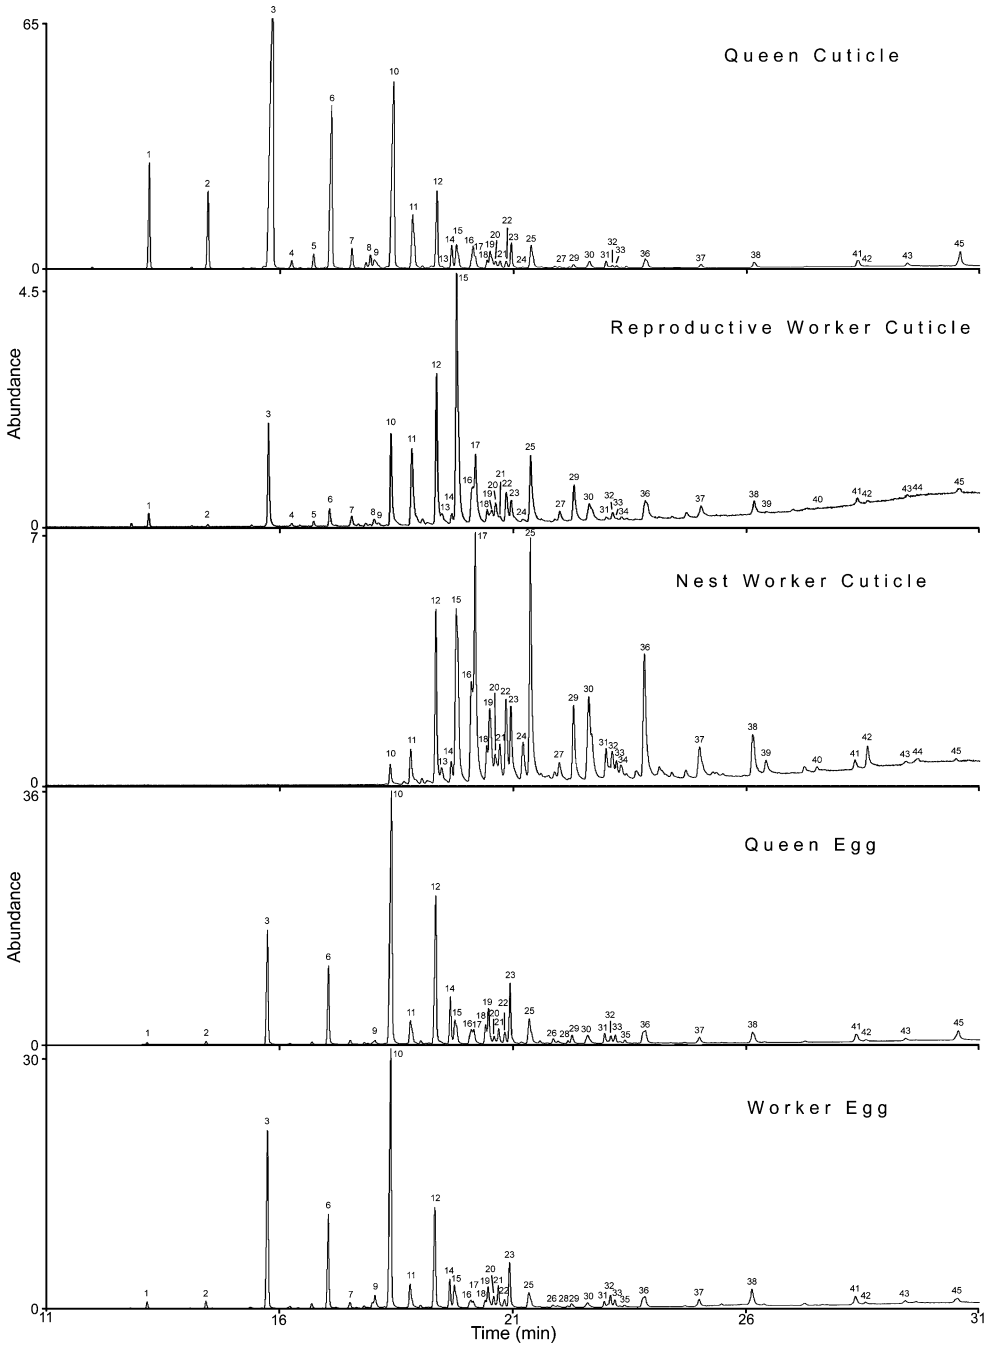

Fig. 2 Representative chromatograms showing hydrocarbon profiles among sampled classes of individuals and eggs. *Numbered peaks* correspond to compounds in Table 1 and are the compounds included in the statistical analyses

Their eggs receive hydrocarbon blends that are similar to those occurring on the cuticle of workers. This makes worker eggs distinguishable from queen eggs, which contain hydrocarbons that vary with fertility and indicators of fertility such as colony size (Endler et al. 2006). Correspondingly, workers in this system are not physically policed, but their eggs are (Endler et al. 2004, 2006, 2007). In contrast to *M. gulosa* and *A. cockerelli*, *C. floridanus* workers are not trophic egg producers and do not have active ovaries under normal queenright conditions.

The ability to produce queen-like hydrocarbon blends may be associated with workers retaining active ovaries. It has been suggested recently (Endler et al. 2007) that workers of more derived ant genera, with low reproductive potential (inactive ovaries, e.g., *C. floridanus*), may have lost the ability to produce a fertility signal due to their

inability to replace the primary reproductive. However, the social organization of *A. cockerelli* is highly derived with distinct worker–queen dimorphism, large colony size, and a single queen, similar to that of *C. floridanus*. The most obvious difference between the two species is the ovarian activity level of workers in the presence of the queen. *A. cockerelli* is, to our knowledge, one of the most derived species of ant in which workers can produce the reproductive signals utilized by the primary reproductive or queen. This is commonly found in more primitive ant societies, in which worker–queen dimorphism is low or non-existent (Liebig et al. 2000; Cuvillier-Hot et al. 2004; Lommelen et al. 2006). In these systems, nestmates have a reproductive potential that rivals that of the queen. The high level of ovarian activity for trophic egg production of *A. cockerelli* workers may be the underlying physiological condition that has led to workers and queen sharing the same reproductive signaling capabilities. Further fertility signaling studies in other trophic egg-producing derived species of ants are needed to verify this hypothesis.

Fig. 3 Two-dimensional configuration of non-metric, multi-dimensional scaling of surface hydrocarbon blend differences between queen-produced eggs and worker-produced eggs

Fig. 4 Two-dimensional configuration of non-metric, multi-dimensional scaling of cuticular hydrocarbon blend differences among queens, reproductive workers, and non-reproductive workers

Acknowledgment We thank Kevin Haight, Dani Moore, Clint Penick, and Dorit Eliyahu for assistance throughout the time this research was performed. C. T. Holbrook provided helpful comments on the manuscript.

var. *melanocarpa* collected in British Colombia, prunasin constituted approximately 3–6% of leaf dry weight. Santamour (1998) reported an average of 3,776±526 ppm cyanide in *P. virginiana* leaves measured from June to September in plants growing in the National Arboretum in Washington, D.C. Thus, previous studies indicated that the leaves fed by colonies of *A. cerasivoranus* are highly cyanogenic. The caterpillars of *A. cerasivoranus* are bright yellow. Their aposematic coloration and their habit of moving outside the nest during the day to pull leaves into the shelter suggest that the larvae are "advertising" their toxicity. In response to disturbance, the caterpillars regurgitate (Grant 2006) exuding a viscous liquid from their mouthparts. We tested the hypothesis that larval aposematism in *A. cerasivoranus* is associated with sequestration of host-derived HCN. Specifically, we conducted chemical assays to determine the concentration of HCN in the caterpillar's body, regurgitant, and frass. We also assessed the influence of the rate of ingestion on foregut pH and cyanogenesis.

Methods and Materials

Study Site The study was conducted during spring/early summer of 2006–2008. Colonies of *A. cerasivoranus* and leaves of *P. virginiana* used were collected from field locations in Cortland County, New York, during June.

Chemical Analysis of Cyanide To prepare leaf and fecal pellet samples for analysis, material was weighed to 0.1 mg, then ground in 0.5 ml of 0.2 M phosphate buffer ($NaH_2PO_4 \cdot H_2O$, pH 6.2 (Brinker and Seigler 1989, 1992) with a mortar and pestle (5 cm barrel length×0.3 cm diameter). Both the buffer, mortar, and pestle were chilled to approximately 4°C in an ice bath immediately prior to use to prevent the loss of cyanide as HCN (Fitzgerald et al. 2002). The buffer was transferred to an 18-ml capacity Warburg flask, the center well of which was preloaded with 0.2–0.3 ml of 1 M NaOH. The entire process of grinding and transfer took less than 10 s. The flask was then sealed and held at 35°C for a minimum of 18 h. For some analyses, as noted below, we added 7 units of β-glycosidase (Sigma-Aldrich product number G4511) to the Warburg flask (Swain et al. 1992). HCN volatilizing from the sample during the distillation process was trapped in the center well (preloaded with NaOH) as CN^-. Samples were analyzed with a Dionex Ion Chromatograph with a GP 50 gradient pump and ED 40 electrochemical detector. The machine was fitted with a 4 mm AG9-HC guard column and a 250×4 mm AS7 analytical column. The eluent consisted of 41 g $NaC_2H_3O_2$, 5 ml ethylenediamine, and 16.5 ml of 6.0 M NaOH per liter, delivered at a flow rate of 1.0 ml/min. Twenty-five microliter of the NaOH center well solution were injected into the apparatus. CN^- eluted at approximately 6 min. A standard curve was prepared prior to each run by injecting known concentrations of CN^- into the apparatus.

Cyanide Content of Leaf, Frass, and Regurgitant Samples The HCN-p of a total of 31 leaves of *P. virginiana* collected from five trees was determined. Sixteen of these leaves were partially expanded leaves growing at the tips of shoots (young leaves) and 15 were fully expanded leaves found at the base of the current years growth (aged leaves). A 2–4 mg section (3.0±0.1 mg SE) was cut from the leaves and prepared for analysis as described above.

Frass was collected from 11 caterpillars allowed to feed ad libitum in plastic containers on leaves of *P. virginiana* of mixed age in the laboratory and prepared for analysis as described above. In addition, we attempted to relate cyanide content of frass to leaf age using the following procedure. Five caterpillars of *A. cerasivoranus* (fourth instar) were housed in each of 20 vented plastic containers (10.5 cm diameter×4 cm deep). Caterpillars in ten of these containers were allowed to feed ad libitum for 4 d on young leaves and caterpillars in the other ten containers on aged leaves. Leaves were kept fresh by inserting their stems in water piks. Consumed leaves were replaced daily. Samples of dried frass (4.3±0.5 mg) were collected from five containers having old leaves and five having young at the end of the 4-day period and prepared for analysis as described above. In addition, similarly sized samples of frass from four more containers having young leaves were distilled in buffer to which 7 units of β-glycosidase were added.

Caterpillars aggregate their pupal cells in a central core of the leaf shelter. Each is encased in frass. We determined the cyanide content of frass taken from the core for four groups of caterpillars fed on young leaves and 4 groups fed on aged leaves under laboratory conditions. Stems bearing young or aged leaves of *P. virginiana* were placed in vials to provide foraging arenas. Twenty last instar caterpillars were placed into each arena. The caterpillars eventually bound the stems into tight nests. When they had finished feeding, they constructed a central core of pupa cells. Samples of the frass encasing the pupal cells (6.1±1.1 mg) were collected from each nest and processed as described above.

We collected samples of regurgitant from caterpillars housed in the 20 containers as described above at the end of the 4-day feeding period. Samples of 1–6 μl of regurgitant were collected from caterpillars in each container depending upon the amounts expressed by the caterpillars. Regurgitant was collected by holding a caterpillar between the thumb and forefingers and gently brushing the tip of a micropipette against its mouthparts causing it to express a

droplet that was drawn by capillary action into the pipette. The regurgitant samples were injected directly into microvials filled with an exact known quantity (0.1–0.2 ml) of 1 M NaOH. Some caterpillars produced little or no regurgitant, and it was usually necessary to collect droplets from several caterpillars from each container. The caterpillars in two containers maintained on young leaves failed to produce regurgitant. Thus, we analyzed eight samples of regurgitant from caterpillars maintained on young leaves and ten from caterpillars maintained on aged leaves. In addition, we analyzed 25 samples (each 5 μl) of regurgitant collected in the same manner from 12 different colonies in the field. As was the case for our experimental caterpillars, caterpillars in field colonies expressed varying amounts of regurgitant, and it was necessary to combine the regurgitant of several caterpillars from each colony to obtain 5-μl samples.

Cyanide Content of Whole Caterpillars We determined the cyanide content of 18 whole caterpillars that had been allowed to feed on either young or aged leaves. Caterpillars used for this study were those housed in the 20 containers as described where they were able to feed ad libitum. At the end of their 4-day feeding period, the caterpillars were killed by freezing and held at −21°C until processed 7 days later. To prepare specimens for analysis, a frozen caterpillar was weighed, then immediately sandwiched between the leaves of a folded sheet of aluminum (0.15 mm thick× 25 mm long×12 mm wide) and immersed in liquid nitrogen. When fully frozen, the aluminum case was withdrawn, and the caterpillar within shattered by crushing the case with a small mallet. The case was then opened, and the frozen, pulverized caterpillar was washed into a Warburg flask with chilled buffer and incubated as described above. Five of the caterpillars that were pulverized were each incubated separately with 7 units of β-glycosidase.

Cyanide Loss to Atmosphere A study was conducted to obtain an estimate of the fraction of the cyanide potential of a leaf lost to the atmosphere as HCN while the leaf was consumed by the caterpillars.

Five to 15 caterpillars were housed in a sealed feeding chamber (8 cm long×2 cm diameter) with a half leaf of *P. virginiana* of known mass (Fig. 1). A tube leading into the chamber carried a humidified air stream to the bottom of the chamber, and another tube at the top carried the air to a second, capture chamber. Air entering the capture chamber was directed to the bottom of the chamber and bubbled through 10 ml of 1 M NaOH. Glass beads were used to cause the rising bubbles to take a circuitous route through the NaOH, thus increasing the capture success. Air exited the chamber though an opening at the top. The air flow rate was adjusted to 2–3 ml/min. Caterpillars were allowed to consume the leaf for 24 h, after which the NaOH was retrieved and analyzed as described above. We determined the mass of leaf tissue that was left at the end of the feeding period to obtain a measure of the amount consumed by the caterpillars over the course of the study.

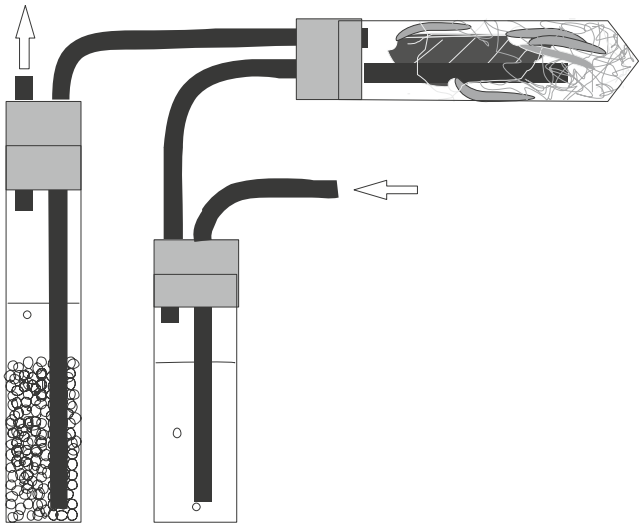

Fig. 1 Apparatus used to collect cyanide escaping into the atmosphere as *Archips* caterpillars feed

Effluent from the other half of the leaf was collected simultaneously with an identical apparatus except that the feeding chamber was used as an extraction chamber immersed in a water bath at 35°C. The purpose of this was to determine the total HCN-p of the leaf. In preparation, the leaf section was placed onto the bottom of the extraction chamber, and the chamber was immersed in liquid nitrogen. The frozen leaf was then ground to a powder. Approximately 1 ml phosphate buffer was added, and the chamber was sealed immediately. An air stream adjusted to the same rate as that used in the chamber housing the caterpillars was then passed through the chamber housing the leaf and then into the capture chamber for 24 h.

pH of Leaf and Foregut Regurgitant The pH of approximately 1 g of leaves of *P. virginiana* macerated in 100 ml of DI water was measured. The pH of leaves from four different trees was determined. We measured the pH of the foregut regurgitant of 13 *Archips* caterpillars that were allowed to feed ad libitum. For comparative purposes, we also measured the pH of the regurgitant of fourth–sixth instar eastern tent caterpillars (N=10), *Malacosoma americanum*, deprived of food for 8 h. Measurements were started immediately after they had fed on the leaves of *P. serotina*. The pH was measured with a 100-μm-diameter Beetrode® NMPH1 pH electrode and a 450-μm-diameter Dri-Ref ® 450 reference electrode. To produce standard pH

readings on an Acumet AR10 pH meter, a Bee-Cal® compensator was used. All electrode components were manufactured by World Precision Instruments, Sarasota, FL, USA. The meter was calibrated prior to each measurement with Hydrion® buffer with a pH of 12.0± 0.02 at 25°C. Meter accuracy was monitored with Hydrion pH 7 and 10 buffers. To obtain regurgitant, the opening of a 5-µl micropipette was lightly pushed against a caterpillar's mouthparts causing it to regurgitate. The liquid was drawn into the pipette by capillary action. Approximately 2 µl of the collected regurgitant were then injected into a glass sample tube (2 mm long×1.4 mm I.D.) fixed horizontally to the top of a 30-mm-long glass tube of the same diameter forming an upright 'T'. To determine the pH of the regurgitant, the pH electrode was inserted into one end of the sample tube and the reference electrode into the other. Measurements were made under the low power of a dissecting microscope to facilitate the placement of the electrodes.

Rate of Ingestion To obtain a comparative index of the rate of food intake, we weighed 4th instars (N=10, each of *Archips* and *M. americanum*) that had been deprived of food for 24 h, then were exposed to a host leaf and allowed to feed ad libitum (initial mass of *M. americanum*=44.4± 2.0 mg, of *Archips*=68.3±4.4 mg). The duration of the feeding bout was determined by direct observation. The mass gained by each caterpillar was determined immediately after it finished feeding. In addition, four *Archips* caterpillars were individually housed with a host leaf and video-recorded continuously for a total of 56 h to obtain a record of the frequency and duration of feeding bouts of individuals over extended periods. Caterpillars were maintained under a 14:10-L:D photoperiod regime. Red light was used during the scotophase to illuminate the foraging arena.

Effect of pH on Cyanogenesis We determined the effect of the pH of the buffer used to incubate leaf samples of *P. virginiana* on cyanogenesis. The same protocol for preparing leaf samples for cyanide analysis with Warburg flasks as detailed above was used except that the pH of the buffer was varied. Five 3–4 mg samples were cut from adjacent sites on the same leaf, then each sample was ground and incubated in a buffer with a different pH value. The pH ranged from 7–11. Two different leaves were treated in this same manner.

Susceptibility of Caterpillars to Cyanide The tolerance of the caterpillars to cyanide gas was determined by grinding 0.54±0.01 g of young leaves of *P. virginiana* in 2 ml of pH 6.2 buffer and placing the mixture in the bottom section of a gas chamber (Fitzgerald et al. 2002). HCN liberated from the macerated leaf passed into an upper chamber housing the caterpillar. To test the effect of liberated HCN on the caterpillars, an *Archips* caterpillar and, for control, a milkweed bug (*Oncopeltus faciatus*) were placed together in the chamber and observed for 1 hr; the point of immobility was noted (N=5 replicates of this study). The milkweed bug was used for control, since a previous study showed that this species is highly sensitive to HCN (Fitzgerald et al. 2002). In a second study, five caterpillars were housed together in the gas chamber and observed for 24 hr.

Statistical Analysis T-tests and Mann–Whitney rank sum tests, as detailed below, were carried out with ProStat and SigmaStat statistical software. All error values are standard errors.

Results

Cyanide Content of Leaf, Frass, and Regurgitant Samples Young leaves of *P. virginiana* had 2,473±130 (1,411–3,446) ppm cyanide (N=16). Aged leaves had 1,058±98 (360–1513) ppm cyanide (N=15). The difference between the HCN-p of young and aged leaves was highly significant (T-test, t=8.20, $P\leq0.001$). The frass collected from 11 caterpillars allowed to feed ad libitum on variously aged leaves contained no detectable cyanide. The frass collected from five caterpillars fed young leaves and five fed aged contained no detectable cyanide. The frass of four caterpillars fed young leaves and incubated in exogenous β-glycosidase contained no cyanide. Frass collected from the surface of pupal cells in the shelter's pupation core from colonies fed either young leaves or aged leaves contained no detectable cyanide.

Regurgitant collected from caterpillars housed with young leaves in six of the eight containers had 74.5± 28.2 ppm cyanide (2–153). Caterpillars from the other two containers produced no regurgitant. Regurgitant samples were obtained from all groups of caterpillars housed with aged leaves. Of these, six contained 2.7±1.2 ppm (1–4), and the remainder had no detectable cyanide. The difference between the cyanide content of the regurgitant of caterpillars fed young and aged leaves was significant (Mann–Whitney rank sum test, P=0.015). Six of 25 regurgitant samples collected from 12 field colonies contained cyanide (17.6±6.5), the remaining samples had no detectable cyanide.

Cyanide Content of Whole Caterpillars Seven of the 13 whole caterpillars incubated without exogenous β-glycosidase had trace quantities of cyanide (3.9±0.9 ppm). The

remaining caterpillars including the five incubated with exogenous β-glycosidase had no detectable cyanide or less that 1 ppm.

Cyanide Loss to Atmosphere Only small quantities of cyanide were recovered from air passed over caterpillars maintained in feeding chambers. The amount of cyanide collected averaged 2.6±0.33% (N=7) of the total amount in the leaf as measured by this same technique.

pH of Leaf and Foregut Regurgitant The pH of the four leaf samples of *P. virginiana* was 6.1±0.0. The mean pH of the regurgitant of 13 *Archips* caterpillars feeding ad libitum was 11.6±0.2. The pH of the ten starved caterpillars of *M. americanum* was 10.0±0.2, while the pH of the regurgitant immediately after the caterpillars had fed was 7.0±0.1. The difference between these values for *M. americanum* was significant (T-test, t=−15.9, P<.001). The difference between the regurgitant pH of *Archips* and unfed *M. americanum* was also significant (Mann–Whitney Rank Sum Test, P<0.001).

Rate of Ingestion Archips caterpillars had brief feeding bouts and took in little food compared to *M. americanum*. The ratio of mass gain to initial mass following a bout of feeding in previously starved *Archips* caterpillars was 0.02± 0.00 while that of the tent caterpillars was 0.37±0.04. The difference between mass gain in the two species was highly significant (Mann–Whitney rank sum test, P<0.001). The duration of the feeding bout was 5.7±0.63 min in *Archips* and 27.4±2.2 min in *M. americanum*. The difference between time spent feeding for the two species was highly significant (Mann–Whitney rank sum test, P<0.001). Four *Archips* caterpillars observed for a total of 56 h fed for intervals of 4.1±0.4 min (n=58 feeding bouts) at the rate of 1.8±0.7 bouts/h. Intervals of feeding punctuated near continuous bouts of silk spinning. Inspection of the foreguts of the two species opened by dissection after a meal, showed that the foregut of the tent caterpillars was fully packed with food and emitted a strong odor of benzaldehyde. The foregut content of *Archips* caterpillar was watery and loosely packed with food particles; no odor of benzaldehyde was evident. Previous studies of *M. americanum* showed that the caterpillars feed at intervals of 6–8 h.

Effect of pH on Cyanogenesis Cyanide production decreased precipitously when leaves were ground and incubated in buffers with pH>9. Leaf samples incubated in buffer with pH 11 yielded no cyanide (Fig. 2).

Susceptibility of Caterpillars to Cyanide All of the milkweed bugs (N=5) tested for control succumbed with complete immobility occurring after 136±6 s. All of the

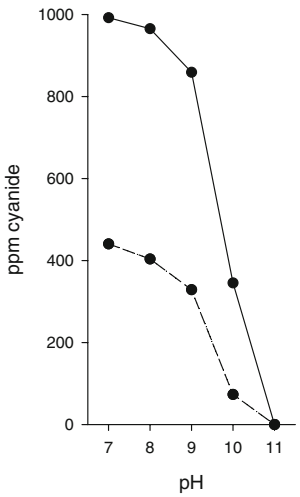

Fig. 2 The relationship between buffer pH and the release of cyanide from samples of two leaves of *Prunus virginiana*

Archips caterpillars (N=5) survived the 1-h exposure time without apparent effects of HCN. All of five caterpillars housed in the chamber were alive after 24 h. That the chamber contained HCN during the 24-h experiment period was verified by placing a milkweed bug in the chamber with the caterpillars after the 24 h interval and noting that it rapidly succumbed to the fumes. All five of the caterpillars were then placed on food. They continued to feed and grew normally when observed over a 3-day period.

Discussion

Our study shows that the caterpillars of *A. cerasivoranus* feed on leaves with moderate to high HCN-p. A small quantity of cyanide escapes into the atmosphere as the caterpillars feed, but most of a leaf's potential cyanide is ingested by the caterpillar. Nonetheless, our investigation indicates that aposematic coloration is probably not attributable to sequestration of cyanide. The first line of defense of *Archips* caterpillars is regurgitation, but the regurgitant of the caterpillars sampled in this study typically contained little or no cyanide. Only when caterpillars were fed exclusively in the lab on a tree's youngest leaves with the highest HCN-p, their regurgitant contained more than a trace amount of cyanide. The regurgitant of laboratory-reared caterpillars fed with aged leaves that make up the bulk of the insect's diet under field conditions contained only trace amounts or no detectable cyanide. The regurgitant of caterpillars feeding ad libitum in the field also contained only trace amounts of cyanide.

Assays of whole caterpillars showed that the toxin is not stored in appreciable quantities in any other of body compartments than the foregut (regurgitant). Although the pupae might gain protection by encasing themselves in

cyanide-containing frass, no cyanide occurs in the fecal pellets that surround their cocoons nor was any cyanide detected in the frass the caterpillars expel as they feed within the leaf shelter.

The results of this study contrast with those of a study of the tent caterpillar *M. americanum*. Peterson et al. (1987) determined that the regurgitant of *M. americanum* caterpillars fed with leaves of *P. serotina* having cyanide levels comparable to those ingested by caterpillars in our study contained approximately 400 ppm cyanide. The regurgitated droplets were shown to repel predacious ants but the deterrent effect was due to benzaldehyde rather then HCN. While we did not measure the concentration of benzaldehyde in the regurgitant of *Archips*, the release of benzaldehyde is stoichiometric with that of HCN. Since few of the caterpillars in our samples had HCN in their regurgitant, neither of these two products of cyanogenesis can be considered essential for any noxious effects the regurgitant may have in this species.

Our study shows that cyanogenesis in *P. virginiana* is largely inhibited at the upper pH range that characterizes the foregut fluids of *Archips* feeding ad libitum. The fluids of the empty foregut of *M. americanum* are also alkaline but the caterpillars take large meals (Snodgrass 1961), packing their guts with sufficient leaf material to lower gut pH to a range that enables cyanogenesis. In contrast to *Malacosoma*, *Archips* caterpillars feed for comparatively brief periods and ingest little food during a bout of feeding so that the pH of the meal has little influence on the pH of the foregut fluids. The foregut of *Archips* is relatively long, constituting 31% of the total gut length compared to 21% for *M. americanum*. It is the fourth longest foregut among 33 species of phytophagous caterpillars (Grant 2006). The more capacious foregut of *Archips* coupled with the small amounts of food the caterpillars process during bouts of feeding may facilitate the maintenance of high gut pH in the presence of food. Inspection of the foreguts of the two species opened by dissection after a meal, showed that the foregut of the tent caterpillar is fully distended with food and emits a strong odor of benzaldehyde. Analysis of the foregut boluses of recently fed tent caterpillars shows they contain a mean of over 600 ppm cyanide (Fitzgerald et al. 2002) consistent with the neutral pH of the regurgitant of recently fed tent caterpillars we measured in the present study. The foregut of recently fed *Archips* caterpillars is watery, loosely packed with food particles. It does not emit odor of benzaldehyde and contains little or no cyanide. The occurrence of some cyanide in the regurgitant of *Archips* caterpillars fed the most cyanogenic leaves of the host plant shows that the process of cyanogenesis in not entirely prevented by the maintenance of high gut pH. Moreover, the lack of susceptibility of the caterpillars to cyanide poisoning shows that they are adapted to deal with cyanide. This is not surprising since the insect is a *Prunus* specialist. The extent to which prunasin molecules that enter the foregut are not cleaved by β-glycosidase in the alkaline environment is unknown. However, the lack of any cyanogenic potential in the frass, even when incubated with exogenous β-glycosidase, indicates that an intact cyanogenic compound does not survive gut transit.

Fall webworms (*Hyphantria cunea*) feeding upon black cherry, *P. serotina*, employ a mechanism similar to that of *Archips* to inhibit cyanogenesis (Fitzgerald 2008). Webworms have a low rate of ingestion and capacious foregut enabling them to maintain a foregut pH of approximately 12 in the presence of the bolus. The relationship between buffer pH and cyanogenesis in *P. serotina* is the same as that for *P. virginiana*. However, webworms exposed to the fumes of macerated *P. serotina* leaves in gas chambers collapsed after 10 min exposure, and none recovered. The webworm also differs from *Archips* in that a significant percentage of the cyanogen survives gut transit. Pellets of webworms processed in the same manner as those in the present study contained a mean of approximately 2,900 ppm cyanide.

In contrast to both *Archips* and *Hyphantria*, the caterpillars of *M. americanum* do not inhibit cyanogenesis (Fitzgerald et al. 2002). It is not known how tent caterpillars detoxify cyanide, but the activity of L-3-cyanoalanine synthase at the mitochondrial level, as described for other species, may be involved (Witthohn and Naumann 1987; Meyers and Ahmad 1991). The enzyme catalyzes the reaction of HCN and cysteine to produce 3-cyanoalanine and H_2S, thus, rendering the cyanide ion innocuous. Tent caterpillars feed preferentially on a tree's most cyanogenic leaves, and while Peterson et al. (1987) suggested that this may enhance the deterrency value of the regurgitant, preference for these leaves may maximize the harvest of nitrogen from the plant's cyanogens. Compared to this detoxification mechanism and others previously described (Conn 1979; Engler et al. 2000) for other caterpillars, the inhibition of cyanogenesis by the maintenance of high foregut pH in the presence of food and paced feeding is a relatively simple means of dealing with a cyanogen.

compounds be replaced by more environmentally friendly protection methods. One promising strategy is the application of plant-derived protective antifeedant compounds onto plants (Klepzig and Schlyter 1999; Bratt et al. 2001; Sibul et al. 2001; Thacker et al. 2003; Schlyter 2004).

The adult pine weevil accepts numerous non-host species for feeding but prefers Scots pine (*Pinus sylvestris* L.) over most woody species of the Scandinavian flora (Manlove et al. 1997; Månsson and Schlyter 2004). However, there are at least 11 woody species upon which the weevil will avoid feeding even in no-choice tests (Månsson and Schlyter 2004). These are alder (*Alnus glutinosa* (L.) Gaertner), aspen (*Populus tremula* L.), beech (*Fagus sylvatica* L.), guelder rose (*Viburnum opulus* L.), holly (*Ilex aquifolium* L.), horse chestnut (*Aesculus hippocastanum* L.), linden (*Tilia cordata* Mill.), lilac (*Syringa vulgaris* L.), spindle tree (*Evonymus europaeus* L.), walnut (*Juglans regia* L.), and yew (*Taxus baccata* L.). Our general hypothesis is that the avoidance of weevils feeding on these species is caused by antifeedants present in the bark. Thus, we investigated chemical compositions.

The bark of one species, linden (*Tilia cordata*), contains nonanoic acid, which is a potent antifeedant against the pine weevil (Månsson et al. 2005). Several analogues of nonanoic acid are also active antifeedants (Månsson et al. 2006). While reports of the occurrence of similar carboxylic acids in bark tissue are sparse, several have been found in other tissues from some of the 11 woody species (Nahrstedt et al. 1981; Buttery et al. 2000).

To determine if the bark of the ten species rejected by the weevil, except for *Tilia*, also contains antifeedants against *H. abietis*, their barks were extracted with non-polar and polar solvents, and the extracts were tested for activity. Tests were made with doses corresponding to those occurring naturally in bark. The content of known antifeedants in the extracts was determined by gas chromatography (GC)–mass spectrometry (MS). The major compounds identified in the extracts were tested for activity. Additionally, an antifeedant active methanol extract of horse chestnut was fractionated. Stimulatory and inhibitory compounds in the resulting fractions were identified and bio-assayed.

Methods and Materials

Bark Extraction Branches and shoots (5- to 30-mm diam) from the ten plants, *Viburnum*, *Evonymus*, *Alnus*, *Juglans*, *Fagus*, *Aesculus*, *Taxus*, *Ilex*, *Populus*, and *Syringa*, were collected during the summer in southern Sweden. Only young plant material (second-year shoots and branches) was used. Preparation and extraction of the bark were performed as previously described (Månsson 2005; Månsson et al. 2005). Prior to removal of bark from twigs, the total bark area was measured. Outer and inner bark were cut or scraped off the stem, immersed in liquid nitrogen, and ground in a mortar. Pulverized bark was extracted first in a Soxhlet apparatus (Furniss et al. 1989) with boiling pentane (300 ml). After 2 h, the solvent was changed to methanol (MeOH; 300 ml), and the extraction continued for another 2 h. The resulting extracts (one non-polar pentane and one polar MeOH for each species) were filtered through silica gel (~1 g), which was, in both cases, washed with MeOH (~5 ml) prior to being concentrated in a rotary evaporator.

Bioassays Adult *H. abietis* were collected and stored with a food source (pine twigs) and water in buckets kept in darkness at 8–10°C as described earlier (Klepzig and Schlyter 1999; Schlyter et al. 2004a). Before starting an assay, buckets were moved into a growth chamber in which the parameters were set to those found in the field at the time of the weevil collection [24°C, 75% RH, and a photo period of 20:4 h (L/D)]. Twigs were removed 6 days before the start of a micro-feeding assay (24 h before a twig test), and water was removed 1 day before (Schlyter et al. 2004a).

The micro-feeding assay is a choice test that uses two plates, cut from thin-layer cellulose chromatography Al plates (5×5 mm, Merck #1.0552), that were placed in Petri dishes (9-cm diam) and were allowed to run for 4 h. The method is described in detail previously (Schlyter et al. 2004a). Concentrated extracts were diluted with either pentane or methanol. The amount of solvent was determined on the basis of the total bark area extracted. Thus, if the bark area corresponded to, for example, 200 thin-layer chromatography (TLC) plates, each of 25 mm^2, solvent was added until a volume of 200×10 µl (2×5 µl) was reached. Then, 2×5 µl of the diluted extract were applied to the TLC test plate (Månsson et al. 2005). Hence, the dose (amount/area unit) of any compound on the test plate equaled that in the bark, assuming no loss during extraction and a bark thickness equal to the cellulose layer. These assumptions are not met exactly, but the deviations from the two assumptions will be of opposite directions and will partly cancel out.

Synthetic compounds tested (Tables 1, 2, and 3) were applied in 1.5-µl aliquots in a 10% MeOH solution. After solvent evaporation from both the treatment and solvent blank plates, 5 µl of 1 M sucrose in water were added as a feeding stimulant to both (Schlyter et al. 2004a).

Twig no-choice tests were performed on 12-mm long *P. sylvestris* twig sections of approximately equal diameter (6- to 10-mm diam), which were dipped in solutions of the compound to be tested. The method is described in detail (Klepzig and Schlyter 1999; Schlyter et al. 2004a).

The Anti-Feedant Index, AFI, was the variable used to quantify results from the assays (Schlyter et al. 2004a). The

**) Stereoisomeric composition in the extract not determined

area eaten on the control plate (*C*) is related to the area eaten on the test plate (*T*): AFI = (*C* − *T*)/(*C* + *T*). Negative values (<0) indicate a feeding stimulation, while a value of 1.00 corresponds to total feeding inhibition. A value of 0.50 indicates a half effect and 0 no effect. AFI values are presented as their arithmetic means ± SE (standard error of the mean), and activity is considered significant if the 95% confidence interval for the mean (95% CI) does not overlap zero.

The AFI obtained from the dose-response test with 10%, 1%, and 0.1% solutions in the micro-assays provides an ED_{50} value. The ED_{50} is the effective dose (expressed as concentration in percent of the treatment solution) that is needed for achieving a 50% feeding deterrent effect (i.e., the dose required to get an AFI=0.5).

Fractionation of Aesculus Methanol Extract All solvents were distilled prior to use. The MeOH extract from *Aesculus* bark (M1) was fractionated by reverse phase LC by using octadecyl functionalized silica gel (12 g, Sigma-Aldrich Sweden AB) in a flash column (10 mm i.d.). The gradient used was one-column volume (10 ml) of MeOH followed by 10 ml of 50% CH_2Cl_2 in MeOH, 10 ml CH_2Cl_2, 10 ml 50% pentane in CH_2Cl_2, and finally, 20 ml of pentane. In total, 14 fractions, each of ≈4 ml, were collected. The fractions containing similar compounds (as judged by TLC) were pooled. Each of the resulting eight fractions (M1:1–8) were concentrated to 1 ml by flushing a gentle stream of argon over the solution, and they were subsequently tested in the micro-feeding assay.

One fraction (M1:3) had antifeedant activity and was further fractionated on silica gel 60 (6.5 g, Fluka) on a flash column (10 mm i.d.). The elution gradient was 20 ml of CH_2Cl_2 followed by 10 ml of 10% MeOH in CH_2Cl_2, 10 ml 20% MeOH in CH_2Cl_2, 10 ml 50% MeOH in CH_2Cl_2, 10 ml 75% MeOH in CH_2Cl_2, and finally, 50 ml MeOH. In total, 30 fractions, each of ≈4 ml, were collected. By merging fractions of similar chemical content as determined by TLC, the number of fractions was reduced to nine (M1:3:1–9), concentrated, and tested in the micro-feeding assay.

Chemical Analysis Bark extracts were analyzed by GC–MS on a Varian 3800 GC instrument with a CP-sil 5CB low-bleed column (Varian, 30 m×0.25 mm i.d., 0.25 μm film thickness), in series with a Saturn 2000 MS, ion trap detector, EI mode. All compounds in Tables 1 and 2 were identified by comparing their retention times and mass spectra with those of the reference compounds co-injected on the same instrument under the same analytical conditions.

Chemical Compounds (*Z*)-3-Hexenyl hexanoate was purchased from Bedoukian Research, β-sitosterol was purchased from Fluka. Tetradecyl hexanoate was synthesized

from hexanoic acid and tetradecanol; spectral data (^1H, ^{13}C NMR, and MS) were satisfactory. All other chemical compounds in Tables 1, 2, and 3 were purchased from Sigma-Aldrich Sweden AB.

Results

Twenty extracts (one pentane and one methanol of each species) of A*lnus*, *Populus*, *Fagus*, *Ilex*, *Aesculus*, *Viburnum*, *Syringa*, *Evonymus*, *Juglans*, and *Taxus* were tested twice in the micro-assay. In the first run, the highest antifeedant activity was found for the methanol extract of *Aesculus* (*N*=7). Combining the results from both test runs, the methanol extracts of *Populus*, *Ilex*, *Aesculus*, and *Taxus* were all active in inhibiting feeding (AFI 95% CI were all >0, Fig. 1). None of the pentane extracts displayed any antifeedant activity in these species. In contrast, the pentane extracts of *Fagus*, *Viburnum*, *Aesculus*, and *Syringa* significantly stimulated feeding (AFI 95% CI were all <0, Fig. 1).

The content of known antifeedants, such as straight-chained aliphatic carboxylic acids in the range C6–C9 (Månsson et al. 2006), carvone, and carvacrol (Schlyter et al. 2004b) in the 20 extracts was determined by GC–MS (Table 1). Among known active carboxylic acids, the feeding deterrents hexanoic acid (in the pentane extract of *Ilex* and *Alnus*) and nonanoic acid (in the pentane extract of *Ilex*) were detected. The known pine weevil antifeedants carvone and carvacrol were found in the pentane extracts of *Fagus* and *Ilex*, and in the methanol extract of *Aesculus*, respectively (stereoisomeric composition of carvone in the extracts was not determined; however, both enantiomers are active antifeedants, Table 1).

Additionally, major compounds in the extracts were identified, and those available were tested in the micro-assay (Table 2). The antifeedant active methanol extracts of *Aesculus*, *Taxus*, and *Populus* contained one or more of the deterrent, aromatic compounds carvacrol, eugenol, or benzyl alcohol (Tables 1 and 2). To our knowledge, the latter, together with 2-phenylethanol that was found in the pentane extracts of *Ilex* and *Populus*, have not been reported previously as feeding deterrents for the pine weevil. Two aldehydes, 2-furaldehyde (furfural) and 5-(hydroxymethyl)-2-furaldehyde (5-hydroxymethylfurfural), were found in some extracts with antifeedant activity. While no activity was found for 2-furaldehyde, 5-(hydroxymethyl)-2-furaldehyde stimulated feeding (AFI significantly <0). Another feeding stimulant, β-sitosterol, was detected in the majority of the extracts (Table 2). Hexadecanoic acid, which was identified in almost all extracts (both pentane and methanol), did not exhibit any antifeedant activity (Table 2). Two other long-chain carboxylic acids, linoleic acid that was found in several pentane and methanol extracts and linolenic acid present in the pentane extract of *Populus*, seemed to

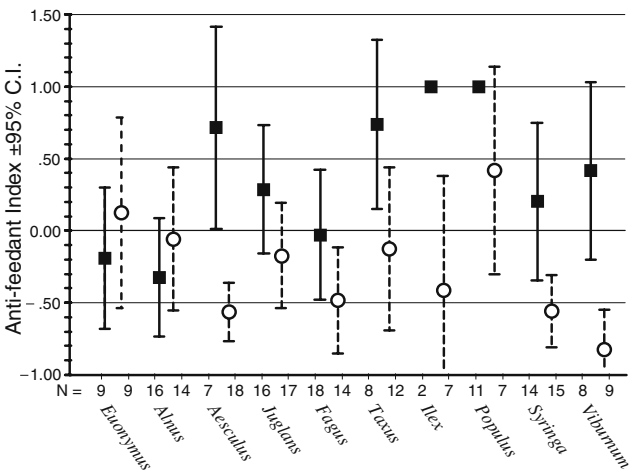

Fig. 1 Antifeedant index (*AFI*) of pentane (*lines with open circles*) and methanol (*lines with filled squares*) extracts in micro-feeding assay choice test of ten woody non-hosts. Plants extracted included spindle tree (*Evonymus europaeus*), alder (*Alnus glutinosa*), horse chestnut (*Aesculus hippocastanum*), walnut (*Juglans regia*), beech (*Fagus sylvatica*), yew (*Taxus baccata*), holly (*Ilex aquifolium*), aspen (*Populus tremula*), lilac (*Syringa vulgaris*), and guelder rose (*Viburnum opulus*). *N* on the *x*-axis is the number of data points (individual beetles in Petri dishes) where an AFI could be calculated, i.e., when feeding occurred on at least one of the paired plates in the dish. AFI relates the area eaten on the control plate (*C*) to that on the test plate (*T*): $AFI = (C - T)/(C + T)$ and ranges from −1 to +1

stimulate feeding but not significantly so (both AFI <0). Five common plant constituents, limonene, vanillin, benzoic acid, cinnamic acid, and benzaldehyde, were identified in some extracts but showed no effect on the weevil (AFI ~0, Table 2).

Since *Aesculus* was the only species that yielded both inhibitory (methanol) and stimulatory (pentane) extracts and was active in the first micro-feeding test, the active methanol extract (M1) was chosen for fractionation. Reverse-phase liquid chromatography resulted in eight fractions, of which several (M1:4 to M1:8) were phagostimulatory. Only fraction M1:3 displayed significant antifeedant activity (Fig. 2). However, when the eight fractions were combined, the activity was lost (M1 sum, Fig. 2). Fractions M1:2 (slightly antifeedant) and M1:3 (active antifeedant) contained similar patterns of compounds with one exception; fraction M1:2 contained a large amount of the feeding stimulant 5-(hydroxymethyl)-2-furaldehyde, while M1:3 did not.

A second chromathographic separation of the antifeedant active fraction M1:3 on straight phase silica gel resulted in nine fractions of which the last (M1:3:9) exhibited the highest activity (Fig. 3). In contrast, several fractions had AFI<0, and fraction M1:3:5 strongly (AFI<<0) and significantly stimulated weevil feeding on treated plates (Fig. 3). Two compounds were common in fractions M1:3:8 and M1:3:9, and their mass spectra showed they were aliphatic esters of hexanoic acid. The mass spectra and retention times of these compounds were compared with

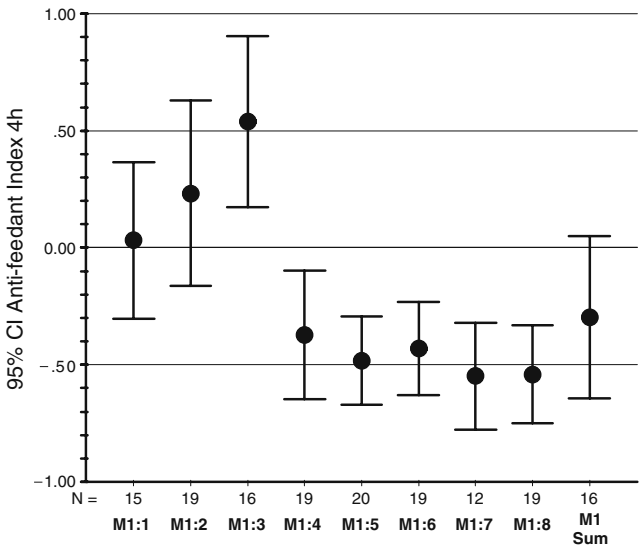

Fig. 2 Feeding activity of fractions of the first *Aesculus* methanol extract in micro-feeding assay no-choice tests. *N* on the *x*-axis is the number of data points (individual beetles in Petri dishes) where an AFI could be calculated, i.e., when feeding occurred on at least one of the paired plates in the dish. *M1:sum* joined extract from pooling all fractions

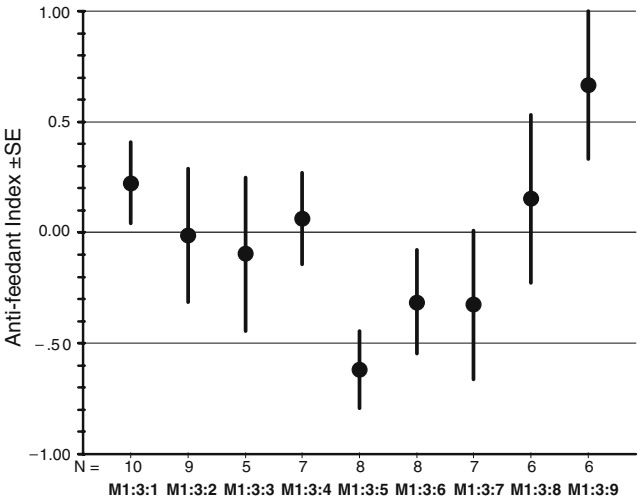

Fig. 3 Feeding activity of the sub-fractions of fraction M1:3 from the first *Aesculus* methanol extract in micro-feeding assay no-choice tests. *N* on the *x*-axis is the number of data points (individual beetles in Petri dishes) where an AFI could be calculated, i.e., when feeding occurred on at least one of the paired plates in the dish

those of reference samples of some esters of that type (tetradecyl-, tridecyl-, dodecyl-, and hexyl hexanoate), but neither the mass spectra nor the retention times were identical with any of the reference esters. Interestingly, when six available esters of this type were tested in the micro-feeding assay, five out of six were active antifeedants with AFIs>0.80 (Table 3). The most active was (*Z*)-3-hexenyl hexanoate, followed by hexyl hexanoate, 2-methylbutyl hexanoate, 3-methylbutyl hexanoate, and *iso*-butyl hexanoate. The heavier tetradecyl hexanoate was not active.

The mass spectra of other major components in the slightly antifeedant active fraction M1:3:8 indicated they were branched aliphatic alcohols. Three alcohols of that type were available, namely 2-butyl-1-octanol, 2-ethyl-1-hexanol, and 2-hexyl-1-decanol, but their retention times were not identical with those in the extracts. In the micro-feeding assay at a 10% dose, they displayed varying antifeedant activities (Table 3): high activity for 2-butyl-1-octanol and 2-ethyl-1-hexanol but low activity for 2-hexyl-1-decanol. The ED_{50} for 2-butyl-1-octanol in the choice micro-assay was as low as 0.8% (±0.6 *N*=2), indicating high activity. When tested on twigs, less activity than in the micro-feeding assay was obtained for 2-butyl-1-octanol and 2-ethyl-1-hexanol, while 2-hexyl-1-decanol showed the same low activity as in the micro-feeding assay.

Discussion

Eleven new active compounds were found during this study. Two of these, β-sitosterol and 5-(hydroxymethyl)-2-

furaldehyde (5-hydroxymethyl furfural), are the first reported feeding stimulants from non-host plants of the pine weevil. Another two, benzyl alcohol and 2-phenylethanol, were new antifeedants that were identified in several non-host plants. Aliphatic esters of hexanoic acid and branched aliphatic alcohols were tentatively identified in active extracts. Nine compounds belonging to either of these classes of compounds were tested, and seven were antifeedants.

Apart from the 11 new active compounds and the four known antifeedants identified in non-host plants (Table 1), the contrasting activity of polar and nonpolar extracts is a striking finding. Activities of extracts are related to the polarity of the solvent used for extraction (Fig. 1). Thus, only four out of ten plant barks furnished active inhibitory extracts (*Populus*, *Ilex*, *Aesculus*, and *Taxus*), and all of these were methanol extracts. In contrast, the pentane extracts of *Fagus*, *Viburnum*, *Aesculus*, and *Syringa* were strongly feeding stimulatory. Only the bark of one species, *Aesculus*, produced extracts that were both stimulatory (pentane) and inhibitory (MeOH).

We previously showed that some aliphatic carboxylic acids (in the range C6–C10) act as antifeedants against the pine weevil (Månsson et al. 2005, 2006). Of these, nonanoic acid was found in a dichloromethane/methanol bark extract of *Tilia* (Månsson 2005; Månsson et al. 2005). In addition, hexanoic, heptanoic, octanoic, and nonanoic acids have been found in *Fagus* wood (Guillén and Ibargoitia 1996). We found only hexanoic acid in the pentane bark extracts of *Ilex* and *Alnus*, and nonanoic acid in the pentane bark extract of *Ilex* (Table 1). Thus, the feeding avoidance of *H. abietis* on the ten woody species investigated in this work is not fully explained by the presence of these carboxylic acids, as it was for linden (Månsson et al. 2005, 2006).

Fractionation of the *Aesculus* methanol extracts led to the discovery of two new groups of pine weevil antifeedants, i.e., esters of hexanoic acid and branched alcohols. Additionally, the aromatic compounds benzyl alcohol and 2-phenylethanol were identified as new antifeedants. Eugenol had earlier been found in a polar extract of the feces of *H. abietis* females. Similar to our results, the compound exhibited antifeedant activity against the weevil when tested in a feeding bioassay (Borg-Karlson et al. 2006). In accordance with the decreased antifeedant activity found for carboxylic acids with chains longer than C10 (Månsson et al. 2006), no antifeedant activity was found for hexadecanoic-, linoleic-, or linolenic acids that were present in almost all extracts (Table 1).

The heteroaromatic aldehyde 5-(hydroxymethyl)-2-furaldehyde showed feeding stimulating properties. Previously, 5-(hydroxymethyl)-2-furaldehyde was reported as a constituent of the essential oil and head space extract of *Aesculus* flowers (Buchbauer et al. 1994). However, both 5-(hydroxymethyl)-2-furaldehyde and 2-furaldehyde, which was also found in some extracts, could be artifacts formed by carbohydrate dehydration (Kallury et al. 1986; Antal Jr. et al. 1990), either during the extraction procedure or in the injector of the GC.

In contrast to the high feeding-deterrent activity found for some methoxy-substituted benzaldehyde derivatives (Eriksson 2006), benzaldehyde itself showed no antifeedant activity. However, the inactivity of cinnamic acid and benzoic acid was not surprising since earlier studies have shown that methoxy-substituted benzoic- and cinnamic-acid derivatives are less active antifeedants than the corresponding aldehydes (Eriksson 2006) or methyl esters (Unelius et al. 2006).

All extracted species, except holly, contained β-sitosterol, which strongly stimulated feeding of *H. abietis*. This compound has been identified as a feeding stimulant for the obscure root weevil, *Sciopithes obscurus* Horn (Doss et al. 1982), an effect that was synergistically enhanced by adding sucrose (Shanks and Doss 1987). In our tests of β-sitosterol, sucrose was always added to the test plate.

Most extracts contained a complex mixture of antifeedant and feeding stimulatory compounds. Whether the final outcome of an extract was a feeding deterrent or a stimulatory effect was dependent on the mixture of compounds therein and on their concentrations. The feeding stimulant β-sitosterol, occurring in almost all extracts, was a minor constituent in the antifeedant active extracts, whereas in the feeding stimulatory and inactive extracts, it was a major constituent. Hence, the deterrent activity of the extracts appears to be partially dependent on the efficiency by which β-sitosterol is removed during the non-polar pentane extraction. The concentration dependence was exemplified by the fact that when the eight fractions of the active methanol extract of *Aesculus* were combined, deterrent activity was lost. Probably, this can be ascribed to the fact that the concentrations of the specific deterrents became too low relative to that of β-sitosterol.

Even after extensive fractionation of extracts, the difficulty of identifying antifeedants in the presence of feeding stimulating compounds remains. After fractionation of the first methanol extract of *Aesculus*, fractions M1:2 and M1:3 were found to have a similar composition. However, only fraction M1:3 (Fig. 2) showed feeding deterrent activity. This is possibly due to the absence of the feeding stimulant, 5-(hydroxymethyl)-2-furaldehyde, which was detected only in the less active fraction 2 (M1:2, Fig. 2).

In conclusion, eleven new active compounds were found in this study. Two of these, β-sitosterol and 5-(hydroxymethyl)-2-furaldehyde, are the first reported feeding stimulants for the pine weevil, while another two compounds, benzyl alcohol and 2-phenylethanol, were

found to be new antifeedants identified from several non-hosts of the weevil. Seven compounds belonging to either of the two classes of aliphatic esters of hexanoic acid or branched aliphatic alcohols were found to be active antifeedants. In addition, four earlier known antifeedant compounds were identified from four non-host plants. Our work suggests that further active compounds in the bark of these woody species remain to be identified.

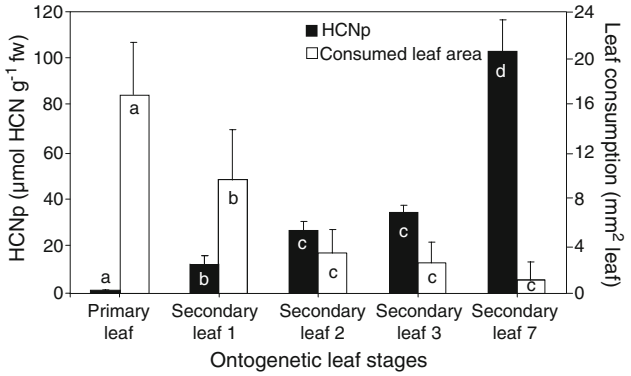

Fig. 1 Cyanogenic potential (*HCNp*) of different *P. lunatus* leaf developmental stages and preferences of herbivorous beetles. In choice experiments presenting all leaf stages simultaneously, attractiveness of leaf material to Mexican bean beetles was quantified. Values shown are means±standard deviation. Letters in/at the columns indicate significant differences in HCNp [according to LSD *post hoc* analysis ($P<0.01$) after one-way ANOVA]

(Mattson 1980). In addition, we measured the feeding rates of a natural herbivore, the Mexican bean beetle (Coccinellidae: *Epilachna varivestis* Mulsant) on these different leaf stages. This combined analysis of a defensive and a nutritive plant feature contributes to understanding the intra-individual variation of plant defensive traits in the interaction with herbivores.

Materials and Methods

Plants Lima bean plants (Fabaceae: *P. lunatus* L.) were derived from seed material collected in a natural population in Oaxaca, South Mexico (15°55′ N, 097°09′ W). Plants were cultivated in a climatic chamber adjusted to mimic conditions as recorded for the natural site in August–October 2007 (13:11 h light to dark ratio; 30:23°C; 60–70% air humidity and a photon flux density of 450–500 µmol s^{-1} m^{-1} at table height). Plants were cultivated in standard substrate (TKS®-1-Instant, Floragard, Oldenburg, Germany) mixed 1:3 with sand (grain size of 0.3–0.7 mm). Plant containers were 80 mm in diameter. We fertilized plants twice a week with an aqueous solution (0.5%) of a NPK-fertilizer (Flory-3®, EUFLOR GmbH, Munich, Germany). Plants were used for experiments when they had developed 9 to 10 leaves (6 weeks after germination; $N=8$ plants). In addition to primary leaves, we selected four secondary leaf stages for analyses. We defined the ontogenetically oldest secondary leaf as 'secondary leaf 1', while 'secondary leaf 7' was the youngest one, inserting seven positions above the primary leaves.

Cyanogenic Potential HCNp was quantified by complete enzymatic degradation of cyanogenic precursors by using specific β-glucosidase isolated from cyanogenic *Hevea brasiliensis*. Concentration of released cyanide was quantified spectrophotometrically (at 585 nm) by using the Spectroquant®Cyanide kit (Merck KGaA, Darmstadt, Germany) according to Ballhorn et al. (2007).

Protein Concentration We quantified soluble protein contents in leaves according to Bradford (1976). Polyvinylpolypyrrolidone (Sigma-Aldrich, Buchs, Switzerland) was added to leaf extracts to avoid potential interference of plant phenolics with protein.

Electron Transport Rate Photosynthetic activity of leaves was measured *in situ* in the climatic chamber. For nondestructive measurements, a chlorophyll fluorometer (Junior PAM, Walz GmbH, Effeltrich, Germany) was used. After 10 min of shading, leaf spots were illuminated with blue light at 400 µmol photons m^{-2} s^{-1} for 7 min and steady state photosynthesis was quantified as electron transport rate (ETR) values (µmol electrons m^{-2} s^{-1}).

Feeding Trials The feeding rates of adult Mexican bean beetles on leaves of different ontogenetic stages were analyzed in Petri dishes (9.5 cm) lined with moist filter paper. Beetles were starved for 4 h before leaf discs (16 mm in diameter; representing each one of the five leaf

Table 1 Photosynthetic activity and soluble protein concentration in different ontogenetic leaf stages of *P. lunatus*

Physiological characteristics of leaves used in feeding trials	Leaf developmental stages				
	Primary leaf	Secondary leaf 1	Secondary leaf 2	Secondary leaf 3	Secondary leaf 7
ETR [µmol electrons m^{-2} s^{-1}]	98.9±3.5a	101.4±2.0a	99.2±2.7a	96.6±2.6a	92.4±3.5a

Values shown for electron transport rate and soluble protein concentration of different ontogenetic leaf stages are means±standard deviation ($N=8$ plants). Letters indicate significant differences among leaf stages according to *post hoc* analysis (LSD; $P<0.01$) after one-way ANOVA
ETR Electron transport rate

developmental stages) were offered to individual animals for 2 h. Position of leaf discs was set at random. After the experiment, leaf discs were scanned and the missing leaf area was quantified with Analysis® software (Olympus, Hamburg, Germany).

Statistical Analysis We used SPSS 16.0 (SPSS for Windows, SPSS, Chicago, IL, USA) for all statistical analyses.

Results

Cyanogenic Potential HCNp in primary leaves was significantly lower than in secondary leaves [according to least significant difference (LSD) *post hoc* analysis ($P<0.01$) after univariate analysis of variance (ANOVA); Fig. 1]. Among secondary leaves, the youngest leaves showed highest HCNp values (Fig. 1).

Protein Concentration The youngest secondary leaves contained significantly more soluble proteins than the primary leaves (one-way ANOVA with 'ontogenetic stage' as factor: $F_{4,35}=5.70$, $P<0.01$), whereas protein concentrations in older secondary leaves and primary leaves were not significantly different (Table 1).

Electron Transport Rate Chlorophyll fluorescence measurements revealed that plants showed high ETR in all leaf developmental stages analyzed. The ETR values were not significantly different among all leaf stages (Table 1).

Feeding Trials Beetles significantly preferred primary over secondary leaves (Fig. 1). Young secondary leaves were less consumed by beetles than relatively older secondary leaves. Among all leaf stages, consumed leaf area and HCNp in leaves were significantly negatively correlated (according to two-tailed Pearson correlation: $r=-0.638$, $P<0.001$).

Discussion

Primary leaves of wild-type lima bean plants were long living and showed high photosynthetic activity for a period of time that exceeded early seedling stages (>6 weeks after germination). In addition, protein concentrations in primary leaves were similar to those of the three following secondary leaves, indicating that no strong reallocation of resources from primary to the secondary leaves occurred as part of a beginning senescence of primary leaves during the considered time span.

Although presumably being valuable source organs for carbohydrates, primary leaves were poorly defended by cyanogenesis—and, consequently, Mexican bean beetles significantly preferred them over higher cyanogenic secondary leaves. Higher protein concentrations in the youngest secondary leaves ('secondary leaf 7') did not compensate for low attractiveness due to higher HCNp (Fig. 1; Table 1). In accordance with a previous study, cyanogenesis proved to be highly efficient in deterring the Mexican bean beetle (Ballhorn and Lieberei 2006).

In the present study, we focused on ontogenetic variation of cyanogenesis as a direct defense against herbivores, whereas indirect defense by VOCs was not measured. However, we demonstrated previously that the primary leaves of lima bean are not without defense, as they released high amounts of VOCs, whereas high cyanogenic secondary leaves emitted much lower amounts of VOCs (Ballhorn et al. 2008). Why do different leaf developmental stages express different types of defense? It appears to be a general phenomenon that plants do not rely on a single defense mechanism but rather express multiple defenses (Agrawal and Fishbein 2006). Nevertheless, despite beneficial effects, co-occurrence of defenses might be costly for a plant (Mauricio 1998), since investment in defensive traits is assumed to reduce the resource availability for growth and reproduction (Herms and Mattson 1992). Simultaneous resource allocation to growth and expensive nitrogen-based defenses (such as cyanogenesis) likely is constrained, particularly during the first weeks of plant development. Thus, carbon-based indirect defenses (VOCs) may be a good alternative for these early leaves, particularly when regarding their high photosynthetic capacities that were found in the present study. Although individual leaves of lima bean apparently could not express more than one type of defense at high quantities, plants may defend different leaf stages via different strategies. We suggest that multiple defense syndromes also may emerge at the 'plant level', not only at the level of individual leaves. Future studies should focus on effects of ontogenetic variation in defense mechanisms against herbivores and pathogens.

Acknowledgements We thank Monika Fillippek for excellent assistance in plant cultivation and maintenance of beetles. Financial support by the University of Duisburg Essen and the DFG (grant He 3169/4-2) is gratefully acknowledged.

side chain, are characteristically accumulated as the major secondary metabolite. Together with endogenous myrosinase (β-thioglucoside glucohydrolase, 3.2.1.147) glucosinolates serve a central role in defense against herbivores and pathogens (Wink 1988; Jander et al. 2001; Kliebenstein et al. 2005a, b). Tissue damage brings together myrosinase and glucosinolates, which are otherwise spatially separated (Kelly et al. 1998; Koroleva et al. 2000) yielding a variety of hydrolysis products such as isothiocyanates, epithionitriles, thiocyanates, and nitriles (Bones and Rossiter 1996, 2006; Halkier and Gershenzon 2006).

The final outcome of myrosinase-catalyzed hydrolysis of glucosinolates is determined by the epithiospecifier protein (ESP) and related proteins. The most common products are isothiocyanates, which are formed after myrosinase-catalyzed glucosinolate hydrolysis in the absence of ESP, by a spontaneous 'Lossen' like rearrangement (Bones and Rossiter 2006). By contrast, alkenylglucosinolates are converted to thiiranylalkylnitriles, commonly known as epithionitriles, and nitriles when ESP is present together with ferrous/ferric ions, while non-alkenylglucosinolates and indoleglucosinolates form simple nitriles. While epithionitrile formation is dependent on the presence of both ESP and iron, formation of nitriles may occur in the absence of ESP if iron is present (Zabala et al. 2005). Figure 1 shows the structures of the alkenylglucosinolate-derived isothiocyanates, epithionitriles, and nitriles. Despite this range of hydrolysis products, the toxicity of glucosinolates to pathogens and herbivores can be attributed mainly to the isothiocyanates and compounds derived from them (Halkier and Gershenzon 2006). Indeed, in studies of insect herbivory, *Arabidopsis thaliana* (L.) plants that express ESP and, therefore produce nitriles, were apparently less well defended against two species of generalist insect herbivore compared with plants that produced isothiocyanates (Lambrix et al. 2001; Burow et al. 2006). However, as short chain nitriles are volatile compounds, it has been speculated that they may serve as signals in indirect defense responses (Wittstock and Burow 2007). By contrast, little is known about the function of epithionitriles, as few bioassays have been carried out with epithionitriles derived from glucosinolates. This is, in part, due to their perceived instability, but also because they require either chemical synthesis or preparative isolation.

The braconid wasp, *Diaeretiella rapae* (McIntosh), is a solitary endoparasitoid that characteristically attacks aphids

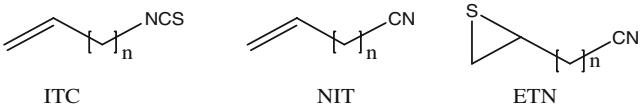

Fig. 1 Diagram showing the possible hydrolysis products from 2-propenyl- or 3-butenylglucosinolate; *ITC* isothiocyanate, *NIT* nitrile, *ETN* epithionitrile

that feed on crucifers, including crucifer specialists *Brevicoryne brassicae* (L.) and *Lipaphis pseudobrassicae* (= *L. erysimi*) (Kaltenbach). In several olfactometry studies, female *D. rapae* discriminated between aphid infested and uninfested crucifers of agricultural importance (Read et al. 1970; Reed et al. 1995; Blande et al. 2007), as well as the model crucifer, *A. thaliana* (Girling et al. 2006). Air entrainments completed by Blande (2004) confirmed that higher levels of isothiocyanates were produced by aphid infested turnip plants compared with uninfested plants. In addition, isothiocyanates also have been indicated as signaling chemicals by a number of olfactometry studies in which female *D. rapae* orient toward pure compounds, which were presented in place of aphid-infested plants (Read et al. 1970; Vaughn et al. 1996; Blande et al. 2007).

A number of studies demonstrated that host finding behavior of some species of aphid parasitoids may be determined by the plant on which the insect develops (Wickremasinghe and van Emden 1992; Storeck et al. 2000). From these studies, it is suggested that conditioning of the parasitoid occurs as it chews its way out of the aphid mummy. Blande et al. (2007) similarly suggest that *D. rapae* acquires chemical cues, probably glucosinolates, as it emerges from the mummy case, although it was proposed that these cues play a role in host recognition rather than host-finding behavior. In an olfactometry study by Bradburne and Mithen (2000), experienced *D. rapae* oriented into the air stream containing the odor from ground plant material of one of two near-isogenic *Brassica oleracea* L. lines, one of which primarily produced 3-isothiocyanatoprop-1-ene (3-PROP-ITC) and the other 4-isothiocyanatobut-1-ene, (4-BUT-ITC) when presented opposite a blank control. However, when the two lines were presented opposite each other, significantly more parasitoids oriented to the air stream containing the odor of the 3-butenylglucosinolate-producing line. This response was recorded regardless of the line on which the insects were reared and, therefore, suggests an innate preference for 4-BUT-ITC over 3-PROP-ITC, although the role of other plant volatiles in this study cannot be excluded.

Given that the chemical functionalities of the epithionitriles, isothiocyanates, and nitriles are different, it might be expected that the electrophysiological and behavioral responses of *D. rapae* would be affected. Thus, we used naïve *D. rapae* females to test their responses to a range of 2-propenyl and 3-butenylglucosinolate hydrolysis products.

Methods and Materials

Insects Two cultures of the crucifer specialist aphid *B. brassicae* (L.) were maintained at 18°C, with a 16/8 hr, L/D photoperiod. Aphids were cultured either on individual

4 wk-old *B. nigra* (L.) plants or similar age *B. rapa* L. var *rapifera* plants, each plant being enclosed within a perforated bread bag. Aphids were transferred to fresh plants to establish new colonies every 1–2 wk.

The aphid parasitoid *D. rapae* (obtained from Rothamsted Research) was maintained at 21°C and 18°C (16:8 hr, L/D). Standardized cohorts were produced by allowing mated 2- to 3-d-old adults to parasitize mixed-age *B. brassicae* in a Petri dish for approximately 2 hr. Parasitized aphids were transferred to a fresh *B. nigra* or *B. rapa* var *rapifera* plant on which they continued to feed. Aphid mummies were removed approximately 8 d later. Adult parasitoids were provided with a dilute honey solution on emergence.

Synthesis of Isothiocyanates and Epithionitriles Hydrolysis products derived from 2-propenylglucosinolate and 3-butenylglucosinolate were prepared for use in this study. For 2-propenylglucosinolate, 3-isothiocyanatoprop-1-ene (3-PROP-ITC) and but-3-enenitrile (3-BUT-NIT) were purchased from Sigma-Aldrich (>95% purity), while 2-(thiiran-2-yl)acetonitrile (2-ACETO-ETN) was synthesized according to the method of Luthy and Benn (1979). For 3-butenylglucosinolate, 4-isothiocyanatobut-1-ene (4-BUT-ITC) was purchased from Sigma-Aldrich (>95% purity), pent-4-enenitrile (4-PENT-NIT) was synthesized from 3-butenylbromide and sodium cyanide, and purified by distillation and 3-(thiiran-2-yl)propanenitrile (3-PROP-ETN) again synthesized according to the method of Luthy and Benn (1979).

Electroantennogram (EAG) Recordings To prepare *D. rapae* females for EAG recordings, insects were anaesthetized with CO_2 before the head was separated from the thorax and the distal portion of the last antennal segment of one antenna removed. Glass electrodes (borosilicate glass capillary, 1.5 mm O.D.×1.17 mm I.D. with filament; Clark Electromedical Instruments®, UK) were filled with 0.1 M KCl. The base of the head was mounted on the reference electrode, while the cut end of the antenna was inserted a short way into the recording electrode. Chlorided-silver wire connected the recording electrode to a probe with an internal amplifier (Syntech®, the Netherlands). Responses were recorded by using a PC fitted with an IDAC interface board (Syntech®, the Netherlands) and running EAG software (Syntech®, the Netherlands).

Test Compounds and Stimulation Each compound tested was dissolved in paraffin liquid (Fisher Scientific, UK, density 0.83–0.86 g/ml) to make a 1% (*v*/*v*) solution. Twenty-five microliters of each solution were applied to a piece (8×60 mm) of filter paper (Whatman®, No. 2 ashless) immediately before each insect preparation was tested. The filter paper was inserted into a glass Pasteur pipette. The same amount of paraffin liquid was used as a blank control. The tip of the glass Pasteur pipette was inserted about 3 mm into a small hole of a glass tube (9 mm diam., 120 mm long) directed at the antennal preparation. An air stimulus controller (model CS-05, Syntech®, the Netherlands) was used for air and odor delivery. A constant flow (1.8 l/min) of charcoal-filtered and humidified air passed over the antenna through the open end of the glass tube, positioned 15 mm from the antenna. During odor stimulation, 60 ml/min of air was applied through the Pasteur pipette into the main air flow for 2 sec, with a 1-min interval between stimulations. In each case, EAG peak amplitude in response to a compound was determined and then normalized against the mean of two responses to (*E*)-2-hexenal (the standard stimulus, purchased from Sigma-Aldrich) presented before and after the test stimulus.

The EAG responses to 2-propenyl- and 3-butenylglucosinolate hydrolysis products were recorded from naïve female *D. rapae*. Eight insect preparations (replicates) were tested against each of the compounds, which were presented in random order. Differences between mean EAG responses to each compound were assessed by Fisher's least significant difference tests (LSDs). Additional analysis of recovery rates of antennal receptors after maximum depolarization was completed for each compound tested by using the method of Baker & Roelofs (1976).

Olfactometry A glass Y-tube olfactometer, of the design previously described by Du et al. (1996), was used to record behavioral responses of female *D. rapae* to pure compounds (glucosinolate hydrolysis products). The olfactometer had 12 mm internal diam, 100 mm stem, and 100 mm arms at 60° angle. Air was pumped through Teflon tubing by a Dymax30 pump (Charles Austen Pumps Ltd., Byfleet, Surrey, UK) through an activated charcoal filter before being regulated by a flowmeter to 800 ml/min. The airflow was split by a brass T-junction (Swagelok, OH, USA), each flow of 400 ml/min then passing into an airtight glass chamber (T. J. Adams—Artistic & Scientific Glassblower, Kidlington, Oxfordshire, UK) into which the volatile source was placed. From the two glass chambers, air flowed through additional Teflon tubing into the arms of the olfactometer via modified glass quick fit sockets. A white cardboard screen was placed around the olfactometer to exclude visual cues, and diffused lighting was provided by a fluorescent strip held 300 mm above and 100 mm in front of the branches of the olfactometer. A single female was introduced into the stem of the olfactometer and then given 5 min to make a choice. During this period, if the parasitoid failed to move more than 50 mm up the stem of the olfactometer, it was excluded from the experiment. Insects were recorded as having selected an odor if they moved more than 50 mm up one of the arms and remained beyond this

point for more than 30 sec. Insects that moved more than 50 mm up the stem but did not select an arm of the olfactometer were recorded as not having selected an odor. After each individual was tested, the position of the odor sources was swapped in order to account for any directional bias by the parasitoids. These criteria are similar to those previously described (Girling et al. 2006; Blande et al. 2007). Between bioassay sets, glassware was washed with acetone and distilled water and then baked overnight at 200°C.

Pure compounds were prepared as 1 mg/ml solutions in diethyl ether. Test solutions were presented in 50-µl aliquots applied to a piece of filter paper (Whatman No. 1), which was changed after every fifth individual. Naïve female parasitoids were used in bioassays. Aphid mummies were removed from plants so that on emergence parasitoids were not provided with cues that might influence behavioral responses. Adult male and female *D. rapae* were kept together, and mating was assumed. Parasitoids were provided with a dilute honey solution, and females were used in the bioassays approximately 72 hr after emergence.

The following olfactometry experiments were completed with *D. rapae* females. In each case, responses of 30 naïve wasps were recorded:

1. Responses of naïve *D. rapae* females to (a) 2-propenylglucosinolate hydrolysis products, and (b) 3-butenylglucosinolate hydrolysis products. Naïve *D. rapae* were reared on *B. brassicae*, which in turn were reared on *B. nigra*.
2. Responses of naïve *D. rapae* females to 3-PROP-ITC and 4-BUT-ITC when parasitoids were reared on *B. brassicae*, which in turn were reared on (a) *B. nigra* or on (b) *B. rapa* var *rapifera*.

Results

EAG Responses EAG responses of *D. rapae* females to 2-propenyl- and 3-butenylglucosinolate hydrolysis products were recorded (Fig. 2). Responses are presented normalized against a standard stimulus, (*E*)-2-hexenal. However, mean absolute responses recorded to isothiocyanates, 3-PROP-ITC and 4-BUT-ITC, were 0.53 and 0.57 mV, respectively.

Diaeretiella rapae females responded significantly to all 3-butenylglucosinolate hydrolysis compounds tested, with normalized EAG responses 3.2, 2.0, and 1.9 times larger than that of the paraffin control for the isothiocyanate, nitrile, and epithionitrile, respectively (Fig. 2). By contrast, when compounds derived from 2-propenylglucosinolate were tested, females responded significantly only to 3-PROP-ITC, with a normalized EAG response 2.7 times larger than that of the paraffin control. Similarly, EAG responses to the 3-butenylglucosinolate derived 4-PENT-NIT and 3-PROP-ETN were significantly larger than responses to the corresponding 2-propenylglucosinolate derived nitrile and epithionitrile. There was no significant

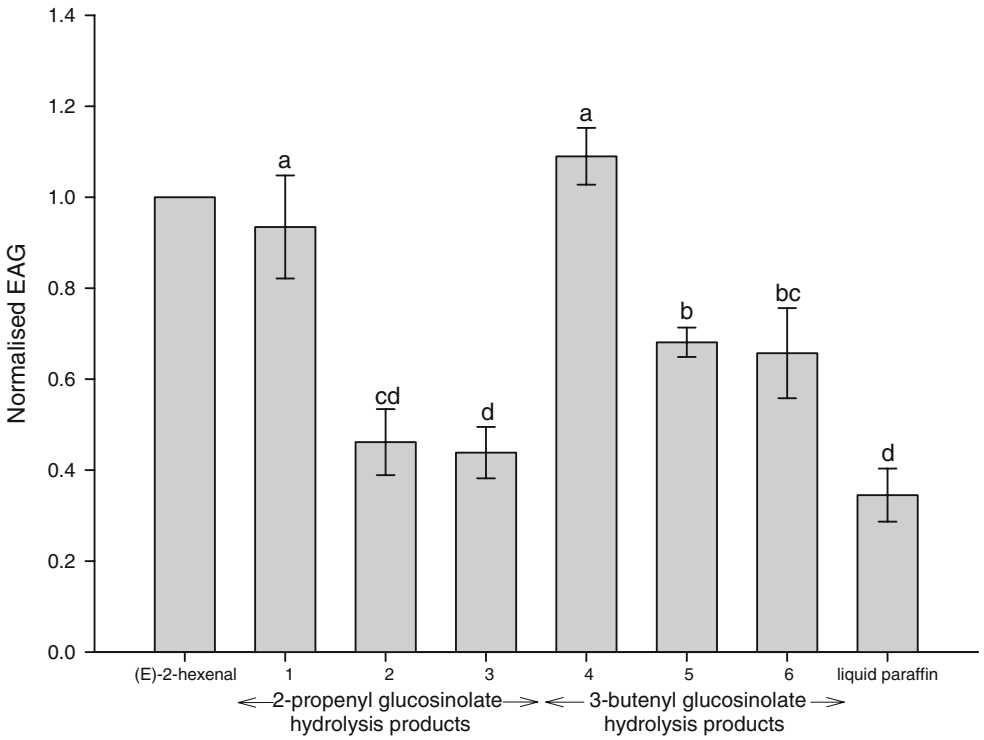

Fig. 2 EAG responses of *Diaeretiella rapae* females to 2-propenyl- and 3-butenylglucosinolate hydrolysis products (mean ± SE, *N*=8). Stimuli: 1 = 3-isothiocyanatoprop-1-ene; 2 = but-3-enenitrile; 3 = 2-(thiiran-2-yl)acetonitrile; 4 = 4-isothiocyanatobut-1-ene; 5 = pent-4-enenitrile; 6 = 3-(thiiran-2-yl)propanenitrile. Different letters indicate significant differences (Fisher's LSD, $P<0.05$)

difference in EAG response size to 4-BUT-ITC and 3-PROP-ITC. Although *D. rapae* responded significantly to all 3-butenylglucosinolate hydrolysis products, the EAG response to 4-BUT-ITC was significantly larger than to the nitrile or to the epithionitrile. EAG response size was, however, similar for 4-PENT-NIT compared with 3-PROP-ETN (Fig. 2).

Receptor recovery rates were affected by the compound with which they were stimulated (F=2.64, P=0.02). Individual contrasts revealed that the recovery rate following stimulation by (*E*)-2-hexenal (x=0.27 ± 0.06) was faster, between 1.7 and 2.9 times, than recovery rates following stimulation by the other compounds tested. Recovery rates following stimulation by the glucosinolate hydrolysis products were similar.

Olfactometry Naïve *D. rapae* females reared on *B. brassicae* in turn feeding on *B. nigra* were presented with 3-butenylglucosinolate hydrolysis products. When each compound was presented opposite a solvent control (diethyl ether), more parasitoids oriented toward 4-BUT-ITC (χ^2= 4.17, P<0.05), but the insects did not respond to either the corresponding nitrile or epithionitrile (Fig. 3a). In comparisons between these compounds, more females selected the arm containing 4-BUT-ITC than either the nitrile or epithionitrile. However, in both cases differences were not significant. The comparison between the 3-butenylglucosinolate derived 4-PENT-NIT and 3-PROP-ETN was also not significant. A second experiment was completed in which similarly reared naïve *D. rapae* females were presented with a range of 2-propenylglucosinolate hydrolysis products.

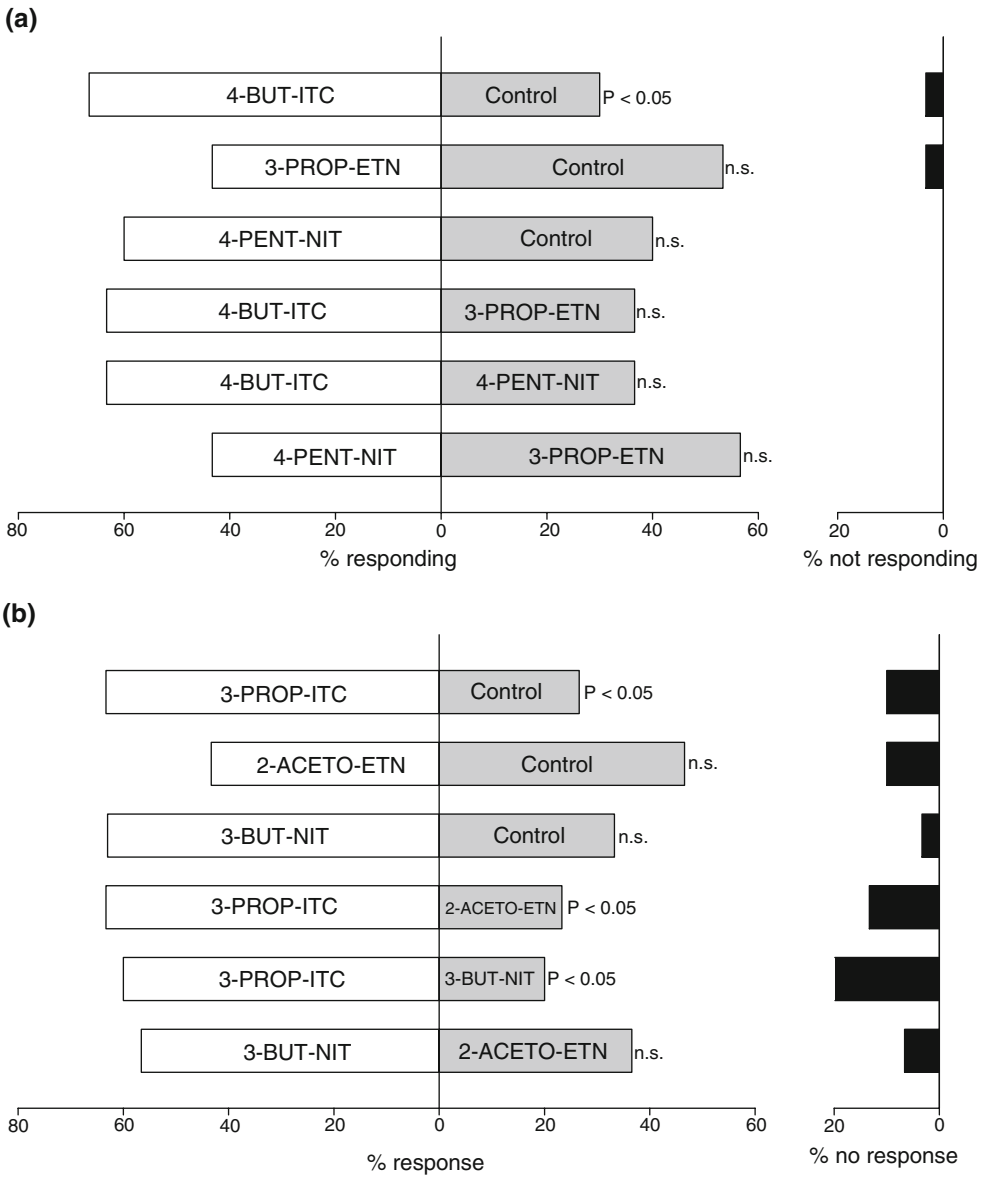

Fig. 3 Responses of naïve *Diaeretiella rapae* females in a Y-tube olfactometer to (**a**) 3-butenylglucosinolate hydrolysis products, where 4-BUT-ITC = 4-isothiocyanatobut-1-ene; 4-PENT-NIT = pent-4-enenitrile; 3-PROP-ETN = 3-(thiiran-2-yl) propanenitrile and (**b**) 2-propenylglucosinolate hydrolysis products, where 3-PROP-ITC = 3-isothiocyanatoprop-1-ene; 3-BUT-NIT = but-3-enenitrile; 2-ACETO-ETN = 2-(thiiran-2-yl) acetonitrile. A total of N= 30 naïve *D. rapae* females were tested for each comparison

More parasitoids responded to the isothiocyanate, in this case 3-PROP-ITC (χ^2=4.48, P<0.05) when presented opposite a solvent control (Fig. 3b). In contrast, although more *D. rapae* females oriented toward 3-BUT-NIT compared to the control, this difference was not significant. Similar numbers of insects moved toward 2-ACETO-ETN and the solvent control. From comparisons between 2-propenylglucosinolate derived hydrolysis products, more *D. rapae* responded to 3-PROP-ITC compared with either the corresponding nitrile (χ^2=6.00, P<0.05) or epithionitrile (χ^2=5.54, P<0.05). Similar numbers of insects moved toward 3-BUT-NIT and 2-ACETO-ETN when they were presented opposite each other.

Naïve *D. rapae* females reared on *B. brassicae*, which in turn were feeding on *B. nigra*, were presented with 4-BUT-ITC or 3-PROP-ITC. Each compound was presented opposite a solvent control and also opposite each other. More parasitoids moved into the air stream that contained the 4-BUT-ITC (χ^2=9.85, P<0.01) or 3-PROP-ITC (χ^2=7.76, P<0.05) compared with the control (Fig. 4a). When 4-BUT-ITC was presented opposite 3-PROP-ITC, more *D. rapae* responded to 3-PROP-ITC (χ^2=4.48, P<0.05). A second similarly designed experiment was completed that used naïve *D. rapae* females reared on *B. brassicae*, which in turn were feeding on *B. rapa* var *rapifera*. Again, more parasitoids moved into the air stream containing the 4-BUT-ITC (χ^2=5.14, P<0.05) or 3-PROP-ITC (χ^2=10.80, P<0.01) compared with the control (Fig. 4b). However, when 4-BUT-ITC was presented opposite 3-PROP-ITC similar numbers of insects responded to each compound.

In each of these experiments, the number of insects not responding was low. In the majority of cases, less than 10% of parasitoids did not respond with a maximum of 20%.

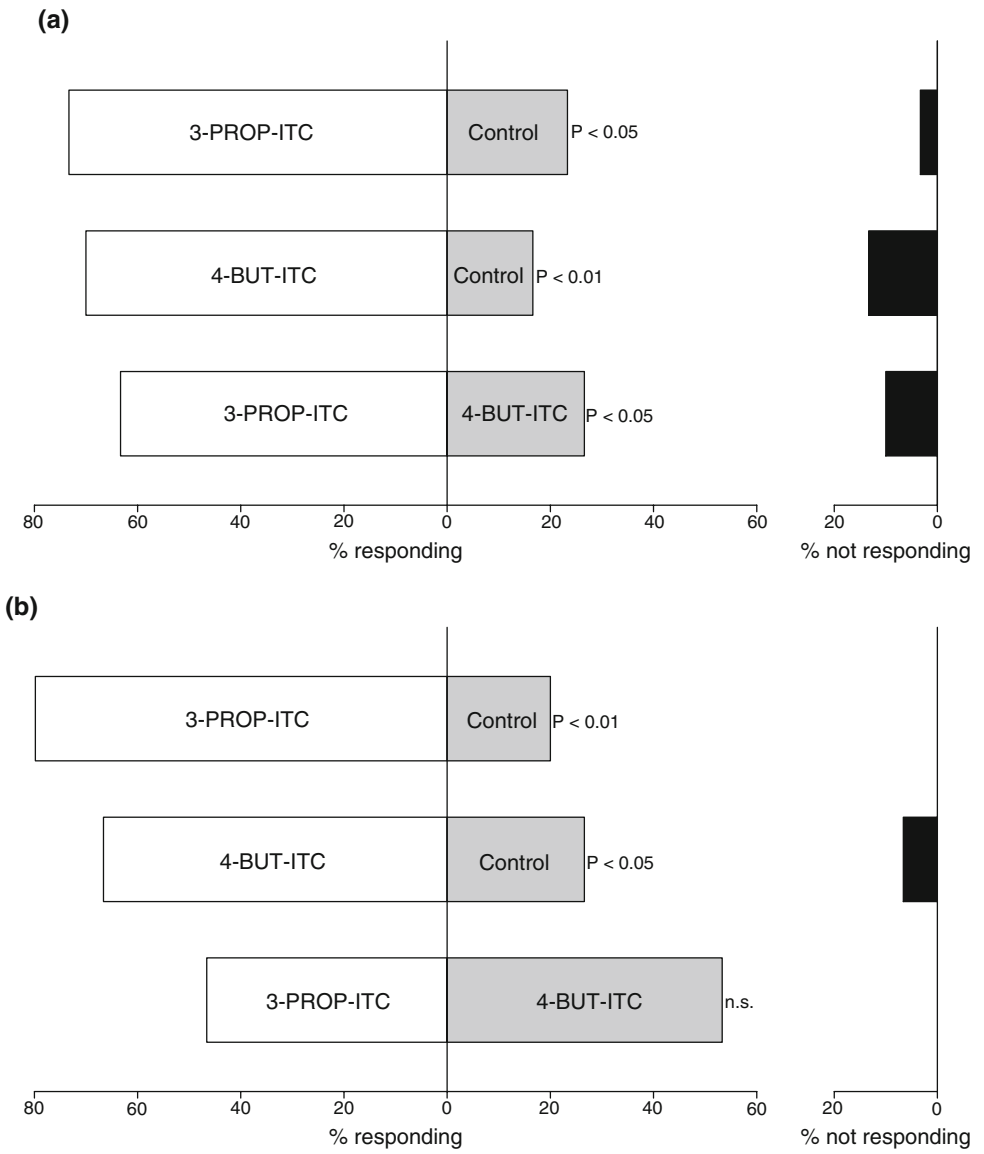

Fig. 4 Responses of naïve *Diaeretiella rapae* females to 3-PROP-ITC = 3-isothiocyanato-prop-1-ene and 4-BUT-ITC = 4-isothiocyanatobut-1-ene, having previously been reared on *Brevicoryne brassicae* feeding either on (**a**) *Brassica nigra* or (**b**) *Brassica rapa* var *rapifera*. A total of N= 30 naïve *D. rapae* females were tested for each comparison

Discussion

Research that has investigated the importance of the myrosinase–glucosinolate defense against insect herbivores has so far largely focused on the role of isothiocyanates (Halkier and Gershenzon 2006; Wittstock and Burow 2007). Many studies have investigated the direct effects of isothiocyanates against herbivores, while others have focused on indirect effects of isothiocyanates that act as cues for parasitoids, including *D. rapae*. However, little is currently known about the peripheral odor perception of *D. rapae* to glucosinolate hydrolysis products. Indeed, *D. rapae* has previously been tested only against, and shown to respond to, 3-PROP-ITC (Vaughn et al. 1996).

Here, we confirmed this earlier result while also recording EAGs from naïve *D. rapae* females in response to 3-butenyl- and 2-propenylglucosinolate hydrolysis products, including isothiocyanates and (for the first time) nitriles and epithionitriles. Although significant EAG responses were recorded to 3-PROP-ITC, parasitoids did not respond to the corresponding nitrile or epithionitrile, reflecting either the lower volatility of these compounds or a lack of olfactory receptors. By contrast, *D. rapae* females showed peripheral odor perception to all of the 3-butenylglucosinolate hydrolysis products tested, including 4-BUT-ITC, 4-PENT-NIT, and 3-PROP-ETN, although again the largest response was to the isothiocyanate. Large EAG responses were also recorded in response to (*E*)-2-hexenal, and *D. rapae* females have previously been shown to respond to another green leaf volatile, (*Z*)-3-hexenol (Vaughn et al. 1996).

Vaughn et al. (1996) noted that although *D. rapae* females responded to both (*Z*)-3-hexenol and to 3-PROP-ITC; there were clear differences in the recovery rates following stimulation by each compound, suggesting possible differences in receptor type. Similarly, in the present study, antennal response recovery rates were significantly faster for (*E*)-2-hexenal than to the alkenylglucosinolate hydrolysis products tested. This result further supports the idea that, like its aphid hosts, *L. pseudobrassicae* and *B. brassicae*, female *D. rapae* possess more than one receptor type (Dawson et al. 1987; Nottingham et al. 1991). Slower recovery rates previously have been attributed to chemical-specific receptors (Baker and Roelofs 1976). Results presented here suggest that *D. rapae* females possess receptors specific for isothiocyanates, as previously identified by (Vaughn et al. 1996), and in addition for certain nitriles and epithionitriles. The physico-chemical properties of the isothiocyanates are quite different from that of the nitrile group, being more polar and electrophilic and with more potential for interaction with proteins. The thiirane ring of the epithionitriles, while less polar than that of the isothiocyanate group, is also electrophilic, and has the potential for ring opening with biological nucleophiles to form conjugates. Although no specific work has been carried out on isothiocyanate receptors in insects, a recent report describes the effect of mustard oil (3-PROP-ITC) on endogenous porcine transient receptor potential V1 (pTRPV1) channels (Ohta et al. 2007). It was found that 3-PROP-ITC acts as an agonist for porcine TRPV1. Other notable receptors of this type are the vanilloid and capsaicin receptors present in *Drosophila* that have been well characterized (Caterina et al. 1997, 1999). Another class of receptors is the odorant receptors (OR), which are undergoing characterization in *Drosophila* and are potential candidates for interactions with glucosinolate hydrolysis products (Benton 2006). It would be of interest to explore the action of glucosinolate-derived isothiocyanates as chemical cues and repellents at a molecular level in order to understand at the physiological level the behavior of insects.

There is considerable evidence that isothiocyanates function as signals in indirect plant defense responses, thus enhancing attraction of beneficial parasitoids (Read et al. 1970; Vaughn et al. 1996; Bradburne and Mithen 2000; Blande et al. 2007), and it has been speculated that simple nitriles may serve also as similar signals induced by herbivory (Wittstock and Burow 2007). Indeed, female *Cotesia rubecula* Marshall, a specialist parasitoid of *Pieris rapae* L. caterpillars, may use nitriles to discriminate between infested and uninfested *A. thaliana* plants (van Poecke et al. 2001). Air entrainments of these plants implicated two nitriles, 5-(methylthio) pentanenitrile and 6,7-dithiooctanenitrile, along with the monoterpene myrcene and higher levels of methyl salicylate, as potential cues used by this parasitoid. In the present study, there was a lack of orientation behavior to the 2-propenylglucosinolate-derived nitrile and epithionitrile, which supports the apparent lack of peripheral perception of these compounds indicated by the EAG results. By contrast, although EAG results indicated peripheral odor perception to all of the 3-butenylglucosinolate hydrolysis products tested, olfactometry results indicated only a significant behavioral response to 4-BUT-ITC. However, when 4-BUT-ITC was presented opposite either the corresponding nitrile or epithionitrile, there was no significant difference in the numbers of *D. rapae* orienting to each compound. This result suggests either a weak response to the 3-butenylglucosinolate-derived 4-PENT-NIT and 3-PROP-ETN or that these compounds in some way disrupt the response to 4-BUT-ITC. A similar result was recorded by Blande et al. (2007) who noted that there was no difference in the number of *D. rapae* females orienting to 4-BUT-ITC and 5-isothiocyanatopent-1-ene when the compounds were presented opposite each other. This result was recorded despite the fact that when each compound was presented opposite a solvent

control, parasitoids oriented toward the 4-BUT-ITC but not toward the 5-isothiocyanatopent-1-ene.

The results from this study provide no evidence for naïve *D. rapae* females responding behaviorally to either the nitriles or epithionitriles tested. However, subtle effects such as potential interactions between compounds cannot be excluded. Indeed, the nitriles implicated as host-finding cues utilized by *C. rubecula* were present against a background of plant odors (van Poecke et al. 2001). In contrast with the lack of behavioral response to either the nitriles or epithionitriles, results from the olfactometry experiment indicated that naïve *D. rapae* females did orient toward both 3-PROP-ITC and 4-BUT-ITC. This result supports a number of earlier studies in suggesting that these two isothiocyanates provide an indirect defense by acting as host finding cues for *D. rapae*, a natural enemy of aphids feeding on crucifers (Read et al. 1970; Vaughn et al. 1996; Bradburne and Mithen 2000; Blande et al. 2007). In the present study, naïve *D. rapae* females responded positively to both 3-PROP-ITC and 4-BUT-ITC, whether the parasitoids were reared on *B. nigra* or *B. rapa* var *rapifera*. This is despite the fact that *B. nigra* is characterized by the accumulation of 2-propenylglucosinolate (Cole 1976), while *B. rapa* var *rapifera* accumulates 3-butenylglucosinolate (Carlson et al. 1981). In both cases, the glucosinolates are hydrolyzed to the corresponding isothiocyanates (unpublished data).

When the two compounds were presented opposite each other in the olfactometer, the responses of naïve *D. rapae* females were, however, affected by the host plant on which the insects were reared. When reared on *B. nigra*, more parasitoids oriented toward 3-PROP-ITC, but when reared on *B. rapa* var *rapifera* there was no difference in the numbers of females responding to the two isothiocyanates. This result contrasts with that of Bradburne and Mithen (2000) who also used a Y-tube olfactometer to record *D. rapae* behavior but utilized two near-isogenic *B. oleracea* lines. Hydrolysis analysis, rather than air entrainments of aphid-infested plants such as that used by Blande et al. (2007), was used to confirm that one of these isogenic lines produced predominantly 4-BUT-ITC and the other mainly 3-PROP-ITC. Bradburne and Mithen (2000) recorded more *D. rapae* orienting toward the 4-BUT-ITC line as opposed to the 3-PROP-ITC producing line, regardless of the line on which the insects were reared. It is unclear why these two studies produced contrasting results, although this may reflect differences in the way that the parasitoids interpret individual volatiles as opposed to a bouquet of different compounds. This point is particularly relevant, as Bradburne and Mithen (2000) presented hydrated ground plant material, which is likely to have presented the insects with many volatile compounds that may or may not be associated with aphid infested plants. In contrast, here, individual compounds were presented as cues in the olfactometry experiments.

Host plant chemistry plays a role in both host-finding and host recognition in other species of aphid parasitoids (Wickremasinghe and van Emden 1992; Storeck et al. 2000). The cereal aphid specialist *Aphidius rhopalosiphi* De Stefani Perez discriminated between different cultivated varieties of winter wheat in a Y-tube olfactometer, but showed a preference for the cultivar on which it was reared (Wickremasinghe and van Emden 1992). Similarly, the generalist aphid parasitoid *Aphidius colemani* Viereck also showed a preference for the host-plant on which it was reared (Storeck et al. 2000). In both cases, this preference was associated with chemical cues present on the mummy case, which the adult parasitoid comes into contact with at the time of emergence.

Interestingly, Blande et al. (2007) also suggest that *D. rapae* encounters chemical cues, probably glucosinolates, as the wasp emerges from the aphid mummy. Indeed, when naïve *D. rapae* females were presented with *B. rapa* var *rapifera* plants infested either with *L. pseudobrassicae* (which characteristically accumulates glucosinolates) or *Myzus persicae* (Sulzer) (not known to accumulate glucosinolates), parasitoids attacked a higher proportion of the *L. pseudobrassicae* regardless of the aphid species on which the wasps were reared (Blande et al. 2004). However, subsequent olfactometry experiments, again using experienced *D. rapae* reared on *L. pseudobrassicae* or *M. persicae* feeding on *B. rapa* var *rapifera*, found no evidence for parasitoids preferentially orienting toward either plant/aphid complex (Blande et al. 2007). From these results, the authors suggest that glucosinolate cues accumulated as the parasitoid emerges from the aphid mummy are important in host acceptance but that similar cues appear to be utilized for locating *L. pseudobrassicae* or *M. persicae* feeding on *B. rapa* var *rapifera*. Here, by using one species of aphid and altering the species of host plant rather than, in the case of Blande et al. (2007), using two aphid species reared on the same species of host plant, we recorded changes in orientation behavior. This result raises interesting questions about the type of chemical cue that may be acquired as the wasp emerges from the aphid mummy and in particular whether these results are explained by non-volatile glucosinolates and/or the volatile isothiocyanates.

Acknowledgments We thank Valerie Elliot for technical assistance and the BBSRC for providing financial support.

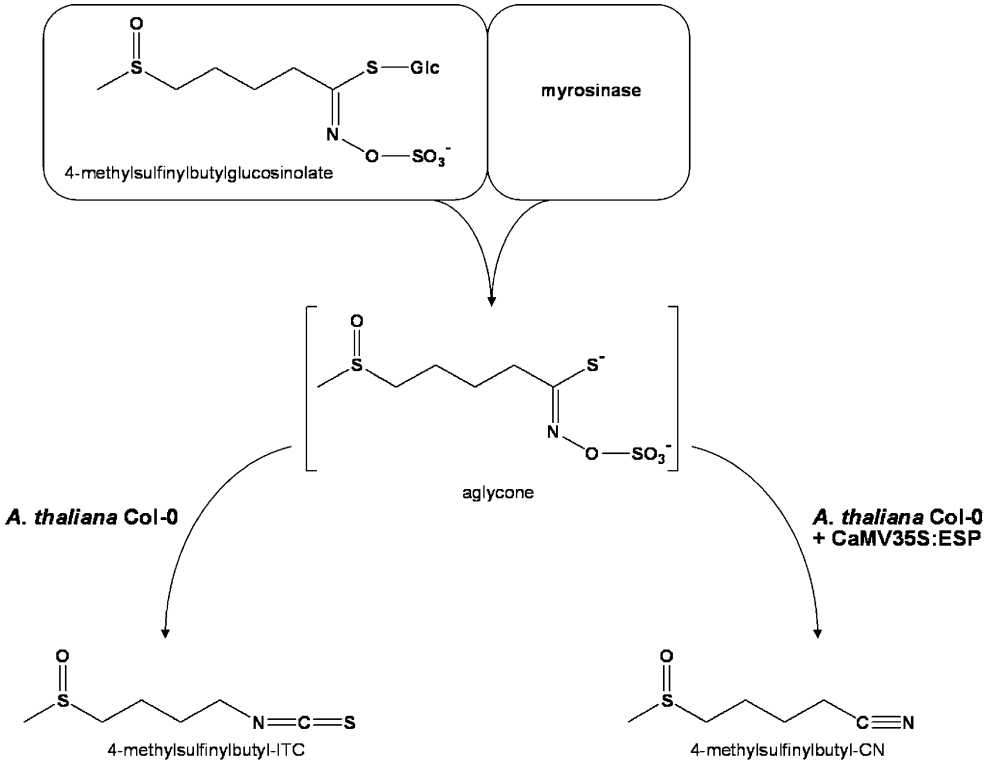

Fig. 1 Glucosinolate hydrolysis in *A. thaliana* Col-0 wild-type and 35S:*ESP* plants as shown for 4-methylsulfinylbutylglucosinolate, the main glucosinolate found in the Col-0 ecotype. Glucosinolates and their hydrolytic enzymes, the myrosinases, are stored in different cells in intact plant tissue. Damage to the tissue results in myrosinase-catalyzed hydrolysis of glucosinolates yielding glucose and unstable aglucones. In the ecotype Col-0, these aglucones predominantly rearrange into isothiocyanates due to the absence of a functional epithiospecifier protein. Expression of ESP from the *Arabidopsis* ecotype L*er* under the control of the constitutive CaMV35S promoter results in nitrile formation upon leaf damage

(Fig. 1) (Rask et al. 2000). Spontaneous rearrangement of the aglucone then leads to the formation of an isothiocyanate. Under the influence of specifier proteins that are present in many glucosinolate-containing plants including *Brassica napus* and some *Arabidopsis* accessions, alternative products such as simple nitriles and epithionitriles are formed at the expense of isothiocyanates (Bernardi et al. 2000; Foo et al. 2000; Lambrix et al. 2001; Wittstock and Burow 2007). Glucosinolate hydrolysis in intact plant tissue is prevented by spatial separation of glucosinolates and myrosinases through storage in different cells and thus occurs only upon tissue disruption, e.g., by a feeding herbivore (Andréasson and Jørgensen 2003).

The glucosinolate–myrosinase system is involved in defense responses against herbivorous insects of different feeding guilds (Kliebenstein et al. 2002; Agrawal and Kurashige 2003; Wittstock et al. 2003; Kliebenstein 2004; Mewis et al. 2005; Barth and Jander 2006; Kim and Jander 2007). Its role in direct defense has been attributed mainly to the isothiocyanates, which are the predominant hydrolysis products in many plant species. Isothiocyanates are toxic upon ingestion, contact, or when present in the gas phase (Agrawal and Kurashige 2003; Wittstock et al. 2003). However, the glucosinolate–myrosinase system appears to differentially affect specialist and generalist herbivores (Giamoustaris and Mithen 1995; Li et al. 2000). Several specialist insects have developed counteradaptations to circumvent the toxic effects of glucosinolates and their hydrolysis products (Müller et al. 2001; Alibadi et al. 2002; Ratzka et al. 2002; Wittstock et al. 2004; Agerbirk et al. 2006; Vergara et al. 2006; Wheat et al. 2007). Moreover, glucosinolates and isothiocyanates often serve as attractants or oviposition and feeding stimulants for these insects (Van Loon et al. 1992; Huang and Renwick 1994; Wittstock et al. 2003; Miles et al. 2005; Schoonhoven et al. 2005; Renwick et al. 2006; Barth and Jander 2006; Smallegange et al. 2007). Still, several studies have shown negative correlations between the glucosinolate content of the diet and the larval performance of herbivorous insects specialized on Brassicaceae (Mewis et al. 2005, 2006; Gols et al. 2007, 2008; Kim and Jander 2007).

Little is known about the biological activities of hydrolysis products other than isothiocyanates. In general, simple nitriles are considered less toxic than isothiocyanates (Lambrix et al. 2001; Wittstock et al. 2003; Burow et al. 2006b). For example, larvae of the generalist *Tricho-*

plusia ni (cabbage looper, Lepidoptera, Plusiinae) feed more, and larvae of the generalist *Spodoptera littoralis* (Egyptian cotton leafworm, Lepidoptera, Noctuidae) perform better on nitrile-producing *Arabidopsis* plants than on isothiocyanate-producing plants (Lambrix et al. 2001; Burow et al. 2006b; Zhang et al. 2006). Given that insect herbivores seem to suffer less from simple nitriles than from isothiocyanates, the ecological rationale for nitrile formation in the Brassicaceae is not easy to understand. Different scenarios can be drawn in which a plant may benefit from producing nitriles. For example, nitrile formation could be advantageous in direct and indirect defense against specialized herbivores. Direct plant defense negatively affects the feeding stages or the egg deposition of the herbivore, whereas indirect defense acts by recruiting natural enemies of the herbivore, such as predators and parasitoids (Hilker and Meiners 2002). Since isothiocyanates are often exploited as attractants, oviposition, or feeding stimulants by specialized herbivores (Rask et al. 2000; Renwick 2002; Wittstock et al. 2003; Renwick et al. 2006), plants that do not produce isothiocyanates upon damage may become less apparent to specialists. Alternatively, carnivorous insects such as predators and parasitoids may be differentially attracted by isothiocyanates and nitriles. A few studies have demonstrated that parasitoids are attracted to isothiocyanates (Titayavan and Altieri 1990; Pivnick 1993; Murchie et al. 1997; Bradburne and Mithen 2000; Reddy et al. 2002; Blande et al. 2007). However, parasitoid and predator performance is also known to correlate negatively with glucosinolate content (Harvey et al. 2003; Kazana et al. 2007; Gols et al. 2008). This negative relationship might favor a behavioral response of predators and parasitoids to plant volatiles that contain simple nitriles instead of isothiocyanates.

Because the glucosinolate–myrosinase system is an activated plant defense, the role of specific glucosinolate hydrolysis products is difficult to study in experimental settings. Plants that differ in the type of hydrolysis products they form often also differ in other properties such as glucosinolate content or myrosinase activity. The use of synthetic compounds alone or in mixtures to compare the defensive role of certain hydrolysis products also can be misleading due to differences in volatility. Moreover, many of them cannot be obtained as pure compounds. However, the availability of molecular tools to genetically manipulate model plants such as *Arabidopsis* provide an opportunity to overcome these difficulties (e.g., Degenhardt et al. 2003; Snoeren et al. 2007). The use of transgenic *Arabidopsis* lines that have been modified in glucosinolate hydrolysis provide a more natural system to compare the effects of naturally occurring relative and absolute amounts of members of different types of glucosinolate hydrolysis products.

Arabidopsis accessions differ in the type of glucosinolate hydrolysis products they produce upon tissue damage. This is due to allelic variation at the locus that encodes the epithiospecifier protein (ESP, Lambrix et al. 2001). For example, plants of the Landsberg *erecta* (L*er*) accession possess a functional *ESP* gene and produce predominantly simple nitriles upon tissue disruption, while isothiocyanates are the major glucosinolate hydrolysis products of the Columbia-0 (Col-0) accession that lacks functional ESP (Lambrix et al. 2001). We used a transgenic line of *Arabidopsis* Col-0, which expresses the *ESP* cDNA from the L*er* accession under the control of the CaMV35S promoter (35S:*ESP* plants; Burow et al. 2006b). In the 35S:*ESP* plants, glucosinolates are predominantly hydrolyzed to simple nitriles, whereas Col-0 wild-type plants mainly produce isothiocyanates upon damage (Burow et al. 2006b). For example, in Col-0 wild-type plants, the hydrolysis of 4-methylsulfinylbutylglucosinolate, the most abundant glucosinolate in the rosette leaves of this ecotype, leads to the formation of 4-methylsulfinylbutyl isothiocyanate. If ESP is overexpressed, however, the corresponding nitrile is produced (Fig. 1). However, neither the glucosinolate profile, the myrosinase activity levels, nor the morphology is altered in 35S:*ESP* plants compared with Col-0 wild type (Burow et al. 2006b).

In the present study, we used the 35S:*ESP* plants to investigate the role of simple nitriles in the interaction between *Arabidopsis*, the specialist cabbage white butterfly *Pieris rapae* L. (Lepidoptera, Pieridae), and its specialist larval endoparasitoid *Cotesia rubecula* (Marshall) (Hymenoptera, Braconidae). *P. rapae* is one of the most abundant butterflies in Northern and Central Europe and is neurophysiologically and biochemically adapted to using glucosinolate-containing plants as its sole hosts (Renwick 2002; Wittstock et al. 2004; Schoonhoven et al. 2005; Braby and Trueman 2006, and references therein). Most interestingly, caterpillars of *P. rapae* excrete simple nitriles in their feces (Agelopoulos et al. 1995) due to the action of a midgut nitrile-specifier protein that directs the hydrolysis of ingested glucosinolates from isothiocyanate towards simple nitrile formation (Wittstock et al. 2004; Burow et al. 2006a). *P. rapae* is able to complete its development on *Arabidopsis* (Van Loon et al. 2000; Harvey et al. 2007).

Volatiles of different plant species, including *Arabidopsis*, that are infested with *P. rapae* caterpillars are known to attract *C. rubecula* females (Agelopoulos and Keller 1994a; Geervliet et al. 1994, 1996; Van Poecke et al. 2001). The headspace of *P. rapae*-infested *Arabidopsis* plants contains nitriles that may originate from the frass of the caterpillars or the wounded plant tissue (Van Poecke et al. 2001; Van Poecke 2007; Wittstock et al. 2004). The feces of *P. rapae* caterpillars are attractive to *C. rubecula* from a distance, and their headspace contains predominantly nitriles (Agelopoulos

et al. 1995; Wittstock et al. 2004). Electrophysiological studies have demonstrated that antennae of *C. rubecula* respond to certain isothiocyanates and nitriles (J.J.A. van Loon, unpublished results; Smid et al. 2002). Therefore, we used wind tunnel experiments to test whether *Arabidopsis* plants that overexpress ESP are more attractive to *C. rubecula* than the isothiocyanate-producing Col-0 wild-type plants.

Isothiocyanates are involved in long-distance host recognition by a number of specialized insect herbivores (reviewed in Wittstock et al. 2003). Therefore, we investigated whether the higher proportion of nitriles formed in 35S:*ESP* plants as compared to wild-type plants influences the oviposition behavior of *P. rapae* butterflies. Glucosinolates stimulate egg deposition by *P. rapae* upon contact, but in nature butterflies might also be exposed to glucosinolate hydrolysis products, e.g., when host plants are already infested with feeding caterpillars (e.g., Huang et al. 1993, 1994). Additionally, we tested whether the feeding preference and performance of *P. rapae* differs between 35S:*ESP* plants and Col-0 wild-type plants. Despite the known glucosinolate detoxification mechanism in the midgut of *P. rapae* caterpillars, high concentrations of isolated isothiocyanates reduce *P. rapae* caterpillar growth and survival (Agrawal and Kurashige 2003). Combining these diverse bioassays, we aimed at obtaining a better insight into the contribution of nitriles to the relationships of *P. rapae* with its host plant and its enemies.

Methods and Materials

Plants *A. thaliana* Col-0 and the transgenic line 35S:*ESP* (2.6, T4; in the Col-0 background; Burow et al. 2006b) used for wind tunnel and oviposition experiments were grown from seed in soil (Lentse Potgrond, Cuijk, the Netherlands) in a controlled-climate room at 21 ± 1°C, a L8:D16-h photoperiod, 80–110μmol m^{-2} s^{-1} photosynthetically active radiation (PAR), and 55 ± 5% relative humidity (RH). Two-week-old seedlings were transferred to pots (Teku, Pöppelmann, Lohne, Germany) containing the same soil. Plants used for the experiments were 4–6-week-old and in the vegetative stage. Plants used to test the feeding preference and larval performance of *P. rapae* were grown under similar conditions for 4–5weeks except that the photoperiod was a L10:D14-h photoperiod and the relative humidity was 60 ± 5%.

Insects A continuous rearing of *P. rapae* for oviposition preference tests was maintained on Brussels sprouts plants in a climatized room at 21 ± 1°C, 60 ± 10% RH and an L16:D8-h photoperiod. *P. rapae* larvae used for feeding preference tests and larval performance tests were raised under similar conditions except that relative humidity was 75 ± 5%. The parasitoid *C. rubecula* was reared on *P. rapae* caterpillars feeding on Brussels sprouts plants in a greenhouse at 24 ± 4°C, 60 ± 20% RH, and a L16:D8-h photoperiod. For experiments, *C. rubecula* pupae were collected and kept in a cage in a climate cabinet (23 ± 1°C, 60 ± 10% RH, and L16:D8-h photoperiod). Emerging wasps were provided with water and honey. Male and female wasps were kept together until the experiment.

Plant Treatments for Parasitoid and Oviposition Experiments Plants were either artificially damaged or infested with ten first-instar *P. rapae* caterpillars. Plants were infested for 24 h and were kept in a climate chamber at 21 ± 1°C, a L8:D16-h photoperiod, 80–110μmol m^{-2} s^{-1} photosynthetically active radiation, and 55 ± 5% RH until the experiments. Artificially damaged plants were obtained by punching a ~7-mm^2 hole into each of six leaves of a plant right before the experiment. Intact *Arabidopsis* plants served as controls.

Wind Tunnel Experiments Behavioral choice experiments with the parasitoid *C. rubecula* were done with a wind tunnel setup (25 ± 1°C, 60 ± 10% RH, 35μmol m^{-2} s^{-1} PAR) as described by (Geervliet et al. 1994). The wind speed was adjusted to 0.2m s^{-1}. Two-choice experiments were conducted by placing two odor sources each consisting of six *Arabidopsis* plants at the upwind end of the tunnel as described by Van Poecke et al. (2001). Naïve *C. rubecula* females (without oviposition experience) were separated from males 3h prior to the experiment and transferred to another cage that was placed in the experimental room to acclimatize the parasitoids to the new environment. The wasps were individually introduced into the wind tunnel on *Arabidopsis* leaves of the treatments that they were also exposed to in the wind tunnel. These leaves were used in an alternating way, i.e., in the case that *P. rapae*-infested Col-0 wild-type was tested against caterpillar-infested 35S:*ESP* plants, the first, third, fifth, etc. wasp was introduced on an Col-0 wild-type leaf from which the caterpillars and their products had been carefully removed. Consequently, the second, fourth, sixth, etc. tested parasitoid was introduced on an 35S:*ESP* leaf from which the caterpillars and their products had been carefully removed as well. This increases the general behavioral response of the parasitoids to plant cues but likely does not induce a shift of preference (Kaiser and Cardé 1992; Bleeker et al. 2006; Smid 2006). Wasps were allowed to walk onto the leaves themselves. The leaf with the wasp was placed at the middle of the release cylinder, which was 60cm downwind from the two odor sources. As soon as the parasitoid had left the leaf for a few seconds, the leaf was carefully removed with tweezers without

disturbing the parasitoid. The flight behavior of the wasps was observed. Flights that resulted in a landing on one of the two odor sources were recorded as a "choice." Parasitoids that did not leave the release cylinder or landed on other parts of the wind tunnel within 10min were recorded as "no choice." Every parasitoid was used once. In order to correct for unforeseen asymmetry in the setup, the position of the odor sources was swapped after five tested parasitoids. After testing ten parasitoids, the odor sources were replaced with new ones. Every experiment was repeated at least five times over the course of several days. In order to check whether parasitoid discrimination was influenced by the amount of the caterpillar feeding, the leaf area removed by caterpillars from three infested Col-0 wild-type plants and three 35S:*ESP* plants from three experimental days was analyzed using the program ImageJ 1.37v (http://rsb.info.nih.gov/ij/).

Oviposition Preference Test Freshly emerged *P. rapae* adults were transferred to a large cage (67 × 100 × 75cm) in a greenhouse compartment at 24 ± 4°C, 60 ± 20% RH, and an L16:D8-h photoperiod. Butterflies were provided with 10% sucrose solution. Three to 5 days after emergence, one male and one female butterfly were transferred to each of the oviposition cages (67 × 50 × 75cm) in the same greenhouse compartment. Each butterfly couple was also provided with a 10% sucrose solution. In addition to natural daylight, the cages were illuminated by sodium vapor lamps (SON-T, 500W, Philips, the Netherlands) from 10:00a.m. to 4:00p.m. At 48h prior to the experiment, a single untreated Brussels sprouts leaf was placed in each cage as an oviposition substrate. After 6h, the leaf was removed. On the experimental day between 10:00a.m. and 11:00a.m., a transgenic 35S:*ESP* plant and a Col-0 wild-type plant were placed approximately 40cm apart from each other in each cage. In one experiment, both plants were intact, and in a second experiment both plants were artificially damaged. *P. rapae* was allowed to lay eggs on the two plants for 5 h. The plants were then removed, and the eggs laid were counted. The experiments were conducted in several cages at the same time and on several days per treatment, each replicate with new plants and butterflies.

P. rapae *Feeding Preference Test* Feeding choice tests were carried out in a climate chamber with an L16:D8-h photoperiod, 75 ± 5% RH, and a temperature of 21 ± 1°C. For each replicate, three Col-0 plants and three 35S:*ESP* plants were alternately arranged in a circle. A single *P. rapae* third instar was released in the center of each arena at the level of the leaf rosettes, and the larvae were allowed to feed for 24 h. A total of 18 replicates was carried out on three experimental days with independently grown sets of plants. Leaf areas removed from the three wild-type plants and the three 35S:*ESP* plants in each arena were measured. Leaf rosettes were digitally photographed with a reference mark before and after the experiments to calculate the removed leaf area using the program ImageJ 1.37v (http://rsb.info.nih.gov/ij/).

P. rapae *Performance and Developmental Studies* To compare the performance of *P. rapae* on the 35S:*ESP* plants and Col-0 wild-type plants, larvae were reared from emergence to pupation on 5-week-old 35S:*ESP* plants in a climate chamber (21 ± 1°C, L16:D8-h photoperiod, 75 ± 5% relative humidity). Single newly emerged larvae (<24 h old) were placed on individual plants that were then covered with perforated plastic bread bags to prevent insects from escaping. The weight of each larva was recorded on day 7 after hatching, when the larvae were transferred to fresh plants for the first time, and again on day 10. The larvae were transferred to new plants three to four times depending on their consumption rate. One to 2 days after pupation, the pupae were removed from the plants and placed individually in small ventilated plastic vessels. The emergence of adults was monitored every day for a period of 30 days.

Statistical Analysis In the wind tunnel experiments, a *binomial test* was used to analyze whether the behavioral choices of the parasitoids differed from a 50:50 distribution between the two odor sources. Parasitoids that did not make a choice were excluded from the statistical analysis. To check whether introducing the parasitoids on different leaves influenced the subsequent choice of the parasitoids, a *McNemar test* for marginal homogeneity was applied. In the oviposition choice tests, most individuals of *P. rapae* laid eggs on both the Col-0 wild-type and the 35S:*ESP* plant. The number of eggs on each treatment per individual were considered as a paired sample and were analyzed with the nonparametric *Wilcoxon signed ranks test*. In addition, we also analyzed the egg incidence by using a *sign test*. For the feeding choice experiments with *P. rapae*, the removed leaf area from each of the three Col-0 wild-type and the three 35S:*ESP* plants of each replicate were pooled, and a mean was calculated. A *Wilcoxon signed ranks test* was applied to test whether means were statistically different. *Mann–Whitney U tests* were applied to test for differences in performance-related parameters between Col-0 wild-type and 35S:*ESP* plants. All tests are described by Glantz (2005), and for some tests the statistical software package SPSS 12.0.1 (SPSS Inc., Chicago, IL, USA) was used.

Results

Behavioral Response of C. rubecula *to Volatiles of ESP Overexpressing and Wild-Type Arabidopsis Plants. P.*

rapae-caterpillar-infested 35S:*ESP* plants attracted more *C. rubecula* parasitoids than caterpillar-infested Col-0 plants in a two-choice wind tunnel setup (*binomial test*, $p < 0.05$; Fig. 2). However, when artificially damaged before the experiment, 35S:*ESP* plants attracted significantly fewer parasitoids than caterpillar-infested Col-0 wild-type plants (*binomial test*, $p < 0.05$; Fig. 2). When caterpillar-infested 35S:*ESP* plants were compared with artificially damaged ones, more parasitoids landed on the caterpillar-infested plants (*binomial test*, $p < 0.005$; Fig. 2). However, artificially damaged 35S:*ESP* plants were more attractive to *C. rubecula* than intact plants of the same line (*binomial test*, $p < 0.001$; Fig. 2). The introduction of the parasitoids to the wind tunnel on leaves of either Col-0 or 35S:*ESP* plants did not bias their subsequent choice but stimulated the general response of the wasps to plant volatiles (data not shown, *McNemar test*, $p > 0.05$). The leaf area removed by the caterpillars did not differ between 35S:*ESP* and Col-0 wild-type plants (35S:*ESP*: $1.62 \pm 0.11 cm^2$, Col-0: $1.61 \pm 0.22 cm^2$; mean ± SE, $N = 18$; *Mann–Whitney U test*, $p > 0.4$).

Oviposition Preference of P. rapae *P. rapae* lays individual eggs that are usually distributed over the plants. In general, *P. rapae* females began to lay eggs soon after being exposed to the experimental plants, and they deposited eggs on both the transgenic and the wild-type plant in more than 99.5% of all replicates. When plants were undamaged, ovipositing butterflies did not discriminate between 35S:*ESP* and Col-0 wild-type plants (Fig. 3): the average number of eggs laid per female did not differ between plant genotypes (*Wilcoxon signed ranks test*, $p > 0.05$, $N = 18$, Fig. 3). In 56% of the cases, the butterflies laid more eggs on the wild-type plant, while in 44% they deposited more eggs on the 35S:*ESP* plant (*sign test*, $p > 0.05$, $N = 18$). However, the situation changed when plants were artificially damaged before being exposed to the butterflies. In this case, the butterflies significantly preferred to lay eggs on wild-type plants. In 81% of the cases, *P. rapae* laid more eggs on Col-0 plants than on the 35S:*ESP* plants (*sign test*, $p < 0.01$, $N = 22$, Fig. 3). This trend is also reflected in the significantly larger number of eggs laid per female on wild-type plants (Fig. 3). Overall, when plants were damaged, the nitrile-producing 35S:*ESP* plants were significantly less attractive for egg deposition by *P. rapae* than the isothiocyanate-producing wild-type Col-0.

Feeding Choice Experiments and Performance of P. rapae The next step was to test whether caterpillars show the same preference as adult female butterflies. In a multiple-choice experiment, young *P. rapae* caterpillars were allowed to choose between three 35S:*ESP* plants and three Col-0 wild-type plants for 24h. All tested caterpillars fed on both the transgenic and the wild-type plants. There was no significant difference in the mean leaf area removed between 35S:*ESP* and wild-type plants (35S:*ESP*: 7.0 ± 4.7 cm^2, Col-0: 6.1 ± 3.6 cm^2; $N = 18$; *Mann–Whitney U test*, $p > 0.05$). Furthermore, we analyzed the performance of *p. rapae* caterpillars on the 35S:*ESP* line and on wild-type plants. We recorded the larval weight after only 7 and 10

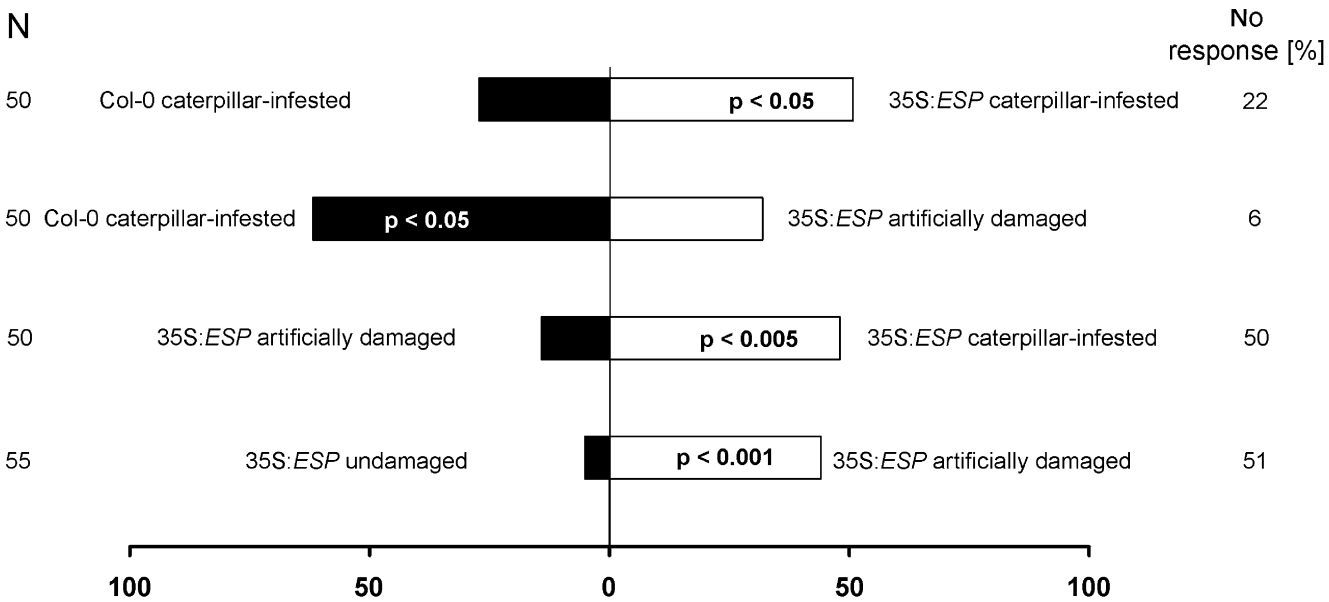

Fig. 2 Response of *C. rubecula* to odors of wild-type *Arabidopsis* Col-0 and transgenic 35S:*ESP* plants in a two-choice wind tunnel setup. Plants were either intact, artificially damaged right before the experiment, or infested with *P. rapae* caterpillars for 24 h. Parasitoids that did not make a choice were not included in the analysis. Choices between odor sources were analyzed using a *binomial test*

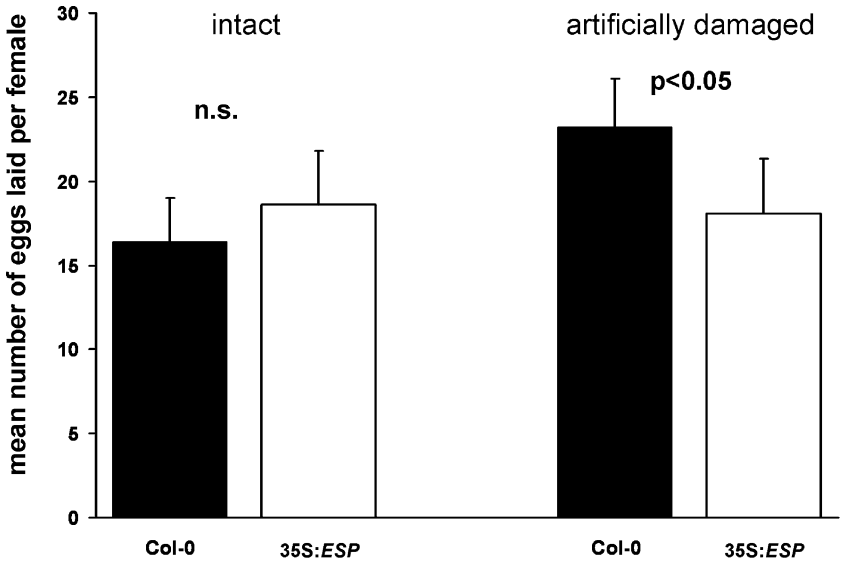

Fig. 3 Oviposition by *P. rapae* on wild-type *Arabidopsis* Col-0 (*black bars*) and transgenic 35S:*ESP* plants (*white bars*). Plants were either intact (*left*) or artificially damaged (*right*) before the experiment. Depicted is the mean number of eggs laid per female+standard error (analyzed using the *Wilcoxon signed ranks test* (N=18 with intact plants, N=22 with damaged plants)

days as differences in food quality at this early stage have a particularly strong effect on caterpillar growth and development (J.J.A. van Loon, personal communication). However, larval weight of caterpillars did not significantly differ between the plant genotypes at day 7 or 10 (Table 1). Likewise, pupal weight, developmental time until pupation, and the total developmental time were not significantly different between *P. rapae* caterpillars that fed on either 35S:*ESP* or Col-0 wild-type plants (Table 1).

Discussion

Our study demonstrates that glucosinolate-containing plants can benefit from producing predominantly simple nitriles instead of isothiocyanates upon herbivore damage despite the fact that simple nitriles are less toxic than isothiocyanates to insect herbivores. The experiments described employed a transgenic 35S:*ESP* line that upon tissue maceration hydrolyzes glucosinolates to simple nitriles rather than to isothiocyanates as in Col-0 wild-type plants (Burow et al. 2006b). Despite the differences in glucosinolate hydrolysis, there were no significant alterations between 35S:*ESP* and wild-type plants in glucosinolate content and composition and myrosinase activity (Burow et al. 2006b). The nitrile-producing 35S:*ESP* plants attracted significantly more *C. rubecula* parasitoids than Col-0 wild-type plants when both were infested by *P. rapae* (Fig. 2).

Simple nitriles are not only released by plants but are also the predominant volatiles emitted by the frass of *P. rapae* caterpillars, which is known to attract *C. rubecula* from a distance (Agelopoulos and Keller 1994b; Geervliet et al. 1994; Agelopoulos et al. 1995; Wittstock et al. 2004). Hence, nitrile-producing plants such as 35S:*ESP* plants may indicate the presence of feeding and defecating host larvae to reinforce the response of the parasitoids to *P. rapae*-induced volatiles (Fig. 2). This explanation is supported by a previous study showing that a combination of volatiles from *P. rapae*-infested cabbage and *P. rapae* feces was more attractive to *C. rubecula* than those of caterpillar-infested plants alone depending on the infestation level (Agelopoulos et al. 1995). In the present study, significantly more parasitoids were attracted to infested 35S:*ESP* and infested Col-0 plants compared to artificially damaged 35S:*ESP* plants. This demonstrates that the volatile blend emitted upon herbivory, including plant volatiles and volatiles derived from the herbivore, is more attractive to *C. rubecula* than volatiles emitted from the plant after mechanical damage (Fig. 2). Volatile blends of mechanically damaged 35S:*ESP* plants are most likely dominated by green leaf volatiles and simple nitriles, whereas the blend of caterpillar-infested plants is more complex, including also terpenoids and methyl salicylate (Van Poecke et al. 2001; Burow et al. 2006b). Indeed, *C. rubecula* parasitoids show electroantennogram responses to terpenoids and methyl salicylate in addition to responses to green leaf volatiles (Smid et al. 2002), indicating that these compounds have an important role in attracting the parasitoids as well. That the attraction of parasitoids is beneficial to the reproductive fitness of *A. thaliana* was demonstrated previously (Van Loon et al. 2000).

Many parasitoids change their behavioral preference to certain infochemicals by associative learning of these odors after a rewarding experience, e.g., an oviposition (Turlings et al. 1993; Vet et al. 1995). Also, *C. rubecula* can learn associatively to respond to certain plant odors either after an oviposition experience or by simply having contact with

Table 1 Performance of *P. rapae* on *Arabidopsis* Col-0 and 35S:*ESP*

	Col-0 wt (*N*=39)	35S:*ESP* (*N*=37)	Mann–Whitney *U* test (*p* value)
Larval weight on day 7 [mg]	24±2.1[a]	27±1.8	>0.05
Larval weight on day 10 [mg]	150±7.7	157±5.8	>0.05
Pupal weight [mg]	146±2.1	141±3.0	>0.05

host products. However, unlike the situation in the closely related parasitoid species *Cotesia glomerata*, learning in *C. rubecula* results in an increased behavioral response towards the learned odor but does not shift an innate preference towards another odor (Bleeker et al. 2006; Smid 2006). This is confirmed by results of our study because introducing the parasitoids into the wind tunnel on a host-damaged leaf, alternating between a wild-type and a transgenic leaf, did not bias the subsequent choice to the leaf type they previously experienced. Moreover, giving *C. rubecula* females an oviposition experience in the presence of the odor of one of the two plant types would likely not result in a preference for that learned odor (Bleeker et al. 2006; Smid 2006).

P. rapae females laid significantly fewer eggs on mechanically damaged 35S:*ESP* plants than on mechanically damaged Col-0 wild-type plants. However, there was no preference when plants were undamaged suggesting that glucosinolate hydrolysis products rather than the glucosinolates themselves influenced plant acceptance by *P. rapae* (Fig. 3). De Vos et al. (2008) showed that ovipositing *P. rapae* preferred isothiocyanate-producing *Arabidopsis* Col-0 plants over 35S:*ESP* plants, even when the plants were not damaged. Numerous studies have shown that the nonvolatile glucosinolates serve as oviposition stimulants for *P. rapae* and closely related species (overview given by Chew and Renwick 1995; Hern et al. 1996; Schoonhoven et al. 2005). However, given that most glucosinolate hydrolysis products are volatile, while the parent glucosinolates are not, the hydrolysis products might be important cues for *P. rapae* at an earlier stage of the host location process. In fact, isothiocyanates in particular are known to attract many specialist herbivorous species (reviewed by Wittstock et al. 2003) and even to stimulate oviposition (Renwick et al. 2006). On the other hand, only a few studies have demonstrated that nitriles attract herbivores, and in general these were less attractive than isothiocyanates (Pivnick et al. 1992; Bartlet et al. 1997; Smart and Blight 2000; De Vos et al. 2008). Whether the preference of *P. rapae* to oviposit on isothiocyanate-emitting wild-type plants is due to the repellent effect of nitriles or to the stimulating effect of isothiocyanates or both remains to be investigated. However, oviposition preference of *P. rapae* for isothiocyanate-emitting wild-type plants is likely to benefit the butterflies either because isothiocyanates would indicate the presence of a (glucosinolate-containing) host plant or because nitrile emission could indicate a host plant that is already infested with conspecific larvae. Butterflies that avoid laying eggs on already infested host plants should reduce intraspecific competition and parasitism (Thompson and Pellmyr 1991). In fact, *P. rapae* is known to avoid laying eggs on plants that are infested with conspecific larvae or that carry conspecific eggs (Rothschild and Schoonhoven 1977; Schoonhoven et al. 1990; Sato et al. 1999). Nitriles, acting as indicators of feeding and defecating larvae, may not only signify the presence of competitors but may also hint at increased levels of glucosinolates and other defense compounds in the host plant as a result of induction that have a negative influence on the performance of the offspring (e.g., Agrawal and Kurashige 2003; Mewis et al. 2005, 2006; Gols et al. 2008). Accordingly, cabbage plants that were treated with jasmonic acid, a key hormone involved in induced plant defense, received significantly fewer eggs from *P. rapae* than respective control plants (Bruinsma et al. 2007).

The preference of *P. rapae* to oviposit on plants emitting isothiocyanates is likely due to the fact that isothiocyanate release indicates a functioning glucosinolate–myrosinase system. As many herbivores are not as well adapted to the glucosinolate–myrosinase system, the preference for a glucosinolate-containing plant by *P. rapae* butterflies is one key to avoid interspecific competition. Our present results show that *P. rapae* performed just as well on the isothiocyanate-producing Col-0 wild-type as on the nitrile-producing 35S:*ESP* line. In contrast, generalist herbivores are known to perform significantly better on nitrile-producing plants vs. isothiocyanate-producing plants (Lambrix et al. 2001; Burow et al. 2006b). *P. rapae* butterflies thus may be able to use isothiocyanates to select competitor-sparse food plants for their offspring (De Vos et al. 2008). To recap, gravid *P. rapae* females foraging for suitable host plants may have a number of reasons to prefer isothiocyanate-producing vs. nitrile-producing plants as an oviposition site. The release of nitriles upon damage may signal a higher risk of interspecific and intraspecific competition, an increased chance of parasitism, and a poorer substrate for larval

development. Alternatively, nitrile-producing plants might receive fewer eggs due to the lack of isothiocyanates as oviposition stimulus.

In summary, this paper has demonstrated that *A. thaliana* plants producing simple nitriles rather than isothiocyanates are better defended against the specialist herbivore, *P. rapae*, because of reduced oviposition and increased attraction of a specialist larval parasitoid. In contrast, isothiocyanate-emitting plants appear to be better defended against generalist herbivores. These findings provide a rationale for the existence of a polymorphism among *A. thaliana* ecotypes (Lambrix et al. 2001). The selective balance between these glucosinolate hydrolysis phenotypes may shift depending on the proportion of specialist to generalist herbivores present.

Acknowledgements Many thanks are due to Leo Koopman, Frans van Aggelen, and André Gidding for culturing the insects and the experimental farm of Wageningen University (Unifarm) for rearing the Brussels sprout plants. We also thank Rieta Gols for help with some experiments. The study was financially supported by the European Commission contract MC-RTN-CT-2003-504720 "ISONET", by a VICI grant (nr 865.03.002) from the Earth and Life Sciences Foundation, which is subsidized by the Netherlands Organization for Scientific Research and by the Max Planck Society.

addition, mycorrhizal fungi can alter host plant responses to herbivory in many ways, i.e., by inducing changes in host plant chemical quality, host plant defense (Bezemer and van Dam 2005; Bennett et al. 2006), and host plant tolerance (Bennett et al. 2006).

To better understand the effects of mycorrhiza on aboveground herbivory, Jones and Last (1991) constructed a conceptual model that predicts the effects of ectomycorrhizal (ECM) infection on plant defense and growth in different environmental conditions. In that model, ECM should increase antiherbivore defense of host plants aboveground through carbon allocation under low soil nutrients and high light conditions. Bennett et al. (2006) used mostly arbuscular mycorrhiza (AM) as a model organism to predict how mycorrhizal fungi could affect plant enemies by improving plant nutrition, modifying plant tolerance, or modifying plant defenses for the long-term dynamics of the plant–enemy interactions. However, experimental evidence to support the predictions of these model systems is still limited. Earlier studies with ECM have shown positive (Gehring et al. 1997; Manninen et al. 1999, 2000), negative (Gehring et al. 1997; Manninen et al. 1998a; Rieske 2001; Gange et al. 2005b), or no effects (Manninen et al. 1998a, 2000; Palermo et al. 2003) on insect herbivore performance compared to performance on nonmycorrhizal or low-ectomycorrhizal conspecific plants. Similarly, the few earlier studies with AM plants show that fungal inoculation either improves (Borowicz 1997; Gange and West 1994; Gange et al. 2005a; Bennett and Bever 2007), reduces (Rabin and Pacovsky 1985; Gange and West 1994; Gange 2001; Bennett and Bever 2007), or does not affect (Gange 2001; Bennett and Bever 2007) the performance of aboveground herbivores. The responses of herbivores on certain plant species could be dependent on the AM species associated in the root system (Bennett and Bever 2007).

The effects of mycorrhizas on the performance of aboveground insect herbivores seem to be dependent on the insect feeding guild and also on the degree of specialization of the insect studied. Specialist insects, both sucking (Manninen et al. 1999; Gange et al. 2002) and chewing (Gange et al. 2002), have performed better on mycorrhizal plants (ECM in Manninen et al. 1999; AM in Gange et al. 2002), whereas generalist sucking (Manninen et al. 2000) and generalist chewing (Gange et al. 2002) have shown lowered performance. Insect responses to plants that live in association with mycorrhizal fungi may be due to host plant chemistry affected by mycorrhizae (Manninen 1999; Gange et al. 2002), but chemical changes of a plant as such have not been clearly linked with the mycorrhizal status of host plants (Manninen 1999). Often, generalist insects are deterred by high concentrations of defense compounds, whereas specialists in contrast use them to identify potential hosts (van der Meijden 1996).

In our laboratory study, we compared how a generalist and specialist insect herbivore, with either sucking or chewing feeding behavior, perform on silver birch with different ECM infection levels in their roots. Different ECM infection levels were achieved by artificially inoculating already naturally infected plantlets with two different species of ECM fungi or by reducing the natural infection with a fungicide. Our hypotheses were, following the allocation model of Bennett et al. (2006), that the ectomycorrhizal infection level would influence aboveground insect herbivore performance on deciduous tree plantlets either positively (1) by increasing available plant biomass, (2) by enhancing availability of nutrients, or negatively (3) by modifying the concentration of defense compounds, i.e., phenolics, in birch foliage.

Methods and Materials

Plant Material Tissue-cultured clonal silver birch plantlets (clone KL-5-M) grown in the Research Garden of Kuopio University were transplanted into mini-greenhouses in a mixture (2:1, *v*/*v*) of prefertilized (Vapo *Sphagnum* peat, 12:9:18, N/P/K) and γ-sterilized (Kolmi-Set Ltd. Ilomantsi, Finland) peat and autoclaved sand (particle size 0.5–1.2 mm). This clone was chosen because we already had some background information, e.g., it is fast growing (Pääkkönen et al. 1993). Plantlets (N=140, 8-week old) were transplanted into 0.8-L plastic pots in the same growth medium as mentioned above and transported to the growth chamber at the University. Growth conditions in the chamber simulated weather conditions of June in Finland (day–night temperature 19°C:12°C, photoperiod 22 L:2 h/day, and maximum daytime irradiance about 500 μE m^{-2} s^{-1}).

Plantlets were divided randomly into four mycorrhizal treatments (35 plantlets per treatment): (1) C = control (natural mycorrhizal infection from the growth medium); (2) PI+ = *Paxillus involutus*-inoculated (our own collection, strain number 62); (3) LV+ = *Leccinum versipelle*-inoculated (our own collection, strain number 58); and (4) F− = fungicide-treated plantlets. Artificial inoculations were done once by adding 10 ml of fungal suspension into each pot, whereas fungicide propiconazole (TILT 250 EC, Syngenta Crop Protection, Ltd.) was applied twice at intervals of 1 week, so that the amount of active ingredient reached 0.025 g m^{-2} in each pot. Plantlets were watered when needed. Because quartz sand and *Sphagnum* peat are so poor in nutrients that reduced ectomycorrhizal growth can be expected (Kainulainen et al. 1996), plantlets were fertilized once a week at the age of 10–18 weeks with 0.1% 9-Superex (19:5:20, N/P/K, Kekkilä Oy), yielding 95 mg nitrogen per plantlet (corresponds approximately 148 kg N ha^{-1}).

All insect bioassays were performed under laboratory conditions during summer when these particular insects also are naturally feeding on their host plants in Finland (i.e., the age of plantlets during the insect bioassays was between 12 and 18 weeks). Final sampling for all chemical analyses was conducted when plantlets were 20-week old.

Lygus rugulipennis Experiment The phloem-feeding generalist, the tarnished plant bug, *Lygus rugulipennis*, Popp., (Heteroptera: Miridae) causes damage especially in forest nurseries by damaging the apical meristem and causing growth disturbance. Adults were collected from silver birch stocks in a forest nursery, kept at +12°C, and transferred to +20°C 1 day before the oviposition test started. For the oviposition test, 12-week-old silver birch plantlets were evenly distributed among 12 plastic containers. Thus, each container (360× 260 mm with a height of 220 mm) had one plantlet with each mycorrhizal treatment (C, PI+, LV+, F−; N=12 per treatment). Containers were covered with nylon gauze, and two adult females plus one male *L. rugulipennis* were released into each container for mating and egg laying (+21°C). After 12 days, adults were removed and nymphs were allowed to hatch from eggs in chamber conditions described above. Every second day during the following 24-day period, plantlets were shaken gently to access the new emerged nymphs. Afterwards, these plantlets were maintained under the same chamber conditions described above and used in the following *L. rugulipennis* feeding test.

For the feeding test, *L. rugulipennis* nymph (first to fourth instar; the same colony as mentioned above and maintained on barley, *Hordeum vulgare*) was weighed and enclosed in a clip cage (one nymph per seedling) on the upper surface of the second or third leaf of a side branch of the same plants used in the oviposition test (12 plantlets/treatment, age of plants 18 weeks). The clip cage was made of a pair of plastic cylinders (diam. 1.5 cm, length of each 1.2 cm) and fixed on the leaf with a curtain clip. To prevent leaf damage by the clip cage, plastic foam was attached to the cylinder edges. Nylon mesh at both ends of the cylinders prevented escape of the nymphs. Nymphs from different instars were distributed evenly among the four treatments. Three days later, nymphs were reweighed, and their relative growth rate (RGR; [ln(final fresh mass) − ln (initial fresh mass)]/number of days) was calculated (Waldbauer 1968).

Calaphis flava and Epirrita autumnata Experiment *C. flava* Mordvilko (Homoptera: Drepanosiphidae) is a phloem-feeding specialist aphid that causes damage both in forest nurseries and forests in Finland. Damage may be harmful especially for young seedlings. RGR was determined by using 5-day-old aphid nymphs (laboratory culture, age less than 1 year). Sets of plantlets (N=11 per treatment) different from those in the previous *Lygus* experiment were selected randomly from the original plantlet material. Four weeks after fungal inoculation, two weighed nymphs per 13-week-old plantlet were individually enclosed inside clip cages as described earlier on the lower side of two distinct leaves. For determination of RGR, nymphs were reweighed after 3 day and, thereafter, allowed to develop into adults on the same plantlets. The cumulative number of nymphs produced during 15 days was counted (age of plantlets approximately 15 weeks at the end of the experiment).

Epirrita autumnata Bkh (Lepidoptera: Geometridae) is a chewing generalist that causes damage especially to mountain birches in northern Finland. This herbivore is ecologically important at the timber line area. RGR of fifth instars, originating from Kevo Subarctic Research Station in northern Finland (one brood), was determined during a 24-h feeding period (N=12 per treatment, same plantlets as in *C. flava* test above plus one more selected from the original plantlet material, age of plants approximately 16 weeks). A weighed larva and the fourth birch leaf from the top of a plantlet were enclosed in a moistened gypsum container for 24 h at room temperature (+21°C). The initial and final mass of larvae and the dry weight of leaf material eaten were used to determine the efficiency of conversion of ingested material (ECI=100 × larval dry weight gain/dry weight of plant material eaten). RGR of larvae was calculated as described above.

Host Plant Parameters From the birches used in *L. rugulipennis* tests, two leaves were collected at the end of the oviposition test from 18-week-old plantlets, and air-dried for phenolic analyses by high performance liquid chromatography (HPLC; Lavola et al. 1994) to detect possible ectomycorrhiza-induced compounds. Two weeks later at the final harvest, when the plants were 20-week-old, separate leaves from the same birches were put into liquid nitrogen, stored in a deep-freezer (−80°C), and later freeze-dried for the enzymatic starch analysis (Boehringer starch kit for food analysis, Mannheim, Germany). Also at the final harvest, leaves from all plantlets used in the *L. rugulipennis* and *C. flava* tests described above were collected for nutrient analyses (N=92; 23 samples per treatment). Major nutrient (N, P, K, Ca, Mg) concentrations of oven-dried (+60°C) and wet-digested (Allen 1989) leaves were analyzed as described earlier (Manninen et al. 1999). The length of the main stems and the fresh and dry masses (oven drying at +70°C, 2 days) of the leaves were determined as well (N=92). All roots were washed with tap water and stored at −24°C for microscopic and biomass analysis, except sub-samples of roots taken from *C. flava* plantlets; these were stored at −80°C before being freeze-dried for ergosterol analysis. HPLC analysis of roots to determine ergosterol quantities was conducted as

described earlier (Nylund and Wallander 1992; Markkola 1996; Manninen et al. 1998b). For the determination of mycorrhizal infection and number of short roots, frozen roots were allowed to thaw, and a 1-m long sample from fine roots (∅≤2 mm) was randomly collected individually from each plantlet, stained with Ponceau S (Daughtridge et al. 1986), and analyzed visually under a stereomicroscope. Thereafter, roots were oven-dried, and the total dry weight was measured.

Statistical Analyses The data were checked for normal distribution and homogeneity of variances. The effects of different mycorrhizal treatments on parameters were tested either with one-way ANOVA (Tukey's or Dunnett's T3 a-posteriori test, $P<0.05$) or Kruskal–Wallis (Mann–Whitney U a-posteriori test, $P<0.05$). Before testing with ANOVA, data were log ($n+1$)- or arcsin-transformed when necessary. Correlation analyses were done with pooled data only ($N=44$–48) using Spearman's correlation coefficient. All analyses were done with the SPSS Software package.

Results

In the plantlets used in *L. rugulipennis* and *C. flava* experiments, both PI+ and LV+ treatments increased mycorrhizal infection level compared to the control treatment. Fungicide (F−) treatment reduced mycorrhizal infection significantly in the plantlets of both experiments (Fig. 1a,b), but it was not possible to produce totally nonmycorrhizal birch plantlets. Correspondingly, ergosterol concentration of roots, determined from *C. flava* plantlets only, increased significantly after PI+ and LV+ treatment but decreased after F− treatment (Fig. 1c). However, the total amount of short roots did not vary between treatments (data not shown).

Silver birch plantlets inoculated with PI+ had the lowest leaf and root dry mass (Table 1). The main stem dry mass of the plantlets used in *C. flava* experiment clearly decreased after both PI+ and LV+ inoculations compared to C and F− treatments. The total height of plantlets was also significantly reduced after PI+ inoculation compared to C and F− treatments (Table 1).

The nutrient concentrations of leaves responded to mycorrhizal manipulations quite variably. In the *C. flava* experiment, N concentrations of leaves were lowest in LV+ plantlets and highest in PI+ plantlets; phosphorous (P) concentration was highest in LV+ plantlets differing significantly from F− treatment (Table 2). F− treatment of plantlets used in the *C. flava* experiment led to a significant decrease of leaf calcium (Ca) concentration only compared to all other treatments. When considering plant samples

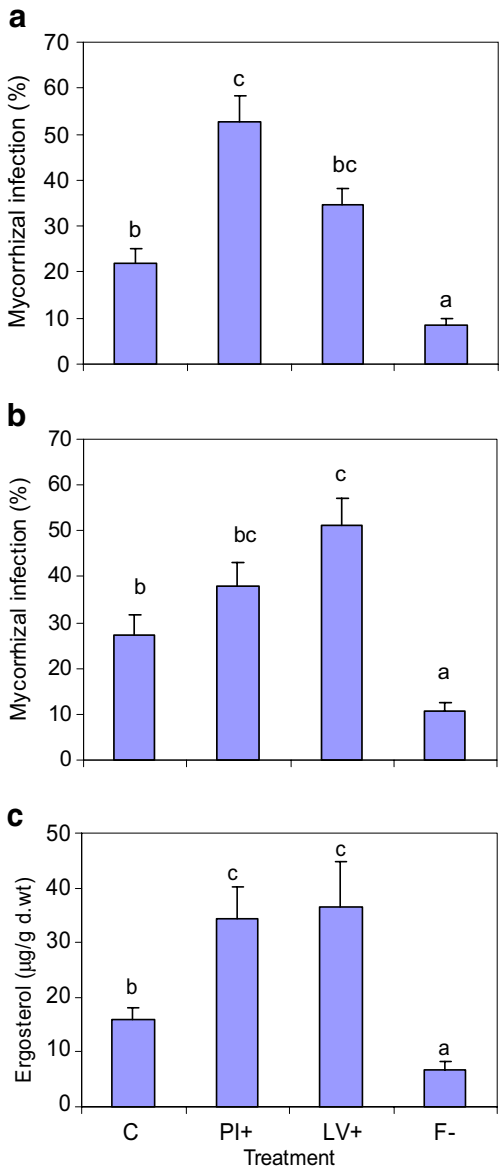

Fig. 1 Mycorrhizal infection (%) (+SE) of birch roots in different mycorrhizal treatments (**a**) in *Lygus rugulipennis* experiment ($N=12$) and (**b**) in *Calaphis flava* experiment ($N=11$), and (**c**) root ergosterol concentration (+SE) in plantlets used in *Calaphis flava* experiment ($N=11$). Treatments: *C* control, natural mycorrhizal infection, *PI+ Paxillus involutus*-inoculated, *LV+ Leccinum versipelle*-inoculated, and *F−* fungicide treated. Data tested with one-way ANOVA, and means followed by different letter are significantly different ($P<0.05$) according to Dunnett T3 (**a**, **b**) or Tukey's test (**c**)

used in the *L. rugulipennis* experiment and pooled plantlets from both type of experiments, leaf magnesium (Mg) concentrations significantly increased after F− treatment compared to C and LV+ treatments (Table 2). Starch concentration did not vary significantly between mycorrhizal treatments (Table 2). Altogether, 11 phenolics (Table 3) were analyzed from the leaves of the plantlets used in *L. rugulipennis* experiment, myricitrin, and quercitrin being

SD in parentheses. Pooled plantlets (*N*=23). *P* values according to Kruskal-Wallis or One-way ANOVA. Different letters after the mean and SD indicate statistically significant differences between the treatments ($P<0.05$). The mean main stem dry mass (g) and root/shoot ratio (%) (SD in parentheses) are determined from *C. flava* experiment plantlets only.
C Control, natural mycorrhizal infection, *PI+ Paxillus involutus*-inoculated, *LV+ Leccinum versipelle*-inoculated, *F−* fungicide treated.

the major compounds. We did not find evidence of ectomycorrhiza-induced phenolic production in the foliage.

RGR (Table 4) and fecundity (Fig. 2a) of *L. rugulipennis* did not differ among treatments, whereas *E. autumnata* had significantly higher RGR on PI+ plantlets than on LV+ plantlets (Table 4). ECI of *E. autumnata* larvae was not different among the treatments (data not shown). *C. flava* performed poorly on plantlets with enhanced ECM level: the cumulative number of nymphs decreased remarkably when feeding took place on PI+ and LV+ treated plants

Table 2 Main nutrient (N, P, Ca, Mg and K) concentrations (mg g^{-1} of leaf dry mass) of birch leaves in differently treated plantlets (treatments as in Table 1) used in experiments with *Lygus rugulipennis* (*N*=12) and *Calaphis flava* (*N*=11)

SD in parentheses. N=8–9, DHPPG; 3,4′-dihydroxypropiophenone-3-glucoside; P values according to Kruskal–Wallis or one-way ANOVA.

(Fig. 2b). RGR was lowest after feeding on PI+-treated plantlets, but it did not differ significantly from RGR of nymphs that were offered the other treatments (Table 4).

RGR of *C. flava* aphids (N=44) correlated negatively with foliar P (r=−0.401, P<0.001), foliar N (r=−0.307, P=0.001), and root ergosterol concentrations (r=−0.415, P=0.0001). Similarly, the fecundity of aphids on the plantlets decreased when the amount of foliar P (r=−0.386, P<0.001) and Ca (r=−0.331, P<0.001) as well as root ergosterol concentration increased (r=−0.358, P<0.001). Interestingly, increasing avicularin concentration of leaves (r=−0.361, P=0.083, N=24) seemed to be marginally related to the reduced RGR of *L. rugulipennis*, while the RGR of *E. autumnata* correlated positively with leaf N concentration (r=0.409, P=0.006, N=44).

Discussion

Host Plant Quality We hypothesized according to the allocation model of Bennett et al. (2006) that mycorrhizal plants with better nutrient uptake would have more foliar biomass and a higher carrying capacity of herbivores than nonmycorrhizal plants. Our findings do not support this hypothesis. PI+-inoculated plantlets showed reduced foliar biomass, and LV+ inoculation did not significantly affect leaf dry mass. The result that growth responses of host plants may depend on the ectomycorrhizal fungal species was demonstrated earlier with *Pinus sylvestris* (Manninen et al. 1999; Jonsson et al. 2001) and birch (Jonsson et al. 2001) seedlings, and also with host plants having AM fungi (Bennett and Bever 2007). Plantlets in our experiments were young; the initial establishment of ECM on roots of these young plants may have demanded more plant resources then were available, thus, leading to the observed suppressive effects on host plant growth. At a later developmental stage, ECM might become beneficial for the plants. Corrêa et al. (2006) have found that ectomycorrhiza formation had detrimental effects on plant's productivity during the establishment stage, and they suggested that the age of host plants determines whether the impact of mycorrhizas on host plants is negative or not.

According to our second hypothesis, elevated ECM colonization should increase the nutritional quality of foliage by enhancing nutrient uptake. Consequently, depletion of mycorrhizae with fungicide should reduce nutrient uptake. There was some evidence of increased macronutrient concentration in plantlets with enhanced ECM colonization, i.e.,

Table 4 Relative growth rate (mg mg^{-1} day^{-1}) of *Lygus rugulipennis* (N=12), *Calaphis flava* (N=11) and *Epirrata autumnata* (N=12) feeding on birch leaves of differently treated plantlets (treatments explained in Table 1)

Insect species	C	PI+	LV+	F−	*P* value
L. rugulipennis	0.081(0.072)a	0.064(0.064)a	0.075(0.063)a	0.068(0.047)a	0.933
C. flava	0.203(0.092)a	0.138(0.065)a	0.204(0.066)a	0.192(0.042)a	0.092
E. autumnata	0.296(0.145)ab	0.443(0.223)b	0.204(0.259)a	0.342(0.200)ab	0.059

SD in parentheses. P values according to one-way ANOVA. Different letters after the mean and SD indicate statistically significant differences between the treatments according to Tukey's test (P<0.05).

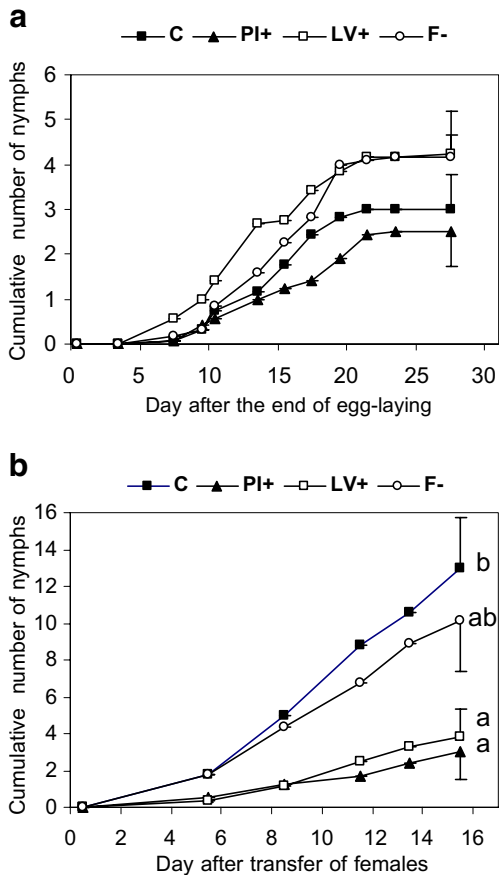

Fig. 2 (**a**) Cumulative number of *Lygus rugulipennis* nymphs hatched on birches in different mycorrhizal treatments (explained in Fig. 1) after the end of oviposition tests. Earlier hatching indicates earlier oviposition preference of females. (**b**) Cumulative number of nymphs produced by *Calaphis flava* females on birches in different mycorrhizal treatments. Standard error bars are shown only at the end of the experiment. Means in **b** followed by different letter are significantly different according to Tukey's test ($P<0.05$)

higher foliar P (PI+-pooled plantlets and LV+ plantlets in *C. flava* experiment) and N (PI+ plantlets in *C. flava* experiment) concentration, but at the same time, PI+ plantlets were considerably smaller than plantlets of other treatments. On the other hand, experimental depletion of ECM-reduced concentration of foliar micronutrient (Ca in *C. flava* experiment), and F− plantlets also had the lowest P concentration in the *C. flava* experiment (see also pooled data, Table 2). These results are in line with an earlier study where ectomycorrhizal pine seedlings had reduced P uptake after fungicide treatment (Manninen et al. 2000). Thus, our results confirm the importance of mycorrhizas in facilitating nutrient uptake even in a relatively early phase of plant development (Smith and Read 1997; Read and Perez-Moreno 2003).

The formation of ECM in roots activates a sequence of gene expression typical to different morphological and developmental stages, such as preinfection and adhesion, and formation of mantle and Hartig net (Le Quere et al. 2005). During mantle and Hartig net development in a birch root system, several genes normally involved in defense responses against pathogenic fungi are upregulated (Le Quere et al. 2005). Thus, it is obvious that the production of defensive plant chemicals in plant tissues and probably also in aboveground parts of the plant may vary in different stages of ECM formation. The plantlets studied in our experiment were young but had well-established ectomycorrhiza at the end of the experiment. There were no treatment effects, however, on major leaf phenolic compounds. Thus, our results did not support the third hypothesis of altered concentration of defense compounds in the foliage of mycorrhizal plants. Possibly, sampling of phenolic compounds at several time points (Peltonen et al. 2005) might have revealed some temporal foliar responses related to the dynamic process of mycorrhizal colonization. Since plant genotype is known to determine silver birch leaf phenolics (Keinänen et al. 1999), future studies of several clones are needed to interpret the relationships between leaf phenolic concentrations and mycorrhizal colonization.

Insect Performance Many herbivorous insect species show preference for fast-growing plant shoots because the capacity of these plants to regrow and maintain herbivore population is better (Price 1991). For example, large Scots pine shoots (Manninen et al. 1998c) have been more attractive to the generalist *L. rugulipennis* as an oviposition site than small ones. Bennett et al. (2006) predicted that plants with well-developed mycorrhizae should produce more foliage through improved plant nutrition, but we were unable to demonstrate this with the relatively young birch plantlets, even though the ectomycorrhiza was already well developed. Chewing larvae of the generalist *E. autumnata* grew better on PI+ plants than on LV+ plants, but PI+ plantlets had significantly reduced leaf dry mass compared to controls. Thus, the result with the chewing generalist was the opposite of that expected. The phloem-feeding specialist aphid *C. flava*, in contrast, behaved according to the "foliar quantity hypothesis" (Bennett et al. 2006): it showed a significantly reduced reproduction rate on PI+ plants. Additionally, the performance of the phloem-feeding generalist, *L. rugulipennis*, was lowest on PI+ plantlets, which had lower leaf dry mass than plantlets of other treatments and also had the lowest root dry mass, thus, supporting our first hypothesis.

Nitrogen is the most important limiting nutrient and can explain insect herbivore performance (Holopainen et al. 1995). In earlier studies, the performance of aphids (Kainulainen et al. 1996; Manninen et al. 1999) and *L. rugulipennis* (Manninen et al. 1998a) has been better on conifer seedlings with high N concentration, but performance

of these herbivores has not been associated with the mycorrhizal status of Scots pine roots as such. In the current study, a poor nitrogen status of LV+ plantlets might explain the reduced reproduction of the specialist *C. flava* aphids. However, the low reproduction rate of *C. flava* on the nitrogen-rich PI+ plants and the negative correlation of aphid RGR with leaf N concentration are not easy to explain. The present results suggest that PI+ treatment of plantlets may have a retarding effect on aphid growth that is not directly related to plant N status but to some other factor, such as the ratio of free amino acids in the phloem of inoculated plantlets. For instance, the ratio of, e.g., glutamine and other amino acids in phloem is an important factor for aphid performance (Karley et al. 2002). This ratio may have changed in the amino acid pool of *P. involutus*-inoculated birch seedlings (Blaudez et al. 1998) in a suboptimal way for this aphid species (Day et al. 2004). On the other hand, RGR of the generalist *E. autumnata* was highest on PI+ plants that had significantly higher N concentration than LV+ plants, and RGR of *E. autumnata* also correlated positively with leaf N in accordance with our second hypothesis. The importance of host plant nitrogen for performance of *E. autumnata* was observed also earlier (Kaitaniemi et al. 1998; Kause et al. 1999).

Many flavonoids are assumed to be associated with insect herbivore performance, both as determinants of a particular feeding choice and as feeding deterrents (Harborne 1991). However, experiments have shown that birch leaf phenolics poorly explain performance (Nurmi et al. 1996; Ossipov et al. 2001) or host plant selection (Peltonen et al. 2006) of insect herbivores. In our experiment, only high avicularin concentration of birch leaves was marginally inversely related to the growth of generalist *L. rugulipennis*, but it was not related to any mycorrhizal treatment. Furthermore, our finding that growth rates of the specialist insect herbivores were not affected by birch leaf phenolics did not support our third hypothesis. In earlier studies larval growth of *E. autumnata* has been reduced by high soluble proanthocyanidin concentration of mountain birch leaves (Kause et al. 1999) and high condensed tannin concentration (Mutikainen et al. 2000), but not by gallotannins (Kause et al. 1999).

The simplistic models that expect insect herbivore performance on ectomycorrhizal plants as a result merely of variation in carbon or nitrogen balance (Jones and Last 1991) or plant biomass (Bennett et al. 2006) were not supported by this study, since insect herbivore response was dependent on the fungal species forming the ectomycorrhiza. Our results indicate further that the interaction between host plant mycorrhizal status and above-ground insect herbivore performance is multifaceted, particularly with respect to the degree of specialization and feeding guild of insects. Thus, a generalization as to the effects of mycorrhizal colonization of plants on insect herbivores is not currently possible. Continuous monitoring of the dynamic balance of nutrients and secondary metabolites in host plant foliage might help us construct more precise mechanistic models for further understanding of the ectomycorrhizal effects on above-ground herbivory.

In plants, AO appears to be located in the cell wall, where it is believed to help regulate cell expansion (Gonzalez-Reyes et al. 1995; Kato and Esaka 2000) and the redox status of the apoplastic space during growth or stress signaling (Pignocchi et al. 2003, 2006; Sanmartin et al. 2003, 2007). In some plants, AO is also induced by herbivory or wounding and has been proposed to act as an antiherbivore defense (Felton and Summers 1993; Bi and Felton 1995; Bi et al. 1997; Garcia-Pineda et al. 2004). For example, AO in soybean leaves was believed to be responsible for the complete loss of ascorbate from the midgut contents of *Helicoverpa zea* caterpillars (Felton and Summers 1993). However, demonstration of a direct impact of foliar AO on insect herbivores has been confounded by the many other changes that occur when plants are stressed or induced by herbivory. For example, levels of essential nutrients, secondary chemicals, and many defensive proteins are all commonly altered in herbivore-damaged leaves (e.g., Duffey and Stout 1996; Karban and Baldwin 1997; Hermsmeier et al. 2001; Major and Constabel 2006). Therefore, in this study, AO-overexpressing transgenic poplar trees were produced in order to perform controlled experiments on the potential role of AO as a plant defense against herbivorous insects.

Tree-feeding caterpillars often ingest high levels of phenolic compounds, and an ascorbate-based antioxidant system is central to the defense of caterpillars against the oxidation of these phenolics caused by the high pH of the midgut (Felton and Duffey 1992; Barbehenn et al. 2001). In the absence of sufficient ascorbate in the midgut contents, phenolic oxidation produces elevated levels of reactive oxygen species (ROS), including semiquinone radicals, peroxides, and hydroxyl radicals (Barbehenn et al. 2003, 2005a,b). The production of ROS is associated with oxidative damage to nutrients in the gut lumen and oxidative stress in gut tissues (Summers and Felton 1994; Barbehenn et al. 2005a). Thus, AO might act synergistically with phenolics to increase their pro-oxidant effects on herbivores. Oxidative stress in the midgut lumen was examined with electron paramagnetic resonance (EPR) spectrometry to measure changes in free radical levels. The potential for synergism between AO and phenolics was examined by comparing semiquinone radical levels in larvae that fed on either low or high AO leaves coated with tannins. This work tested the hypothesis that elevated foliar AO activity (1) decreases levels of reduced ascorbate in the midgut contents of *Lymantria dispar* L. caterpillars, (2) produces oxidative stress in the gut lumen, and (3) decreases insect performance. To increase the generality of our results, the potential impact of AO-overexpressing poplar on ascorbate levels in the acidic guts of *Melanoplus sanguinipes* (Fabricius) grasshoppers was also examined.

Methods and Materials

Transgenic Poplars Hybrid poplar was chosen for this study because it is an acceptable host plant for *L. dispar*, is easily transformed, grows rapidly, and has been widely studied as a model tree in plant molecular biology and in studies of insect–plant interactions. AO-overexpressing poplars were produced by introducing the cucumber AO gene into *Populus tremula*×*Populus alba* (INRA 717I-B4) via *Agrobacterium*-mediated transformation using the method of Leplé et al. (1992). The complete cucumber AO-coding sequence (GenBank accession number J04494), including the signal peptide sequence, was inserted into the binary plasmid pGA643 (An et al. 1988) between the cauliflower mosaic virus 35S promoter and the T7-5 terminator, giving rise to pGA-CAO, as described previously (Sanmartin et al. 2003). Putative transformed shoots were first tested by rooting ability on kanamycin, and the presence of the transgene was confirmed by using polymerase chain reaction. Independently transformed plantlets were assayed for AO activity as described below, and plants with the highest AO levels were selected and moved to a greenhouse. The high expression of the AO transgene and the size of the AO transcript were confirmed in greenhouse-grown plants by Northern analysis by using a fragment of the cucumber AO gene as a probe (Sambrook and Russell 2001). Plantlets were propogated *in vitro* or as green cuttings and rooted in potting mix under high humidity in a mist chamber. Of the more than 10 independent transformants, three lines that showed high AO activities (designated genotype AO1, AO2, and AO3) were selected for further analysis. Untransformed parental stock plants served as the control (wild type) genotype. Seedlings were shipped from the University of Victoria to the University of Michigan.

Saplings were grown in a greenhouse in 8-l "Treepots" (Hummert International, Earth City, MO, USA) in Sunshine potting mix (Type 4), with Osmocote slow-release fertilizer (14–14–14) (Scotts, Marysville, OH, USA) and watered as needed. Growth lights with 400 W high-pressure sodium bulbs (PL Light Systems; Beamsville, ON, Canada) were used from September to May (L16/D8). Saplings were grown to a height of ≥1 m over a period of 3–4 mo before their use in experiments. Leaves were numbered sequentially from the shoot apex using the leaf plastochron index (LPI; Larson and Isebrands 1971). The first leaf lamina with a length greater than 2 cm was defined as LPI 0. Leaves for all experiments were excised with a sterile razor blade from LPI 10–20 from at least three trees of each genotype. Two to three leaves per day from each tree were excised, beginning with the upper leaves. After washing for 20 min in a water bath, leaf surfaces were blotted dry with paper towels and allowed to air dry with their petioles placed in tubes of water. Leaf disks were cut with a cork

borer (23 mm diameter), and all disks within each genotype were mixed to randomize potential effects of leaf position and individual tree.

Insects L. dispar is a polyphagous tree-feeding species that has been used widely as a model herbivore in studies of plant–insect interactions. It has a mildly acidic to neutral foregut (pH 5.2–7.2) and a basic midgut ranging from pH 8.0 to 11.0 (Schultz and Lechowicz 1986; Appel and Maines 1995). Eggs of *L. dispar* were obtained from the US Department of Agriculture (Otis Air Force Base, Massachusetts, USA). Third- and fourth-instar larvae were reared on an artificial diet prepared as described previously (Barbehenn et al. 2001), with the exceptions that linseed oil was used instead of wheat germ oil and sodium alginate (2.6%) was added to the dry ingredients. Larvae were reared in Petri dishes in incubators at either 18°C or 23°C to regulate developmental rates. Newly molted larvae (containing empty midguts) were switched from the rearing diet to an experimental food.

M. sanguinipes is a polyphagous grasshopper that normally feeds on a wide variety of forbs and grasses but will readily accept hybrid poplar leaves. It was chosen for comparison with *L. dispar* because it has both an acidic foregut (pH 5.5) and midgut (pH 6.8; Barbehenn et al. 1996), which could permit high AO reaction rates. Eggs of a non-diapause strain were obtained from the US Department of Agriculture (Sidney, MT, USA). Nymphs were reared on romaine lettuce and wheat bran in a wire mesh cage with an adjacent 100 W light bulb on a L16/D8 photoperiod.

Chemical Analyses Ascorbate oxidase was analyzed in leaf disks that were stored frozen (−80°C) in airtight plastic bags. Samples for analysis were collected on five dates across 2 mo during feeding experiments on first and fourth instars. Groups of three frozen disks were weighed quickly and ground with a chilled pestle and mortar in a mixture of 1.0 ml of pH 5.6 sodium phosphate buffer (0.1 M) containing 1 mM ethylenediaminetetraacetic acid (EDTA), 10 mg polyvinyl polypyrolidone, and approximately 15 mg sand. Leaf homogenates were centrifuged for 3 min (4°C; 8,000×*g*), and the supernatant solutions were used immediately for AO analysis. One-milliliter reaction mixtures contained 960 µl of pH 5.6 buffer, 20 µl of ascorbate in buffer (37.5 mM), and 20 µl of the supernatant solution. The AO reaction was measured as the rate of decrease in absorbance at 290 nm. An extinction coefficient of 2.8 mM^{-1} cm^{-1} was used to express change in absorbance units on a molar basis (Yoshimura et al. 1998). Boiled control supernatant solutions showed no AO activity. Comparisons of AO activity at pH 5.6 and 10 (70 mM carbonate–bicarbonate buffer) were made by using fresh leaf disks from each of three trees per AO genotype (LPI 15). Rates of ascorbate autoxidation at pH 10 were subtracted from the overall oxidation rates to measure the enzymatic component. AO rates were also compared by using commercial AO prepared from a *Cucurbita* species (Calbiochem, San Diego, CA, USA). AO activities provided by the manufacturer were 325 U/mg solid or 1,625 U/mg protein, where 1 U was defined as the amount of enzyme that will oxidize 1.0 µmol of ascorbic acid per minute at 30°C (pH 5.6). The reaction mixtures were prepared as described above with the exception that the pH 10 solution was prepared by adjusting the phosphate buffer with sodium hydroxide.

Ascorbate in each genotype was measured in the same collections of leaf disks used for measuring AO activity. Samples (approximately 100 mg) were weighed quickly and ground in liquid nitrogen to avoid artifacts caused by thawing. Frozen ground samples were transferred to 15-ml plug-seal cap centrifuge tubes and extracted in 1.0 ml 5% metaphosphoric acid (containing 1 mM EDTA). Following a 30-min extraction with continuous mixing, samples were centrifuged (1,000×*g*, 4°C, 5 min), the supernatant solutions removed, and the extraction repeated. Supernatant solutions were pooled within samples, mixed, and stored frozen (−80°C) until analysis with high performance liquid chromatography (HPLC; Barbehenn 2003).

To examine the impact of ingested AO on ascorbate levels in caterpillars, ascorbate was measured in the midgut contents of fourth instars that fed for 2 d on leaf disks from one of the four genotypes. Midgut contents were dissected (N=11–13 replicate larvae/genotype), dispersed in tared centrifuge tubes containing 300 µl of 5% metaphosphoric acid, and weighed to the nearest 0.1 mg. Ascorbate was measured with HPLC as described above.

Ascorbate was measured in adult *M. sanguinipes* after they fed on either a mixture of leaf disks from control genotype trees (N=15 insects) or a mixture of leaf disks from all three AO-overexpressing genotypes (N=15 insects). Grasshoppers were placed in individual containers in a 26°C incubator and were starved overnight to clear their guts and stimulate rapid feeding. Insects were dissected soon after they had eaten one or more leaf disks to ensure that their foreguts and midguts were full. Sample collection and ascorbate analysis were done as described above, with the exception that the foregut and midgut contents were extracted in 400 and 250 µl of metaphosphoric acid, respectively. Ascorbate was measured in a haphazard subset of the collected samples (N=8–10 per genotype and site), since this was sufficient to determine the effects of AO on ascorbate levels in *M. sanguinipes*.

Oxidative Stress in the Midgut To test the hypothesis that AO-overexpressing leaves have a synergistic effect on the oxidation of phenolics, leaf disks from the control genotype

and AO2 (LPI 13 and 14) were prepared as described above and treated with 20-µl aliquots of a tannin solution, producing an increase of 7.5% dry weight of pedunculagin and 7.5% pentagalloyl glucose. Fourth instars (N=9) fed on the leaf disks for 18–22 hr (18°C), following which the levels of semiquinone radicals in midgut contents, were measured with EPR spectrometry. Sample preparation and EPR analyses were performed as described previously (Barbehenn et al. 2005a). Briefly, midgut contents were dissected, weighed in a tared centrifuge tubes containing 300 µl of pH 10 carbonate buffer (containing 10% dimethylsulfoxide), dispersed, and then centrifuged. Supernatant solutions (200 µl) were placed directly in a flat cell in the EPR sample cavity, and the resulting first derivative spectra were integrated with WinEPR software. Radical levels were calculated in the midgut fluid volumes (approximately 90% of the mass) using 2,2,6,6-tetramethyl-1-piperidinyloxy radical standards. A synergistic effect would be indicated by the presence of higher semiquinone concentrations in the midgut contents of larvae that fed on the AO-overexpressing genotypes. At the time of dissection, all larvae were found to have produced dark frass pellets and to have full midguts, indicating that they fed well on the treated disks.

The potential for commercial AO (Calbiochem; purified from *Cucurbita* sp.) to produce oxidative stress in caterpillars was examined by measuring free radicals in the midgut contents of fourth instars that fed on AO-treated leaf disks from the control genotype. AO was suspended in 50% acetone (containing 5.7 mg/ml sucrose) at 0.33 mg/ml (low level) and 1.6 mg/ml (high level). Leaves were cut and prepared from LPI 10–20 as described above. Leaf disks were treated with 20-µl aliquots of either the high or low AO suspensions or the AO-free control solution. Based on a recovery of AO activity from treated leaves of 33% (±2%, N=6), we calculated that the AO activity of control genotype leaves was increased by fourfold (low level) or 20-fold (high level). Newly molted larvae were placed at random on each of the three treatment groups and fed poplar leaf disks for a 2-d period. Freshly treated disks were provided daily, and a moist filter paper was placed in each plastic cup to maintain leaf turgidity. Larvae were fed fresh disks prior to examination of their gut contents on the third day with EPR spectrometry. Between eight and 10 larvae were examined in each treatment group. This experiment was repeated 1 wk later with a different set of saplings.

Larval Performance To confirm that the performance of *L. dispar* larvae is affected by the absence of ascorbic acid from their food, performance was measured in fourth instars on artificial diet containing either 2.5% dry weight ascorbic acid or diet containing no ascorbic acid. The ascorbate-free diet contained an additional 2.5% DW cellulose instead of ascorbate. Newly molted fourth instars were assigned at random to the two diets. Larvae were fed with freshly prepared diets daily and kept in individual 35-ml plastic cups in a 23°C incubator (L16/D8). Upon molting to the fifth instar, larvae were frozen and then dried to determine their final weights. Initial larval dry weights were determined by using a fresh weight/dry weight ratio from newly molted fourth instars. Frass was collected and weighed after drying to completion (70°C). Previous work found no effects of ascorbate concentration on the approximate digestibility of an artificial diet (Lindroth and Weiss 1994), and therefore, frass production was measured to compare the amounts of each diet consumed. Relative egestion rate (RER) was defined as milligram frass per milligram initial body mass per day. Relative growth rate (RGR) was measured as milligram growth per milligram initial body mass per day. RER and RGR were measured on a dry mass basis.

The performance of first instars was measured on the control and transgenic genotypes. Newly hatched larvae were randomly assigned to each genotype (N=15 larvae/genotype). Larval fresh weights were measured to the nearest 0.01 mg on a Cahn 25 Electobalance (Cahn Instruments, Cerritos, CA, USA) and converted to dry weights based on fresh weight/dry weight ratios of five killed larvae. Larvae were kept in individual plastic cups, as described above. Leaf disks were prepared daily, also as described above. A moist filter paper was placed in each cup to maintain the water content of the leaf disks. To estimate the amount consumed by each larva, frass pellets were collected and dried daily (70°C) during the first instar. Upon molting to the second instar, larvae were frozen, dried, and weighed.

This experiment was repeated using newly molted fourth instars. To measure consumption, fresh weights of leaf disks fed to each larva were recorded, and fresh weight/dry weight ratios of representative leaf disks (N=5) from each genotype were measured daily to convert food fresh weights to dry weights. The difference between the dry weight of the food and the dry weight of the uneaten remains was defined as the amount consumed. Approximate digestibility (AD) was measured as (mg ingested−mg egested)/mg ingested× 100. Efficiency of conversion of digested matter to body mass (ECD) was measured as mg growth/(mg ingested − mg egested)×100. Efficiency of conversion of ingested matter to body mass (ECI) was measured as mg growth/mg ingested× 100 (Waldbauer 1968).

Third-instar *L. dispar* were used to compare larval performance on the intact plants of each genotype. The third instar was chosen to ensure that sufficient leaf material was available to complete this developmental stage. Newly molted larvae were weighed initially and placed at random on separate leaves in fine nylon mesh bags, which were tied

around the petioles. Trees were maintained in the greenhouse (16-hr photoperiod), and pots were rotated daily to provide even exposure of light and heat to all larvae. Five larvae were bagged (one larva per leaf) on four trees per genotype, using leaf LPI 12 through 16. Less than 5% of each leaf was eaten over a 4-d period. Frass was recovered from each bag at the end of the third instar and dried at 70°C. Larvae were frozen upon molting to the fourth instar and then dried to determine their final weights. Larval fresh weights at the beginning of the experiment were converted to dry weights using fresh weight/dry weight ratios from six representative larvae. RER was measured in lieu of RCR.

Statistical Analysis AO activity and ascorbate levels in the four genotypes were compared with one-way analysis of variance (ANOVA; SAS 2003). The normality of residuals was tested with Proc Univariate. Pairwise comparisons between genotypes were made by differences of least squares means (P=0.05 for *a priori* comparisons). To test the hypothesis that the control genotype differed from the three AO genotypes, these two groups were compared with contrasts (weighted as −3, 1, 1, 1) (Proc Mixed). Ascorbate concentrations in midgut fluids of larvae were compared across genotypes and by contrasts, as described above. Ascorbate levels in the foreguts and midguts of *M. sanguinipes* were compared with two-way ANOVA, using plant genotype and gut site as main effects. Ascorbyl radical levels in *L. dispar* fed AO-treated leaf disks were compared across treatment levels with one-way ANOVA. Comparison between levels of semiquinone radicals in *L. dispar* fed control genotype foliage treated with tannins and AO2 foliage treated with tannins were made with the Kruskal–Wallis test (Wilkinson 2000).

RCR, RER, RGR, and nutritional indices (AD, ECD, and ECI) were compared across artificial diets or tree genotypes with analysis of covariance (ANCOVA; Proc Mixed). Main effects used in all models were ascorbate level or tree genotype, respectively. ANCOVA models used to compare insect performance across poplar genotypes were as follows: RGRs were compared with growth rate as the dependent variable and initial dry mass as the covariate. RERs and RCRs were compared across treatments or genotypes with egestion rate or consumption rate as the dependent variable and initial dry mass as the covariate. Developmental times and growth were compared with one-way ANOVA (diet experiment) or ANOVA with contrasts (poplar experiments). ADs were compared by using frass production as the dependent variable and ingested mass as the covariate. ECDs were compared by using growth as the dependent variable and mass digested as the covariate. ECIs were compared with growth as the dependent variable and mass ingested as the covariate. In all cases, models testing for a significant interaction between the dependent variable and covariate were first tested to confirm that the regression slopes were parallel. To test the hypothesis that larvae on the control genotype differed from larvae on the three AO genotypes, these two groups were compared with contrasts, as described above. Where necessary, log or square root transformations were used to normalize residuals, and where indicated, statistical outliers were removed. Data that could not be transformed to meet the assumptions of ANOVA were analyzed with Kruskal–Wallis tests (Wilkinson 2000). Individual insects were used as replicates in all experiments.

Results

Transgenic poplars overexpressing the cucumber AO gene were produced by *Agrobacterium*-mediated transformation, and lines (genotypes) were selected based on transcript accumulation (Fig. 1) and elevated AO activity. AO activities (measured at pH 5.6) were increased by 14- to 37-fold in the transgenic genotypes compared with the control (wild type) genotype (Table 1). Sapling growth rates and leaf morphology showed no obvious differences between AO-overexpressing and untransformed lines when grown to a height of approximately 2 m. However, ascorbate levels in the AO-overexpressing genotypes were significantly lower by 19–54%, compared with the control genotype (contrast P=0.005; Table 1). Thus, AO activity was negatively correlated with ascorbate levels in the poplars (R^2=0.883; Fig. 2). However, when AO activity in AO-overexpressing leaves was measured in pH 10.0 reaction mixtures (representative of many caterpillar midguts), it was reduced to 9% of the activity at pH 5.6 (representative of caterpillar and grasshopper foreguts). Similarly, the activity of purified cucumber AO at pH 10.0 was only 5% of its activity at pH 5.6.

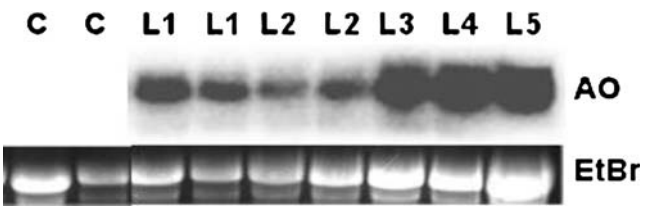

Fig. 1 Northern blot comparing expression of cucumber AO in control (wild type) and transgenic poplar. The blot was probed with a ^{32}P-labeled fragment of the AO-coding sequence. Ethidium bromide-stained ribosomal RNA bands (*EtBr*) are shown as loading controls. *C* refers to untransformed control lines and *L1–L5* represent confirmed AO-overexpressing lines. Lanes with different designations are from independently transformed lines, and lanes sharing the same designation represent separate individuals from the same line. *L1*, *L4*, and *L5* were used in subsequent experiments and were designated genotypes AO1, AO2 and AO3, respectively. No AO RNA bands were visible in the control lines

Table 1 Ascorbate oxidase (AO) activity and ascorbate levels in control (wild type) and transgenic poplar genotypes

Genotype	Ascorbate oxidase (μmol min^{-1} g FW^{-1})	Ascorbate (μmol/g FW)
Control	17.1±3.3a	6.8±0.6c
AO1	276.5±73.3b	5.5±0.5bc
AO2	642.5±67.2c	3.1±0.8a
AO3	250.3±76.8b	4.4±0.8ab
Significance of effects		
Genotype	$P<0.001$	$P=0.008$
Contrast	$P<0.001$	$P=0.005$

Samples of each genotype were analyzed from five dates for ascorbate oxidase and seven dates for ascorbate.

When *L. dispar* larvae consumed leaves from the control or AO-overexpressing genotypes, ascorbate levels did not differ in their midgut contents when contrasted between both types (Fig. 3; $P=0.480$). Thus, AO activity in the control and AO-overexpressing genotypes was not associated with larval ascorbate levels ($R^2=-0.112$). Regardless of the genotype ingested, ascorbate in the midgut contents dropped to only 7.0% (±0.5) of foliar ascorbate levels. Similarly, in *M. sanguinipes*, there were no significant differences between ascorbate levels in the foreguts of adults on control or AO leaf disks (3.0±0.7 and 3.2±0.7 mM, respectively) or in the midguts of adults on control or AO leaf disks (0.16±0.03 and 0.16±0.04 mM, respectively; genotype effect $P=0.818$). Foreguts contained more ascorbate than midguts (gut site effect, $P<0.001$), but there was no significant genotype×gut site interaction ($P=0.830$).

Contrary to expectation, *L. dispar* that fed on AO leaf disks coated with tannins did not have significantly higher levels of oxidative stress than larvae that fed on control genotype leaf disks treated with tannins. Semiquinone

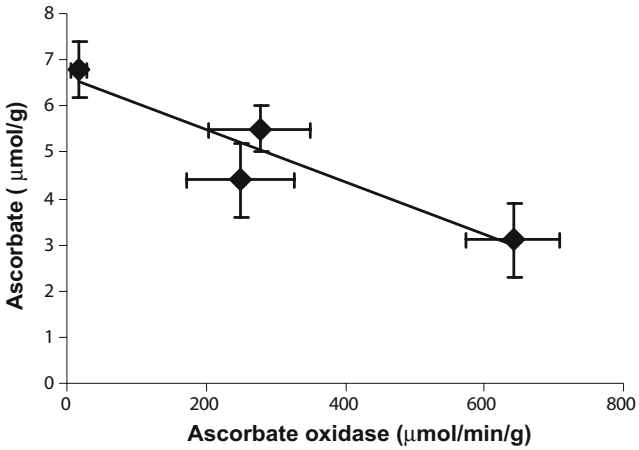

Fig. 2 Negative association between AO activity and ascorbate levels in control and AO-overexpressing poplar leaves ($R^2=0.883$). Standard error bars are presented

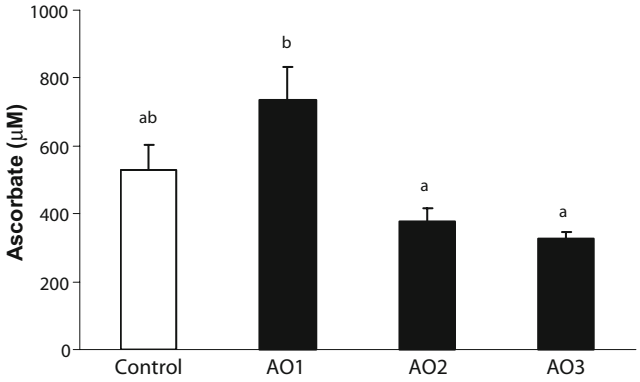

Fig. 3 Ascorbate concentrations in the midgut fluids of fourth-instar *Lymantria dispar* larvae after feeding on control or AO poplar genotype leaf disks. No significant differences were observed between larvae that fed on AO genotypes compared to the control genotype (contrast $P=0.480$)

radical concentrations in the midgut contents were 10.6±1.5 and 8.9±1.7 μM in larvae on the AO transgenic and control genotype foliage, respectively ($P=0.233$). The consumption of AO-coated leaf disks also had no significant effect on oxidative stress in the midgut; similar levels of ascorbyl radicals were present in the midgut across AO treatment levels in the first experiment (229–293 nM; $P=0.644$) and in the second experiment (119–147 nM; $P=0.831$). A similar experiment performed on final-instar *Orgyia leucostigma* larvae also showed a lack of effect from feeding on AO-treated leaf disks ($P=0.570$; unpublished data). No further work was performed on the potential effects of elevated AO levels in transgenic poplar on oxidative stress, since there was no effect of elevated AO levels on ascorbate or phenolic oxidation in *L. dispar* larvae.

When *L. dispar* larvae consumed artificial diet that lacked ascorbate, their performance was significantly decreased: weight gain decreased, developmental time increased, and RGR decreased (Table 2). Relative egestion rate was also decreased in larvae on the ascorbate-free diet, potentially explaining their decrease in performance. However, an analysis of larval growth rate adjusted for frass production (ANCOVA; Fig. 4) demonstrated that the effect of ascorbate was primarily post-ingestive. For any given level of frass production (directly proportional to consumption), larvae on the ascorbate-containing diet had higher growth rates than did larvae on the ascorbate-free diet.

Relative egestion rates did not differ between first-instar caterpillars on the control genotype and the AO-overexpressing genotypes (contrast $P=0.161$; Table 3), suggesting that consumption rates did not differ as a result of AO overexpression. Relative growth rates of first-instar caterpillars also did not differ significantly between larvae on the control genotype and the AO-overexpressing genotypes (contrast $P=0.515$). Similarly, third instars that fed in mesh bags on intact saplings also showed no effect of the high

Table 2 Effects of ascorbic acid on fourth-instar *Lymantria dispar* performance on artificial diets

Diet	Relative egestion rate	Growth (mg)	Development time (days)	Relative growth rate	*N*
+Ascorbic acid	0.881±0.159b	16.1±3.2b	5.1±0.8a	0.349±0.072b	14
−Ascorbic acid	0.548±0.156a	9.6±0.8a	7.0±0.4b	0.143±0.068a	15
Significance of effects					
Diet	$P<0.001$	$P<0.001$	$P=0.004$	$P<0.001$	

Larvae were fed artificial diets. Comparisons of RER and RGR were made using ANCOVA, with initial dry weight as the covariate.
RCR=mg ingested/mg initial body mass/day; RGR=mg growth/mg initial body mass/day

AO activities in the transgenic genotypes on their RER (contrast $P=0.411$) or RGR (contrast $P=0.760$; Table 4). It was assumed that AO activities were unaffected by larval feeding, since no evidence of AO induction by caterpillars has been observed in hybrid poplar (Major and Constabel 2006; Ralph et al. 2006). Finally, the consumption and growth rates and nutritional indices (AD, ECD, and ECI) of fourth instars did not differ when contrasted between the control and AO-overexpressing genotypes (contrast P's$\geq$ 0.690; Table 5). Unlike larvae on an artificial diet without ascorbate, larval growth and developmental times were not significantly altered in *L. dispar* on AO-overexpressing genotypes (data not shown).

Discussion

Contrary to our hypothesis, elevated AO levels in ingested leaf tissues did not compromise the ascorbate-based antioxidant defenses in the midgut lumen of *L. dispar*. As a result, no synergistic interactions were found between AO and tannins on oxidative stress levels in the midguts of *L. dispar*. Neither ingested AO purified from *Cucurbita* or overexpressed in poplar were able to change ascorbate or ascorbyl free radical levels in the midguts of *L. dispar*. Similarly, consumption of AO-overexpressing poplar leaves by the grasshopper *M. sanguinipes* had no impact on levels of ascorbate along the length of its gut. It is noteworthy that ascorbate levels in the guts of *M. sanguinipes* that fed on wheat leaves (Barbehenn 2003) were similar to levels measured in this study on poplar, suggesting that poplar does not have an unusual impact on the post-ingestive fate of ascorbate. The large drop in ascorbate levels observed in the midguts of *L. dispar* on poplar are presumed to be the result of ascorbate oxidation by non-AO reactions, since such decreases in ascorbate concentration can also occur in the midguts of caterpillars feeding on an artificial diet (Barbehenn et al. 2001).

Larval performance was unaffected by high levels of AO, consistent with the inability of ingested AO to oxidize ascorbate in the midgut contents of the tested caterpillars. The results of our artificial diet study suggest that, had AO greatly decreased ascorbate levels available to *L. dispar* larvae, performance would have been decreased as a result of post-ingestive effects on growth rates (Horton and Redak 1993; cf. Lindroth and Weiss 1994). The lack of effect of high levels of AO on midgut ascorbate levels, oxidative stress, or performance calls into question how AO might function more effectively in a wide variety of other plant–insect interactions.

The low levels of oxygen present in the guts of caterpillars and grasshoppers may limit post-ingestive AO

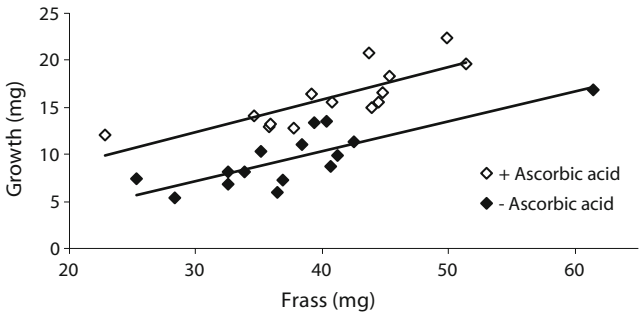

Fig. 4 Effect of ascorbate on growth of fourth-instar *Lymantria dispar* larvae on artificial diets. Previous work showed no effect of ascorbate on the digestibility of the diet, so frass was measured as an estimate of ingestion. In this case, ANCOVA on growth using frass as a covariate provides a comparison of food utilization efficiencies analogous to comparing ECI (efficiency of conversion of ingested matter to body mass)

activity in these herbivores. The K_m of AO for oxygen is 0.5 mM (Strothkamp and Dawson 1978), while midgut oxygen levels in caterpillars are commonly on the order of 0–0.01 mM, and the foregut and midgut of *M. sanguinipes* have lower oxygen levels than are found in most caterpillars (Johnson and Barbehenn 2000). The large foregut of *L. dispar* has a relatively high oxygen level compared with the foreguts of other caterpillars (approximately 0.06 mM in larvae on artificial diet). However, our results showed that any potential AO activity in the foregut had an inconsequential effect on the levels of ascorbate available to *L. dispar* for absorption or antioxidant defense of the midgut. Other taxa of insect herbivores that have been examined to a more limited extent, including a beetle (Coleoptera) and several grasshoppers, also have nearly anoxic gut contents (Johnson and Barbehenn 2000; Krishnan et al. 2007).

A second factor that also may limit AO activity in the midguts of caterpillars is high pH. At the extremely basic pH typical of caterpillar midguts (e.g., pH 10), rates of ascorbate oxidation by AO from transgenic poplar and *Cucurbita maxima* were reduced to less than 10% of their rates at an acidic pH (Maccarrone et al. 1993; this study). However, the lack of extensive AO activity in the acidic foreguts of either *L. dispar* or *M. sanguinipes* suggests that low oxygen level may be the main factor limiting the oxidation of ascorbate by ingested AO.

If post-ingestive conditions limit AO activity, pre-ingestive AO activity would be a plausible alternative mode of action. Neither oxygen nor high pH would limit AO activity at a herbivore-damaged leaf edge or during ingestion. However, if pre-ingestive AO activity were an important defense mechanism, one might expect greater treatment effects than were observed in this study. No AO effects on the performance of *L. dispar* were observed for neonate and fourth instars on leaf disks or for third instars on intact saplings.

Since high AO levels in the AO-overexpressing genotypes were not able to eliminate ascorbate in the midgut in either of the species tested in this study, our conclusions differ substantially from previous work on the potential role of AO as an inducible plant defense (Felton and Summers 1993). Previous work on induced plants did not isolate the effects of AO from those of other enzymes and non-enzymatic defenses (e.g., Bi et al. 1997). It is possible that effects ascribed to AO previously, such as the loss of ascorbate from the midgut contents of *H. zea* larvae, were produced by other enzymes that can function in the caterpillar midgut, such as peroxidases (unpublished data). It is also unclear to what extent the damage caused to nutrients by AO activity *in vitro* in oxygenated solutions is relevant to the low-oxygen conditions found *in vivo*. Finally, measurement of AO activity in the gut contents of caterpillars presents a quandary, since assays for AO are done at ambient oxygen levels, but AO in the gut is present at nearly anoxic levels. Presumably, the low levels of AO activity measured in the gut lumen and regurgitate of *H. zea* would be even lower or negligible in the low-oxygen conditions found *in vivo*.

Table 5 Effects of AO-overexpressing poplars on fourth-instar *Lymantria dispar* performance

Genotype	RCR	RGR	AD	ECD	ECI	*N*

[a] Contrast between control genotype and three AO genotypes

A variety of ecological functions of induced AO have been examined recently, including responses to stresses such as wounding, pathogens, salinity, and heat (Bi et al. 1997; Sanmartin et al. 2003, 2007; Yamamoto et al. 2005; Fotopoulos et al. 2006; Pignocchi et al. 2006). AO activity in damaged or infected leaf areas would potentially increase the effectiveness of oxidative defenses against microbes that gain entry via insect-feeding sites (e.g., Harris et al. 1980). The formation of ROS is part of the antimicrobial response in plants (Bolwell and Wojtaszek 1997). With decreased ascorbate levels, oxidases such as polyphenol oxidase and peroxidase would have increased net rates of production of quinones and other ROS. Therefore, it may be difficult to distinguish between anti-pathogen and anti-herbivore reactions when plant stress responses such as AO are induced.

In summary, the lack of effect of elevated levels of AO in poplar on ascorbate or ascorbyl radical levels in the midgut contents of *L. dispar* is consistent with the lack of effect of elevated levels of AO on larval performance. The lack of effect of AO on ascorbate levels in the grasshopper *M. sanguinipes* suggests that AO activity is also limited in the guts of insects with acidic pH. As in previous work on polyphenol oxidase-overexpressing poplars (Barbehenn et al. 2007), we conclude that low oxygen levels appear to limit the effectiveness of these oxygen-dependant enzymes as post-ingestive defenses against a variety of leaf-chewing insects.

Acknowledgments This project was supported by the National Research Initiative of the USDA Cooperative State Research, Education and Extension Service, grant number 2004-35302-14840 to RVB and CPC. We thank Juha-Pekka Salminen for providing pedunculagin and pentagalloyl glucose, John Tanner for providing *L. dispar* eggs, Stefan Jaronski for providing *M. sanguinipes* eggs, Cara Mozola for measuring AO activity, Grace Lee for measuring ascorbate, and Robin Mellway for assistance in transforming the poplar.

response to root feeders (Gange and Brown 1989; Masters et al. 1993), or the induction of secondary metabolites (Bezemer et al. 2003, 2004). However, these studies focused on tissue feeding root herbivores. In contrast, nematodes such as the gall-forming *Meloidogyne* spp. act as a metabolic sink that directs nutrients to the site of nematode parasitism (Burgeson 1966; McClure 1977).

Secondary plant compounds often have a negative effect on non-adapted herbivores (Karban and Baldwin 1997). Cotton (*Gossypium* spp.) produces a variety of terpenoids that exhibit toxicity to a wide range of herbivores and pathogens (Stipanovic et al. 1990; Bezemer et al. 2004; Wang and Plhak 2004; Xu et al. 2006). Gossypol, a triterpene aldehyde, is found in the roots, foliage, and seed of the cotton plant. Additionally, the terpenoids desoxy-hemigossypol and hemigossypol are present in the roots. Further, so-called gossypol-like terpenoid compounds such as hemigossypolone, heliocide H1, heliocide H2, heliocide H3, and heliocide H4 are found in cotton leaves, flower buds, and seeds. The latter compounds are called heliocides because of their toxicity to *Heliothis* (Nazarova et al. 1981).

Plants may also feature indirect induced defenses that enhance the performance of herbivore natural enemies, rather than acting on herbivores directly. These inducible mechanisms include the production of extrafloral nectar that leads to the recruitment of sugar-seeking carnivores (Wäckers et al. 2001), and the emission of plant volatile chemicals in response to herbivore feeding and egg deposition that serve as signals that allow natural enemies to locate prey (reviews in Röse and Tumlinson 2004; Turlings and Wäckers 2004; Rasmann et al. 2005). In cotton, *Gossypium hirsutum* L. (Malvaceae), much is known about constitutive and induced defenses (Wäckers et al. 2002; Röse and Tumlinson 2004; Anderson and Agrell 2005). Many of the herbivore-induced volatiles involved in cotton defenses have been identified and characterized, including the timing and location of release, and tissue-specific and herbivore-specific release (reviews in Röse and Tumlinson 2004). Recent studies also have shown that nitrogen levels in cotton affect the release of these volatile attractants (Olson et al., unpublished).

Most of the work on below- and aboveground interactions has focused on tissue-feeding herbivores. However, van Dam et al. (2005) found that the migratory endoparasitic root lesion nematode species, *Pratylenchus penetrans* Cobb (Tylenchida: Pratylenchidae), reduced the quality of *Brassica nigra* L. Koch (Brassicaceae) for the larval shoot herbivore species, *Delia radicum* L. (Diptera: Anthomyiidae). This reduction was attributed to enhanced production of phenolics and glucosinolates in shoot tissues following root and shoot feeding. Mateille (1994) reviewed the relatively sparse literature on the mechanisms of plant defense in response to migratory root nematode species and generalized the reactions of hormonal metabolism that produce toxins into those that: (1) are directly toxic to the nematode, (2) regulate defense reactions, and (3) modify tissue development.

In this study, we looked at the sedentary, gall-forming root-knot nematode species, *Meloidogyne incognita* (Kofoid and White) Chitwood. Root-knot nematodes are sedentary endoparasites that retard growth and development of cotton by parasitizing the root system, causing galling, stunting, and other adverse effects (Khoshkhoo et al. 1993). Root-knot nematode parasitism reduces the rate of photosynthesis in plants (Melakeberhan et al. 1987). Although parasitism reduces the rate of nitrogen uptake by roots (Vaast et al. 1998), plants accumulate nitrogen in the parasitized root tissues (Hunter 1958; Shafiee and Jenkins 1963; Burgeson 1966). The effects of root-knot nematode parasitism on the nitrogen content in shoots are not consistent with the parasitism that was reported to increase the percentage nitrogen (Melakeberhan et al. 1985), to have no effect (Hunter 1958; Shafiee and Jenkins 1963), or to decrease the percentage (Mohanty et al. 1990).

In this study, we evaluated whether a root-parasitic nematode (*M. incognita*) and a foliar-feeding insect (*Helicoverpa* (=*Heliothis*) *zea* (Boddie)) interact to affect the direct and indirect defenses of cotton. Our specific objectives were to determine if:

- foliage feeding, root feeding, or their combination affects attraction of the parasitic wasp *Microplitis croceipes* Cresson (Hymenoptera: Braconidae) to cotton plants. The braconid wasp is a solitary and specialized larval parasitoid of *Heliothis* and *Helicoverpa* species;
- terpenoids are induced in cotton plants (whole plant, leaf and root tissue) through foliage feeding, root feeding, or their combination;
- commonly induced volatiles from aboveground herbivore damaged cotton are affected by belowground parasitism by the nematode *M. incognita;*
- the nitrogen level in cotton leaves or petioles is affected by *M. incognita* root parasitism.

Methods and Materials

Insects Corn earworm, *Helicoverpa zea*, were reared at 28° C, 50–70% (RH), and a 16:8 hr L/D photoperiod, as described by Burton (1969). *Microplitis croceipes* were reared on *H. zea* larvae according to the method of Lewis and Burton (1970). *Meloidogyne incognita* inoculum was collected from tomato roots (*Lycopersicon esculentum* Mill. cv. Rutgers) by agitating roots in 0.5% sodium hypochlorite solution for 2 min (Hussey and Barker 1973) approximately 1 hr before inoculation.

Plants Deltapine 5690 cotton plants (*G. hirsutum* L.) were grown in Promix® for 3 wk and transferred to pots (15 cm diameter) with sterilized soil, Tifton sandy loam with 82% sand, 11% clay, 7% silt, and less than 1% organic matter. One gram of ammonium nitrate crystals was added to the soil at transplant and watered with 100 ml of water. Plants were watered as needed over the next 6 wk. For the volatile collections, a single third instar of *H. zea* was placed on each of three mid-level leaves per plant and clipped to the leaf for 2 d with a 23.76-cm^2 cage, with the connecting inner sides of the cage lined with foam to prevent additional leaf damage. The outsides were covered with screen mesh. After the volatile collections, larvae were replaced on the plant for an additional day for the flight tunnel bioassays and the plant tissue analyses. Cages were used to standardize the level of aboveground herbivory: approximately 75% of the leaf area in the cage was consumed by the time of the air sample collection, and approximately 85% of the leaf tissue was consumed at the time of the flight tunnel bioassays and plant tissue collection regardless of treatment. For those treatments that included nematode parasitism, inoculum of 20,000 *M. incognita* race three eggs/pot (approximately 800 eggs/150 cm^3 soil) was distributed into two holes (approximately 2.5 cm deep) and covered with soil when plants were 3 wk old. Pots were watered immediately following inoculation.

When plants were 9-wk-old, they were excised above the point of damage so that four to five leaves remained. Plant tops were placed in a 125-ml glass flask filled with water for the wind tunnel bioassays (below). Prior to the bioassay, a single mature leaf and an immature leaf above the damaged leaves, and a root sample were excised from each plant for the analyses of gossypol and gossypol-like compounds. Nematode damage was classified on a scale of 1 to 10 based on the percentage of the root surface with galls (0=no galling, 1=1–10% of the root surface galled, 2=11–20% of the root surface galled, etc., with 10=91–100% of the root surface galled).

Volatile Collections After 48 hr of herbivore feeding, 9-wk-old plants were placed under a modified 9-l Kimax beaker with the bottom removed and a glass top with a 6.2-mm outlet added. The top 30 cm of each plant was placed within the beaker. This area included the damaged part of the plant. Thus, plant volatiles were collected from the damaged and undamaged parts of the plant after removal of the larvae. At the bottom of the beaker, the plant main stem was guillotined by two Teflon plate halves with a hole in the center, and glass wool was used to fill in space around the main stem. Zero air was introduced into the beaker and adjusted with a panel-mount flow meter (Gilmont GF 6341–1115) to 2.0 l/min. Sample air was pumped out of the beaker from the top with a vacuum pump (Barnant, Model 420-1901) and adjusted to 400 ml/min with a mass flow controller (Aalborg Model AFC2600D). Sampled air was pulled through 1,000 mg of desiccant, followed by 100 mg of SuperQ (Supelco) adsorbent material to trap volatile compounds. Volatiles were trapped on the SuperQ absorbent material for 3 hr for a total of 36 l of air through the trap. Air samples were collected from 12:00 to 3:00 P.M. from a total of 16 plants (four plants per treatment). Collections from plants damaged for 48 hr were made from two treatment plants per day over 8 d. Each treatment was randomly assigned to collection chamber and day of collection. Two additional collections were made without plants as controls for non-plant contamination.

Volatile Extraction and Analyses Adsorbent tubes were eluted with 10 ml of methylene chloride. Eluents were concentrated under a stream of N_2 gas to approximately 0.1 ml. Extracts were then transferred to 0.25-ml glass inserts inside 2-ml autosampler vials. Extract volume was determined by weight. As internal standard, 1 µg methyl palmitate (Sigma-Aldrich, St. Louis, MO, USA) was added to each extract.

GC/MS A ThermoFinnigan DSQII (San Jose, CA, USA) gas chromatograph-quadrupole mass spectrometer was used. The oven was fitted with a 30 × 0.25 mm (i.d.) DB-5 fused silica capillary column (Agilent, Santa Clara, CA, USA). The liquid film thickness of the column was 0.25 µm. Helium carrier gas flow was maintained 1.0 ml min^{-1}. The initial oven temperature (40°C) was held for 1 min. Temperature was then increased to 220°C at 4°C min^{-1} and held for 4 min. Splitless injections were made by using an autosampler with the injection port temperature held at 220°C. Ionization was by electron impact (70 eV) with full scans (m/z^+=33 to 300) made every 0.5 sec. Prior to use, the mass spectrometer was tuned to meet performance criteria for perfluorotributylamine. Authentic standards of a mixture of (α)- and (β)-ocimene (International Flavors and Fragrances, New York, NY, USA), which we refer to as ocimene 1 and ocimene 2, trans-(β)-farnesene (ChromaDex, Irvine, CA, USA), linalool (TCI America, Portland, OR, USA), and indole (Spectrum Chemical MFG CORP., Gardena, CA, USA) were analyzed. Tentative structural assignments for (*E*)-4, 8-dimethyl-1, 3, 7-nonatriene and (*E, E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene were based on comparison to published mass spectra (Maurer et al. 1986). Tentative assignments for (*Z*)-3-hexenyl acetate and (α)-farnesene were made by comparison to the NIST/EPA/NIH Mass Spectral library version 2.0 (NIST, Gaithersburg, MD). Quantification of all compounds was by electronic integration of the base peaks of their mass spectra. The one exception was linalool. In this case, a secondary ion, m/z^+=

93, was used. This was done since linalool was found to co-elute with *n*-undecane, a compound present in all extracts. This ion was prominent in the mass spectrum of linalool (60% of the base peak) as it is in mass spectra of most terpenoids, and it is generally not detected (<0.1% of the total ion current [TIC] of *n*-alkanes such as *n*-undecane). The *n*-undecane contribution to "linalool-undecane" peaks in total ion current (TIC) chromatograms shown in the text was substracted by computing the relative contribution of $m/z^+=93$ to the TIC in the spectrum of our linalool standard and then adjusting the TIC for the peak accordingly.

Nitrogren Analyses A set of eight plants with treatments similar to those used in the bioassays had the leaf and petiole removed from the fifth mature leaf (above the damaged leaves) from the top of the plant. Percent nitrogen was calculated on a per gram weight basis of dried plant material.

Wind Tunnel and General Bioassay Procedure The wind tunnel used in the experiments was described by Drost et al. (1988). All flight responses were tested at 26–28°C, a wind speed of 55 cm/sec, and a light intensity of 2,000 lx. Female *M. croceipes* were mated, fed, and were 3-d-old at the time of the experiments. Each female was allowed to antennate frass of *H. zea* larvae fed on pinto bean diet for 10 sec, given a single sting on a third-instar pinto bean-fed *H. zea* larva, and placed immediately in the wind tunnel 80 cm downwind of the dual choice tests. The dual choices were: 1) control (no damage) vs. *H. zea* damaged plants; 2) control vs. *M. incognita* damaged plants; 3) *H. zea* plus *M. incognita* damaged plants vs. *M. incognita* damaged plants; and 4) *H. zea* plus *M. incognita* damaged plants vs. *H. zea* damaged plants. Each female was used only once, and plants were switched in position after each female tested to minimize potential variance from any side of wind tunnel preferences. Females were given three opportunities to fly upwind and land on a plant. Individuals that failed to do so within 5 min were recorded as no choice. A total of 20 females was tested per dual choice with five females tested per day over a total of 4 d. Fresh plants (9-wk-old) that had 3 d of feeding damage were used each day. Days and/or plants served as replication.

Plant Tissue Analysis All leaf and root material was freeze-dried, ground, and extracted individually for terpenoid analysis. Plant tissues were collected from a total of eight plants per treatment. The methods of sample preparation and HPLC analyses were as described by Bezemer et al. (2004).

Statistics *Chi*-square analyses were used to test the effect of treatment on female parasitoid choice, and analysis of variance (ANOVA) was used to test for effect of treatment on gossypol and gossypol-like compound levels, percentage nitrogen in leaf and petiole samples, and the induced volatiles (i.e., induced terpenes, (*Z*)-3-hexenyl acetate, and indole) (SAS Institute 1998). We log-transformed quantities of volatile terpenes and (*Z*)-3-hexenyl acetate (Levene's test $P>0.117$). No transformation stabilized the variance for indole quantities, but we report the results of the untransformed data.

Results

Microplitis croceipes females chose the corn earworm damaged plants more often than the undamaged control plants (Fig. 1a, $\chi^2=8.89$, $df=1$, $P<0.003$) or the root-knot damaged plants (Fig. 1b, $\chi^2=7.12$, $df=1$, $P<0.008$). There were no significant differences in female choices between

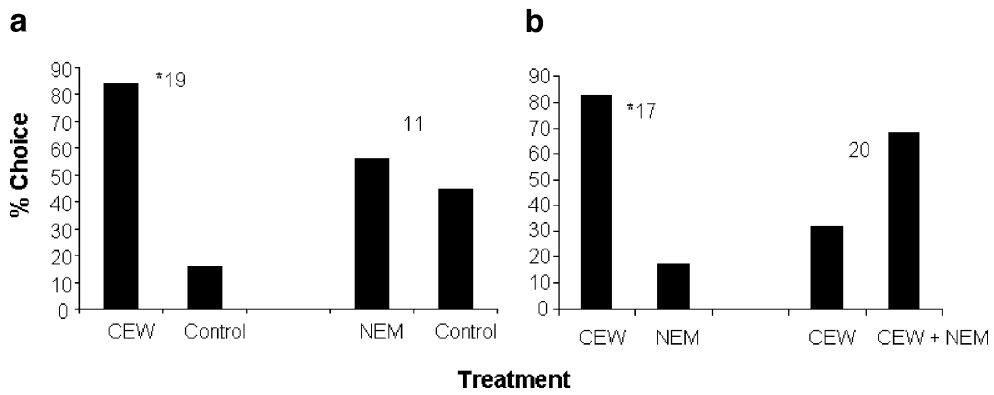

Fig. 1 Percentage flight and landing response to choice of plants damaged by (**a**) corn earworm (*CEW*) and root-knot nematodes (*NEM*) vs. undamaged (*Control*), or plants damaged by (**b**) root-knot nematodes vs. corn earworm, and root-knot nematodes and corn earworm vs. corn earworm only. *Asterisks* indicate statistical significance at $P<0.05$. Numbers *above the bars* are number of females making choices out of a total of 20 females tested

the root-knot nematode damaged and control plants (Fig. 1a; χ^2=0.09, *df*=1, *P*=0.763), nor between plants damaged by corn earworm and those damaged by corn earworm and root-knot nematode (Fig. 1b, χ^2=2.57, *df*=1, *P*=0.108). Root gall ratings of plants damaged by root-knot nematodes varied between 4 and 8 on a 0-to-10 scale (mean ± SD = 6.5±1.2), indicating moderately severe to severe damage.

There were no significant differences in the nitrogen levels from the leaf and petiole samples across treatments (Table 1). Furthermore, root gossypol levels did not differ across treatments (Fig. 2, $F_{3,\ 28}$=0.52, *P*=0.669). Hemigossypolone ($F_{3,\ 28}$=0.02, *P*=0.995), gossypol ($F_{3,\ 28}$=0.27, *P*=0.844), heliocide H1+4 ($F_{3,\ 28}$=0.15, *P*=0.928), heliocide H2 ($F_{3,\ 28}$=0.11, *P*=0.954), and heliocide H3 ($F_{3,\ 28}$=0.23, *P*=0.877) levels in mature leaves and hemigossypolone ($F_{3,\ 28}$=0.44, *P*=0.723), gossypol ($F_{3,\ 27}$=0.44, *P*=0.723), heliocide H1 + 4 ($F_{3,\ 28}$=0.14, *P*=0.142), heliocide H2 ($F_{3,\ 28}$=0.16, *P*=0.922), and heliocide H3 ($F_{3,\ 28}$=0.13, *P*=0.940) levels in immature leaves also did not differ significantly across treatments (Fig. 2).

There was an effect of plant treatment on the release of volatile terpenes ($F_{3,\ 10}$=24.71, *P*<0.001). Plants damaged by corn earworm only and corn earworm plus nematodes had a higher release of volatile terpenes than those plants damaged by nematodes only and undamaged plants (Fig. 3, Table 2). These terpenes were ocimene 1, ocimene 2, linalool, (β)-farnesene, (α)-farnesene, (*E*)-4, 8-dimethyl-1, 3, 7-nonatriene, and (*E, E*)-4, 8, 12-trimethyl-1, 3, 7, 11-tridecatetraene. Plants damaged by nematodes had chemical profiles for volatile terpenes similar to control plants (Fig. 3, Table 2). Chemical analyses of the headspace of "non-plant collections" indicated no contamination within the system.

Plant treatment affected the release of (*Z*)-3-hexenyl acetate ($F_{3,\ 10}$=14.86, *P*<0.001). Plants damaged by corn earworm plus nematodes had significantly higher release rates of (*Z*)-3-hexenyl acetate than those plants damaged by nematodes only, corn earworm (CEW) only, and undamaged plants (Fig. 3, Table 2).

Plants damaged by corn earworm and corn earworm plus nematodes had a higher release of indole than those plants damaged by nematodes only and undamaged plants (Fig. 3, Table 2). Plants damaged by nematodes showed levels of release of indole similar to control plants (Fig. 3, Table 2).

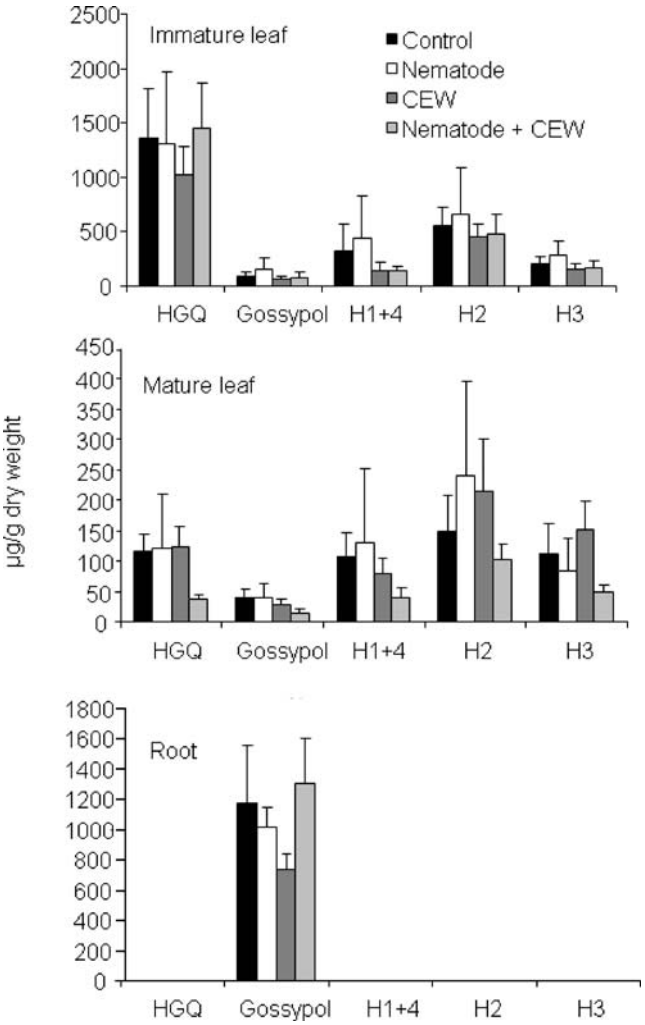

Fig. 2 Mean ± SE µg g^{-1} dry weight hemigossypolone (*HGQ*), gossypol, heliocide 1 plus heliocide 4 (*H1+H4*), heliocide 2 (*H2*), and heliocide 3 (*H3*) in immature leaves, mature leaves and roots of *Gossypium hirsutum* plants not damaged (Control), damaged by root-knot nematodes (Nematode), damaged by corn earworm larvae (CEW), and damaged by root-knot nematodes and CEW larvae (Nematode + CEW). *N*=8

Table 1 Nitrogen (mean percentage of dry weight ± SD) in leaf and petiole samples of the fifth mature leaf from the top of a cotton plant (9 wk after planting)

Treatment	Leaf (% *N*)	Petiole (% *N*)
CEW	3.10±0.11	1.33±0.18
CEW + NEM	2.91±0.20	1.30±0.29
NEM	2.81±0.29	1.21±0.17
CON	2.96±0.24	1.08±0.09

N=8.
CEW corn earworm leaf damage, *CEW + NEM* corn earworm and root-knot nematode damage, *NEM* root-knot nematode damage, *CON* no damage

Discussion

Bezemer et al. (2003) found increased levels of gossypol and gossypol-like compounds in immature leaves of *Gossypium herbaceum* (L.) in response to feeding damage
