EDITORIAL NOTES

Note from the Editor-in-Chief

Since the Journal's inception, it has been printed in a 6×9-in. format. In 2002, the cover appearance was modified, but this issue (January, 2008) is the first substantive change. The new 8.5×11-in. format with two-column text will allow us to better accommodate large figures and tables. Additionally, each cover will now have a color photograph that relates to an article contained in that issue. We invite authors to submit color photographs for consideration *after* an article has been accepted. These should be sent directly to the Journal e-mail jce@chuma1.cas.usf.edu.

The process of electronic submission of articles through our Editorial Manager system https://www.editorialmanager.com/joce/default.asp, and the practice of "Online First" publication, followed by electronic and hard copy issues will continue without change.

We believe that all of these are positive changes that will be welcomed by authors and readers.

The Defensive Role of Volatile Emission and Extrafloral Nectar Secretion for Lima Bean in Nature

Christian Kost · Martin Heil

Received: 9 August 2007 / Revised: 3 November 2007 / Accepted: 14 November 2007 / Published online: 12 December 2007

Abstract Lima bean (*Phaseolus lunatus*) features two indirect anti-herbivore defenses—emission of volatile organic compounds (VOCs) and secretion of extrafloral nectar (EFN)—which are both inducible upon herbivore damage. In a previous field study, Lima bean benefited from the simultaneous induction of the two defenses, yet it remained unclear whether both had contributed to plant protection. Our experimental approach aimed at studying the defensive role of both indirect defenses simultaneously. Tendrils were sprayed with jasmonic acid (JA) to induce both defenses, and performance was compared to that of others that were treated with a synthetic blend of either EFN or VOCs. Confirming earlier results, JA treatment and application of the VOC mixture induced EFN secretion in treated tendrils in quantitatively similar amounts. The composition of the applied synthetic blend of EFN was adjusted to match the concentration of EFN secreted from JA- and VOC-treated tendrils. Repeated application of either enhanced the performance of several fitness-relevant plant parameters such as growth rate and flower production. Tendrils treated with JA showed a similar trend, yet some fitness-related parameters responded less to this treatment. This suggests a minor importance of any putative JA-dependent direct defense traits or higher costs of JA-elicited responses as compared to VOCS and EFN, as otherwise JA-treated tendrils should have outperformed VOC- and EFN-treated tendrils. Moreover, the beneficial effect of applying synthetic EFN alone equaled or exceeded that of VOCs and JA. Ants were by far the dominant group among the arthropods that was attracted to JA-, VOC-, or EFN-treated tendrils. The results suggest that EFN plays a more important role as an indirect defense of lima bean than VOCs or any other JA-responsive trait.

Introduction

Plants respond to herbivore attack with an array of changes in plant chemistry, morphology, and physiology, which frequently result in the increased resistance of plants to further attack (Karban and Baldwin 1997). Induced resistance may be caused by direct effects on the herbivore through plant-derived toxic metabolites or anti-digestive and anti-nutritive compounds. Furthermore, plants may utilize indirect defenses that facilitate top-down control of

herbivore populations by the herbivore's predators and parasitoids (Price et al. 1980).

One way a plant may attract beneficial arthropods is by providing suitable food sources such as extrafloral nectar (EFN; Koptur 1992). EFN is an aqueous solution, with sugars and amino acids being the most abundant solutes (Ruffner and Clark 1986; Galetto and Bernardello 1992; Heil et al. 2000), which is secreted from specialized organs, the extrafloral nectaries. In addition, plants may increase the emission rate of volatile organic compounds (VOCs) in response to herbivore attack. VOCs can serve as a cue that guides foraging parasitoids and predators to the feeding herbivore (Turlings et al. 1990; Paré and Tumlinson 1997). The composition of the herbivore-induced volatile blend depends not only on the plant species or cultivar but also varies with the species and even the larval stage of the herbivore (for review, see Arimura et al. 2005), thus providing highly reliable signals to the members of the third trophic level.

In many cases, plants do not rely on a single defense strategy but employ a complex array of different defensive mechanisms. For example, several plant species feature both VOC emission and EFN secretion (Arimura et al. 2005). The presence of two indirect defenses within one individual plant gives rise to the questions whether both defenses contribute to plant fitness and how they interact in attracting beneficial arthropods (Price et al. 1980). Studies on the benefit of indirect defense traits in nature are generally rare (but see Thaler 1999 and Kessler and Baldwin 2001). No study to date has tried to study the defensive roles of two indirect defenses within one plant species simultaneously.

The lima bean (*Phaseolus lunatus*) is a common model system in studies on induced indirect defenses. Heil (2004b) showed that plants growing in the wild, which had been induced by exogenous application of the phytohormone jasmonic acid (JA), responded by increasing both their VOC emission and EFN secretion. The application of JA repeatedly (i.e., every 3 days) resulted in benefits for the treated plants as reflected by a decreased herbivory rate and an increased seed set. However, JA also affects fitness-relevant processes such as fruit development and ripening (Creelman and Mullet 1997). Thus, the multiple effects constrain the interpretation of the observed morphological changes as being exclusively attributable to induced defenses. Furthermore, Kost and Heil (2005) demonstrated that an artificial increase of the amount of available EFN benefits lima bean in nature by attracting predacious and parasitoid arthropods. These two pilot studies represented a starting point for unraveling whether both induced defense traits contribute to plant defense or whether EFN secretion solely is responsible for lima bean protection.

We chose an experimental approach similar to the one used in Heil (2004b): Groups of five tendrils were used as experimental units (Fig. 1; Table 1). Within each unit, two tendrils were either treated with JA or left untreated. The inclusion of two additional bean tendrils with artificially increased amounts of either VOCs or EFN enabled us to study the protective effect of the two defenses. A fifth group served as a treatment control.

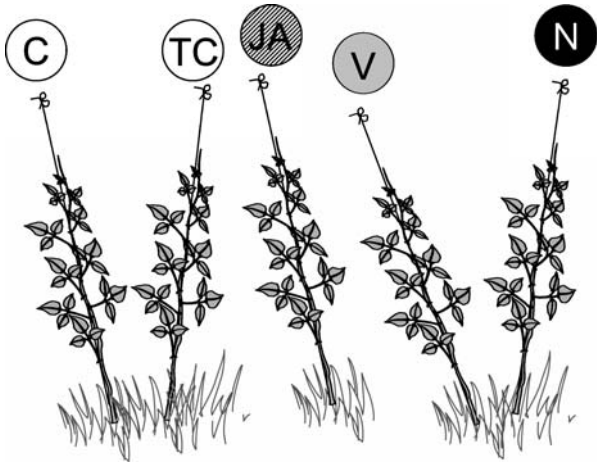

Fig. 1 Experimental design. Five groups of lima bean tendrils (*P. lunatus*) served as experimental unit with *C* no treatment, *TC* application of lanolin paste, *JA* spraying with jasmonic acid, *V* application of a synthetic volatile blend dissolved in lanolin paste, and *N* application of a synthetic mixture of EFN. See Table 1 for details

We repeatedly applied these five treatments to address the following questions: (1) What is the relative contribution of the two indirect defenses—volatile emission and extrafloral nectar secretion —to the overall herbivore defense of the lima bean? (2) Is there an additional influence of a putative JA-dependent direct defense? And (3) what kind of arthropods (including putative defenders) are attracted to the treated tendrils?

Methods and Materials

Study Site and Species This study was conducted in the coastal area near Puerto Escondido in the state of Oaxaca, Mexico. The climate in the study area is characterized by one main rainy season from June to October, which follows a bimodal distribution peaking in July and September. Annual rainfall averages between 1 and 1.4 m, and the mean annual temperature is 28°C (Strässne 1999). The two sites were used in previous studies (Heil 2004b; Kost and Heil 2005) and located 15 km northwest of Puerto Escondido and about 3 km apart (15°55.596N/097° 09.118W and 15°55.357N/97°08.336W). In this study, lima bean grows naturally along dirt roads that lead to extensively used pastures or plantations. All experiments were performed on this native population of lima bean plants in 2003 and 2004, during the transition from wet to dry season (October to December).

Table 1 Five chemical treatments and their effect on treated tendrils

Group Name (Abbreviation)	Treatment	Defensive Traits (*i*=Induced, *e*=Experimentally Increased)	Effect
Control (C)	Untreated	None	Untreated control
Treatment control (TC)	Lanolin paste	None	Lanolin paste only
JA-treatment (JA)	JA	VOCs (i) EFN (i) putative direct resistance (i)	Induction of VOCs, EFN, and putative JA-dependent direct defenses (Heil 2004b)
Volatile treatment (V)	Volatile mixture dissolved in lanolin paste	VOCs (e) EFN (i)	Induction of EFN, attraction of arthropods to VOCs and EFN (Kost and Heil 2006)
Nectar treatment (N)	Synthetic mixture of EFN	EFN (e)	Attraction of arthropods to EFN (Kost and Heil 2005)

JA Jasmonic acid, *EFN* extrafloral nectar, *VOC* volatile organic compound

Design of the Long-Term Experiment To reduce environmental and genotypic variability, 23 groups of five lima bean tendrils were selected as experimental units. Within a unit, the maximum distance between the two outer tendrils was less than 3 m, and tendrils forming one group usually were part of the same plant individual, although this could not always be ensured because of the tangled growth of the lima bean. Eleven groups were located at site 1 and 12 at site 2. All selected tendrils were trained along supporting ropes, and the tendrils of each group assigned randomly to one of five treatments (for details, see the next section): Tendrils were either left untreated (control group) or treated every 3–4 days with lanolin paste only (treatment control group), sprayed with an aqueous solution of JA (JA group), or supplied with a synthetic blend of VOCs (volatile group) or EFN (EFN group; Fig. 1; Table 1). Application of pure lanolin served as a procedural control to test for any effect caused by lanolin alone. See Table 1 for a summary of the expected treatment effects. Starting 27th October 2003, the experiment lasted 25 days and comprised six applications. During this time, the initial number of tendril groups was reduced to a final sample size of 17 because of cattle and human impact.

Treatment of Tendril Groups Tendrils of the JA group were sprayed with an aqueous solution of 1 mmol JA until runoff (i.e., approximately 10 µl per cm^2 leaf area). Levels of JA were adjusted to those of previous experiments in which similar concentrations were applied without phytotoxic effects becoming apparent (Heil 2004b). The synthetic volatile blend and the synthetic mixture of EFN were adjusted to mimic their natural models within 3 days post-induction according to previous experiments (Kost and Heil 2005, 2006). However, the amount of VOCs and EFN cumulatively applied ranged largely below the physiological limit of a plant for producing the two indirect defenses within this period (Kost and Heil 2005, 2006).

The synthetic volatile blend consisted of 0.12 µg (*R*)-(−)-linalool, 0.13 µg β-caryophyllene, 0.19 µg methyl salicylate, 0.26 µg (*Z*)-jasmone (all purchased from Sigma-Aldrich), 0.02 µg (3*Z*)-hexen-1-yl acetate (Avocado Research Chemicals Ltd., Leysham, Lancaster, UK), 0.85 µg (*E*,*Z*)-β-ocimene (mixture of *E*/*Z*-isomers approximately 70:30; kindly provided by Roger Snowden, Firmenich, Geneva, Switzerland), 0.63 µg (3*E*)-4,8-dimethyl-nona-1,3,7-triene (DMNT), and 0.9 µg (3*E*,7*E*)-4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT; synthesized by standard methods; Pattenden and Weedon 1968) per microliter lanolin. The purity of all compounds was >98%. Pure lanolin and lanolin paste that contained volatiles were spotted on green plastic strips attached to tendrils to prevent any diffusion of compounds into the treated plant. A total of 120 µl of paste were applied per five leaves of either the volatile- or the treatment-control group.

The synthetic EFN consisted of an aqueous solution of 4.01 g l^{-1} sucrose and 24.24 g l^{-1} of each fructose and glucose. Of this blend, 40 µl were applied with an Eppendorf pipette directly to the extrafloral nectaries of every trifoliate leaf of the EFN group.

Comparison of Treatments To ensure comparability between experimental groups of the long-term experiment, we quantified VOC and EFN levels of differently treated tendrils in preceding experiments.

The ability of our VOC mixture to mimic the volatile emission of herbivore-damaged and JA-induced tendrils was examined by quantifying the VOCs present in the headspace of tendrils that had received one of five treatments. Tendrils were either left untreated or treated with lanolin paste, infested for 48 h with a representative mixture of natural herbivores of lima bean (six Ensifera or Caelifera and ten beetles of various species, i.e., *Cerotoma ruficornis*, *Gynandrobrotica guerreroensis*, *Epilachna var-*

ivestis, and a curculionid species; for details, see Kost and Heil 2006), treated with a blend of synthetic VOCs, or sprayed with a 1-mmol aqueous solution of JA. Each treatment was replicated six to eight times. Groups of five tendrils that had received the different treatments originated from plants that were spaced apart at a maximum distance of approximately 3 m, had five leaves, matched each other in terms of leaf age and visual appearance, and were collected at the same time for simultaneous volatile collection. Treated tendrils were detached, immediately supplied with a water reservoir, and bagged in a PET foil ('Bratenschlauch', Toppits, Minden, Germany) that does not emit detectable amounts of volatiles by itself. Emitted VOCs were collected continuously on charcoal traps (1.5 mg charcoal, CLSA Filters, Le Ruisseau de Montbrun, France) by using air circulation, as described by Donath and Boland (1995). After 24 h, volatiles were eluted from the carbon trap with dichloromethane (40 µl) that contained 1-bromodecane (200 ng μl^{-1}) as an internal standard. Samples were transferred to glass capillaries, sealed by melting the open end, and stored at <5°C for transport. Samples were analyzed on a gas chromatography–trace mass spectrometer (Thermo Finnigan, http://www.thermofinnigan.com) according to Koch et al. (1999). Individual compounds (peak areas) were quantified with respect to the peak area of the internal standard.

To compare quantitatively the amount of EFN secreted from tendrils after exposure to airborne VOCs or induction with JA, 11 groups of three tendrils spread across the two sites were selected; these groups were located <1 m apart. Each tendril was basifixed and had five leaves. The first tendril within each group was treated with lanolin paste, the second with lanolin paste that contained volatiles, and the third was sprayed with JA. All treatments were similar to those described above. The three tendrils were then placed in gauze bags (mesh size, 0.5 mm), and a ring of sticky resin (Tangletrap®, Tanglefoot Company, Grand Rapids, MI, USA) was applied at the base as protection against flying and crawling nectar consumers. After 24 h, the amount of newly produced EFN was measured as the amount of secreted soluble solids (i.e., sugars, amino acids; see Heil et al. 2000) by quantifying the nectar volume with micro-capillaries and the nectar concentration with a portable, temperature-compensated refractometer (Heil et al. 2000, 2001). Both the amount of VOCs emitted and EFN secreted were referenced to the dry weight of the measured tendrils.

Fitness-Relevant Plant Parameters To assess the effect of treatments on the fitness of the study tendrils, the following fitness-relevant plant parameters were considered: number of leaves, inflorescences, living and dead shoot tips, and herbivory rate. Herbivory rate was estimated as percent leaf loss, as described in Kost and Heil (2005), and the remaining parameters were quantified by counting. All five parameters were assessed at the beginning of the experiment and after 25 days. Differences between these two values were calculated to determine the development of the respective parameter in the course of the study period.

Insect Counts and Sticky Traps The insect community that visited the treated bean tendrils was assessed by counting and with sticky traps. Two series of insect countings were performed, in which 20 tendril groups of the long-term experiment located at both sites were visited repeatedly. The first series of countings started on day 7 and the second on day 18 after the onset of the experiment. Ten groups of tendrils were selected at each study site, and the number of ants, wasps, or flies present on the plants was recorded, as these insects represented the most abundant groups. The first census was performed before tendril treatment at 8:00 A.M. Thereafter, all tendrils were treated, and insects on all experimental tendrils were counted repeatedly every 2 or 3 h until midnight. Two additional censuses were performed at 9:00 and 10:00 A.M. on the following 2 days, resulting in a total of 14 monitorings. The number of all insects counted per tendril was summed up to test for an effect of the treatment on the total number of insects observed.

To assess the functional groups of insects attracted to the experimental tendrils, two sticky traps were attached with plastic strings to each tendril of 14 groups that were equally distributed between the study sites. The sticky traps consisted of 100 cm^2 pieces of green plastic foil that had been coated with a thin layer of a trapping adhesive (Tangletrap®). After 24 h of exposure, traps were collected and the insects transferred to 75% ethanol. Insects were identified to order or family level with keys and information provided by Arnett (2000), Schaefer et al. (1994), and Noyes (2003). On the basis of the natural history information provided by Kelsey (1969, 1981), Honomichl et al. (1996), Matile (1997), and Daly et al. (1998), the collected arthropods were assigned to the following guilds according to nutritional or functional aspects: Predator/entomophaga (R), parasitoid (P), utilization of plant-derived resources including floral or extrafloral nectar, pollen and honeydew (S), frugivore (F), herbivore and flower feeder (H), detrivore including phytosaprophage and zoosaprophage (D), blood-sucking and ectoparasitic (B), and fungivore (M).

Statistical Analysis Amounts of volatiles emitted from differentially treated tendrils were compared with a Kruskal–Wallis rank sum test and a subsequent nonparametrical multiple test procedure of the Behrens–Fisher type (Munzel

and Hothorn 2001) by using the open source software R 2.3.1 (http://www.r-project.org).

Our randomized complete block design allowed us to analyze the data of the EFN-induction experiment, the fitness-relevant plant parameters, and the cumulative insect numbers with a mixed-effect model (univariate GLM procedure) with 'treatment' as a fixed and 'tendril group' as a random factor. The following variables were transformed to meet the assumption of homogeneity of variances (transformation in brackets): number of living shot tips and number of wasps (square root), number of inflorescences and dead shoot tips (log), number of leaves, cumulative number of ants and flies (ln). Post hoc comparisons (least significant difference, LSD) were performed to test for statistically significant differences among treatments. These statistical analyses were done using Statistical Package for the Social Sciences 13.0 (SPSS Inc., Chicago, USA).

Results

Comparison of Treatments The headspace of lima bean tendrils, which had been treated with either a blend of synthetic VOCs or with JA, largely resembled the volatile blend typically emitted from herbivore-damaged bean tendrils in terms of quantity and quality (Table 2). Only (3*Z*)-hexen-1-yl acetate was emitted in significantly lower amounts from the synthetic VOC mixture than from herbivore-induced tendrils. Also, JA- and herbivore-treated tendrils showed a marked quantitative similarity in the composition of their emitted volatile bouquets. However, JA-treated tendrils emitted significantly lower amounts of (*R*)-(−)-linalool and higher amounts of DMNT compared to herbivore-damaged tendrils. In general, volatile blends emitted from herbivore-, volatile-, and JA-treated plants were characterized by high quantitative variability (Table 2).

A similar trend became obvious when EFN secretion rates were compared among treatments. Both the application of the synthetic volatile mixture and the JA treatment increased the EFN secretion rate within 24 h compared to controls treated with lanolin only (univariate analysis of variance, ANOVA, $P < 0.01$, $N=11$). The EFN secretion rate in both treatments was twice that of the treatment control (Fig. 2). However, no significant difference was detected between the volatile- and the JA-treated group (LSD post hoc test, $P>0.05$).

Effect of the Treatments on Fitness-Relevant Plant Parameters The three treatments, JA, volatiles, and EFN, significantly affected vegetative and reproductive plant traits after 25 days as compared to the controls. Tendril groups treated with volatiles or EFN showed a significant increase in the number of newly produced leaves, shoot tips, and inflorescences, bore fewer dead shoot tips, and had suffered less herbivore damage than the controls (Fig. 3). JA treatment also significantly decreased the number of dead shoot tips and the herbivory rate, whereas no difference could be detected for the number of living shoot tips, leaves, and inflorescences. According to a LSD post hoc test, the tendrils of the JA group ranked between the volatile and EFN group on one hand and the two controls on the other (Fig. 3).

Table 2 Quantitative comparison of five-leaved lima bean tendrils, which were left untreated (C); treated with lanolin paste (Tc); exposed to a mixture of herbivores, which are characteristic for the lima bean for 48 h (H); treated with the artificial volatile blend dissolved in lanolin paste (V); or sprayed with JA

The dominant emitted volatiles are given as mean peak area (±95% confidence interval) relative to the peak area of an internal standard per 24 h and per gram dry weight. The last column shows *P* values of a Kruskal–Wallis (KW) test. Significant treatment effects are indicated by different superscript letters (nonparametrical multiple test procedure of the Behrens–Fisher type, $P<0.05$).

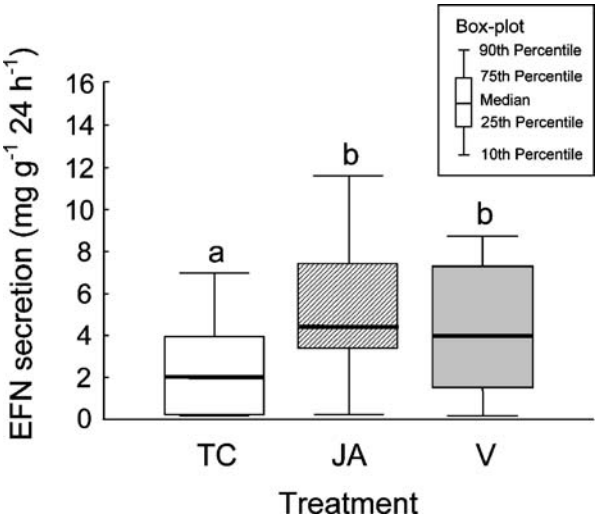

Fig. 2 Effect of different treatments on the secretion rate of extrafloral nectar (*EFN*) given in milligrams soluble solids per gram leaf dry mass per 24 h. Comparisons between tendrils treated with lanolin paste (*TC*), the synthetic volatile blend dissolved in lanolin (*V*), and jasmonic acid (*JA*) are shown. *Different letters* indicate significant differences among treatments (univariate ANOVA, $P<0.05$ according to LSD post hoc test). Sample size was eleven groups of tendrils

Effect of the Treatments on Insect Abundance Ants, wasps, and flies were the most abundant groups observed visiting the study tendrils, with ants being by far the dominant group. Their numeric abundance on the experimental tendrils exceeded that of flies 5- to 15-fold and that of wasps 20- to 30-fold (Fig. 4).

The five treatments significantly affected the insect visitation rate of the experimental tendrils. The mean cumulative number of ants was increased significantly on tendrils treated with JA, volatiles, and EFN relative to the two control tendrils (Fig. 4, LSD post hoc test after univariate ANOVA, $P < 0.05$). Volatile treatment doubled the median cumulative number of ants on the experimental tendrils, whereas the JA and nectar treatment led to a threefold increase over the number on the untreated state. Correspondingly, the median wasp number ranged between 1.5 (JA group), 2 (volatile group), and 2.5 (EFN group), whereas these insects were significantly less frequently encountered on control tendrils (Fig. 4; LSD post hoc test after univariate ANOVA, $P < 0.05$). Flies responded less to the five treatments. Despite the significantly increased visitation rate of flies to the JA-treated tendrils as compared to the controls (Fig. 4, LSD post hoc test after univariate ANOVA, $P < 0.05$), no such effect was observed for VOC- and EFN-treated tendrils (Fig. 4). The two latter groups were statistically indistinguishable from the JA-treated tendrils and both control groups (Fig. 4, LSD post hoc test after univariate ANOVA, $P>0.05$).

Community Composition of Arthropods Visiting Lima Bean In total, 899 arthropods were caught on sticky traps, and >94% were identified to the order or family level. Among them, Diptera (55%) and Hymenoptera (26%) were the most abundant (Table 1; Fig. 4). Other groups trapped included Coleoptera (6%), Araneida (5%), and Thysanoptera (3%).

Based on information derived from the literature, the trapped arthropods were assigned to feeding guilds, whereas multiple affiliations per taxon were allowed. This analysis indicated that 73% of all trapped arthropods were characterized by parasitoid or predacious life habits and may, thus, be classified as potentially beneficial to the lima bean (Fig. 5). On the other hand, only 16% of the trapped arthropods were assigned to herbivorous or flower-feeding groups, which potentially could have had detrimental effects on the plant. Other plant-derived food sources, such as EFN, pollen, or honeydew, are known to be used by 67% of all trapped arthropod groups, and 19% of all trapped taxa additionally rely on other food sources such as fungi, fruits, or detritus. The two latter groups may be classified as 'tourists' and are likely to have a neutral effect on the lima bean (Fig. 5; Table S1).

A closer look at the trapped arthropod taxa revealed that Dolichopodidae (34% of all trapped Diptera), Phoridae (24%), and Chloropidae (7%) were the most abundantly trapped Dipterans (Table S1). All three groups share parasitoid and predacious life habits and are occasionally known to feed on EFN (Table S1). Members of the Chalcidoidea contributed preponderantly to the captured Hymenoptera (64%). The individuals trapped by this superfamily of parasitoid wasps belonged to 16 different families, with Eulopidae (13% of all trapped Hymenoptera), Encyrtidae (12%), and Pteromalidae (8%) being most frequently trapped. Among the hymenopterans, Formicidae (12%) and Braconidae (6%) were the most often captured non-chalcid families.

Discussion

Comparison of Treatments The aim of the present study was to study simultaneously the protective effect of the two indirect defenses, EFN secretion and VOC emission, on the lima bean under field conditions. The performance of plants that were induced by spraying with JA and, thus, had increased amounts of VOCs and EFN, was monitored and compared to plants of which the amount of either VOCs or EFN was increased experimentally.

An important prerequisite for any conclusion that can be drawn from such an experimental design is knowledge of the performance of the two indirect defenses under

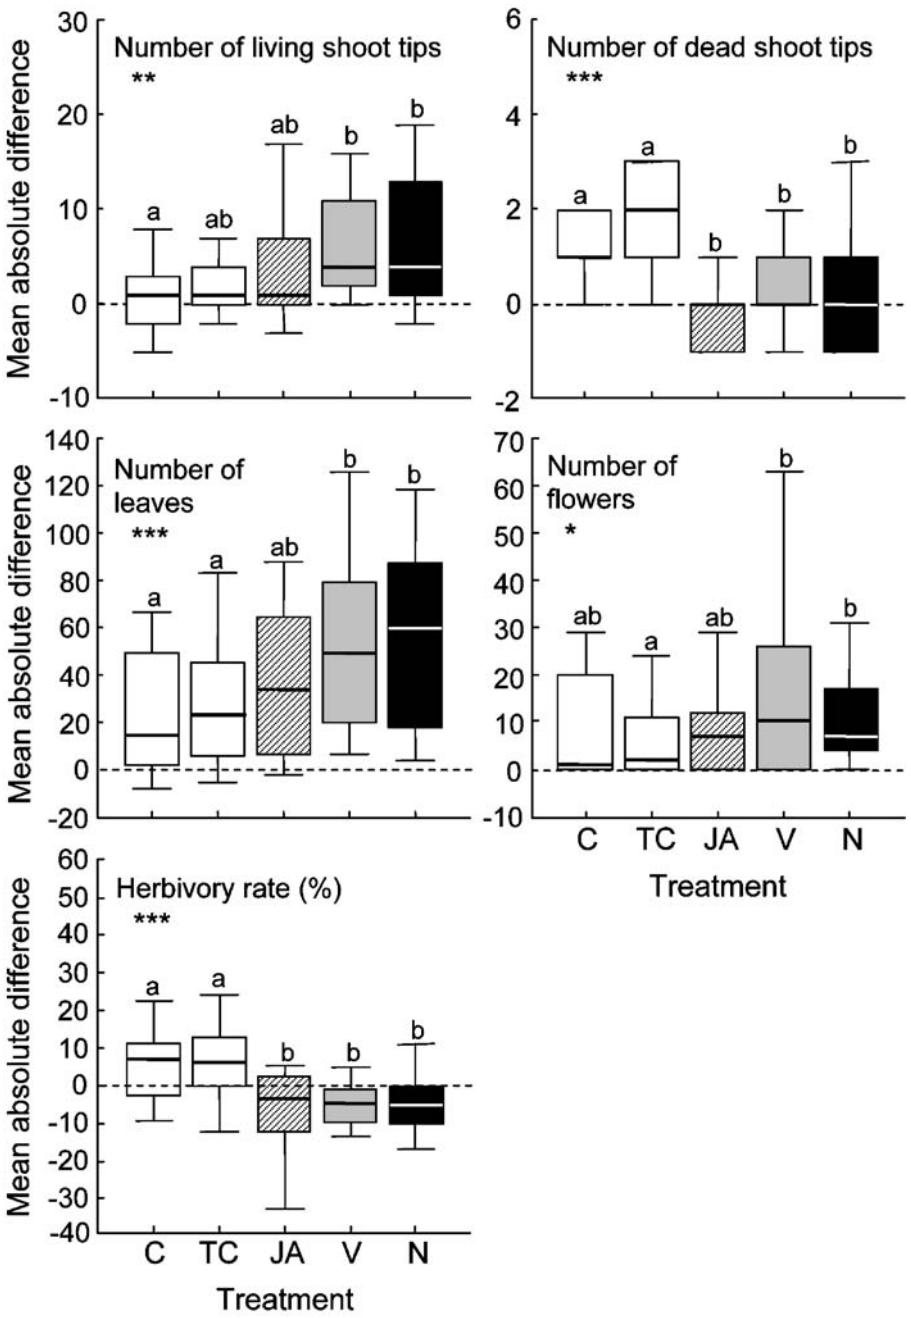

Fig. 3 Effect of five treatments on fitness-relevant plant parameters. Each tendril within groups of five lima bean tendrils received one of five treatments: no treatment (*C*), treatment with lanolin paste (*TC*), spraying with jasmonic acid (*JA*), application of a synthetic volatile blend dissolved in lanolin paste (*V*), and application of a synthetic mixture of EFN (*N*). See Table 1 for details. Mean absolute differences between days 0 and 25 of the experiment are displayed. Values above zero (*dashed line*) indicate an increase and values below a decrease in comparison to the starting situation. *Asterisks* indicate significant treatment effects (univariate ANOVA; $*P<0.05$, $**P<0.01$, $***P<0.001$), and *different letters* indicate significant differences among treatments (LSD post hoc test, $P<0.05$). Sample size was 20 groups of tendrils

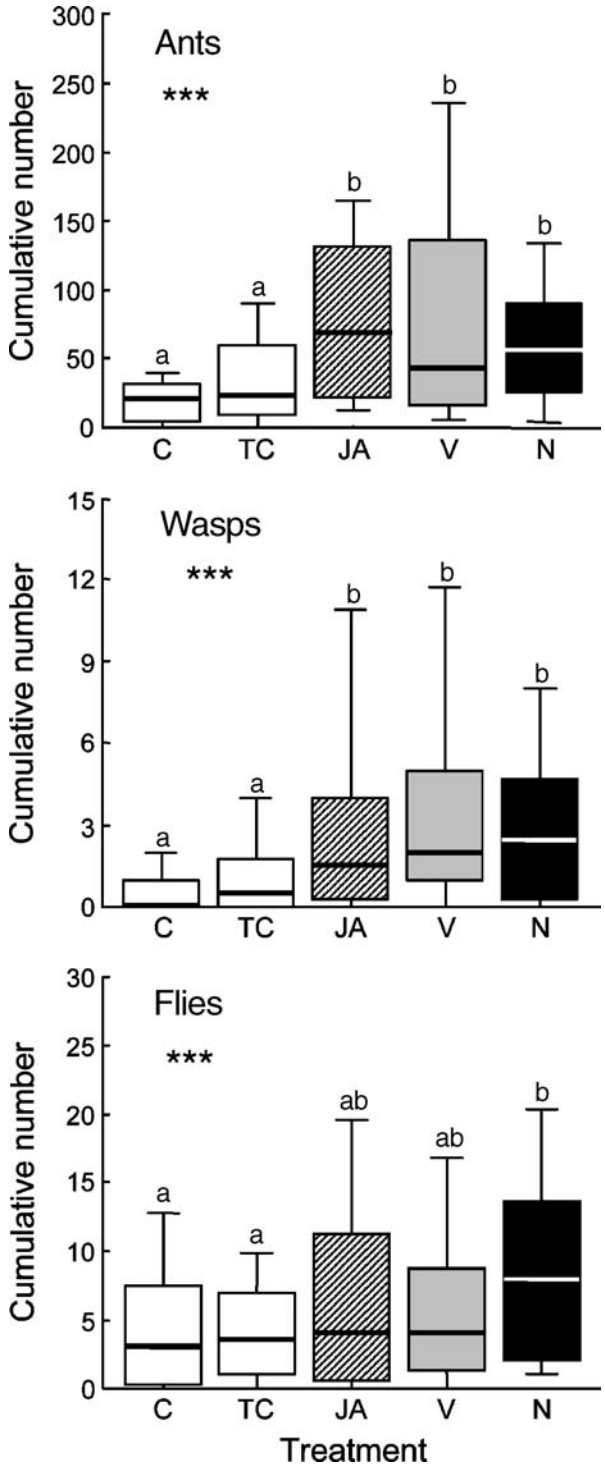
investigation. A quantitative and qualitative comparison of the VOC blends emitted from herbivore-damaged, volatile-treated, and JA-sprayed lima bean tendrils revealed—besides subtle differences—a pronounced similarity among these three groups with respect to the 13 dominant emitted compounds (Table 2). However, the volatile blends emitted from these three groups were characterized by a high degree of quantitative variation, an observation well known from literature (Kessler and Baldwin 2001; Fritsche-Hoballah et al. 2002; Röse and Tumlinson 2004). The question whether such differences hamper the ability of predators and parasitoids to locate the VOC-emitting plant has been studied intensively under laboratory conditions, where it has been shown that carnivorous arthropods can discriminate even minor differences in volatile blends offered (e.g., changes in the enantiomer ratios; Dicke et al. 1990). A species of curculionid beetles, for example, which also was observed feeding on lima bean in this study (C. Kost, personal observation), in laboratory experiments, used VOCs of slightly induced plants as a host-location cue, yet avoided plants with high induction levels (Heil 2004a). In the field, plants generally show a higher quantitative and qualitative variability of their emitted VOCs than under constant laboratory conditions (Gouinguene et al. 2001; Gouinguene



◀ **Fig. 4** Effect of the five treatments on insect numbers visiting the lima bean. Insects perching on lima bean tendrils that received one of five treatments were counted. Treatments were no treatment (*C*), treatment with lanolin paste (*TC*), spraying with jasmonic acid (*JA*), application of a synthetic volatile blend dissolved in lanolin paste (*V*), and application of a synthetic mixture of EFN (*N*). See Table 1 for details. Fourteen censuses were performed within 3 days at two sites (site 1 on day 7 and site 2 on day 18 after the beginning of the experiment). Insect numbers were pooled per counted tendril. *Asterisks* indicate significant treatment effects (univariate ANOVA; $*P<0.05$, $**P<0.01$, $***P<0.001$), and *different letters* indicate significant differences among treatments (LSD post hoc test, $P<0.05$). Sample size was 20 tendril groups

and Turlings 2002; Vallat et al. 2005). Foraging predators should respond to this situation by relaxing the specificity of their search patterns (Dicke et al. 2003). Indeed, field studies on the attractiveness of VOCs suggest that predatory and predacious insects are also attracted to jasmonate-induced plants (Thaler 1999; Kessler and Baldwin 2001), even if the emitted volatiles differ substantially from blends emitted by herbivore-damaged plants (Farag and Paré 2002). Moreover, field experiments indicate that the presence of single compounds can be sufficient to attract carnivorous insects (James 2003, 2005; James and Price 2004), which then act as indirect plant defenders (Kessler and Baldwin 2001). Consequently, under our experimental conditions, the VOCs of both JA- and volatile-treated tendrils likely have attracted plant defenders.

Our volatile treatment induced the secretion of EFN (Fig. 2), thus, confirming recent results obtained for the same plant species under laboratory (Choh et al. 2006) and field conditions (Heil and Kost 2006; Kost and Heil 2006). Hence, the tendrils of the volatile group experienced the combined defensive effect of both VOCs and EFN to an extent comparable to the tendrils of the JA group. These two defenses are not only connected by the shared signaling molecule JA (Heil 2004b) but are also airborne VOCs implicated in the induction of EFN secretion within one (Heil and Silva Bueno 2007) or between two conspecific plant individuals (Kost and Heil 2006). Consequently, this physiological linkage precludes an experimental separation of the two indirect defenses.

Treatment Effects on the Plant Tendrils of the JA, the volatile, and the EFN group generally benefited from the respective treatments, as these tendrils suffered less herbivory by leaf-chewing herbivores and bore fewer dead shoot tips than the two control groups (Fig. 3). The picture, however, changes when other fitness-relevant parameters are considered: The numbers of living shoot tips, leaves, and inflorescences differed significantly from the controls only in tendrils treated with VOCs and EFN (Fig. 3). A possible explanation for the weaker effect experienced by the JA-treated tendrils could be that induction with JA incurred allocation costs to the treated tendrils, which were greater than costs imposed by the VOC-induced EFN secretion and absent in EFN-treated tendrils (Heil 2002; Strauss et al. 2002). Beyond eliciting stress-related responses, such as insect and disease resistance, JA is known to be involved in various physiological or morphological changes not necessarily related to resistance

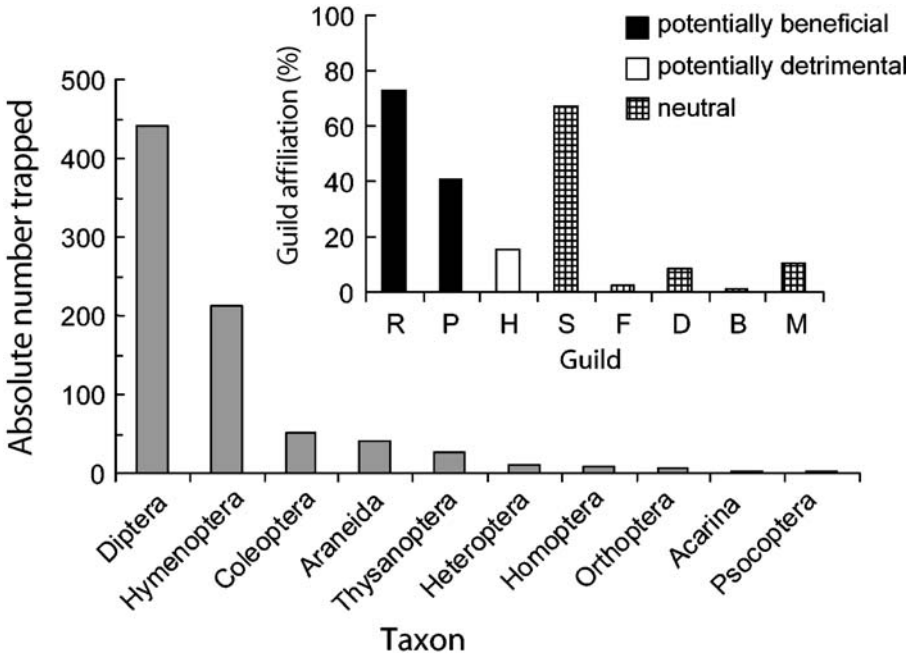


Fig. 5 Arthropods taxa trapped on sticky traps. *Insert* Affiliation of trapped taxa to different guilds: predator/entomophaga (R); parasitoid (P); utilization of plant-derived resources including floral or extrafloral nectar, pollen and honeydew (*S*); frugivore (*F*); herbivore and flower feeder (*H*); detrivore including phytosaprophage and zoosaprophage (*D*); blood-sucking and ectoparasitic (*B*); and fungivore (*M*). Arthropod groups were assigned to guilds according to nutritional or functional aspects whenever larval or adult stages feature the respective trait. Multiple affiliations per taxon were allowed. Sample size was two traps per 14 tendril groups

(Creelman and Mullet 1997). Given that these are costly in terms of metabolic resources, the induction of such processes may have affected the measured fitness parameters and could explain the weaker growth and reproductive status of JA-treated tendrils (Agrawal et al. 1999). JA may also directly affect processes such as fruit development and ripening (Creelman and Mullet 1997). An increased seed set of JA-treated plants, therefore, does not necessarily reflect an enhancement of the plant's defense status. Furthermore, external application of JA in elevated concentrations can, in principle, have detrimental effects on a plant and cause chlorosis, necrosis, or abscission of leaves (Husain et al. 1993; Oka et al. 1999; Pilotti et al. 2004). However, no such symptoms of phytotoxicity were observed. In contrast, the leaves of JA-treated tendrils looked even healthier than those of both control tendrils.

Additionally, JA application may have induced putative direct defenses (Halitschke and Baldwin 2004). However, no such alternative defense strategy has yet been described for lima bean. In its close relative, *P. vulgaris*, English-Loeb and Karban (1991) did not find evidence for induced direct resistance to spider mites. However, the protective effect of a direct defense, which in our long-term experiment could have been induced after JA application, cannot be excluded. In this case, the direct defense did not significantly contribute to plant protection because tendrils with increased amounts of EFN only (EFN group) or volatiles and EFN combined (volatile group) performed better than tendrils with volatiles, EFN, and the putative direct defense (JA group; Fig. 3).

The development of the fitness-relevant plant parameters measured in the JA-treated group and the two controls confirmed a preceding study (Heil 2004b). In both studies, JA treatment increased the number of newly produced leaves and decreased both the number of dead shoot tips, as well as the herbivory rate. The induction of these two indirect defenses was shown to benefit lima bean plants in two independent studies performed in two consecutive years. By applying synthetic VOCs and EFN externally, we could trace the observed effects back to these two kinds of defensive metabolites and corroborate the importance of EFN secretion and VOC emission for lima bean defense in nature.

Treatment Effects on the Insect Community Ants were by far the dominant insect group observed on experimental tendrils, and they were significantly attracted to tendrils that experienced the JA, volatile, and EFN treatment (Fig. 4). Although chemical cues are generally important for ants (Vander Meer et al. 1998; Keeling et al. 2004), little is known about whether plant-derived volatiles also influence ant behavior. Some reports are available on the role of yet unidentified plant chemicals that orient ants to their host plant (Fiala and Maschwitz 1990; Agrawal and Dubin-Thaler 1999; Djieto-Lordon and Dejean 1999a,b) or facilitate within-host plant patrolling behavior (Brouat et al. 2000). In lima bean, herbivory induces both VOC emission and EFN secretion (Heil 2004b). Ants could use herbivore-induced volatiles as long-distance cues to detect patches of increased availability of EFN, which simultaneously are characterized by the increased presence of herbivores (i.e., potential prey). However, preliminary

experiments with *Camponotus novogranadensis*, one of the three dominant ant species that visit lima bean at the two study sites (Kost and Heil 2005) did not support this hypothesis. Given the choice in a Y-olfactometer, workers of *C. novogranadensis* neither preferred lanolin paste that contained volatiles over pure lanolin paste. They also did not discriminate between JA-induced vs water-sprayed control plants. However, in previous trials they significantly chose an arm with mashed banana (C. Kost, unpublished data). More experiments of this kind will clarify the role of plant volatiles in ant foraging behavior.

In contrast to VOCs, EFN is a known attractant to ants (Koptur 1992) that has been reported to translate into enhanced plant protection in the vast majority of studies (for review, see Bentley 1977; Koptur 1992; Heil and McKey 2003; Oliveira and Freitas 2004), although some studies did not detect a defensive effect (O'Dowd and Catchpole 1983; Boecklen 1984; Becerra and Venable 1989; Rashbrook et al. 1992).

Also, wasps were more attracted to the tendrils of the JA, volatile, and EFN groups than to the control tendrils, yet in much smaller numbers than ants. The majority of wasps trapped on experimental tendrils belonged to predacious or parasitoid families (Table S1). These observations suggest that not only ants but also wasps likely contributed to the protection of the treated tendrils. Because of the intrinsic physiological linkage between volatiles and EFN, however, it remains unclear which indirect defense was mainly responsible for wasp attraction. As the emission of VOCs from a lima bean plant is correlated with its amount of EFN secreted, it appears reasonable to assume that wasps may have used VOCs as long-distance cues to detect patches with an increased herbivore density and/or EFN availability.

Comprehensive evidence for the volatile-mediated attraction of wasp is available from many laboratory-based studies (e.g., Turlings et al. 1990; Takabayashi et al. 1995; Du et al. 1996), yet relatively few field studies. Among them, James (2005) identified methyl salicylate as an attractant for parasitic wasps such as Encyrtidae and Mymaridae. Furthermore, braconid wasps were attracted to (3*Z*)-hexen-1-yl acetate and (*Z*)-jasmone (James 2005). These three compounds were also constituents of the synthetic volatile blend used in our study, and the above-mentioned parasitic wasps were also trapped on our experimental tendrils. In another study, DMNT (another constituent of the lima bean's induced VOC blend) emitted from molasses grass (*Melinis minutiflora*) significantly attracted parasitoid wasps in the Y-tube olfactometer and was likely involved in increasing the parasitation rate of stem-borer larvae that were feeding on nearby growing maize plants (Khan et al. 1997). Wasps feeding on EFN have been reported for several different plant species (for review, see Koptur 1992), yet so far, only one study has also demonstrated a fitness-benefit for the EFN-secreting plant (Cuautle and Rico-Gray 2003). A more detailed analysis of the attractive effects of VOCs and EFN on wasps is required, in which single blend constituents should be tested under field conditions.

Flies responded differently to tendril treatment than ants and wasps. They were only significantly attracted to tendrils of the nectar group (Fig. 4), suggesting that flies were more attracted to synthetic EFN than to airborne VOCs. The community of trapped Diptera covered a diverse spectrum of feeding habits ranging from predacious or parasitoid over herbivorous to detritus- or fungi-feeding (Table S1). This heterogeneous composition complicates a clear functional assignment of the caught flies. In most cases, the offered EFN seems to have been exploited by the flies as an additional food source rather than having contributed to a large extent to plant protection. In this case, the consumption of EFN without providing plant protection would cause ecological costs because the EFN-producing plant would be less protected against herbivores (Heil 2002; Heil et al. 2004).

In summary, ecological studies on the benefit of indirect defenses have generally focused on the protective role of a single defensive trait. While this simplification is easy to understand from the viewpoint of experimental feasibility, such univariate approaches may be inappropriate because they do not appreciate the complex interplay of several plant defenses that can co-occur within one plant species (Duffey and Stout 1996). This study takes a first step in this direction.

The mere application of synthetic EFN (nectar group) resulted in a fitness benefit that was always stronger or quantitatively similar to that experienced by tendrils of the JA and VOC treatments (Fig. 3). Moreover, the number of ants observed on the experimental tendrils (i.e., typical EFN feeders but less known to respond to VOCs) overwhelmingly exceeded the number of all other arthropod groups (Fig. 4). These observations suggest that, under our experimental conditions, the presence of EFN was more important for plant defense than was the VOC-mediated attraction of arthropods.

However, the inducing effect of VOCs on EFN impeded an experimental separation of VOCs and EFN and, thus, the exclusion of an attractive effect of airborne VOCs on flying or crawling arthropods. This finding underlines the necessity of studying different plant traits such as indirect defenses simultaneously in their ecological context. Studying them separately may provide a distorted picture of their true function and likely cause an under- or overestimation of their true effect.

This issue needs to be addressed in future studies, which should focus especially on the role of volatiles and EFN for

short- and long-distance attraction of herbivores and plant defenders. Several of the arthropod taxa that were identified in this study could serve as possible targets for such analyses. Further laboratory and field-based experimentation is needed to study whether inductive situations exist, in which either the volatile emission or the EFN secretion is differentially up- or down-regulated or if both defenses always respond similarly to herbivore attack.

Acknowledgment We thank W. Boland for the use of all the facilities of the Department of Bioorganic Chemistry, and S. Adolph and M. Mekem Sonwa for the technical advice on organic synthesis. This manuscript benefited greatly from constructive comments of S. Schmidt, C. C. von Dahl, E. Wheeler, A. Giri, and M. Hartl. Financial support by the German Research Foundation (DFG grant He 3169/2-1, 2) and the Max-Planck-Society is gratefully acknowledged.

Received: 26 June 2007 / Revised: 7 September 2007 / Accepted: 19 October 2007 / Published online: 5 December 2007

Abstract Inflorescence scent samples from nine populations of dioecious *Silene otites*, a plant pollinated by moths and mosquitoes, were collected by dynamic headspace extraction. Sixty-three scent samples were analyzed by gas chromatography–mass spectrometry. Out of 38 found, 35 compounds were identified, most of which were monoterpenoids, fatty acid derivatives, and benzenoids. Phenyl acetaldehyde was the most dominant compound in the majority of samples. The variability in scent composition was high, and population and sex differences were found. Nevertheless, wind tunnel experiments proved similar attraction of *Culex pipiens pipiens* biotype *molestus* mosquitoes to the inflorescence odor of *S. otites* of different populations, indicating that different blends are similarly attractive to mosquitoes. The electrophysiological responses of mosquitoes to the 12 most common and abundant odor compounds of *S. otites* differed. Linalool oxide (furanoid) and linalool evoked the strongest responses in male and female mosquitoes, and (*Z*)-3-hexenyl acetate was strongly active in females. Medium responses were evoked in males by (*Z*)-3-hexenyl acetate, in females by benzaldehyde and methyl salicylate, and in both sexes by lilac aldehyde, lilac alcohol, and linalool oxide (pyranoid).

Keywords *Silene otites* · Flower odor variability · Wind tunnel bioassays · *Culex pipiens pipiens* biotype *molestus* · Electroantennography · Attraction · Nectar host plant

Introduction

Carbohydrates are vital resources for adult male and female mosquitoes. Uptake of sugar plays a critical role in longevity, fecundity, flight capacity, and host-seeking behavior (Harada et al. 1971; Nayar and Saurman 1971, 1975; Magnarelli 1978; Klowden 1986). The primary sugar source for mosquitoes is nectar (Haeger 1955; Sandholm and Price 1962; Grimstad and DeFoliart 1974), and mosquitoes prefer some plants to others as nectar sources (Grimstad and DeFoliart 1974; Magnarelli 1978; Gadawaski and Smith 1992). However, the specific cues that mosquitoes use to find and to select nectar sources are not well understood. Many flower visitors, mosquitoes included, are known to be attracted to floral scents (Vargo and Foster 1982; Dudareva and Pichersky 2000).

For finding effective nectar-related attractants for biological control of mosquitoes, it is important to determine which plant species produce the most attractive floral compounds and to identify these compounds. Plant species adapted to mosquitoes as pollinators are expected to emit more mosquito-attracting compounds than plants pollinated primarily by other pollen vectors.

Worldwide, effective pollination by mosquitoes has been described only in the orchid *Habenaria (Platanthera) obtusata* (Banks ex Pursh) Richardson (Stoutamire 1968) and in *Silene otites* L. Wibel (Caryophyllaceae) (Brantjes and Leemans 1976), which is usually a perennial and dioecious species widely distributed in Middle, East, and South Europe and in Central Asia. The small and white-greenish flowers are arranged in terminal cymes. Jürgens et al. (2002) described the floral scent composition of *S. otites*. The scent of a few plants of a single *S. otites* population was analyzed. Therefore, nothing is known about the variability in the scent of this plant among populations or between males and females.

Compounds with low variability may be more important for the attraction of pollinators than compounds with high variability (Ayasse at al. 2000), as pollinators may exert selective pressure on scent composition, resulting in regular emission of attractive compounds, whereas nonattractive compounds may be more variable. So far, only a single major volatile component of *S. otites*, phenyl acetaldehyde, has been shown to attract mosquitoes (Jhumur et al. 2006), whereas the importance of the total floral scent emitted by *S. otites* is unknown for attraction of its flower-visiting mosquitoes (e.g., *Culex pipiens* L. and *Culiseta annulata* Schrank; Brantjes and Leemans 1976).

The aim of this study was to analyze the geographic variability of the floral scent composition of *S. otites* (L.) Wibel (Caryophyllaceae), and to assess the attractiveness of floral bouquets of different *S. otites* populations to *Culex pipiens pipiens* biotype *molestus* Forskal 1775. Furthermore, the antennal electrophysiological responses of *C. p. molestus* to the most common and abundant odor compounds in *S. otites* were measured.

Methods and Materials

Plant Material Inflorescence scent samples were collected from 63 individuals of 9 different populations. The geographic origin of eight populations and the number of females and males sampled are shown in Fig. 1. For one population (h), from which three males and four females were sampled, the geographic origin is unknown. Seed of the different populations were provided by several botanical gardens. To reduce environmental variation among populations, plants were grown under the same conditions (e.g., soil, temperature) in pots in the greenhouse until they built up a rosette, and thereafter the pots were placed in flower beds in the field.

Odor Collection S. otites is a nocturnal plant. Its floral scent emission is strongest in the early night hours (Jürgens et al. 2002). Male flowers remain functional for two nights, whereas female flowers emit scent over several days until they are pollinated (Brantjes and Leemans 1976). For studying the variability of floral scents, floral odors of *S. otites* were collected from one to four inflorescences of each individual plant 2–3 d after the onset of floral bloom when most of the flowers in an inflorescence had opened for the first time. Thus, the inflorescences used were of the same age; however, the flowers of these inflorescences were in different developmental stages. It is unclear whether there is variation in scent of *S. otites* among flowers of different ages on the same plant and whether this possible variation contributed to the observed variability among populations. However, as scent was collected from inflorescences of the same age, the possible variation in scent among flowers of different ages is not expected to have influenced our measurements. Furthermore, in a closely related species, *S. latifolia*, no differences in scent composition of flowers of different stages were found (Dötterl et al. 2005b).

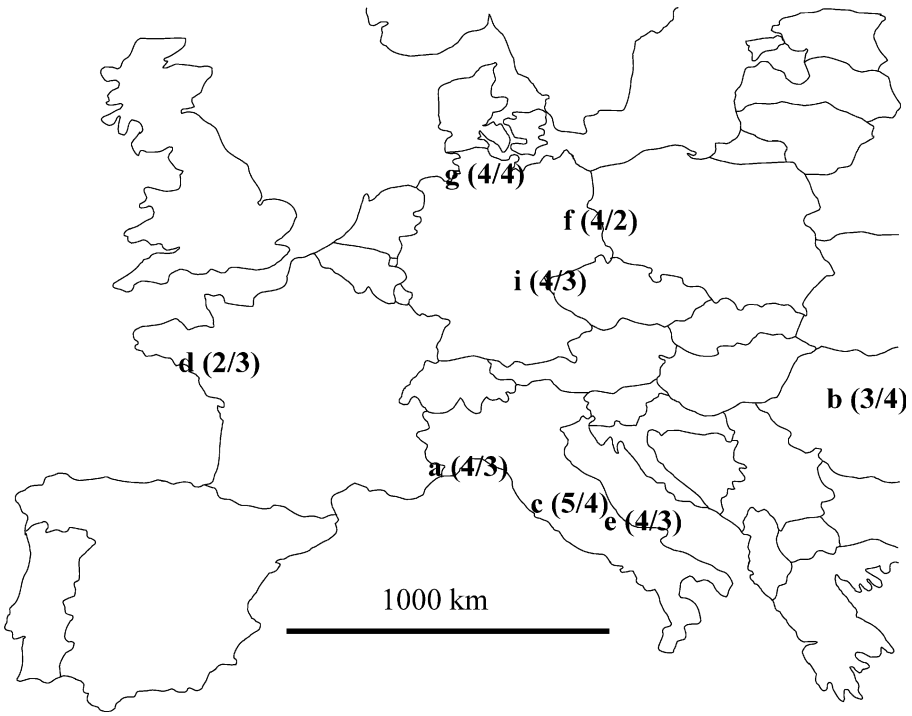

Fig. 1 Geographic origin of eight out of nine *S. otites* populations analyzed (a–f, i; the geographic origin of population 'h' is unknown). The number of sampled male and female individuals of each population is given in parenthesis

To collect odors, potted plants were placed under the extractor hood in the laboratory. Volatiles were collected by using the dynamic headspace method described by Dötterl et al. (2005b). Inflorescences were enclosed in a polyester oven bag (20×8 cm; Toppits®, Germany) 1–1 1/2 hr after sunset, and volatiles were trapped in an adsorbent tube for 2 min by using a membrane pump (ASF Thomas) with a flow rate of 200 ml/min. The adsorbent tubes were filled with a mixture (1:1) of 3 mg Tenax-TA (mesh 60–80) and Carbotrap (mesh 20–40). To distinguish between plant volatiles and ambient contaminants, surrounding air was collected for comparison. Furthermore, to discriminate odor emitted by flowers from odor derived from vegetative parts, scent was also collected from nonflowering shoots. However, as insects attracted to plants may detect green leaf volatiles and floral odors, we also included vegetative odors in subsequent analyses (see below).

Preparation of Plant Material for Bioassays To facilitate the work with the night-active plant-flower visitor system, plants were shifted from flower beds to a climatic chamber with an inverted day and night rhythm shortly before onset of flowering. Maintenance of the climatic chamber was dark (9 hr: from 9 A.M. to 6 P.M.) and light (15 hr: from 6 P.M. to 9 A.M.) with 20.5°C and 24.5°C, respectively. One or 2 d after moving, when flower opening had adjusted to the changed day and night rhythm, inflorescences were used for bioassays. Flower odors were collected before and after each bioassay, and are expressed as the mean total amount of emitted odors during bioassays. Flowering inflorescences (three to five) of males or females of a population were cut and placed together in small glass bottles filled with water. Within 5 min, inflorescences were bagged, and thereafter volatiles were collected for 2 min as described above. With the exception of higher amounts of green leaf odors in cut plants, the scent compositions of clock-shifted plants were the same as those of *in situ* plants (Jhumur, unpublished data).

Preparation of Insects for Bioassays We used flower-naïve individuals of the autogenous *Culex pipiens pipiens* biotype *molestus* Forskal 1775 (European strain) for experiments. Mosquitoes were reared according to Jhumur et al. (2006) with an inverted day and night rhythm in accordance with the designed bioassays. For bioassays, the sugar supply was removed 61–63 hr before the experiment. For electrophysiological measurements, regularly fed mosquitoes were used.

Chemical Scent Analysis Scent samples were analyzed on a Varian Saturn 2000 mass spectrometer coupled to a Varian 3800 gas chromatograph equipped with a 1079 injector that had been fitted with the ChromatoProbe kit. The adsorbent tube containing sample was placed in the Chromatoprobe and then inserted into the modified GC injector. The injector split vent was opened (1/20), and the injector was heated to 40°C to flush any air from the system. The split vent was closed after 2 min, and the injector was heated to 200°C (200° C/min); this temperature was held for 4.2 min. Then, the split vent was opened again (1/10) while the injector was cooled. For analyses, a ZB-5 column (5% phenyl polysiloxane; 60 m long, i.d. 0.25 mm, film thickness 0.25 μm, Phenomenex) was used. A constant flow of carrier gas (helium, 1.8 ml/min) was maintained by electronic flow control. The GC oven temperature was held for 7 min at 40°C, then increased by 6°C/min to 250°C, and held for 1 min. The MS interface was 260°C, and the ion trap worked at 175°C. The mass spectra were taken at 70 eV (in EI mode) with a scanning speed of 1 scan sec^{-1} from *m/z* 30 to 350. The GC–MS data were processed by using the Saturn Software package 5.2.1. Component identification was carried out with the NIST 02 mass spectral data base or MassFinder 2.3, and confirmed by comparison of retention times with published data (Adams 1995). Identification of individual components was confirmed by comparison of both mass spectra and GC retention data with those of authentic standards.

For quantification of odors emitted from inflorescences, known amounts of lilac aldehydes (>99%, synthesized according to Dötterl et al. 2006b), (Z/E)-β-ocimene (>99%, provided by Jette T. Knudsen, Lund University, Sweden), (*Z*)-3-hexenyl acetate, benzaldehyde, phenyl acetaldehyde, and veratrole (all purchased from Sigma-Aldrich with highest purity available) were injected into the GC for calibration.

Bioassays A 160×75×75-cm wind tunnel (Dötterl et al. 2006b; Jhumur et al. 2006) was used for bioassays. A Fischbach speed controller fan (D340/E1, FDR32, Neunkirchen, Germany) continuously circulated air through the tunnel with an air speed of 0.35 m/sec. Incoming air was cleaned through four charcoal filters (145×457 mm, carbon thickness 16 mm, Camfil Farr). To allow mosquitoes to adapt to the wind tunnel environment, they were kept in the wind tunnel room for about 12 hr before the experiment started. To avoid contamination, all equipment was cleaned with ethanol, burned in flame, and then sterilized at 200°C, and surgical gloves were worn during mosquito handling and bioassays.

At the conditions described above, *S. otites* emitted the highest amounts of floral odors in the 2nd and 3rd hr after onset of darkness (Jhumur, unpublished data). Therefore, bioassays were conducted within this time frame. The inflorescences, the cut ends of which were already inserted in water, were placed at the upwind end of the tunnel

behind gauze and different aluminum screens. They were invisible to the mosquitoes.

A group of 10–15 randomly chosen male and/or female mosquitoes (the behaviors of mosquitoes were not influenced by the opposite sex, see also Jhumur et al. 2006) were released from a chamber (16×8 cm) at the downwind end of the tunnel. Mosquitoes were observed for 1 hr. Landing on the gauze (20×10 cm) in front of the odor source was considered as attraction to the source. In addition, the latency time before landing was measured. After landing, the behavior was classified into two types: "sitting" and "searching". "Sitting" was characterized simply as sitting without moving or doing anything on the gauze for 15 sec after landing, and "searching" was characterized by excited movement of mosquitoes on the gauze and repeated penetration of gauze with their proboscis, presumably in search for a food source. To avoid recording the behavior of any responding mosquito twice, landing mosquitoes were removed from the wind tunnel after 15 sec with an aspirator.

From other tests with mosquitoes in the same wind tunnel, we know that almost no mosquitoes land just by chance in front of the odor source (Jhumur et al. 2006). Therefore, we did not test the mosquitoes' response to clean air or room air. Furthermore, given that a small number of mosquitoes would land just by chance on the gauze in front of the odor source, this number should be similar for odor from all *S. otites* populations, and thus, not affect the comparison of attractiveness of *S. otites* odor from different populations.

Dependent upon the availability of flowers, 25 bioassays were conducted with *S. otites* plants of six populations. Male and female inflorescences were tested separately. However, female inflorescences were not available for the 'a' and 'c' populations (Table 2). Nine bioassays were conducted with population 'i', six with 'f', four with 'g', and two each with 'c', 'b', and 'a'. Most of the inflorescences of one plant (one bioassay) were tested with two groups of mosquitoes, and the behavioral responses (percentage of individuals landing) of these 20–30 mosquitoes were used for subsequent statistical analyses (see below). However, for population 'a', only one group of mosquitoes was used for each of the two inflorescence samples. In total, 113 male and 531 female mosquitoes were tested. Male mosquitoes were not available during the bioassays with male inflorescences of populations 'a', 'c', and 'g', and female inflorescences of population 'b'.

Electrophysiology

Authentic Standard Compounds The most frequently found 12 floral scent compounds of *S. otites* were used for electrophysiological measurements. Among these, lilac aldehyde (purity >99%) was synthesized as described by Dötterl et al. (2006b); lilac alcohol and linalool were provided by Karlheinz Seifert (University Bayreuth, Germany; purity >99%); and the other compounds were purchased from Sigma-Aldrich (hexanol, (*Z*)-3-hexen-1-ol, and (*Z*)-3-hexenyl acetate >98%; benzaldehyde 99%; phenylethyl alcohol 99%, acetophenone 98%; linalool oxide [furanoid] 97%; phenyl acetaldehyde 90%; methyl salicylate 98%) or Wako (linalool oxide [pyranoid] 98%). Among these 12 compounds, all monoterpenoids were used as stereoisomeric mixtures. To obtain dose–response curves and to compare the sensitivity of mosquitoes to different compounds, electroantennographic (EAG) recordings were performed with a dilution series of standard compounds (Schütz et al. 1999). Dilutions were prepared in paraffin oil (Uvasol, MERCK, Darmstadt, Germany).

Preparation Four- to 5-d-old *C. p. molestus* were used for EAG. For measurements, an excised antenna was mounted between glass micropipette electrodes filled with insect ringer (8.0 g/l NaCl, 0.4 g/l KCl, 0.4 g/l $CaCl_2$). The electrodes were connected to silver wires. Signals were interfaced with a two-channel USB acquisition controller (provided by Syntech, Hilversum, The Netherlands) to a PC as described by Dötterl et al. (2005a). Twenty microliters of a test compound was placed onto a piece of filter paper (2.5×1.5 cm^2) inside a 5-ml plastic syringe (Omnifix, B/Braun, Melsungen). Separate syringes were used for each stimulus. Stimuli were released into a continuous flow of humidified air that passed over the antenna with a pulse duration of 0.5 sec, and a flow of 10 ml/sec regulated by a CS-01 Stimulus Controller (Syntech). Each compound and each dilution was tested on four to six mosquitoes. In all EAG tests, antennae were stimulated at 30–40 sec intervals. To discriminate between the antennal response elicited by the air flow or by paraffin and by the tested scent compound, a filter paper that contained only paraffin was tested as the first and last measurement on each antenna. To counterbalance for the loss of antennal sensitivity during measurements, the antennal response to a syringe containing (*Z*)-3-hexen-1-ol (10^{-1} in paraffin) was recorded as the second measurement from the beginning to the end. (*Z*)-3-Hexen-1-ol is a compound frequently found in sampling of *S. otites*. As this was used as the standard for EAG recordings, it was not used to obtain dose–response curves.

Statistical Analysis We used the Primer 6 program (Clarke and Warwick 2001; Clarke and Gorley 2006) to assess the variability in scent of *S. otites* individuals of different populations. Semiquantitative data of compounds (percentages=relative amounts with respect to total peak areas) were used because the total amount of emitted volatiles varied greatly among different individuals (see also Dötterl

et al. 2005b). We used multidimensional scaling (MDS) based on Bray–Curtis similarities to detect similarities among samples. To evaluate how well or poorly the particular configuration produces the observed distance matrix, the stress value is given. The smaller the stress value, the better the fit of the reproduced ordination to the observed distance matrix (Clarke 1993). We used ANOSIM (two-way crossed design, factors: sex, population) in Primer to test for the differences in scent between male and female flowers and among populations. SIMPER (two-way crossed design, factors: sex, population) was used in Primer to identify the compounds responsible for dissimilarities between sexes and among populations. RELATE was used in Primer to correlate the scent matrix with the distance matrix (in km) of the populations. To obtain the scent matrix, mean relative amounts of compounds were calculated for the different populations, and these values were used to calculate the Bray–Curtis similarities finally used for the analysis.

Chi-square tests were used to assess the differences in attractiveness between male and female mosquitoes (number of males responding–males not responding vs. number of females responding–females not responding) to male and female inflorescences of different populations of *S. otites*. No differences in responses between males and females were found (Jhumur, unpublished data). Therefore, the responses of males and females were pooled for further analyses.

In individual bioassays with specific inflorescences, the number of landing (attractive) mosquitoes (%) was determined at first, and among the landed mosquitoes thereafter the proportion of searching mosquitoes (%) was calculated. Kruskal–Wallis–ANOVA followed by the Tukey–Kramer post hoc test for nonparametric data in STATISTICA (StatSoft 2004) was used to compare these behavioral responses to the flower odors of different populations. ANOVA was used to compare the latency time of individual mosquitoes to different populations. Normality was tested with the Kolmogorov–Smirnov test; homogeneity of variances was tested by using the Hartley test.

For analyzing the EAG recordings, at first, the responses from the blank syringes were measured and subtracted from the recordings in between. Then, the response to (*Z*)-3-hexen-1-ol as the second measurement from the beginning of each measurement was set to 100%. As the sensitivity of antennae decreased during measurements, the response to (*Z*)-3-hexen-1-ol was also measured as the second measurement from the end, to determine the loss of sensitivity and to compensate for this. The responses to different compounds and dilutions are given as proportions of the responses to (*Z*)-3-hexen-1-ol (10^{-1} in paraffin). These data were directly used without transformation for further analyses. A general linear model (GLM) in STATISTICA was used to compare the differences in the responses of males and females to different dilutions and different compounds. The α-level for all statistical analyses was 0.05.

Results

Variability in Floral Scents of S. otites Thirty-eight compounds were detected in the inflorescence odor samples of *S. otites* of 9 geographical locations, 35 of which were tentatively identified by comparing mass spectra and retention index with literature data (Adams 1995). In addition, the identity of 27 of these compounds was confirmed by authentic standards (see Table 1). Among these, six compounds were also emitted from leaves. The identified compounds belong to 5 classes: fatty acid derivatives (8), benzenoids (6), nitrogen-containing compounds (1), monoterpenoids (18), and sesquiterpenoids (2). The benzenoid phenyl acetaldehyde (PAA) was the dominant odor compound in most of the individuals. However, one specimen emitted no PAA but instead high relative amounts of lilac aldehyde. Out of the 38 compounds, 19 were common to the scent samples of all populations.

Semiquantitative differences in the odor samples based on Bray–Curtis similarities are shown in Fig. 2. Variation among samples was high with significant differences among the samples from different populations (within sexes; two-way ANOSIM: $R=0.454$; $P<0.001$). SIMPER analyses revealed the compounds responsible for the differences among populations. Most populations and samples were dominated by phenyl acetaldehyde, but in some samples, high relative amounts of lilac aldehyde (e.g., samples of population ‘g’) or (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate (e.g., samples of population ‘h’) were present. One sample of population ‘i’ was characterized by a high percentage (33%) of linalool. There was no correlation between scent and the distance matrix of the populations (RELATE: $\rho=-0.02$, $P=0.52$), indicating that populations close to each other were not more similar in their scents than distant populations.

Within populations, we found significant differences in scent between male and female plants (two-way ANOSIM: $R=0.129$; $P=0.038$). However, differences between males and females were less pronounced than the observed differences among populations. Within populations, both males and females emitted the same compounds, but the proportions of some differed between males and females. According to the SIMPER analysis, phenyl acetaldehyde and (*Z*)-3-hexenyl acetate were the main compounds responsible for the differences between males and females

The number of individuals sampled in each population (a–i) is given in parenthesis.
[a] Compounds were also found in samples collected from leaves.
[b] Compounds were identified by comparing mass spectra and retention times with authentic standards.
[c] Enantiomeric composition was not determined
[c] Enantiomeric composition was determined by Dötterl et al. (2006a).

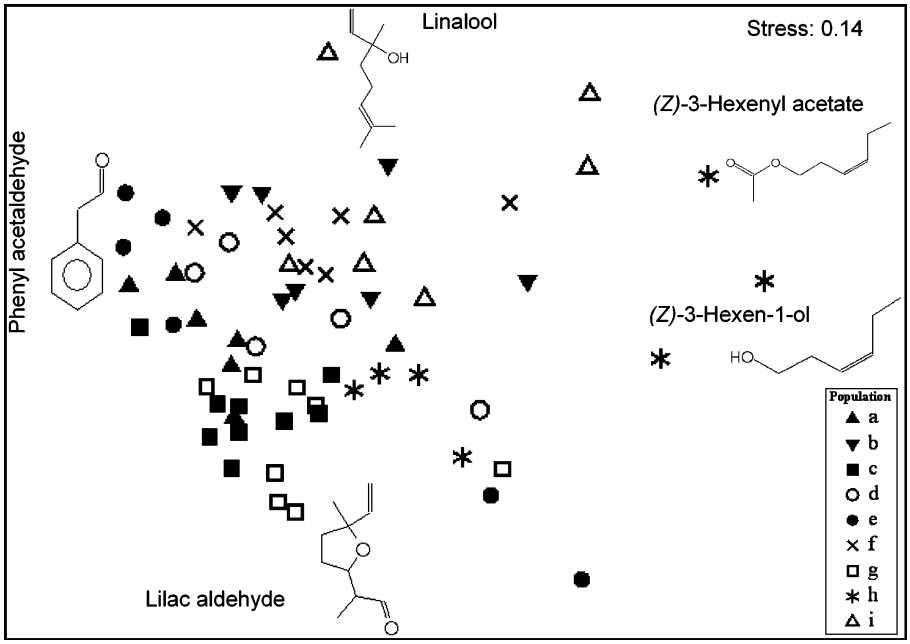

Fig. 2 MDS based on Bray–Curtis similarities of the odor composition of 63 inflorescences from 9 populations of *S. otites*. Most of the samples were dominated by high relative amounts of phenyl acetaldehyde; however, in some samples, high relative amounts of other compounds, such as lilac aldehyde, were found

(PAA=38% in males, 31% in females; (*Z*)-3-hexenyl acetate=8% in females, 6% in males).

Behavioral Responses of Mosquitoes to Odors of S. otites Inflorescences The wind tunnel bioassays revealed that about 50% of tested mosquitoes were attracted to scents emitted from inflorescences of *S. otites* of different populations. Male and female inflorescences were equally attractive to mosquitoes ('b': *Chi-square test*: $\phi^2_{df=1}=0.25$, $P=0.62$; 'f': $\phi^2_{df=1}=0.03$, $P=0.87$; 'g': $\phi^2_{df=1}=1.26$, $P=0.26$; 'i': $\phi^2_{df=1}=1.74$, $P=0.19$). Therefore, the responses to female and male inflorescences were pooled for further analyses. No differences in attractiveness among populations were found (Kruskal–Wallis–ANOVA: H (5, 25)=4.3; $P=0.5$). There was high variability in attraction within populations, which could not be explained by the different total amounts of scent emitted (Table 2, Fig. 3). As an example, most inflorescences of populations 'i' emitted similar total amounts of floral scent, but their attractiveness differed strongly (34–73%).

The latency time of mosquitoes did not differ among populations (ANOVA: F (5, 314)=0.33; $P=0.89$), and was on average 30 min. However, overall significant differences were found in the post choice behavior (Kruskal–Wallis–ANOVA: H (5, 25)=11.139; $P=0.049$). The 'searching' behavior was recorded most often when inflorescences of population 'a' were offered to the mosquitoes, and less often when they were offered inflorescences of population 'c'. Nevertheless, there were no significant differences in post hoc tests.

Electrophysiological Recordings EAG responses of male and female *C. p. molestus* to several odor components of *S. otites* are shown in Fig. 4. All tested compounds elicited EAG responses, and the effect of dilution was evident for each compound. EAG responses generally increased with increasing dose of tested compounds. However, mosquitoes responded differently to compounds tested, and we also recorded differences in the responses of males and females to different compounds (Table 3). The strongest responses (110–151%) were elicited by linalool oxide (furanoid) and linalool. Furthermore, females responded strongly to (*Z*)-3-hexenyl acetate. Weak responses (<80%) were obtained from both sexes to phenyl acetaldehyde, phenylethyl alcohol, acetophenone, and hexanol.

Discussion

Most compounds found in this study have been reported earlier as part of the floral odor bouquet in other angiosperms (Knudsen et al. 2006), but only nine of the compounds identified in this study were also found in the *S. otites* samples analyzed by Jürgens et al. (2002). In total, we found 22 new compounds in the floral scent of *S. otites* that have not been reported previously in that species. On the other hand, Jürgens et al. (2002) identified nine compounds that were not detectable in our samples. Furthermore, only small amounts of phenyl acetaldehyde were found in that study, but we found that this was the dominant compound in nine populations. Some of these differences might be ascribed to different scent collection

Table 2 Attraction, post choice behavior, and latency time of mosquitoes with respect to the emitted scent from *S. otites* inflorescences (three to five) of different populations (a–i)

Population (Numbers of Female (F) and Male (M) Inflorescence Samples Tested in Bioassays)	Number of Mosquitoes Tested	Odor Emission of Inflorescence Samples (ng/2 min) Median (Min–Max)	Number of Landed (Attracted) Mosquitoes (%) Median (Min–Max)[a]	Number of Landed Mosquitoes Showing Searching Behavior (%) Median (Min–Max)[b]	Latency Time of Mosquitoes Until Landing (Min) Median (Min–Max)[c]

methods, but probably such differences are also due to sampling of plants of different geographical origin. Different populations of *S. otites* emit population-specific scent profiles with only 19 out of 38 inflorescence volatiles being common to plants of the 9 populations studied here.

Although intraspecific variation in floral scent has been observed for many angiosperms, comprehensive screening for population/geographic variation in floral scent composition has been investigated only in few species, e.g., *Yucca filamentosa* L (Agavaceae; Svensson et al. 2005), *Magnolia kobus* DC (Magnoliaceae; Azuma et al. 2001), *Geonoma macrostachys* Mart. (Arecaceae; Knudsen 2002), *Silene latifolia* L. (Caryophyllaceae; Dötterl et al. 2005b), and *Ophrys* species (Orchidaceae; Mant et al. 2005). The intraspecific variability found in our dataset was comparable to variability found in other studied taxa. Such variability may be the result of genetic drift or natural selection (Tollsten and Bergström 1993). Furthermore, different chemotypes may be adapted to different pollinators (Whitten and Williams 1992; Tollsten and Bergström 1993).

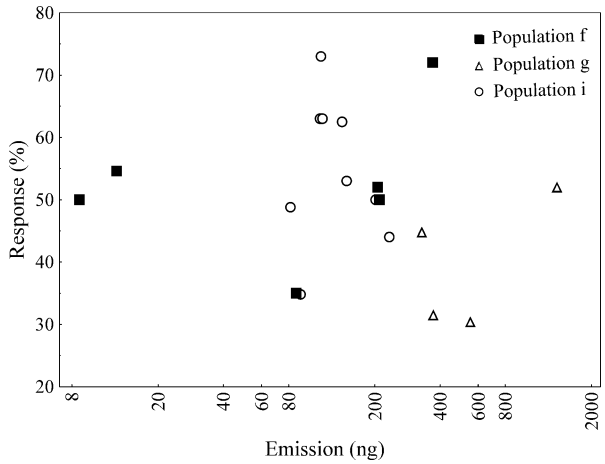

Fig. 3 Total amount of scent emission from *S. otites* inflorescences and % mosquitoes attracted in the wind tunnel (N=100%=170, 98, 260 for 'f', 'g', and 'i' population, respectively)

So far, we do not know the evolutionary factors that trigger the observed odor variability among *S. otites* populations. Different pollinators associated with the different populations might exert different selective pressures on the odor. Only a few species of nocturnal Lepidoptera and mosquitoes have been recorded as pollinators in this species (Brantjes and Leemans 1976); among them, *Autographa gamma* L. and *Culex pipiens*. Whereas *A. gamma* is known to be strongly attracted by lilac aldehyde (Plepys et al. 2002a, b), *C. pipiens* is known to respond strongly to phenyl acetaldehyde (Jhumur et al. 2006).

In this study, phenyl acetaldehyde was the dominant and abundant odor compound, followed by lilac aldehyde, (*Z*)-3-hexenyl acetate, linalool oxide (pyranoid), (*Z*)-3-hexen-1-ol, benzaldehyde, phenylethyl alcohol, linalool, linalool oxide (furanoid), lilac alcohol, acetophenone, methyl salicylate, and hexanol. Most of these compounds are known to elicit strong antennal responses and/or to be attractive to moths such as *Hadena bicruris* Hufn. (Lepidoptera: Noctuidae, Dötterl et al. 2006b), *Sphinx perelegans* Edwards (Lepidoptera: Sphingidae, Raguso and Light 1998), *Hyles lineata* L. (Lepidoptera: Sphingidae, Raguso et al. 1996), *Argyresthia conjugella* Zeller (Lepidoptera: Argyresthiidae, Bengtsson et al. 2007), *Cydia pomenella* L. (Lepidoptera: Tortricidae, Bengtsson et al. 2007), and *Mamestra brassicae* L. (Lepidoptera: Noctuidae, Rojas 1999), whereas only phenyl acetaldehyde has been reported as being attractive to mosquitoes (Howse 2003; Jhumur et al. 2006). It is interesting to note that 19 out of 35 identified compounds in *S. otites* were also found in other closely related *Silene* species, which have been described as moth-pollinated flowers (Jürgens et al. 2002). Thus, it is not surprising that besides mosquitoes, moths

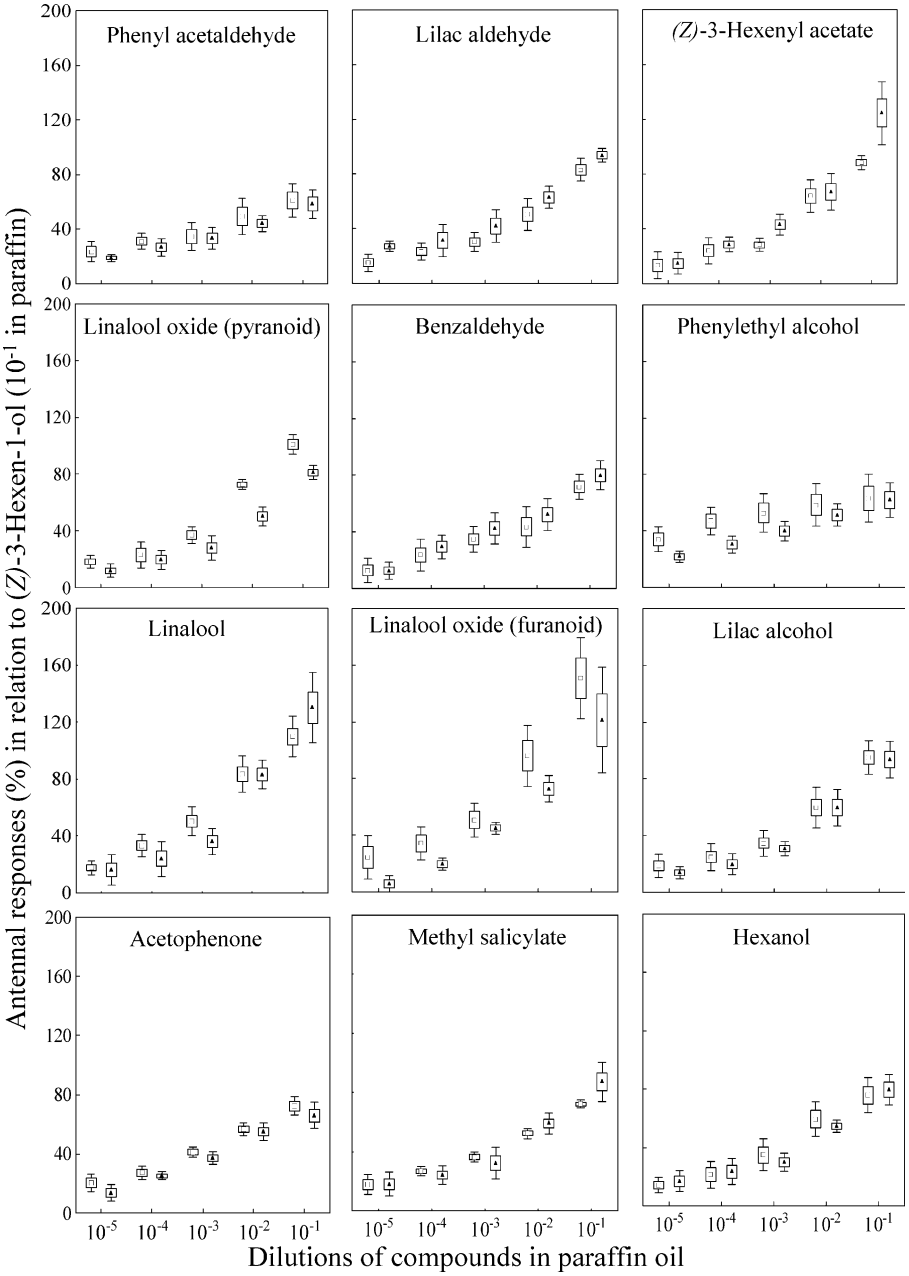

Fig. 4 EAG responses of male (*rectangular*) and female (*triangular*) *Culex pipiens pipiens* biotype *molestus* to different dilutions (in paraffin) of common floral scent compounds of *S. otites* of different populations. Twenty microliters of each dilution of 12 scent compounds were tested on 4–6 mosquitoes. The antennal responses are given in relation to a standard stimulus (Z-3-Hexen-1-ol). Odor compounds have been sorted according to their mean percentage amounts in *S. otites*. All monoterpenoids were used as stereoisomeric mixtures

have also been reported as pollinators of *S. otites* (Brantjes and Leemans 1976).

Our study showed that in the absence of visual stimuli, mosquitoes were attracted to male and female inflorescences of *S. otites* by scent only. The attractiveness of both sexes of this dioecious plant was similarly strong in bioassays, although female and male inflorescences differed with respect to the relative amounts of scent compounds. We found no significant differences in intensity or latency time of response to the inflorescence scents of six different populations. Therefore, different compound mixtures seem to have the same attractiveness.

Table 3 Multiple comparisons based on a GLM of antennal responses of male and female mosquitoes to different compounds and dilutions

Effect	*df*	MS	*F*	*P*

Error	455	106		

Even within *S. otites* populations that showed low qualitative and semiquantitative scent variation, no positive relation between the total amount of scent emitted and the number of mosquitoes attracted was found. This finding is in contrast to the results of Bowen (1992) who found that behavioral response increased with stimulus concentration. Microclimatic conditions in the wind tunnel, such as temperature (which ranged from 20°C to 25°C), humidity, and atmospheric pressure, might have influenced the results obtained in this study (Grimstad and DeFoliart 1975). Furthermore, inflorescences might have emitted not only attractive compounds, but also compounds repellent to mosquitoes (Kessler and Baldwin 2007). The effect of repellency could increase with increasing concentration of these repellent compounds. Jhumur et al. (2006) found that the dominant odor compound of *S. otites*, phenyl acetaldehyde, attracted about 65% of *C. p. molestus*, whereas only about 50% of the mosquitoes were attracted to the entire *S. otites* inflorescence odor in our study. This finding supports the hypothesis that *S. otites* emits not only attractive, but also repellent compounds.

EAG studies were conducted to examine whether mosquitoes are able to detect components of the *S. otites* odor profile other than phenyl acetaldehyde. Mosquitoes responded to all tested compounds, and all may be involved in host-plant finding by mosquitoes. Bioassays are needed to test the behavioral response of *C. pipiens* to these compounds. Compounds tested in the EAG studies were representative of the floral scent composition of *S. otites*, accounting for 97% on average of all samples of this species. Both male and female mosquitoes detected all 13 floral scent compounds (including (*Z*)-3-hexen-1-ol) till 10^{-5} dilutions. Therefore, if some of these compounds also prove to be attractive, then they might be used as reliable cues for finding *S. otites*, and as long-range attractants by *C. pipiens*.

From this and previous studies, mosquitoes have been proven to detect or be attracted to 15 floral volatiles (Mauer and Rowley 1999; Howse 2003; Kline et al. 2003; Jhumur et al. 2006). It is interesting to note that the ranking of the EAG responses does not correlate with the dominance of the volatiles in floral scent profiles. For example, phenyl acetaldehyde elicited only weak responses in EAGs although it is the main compound (35% mean percentage amount) in the scent of *S. otites*. Furthermore, this compound was attractive to mosquitoes (Jhumur et al. 2006). On the other hand, the mean percentage amounts of linalool and linalool oxide (furanoid) were only 3% and 2%, respectively, but elicited the strongest EAG responses.

Several studies provide evidence that release of linalool oxide (furanoid) and linalool may reflect adaptations by plants to attract lepidopteran pollinators (Raguso et al. 1996; Raguso and Light 1998; Andersson et al. 2002; Andersson and Dobson 2003). Linalool also occurs in plants pollinated by bats, bees, flies, beetles, and wasps (Borg-Karlson et al. 1996; Raguso and Pichersky 1999). These monoterpenoids may also be important for attraction of mosquitoes and could explain the mixed pollinator guild found in *S. otites*, mainly moths and mosquitoes. Indeed, the attractiveness of linalool for mosquitoes was confirmed by Kline et al. (2003). In a dual-port olfactometer, more *Aedes aegypti* (L.) individuals were attracted by linalool than by a control. Although these two oxygenated monoterpenes are generally assumed to be pollinator attractants, Ômura et al. (2000) reported that linalool oxide (furanoid) acted as a weak deterrent in proboscis extension responses and a weak repellent in flower alighting tests with the cabbage butterfly *Pieris rapae* L., indicating that this compound can be repellent and attractive to insects. Bioassays are needed to determine the behavioral response to linalool oxide in mosquitoes.

Similarly to phenyl acetaldehyde, phenylethyl alcohol (3% mean percentage) elicited only weak EAG responses, although this compound may also be attractive to mosquitoes. Mauer and Rowley (1999) found that *C. pipiens* was attracted to the scent of the common milkweed *Asclepias syriaca* L., which is dominated by phenylethyl alcohol and benzyl alcohol. The authors assumed that these two benzenoids were responsible for the attraction of mosquitoes to *A. syriaca*, but they failed to attract mosquitoes in a dual-port olfactometer to a synthetic mixture of these two compounds.

It is interesting to note that in our study, *C. pipiens* also responded to the typical green leaf odors of *S. otites*, such as (*Z*)-3-hexenyl acetate. These compounds are not only released from several plant species in response to herbivory, but also serve as attractants for a variety of predatory and parasitic insects (see Röse et al. 1998; James 2005). In the natural environment, green leaf compounds are widespread and would not necessarily guide insects directly to flowers (Honda et al. 1998), although being directed to vegetation would certainly increase the probability of finding flowers.

In summary, floral scent compositions of *S. otites* populations from different geographical origin are highly variable, but nevertheless similarly attractive to *Culex pipiens molestus* mosquitoes. Mosquitoes can detect the most common and abundant scent compounds of *S. otites* inflorescences, but knowledge of the biological significance of most of the compounds is still lacking (e.g., attractant or repellent). By means of bioassays, we are presently evaluating the role of these compounds in the plant–pollinator interactions of *S. otites* and mosquitoes, which might lead to the development of new means of pest control and mosquito attractants and repellents.

Acknowledgements The authors thank Sigrid Liede-Schumann for supporting this study and Taina Witt who gave valuable comments on earlier versions of the manuscript. Karlheinz Seifert and Jette Knudsen provided authentic standard compounds. Rainer Krug and Deinlein Heike helped in the cultivation of the plants. The comments of Monika Hilker and two anonymous referees were especially helpful for the improvement of the manuscript. Umma Salma Jhumur was funded by the German Research Foundation (DFG Research Training Group 678).

Received: 21 May 2007 / Revised: 14 September 2007 / Accepted: 25 October 2007 / Published online: 29 November 2007

Abstract We tested whether changes in long-term nutrient availability would affect the xylem quality and characteristics of Scots pine trees as a food source for the larvae of the xylophagous wood borer *Hylotrupes bajulus* L. (Cerambycidae). We looked for an effect of host plant growth and xylem structural traits on *H. bajulus* larval performance, and looked for delayed effects of long-term forest fertilization on xylem chemical quality. In general, larval performance was dependent on larval developmental stage. However, the growth of larvae also varied with host plant quality (increases in the concentration of nitrogen and carbon-based secondary compounds of xylem were correlated with a decrease in the larval growth rate). The greater annual growth of trees reduced tracheid length and correlated positively with second-instar *H. bajulus* growth rate. This is consistent with the hypothesis that intrinsic growth patterns of host plants influence the development of the xylophagous wood borer *H. bajulus.*

Introduction

Wood-boring beetles (Coleoptera: Cerambycidae) are predominantly xylophagous insects and are commonly referred to as long-horned beetles when they are adults and as round-headed borers when they are larvae (Linsley 1959). They attack the xylem of host plants in a variety of conditions ranging from living trees to dead decaying wood (Linsley 1959; Hanks 1999). Since they have adapted to such highly variable hosts, wood borer species have tremendous diversity, and many of these species are serious pests of forest trees. The larvae of the old house borer, *Hylotrupes bajulus* L. (Coleoptera: Cerambycidae) feed on the sapwood of dying or dead host species such as pine, spruce, or fir in both natural and managed forests as well as construction timber used in buildings. *H. bajulus* larvae may consume heartwood only if the sapwood has been destroyed by the larvae (Robinson and Cannon 1979). The larvae spend most of their lifetime (2–12 years) inside the trunk consuming the xylem tissue. Although the taxonomy, species distributions, and larval host ranges of long-horned beetles have been extensively studied, little is known about their chemical ecology in relation to growth and survival (Ljungkvist 1983; Allison et al. 2004).

Nitrogen is a vital component of the diet of insects, and the levels of nitrogenous compounds can influence the interactions between herbivorous insects and their host plants (Mattson 1980; Holopainen et al. 1995). In forestry, nitrogen fertilizers are used to enhance timber production,

but much less attention has been paid to the effects of fertilizers on the characteristics of xylem and on the performance of the xylophagous insects that attack woody plants (Kytö et al. 1996). The modification of plant resource balances by fertilization treatments might change the structure of the wood, e.g., tracheid properties (Mäkinen et al. 2002), as well as have effects on mechanical properties of xylem (Lucas et al. 2000). This, in turn, might have an impact on the performance of herbivores. These are all topics that need clarification. It is known that the carbon-based secondary compounds (e.g., terpenes and resin acids) in conifers deter insect pests and fungal pathogens (Gershenzon and Croteau 1991; Nerg et al. 2004). Xylem resin reduces the feeding activity of *H. bajulus* larvae (Holm and Ekbom 1958). This study examined the effects of a long-term increase in nutrient availability on tree growth, tracheid properties, the nutritional value of xylem tissue, and the growth of wood-boring *H. bajulus* L. larvae.

Methods and Materials

Site Description and Treatments The Scots pine (*Pinus sylvestris* L.) trees used in this study were part of an earlier experiment established by the Finnish Forest Research Institute in which several experimental sites in Finland were set up in the 1950s to investigate the effects of forest fertilization on tree growth. The experimental sites used were SITE1—Padasjoki (61°23′N, 25°3′E), SITE2—Vilppula (62°4′N, 24°29′E), and SITE3—Punkaharju (61°40′N, 29°18′E) (Turtola et al. 2002). Three fertilization treatments were applied to the plots at each site: 1) plots with no fertilization (control), 2) plots fertilized with nitrogen (N), and 3) plots fertilized simultaneously with calcium, nitrogen, and phosphorus (CaNP). There was one plot per treatment at each site, as individual trees were considered to act as replicates in these forestry experiments designed in the 1950s. The size of each plot was 40×40 m, with a 30×30 m area delimited for tree felling centered in each plot. Fertilization treatments (year of fertilization) were initiated in SITE1 when the trees were 12 yr old: N (1958, 1963, 1968, 1973, 1978, 1983, 1988, 1993, 1998); Ca (1959, 1978); P (1958, 1978, 1993); SITE2 when trees were 12 yr old: N (1959, 1964, 1969, 1974, 1979, 1984, 1989, 1994); Ca (1959, 1979); P (1959, 1979, 1994); SITE3 when trees were 14 yr old: N (1959, 1969, 1979, 1989); Ca (1959, 1979); P (1959, 1979). Fertilization treatments: N=82 kg ha^{-1} of nitrogen applied as ammonium sulfate in 1958–1959, 92 kg ha^{-1} as urea in 1963–1969, and 150–180 kg ha^{-1} as ammonium nitrate in 1973–1998; Ca=calcium applied as limestone, first at 2000 kg ha^{-1}, and later at 4000 kg ha^{-1}; P=phosphorus, initially applied at 29 kg ha^{-1} as finely ground rock phosphate, and subsequently at 40 kg ha^{-1} as superphosphate.

Sampling All trees from the 30×30 m area were divided into three groups according to their basal area. From each of these groups, two trees were randomly selected for felling. In April 2000, 18 trees (six per treatment) from each site were harvested. For chemical and xylem property analysis, consecutive xylem disks (about 2 cm thick) with bark from breast height (H1; 130 cm from ground level) and canopy height (H2; 0.7 × tree height) were sawed. The xylem disks were frozen and stored at −20°C before analysis. All xylem used in the following analysis was taken from the sapwood. The analyses of nutrient and tracheid properties were performed on xylem disks from both H1 and H2, while for secondary compound analysis, only xylem disks from H1 were used. To examine the growth performance tests of *H. bajulus* L. larvae, an additional 20-cm-long xylem disk was sawed from each tree, just above the disks taken from H1 and H2 for chemical and xylem property analysis. The sapwood of these xylem disks was sawed into blocks 80×40×20 mm and air-dried at room temperature before use in the insect performance tests. The sapwood diameter from the latest 20 annual rings was measured.

Tracheid Properties At H1, tracheid length was measured from annual ring numbers 12, 30, and 40 from the pith outwards. The annual ring number 12 was at the border of the sapwood and heartwood. At H2, tracheid length was measured from annual ring numbers 5, 10, and 12 from the pith outwards. Early- and latewood samples were separated from these annual rings and macerated with glacial acetic acid/hydrogen peroxide (1:1, *v*/*v*) at 60°C overnight. The suspension was washed with distilled water and stained with safranin (1%, 10 sec). Tracheids were placed on glass slides, and 50 unbroken tracheids were measured with a light microscope.

Chemical Analysis A 0.125-g (dry weight) powdered xylem sample was weighed for the nitrogen (N) analysis. Nitrogen was analyzed with a LECO CHN 2000 analyzer (USA). The analyzer was calibrated with EDTA (containing 40.97 % carbon, 9.57 % nitrogen, and 5.48 % hydrogen) as a standard with every eighth sample being a pine control sample. The performance of the apparatus was monitored once a day with certified reference samples (BRC 101 and NIST 1547). The total nitrogen content was calculated as mg g^{-1} dry weight. Other xylem characteristics, such as, cellulose, hemicellulose, lignin, and starch were measured (Heijari et al. 2005), but these parameters did not have any significant effect on *H. bajulus* performance (data not

shown). In the monoterpene analysis, sapwood samples (two replicate wood pieces) were extracted with *n*-hexane as described earlier by Manninen et al. (2002). Wood resin acids were extracted from freeze-dried and powdered xylem samples (two replicate wood pieces) with petroleum ether-diethyl ether. Monoterpene and resin acid extracts were analyzed by gas chromatography-mass spectrometry (Hewlett Packard GC type 6890, MSD 5973) using a 30-m-long HP-5MS (0.25 mm ID, 0.25-µm film thickness, Hewlett Packard) capillary column (Manninen et al. 2002). Helium was used as the carrier gas. The temperature program for monoterpenes rose from 50°C to 250°C, and for resin acids from 50°C to 270°C. The heating rate was 5°C min^{-1}. The SCAN technique (mass numbers from *m*/*z* 30 to 350 were recorded; signal ions in monitoring; 93, 133, 136, 161, 204 *m*/*z*) was used for monoterpene samples, and the technique of selected ion monitoring (SIM) 299, 301, 314, 316 *m*/*z* for resin acid samples. For quantification of resin acids and terpenes, calibrations were made from known amounts of available pure compounds relative to known amounts of the internal standard (1-chloro-octane for monoterpenes and heptadecanoic acid for resin acids).

Larval Performance Laboratory grown *Hylotrupes bajulus* L. larvae were pre-grown on protein-yeast enriched pine sapwood to accelerate growth. The growth conditions were 27°C and 70% relative humidity (RH) in darkness. Adults and larvae were reared as described by Berry (1972) and the European Standard EN 47 (1988).

Two sawed Scots pine xylem blocks, from both H1 and H2, were placed against each other and held together with an elastic band. A groove (45×15×10 mm) was gouged into the point of contact. The double xylem block system was weighed, and one randomly selected second- (ca. 200 mg) or third-instar (ca. 355 mg) *H. bajulus* was enclosed into each groove under a glass plate, which was tightened by an elastic band to prevent the larvae from escaping. The double xylem block system (four replicates per tree per sampling height) with larvae were enclosed inside plastic boxes (volume 750 ml). The larvae were allowed to feed for 127 d in a dark culture room at 21°C and 60% RH. The mortality of the whole larval population feeding on xylem taken from H1 and H2 was 8.6% and 19.3% for I2L and 3.8% and 4.5% for I3L, with no statistical differences between sampling heights or instars (data not shown). After feeding, the relative growth rate (RGR) for the living larvae was calculated ($RGR = (\ln W_2 - \ln W_1) / (t_1 - t_2)$, where W_1 and W_2 were the fresh biomass at the beginning (t_1) and end (t_2) of the sampling period, and *ln* is the natural logarithm; Waldbauer 1964).

After the feeding tests, larvae were placed on the Scots pine wood to complete their development. Emerging adults were allowed to copulate. Females were allowed to lay eggs in Petri dishes with Scots pine wood disks, and the eggs hatched after about 9 d. The neonatal larvae (I1L), mean weight 0.24 mg) were transferred after hatching into a 5-mm deep hole. The hole was drilled into the top of the 50×20×20 mm size Scots pine xylem blocks taken from the trees of different fertilization treatments and sites described above, both at H1 and H2. Progenies of each female were randomized among the treatments. Larvae were allowed to feed for 194 d in a dark culture room at approximately 25°C and 85% RH. The relative growth rate for the I1L larvae was calculated as described.

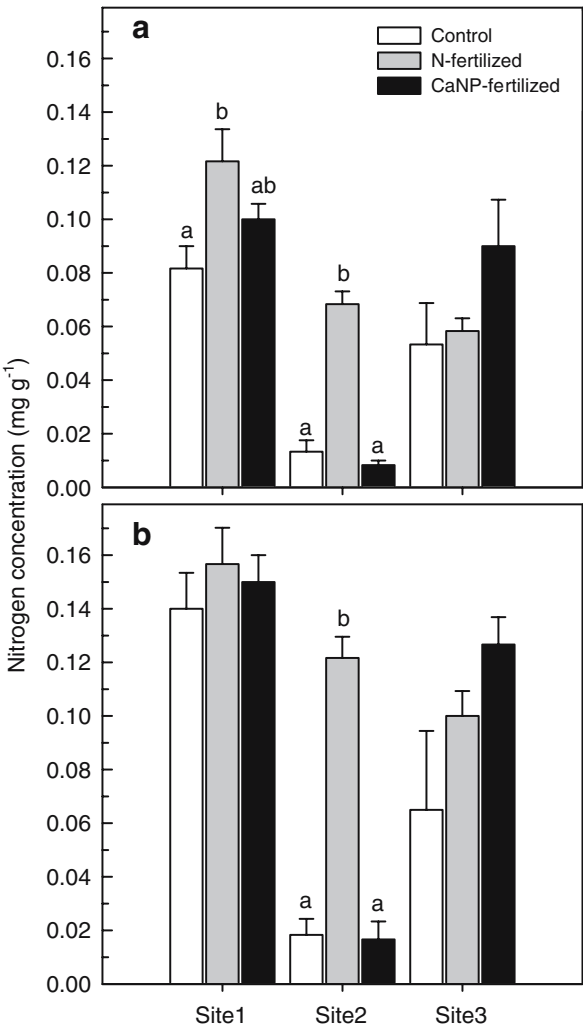

Fig. 1 The concentration of nitrogen (mean + SE) in Scots pine sapwood at breast- (H1; **a**) and canopy height (H2; **b**) in three experimental sites and fertilization treatments (control=no fertilization, N-fertilized=fertilization with nitrogen, CaNP-fertilized= fertilized with calcium, nitrogen and phosphorous). Means indicated with different letters within sites are significantly different according to ANOVA, $P<0.05$, $N=6$

Statistical Analyses The effect of fertilization treatments at each site was analyzed by analysis of variance (ANOVA) (GLM Univariate) and followed by the Tukey multiple range test (significance level $P<0.05$). *T* test (*t*) (or Chi-Square for larval mortality) was used when differences between sampling heights were tested. The relative growth rate (RGR) of *H. bajulus* larvae was calculated separately for the different larval stages. Correlation coefficients (*r*) between RGR and consumed xylem with different xylem properties were tested by Pearson correlations. Statistical analyses were carried out with SPSS 11.5.1 for Windows statistical software package.

Results and Discussion

It is known that nitrogen in plant tissue can positively affect host utilization by insects (Mattson 1980; Holopainen et al. 1995). In our study, *H. bajulus* larval performance was similar in wood taken from fertilized and non-fertilized trees (Table 1). Interestingly, we found that for 2nd- and 3rd-instar *H. bajulus*, RGR was lower for xylem from canopy height than that found in xylem collected from breast height SITE2 ($t_{10}=-2.343$, $P=0.041$ and $t_8=-2.893$, $P=0.020$) and SITE3 ($t_{10}=-2.884$, $P=0.018$ and $t_9=-4.482$, $P=0.002$). Conversely, the mean (± SD) final weight of neonatal larvae was marginally lower 0.58± 0.16 mg at H1 compared to 0.72±0.31 mg at H2 (Table 1). Similarly, Körting (1972) observed that neonatal larvae of *H. bajulus* had a three-fold higher growth rate on Scots pine canopy height xylem than at breast height xylem. The differences in neonatal larval growth rates at H1 and H2 may be a consequence of the within-tree variation in nitrogen concentration. As a consequence of its higher nitrogen concentrations, canopy height xylem may be a superior food source for neonatal *H. bajulus* larvae. The nitrogen concentration was significantly lower at H1 than at H2 in SITE1 in control ($t_{10}=-3.693$, $P=0.004$) and CaNP-fertilized trees ($t_{10}=-4.330$, $P=0.001$) and in SITE2 ($t_{10}=-5.766$, $P<0.001$) and SITE3 ($t_{10}=-3.983$, $P=0.003$) in N-fertilized trees (Fig. 1). Addition of nitrogen to Scots pine (*Pinus sylvestris* L.) plots increased the xylem nitrogen concentration (Fig. 1). This observed increase in nitrogen concentration is consistent with earlier studies (Helmisaari and Siltala 1989; Finér and Kaunisto 2000). We propose that for late instars, the nitrogen content of food is not as essential in the maintenance of daily metabolism as it is for neonatal larvae that are increasing their body mass.

Interestingly, we found that the performance of wood-boring *Hylotrupes bajulus* larvae was explained by the tree radial diameter; tree diameter correlated positively with the RGR of I2L in SITE2 ($r=0.609$, $P<0.001$, $N=34$) and in SITE3 ($r=0.430$, $P=0.010$, $N=35$). These results agree with Hanks et al. (2005) who reported that larvae of *P. semipunctata* (Cerambycidae) increased their body size more in large circumference eucalyptus host trees than in small trees. Furthermore, Ruel and Whitham (2002) found that pinyon pines (*Pinus edulis*) that had grown vigorously during the juvenile stage suffered greater herbivory when these trees matured and produced smaller growth rings. On the whole, these results provide evidence that some long-living wood-boring larvae may perform better in large host trees than in slow-growing trees. Future studies should examine larval performance in host trees undergoing different intrinsic growth patterns (e.g., provenance experiments).

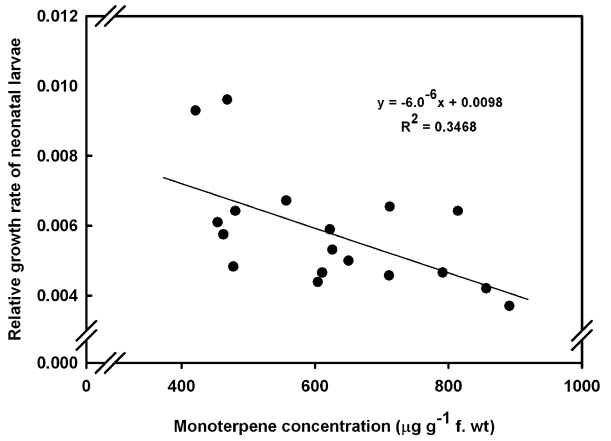

Fig. 2 Correlation between relative growth rate of neonatal *H. bajulus* larvae during 194-d feeding and total monoterpene concentration (μg g^{-1} fresh weight) at breast height of Scots pine sapwood in control trees. $P<0.05$, $N=18$

Although, the differences in the trunk diameter and volume of trees from fertilized and non-fertilized plots were significant (see Turtola et al. 2002; Heijari et al. 2005), fertilization treatments did not cause any changes in carbon allocation to secondary compounds in the xylem. Total resin acid concentration per volume of xylem (mean ± SE) in SITE3 trees (3.8±0.5 mg cm^{-3} dry weight) was significantly ($F_{2,\ 15}=7.568$, $P=0.005$) higher than in SITE2 trees (2.5±0.2 mg cm^{-3} dry weight) and also marginally ($P=0.061$) higher than in SITE1 trees (2.7±0.4 mg cm^{-3} dry weight). We observed that the total monoterpene concentration of sapwood had a negative effect on the growth rate of neonatal larvae (Fig. 2), whereas the concentration of resin acids did not affect larval growth. This result is consistent with earlier studies, which indicate that specific constitutive defense chemicals have effects on the performance of *H. bajulus* neonatal larvae and that early instars are more sensitive to host plant quality than late instars (Montgomery 1982), with high mortality occurring generally among early instars (Preszler and Price 1988). Furthermore, in SITE3, the generally lower growth and smaller diameter of the trees might be the reason for the high content of resin acids per volume of xylem. The inconsistent results among sites may also be caused by the fact that all of the sites were *Myrtillus* type forests, and thus might have been more nutrient-rich than the pines generally grown in Finland (Saarsalmi and Mälkönen 2001). Our study showed that the effect of fertilization on xylem constitutive defense was not significant. The genetic structure of the investigated stands might have differed substantially, and thus it is unlikely that the results would have differed in other tree-growing areas in Finland. Concomitantly, our study provides support for the conclusion of Herms (2002), who proposed that in general, fertilization treatments neither enhance nor reduce pest resistance in woody plants.

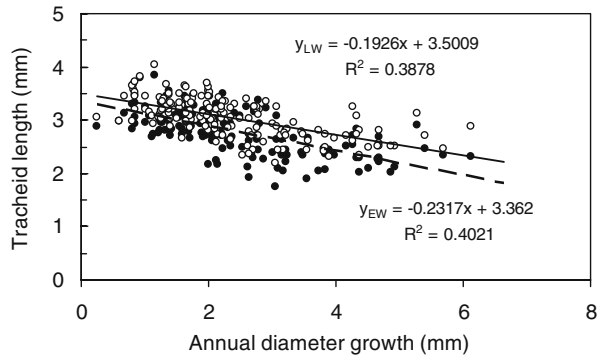

Fig. 3 Linear correlation between tracheid length (mm) and annual diameter growth (mm) at breast height in early (closed circles) and latewood (open circles) of Scots pine. Data (pooled from all sites) are from 12th, 30th, and 40th annual rings of xylem. Equations for relationships and R^2 are shown (y_{EW}=earlywood and y_{LW}=latewood), $P<0.05$

At the breast (H1) and canopy height (H2), the fertilization treatments had no significant effects on tracheid length (data not shown). In SITE3, tracheids in xylem collected from H1 and H2 were significantly ($F_{2,\ 15}>5.141$, $P<0.05$ and $F_{2,\ 15}>4.915$, $P<0.023$) longer than in trees growing at the other sites. In the pooled data, there was a negative correlation between the growth of annual rings and tracheid length (Fig. 3), but this was not associated with the fertilization treatments. Similarly, a fertilization experiment with Norway spruce (*Picea abies*) observed decreased tracheid length (Mäkinen et al. 2002). Lucas et al. (2000) detected differences between the mechanical properties of xylem, and this in turn had an impact on the performance of herbivores. We found that the RGR of I2L exhibited a significant positive correlation ($r=0.359$, $P=0.009$, $N=53$) with the latewood tracheid length, and xylem consumption of I3L showed a positive correlation ($r>0.542$, $P<0.030$, $N=16$) with both early- and latewood breast height tracheid lengths. These results indicate that cell properties could influence the growth of late instar larvae, but not the growth of the neonatal larvae. Furthermore, xylem cell properties may explain some of the differences occurring in growth performance of xylophagous *H. bajulus* larvae.

In summary, the nitrogen concentration of xylem had a positive effect on wood borer performance, but the impact was stronger on early instar than on late instar *H. bajulus* larvae. It is likely that fertilization treatments induce changes in the growth and nutrient concentrations of xylem, but that these do not lead to any major changes in tracheid properties or in constitutive defense level of xylem. The effect of long-term fertilization on the performance of wood-boring xylophagous *H. bajulus* larvae was notable,

and our results suggest that variation in the growth of Scots pine forests can have effects on the utilization of xylem by *H. bajulus* larvae.

Acknowledgments The Graduate School in Forest Sciences and The Academy of Finland (Research Council for Biosciences and Environment, projects 45066 and 43159) have financially supported this research. We thank the Finnish Forest Research Institute and Raino Lievonen for organizing the felling of trees and transportation of the xylem disks. We thank also Terhi Vuorinen, Jaana Rissanen, and Juhani Tarhanen for helping in the chemical analysis and Ewen MacDonald for revising the language of the manuscript.

Abstract Locoweeds (*Astragalus* and *Oxytropis* spp. that contain the toxic alkaloid swainsonine) cause widespread poisoning of livestock on western rangelands. There are 354 species of *Astragalus* and 22 species of *Oxytropis* in the US and Canada. Recently, a fungal endophyte, *Embellisia* spp., was isolated from *Astragalus* and *Oxytropis* spp. and shown to produce swainsonine. We conducted a survey of the major locoweeds from areas where locoweed poisoning has occurred to verify the presence of the endophyte and to relate endophyte infection with swainsonine concentrations. Species found to contain the fungal endophyte and produce substantial amounts of swainsonine were *A. wootoni*, *A. pubentissimus*, *A. mollissimus*, *A. lentiginosus*, and *O. sericea. Astragalus* species generally had higher concentrations of swainsonine than *Oxytropis.* Swainsonine was not detected in *A. alpinus*, *A. cibarius*, *A. coltonii*, *A. filipes*, or *O. campestris*. The endophyte could not be cultured from *A. mollissimus* var. *thompsonii* or *A. amphioxys*, but was detected by polymerase chain reaction, and only 30% of these samples contained trace levels of swainsonine. Further research is necessary to determine if the endophyte is able to colonize these and other species of *Astragalus* and *Oxytropis* and determine environmental influences on its growth and synthesis of swainsonine.

Introduction

Historically, locoweeds (*Astragalus* and *Oxytropis* spp. that contain the toxic alkaloid swainsonine) have caused widespread livestock losses on western rangelands (Kingsbury 1964), and they remain a major impediment to livestock production (Ralphs et al. 2002a). There are 354 species of *Astragalus* and 22 species of *Oxytropis* in the US and Canada (Welsh et al. 2007a), and *Astragalus* and *Oxytropis* plants occur in every major plant community on western rangelands. Only 24 species in North America have been verified to contain swainsonine or have a history of causing locoism (Ralphs et al. 2002a).

Recently, a fungal endophyte, *Embellisia* spp. Pleosporaceae, was isolated from *Astragalus* and *Oxytropis* spp. and

shown to produce swainsonine (Braun et al. 2003). Creamer et al. (2007) summarized recent research on *Embellisia* in locoweeds and its synthesis of swainsonine. The fungus was isolated from the stems, leaves, flowers, and seed of locoweed plants (Braun et al. 2003) and was shown to be solely responsible for the synthesis of swainsonine, and thus the toxicity of the plant (McLain-Romero et al. 2004a). Fungal isolates from *Oxytropis* species were similar, but those from *Astragalus* species were genetically and morphologically diverse (Belfon and Creamer 2003), suggesting they may be different species or subspecies. The fungus is passed to the next generation through the seed coat (Romero et al. 2002), and when the seed coat is removed and the embryo germinated alone, the plants are fungus- and swainsonine-free (McLain-Romero et al. 2004b). Environmental stresses, such as moderate water stress and a decrease in pH, appear to increase swainsonine concentration in *Embellisia* cultures (Oldrup 2005). An increase of the temperature or nutrient deficiency (N, P, K) did not influence swainsonine concentration. Gardner et al. (2004) reported a strong correlation (r=0.92) between swainsonine concentration and presence of the endophyte in plant parts.

There is a need to verify both the endophyte and its synthesis of swainsonine in major locoweed species. Previous studies have shown variability in the ability to culture the endophyte and detect swainsonine among varieties, populations, and individual plants. Of the three varieties of *O. lambertii*, the endophyte was cultured and swainsonine was measured only in var. *bigelovii*, and then only in its populations in the southwest U.S. (Ralphs et al. 2002b). Gardner et al. (2001) reported there were some individual plants within all surveyed populations of both *O. sericea* and *O. lambertii* where swainsonine concentration was below the level of detection, and that plant-to-plant variation in swainsonine concentration was the greatest source of variability in the statistical model.

The objective of this study was to collect the major locoweeds from areas where locoweed poisoning has occurred, verify the presence of the endophyte, and relate endophyte infection with swainsonine concentrations. Other *Astragalus* and *Oxytropis* species encountered in the survey were harvested for a random check of the endophyte in nonlocoweed species.

Methods and Materials

Collection and preparation of samples Locoweed species, varieties, and populations, along with locations are presented in Table 1. All plants at all locations were collected during the flower stage of growth during the spring and summer 2005. Five or 10 plants were collected at each location, and each plant was divided into three subsamples, each containing leaves, stems, and flowers. One subsample was pressed to quickly dry the intact plant for subsequent isolation and culturing of the endophyte. The other two subsamples were frozen immediately on dry ice. One frozen sample was used for polymerase chain reaction (PCR) detection of the endophyte, and the other was later freeze-dried and retained for swainsonine analysis. Two representative plants were pressed at each location; one for positive identification and a voucher specimen that is archived at the S.L. Welsh Herbarium in the Monte L. Bean Life Science Museum, Brigham Young University, Provo, UT, USA, and the other is archived at the Poisonous Plant Research Laboratory herbarium in Logan, UT, USA.

Swainsonine assay Samples were analyzed for the toxin swainsonine by the procedures described by Gardner et al. (2001). In brief, samples were freeze-dried, all parts were ground together, and 100 mg of plant material was extracted with chloroform and acetic acid. The acetic acid portion was passed through a cation exchange resin to retain the swainsonine, which was subsequently removed with a weak ammonium hydroxide solution. An aliquot of the final extract was quantitatively analyzed for swainsonine by liquid chromatography–mass spectrometry. The detection limit of swainsonine was 0.001% of dry weight. In samples with a low swainsonine concentration near the detection limit, the presence in the sample was confirmed by a second assay of the extract by using gas chromatography/mass spectrometry (GC/MS; Gardner et al. 2001). For GC/MS analysis, a 1.0-ml aliquot of the sample extract was evaporated to dryness under a flow of nitrogen at 60°C. To the dried sample was added 0.200 ml of *N*,*O*,-bis (trimethylsilyl) trifluoroacetamide with 1% trimethylchlorosilane (Pierce Chemical) and heated for 30 min at 60°C. The samples were then transferred to a 400-µl glass insert for the GC auto sample vial and analyzed by GC/MS (2 µl injection). Detection of swainsonine was confirmed by comparison of GC retention time and mass spectrum to that of a standard swainsonine sample $(TMS)_3$ derivative.

PCR detection of endophyte Frozen plant specimens were used for the detection of the endophyte with PCR. For each plant, 0.3 g of the frozen tissue was ground with liquid nitrogen. Following the protocol for the DNEasy Plant Mini kit (Qiagen, Valencia, CA, USA), DNA was extracted from the ground samples. The PCR reaction mixture contained a final concentration of 400 µM dNTP's (Promega, Madison, WI, USA), 3 mM $MgCl_2$, 0.25 µM each primer, 1.25 µ GoTaq Flexi DNA Polymerase (Promega, Madison, WI, USA), and 5X Green GoTaq Flexi buffer supplied with the enzyme. Sterile water and 5 µl of the DNA extract were added for a total volume of 50 µl. Primers used to amplify

[a] Voucher specimens held in the S.L. Welch Herbarium, M.L. Bean Natural History Museum, Brigham Young University, Provo, UT.

the internal transcribed spacer (ITS) region were OR1 (5′ GTC AAA AGT TGA AAA TGT GGC TTG 3′) and ITS 5 (White et al. 1990). Conditions for PCR were 94°C for 3 min followed by 30 cycles of 94°C for 45 sec, 48°C for 1 min, and 72°C for 30 sec with a final extension at 72°C for 5 min.

For analyzing the PCR products, a 1.5% agarose gel that contained ethidium bromide was run at 100 V for 1.5 hr and visualized under UV illumination. Positive amplifications resulted in a band of approximately 580 base pairs (bp). Because the primer set can also amplify *Alternaria* species, all positive amplifications were digested with the restriction enzyme *Ava*II. For digestion, 5 μl of PCR product were added to 0.5 μl *Ava*II (Promega, Madison, WI, USA), 1 μl buffer C supplied with the enzyme, and sterile water for a total of 10 μl. After incubation at 37°C for at least 1 hr, restriction fragments were separated by gel electrophoresis according to the conditions above. A result of two fragments of lengths 200 and 380 bp confirmed the positive detection of the locoweed endophyte.

Isolation of endophyte Fungal isolation was conducted from four subsamples of leaves, stems, and flowers (if present) of dried plant specimens. The greenest tissues were selected and surface sterilized for 30 sec in 70% ethanol, followed by 3 min in 20% bleach, and then 30 sec in sterile water. Tissues were dried on sterile paper towels and plated onto water agar media. To expedite the growth of the fungus, the tissues were pressed into the agar. Plates were stored at room temperature and examined weekly for fungal growth. Any observed fungal growth was transferred to potato dextrose agar (PDA) plates and stored at room temperature for comparative morphological analysis.

Culture isolates were labeled positive when the morphology on PDA matched that of known locoweed endophytes. To confirm a positive result, a portion of the culture was dissected away from the media, ground with liquid nitrogen, and analyzed by PCR by using the same protocol as listed above for frozen plant specimens. If samples gave differing results by culture and PCR, PCR was carried out from the dried plant material or the cultured fungus.

Results

Swainsonine Astragalus locoweed species were higher in swainsonine concentration than *Oxytropis* species (Table 2). Within the *Astragalus* genus, *A. wootonii* had the highest concentration of swainsonine (0.37%) followed by *A. pubentissimus* (0.21%). Varieties of *A. mollissimus* (excluding *A. mollissiums* va. *thompsonii*) and *A. lentiginosus* were similar (0.19% vs. 0.15%, respectively). *O. sericea* contained the lowest amount of swainsonine within the locoweeds, 0.04%. Swainsonine was not detected in *A. alpinus*, *A. cibarius*, *A. coltonii*, *A. filipes*, or *O. campestris*.

Endophyte The endophyte was cultured from most samples that contained substantial quantities of swainsonine (>0.025%; Table 3). However, it could not be cultured from *A. m. thompsonii*, *A. amphioxys*, and a few of the individual plants of the other locoweeds, but its presence

A. filipes		2	0			
O. campestris		1	0			

was detected by PCR in all these samples. Furthermore, swainsonine was not detected, or was near the detection limit (0.001%) in these samples. In *A. m. thompsonii*, swainsonine was not detected in collections from Price and Moab UT, and was low or at the detectable limit in collections from Blanding UT, Shiprock NM, and Sanders AZ. Likewise, only one sample of *A. amphioxys* contained swainsonine near the detection threshold (0.005%). A few samples of the other species and varieties did not contain swainsonine, or it was at the detection threshold: *O. sericea* (4/26 plants), *A. l. araneosus* (2/15 plants), and *A. l. wahweapensis* (1/10 plants; Table 3).

Discussion

The locoweed species selected in this study were taken from locations where locoweed poisoning is frequent. This study verified that the locoweed species *A. wootoni*, *A. pubentissimus*, *A. mollissimus* vars. *Earleii* and *mollissimus*, *A. lentiginosus* vars. *diphysus*, *lentiginosus*, *wahweapensis*, and *arenosus*, and *O. sericea* contain the fungal endophyte and produce substantial amounts of swainsonine. This was the first report of endophyte detection by culture or PCR from *A. wootoni*, *A. pubentissimus*, and the four varieties of *A. lentiginosus*.

Table 3 Number of samples in which detectable amounts of swainsonine was found, and the endophyte was detected from culture or PCR

Species	Variety	Swainsonine			Endophyte		
					Culture		PCR
		+	−	Low	+	−	
A. wootoni		11	0	0	11	0	11
A. pubentissimus		10	0	0	9	1	10
A. mollissimus	*earleii*	30	0	0	27	3	30
	mollissimus	15	0	0	12	3	15
A. lentiginosus	*diphysus*	10	0	0	8	2	10
	lentiginosus	5	0	0	5	0	5
	wahweapensis	9	0	1[a]	8	2	10
	araneosus	13	0	2[a]	14	1	15
O. sericea	*sericea*	22	1[a]	3[a]	22	4	26
Total		125	1[a]	6[a]	116	16	132
A. mollissimus	*thompsonii*	0	16[a]	9[a]	0	25	25
A. amphioxys		0	6[a]	1[a]	0	7	7

PCR detected the endophyte in all samples.
[a] Swainsonine near or below detection level (0.001).

Astragalus locoweeds were generally higher in swainsonine than the *Oxytropis* species. The endophytes associated with *Astragalus* spp. may be different species or strains of fungus from those that occur in *O. sericea* and *O. lambertii* (Belfon and Creamer 2003). Braun et al. (2003) reported that locoweed populations that had high concentrations of swainsonine produced endophyte cultures that were also high in swainsonine concentration, suggesting that fungal genetics influence swainsonine production. The amount of fungus within the plant, its growth rate, and environmental stress, may also affect swainsonine concentration of the plant.

We confirmed that samples of *A. alpinus*, *A. cibarius*, *A. coltonii*, *A. filipes*, and *O. campestris* did not contain swainsonine, and are, therefore, not likely poisonous.

The toxicity of two species and some individual plants were equivocal. *A. amphioxys* has not been considered to be a poisonous locoweed; however, we detected the endophyte by PCR in all its samples and found swainsonine near the detection threshold in one sample (0.005%). Swainsonine concentration of some samples of *A. m. thompsonii* were near the detection threshold and others were below it. Vallotton and Sterling (2002) also reported that *A. m. thompsonii* contained very low concentrations of swainsonine. In a phylogenetic analysis of locoweeds from New Mexico, *A. m. thompsonii* was grouped in a different cluster from *A. m. mollissimus* and *A. m. earleii* (Kulshreshta et al. 2004). Taxonomically, *A. m. thompsonii* was originally classified as a separate species based on its densely pubescent pods compared to glabrous pods in the other *A. mollissimus* varieties (Welsh 2007b).

There appears to be a discrepancy in the ability to culture the endophyte, its detection by PCR, and subsequent concentration of swainsonine. The endophyte was cultured from most samples where swainsonine concentration was greater than 0.025%. However, it could not be cultured from samples that contained swainsonine near or below the detection threshold (approximately 0.001%), although the endophyte was detected by PCR. The endophyte appears to be present in these plants, yet it apparently does not grow and produce swainsonine. The endophyte in individual plants of *O. sericea* (four), *A. l. areaneosus* (two), and *A. l. wahweapensis* (one), although present, simply may not have colonized these specific plants. Species and varieties, such as *A. amphioxys*, *A. m. thompsonii*, and *O. l. articulata* and *O. l. lambertii* from the previous study (Ralphs et al. 2002b), may contain an endophyte strain that does not colonize the plant effectively, or these plants may suppress its growth.

Fungal endophytes from the Clavicipitaceae family (*Claviceps*, *Neotyphodium*, *Epichloe*, *Balansia*, *Myriogenspora*) occur in temperate pasture grasses throughout the world and produce alkaloids that cause fescue toxicosis in livestock and insects (Porter 1997). Specific alkaloids and their metabolites vary across endophyte strains, grass varieties, and the environment. The endophyte is transferred from the seed of the maternal plant to the successive progeny, which defines the genetic potential of the endophyte (Adcock et al. 1997). However, the plant genotype exerts a large effect in suppressing the fungal growth and subsequent alkaloid synthesis (Agee and Hill 1994; Roylance et al. 1994). Symbiotic relationships of these endophytes increase the fitness of their host grasses (Omacini et al. 2005) and arid land plants (Barrow and Aaltonen 2001; Barrow 2003; Lulcero et al. 2006). Further research is necessary to determine if *Embellisia* spp. enhances the fitness of locoweeds.

The question remains as to the potential toxicity of plants having swainsonine concentrations near the detection threshold. Molyneux et al. (1994) suggested a conservative threshold of toxicity at 0.001%. Swainsonine doses at or above 0.2 mg/kg/day for at least 21 d produced irreversible neurologic disease (Stegelmeier et al. 1999). Less is known of the effect of lower doses of longer duration, but it has been suggested they produce transient weight loss and biochemical lesions (Stegelmeier et al. 1999). Swainsonine concentration in locoweeds of 0.004% would produce a dose of 0.2 mg/kg/day, based on the average locoweed consumption of 25% in diets (Ralphs 1993) and intake of 2% of body weight. Therefore, swainsonine concentrations near the detection threshold (approximately 0.001%) may be potentially toxic.

In summary, locoweed species that historically caused the majority of locoweed poisoning in the western U.S. were found to contain the fungal endophyte and produced toxic amounts of swainsonine. *Astragalus* species were generally higher in swainsonine concentration than *Oxytropis* species. The inability to culture the endophyte from *A. m. thompsonii* and *A. amphioxys*, and the inconsistency of detection of swainsonine in varieties of *O. lambertii* from the previous study, raises questions as to the genetic relationships among some species and varieties in the transmission of the endophyte, and its ability to colonize the plant and synthesize swainsonine. Further research is required to answer these questions.

Abstract Beneficial bacteria that live on salamander skins have the ability to inhibit pathogenic fungi. Our study aimed to identify the specific chemical agent(s) of this process and asked if any of the antifungal compounds known to operate in analogous plant–bacteria–fungi systems were present. Crude extracts of bacteria isolated from salamander skin were exposed to HPLC, UV-Vis, GC-MS, and HR-MS analyses. These investigations show that 2,4-diacetylphloroglucinol is produced by the bacteria isolate *Lysobacter gummosus* (AB161361), which was found on the red-backed salamander, *Plethodon cinereus*. Furthermore, exposure of the amphibian fungal pathogen, *Batrachochytrium dendrobatidis* (isolate JEL 215), to different concentrations of 2,4-diacetylphloroglucinol resulted in an IC_{50} value of 8.73 μM, comparable to crude extract concentrations. This study is the first to show that an epibiotic bacterium on an amphibian species produces a chemical that inhibits pathogenic fungi.

Keywords Beneficial bacteria · Chytridiomycosis · 2,4-diacetylphloroglucinol · *Plethodon cinereus* · *Lysobacter gummosus* · Pathogenic fungi · Salamander

Introduction

Mutualisms between bacteria and metazoa are ubiquitous and ecologically important. Some well-studied mutualisms involve antifungal bacteria and their hosts, including bacteria that reside on plant roots and on the cuticle of leaf cutter ants (Currie et al. 2006; Raaijmakers et al. 2002). Amphibians, which inhabit moist surroundings hospitable to fungi, not only produce defensive secretions that inhibit fungi and other skin microbes (Simmaco et al. 1998; Rollins-Smith et al. 2005), but also harbor a distinct resident cutaneous bacterial community (Harris et al. 2006; Lauer et al. 2007) that resists removal by thorough rinsing. A specific chemical agent of fungal inhibition, however, has remained unidentified. Therefore, this study aimed to isolate an antifungal substance from the cutaneous bacterial community of an amphibian species and to test for its inhibitory activity against a pathogenic fungal species.

Our previous work demonstrated that bacteria isolated from skin of different amphibian species and grown in a low nutrient medium on a Petri dish inhibit fungi that are pathogenic to amphibian adults and embryos (Harris et al. 2006; Lauer et al. 2007). While these results suggest that antifungal bacteria produce an antibiotic, inhibition by resource competition can also occur. Crude extract removed from bacteria grown in broth culture, however, inhibited a fungal pathogen (Walters 2007), providing evidence that skin bacteria had produced one or more antifungal chemicals. Of the various antifungal species identified by sequencing of the 16S rRNA gene (~1,400 bp), an isolate with 99% genetic match to *Lysobacter gummosus* (AB161361, GenBank) was chosen for this study because of its consistently strong antifungal properties. This species was isolated from the red-backed salamander, *Plethodon cinereus*, and from the four-toed salamander, *Hemidactylium scutatum*.

To begin our study, we focused on antibiotics known to be produced by *Pseudomonas fluorescens*, a relative of

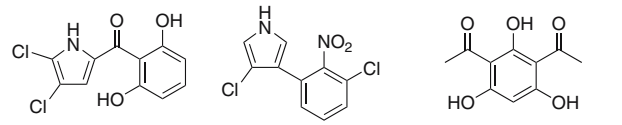

Fig. 1 The chemical structures of pyoluteorin, pyrrolnitrin, and 2,4-diacetylphloroglucinol

Lysobacter. The bacterium *P. fluorescens* is common in soil, on plant roots, and on amphibian skin, and is inoculated onto pea, wheat, and sugar beet roots to protect them from diseases (Timms-Wilson et al. 2005). This widespread bacterium *P. fluorescens* produces many different antibiotics. In this study, three of these were investigated and compared to the *L. gummosus* antibiotics: pyoluteorin, pyrrolnitrin, and 2,4-diacetylphloroglucinol (=2,4-DAPG; Whistler et al. 1998; Ligon et al. 2000; Sako et al. 2001; Brodhagen et al. 2004; Fig. 1).

Materials and Methods

Bacteria Isolates

Pure cultures of *L. gummosus* (AB161361) were obtained from the salamander *Plethodon cinereus* after a thorough rinsing of the animals to remove transient bacteria. Adult salamanders were obtained from James Madison University Arboretum, Harrisonburg, VA, USA. All *L. gummosus* isolates were stored in 20% glycerol solution and frozen at −20°C. When needed, *L. gummosus* was cultured onto R2A solid medium and allowed to grow at room temperature for 72 h. Isolates were cultured this way three times before extraction. Bacterial species identifications were made by sequencing a portion of the 16S rRNA gene and comparing the sequence with the GenBank database (www.ncbi.nlm.nih.gov/blast).

Preparation and Extraction of Crude Organic Samples

To extract bacterial products, broth cultures were grown. The *L. gummosus* isolate was inoculated into separate 250 ml flasks containing 1/10 strength Nutrient Broth medium (NB, Becton, Dickinson and Company, Sparks, MD, USA). Each liquid culture, as well as a 1/10 strength NB control, was kept at room temperature for 72 h in a Lab-Line incubator shaker. Bacterial cells were in stationary phase when they were removed from the nutrient broth to leave a "crude extract" as follows. The cultures were poured into 50 ml Falcon tubes and centrifuged at 5,000×*g* for 5–10 min. The supernatant was filtered through a 25 mm sterile syringe filter with 0.22 μm pores into new Falcon tubes to remove any remaining bacteria. The supernatant was acidified to pH<2 by using 1 M HCl. Each Falcon tube was frozen at −20°C until needed for chemical analysis.

To extract organic compounds, approximately 90 ml of crude extract supernatant from the *L. gummosus* broth culture were poured into a separatory funnel. The aqueous layer was extracted×4 with 35 ml of ethyl acetate (EtOAc). The combined organic layers were dried with Na_2SO_4 and filtered. The EtOAc solvent was evaporated in vacuo, and a crude recovery calculated. The crude samples (3–9 mg) were then kept frozen in a −20°C freezer until further analysis. A total of five samples were extracted.

HPLC Analysis of Extract

Each crude sample was dissolved in high-performance liquid chromatography (HPLC)-grade methanol (2 ml) before analysis. Standard solutions of 2,4-DAPG, pyrrolnitrin, and pyoluteorin were also prepared in HPLC-grade methanol (1 mg/ml). 2,4-DAPG and pyrrolnitrin were used as purchased (Sigma-Aldrich, Saint Louis, MO, USA and Maybridge Trevillett, Tintagel, UK); pyoluteorin was synthesized in three steps, slightly modifying a method described by Rao and Reddy (1990).

RP-HPLC analysis (Agilent Technologies, 1200 series, Wilmington, DE, USA) was used to determine the retention times of the antifungal standards as well as to analyze the components of bacterial samples. The HPLC diode array detector was programmed to observe and record absorbance at 270 and 310 nm. These two wavelengths best correlate to the λ_{max} of the standards: 2,4-DAPG at 270 nm, pyrrolnitrin at 252 nm (broad), and pyoluteorin at 310 nm (Sako et al. 2001; Brodhagen et al. 2004). The samples were injected (20 μl) into the HPLC equipped with a C18 reverse phase column (5 μm; 4.6×150 mm; Agilent Technologies) and eluted at 1 ml/min. The initial eluent, 10% acetonitrile/water (*v*/*v*, both acidified with 0.1% acetic acid), ran for 2 min. This was followed by a linear gradient to 100% acetonitrile (acidified with 0.1% acetic acid), over an 18-min-period. This final solvent was eluted for another 3 min. Samples showing absorbance at 270 or 310 nm were collected.

GC-MS Analysis of Extract

The standards and HPLC eluates were further analyzed by using coupled gas chromatography–mass spectrometry (Thermo/Finnigan Polaris Q, Somerset, NJ, USA; column: Restek, Rtx-5 crossbond 5% diphenyl-95%dimethyl polysiloxane, length: 30 m, i.d.: 0.25 mm; particle size 0.25 μm); 1.0 μl-samples in HPLC grade methanol were injected (injector temperature: 200°C; EI full scan, mass range 50–500 amu, ion source 200°C). Column temperature began

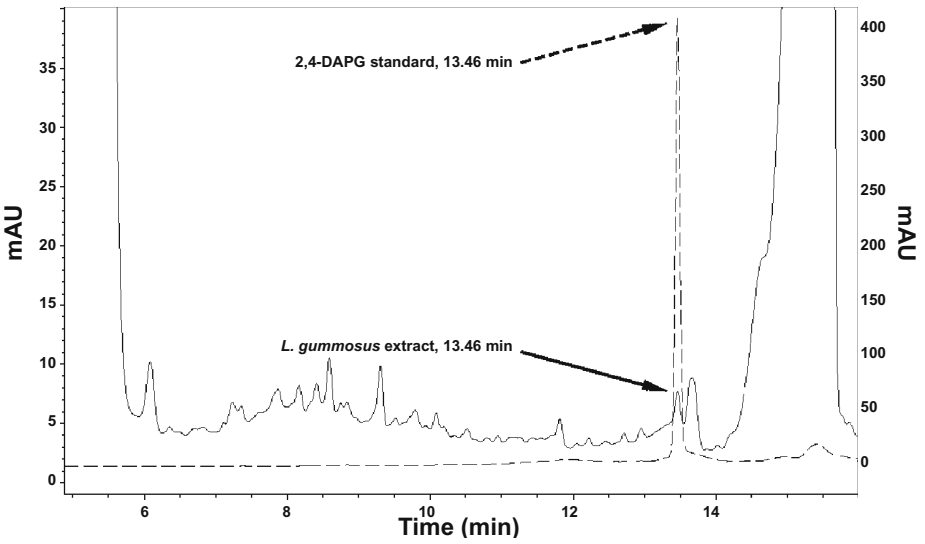

Fig. 2 HPLC chromatogram (270 nm) comparing *Lysobacter gummosus* crude extract (*solid line, left scale*) and 2,4-DAPG standard (*dashed line, right scale*). Both samples had similar retention times on the HPLC chromatograms (13.46 min). The *L. gummosus* extract had several additional peaks, including several very large peaks that were artifacts from the nutrient broth

at 180°C for 2 min and increased to 280°C within 10 min. Retention times and mass spectra of the substances were compared to chemical standards of pyoluteorin, pyrrolnitrin, and 2,4-DAPG.

HR-MS Analysis of Extract

The crude *L. gummosus* extract and 2,4-DAPG were analyzed by high resolution mass spectrometry (HR-MS). ESI mass spectra were obtained with an LCT-TOF mass spectrometer (Micromass, Harvard University Mass Spectrometry Facility).

Inhibitory Assay

To quantify the antifungal properties of 2,4-DAPG, a liquid growth assay was developed by using the fungal pathogen *Batrachochytrium dendrobatidis*. In a 96-well microtiter plate, 12 concentrations of 2,4-DAPG (ranging from 475 to 0.232 μM) as well as positive and negative controls were examined. Five replicates were performed per assay. Each well contained 125 μl of 1% tryptone medium plus 100 μl of fungal zoospores in 1% tryptone medium at a concentration of $\approx 1*10^6$ zoospores/ml (determined by using a hemocytometer). The plates were incubated for 1 day at 23°C before 25 μl of a solution of 2,4-DAPG in dimethyl sulfoxide (DMSO) were added. A volume of 25 μl neat DMSO was added to the positive control wells; heat-killed zoospores were used in the negative control. The optical density at 490 nm (OD_{490}) of each plate was measured with a BioRad microplate reader (model 680, Hercules, CA, USA), on days 0 and 8. Inhibition was determined by comparing the difference of the final and initial growth to the positive control by using a Dunnett's test. The logarithmic trend line was determined by linear regression and used to calculate the IC_{50}.

Results

RP-HPLC analysis of the organic extract of *L. gummosus* revealed a peak at 13.46 min, as observed at 270 nm (Fig. 2). This peak matched the HPLC retention time of the 2,4-DAPG standard (13.46 min). Furthermore, the UV spectra of extract and standard were similar, each showing a

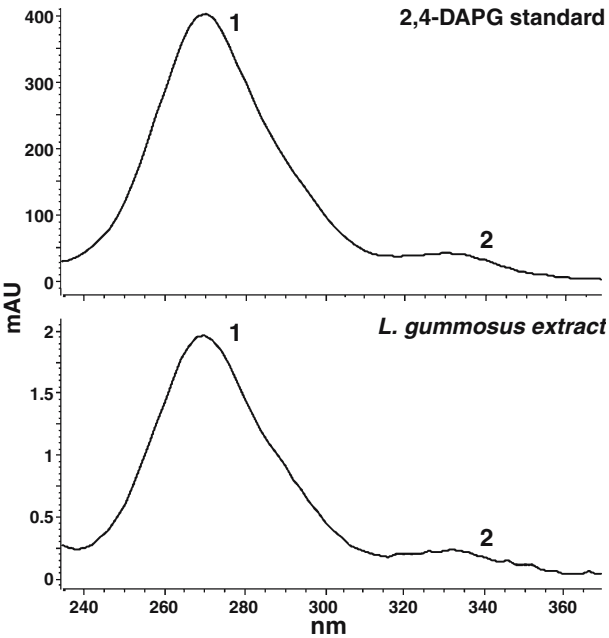

Fig. 3 Comparison of UV-Vis spectrum of 2,4-DAPG standard (*top*) and a *L. gummosus* sample (*bottom*) eluted at same HPLC retention time of 13.46 min. Both UV-Vis spectra share identical peak patterning; (1) a tall peak at 270 nm and (2) a smaller "shoulder" peak at 330 nm

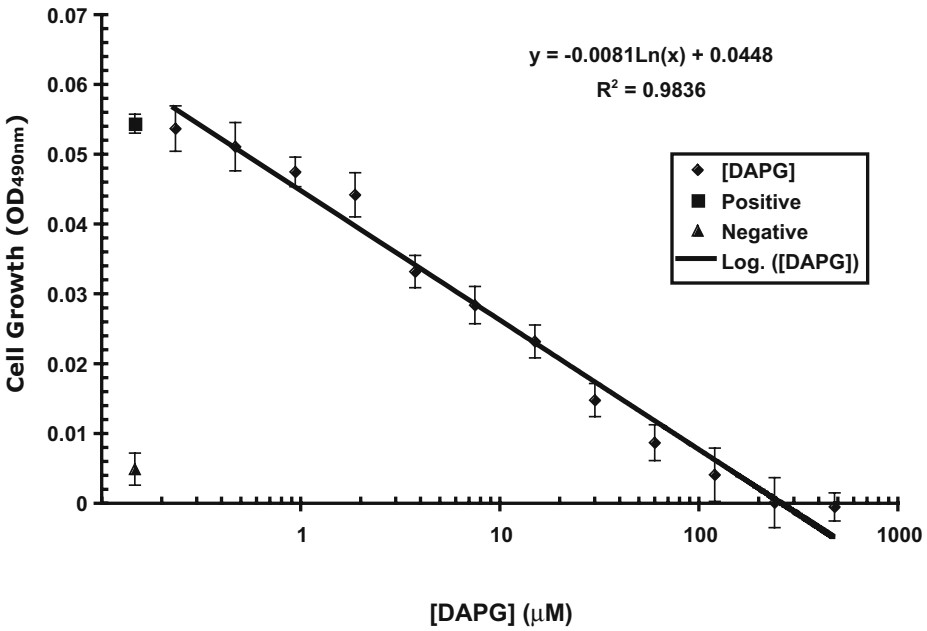

Fig. 4 Inhibitory Growth Assay. Cell growth of the fungal pathogen *B. dendrobatidis* measured in optical density at 490 nm wavelength (OD_{490}) versus concentrations of 2,4-DAPG in μM on a log scale. The trend line is displayed as $y=-0.0081\text{Ln}(x)+0.0448$; $IC_{50}=8.73$ μM; MIC= 136.13 μM; $P<0.001$

λ_{max} of 270 nm (Fig. 3). On GC–MS, the 2,4-DAPG standard displayed a retention time of 6.76 min; the corresponding mass spectrum indicated for M+: 210.1 *m/z* and 211.1 *m/z* (M+H). The extract of *L. gummosus* showed a peak with a retention time of 6.78 min, and a mass spectrum with 210.1 *m/z* (M+) and 211.2 *m/z* (M+H).

HR-MS analysis of the 2,4-DAPG standard showed a peak at 211.0603 *m/z*, corresponding to the calculated (M+H) peak of 211.0607 *m/z*. The *L. gummosus* extract showed a peak at 211.0612 *m/z*.

Analogous investigations (HPLC, UV-Vis, GC-MS) of *L. gummosus* extracts for pyoluteorin and pyrrolnitrin did not provide evidence for the presence of these compounds in the crude sample.

The growth assay (Fig. 4), which used *Batrachochytrium dendrobatidis*, indicated a 2,4-DAPG IC_{50} of 8.73 μM and a minimum inhibitory concentration (MIC) of 136.13 μM. These concentrations were calculated by using a regression of log-transformed OD_{490} values on 2,4-DAPG concentration ($F=1118.22$, $df=1,124$, $P<0.001$). All 2,4-DAPG concentration treatments differed significantly in OD_{490} values from the positive control with the exception of the 0.23 μM and the 0.46 μM concentrations (*a posteriori* Dunnett's *t* tests, $P<0.05$ for all comparisons).

Discussion

Four methods indicate that 2,4-DAPG was produced by the amphibian skin bacterium *L. gummosus*. RP-HPLC analyses repetitively resulted in nearly identical retention times of a peak of the bacterial extract and the 2,4-DAPG standard (Fig. 2); UV-Vis comparison demonstrated a nearly identical spectrum and λ_{max} (270 nm) of this peak and 2,4-DAPG (Fig. 3). Furthermore, GC-MS and HR-MS analyses support the presence of 2,4-DAPG in *L. gummosus* extracts. Although the exact concentration of 2,4-DAPG prevalent on an individual amphibian skin was not investigated in this study, the concentration calculated from the liquid cultures used in this study was about 2 μM. Estimation of 2,4-DAPG concentrations of amphibian skins will be the subject of further investigations.

Biologically, bacteria living on amphibian skin may act as part of the innate immune system of amphibia by preventing pathogens from colonizing. Amphibian species that attend their embryos, such as *H. scutatum*, may use skin bacteria and their antibiotics to keep their embryos free of fungus. Additional studies will be necessary to determine whether there are co-evolved mutualisms between amphibian hosts and skin bacteria. The investigation of other strong antifungal metabolites from a variety of epibiotic bacterial species obtained from frogs and salamanders are the focus of ongoing research. In addition, it would be of interest to determine the relative role of amphibian antimicrobial secretions and those of their bacterial symbionts in deterring pathogens. The study of skin bacteria and their antibiotics may also lead to an understanding of why some species succumb to an emerging infectious disease of the skin, chytridiomycosis, which is caused by *Batrachochytrium dendrobatidis*, and others do not.

Sex-Specific Tyrian Purple Genesis: Precursor and Pigment Distribution in the Reproductive System of the Marine Mollusc, *Dicathais orbita*

Chantel Westley · Kirsten Benkendorff

Received: 19 September 2007 / Revised: 1 November 2007 / Accepted: 14 November 2007 / Published online: 12 December 2007

Abstract Exploitation of Tyrian purple from muricid molluscs, since antiquity, has prompted much interest in its chemical composition. Nevertheless, there remains a paucity of information on the biosynthetic routes leading to observed sexual differences in pigmentation. A liquid chromatography-mass spectrometry (LQ-MS) method was developed to simultaneously quantify dye pigments and precursors in male and female *Dicathais orbita*. The prochromogen, tyrindoxyl sulfate, was detected for the first time, by using this method in hypobranchial gland extracts of both sexes. Intermediates tyrindoxyl, tyrindoleninone, and tyriverdin were detected in female hypobranchial glands, along with 6,6′-dibromoindigo, while males contained 6-bromoisatin and 6,6′-dibromoindirubin. Multivariate analysis revealed statistically significant differences in the dye composition of male and female hypobranchial glands (ANOSIM, P=0.002), thus providing evidence for sex-specific genesis of Tyrian purple in the Muricidae. Dye precursors were also present in male and female gonoduct extracts, establishing a mechanism for the incorporation of bioactive intermediates into muricid egg masses. These findings provide a model for investigating sex-specific chemical divergences in marine invertebrates and support the involvement of Tyrian purple genesis in muricid reproduction.

Introduction

Tyrian purple, also known as Shellfish purple and Royal purple, is a historically important dye, traditionally obtained from the hypobranchial glands of the Muricidae (Neogastropoda: Mollusca). Exploitation of this dye from as early as the 17th Century BC, has attracted the ongoing interest of natural and cultural historians, archeologists, dyers and colorists, artists, chemists, and biologists (Baker 1974; Cooksey 2001a, 2006; Haubrichs 2004, 2006; Karapanagiotis and de Villemereuil 2006; Westley et al. 2006). In Historia Naturalis, Pliny the Elder provided the first detailed description of colors obtained by dyeing with different techniques and muricid species in ancient Rome (Bailey 1929). Much later, Cole (1685) described how the pigment develops in a series of color reactions under the influence of sunlight. This process can now be explained by a series of oxidation, dimerization, and photolytic cleavage reactions (Fig. 1). A major advance was made by Friedlander (1909), who resolved the structure of the principal pigment, 6,6′-dibromoindigo (**5**). Baker and Sutherland (1968) identified colorless tyrindoxyl sulfate (**1**), as the ultimate dye precursor in the Australian muricid, *Dicathais orbita*, and subsequent studies have revealed the intermediate precursors; tyrindoxyl (**2**), tyrindolinone, tyrindoleninone (**3**; Baker and Duke 1973, 1976), and tyriverdin (**4**; Christophersen et al. 1978; Fujise et al. 1980). Further investigations of dyed artifacts and hypobranchial gland secretions from various muricids have uncovered additional precursors, artifacts, and minor pigments (Michel et al. 1992; Wouters 1992; Koren 1995, 2006; Cooksey 2001a, b, 2006; Cooksey and Withnall 2001; Karapanagiotis and de Villemereuil 2006). These include the yellow oxidation by-product, 6-bromoisatin (**6**), the red structural isomer of (**5**), 6,6′-dibromoindirubin (**7**; Fig. 1), indigo (**8**), indirubin (**9**),

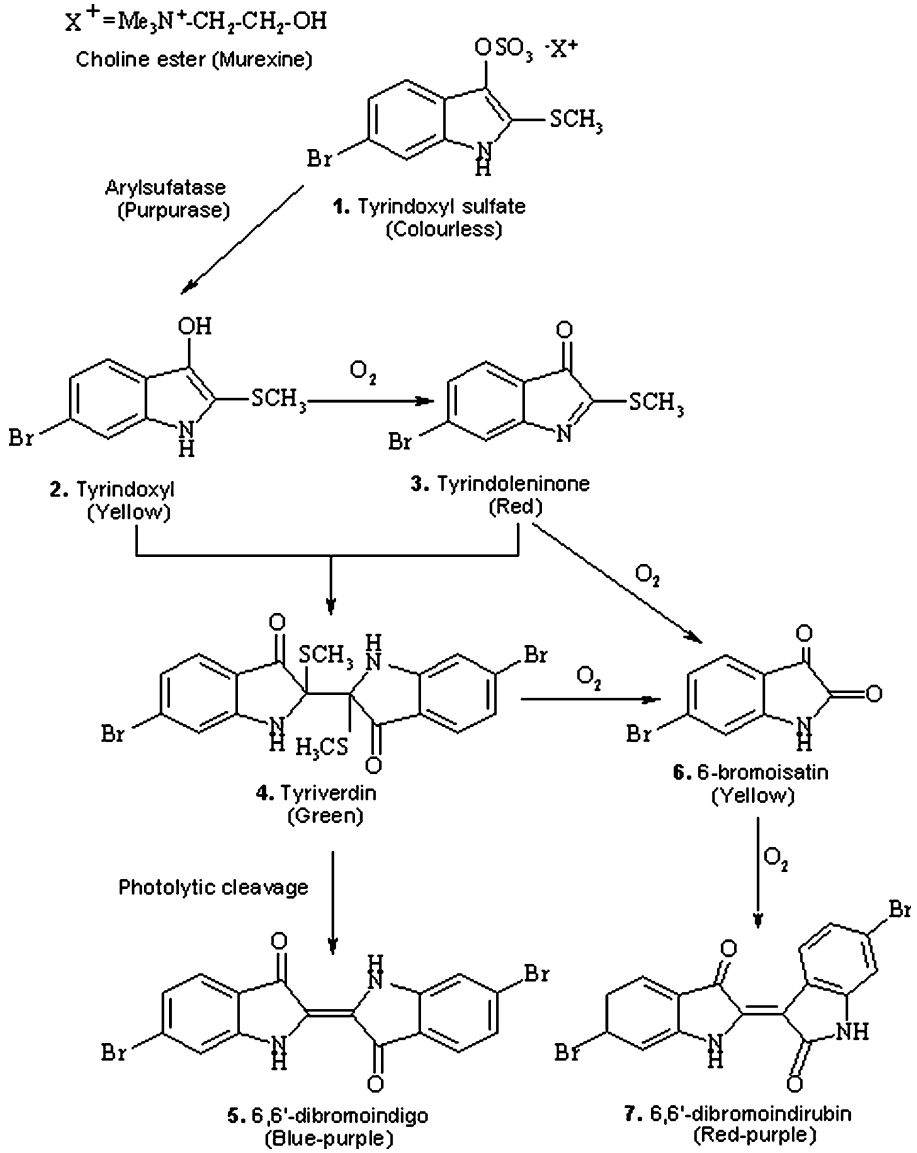

Fig. 1 Tyrian purple genesis from tyrindoxyl sulfate in the hypobranchial gland of *Dicathais orbita*

6-bromoindigo (**10**), 6-bromoindirubin (**11**), and 6′-bromoindirubin (**12**; Appendix).

The first indication of a link between dye production and reproduction in the Muricidae was provided by Aristotle's comments on "purpuras" in Historia Animalium ~350 BC (Peck 1970). He stated that, "When the purpuras have honeycombed (*sic* deposited egg capsules), their bloom (*sic* hypobranchial gland) is at its worst", a fact also reinforced by Pliny the Elder in first Century AD (Bailey 1929). However, this association was overlooked until more recent investigations on egg masses of the Muricidae revealed the presence of indigoid compounds (Palma et al. 1991; Benkendorff et al., 2000, 2001, 2004). In the egg masses of *D. orbita*, Benkendorff et al. (2000) not only reported relatively high concentrations of tyriverdin (**4**) and tyrindoleninone (**3**), but also demonstrated that these intermediates have potent bacteriostatic and mild cytotoxic activity, respectively. This discovery prompted the proposal of a novel biochemical role for indigoid compounds in the Muricidae, whereby they are incorporated into egg masses as a form of maternal investment in the chemical defense of developing embryos (Benkendorff et al. 2000; Westley et al. 2006). The potential for precursor transfer from the adult hypobranchial gland to the adjacent reproductive glands has been supported recently by accounts of deep red pigmentation in capsule and prostate glands of *D. orbita* (Benkendorff et al. 2004). Furthermore, preliminary experiments involving the excision of hypobranchial glands from reproductive organs suggests that the pallial gonoduct influences pigment synthesis (Benkendorff et al. 2004). However, this study was limited to visual accounts. Quantitative analysis is required to confirm the composition

of dye products and, hence, the biochemical relationship between these glandular structures.

Another question that remains to be resolved is whether dye composition and pigmentation differ between sexes of the Muricidae. Studies on hypobranchial gland secretions of *Murex trunculus* by Elsner and Spanier (1985), initially indicated that female glands produce predominantly purple dyes, while dyes of masculine origin gain blue pigmentation due to the presence of indigo (**8**). However, the method of specimen sexing was not reported, and subsequently, Verhecken (1989) proposed the opposite. Verhecken's proposal is consistent with recent visual accounts of red dye pigmentation in male *M. trunculus* and a more blue shade of purple in females (Fig. 2, Boesken Kanold, personal communication). Michel and colleagues (1992) failed to confirm any correlation between dye color and sex; however, a high incidence of pseudohermaphrodism may have influenced their results. Nevertheless, the final pigmentation of male samples after storage in the dark was described as predominantly purple, suggesting that male glands contain relatively less of the non-brominated indoxyl precursors and, hence, less indigo (Michel et al. 1992). An alternative hypothesis for the prevalence of red purple dyes in males could be related to the formation of red indirubins, structural isomers of indigoids that evolve in oxygen-rich environments (Fig. 1). Sensitive chemical analysis of male and female dye is required to assess objectively any sex-related differences in composition.

Over the last couple of decades, advances in chemical analysis by high performance liquid chromatography (HPLC) and mass spectrometry (MS) have facilitated the rapid and accurate detection of indigoid pigments (McGovern et al. 1990; Wouters and Verhecken 1991; Wouters 1992; Koren 1995, 2006; Szostek et al. 2003; Andreotti et al. 2004; Puchalaska et al. 2004; Karapanagiotis and de Villemereuil 2006; Polec-Pawlak et al. 2006). To date, however, no one has applied modern LC-MS techniques to analyze simultaneously the full suite of precursors and pigments that constitute Tyrian purple. In the current investigation, an effort was made to preserve glandular

Fig. 2 Extract preparations (**a**) and dried pigments (**b**) from *Hexaplex (Murex) trunculus* (photos provided by Inge Boesken Kanold, France). Male hypobranchial gland extracts, complete with prostate glands (*left*), display purple/red pigmentation in comparison to the purple/blue hue of female hypobranchial and capsule gland extracts (*right*)

biochemistry to examine dye genesis in the presence of precursors. Extracts from the hypobranchial and reproductive glands of *D. orbita* were employed, as this species possesses a comparatively simple biosynthetic pathway to Tyrian purple from a single brominated prochromogen (**1**; Fig. 1; Baker and Sutherland 1968) that is representative of most Muricidae (Cooksey 2006). Furthermore, previous studies on *D. orbita* provided the first evidence for dye precursors in egg capsules (Benkendorff et al. 2000) and observations of pigmentation in the reproductive organs (Benkendorff et al. 2004). This investigation aimed to quantify precursor and pigment composition in the female pallial gonoduct, specifically, the capsule, albumen, and ingesting glands, as a means for establishing maternal investment in embryonic chemical defense. Following from earlier observations (Benkendorff et al. 2004), analysis of dye composition in hypobranchial glands, attached and detached from male prostate and female capsule glands, was also undertaken to establish further the relationship between dye genesis, reproduction, and sex.

Methods and Materials

Six male and six female *D. orbita* specimens were sampled from subtidal rocky platforms along the metropolitan coastline of South Australia before the breeding season (July–August, 2005 and 2006). An additional three females were collected during breeding season (December, 2005) for dissection and extraction of ingesting glands. Females were identified by the presence of an albumen and capsule gland and the absence of a penis, posterior to the right eye tentacle, and sperm ducts, which occur in pseudohermaphrodites after exposure to tributylin tin (Gibson and Wilson 2003).

The shell of each specimen was removed by cracking with a vice at the junction of the primary body whorl and spire, and the soft body was removed by severing the columnar muscle. The soft body was transferred to a dissecting tray where visceral mass was separated from dorsal mantle by an incision along the lateral margins of the columnar muscle. The dorsal mantle was folded back to reveal the pallial gonoduct and pinned with the ventral surface facing up to expose the hypobranchial gland. In female specimens, care was taken to ensure that ingesting and albumen glands were dissected free of hypobranchial gland tissue. Prostate and capsule glands were dissected away from the medial and brachial regions of the hypobranchial gland in three male and three female specimens, respectively. Removal of the rectal gland and rectal hypobranchial gland from these reproductive structures was not possible. For the "detachment experiment", excised medial and branchial hypobranchial gland regions from both sexes were reserved for inclusion as "detached" replicates. In another three specimens of each sex, the pallial gonoduct and hypobranchial gland were left intact to give comparative "attached" replicates. To produce extracts, which represent the true biochemical composition of dye products from *D. orbita*, all dissected glands were left in their natural posture and exposed to ambient laboratory oxygen and lighting for 12 hr post dissection.

After dye development, each gland (24 in total) was transferred to an amber vial that contained enough dimethyl formamide (DMF) to submerge the tissue. Glands were then macerated and extracted for 48 hr, before being gravity filtered through glass wool. Before compositional analysis, all extracts were sonicated and centrifuged to precipitate tissue residues. Extracts were analyzed with HPLC (Waters Alliance), coupled to a mass spectrometer (MS, Micromass, Quatro micro™). HPLC separation was performed on a Phenomenex, Synergi, Hydro-RP C_{18} column (250× 4.6 mm×4 μm) with parallel UV/Vis diode-array detection (DAD) at 300 and 600 nm. The elution scheme was modified from Szostek et al. (2003) and Puchalaska et al. (2004) with a flow rate of 1 ml/min of 0.1% formic acid and a gradient of acetonitrile in water starting at 30% for 1 min followed by 60% for 3 min, then 100% for 15 min before returning to 30% for 15 min. Compounds were identified with electrospray ionization-mass spectrometry (ESI-MS) with a flow rate of 300 μl/min. Relative proportions of each compound were calculated from integrated absorption data in diode-array by using MassLynx 4.0 software. Proportions were expressed as a percentage of the total dye composition, including all detected precursors and end-products. To facilitate identification of the dye constituents, synthetic standards were analyzed by identical procedures.

Synthetic standards for all possible indole and indirubin end-products (Appendix; Karapanagiotis and de Villemereuil 2006) were prepared in DMF to a concentration of 40 μM. Standards included indigo (Sigma, 229296), 6-bromoindigo (MDPI, 19393), 6,6′-dibromoindigo (courtesy of Prof. P. Imming), indirubin (Apin Chemicals LTD, 20338I), and 6-bromoindirubin, 6′-bromoindirubin, and 6,6′-dibromoindirubin (courtesy of Prof. A. L. Skaltsounis). Apart from retention time (Table 1), discrimination between structural isomers was achieved by differences in visible absorption spectra at λ_{max} 600 nm for indigoids and λ_{max} 550 nm for indirubins. Indigo (**8**) and indirubin (**9**) were discriminated further by the registration of a doubly charged quasi-molecular ion $[M+2H]^{2+}$ at *m/z* 132, which allowed unequivocal identification of **8** (Puchalaska et al. 2004). Major ions in ESI-MS obtained at the apex of HPLC peaks for monobrominated compounds (**10**–**12**) produced duplet ion clusters at *m/z* 339, 341 $[M-H]^+$. Similarly, 6,6′-dibromoindigo (**5**) and 6,6′-dibromindirubin (**7**) were identified by triplet ion clusters at *m/z* 417, 419, 421 for Br^{79} Br^{79}, Br^{79} Br^{81}, Br^{81}, Br^{81}.

Synthetic standards were not available for precursors. However, mass spectra have previously been used to identify intermediate precursors (Michel et al. 1992; Benkendorff et al. 2000; Cooksey and Withnall 2001; Andreotti et al. 2004), based on expected mass and isotopic clusters for the mono- and dibrominated compounds. As the mass spectrum of tyrindoxyl sulfate has not yet been published, the presence of this compound in extracts was confirmed by thin layer chromatography (TLC). TLC was conducted on aluminum-backed silica gel plates (Merck), employing an *n*-butanol–EtOH–acetic acid–water (8:2:1:3) solvent system. Development in 1 M HCl results in the formation of a purple spot, characteristic of tyrindoxyl sulfate (Baker and Sutherland 1968). Presence of murexine and senecioylcholine was also investigated by TLC, as these choline esters are known to be associated with the prochromogen (Roseghini et al. 1996). Dipping plates in Dragendorff Reagent (Fluka-44578) allows visualization of alkaloids and quaternary ammonium bases and has been used to detect choline esters in several muricid hypobranchial gland extracts (Roseghini et al. 1996). Development of yellow and rose pigmentation in UV-active spots indicates the presence of senecioylcholine and murexine, respectively (Roseghini et al. 1996).

Statistical analyses of differences in male and female dye composition (N=6) were undertaken with Primer Version 5 Software. Multivariate analyses were undertaken on square root transformed data to increase the weighting of minor constituents. Nonmetric multidimensional scaling (nMDS) was performed on a Bray-Curtis similarity matrix (Clarke and Gorley 2001) and portrayed in a two-dimensional plot. Significant differences in dye composition between the sexes were then explored by using ANOSIM. SIMPER was undertaken to identify which indigoids contributed to compositional differences.

Results

Dyes and Precursors in Hypobranchial and Reproductive Glands LC-MS analysis revealed the presence of brominated indole derivatives in dimethyl formamide (DMF) extracts from all hypobranchial and reproductive glands (Table 1). The dominant compound in all samples registered an HPLC peak at 5.1 min (e.g., Fig. 3). Major ions in ESI-MS, obtained at the apex of this peak, were at *m/z* 338, 336, which correspond to the molecular ions of tyrindoxyl sulfate (**1**; Br^{79}, Br^{81}, Fig. 3). Fragment ions at *m/z* 240, 242 and *m/z* 224, 226 correlate with the loss of a sulfate ion [$MH–SO_4$], and a methyl group [$M^{-}H–SO_4–CH_3$], respectively, from the tyrindoxyl sulfate molecule. As this compound has not been characterized previously by using

Table 1 High performance liquid chromatography (HPLC) retention times (t_R) and electrospray ionization mass spectrum (*m/z*) values for the various indole derivatives[a] in dimethyl formamide extracts of male and female glandular extracts from *Dicathais orbita*

Dye Component	t_R (min)	Major Ions (m/z)	Males			Females		
			Hypobranchial	Prostate	Hypobranchial	Capsule	Albumen	Ingesting

[a] The relative proportions of each compound were calculated from integration data taken at 300 and 600 nm using a diode array in the HPLC and expressed as the mean percent of total dye composition ±SD, where N=3. It should be noted that extinction coefficients are not available for all these compounds, thus prohibiting adjustment of integrated peak values for absolute quantification. Therefore, percentages of total dye composition should be viewed as relative for comparison between samples rather than actual compound proportions.

[b] Molecular ions corresponding to **1** in ingesting glands registered for peaks at 7.0 and 7.9 min. Despite shifts in t_R, TLC analysis confirmed the presence of **1** in these extracts at R_f 1.0.

[c] **1** was absent from one ingesting gland extract, but represented 100% dye composition in the two remaining replicates.

[d] The large t_R range for **5** is due to a shift downfield in some extracts after HPLC column replacement (Appendix 1).

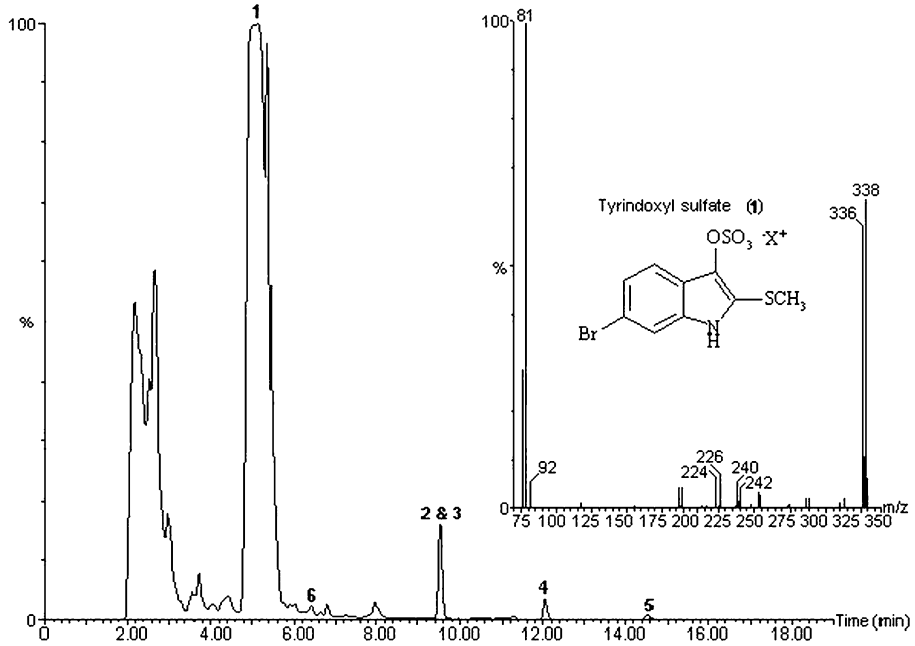

Fig. 3 Liquid chromatography-mass spectrometry analysis of a typical extract from the hypobranchial gland of a female *D. orbita*. The chromatogram obtained from the diode array at 300,600 nm shows the relative composition of the dye precursors and pigments. *Inset* is the electrospray ionization mass spectrum obtained from the apex of the major chromatographic peak obtained at 5.1 min showing dominant signals, which agree with the molecular mass (*m/z* 336, 338) and stable fragment ions of tyrindoxyl sulfate (**1**). Other peaks in the chromatogram correspond to tyrindoxyl/tyrindoleninone (**2**/**3**), tyriverdin (**4**), 6,6′-dibromoindigo (**5**), and 6-bromoisatin (**6**)

mass spectrometry, we used thin layer chromatography (TLC) to confirm the presence of **1**. A single spot (R_f 1.0) that turned purple after exposure to HCl was detected in all extracts except one ingesting gland, which also failed to produce a peak corresponding to tyrindoxyl sulfate in LC-MS (Table 1). TLC analysis also revealed a colorless UV-active spot (R_f 0.12) in all glandular extracts that contained tyrindoxyl sulfate. Application of the Dragendorff Reagent resulted in rose pigmentation, indicative of murexine (Roseghini et al. 1996).

Intermediate dye precursors were detected as minor components in LC-MS analyses (Fig. 3) of male and female hypobranchial and capsule gland DMF extracts (Table 1). Co-eluting peaks at 10.1 min with major ions in ESI-MS at *m/z* 255, 257 and 256, 258 correspond to the molecular mass of tyrindoleninone (**3**) and tyrindoxyl (**2**). Fragment ions at *m/z* 240, 242, formed by the elimination of a methyl group $[M–CH_3]^+$, are consistent with the mass spectrum data for **3**. The second duplet ion cluster at *m/z* 256, 258 and fragment ions at *m/z* 241, 243, correspond to those of **2** $[M–H]^+$ and the loss of a methyl group $[M–H–CH_3]^+$ during electron bombardment. The HPLC peak detected at 6.5 min with *m/z* 224, 226, in both male and female hypobranchial glands (Table 1) is attributed to the pseudomolecular ion $[M–H]^+$ of 6-bromoisatin (**6**), which has a molecular mass of 225, 227 (Br^{79}, Br^{81}).

An additional dye precursor, identified exclusively in female hypobranchial and capsule gland extracts, registered a chromatographic peak at 12.0 min (Table 1). Although major ions in ESI-MS at *m/z* 417, 419, and 421 correspond to the mass of dibrominated standards 5 and 7, the retention times disagree (Appendix). Minor peak isotopic clusters detected at 513, 515, and 517 correspond to the quasi-molecular ion of tyriverdin $[MH^+$; Br^{79} Br^{79}, Br^{79} Br^{81}, Br^{81}, $Br^{81}]$. Additional ion clusters at *m/z* 465 (Br^{79} Br^{81} $[M–SCH_3]^+$ from the elimination of a single methane thiol group) and *m/z* 419 (Br^{79} Br^{81} $[MH–2SCH_3]^+$ formed by the elimination of dimethyl disulphide) further confirm this peak as tyriverdin (**4**).

The dye pigments appear as relatively minor constituents in *D. orbita* extracts (Fig. 3, Table 1). The two dibrominated dye pigments **5** and **7** were detected in some extracts, with retention times and mass spectra that were consistent with synthetic standards (Appendix). No peaks corresponding to the mono- or non-brominated indigo or indirubin standards (Appendix) were detected in any *D. orbita* extracts.

Sex-Specific Pigment Genesis During the exposure period, hypobranchial glands sequentially developed yellow, red, and green pigmentation before gaining various shades of purple and blue, irrespective of sex. The major purple dye pigment extracted from female hypobranchial and capsules glands was identified as 6,6′-dibromoindigo (**5**; Table 1). One male hypobranchial gland extract was also found to contain trace amounts of 6,6′ dibromoindigo (**5**; Table 2).

Table 2 Liquid chromatography-mass spectrometry analyses of Tyrian purple precursors and pigments in dimethyl formamide extracts of attached and detached male and female hypobranchial glands

Dye component	Male		Female	
	Attached[a]	Detached[b]	Attached[a]	Detached[b]
Tyrindoxyl sulfate **1**	+++	+++	+++	+++
Tyrindoxyl **2**/ Tyrindoleninone **3**	+++	+++	+++	+++
Tyriverdin **4**	–	–	+++	+++
6,6′-dibromoindigo 5	+	–	+++	+++
6-bromoisatin 6	+++	+++	+++	+++
6,6′-dibromoindirubin 7	+++	+++	–	–

+++ Indicates presence in all three replicate extracts, + indicates presence in one of three replicate extracts, − indicates absence in all three replicate extracts

[a] Attached extracts represent glands in which connection with the pallial gonoduct was maintained (N=3).

[b] Detached extracts comprise hypobranchial glands excised from the prostate or capsule gland (N=3).

However, in contrast to females, the major dye pigment of male hypobranchial and prostate glands corresponded to 6,6′-dibromoindirubin (**7**; Tables 1 and 2). Within each sex, the dye and precursor composition was identical in all replicate hypobranchial glands whether "attached" or "detached" from the reproductive system. Male extracts were dominated by 6,6′-dibromoindirubin, and females by 6,6′-dibromoindigo (Table 2). Tyriverdin (**4**), was detected only in the female extracts (Table 2).

Multidimensional scaling (MDS) ordination on the dye compositions revealed a distinct separation between male and female hypobranchial gland extracts (Fig. 4). Multivariate analysis of similarities (ANOSIM) confirmed that these differences were statistically significant (Global R= 0.757, P=0.002). Similarity of percentage (SIMPER) analysis revealed an average dissimilarity of 21% in the dye composition between males and females. Intermediates and final pigments contributed substantially to the sexual differences, whereas the ultimate precursor, tyrindoxyl sulfate (**1**), occurred in similar abundance in both sexes. Tyriverdin (**4**) and 6,6′-dibromoindigo (**5**) were consistently more abundant in female samples, whereas 6-bromoisatin (6) and 6,6′-dibromoindirubin (**7**) characterized males. Blind examination of LC-MS chromatograms confirmed that we could reliably determine the sexual origin of *D. orbita* extracts based on these chemical compositions.

Discussion

Analysis of hypobranchial gland extracts by LC-MS, in conjunction with synthetic standards, confirmed the presence of dibrominated dyes generated from a single brominated

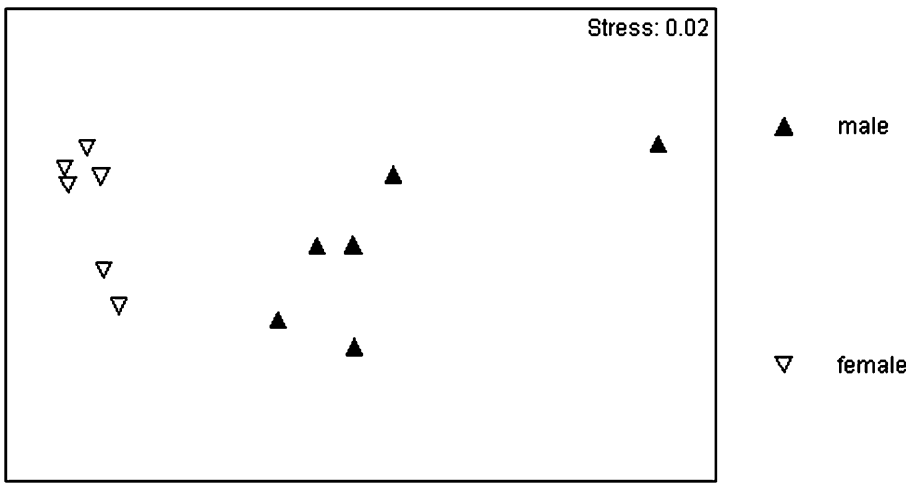

Fig. 4 Two-dimensional nMDS plot for the Tyrian purple composition found in extracts from the hypobranchial glands of male and female *D. orbita*. Data based on the percent composition of each precursor (**1**–**4**) and pigment (**5**–**7**) after square root transformation

prochromogen in *D. orbita*. Tyrindoxyl sulfate (**1**) was detected in hypobranchial gland extracts and also occurred throughout female reproductive glands and male prostate glands (Table 1). Comparison of male and female extracts provided evidence for clear sex-specific Tyrian purple genesis (Table 2, Fig. 4). Females dyes were composed of 6,6′-dibromoindigo (**5**), while male hypobranchial glands contained the red isomer (**7**). This is the first study in which the full suite of Tyrian purple precursors have been analyzed simultaneously alongside the final dye pigments. As suggested by Michel and colleagues (1992), precursors in the final dye product are most likely due to reduced light exposure resulting from the screening affect of mucoid glandular secretions or already formed dye. Consequently, this method of dye development may be viewed as somewhat incomplete compared to the majority of studies where muricid hypobranchial gland secretions were developed on filter paper. However, preservation of the complete glandular biochemistry can prove useful in deciphering the genesis of specific dye products under natural physiological conditions. This approach has enabled a significant advance in understanding the chemistry behind sex-specific color differences in Muricidae dyes (see Fig. 2).

Our findings of only one prochromogen corresponding to tyrindoxyl sulfate (Fig. 3) in *D. orbita* hypobranchial gland extracts are consistent with previous reports that **1** is the sole dye precursor in this species (Baker 1974). By using TLC developed in Dragendorff Reagent, we also detected only one choline ester corresponding to murexine, which is known to be associated with tyrindoxyl sulfate in *D. orbita* (Baker and Duke 1976). While murexine was not detected in our LC-MS analyses, the ability to detect the prochromogen **1** in muricid hypobranchial gland extracts should allow for identification of prochromogens in more complex extracts (e.g., *M. trunculus*), where substituted and un-substituted sulfate esters of indoxyl and 6-bromoindoxyl coexist (McGovern and Michel 1990). The absence of any peaks that correspond to the mono- or non-brominated indigo or indirubin standards (Appendix) in our *D. orbita* extracts (Fig. 3, Table 1), further confirms **1** as the sole ultimate dye precursor (Fig. 1) in this Australian species. This study provides new evidence for 6,6′-dibromoindirubin in glandular extracts of *D. orbita* (Table 1), as 6,6′-dibromoindigo was previously thought to be the sole dye component in secretions from this species (Baker 1974). It now appears that genesis of the structural isomer is also possible, similar to that reported for other Muricidae (Clark and Cooksey 1997; Cooksey 2001a, b, 2006; Cooksey and Withnall 2001; Naegel and Cooksey 2002; Withnall et al. 2003; Koren 2006).

The molecular weight (Table 1) and mass spectrum fragment ion data obtained for the intermediate precursors tyrindoxyl (**2**) and tyrindoleninone (**3**) are consistent with previous studies on Muricidae extracts. Both of these indole precursors have been detected by mass spectrometry of the hypobranchial gland extracts of *Nucella lapillus* (Cooksey and Withnall 2001), with **2** also detected in *Murex brandaris* (Michel et al. 1992), and *M. trunculus* (Andreotti et al. 2004), whereas **3** has been reported from egg mass extracts from *D. orbita* (Benkendorff et al. 2000). Also expected from previous studies was the HPLC peak corresponding to 6-bromoisatin (**6**), which is known to evolve from other dye precursors under oxidative conditions (Cooksey 2001a). This compound was detected in both male and female hypobranchial glands and in the female capsule glands (Table 1) and has been previously detected in the egg masses of *D. orbita* (Benkendorff et al. 2000). The immediate precursor tyriverdin, however, was detected for the first time by using ESI-MS. Field desorption/field ionization MS of tyriverdin has been successful previously in identifying this intermediate (Christophersen et al. 1978), while chemical ionization and electrospray (positive ion) MS failed to produce a molecular ion (Benkendorff et al. 2000). It appears that a change in ionization mode to negative in the ESI-MS facilitates detection of this compound.

Detection of Tyrindoxyl sulfate (**1**) in male prostate and all female capsule, albumen, and in the majority of ingesting gland extracts (Table 1) strongly supports a role for indole derivatives in muricid reproduction. Tyrian purple precursors are thought to be synthesized in the branchial and rectal regions of the hypobranchial gland, before being transported by muco-cilliary action to the medial region for storage (Roller et al. 1995). Similar to other muricids (Middlefart 1992a, b; Roller et al. 1995), the rectal region of the hypobranchial gland in *D. orbita* surrounds the ventral surface of the rectum, which is embedded in the prostate or capsule gland (Benkendorff et al. 2004). This apparent association could facilitate the transfer of dye precursors and pigments from their site of synthesis in the hypobranchial gland to the adjacent prostate and capsule glands. Detection of the prochromogen (**1**) in more posterior female reproductive glands could be explained by residual biosynthetic activity, as muricid genital ducts are thought to arise from an ancestral right hypobranchial gland (Kay et al. 1998). Failure to detect intermediates or pigments (**2**–**7**) in the albumen and ingesting glands of females (Table 1) implies the absence of arylsulfatase, which is required for the hydrolysis of **1** (Fig. 1; Dubois 1909; Baker and Sutherland 1968). By comparison, pigment production in the capsule and prostate glands (Table 1) suggests either the presence of arylsulfatase, in addition to **1**, or diffusion of hydrolyzed intermediates from the hypobranchial gland.

Detection of Tyrian purple precursors in the reproductive glands of *D. orbita* could provide a mechanism for incorporating bioactive intermediates into the egg masses of this species (see Benkendorff et al. 2001). Although the exact location of fertilization remains unclear, the capsule gland has been proposed in *N. lapillus* (Fretter 1941). This poses a practical site for precursor incorporation into egg capsules, as tyrindoxyl sulfate and arylsulfatase (Dubois 1909; Baker and Sutherland 1968) could be acquired from the adjacent hypobranchial gland. An alternative fertilization site in muricids is the albumen gland, where sperm are thought to pass from the duct of the ingesting gland into the albumen gland where eggs are received from the oviduct (Fretter 1941). If so, it may be possible that the prochromogen is incorporated into albuminous secretions before being passed into the capsule gland along with fertilized eggs. Detection of **1** in male prostate gland extracts (Table 1) could provide further means for transferring high concentrations of bioactive dye precursors to the egg masses of *D. orbita* (Benkendorff et al. 2001). As the prostate gland adds prostatic fluid to sperm within the pallial vas deferens during passage to the penis (Middlefart 1992a, b), the prochromogen could also be incorporated into seminal secretions. During copulation, semen is released into the bursa copulatorix or ventral channel of the female uterus (Fretter 1941), where it ultimately combines with albuminous secretions. Consequently, males feasibly could contribute tyrindoxyl sulfate to the intracapsular fluid constituent during capsule manufacture as an additional paternal investment. Previously, it was suspected that precursors in the egg masses of *D. orbita* were of adult origin (Benkendorff et al. 2004; Westley et al. 2006). However, the question remained as to how these compounds arrive in the egg capsules of this species. This investigation provides chemical evidence for Tyrian purple precursors and pigments in the reproductive system of a Muricidae.

Statistically significant sexual dimorphism was found in the chemical composition of Tyrian purple from the hypobranchial glands of *Dicathais orbita* (Fig. 4; $P=0.002$). Our results support previous observations of a more blue-purple pigmentation in female hypobranchial muricid secretions, compared to the red-purple dyes gained from males (Fig. 2, Boesken Kanold personal communication; Verhecken 1989; Michel et al. 1992). In the past, the blue hue of Tyrian purple secretions has been attributed to the presence of indigo (**8**) and/or 6-bromoindigo (**10**; Verhecken 1989; Michel et al. 1992; Benkendorff et al. 2004). However, neither of these blue compounds was detected during quantitative analysis of *D. orbita* extracts (Tables 1 and 2), including glands in which blue pigmentation was clearly observed. This demonstrates the unreliability of simple color observations for drawing conclusions about pigment composition in natural samples. The sex-specific dye pigmentation in *D. orbita* clearly is not due to variations in purple dibrominated vs blue non- or monobrominated indigoids, but is due rather to the presence of precursors and structural isomers of Tyrian purple. The blue-purple color of female secretions can be accounted for by the presence of blue-purple (**5**) and green (**4**), whereas the red hue of male dyes can be attributed to red-purple (**7**) and yellow (**6**; Tables 1 and 2). Previous observations have also suggested that dye pigmentation depends on whether mantle integrity is maintained between the pallial gonoduct and the hypobranchial gland (Benkendorff et al. 2004). Blue secretions in "detached" glands were speculated to result from the evolution of indigo (**8**) in the absence of bromoperoxidase or bromine in the rectal hypobranchial gland or pallial gonoduct. However, in this investigation, both "attached" and "detached" glands displayed consistent blue and purple pigment mixtures (Table 2), confirming that the sexual differences occur directly in the hypobranchial glands and are not dependant on the presence of reproductive glands.

The blue coloration observed in some of our *D. orbita* glands and extracts is most likely due to the molecular behavior of dibromoindigo. In solution or at low concentration, dibromoindigo can appear blue, while at high concentrations or as a textile dye, it develops a purple hue (Cooksey 2001b). The blue pigmentation arises from monomers of 6,6′-dibromoindigo, while the formation of dimers or higher polymers gives a purple color due to the van der Waals attraction between bromine atoms. This results in closer molecular stacking and shifts the absorption maximum towards the red (Cooksey 2001b). Furthermore, as dibromoindigo displays a strong anisotropy of light absorption in the solid state (Susse and Krampe 1979), the absorption maximum (λ_{max} 540 and 640 nm) depends greatly on molecular orientation (Cooksey and Withnall 2001). Consequently, the blue pigmentation in *D. orbita* secretions could result from the molecular arrangement and/or concentration of 6,6′-dibromoindigo, but is not due to isolation from bromoperoxidase or bromine.

Examination of dye genesis in male and female samples under natural conditions has interesting implications for differences in glandular physiology. For example, detection of the Tyrian purple isomer **7** and higher concentrations of 6-bromoisatin (**6**) in male hypobranchial glands suggests more aerobic conditions in comparison to female glands. It is hypothesized that **6** arises from the photochemical oxidation of the tyrindoxyl sulfate, tyrindoxyl, or tyrindoleninone, among other intermediates (Cooksey 2001a, 2006; Cooksey and Withnall 2001). 6-Bromoisatin (**6**) is considered a precursor to brominated indirubins (Clark and Cooksey 1997; Cooksey 2001a, 2006), which supports the

evolution of **7** in male hypobranchial glands, where the highest concentrations of **6** were detected (Table 1). Surprisingly, **6** was not detected in conjunction with **7** in male prostate glands, thus, suggesting a more complete reaction series in this gland. Conversely, in female extracts, the presence of sulfur compounds, such as dimethyl disulfide and the intermediate dye precursors tyrindoleninone (**3**) and tyriverdin (**4**), suggests the female glandular environment may be more reducing than oxidizing. The presence of **4**, in conjunction with comparatively low percentages of **6** explains the evolution of 6,6′-dibromoindigo (**5**) instead of **7**. In the presence of sunlight, photoliable tyriverdin undergoes cleavage to yield dimethyl disulfide (McGovern and Michel 1990; Cooksey 2001a; Cooksey and Withnall 2001) and **5**. The liberation of dimethyl disulfide would help maintain a reducing environment (McGovern and Michel 1990) that results in increased yields of **5** and a relative decrease in the oxidation by-products **6** and **7**. Although oxygen availability appears to explain differences in male and female dye composition, the reason for this divergence in glandular chemistry requires further investigation.

Our LC-MS analyses of hypobranchial gland secretions from *D. orbita* provide the first evidence for sex-specific genesis of Tyrian purple (Tables 1 and 2, Fig. 4) in the Muricidae. Sex-specific pigments that result in visual coloration occur in many species, including marine invertebrates (Bandaranayake 2006). These differences generally aid in mate selection. However, in the case of the Muricidae, the pigmentation from hypobranchial gland metabolites does not exist as an external visual cue and, thus, is more likely to occur as a by-product of their biologically active precursor compounds (Benkendorff et al. 2000; Westley et al. 2006). Sex is a known determinant in the synthesis of antibacterial ceratotoxins in the Mediterranean fruit fly, *Ceratitis capitata* (Marchini et al. 1993; Rosetto et al. 1996), the venom of spiders (Rash and Hodgson 2002), and the allelochemical, sarcophytoxin, in the soft coral, *Sarcophyton glaucum* (Fleury et al. 2006). However, this is the first account of sex-specific secondary metabolite synthesis in the Mollusca and provides a good model for exploring the driving forces for such biosynthetic divergences in marine invertebrates. Indole derivatives have been documented in a huge range of marine invertebrates (Christophersen 1983; Alvares and Salas 1991), including one report of dibromoindigo in the marine acorn worm, *Ptychodera flava laysanica* (Higa and Scheuer 1976). Unlike most other species, however, we now have a good understanding of the biosynthetic origin and anatomical distribution of these indole derivatives in *D. orbita*. This will facilitate future physiological and ecological investigations without confounding from inappropriately pooling between sexes or biosynthetic organs.

Understanding the sexual differences in muricid brominated indoles could also have useful implications for future development of natural medicines from these molluscs. The purple secretion from muricids is currently listed on the Homeopathic Materia Medica (Westley et al. 2006), although chemical and pharmacological research to substantiate the bioactivity of this remedy is lacking. Nevertheless, recent studies indicate that brominated indirubins in muricid Tyrian purple inhibit cell proliferation with selectivity towards GSK-3α/β receptors (Meijer et al. 2003; Magiatis and Skaltsounis 2006). Our results suggest that extracts from male muricids will yield the highest concentrations of these bioactive bromoindirubins. However, extracts from the females contain the intermediate precursors, tyrindoleninone and tyriverdin, with reported anticancer and bacteriostatic activity, respectively (Benkendorff et al. 2000; Westley et al. 2006; Vine et al. 2007). Consequently, there is much scope for future comparative studies to optimize extraction procedures for the development of novel natural remedies from these marine molluscs.

In summary, preservation of the glandular biochemistry, followed by quantification using HPLC-DAD coupled to ESI-MS, enables comparative investigations into the natural genesis of Tyrian purple in Muricidae molluscs. Tyrindoxyl sulfate (**1**) and the immediate precursor tyriverdin (**4**) were detected for the first time by LC-MS, thus providing a suitable procedure for the simultaneous analysis of all brominated precursors and pigments. The ultimate precursor **1** was detected throughout the female reproductive system, thus presenting a means for maternal investment in the chemical defense of *D. orbita* egg masses. A significant difference in the chemical composition of extracts from male and female hypobranchial glands provides evidence for sex-specific biosynthetic routes to Tyrian purple production. This sexual dimorphism is likely to be governed by glandular physiology, giving rise to an oxidizing and reducing environment in males and females, respectively. Together, these findings have useful implications for future investigations into the selective pressures that influence sex-specific metabolite biosynthesis in marine invertebrates and the development of bioactive muricid extracts.

Acknowledgements We thank Dr. D. Jardine (Flinders Advanced Analytical Laboratory) for assistance with the LC-MS analyses. We are also grateful to Ms. A. Bogdanovic for preparation of male extracts, Dr. C. McIver, Assoc. Prof. J. Mitchell and Dr. C. Lenehan for providing useful feedback on the draft manuscript, and Inge Boesken Kanold for personal observations and images. We appreciate the provision of a Flinders University Postgraduate Scholarship to C. Westley. This research was supported by a Philanthropic research grant to K. Benkendorff.

APPENDIX

Table 3 Characteristics of indigoid and indirubin standards and diagnostic parameters obtained by liquid chromatography-mass spectrometry

Compound Number	Standard	Structure	$[M-H]^+$	t_R
5	6,6'-dibromoindigo[a]		417, 419, 421	15.4
7	6,6'-dibromoindirubin		417, 419, 421	16.5
8	Indigo		261	10.7
9	Indirubin		261	10.5
10	6-bromoindigo		339, 341	12.7
11	6-bromoindirubin		339, 341	13.5
12	6'-bromoindirubin		339, 341	13.2

$[M–H]^+$ the pseuomolecular ion (Br^{79}, Br^{81}) registered as the dominant signal in ESI mass spectrums in the negative ionization mode
t_R = the retention time in minutes
[a] Female extracts displayed a shift in retention time compared to the synthetic standard (Table 1). This was attributed to HPLC column replacement (despite identical specifications). To confirm the identity of dye components, a female hypobranchial extract was spiked with the dibromoindirubin standard, which also contained trace amounts of the dibromoindigo isomer. In comparison to un-spiked extracts, an increase in relative peak intensity in the spiked extract at 14.5 min and an additional peak at 16.0 min confirmed the dominance of dibromoindigo in female extracts. Subsequent reanalysis of male extracts confirmed that the retention time shift was due to column replacement rather than any specific properties of the female extracts.

Variation of Phlorotannins Among Three Populations of *Fucus vesiculosus* as Revealed by HPLC and Colorimetric Quantification

R. Koivikko · J. K. Eränen · J. Loponen · V. Jormalainen

Received: 11 October 2007 / Revised: 20 November 2007 / Accepted: 21 November 2007 / Published online: 21 December 2007

Abstract In ecological studies, phlorotannins have conventionally been quantified as a group with similar functionality. Since this group consists of oligo- and polymers, the quantification of their pooled contents alone may not sufficiently describe the variation of these metabolites. Genetic variation, plastic responses to environment, and the ecological functions of separate phlorotannin oligo- and polymers may differ. Two analyses, i.e., the colorimetric Folin–Ciocalteu assay and a normal-phase high-performance liquid chromatographic (HPLC) method were used to study genetic and environmental variation in phlorotannins of the brown alga *Fucus vesiculosus* (L.). The colorimetric method provides the total phlorotannin content, the latter a profile of 14 separate traces from the phenolic extract that represent an individual or groups of phlorotannins. We reared the algae that originated from three separate populations in a common garden for 3 months under ambient and enriched-nutrient availability and found that they differed in both their total phlorotannin content and in phlorotannin profiles. Some individual traces of the profiles separated the populations more clearly than the colorimetric assay. Although nutrient enrichment decreased total phlorotannin content, it did not show a significant influence on the phlorotannin profile. This implies that plastic responses of compounds other than phlorotannins may interfere with the determination of total phlorotannins. However, the phlorotannin profile and the total content showed genetic variation among local populations of *F. vesiculosus*; therefore, phlorotannins may respond to natural selection and evolve both quantitatively and qualitatively.

Introduction

Phlorotannins are polyphenols formed by the polymerization of phloroglucinol (1,3,5-trihydroxybenzene) units and are known only from brown algae (Ragan and Glombitza 1986; Amsler and Fairhead 2006). The variation in total phlorotannin content has been intensely studied, particularly due to the putative adaptive nature of these compounds as deterrents against herbivores (reviews by Targett and Arnold 1998, 2001; Amsler and Fairhead 2006). Total phlorotannin content varies as a response to environmental factors such as salinity, nutrient and light availability, ultraviolet radiation, and the intensity of herbivory (reviews by Targett and Arnold 1998; Amsler and Fairhead 2006; Jormalainen and Honkanen 2008). Due to this high plasticity with respect to the number of distinct environmental cues, the several putative primary and secondary functions, and various methodological concerns, the ecological roles of phlorotannins have been considered somewhat controversial (Amsler and Fairhead 2006).

Total phlorotannin contents also commonly vary among local populations of algae (Pavia et al. 1999, 2003; Honkanen et al. 2002; Hemmi and Jormalainen 2004b). This variation may arise either from genetic divergence

among populations, or from plastic responses of algae to environmental variation, or both. Although the role of genetic differentiation in the among-population variation of phlorotannins has not been directly tested, such differentiation is possible. Phlorotannin concentration in *Fucus vesiculosus* (L.) is genetically variable (Jormalainen and Honkanen 2004). Based on neutral molecular markers, genetic differentiation has been found among adjacent *F. vesiculosus* populations in the Baltic Sea (Bergström et al. 2005; Tatarenkov et al. 2007) and among populations of *F. serratus* (L.), in which species there is substantial genetic substructuring at a scale of less than 2 km along the Atlantic and southern Baltic Sea coastlines (Coyer et al. 2003). While the neutral markers indicate differentiation due to genetic drift, spatial variation in natural selection may, in addition, select for among-population differences in the contents of total phlorotannins (Jormalainen and Honkanen 2004).

Nutrient availability is an environmental factor that is commonly found to influence the resource allocation of plants (e.g., Koricheva et al. 1998), and thus, the contents of total phlorotannins also (review by Amsler and Fairhead 2006). Nutrient enrichment causes a decrease of total phlorotannin content in the growing tips of *F. vesiculosus* (Hemmi et al. 2004; Koivikko et al. 2005). Such an effect can arise due to growth increase at the expense of soluble phlorotannins production, or in eutrophic conditions, due to an increase of epibiota and consequent shading of the thallus. The resource-based theories on this allocation between growth and defense, e.g., the carbon-nutrient balance (CNB) and the growth-differentiation balance (GDB) models, have been used successfully as the contextual framework to understand such plasticity in the contents of total phlorotannins (reviews by Cronin 2001; Pavia and Toth 2008).

In ecological studies, phlorotannin content has practically always been quantified by using colorimetric methods, e.g., Folin–Ciocalteu, Folin–Denis, or DMBA, mainly because individual phlorotannins are difficult to measure with common analytical techniques because of their large size, polarity, and water solubility, and the relative similarity of structures of separate oligo- and polymers (Stern et al. 1996; Targett and Arnold 1998; Koivikko et al. 2007). Such a total quantification, however, may conceal the variation of individual compounds present. In the analyses of total phenolics, the variation in the reactivity of structurally different phlorotannins is combined with that variation caused by different amounts of compounds. For example, phlorotannins of different molecular size differ in their bioactivity (Boettcher and Targett 1993). Therefore, more specific methods to separate individual phlorotannins are needed to measure all the variation of phlorotannins and to evaluate their role in ecological interactions. It may also be possible that genetic variation exists in the phlorotannin profile or that separate phlorotannins respond to different environmental cues in distinct ways.

To study both genetic and environmental variation in the phlorotannin profile of the brown alga *Fucus vesiculosus*, we applied the high-performance liquid chromatographic (HPLC) method for separation of phlorotannins, previously described by Koivikko et al. (2007). Specifically, we tested the occurrence of genetic among-population phlorotannin differentiation by rearing algae that originated from three separate populations in a common environment and by analyzing their phlorotannins. We also examined within-population genetic variance by measuring the variation among cloned genotypes. To examine the environmental plasticity of phlorotannins, algae were reared in both ambient and nutrient-enriched conditions. We compared the phlorotannin variation revealed by using two assay methods which generated total phlorotannin content and phlorotannin profiles, i.e., the Folin–Ciocalteu and HPLC assays, respectively.

Methods and Materials

Study Organism F. vesiculosus is a perennial brown alga that dominates the shallow littoral rocky bottoms in the nontidal study area in the Archipelago Sea, SW Finland. In the naturally fragmented environment of the archipelago, local populations of *F. vesiculosus* are somewhat isolated owing to the low dispersal ability of fucoid propagules (Chapman 1995). The chemical contents of several metabolites (Hemmi and Jormalainen 2004a) and the food quality for herbivores (Honkanen and Jormalainen 2002) vary among populations, even at a scale of a few kilometers. The populations of *F. vesiculosus* in our study area face a gradient of ambient nutrient availability, from high, close to the mainland, to low, in the outer archipelago (Hänninen et al. 2000).

Sampling and Experimental Growing Conditions of Algae We collected 15 *F. vesiculosus* genotypes from three different populations (Aaviikki: 60°21.48′ N, 22°32.45′ E; Jurmo: 59°49.36′ N, 21°36.57′ E; Säppi: 61°28.80′ N, 21° 20.80′ E), located 80–185 km apart, from depths of 0.5–2 meters in May 2002. Genotypes were defined as entities growing from a single branch of thallus on a holdfast. Each of the 45 genotypes was split into four 3- to 5-cm long apical pieces (hereafter "algal individual"). To eliminate among population differences caused by environmental plasticity, these algal individuals were transferred to grow in the common littoral environment of Katava island (60° 14.03′ N, 21°57.51′ E). Algal individuals were attached with a clothes-peg to four plastic grid mats, one piece of each genotype to each mat. Two mats were assigned to the

nutrient enrichment treatment (nutr) and two to ambient nutrient conditions (ctrl). The mats were settled randomly to a depth of 1.5 m, at a minimum distance of 4 m apart. Nutrient enrichment consisted of a nitrogen, phosphorous, and potassium mixture (16:5:9) in a controlled-release fertilizer (Osmocote exact standard 3–4 M). Fabric packages containing nutrients (ca 500 g) were attached to each nutrient enrichment mat and replaced monthly during the experiment to ensure the fertilizer's sufficiency. Nutrient enrichment of this magnitude under comparable conditions in the same area has been shown to increase the concentration of DIN and DIP, 5 and 1.2 times higher, respectively, compared to ambient nutrient concentration (Korpinen et al. 2007). After 3 mo (May 27–August 27), we took samples of the algal individuals, from the apical parts grown during the experiment, for analysis of phlorotannins. We took a sample from each individual, but due to the loss of some individuals, did not get samples from every genotype (total N=138; Aaviikki: 27 ctrl, 21 nutr; Jurmo: 23 ctrl, 19 nutr; Säppi: 24 ctrl, 24 nutr). Samples were frozen immediately, freeze–dried, homogenized, and stored at −20°C until further analyses.

Phlorotannin Analysis The total phlorotannin content for all 138 samples (74 ctrl and 64 nutr) was analyzed according to the procedure reported by Koivikko et al. (2005). We used an extraction procedure for soluble phlorotannins and a quantification protocol with a modification of the Folin–Ciocalteu method with phloroglucinol as the standard agent. Due to the lack of sufficient thallus biomass (200 mg) from all samples, only 84 were analyzed by HPLC (Aaviikki: 18 ctrl, 16 nutr; Jurmo: 9 ctrl, 13 nutr; Säppi: 8 ctrl, 10 nutr). Samples for HPLC analysis were prepared and analyzed by the protocol and conditions described in Koivikko et al. (2007). In the liquid chromatographic analysis of the phenolic fraction, the contents of total phlorotannins were split into fragments. This separation procedure with a selected wavelength of 280 nm, characteristically revealed those phlorotannins which are produced via the polyketide pathway, the only known biosynthetic route for phenolic compounds in brown algae. Each separate trace in the chromatogram represents either individual phlorotannins or groups of phlorotannin molecules of similar size (Koivikko et al. 2007). The HPLC profile gave 14 clearly distinguishable traces (14 of 16 traces described in Koivikko et al. (2007) were used). The size of each individual trace is expressed as the integrated area of the peak and numbered 1 to 14 in the figures and tables, according to Fig. 1.

Statistical Methods To explore the repeatability of the individual traces in the HPLC profile, we analyzed 18 samples (including a random sample of individuals from the experiment and 6 additional samples from the study populations) twice. The whole process from sample preparation to the calculation of the results from HPLC analysis was replicated. Repeatability measures the consistency of repeated measures within a subject (here, a sample), and obtains values from 0 to1, the latter occurring where the repeated measures within a subject are identical (Krebs 1999). A one-way analysis of variance (ANOVA) was carried out for each trace, i.e., the integrated areas of peaks, to obtain the variance components. The repeatability was calculated as a coefficient of intra-class correlation according to Krebs (1999). As a criterion of repeatability, we used the 95% confidence interval of the intra-class correlation coefficient; the measurement was considered non-repeatable when the confidence interval included zero.

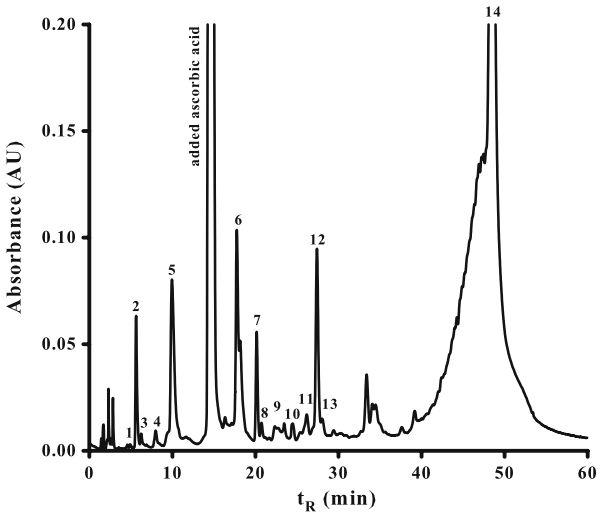

Fig. 1 Traces of soluble phenolics from polar extract of *F. vesiculosus*. *Numbers* indicate the 14 separate traces analyzed in this study

To study the contribution of the HPLC profile to the total phlorotannin content, we calculated the Pearson correlation coefficients between individual traces of the chromatogram and the contents of total phlorotannins. We further estimated how well the variation in the phlorotannin profile can explain the variation of the content of total phlorotannins by conducting a multiple regression analysis, where the total phlorotannin content was explained with all possible combinations of those seven traces that we found to be repeatable (nos. 3, 7, 8, 11–14; Fig. 1, Table 1). We did this both for the pooled data and separately for each population. The best-fitting model was found on the basis of the Akaike Information Criterion.

By using mixed-model ANOVAs, we tested both population and nutrient enrichment effects on the total phlorotannin contents and the area of each individual trace (nos. 1–14). The population and nutrient enrichment treatments were included as fixed effects, and the genotype was treated as a random effect, nested under population. To

estimate the variation of the individual HPLC traces attributable to algal origin, we calculated the among-population variance components. In addition, to quantify the effect of nutrient enrichment on both the individual HPLC traces and total phlorotannin content, we calculated the effect sizes (Gurevitch and Hedges 2001) of nutrient enrichment for each trace and total phlorotannins. We further tested the effects of population, nutrient enrichment, and genotype on the phlorotannin profile (including only the repeatable traces) by using a multivariate analysis of variance (MANOVA). To visualize the among-population differences in the phlorotannin profile, we conducted a principal component analysis (PCA) and plotted the values of the first and second principal component axes. In the PCA, we used genotypic means calculated over both nutrient treatments. All statistics were calculated with the SAS statistical package (SAS Institute 1999).

Results

From the HPLC profile, seven individual traces were repeatable (Table 1). According to the Pearson correlation coefficients, 6 of the 14 traces from the HPLC chromatogram correlated positively and significantly with the total phlorotannin content (Table 1). Multiple regression analysis revealed that the best-fitting model, which explained 22.9% of the variation in total phlorotannin content, included two traces of the phlorotannin profile, i.e., traces nos. 13 and 14. However, the within population analyses explained the variation in total phlorotannins better for some populations, while the profile trace patterns included in the bets-fitting model varied among populations. The best-fitting models for Säppi, Aaviikki, and Jurmo included 1 (no. 7), 2 (nos. 13 and 14), and 5 (nos. 8 and 11–14) traces, respectively, which in turn successively explained 15.3, 25.9, and 44.7% of the variation in the contents of total phlorotannins.

After rearing in a common environment for 3 mo, the three *F. vesiculosus* populations diverged with respect to both their total phlorotannin contents (Fig. 2, Table 2) and phlorotannin profiles (Fig. 2, Table 3). The MANOVA analysis of the HPLC profiles showed a significant among-population difference, particularly in the population from Aaviikki (Table 3). Although some genotypes mixed with those from other populations, the PCA analysis separated the Aaviikki population quite well (Fig. 3), the first two principal components explaining 79% of the total variance in the phlorotannin profile. By contrast, the populations that originated from Jurmo and Säppi did not differ in either the MANOVA (Table 3) or the PCA analyses (Fig. 3).

The among-population tests of the individual traces from the phlorotannin profile revealed a high variability in divergence among the separate traces; some showed none, while others showed a higher degree of divergence than what was found in the total phlorotannin content (Fig. 2). The average areas of individual traces (Fig. 4) showed similar among-population trends to those of the total phlorotannin contents: the population from Aaviikki had the highest (7.47±0.22, percent of DW and SE), with intermediate and lowest total phlorotannin contents from Jurmo (6.92±0.23) and Säppi (6.01±0.18), respectively. However, the amounts of total phlorotannins from the Säppi

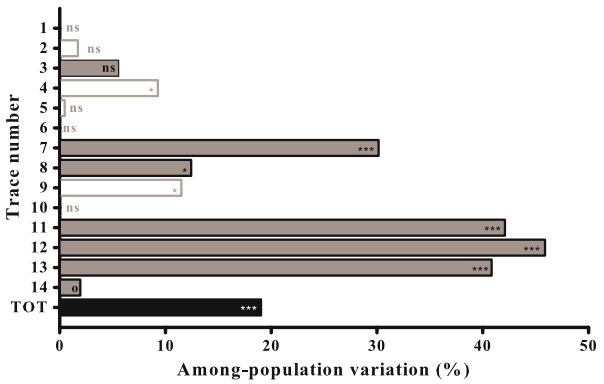

Fig. 2 The proportion of among-population variation of the total variation in the area of the 14 traces of the phlorotannin profile analyzed with HPLC (1–14, *white and light gray bars*) and in the total phlorotannin content measured with the Folin–Ciocalteu assay (TOT, *black bar*). Significances are based on the univariate ANOVA *F* statistics from the tests of among population variation. Source of Variation	Variance Estimates						
	Total Content of Phlorotannins						
	S^2	SE	χ^2	P	ndf, ddf	F	P
Random effects							
Genotype (population)	0.31	0.19	3.8	0.05			
Residual	1.64	0.24					
Fixed effects							
Population					2, 40.8	9.02	<0.001
Aaviikki vs Säppi					1, 38.5	17.93	<0.001
Aaviikki vs Jurmo					1, 42.6	3.13	0.084
Jurmo vs Säppi					1, 41.5	5.62	<0.05
Nutrient enrichment					1, 106	6.53	<0.05
Population × Nutrient enrichment					2, 106	0.34	ns

population deviated most from the other populations (Table 2), while the phlorotannin profile of the Aaviikki showed the greatest variation (Table 3). The area of the peak did not correlate with the magnitude of the among-population response: a rather small trace had an equally high among-population divergence, similar to one that was ten times higher in intensity (traces nos. 13 vs 7, Figs. 2 and 4).

Although the contents of total phlorotannins were significantly lower in the nutrient enrichment (6.47%±0.19, SE) than in the control treatment (7.07%±0.18, SE; Fig. 5, Table 2), the HPLC profile showed no differences between them (Fig. 5, Table 3). In the nutrient enrichment treatment, only the poorly repeatable trace no. 6 was higher than in the control (Fig. 5).

The genotypic variation within the population, in both the content of total phlorotannins (Table 2) and the phlorotannin profile (Table 3) was marginally significant.

Table 3 MANOVA test statistics on the effect of population, nutrient enrichment and genotype on the HPLC profile of phlorotannins (areas of the traces 3, 7, 8, 11–14) in *F. vesiculosus* (N=84)

Discussion

Our main finding was that the three populations of *F. vesiculosus* differed in both their phlorotannin profiles and

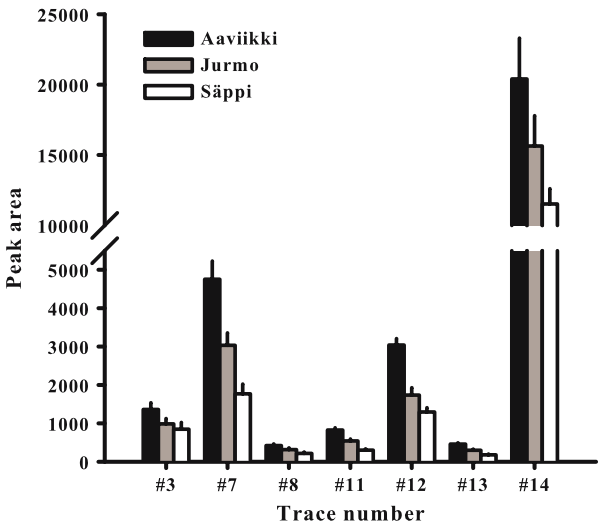

Fig. 4 The mean area (and SE) of the repeatable traces of the phlorotannin profile in different population after a 3-mo growth period in a common environment

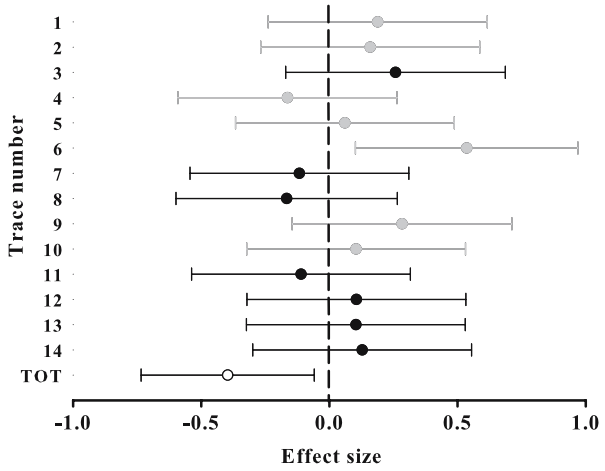

Fig. 5 The effect size (standardized mean difference between nutrient enrichment and control treatment levels±95% confidence intervals) of nutrient enrichment separately for each of the 14 traces of the phlorotannins profile analyzed with HPLC and the total contents of phlorotannins measured using the Folin–Ciocalteu assay (TOT, *white circle*). *Gray bars* indicate traces with poor repeatability

in the total phlorotannin content after the algae had grown for 3 mo in a common environment. A period of 3 mo is plenty of time for the phlorotannin pool to turn over and respond to the new common environment: in brown algae, metabolic turnover of phlorotannins takes place in days under field conditions (Arnold and Targett 2000), and in *F. vesiculosus*, plastic responses to environmental change occur in less than 1.5 mo (Hemmi et al. 2004; Honkanen and Jormalainen 2005; Koivikko et al. 2005). Thus, preservation of differences shows that the among-population variation in phlorotannins is genetic in origin. Further support for the genetic variation came from the marginally significant variation among the cloned genotypes within populations. Although genetic variation in total phlorotannins has also been found previously (Jormalainen et al. 2003; Jormalainen and Honkanen 2004), this is the first report on genetic variation of the phlorotannin profile.

The formation of phlorotannin oligo- and polymers in plants from their precursors necessitates enzyme activity (Waterman and Mole 1994). Those enzymes involved are transcription products of the plant genome (Waterman and Mole 1994); thus, the genetic variability in the profile and amount of phenolic compounds in a plant must reflect evolutionary differentiation among populations. Such a microevolutionary change may be caused either by natural selection or random changes in gene frequencies. We cannot exclude the role of genetic drift in the differentiation of phlorotannins, but they have been shown not to be selectively neutral; the form and intensity of natural selection for total phlorotannins varies among different environments (Jormalainen and Honkanen 2004). Therefore, the geographic variation in environmental conditions among local populations, i.e., in abiotic and biotic selective agents, may explain the observed differentiation.

The populations from Aaviikki and Jurmo were more alike in their contents of total phlorotannins but differed in their phlorotannin profiles, whereas the populations from Jurmo and Säppi differed in their total phlorotannin contents but resembled each other in their HPLC profiles. Thus, how the different compounds appeared varied among populations. Some individual traces differed among the populations. It might be suspected that such traces could be under differential selection, i.e., having ecological functions whose roles vary among populations. As with total phlorotannins, the phlorotannin profile also seems to reflect the quantitative differences among populations to some extent. However, the among-population differences in phlorotannin profile are also qualitative, as the magnitude of divergence varied among the separate traces.

Nutrient enrichment of the growing environment caused a decrease in total phlorotannins but did not change the composition of the profile. Similar effects of nutrient enrichment on total phlorotannins have been found previously in manipulative and correlative studies in *F. vesiculosus* (Peckol et al. 1996; Pavia and Toth 2000; Jormalainen et al. 2003; Hemmi et al. 2004) and in *Ascophyllum nodosum* (Svensson et al. 2007), but not in all studies of brown algae (Cronin and Hay 1996; Pavia and Toth 2000). The negative influence of nutrient enrichment on the total phlorotannin contents is predicted by both the CNB and GDB hypotheses.

The lack of differences in phlorotannin profiles among nutrient levels may indicate that such plasticity includes neither qualitative nor quantitative changes, but that nutrient enrichment induced a plastic response in compounds other than phlorotannins. As the colorimetric method gives the total contents of all compounds that have a similar functional group, it also measures some compounds not classified as phenolic but that include an oxidizable group. For example, amino acids and proteins, ascorbic acid, urea, and diethyl ether are known to cause such inaccuracy (Ragan and Glombitza 1986; Steinberg 1989; Waterman and Mole 1994; Van Alstyne 1995; Stern et al. 1996). It has been suggested that the concentrations of compounds other than phlorotannins in the Folin–Ciocalteu assay range between 3 and 5% (Van Alstyne 1995). Thus, although an increase of about 10% in the value of the FC assay as a response to nutrient enrichment is unlikely to result from non-phlorotannin compounds alone, the lack of any response in the phlorotannin profile may indicate that plasticity in non-phlorotannin compounds may interfere with the determination of total phlorotannins more than has been conventionally assumed. However, there remains the possibility that the profile does not include those phlorotannins that increase with the nutrient level. Some compounds might remain undetected or be underrepresented in liquid chroma-

tography because of low UV response in relation to the concentration, large molecular structure, overlapping of isomers, or an unsuitable polarity for chromatographic determination (Adamson et al. 1999; Lazarus et al. 1999). As the area of a trace is affected by the sensitivity of the compound to detection, the stability of the molecule and its amount can at best, only be an indication of the actual quantity of the compound. However, it is likely that oligomers or polymers up to hexamers are in fact detectable by NP-HPLC (Koivikko et al. 2007).

Six of the fourteen traces of the phlorotannin profile correlated positively with the contents of total phlorotannins. However, when using pooled data, the best multiple regression model of total phlorotannins on the phlorotannin profile explained less than a quarter of the observed variation. In the within-population analyses, the amount of explained variation differed among populations; in one, it increased to 45%. Such variability and increase in the amount of explained variance at the within population level was expected because the phlorotannin profiles of the populations differed. At least two factors contribute to the relatively poor consistency of the total phlorotannins and phlorotannins profile, i.e., the HPLC method may leave some phenolic compounds undetected, while the Folin–Ciocalteu assay might measure some compounds not classified as phlorotannins.

To summarize, the phlorotannin profile shows genetic variation among local populations of *F. vesiculosus*. Thus, not only the total contents of phlorotannins but also the amounts of separate phlorotannins may respond to natural selection and evolve. This implies that local populations of brown algae may become qualitatively different with respect to their major group of secondary metabolites. While understanding the functions and variability of separate phlorotannins remains a challenge, the HPLC assay of the phenolic fraction provides a method to explore their responses to both the abiotic and biotic factors. To better understand the suggested multiple roles of phlorotannins, the phlorotannin profile can give more detailed data than the total phlorotannin content.

Helikauranoside A, a New Bioactive Diterpene

Francisco A. Macías · Adriana López · Rosa M. Varela · Ascensión Torres · José M. G. Molinillo

Received: 24 August 2007 / Revised: 10 October 2007 / Accepted: 4 November 2007 / Published online: 11 December 2007

Abstract A new *ent*-kaurane glucoside, named helikauranoside A (**4**), was isolated from the aerial parts of *Helianthus annuus* L. together with three known *ent*-kaurane-type diterpenoids: (−)-kaur-16-en-19-oic acid (**1**), grandifloric acid (**2**), and paniculoside IV (**3**). The structure of 4 was determined by using a combination of 1D (^{1}H-NMR and ^{13}C-NMR) and 2D (COSY, HSQC, and HMBC) NMR techniques. Bioactivity spectra of isolated compounds were tested by using the etiolated wheat coleoptile bioassay in aqueous solutions at concentrations ranging from 10^{-3} to 10^{-6}M. Helikauranoside A (**4**) was the most active (−84%, 10^{-3}M; −56%, 10^{-4}M). These results suggest that this new compound may be involved in defense mechanisms of *H. annuus*.

Keywords Allelopathic agents · Kaurane · Glycoside · Sunflower · Diterpene

Introduction

Chemical studies of *Helianthus annuus* L. (Spring et al. 1981; Melek et al. 1985; Alfatafta and Mullin 1992; Spring et al. 1992; Macías et al. 1993a, b, 1994, 1996) have shown that this species is a rich source of terpenoids, particularly sesquiterpenoids. A wide spectrum of biological activities has been reported for sunflower extracts and components (Beale et al. 1983; Rieseberg et al. 1987; Spring et al. 1991; Ghisalberti 1997). These activities include potential allelopathic effects of extracts from different sunflower cultivars (Macías et al. 1998, 1999a, b).

The isolations of diterpenoids from *H. annuus* L. that have different skeleton types include the following: trachylobanes (Ferguson et al. 1982; Pyrek 1984; Melek et al. 1985); atisane (Morris et al. 2005); gibberellins (Hutchinson et al. 1988); and the kaurenoid carboxilic acids (−)-kaur-16-en-19-oic acid (**1**) (Fig. 1) (Pyrek 1970), grandifloric acid (**2**) (Fig. 1) (Panizo and Rodriguez 1979; Ferguson et al. 1982), angeloylgrandifloric acid, 15β-acetoxy-kaur-16-en-19-oic acid, 15β-*i*-valeroxy-kaur-16-en-19-oic acid, 15β-angeloxy-kaur-16-en-19-oic acid (Ferguson et al. 1982), *ent*-kauran-16α-ol (Morris et al. 2005), 2β,16β-*ent*-kauranediol, and 15α,16α-epoxy-17β-al-*ent*-kaurane-19-oic acid (Suo et al. 2006).

A bioassay-guided fractionation of *H. annuus* L. extracts was carried out to isolate, identify, and characterize the allelopathic constituents. Four kaurene diterpenes were isolated from SH-222 and Stella cultivars of sunflowers. Helikauranoside A (**4**) (Fig. 1) is characterized by a glycosylated kaurane-type skeleton and is described for the first time. The etiolated wheat coleoptile bioassay in aqueous solutions at concentrations between 10^{-3} and 10^{-6}M were used to complete the bioactivity spectrum of the isolated compounds.

Methods and Materials

General IR spectra (KBr) were recorded on a Perkin Elmer FT-IR Spectrum 1000, Matton 5020 spectrophotometer. NMR spectra were run on Varian INOVA-400 and Varian INOVA 600 spectrometers. Chemical shifts are given in

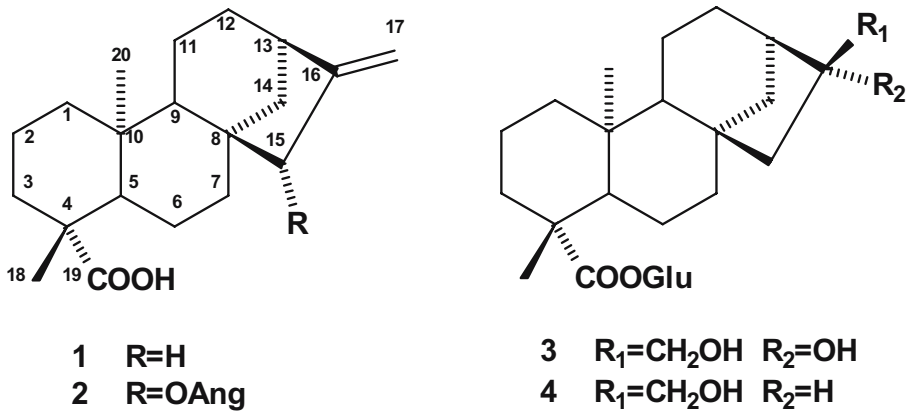

Fig. 1 Isolated diterpenes from *H. annuus* cv. Stella and SH-222

parts per million with respect to residual ^{1}H signals of MeOD-d_4 and py-d_5 (δ 3.30 and 7.55, respectively), as well as ^{13}C with those of the solvent (δ 49.0 and 135.5, respectively). Optical rotations were determined with a Perkin Elmer polarimeter model 241 (on the sodium D line). High-resolution mass spectroscopy (HRMS) was carried out on VG AUTOESPEC mass spectrometer (70eV).

Plant Material Helianthus annuus cv. SH-222 (commercialized by Semillas Pacífico) and Stella were collected during the third plant development stage (Macías et al. 1999c) (i.e., plants were 1.2m tall with flowers, 1month before harvest) and were provided by Rancho de la Merced, Agricultural Research Station (CIFA), Junta de Andalucía, Jerez, Spain.

Extraction and Isolation Fresh leaves of *H. annuus* cv. SH-222 (6kg) were extracted in water (18l) for 24h in the dark at room temperature. The aqueous solution was extracted with CH_2Cl_2 and then with EtOAc at room temperature. The organic layer was removed by reduced pressure evaporation and yielded two extracts of 16g (CH_2Cl_2-W) and 6g (EtOAc-W), respectively. EtOAc-W was chromatographed by using hexane–ethyl acetate mixtures of increasing polarity. The most polar fraction was chromatographed on a reverse-phase column (C-18) with a water–methanol (1:4 to 0:1) solvent system to elute compounds **3** (2mg) and **4** (3mg) (Fig. 1).

Similarly, 4kg of *H. annuus* cv. Stella was extracted and yielded 77g (CH_2Cl_2-W) and 7g (EtOAc-W). CH_2Cl_2-A was chromatographed with hexane–ethyl acetate mixtures of increasing polarity. The fraction eluting with hexane–ethyl acetate (1:1) was chromatographed and yielded two compounds—**1** (28mg) and **2** (1mg).

Known compounds were identified by comparison of their physical and spectroscopical data (m.p., [α], IR, MS, ^{1}H-NMR and ^{13}C-NMR) with those previously reported in the literature. *Helikauranoside A* (**4**) crystalline solid mp 260°C; IR ν_{max} (KBr) cm^{-1}: 3,500 (OH, carboxylic acid) 1,700 (C=O, acid). ^{1}H-NMR data (600MHz) MeOD-d_4: δ 0.95 (s, H-20), 1.20 (s, H-18), 1.91 (m, H-16), 2.17 (m, H-3α), 3.32–3.37 (m, H-4′, H-3′, H-2′), 3.35 (m, 2H, H-17), 3.40 (ddd, 8.0, 1.7, 4.6, H-5′), 3.68 (dd, 11.9, 4.6, H-6′a), 3.81 (dd, 11.9, 1.7, H-6′b), 5.39 (d, 8.1, H-1′); py-d_5: δ 6.26 (d, 7.9, H-1′), δ 4.45 (brd, 11.2, H-6′β), δ 4.38 (brd, 11.2, H-6′α), δ 4.34 (dd, 10, 8.8, H-3′), δ 4.25 (dd, 8.8, 8.8, H-4′), δ 4.22 (dd, 8.1, 7.9, H-2′), δ 3.94 (ddd, 8.8, 4.4, 2.4, H-5′), δ 3.61 (m, 2H, H-17), δ 2.38 (brd, 13.2, H-3a), δ 2.29 (brs, H-13), δ 2.16 (m, H-16), δ 1.79 (brd, 12.3, H-1a), δ 1.61 (dd, 9, 12.1, H-15a), δ 1.44 (m, H-7a), δ 1.27 (s, 3H, H-18), δ 1.22 (s, 3H, H-20), δ 1.08 (dd, 5.1, 12.1, H-15b), δ 0.96 (brd, 8.0, H-3a), δ 0.76 (m, H-7b); ^{13}C NMR data (150MHz): see Table 1; HREIMS *m/s* 482.2884 [M^{+}] (cal. for 482.2880).

Coleoptile Bioassay Wheat seeds (*Triticum aestivum* L. cv. Duro) were sown in Petri dishes (15cm diameter), misted with water, and grown in the dark at 22 ± 1°C for 3days (Hancock et al. 1964). The roots and caryopsis were removed from the shoots. The apical 2mm of the caryopsis was cut off and discarded with a Van der Weij guillotine. The next 4mm of the coleoptiles was removed and used for bioassay. All manipulations were performed under a green safelight (Nitsch and Nitsch 1956). Compounds were predisolved in DMSO and diluted to the final bioassay concentration with a maximum of 0.1% DMSO. Parallel controls treated with water and DMSO were also run at the same concentrations.

Crude extracts, fractions, or pure compounds to be assayed for biological activity were added to test tubes. Assays were run in duplicate. Phosphate–citrate buffer (2ml) containing 2% sucrose (Nitsch and Nitsch 1956) at pH5.6 was added to each test tube. Following the placement of five coleoptiles in each test tube (three tubes per dilution), the tubes were rotated at 0.25rpm in a roller

tube apparatus for 24h in the dark at 22°C. Coleoptiles were measured following digitalization of their images. Data were statistically analyzed by using Welch's test (Martín Andrés and Luna del Castillo 1990). Data are presented as percentage differences from control. Thus, zero represents the control, positive values represent stimulation of the studied parameter, and negative values represent inhibition.

Results and Discussion

Fresh *H. annuus* cv SH-222 leaves were extracted in water in the dark at room temperature. The aqueous solution was extracted with CH_2Cl_2 and then with EtOAc. Following chromatography, the EtOAc extract was separated into eight fractions. Fraction H contained the compounds paniculoside IV (**3**) (2mg) and helikauranoside A (**4**) (3mg) described for the first time in this report (Fig. 1). *Helianthus annuus* cv. Stella was extracted similarly. The fraction eluting with hexane-EtOAc (1:1) yielded compounds **1** (28mg) and **2** (1mg). The spectroscopic data for **1**, (Pyrek 1970; Ohno et al. 1979) **2** (Panizo and Rodriguez 1979; Herz et al. 1983), and **3** (Fig. 1)(Ohno and Mabry 1980) were identical to those previously reported.

Table 2 Selected ^{13}C NMR data for α- and β-isomers of aglycone in $CDCl_3$ and those for compound 4 in methanol

C	α-CH_2OH	β-CH_2OH	4
12	20.0	31.4	32.5
13	36.9	38.1	39.5
15	44.2	45.0	46.3
17	64.2	67.4	67.7

Helikauranoside A (**4**) was isolated as white crystals (mp 260°C) with $[\alpha]_D^{25}$ −6.4 (*c* = 0.14) from fraction H. The molecular formula was deduced to be $C_{26}H_{42}O_8$ on the basis of HRMS that showed an ion peak $[M]^+$ at *m/z* 482.2884. Intense absorption bands at 3,500 and 1,700cm^{-1} were observed in the IR spectrum of **4**, in accordance with the presence of hydroxyl and carbonyl functions, respectively. The ^1H NMR spectrum of **4** was run in methanol (CD_3OD) and pyridine (C_5D_5N). Both spectra exhibited signals for a β-glucopyranosyl moiety in the structure [CD_3OD: δ 5.39 (H-1′, d, *J* = 8.1), δ 3.81 (H-6′β, dd, *J* = 11.9, 1.7), δ 3.68 (H-6′α, dd, *J* = 11.9, 4.6), δ 3.40 (H-5′, ddd, *J* = 8.0, 4.6, 1.7), δ 3.32–3.37 (H-2′, H-3′, H-4′, m); C_5D_5N: δ 6.26 (H-1′, d, *J* = 7.9), δ 4.45 (H-6′β, brd, *J* = 11.2), δ 4.38 (H-6′α, brd, *J* = 11.2), δ 4.34 (H-3′, dd, *J* = 10, 8.8), δ 4.25 (H-4′, dd, *J* = 8.8, 8.8), δ 4.22 (H-2′, dd, *J* = 8.1, 7.9), δ 3.94 (H-5′, ddd, *J* = 8.8, 4.4, 2.4)] (Agrawal 1992; Rakotondraibe et al. 2002; Harinantenaina et al. 2002a, b). This was confirmed by signals in the ^{13}C NMR spectrum [CD_3OD: δ 95.6 (C-1′), δ 78.7 (C-3′), δ 78.7 (C-5′), δ 74.1 (C-2′), δ 71.1 (C-4′), δ 62.4 (C-6′)].

Additionally, the ^1H NMR in methanol exhibited a signal for the protons of two methyl groups at δ 1.20 (3H, s, H-18) and δ 0.95 (3H, s, H-20). The H-17 protons resonate in MeOD at δ 3.35 (2H, m) and suggest that **4** is an ent-kaurane-type diterpene glycoside. The ^{13}C NMR and HSQC spectra of **4** showed the presence of two methyls, 11 methylenes, nine methines, and four quaternary carbons

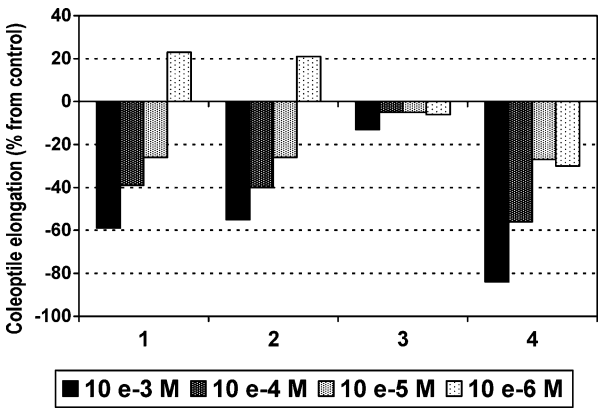

Fig. 2 Bioactivities of compounds **1**–**4** in wheat coleoptile bioassay

containing an ester carbonyl group. We found analogies in the chemical shifts of signals from the ^{1}H NMR and ^{13}C NMR spectra of **4** with those previously described for the epimeric diterpenes at C-16 that correspond to the aglycone (−)-17-hydroxy-kauran-19-oic acid (Table 1). On the basis of the stereochemical studies performed by Yang et al. (2002), the chemical shift of H-17 in methanol (δ 3.35) suggested a β-orientation for the hydroxymethylene moiety (δ 3.40 and 3.72 of the aglycone in $CDCl_3$ for the β and α isomers, respectively). This was confirmed by comparison of the chemical shifts observed in ^{13}C NMR spectrum with those found for the both isomers described by Wu et al. (1996; see Table 2). According to the chemical shift observed for C-17 in the pyridine-d_5 spectrum (δ 67.7), the β-glucopyranosyl moiety must be attached to the carboxylic ester at C-19; otherwise, a glycosylic moiety attached at C-17 should resonate between δ 74 and 75ppm (Shao et al. 1996). These data allow us to propose the structure *O*-β-D-glucopyranosyl-17-hydroxy-16β-kauran-19-oate. This is the first report of this structure, which was named helikauranoside A (**4**).

Bioactivity—Coleoptiles Bioassay There are many antecedents of bioactivity of kaurane diterpenes. Some of them are for compounds described in this report or for structures related to them. Thus, (−)-kaur-16-en-19-oic acid (**1**) has an inhibitory effect on the growth of *Bacillus subtilis* and *Staphylococus aureus* (Phan et al. 2005) and has been tested on the aggregation of Washed Rabbit Platelets, showing complete inhibition induced by collagen at 200μM (Yang et al. 2002). This compound was active in the brine shrimp test (BST LC_{50} 16μg/ml) and was selective for MCF-7 (breast cancer, ED_{50} 1.0μg/ml) cells among six human solid tumor cell lines (Majekodunmi and Oladimeji 1996). Compound **1** and the aglycone of **4** have strong inhibitory effects against cyclooxygenase (COX) (Phan et al. 2005).

The aglycone of **3** gave 46% and was inhibited by HIV reverse transcriptase at a concentration of 33μg/ml (Chang et al. 1998). Epimers at C-16 inhibited HIV replication in H9 lymphocyte cells with EC_{50} of 0.8μg/ml (Wu et al. 1996).

To complete the bioactivity spectrum of the isolated compounds, isolated compounds were tested with the etiolated wheat coleoptile bioassay (Hancock et al. 1964) in a range of 10^{-3}–10^{-6}M. This bioassay has been used to estimate plant growth regulation, herbicide, or phytotoxic activities (Cutler 1984).

The growth of etiolated wheat coleoptiles (Fig. 2) was inhibited ($P<0.01$) by solutions of **1** (−59%, 10^{-3} M; −39%, 10^{-4} M), **2** (−55%, 10^{-3} M; −40%, 10^{-4} M), and **4** (−84%, 10^{-3} M; −56%, 10^{-4} M). The most active compound was **4**, whereas compounds **1** and **2** presented similar activities, but **3** did not show any significant effect.

Chemical differences among diterpenes **1**, **2**, **3**, and **4**, are centered at C-16. Therefore, the differences in the activity must be explained by the different substitutions in this position. Compound **4** has a hydroxymethylene group at C-16 and is highly active, whereas the presence of an additional hydroxyl group (compound **3**) decreases activity dramatically. On the other hand, if a double bond (between C-16 and C-17) is present instead of the hydroxymethylene group, activity also decreases (compounds **1** and **2**). Other positions in the kaurane skeleton seem to be less important in relation to activity, such as those compounds that present an angelate at C-15 or a sugar at C-19. The presence of angelate at C-15 only changes the activity from slightly stimulatory to inhibitory at the lowest concentration (compound **2** vs. compound **1**).

Although diterpenoids are not usually reported as phytotoxic agents, in this case, the most active compound is the glycosylated diterpenoid **4**. The ecological role of these compounds has been associated more with antifeedant, insecticidal, and deterrent activity. Moreover, diterpenoids as giberrellins act as important plant hormones involved in growth regulation (Macías et al. 2007). In contrast, the glycosidic form of active natural products is less active than the aglycones (Macías et al. 2005). Unfortunately, the lack of sufficient quantities of compound did not allow us to hydrolyze it and to bioassay the aglycone to compare their activities.

These results suggest that compound **4** should be involved in defense mechanisms of *H. annuus*. The shown activity indicates that its role may be related with the allelopathic behavior shown by this species.

Solid-Phase Microextraction Method For In Vivo Measurement of Allelochemical Uptake

Rebecca X. Loi · Marissa C. Solar · Jeffrey D. Weidenhamer

Received: 13 August 2007 / Revised: 5 November 2007 / Accepted: 8 November 2007 / Published online: 13 December 2007

Abstract Solid-phase microextraction (SPME) was used to measure allelochemical uptake by tomato plants in vivo. Exogenously applied 1,8-cineole was rapidly taken up by tomato, with the first traces of cineole being detected in the tomato stem just 1–2 h after a single application of 0.5 mM cineole to soil. The pulse of cineole persisted in the tomato stem for 72 h. When cineole concentrations were measured 24 h after a single application, trace amounts of cineole could be detected in tomato stem fluid at application concentrations as low as 50 μM. Tomato was also found to take up camphor, menthol, and coumarin, but not carveol. In preliminary tests with common ragweed (*Artemisia annuifolia* L.) and purslane (*Portulaca oleraceae* L.) plants growing in garden beds, both ragweed and purslane took up 1,8-cineole, and purslane also took up camphor. The quantitation of allelochemical uptake by plants is considered to be a crucial test of hypotheses of allelopathic effects, but demonstration of allelochemical uptake has had to be inferred based on observed toxicity due to the lack of methods to measure uptake in vivo. This new technique now provides a means of tracking compounds within target plants. Furthermore, the demonstrated rapid uptake of 1,8-cineole by plants suggests a potential mechanism whereby brief pulses of allelochemicals over an extended period of time might be able to exert an allelopathic effect on plants.

Introduction

One of the methodological barriers to the study of allelopathy is the lack of techniques to measure the uptake of allelochemicals by target plants. Fuerst and Putnam (1983) asserted that quantification of the amount of toxin released to the environment and taken up by the target plant was crucial to proving a hypothesis of allelopathy. The focus of most investigations has been measurement of allelochemical concentrations in soil by various approaches (Tang and Young 1982; Ponder and Tadros 1985; Dalton et al. 1987; Gallet and Pellissier 1997; Weidenhamer 2005; Blair et al. 2006). Uptake of allelochemicals is typically inferred based on observed toxic effects (e.g., Bais et al. 2003). Because radiolabeled analogs of plant natural products are generally unavailable, studies of allelochemical uptake with the radiotracer techniques commonly employed to monitor herbicide translocation (e.g., Kalnay and Glenn 2000; Chun et al. 2001; Shoup and Al-Khatib 2005) are not feasible.

Arthur and Pawliszyn (1990) introduced solid-phase microextraction (SPME) as a nondestructive, solvent-free sampling technique that is now widely used to monitor volatiles in headspace (Deng et al. 2004a, b; Custódio et al. 2006) and trace organics in aqueous solutions (Boussahel et al. 2002), and it has numerous other applications. Recently, Lord et al. (2004) demonstrated the use of SPME to monitor herbicide levels in living plant tissues. Triazine herbicides were applied to soil and then detected in tomato plants by placement of an SPME fiber directly inside the plant stem. Provided that allelochemicals are translocated into target plants rather than exerting their toxic effects at the root surface or by other means, in vivo SPME could be a tool to monitor the uptake of suspected allelopathic agents by target plants. The objective of this study was to test the

applicability of this method by using tomato plants and several candidate allelochemicals.

Methods and Materials

Chemicals and Supplies (1*R*)-(+)-Camphor (99%), carveol (97%), and 1,8-cineole (99%) were obtained from Aldrich Chemical (Milwaukee, WI, USA). Coumarin (reagent grade) was purchased from Eastman Chemical (Rochester, NY, USA). Menthol (USP grade) was purchased from Mallinckrodt Chemicals (St. Louis, MO, USA). SPME fiber assemblies and holders were obtained from Supelco (Bellefonte, PA, USA). The fibers chosen were coated with a 100-μm layer of polydimethylsiloxane (PDMS).

Plants and Treatment Tomato (*Lycopersicon esculentum* L. cv. "Big Boy") plants were obtained from a local garden store and transplanted into large styrofoam cups that contained a 50:50 mix of sand and potting soil. Common ragweed (*Artemisia annuifolia* L.) and purslane (*Portulaca oleraceae* L.) plants were growing in flower beds as weeds. Allelochemical solutions were applied in aqueous solution. Concentrations of cineole ranged from 0.05 to 0.5 mM. Other compounds were applied at a concentration of 0.5 mM. The volume of solution application was 40 ml with tomato plants and 300 ml for common ragweed and purslane. All analyses of tomato plants were based on duplicate sampling of two identically treated plants, and plants were not reused. Preliminary measurements with common ragweed and purslane were made on single plants.

Sampling Method The SPME sampling method was modeled after that of Lord et al. (2004). Plants were sampled at a stem height of 6.0 cm above the soil, except for the study of concentration with sampling height, in which tomato plants were sampled at heights ranging up to 30 cm. One to 72 h after treatment application, a SPME fiber was inserted into the stem of the test plant. The SPME fiber was preconditioned in phosphate-buffered saline (PBS) for 30 min. The retracted fiber (without spring and unattached to the SPME fiber holder) was then placed into a small 1.5-cm hole, which was made in the stem with a 22-gauge needle and filled with PBS. The outer protective needle was carefully retracted while holding the fiber support wire in place, so that the fiber was exposed to the stem fluid. The SPME fiber assembly was supported during the sampling process (either by leaning against a metal spatula inserted into the soil for the 6-cm sampling point, or by using a loop of masking tape at higher points) so that no stress was put on the fiber. The fiber was equilibrated in the stem for 1 h. It was removed by reversing these steps. The fiber was rinsed with distilled water and then installed into an SPME holder for immediate GC-MS analysis. With care, it was possible to reuse fibers 10 or more times.

Quantitation Cineole was quantified by comparison to direct injections of cineole standard solutions (linear over a range of 1 ng–1 μg; r^2=0.999) and by comparison to static 1-h extractions of cineole solutions in PBS buffer (linear over a range of 0.25–60 μM, r^2=0.978). Stem fluid concentrations were estimated by comparison to the static PBS buffer calibrations.

Chromatographic Methods Samples were analyzed on an Agilent 6890 gas chromatograph equipped with a model 5975 quadrupole mass spectrometer. An HP-5MS column (30 m, 0.25 mm ID×0.25 μm film thickness) was used for separation. SPME fibers were desorbed manually at 250°C for 2 min in splitless injection mode. All injections of liquid standards were made in splitless mode. Two basic temperature gradients were used. With tomato, optimal separation was achieved by holding column temperature at 50°C for 2 min, then increasing at 10°C min^{-1} to 110°C. For preliminary investigations with common ragweed and purslane, column temperature was held at 50°C for 2 min, then increased at 25°C min^{-1} to 200°C. Compound identities were confirmed with the National Institute of Standards and Technology (NIST) Mass Spectral Search Program (Washington, DC, USA).

Results

Cineole was taken up rapidly by tomato plants (Fig. 1). Just 1–2 h after a single application of 0.5 mM cineole to soil, the first traces of cineole were detected in the tomato stem. Cineole concentrations in the stem increased up to 12 h

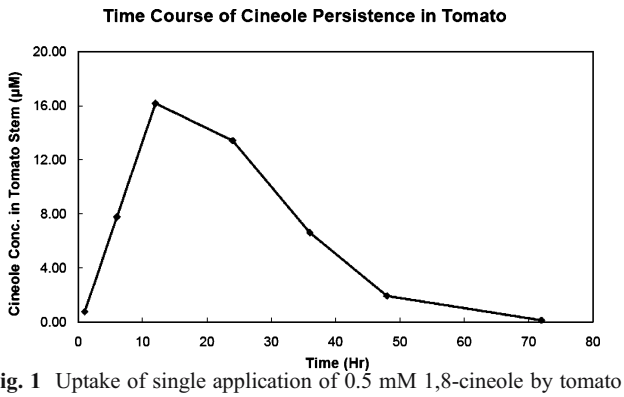

Fig. 1 Uptake of single application of 0.5 mM 1,8-cineole by tomato plants, measured by SPME of stem fluid. Concentration of cineole in stem fluid was estimated by comparison to SPME calibration in PBS solution. Values are the average of separate measurements on two plants

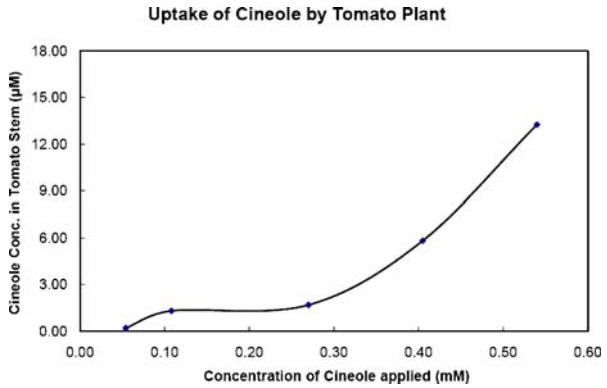

Fig. 2 Uptake of a single application of 1,8-cineole by tomato plants as a function of cineole concentration. Values are the average of separate measurements on two plants

after the initial application, and slowly declined until only a trace amount was detected at 72 h.

When cineole concentrations were measured 24 h after a single application, trace amounts could be detected in tomato stem fluid at application concentrations as low as 50 µM (=0.05 mM, Fig. 2). Concentrations in stem fluid increased with application concentration. Cineole concentrations in tomato stem decreased linearly with sampling height (Fig. 3). Cineole could still be detected in very low concentrations to a height of 30 cm above the soil surface.

Applications of other compounds (0.5 mM solutions except for carveol, which was applied at 0.6 mM) gave variable results. Camphor and menthol, but not carveol, were detected in tomato. Coumarin was also detected after application to tomato, but only after 72 h. 1,8-Cineole was detected following application to both ragweed and purslane. Camphor was detected following application to purslane, but not ragweed. Coumarin, menthol, and carveol were not detected following application to ragweed and purslane.

Chromatograms of cineole-treated tomato and common ragweed are presented in Fig. 4a and b, respectively. Cineole and other exogenously supplied monoterpenes were not detected in control plants. However, several additional monoterpenes and other tentative compounds were detected in stem fluid of control and treated plants. Compounds identified on the basis of their mass spectral NIST library matches in tomato included *p*-mentha-1,4(8)-diene, α-phellandrene, β-phellandrene, and methyl salicylate. In common ragweed, compounds identified included β-myrcene, limonene, and ocimene. Several sesquiterpenes were also detected (data not shown).

Discussion

Analytical Methodology Methyl salicylate and other plant volatiles play important roles in signaling by herbivore-damaged plants that attract herbivore parasitoids (Turlings et al. 1990; Demoraes et al. 1998) and by pathogen-infected plants that induce pathogen resistance in other plants (Shulaev et al. 1997). Therefore, a number of methods have been developed for the analysis of monoterpenes and other plant volatiles. These have included in-plant as well as headspace analyses. Deng et al. (2004a) analyzed methyl salicylate and other volatiles in tomato leaves by HS-SPME/GC-MS after tomato leaves were ground in liquid nitrogen. The analysis required 2.0 g fresh weight of tissue. Deng et al. (2005) removed 1.2-cm-diameter pieces of leaves, placed them in a GC injection liner, and thermally desorbed volatiles directly into GC-MS. The analytical method reported here is a novel approach to measuring compounds *in planta*. Our results demonstrate for the first time the possibility of quantifying the amount of at least some allelochemicals taken up by target plants, a crucial test for hypotheses of allelopathy. The size of current SPME fibers will prevent in vivo sampling of most leaves. Thus, techniques such as those used by Deng et al. (2004a, 2005) may be useful complements to in vivo sampling of stems or for analysis of plants where plant structure does not permit direct insertion of an SPME fiber. We also note that one potential limitation of this method is that it requires that allelochemicals be translocated into target plants. It is conceivable that some compounds may exert their toxic effects at the root surface or within the root (e.g., Bais et al. 2003) and not be translocated to the upper part of the plant. In such cases, other analytical techniques will be needed.

The presence and relative amounts of native mono- and sesquiterpenes and other compounds detected in stem fluid (Fig. 4) varied among tested plants. In particular, methyl salicylate was sporadically found in tomato stem fluid, and levels of methyl salicylate did not change in response to

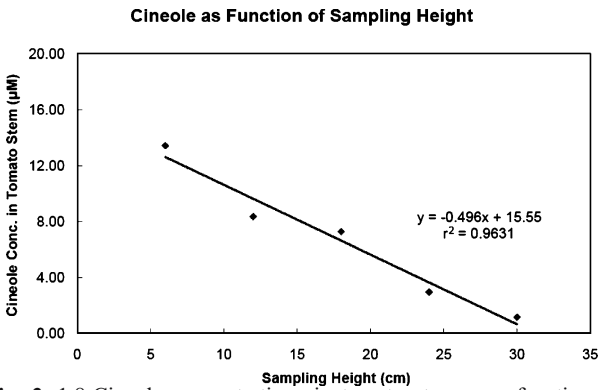

Fig. 3 1,8-Cineole concentrations in tomato stem as a function of sampling height. Samples were taken 24 h after a single application of 0.5 mM cineole to soil. Values are the average of separate measurements on two plants

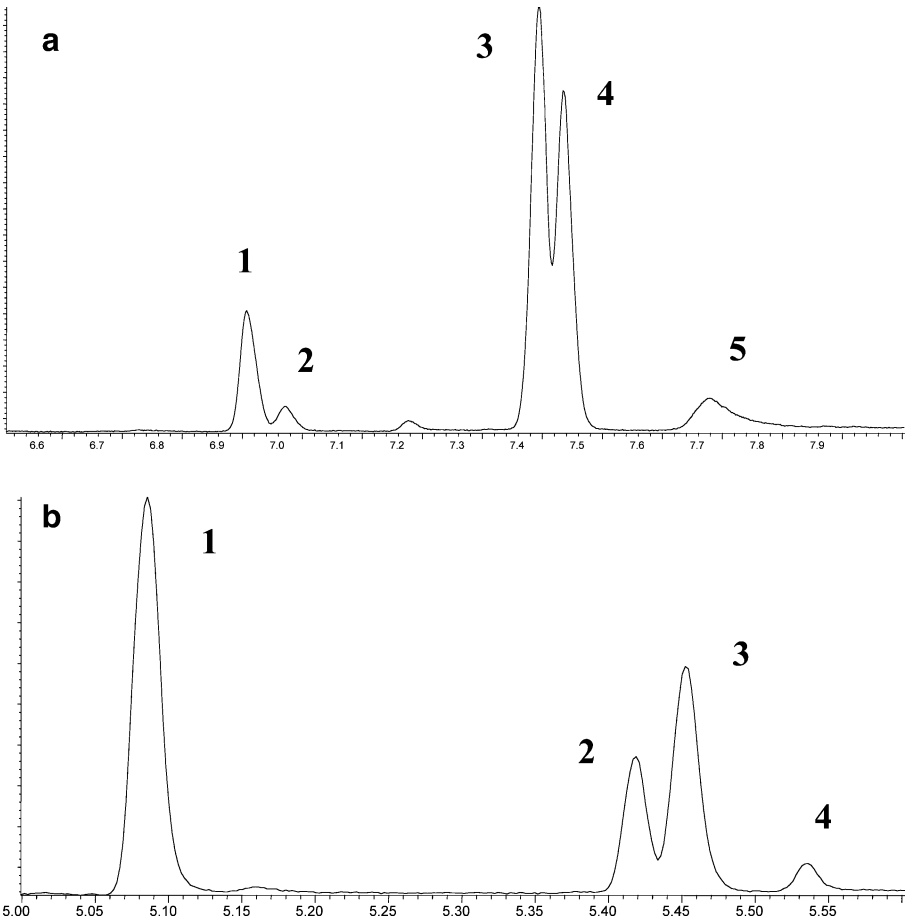

Fig. 4 **A** In vivo SPME total ion chromatogram of tomato stem from cineole-treated plant. Compounds identified by their mass spectra are: *1* β-myrcene, *2* limonene, *3* 1,8-cineole, and *4* ocimene. Chromatographic conditions are described in Methods and Materials

exogenous monoterpene application. However, our results suggest that in vivo SPME may be a useful tool for the study of these compounds within plants.

The 1-h equilibration time used in this study was based on the results of Lord et al. (2004), who also used a 1-h equilibration time. They found that two of three triazine herbicides tested did not equilibrate within 3 h, but that the slope of the extraction profile was not steep. Given the dynamic nature of cineole concentrations, a 1-h sampling time was chosen for this study. Quantitation of stem extracellular fluid concentrations by external calibration with static PBS buffer extraction is probably not valid given the difficulty of preparing a buffer that matches the composition of extracellular fluid (Lord et al. 2004). The results obtained should, thus, be regarded as semiquantitative, but they do provide useful information on the relative amounts of monoterpenes taken up by plants over time. A possible approach to quantitation that could overcome these issues would be to use the newly developed kinetic calibration method in which a standard is preloaded on the SPME fiber and the concentrations of analyte are estimated based on the isotropy of absorption of analyte and desorption of standard (Musteata et al. 2007).

Monoterpenes and Allelopathy Monoterpenes have been implicated in allelopathic interactions in a number of systems. Muller et al. (1964) and Muller (1965) identified several monoterpenes, including 1,8-cineole and camphor, from the California chaparral shrub *Salvia leucophylla* and provided evidence for their role in maintaining bare zones around these shrubs. In the Florida scrub, several fire-sensitive shrubs have allelopathic activity against grasses and herbs that would provide fuel for fires if they were not excluded from the scrub. In two species, oxygenated monoterpenes have been identified as the presumed allelopathic agents. A mixture of compounds including 1,8-cineole, camphor, borneol, mytenal, and several other oxygenated monoterpenes was identified in leaf washes of *Conradina canescens* (Williamson et al. 1989), while derivatives of menthofuran were identified as potential allelopathic compounds from *Calamintha ashei* (Tanrisever et al. 1988; Weidenhamer et al. 1994). In conifer forests, there is experimental evidence that monoterpenes, probably from roots, may play a role in reducing nitrogen mineralization and nitrification (White 1991, 1994; Paavolainen et al. 1998). Recently, Barney et al. (2005) presented evidence that the invasive characteristics of mugwort

(*Artemisia vulgaris*), which can form dense, monospecific stands, can be attributed in part to allelopathic effects derived from a mixture of monoterpenes that include 1,8-cineole and camphor.

Numerous studies have shown that monoterpenes are potent toxins and exert a number of toxic effects on plant cells and seedlings (Vaughn and Spencer 1993; Weidenhamer et al. 1993; Peñuelas et al. 1996; Koitabashi et al. 1997; Abrahim et al. 2000; Romagni et al. 2000). Nishida et al. (2005) found that the volatile monoterpenes of *S. leucophylla*, including camphor and 1,8-cineole, inhibited germination and growth of *Brassica campestris* and decreased cell proliferation in the root apical meristem. Zunino and Zygadlo (2005) showed that monoterpenes, including camphor and 1,8-cineole, affected the phospholipid fatty acid and sterol composition of maize root. These changes in membrane lipids could interfere with seedling growth.

One of the questions about the plausibility of allelopathic mechanisms that involve monoterpenes, as with other proposed allelopathic compounds, is their generally short persistence in the environment. The results of this study that show rapid uptake of 1,8-cineole and camphor by plants suggests a potential mechanism whereby brief pulses of allelochemicals over an extended period of time might be able to exert an allelopathic effect on plants. The mechanism by which certain compounds are taken up by plants, while others with similar functional groups (e.g., carveol) are not, is in need of further study, as is the extent to which monoterpenes are taken up by other species. It is interesting to note that with two of the monoterpenes most widely implicated in allelopathic interactions, 1,8-cineole and camphor, 1,8-cineole was taken up by all three species tested and camphor by two of the three species tested.

Abstract Upon attack by predators or parasitoids, aphids emit volatile chemical alarm signals that warn other aphids of a potential risk of predation. Release rate of the major constituent of the alarm pheromone in pea aphids (*Acyrthosiphon pisum*), (*E*)-ß-farnesene (EBF), was measured for all nymphal and the adult stage as aphids were attacked individually by lacewing (*Chrysoperla carnae*) larvae. Volatilization of EBF from aphids under attack was quantified continuously for 60 min at 2-min intervals with a rapid gas chromatography technique (zNose™) to monitor headspace emissions. After an initial burst, EBF volatilization declined exponentially, and detectable amounts were still present after 30 min in most cases. Total emission of EBF averaged 16.33±1.54 ng and ranged from 1.18 to 48.85 ng. Emission was higher in nymphs as compared to adults. No differences between pea aphid life stages were detected for their speed of alarm signal emission in response to lacewing larvae attack. This is the first time that alarm pheromone emission from single aphids has been reported.

Introduction

Insects possess a wide range of chemical defenses that aid in protection against predation. Aphids are soft-bodied insects and are especially prone to attack by predators and parasitoids (Dixon 1998). Whereas aphids have means of protection against natural enemies through physical adaptations such as wax production (Smith 1999) and sclerotization among soldier forms of social aphids (Wool 2004), their primary protection from predators and parasitoids consists of escape responses mediated by the use of alarm pheromone signaling (Pickett et al. 1992; Dixon 1998). Aphids emit alarm pheromone by secreting a droplet of liquid from the ends of the siphunculi that contain chemical compounds. These compounds volatilize from the surface of the cornicle droplet and induce defense-related behavioral changes in conspecifics. Specifically, when aphids secrete a cornicle droplet in response to an attack by a predator or parasitoid, or in response to an artificial probe to simulate an attack, nearby aphids move away from the area and will often drop from their host plants (Losey and Denno 1998a; Braendle and Weisser 2001). Aphids have also been shown to mark predators with alarm pheromone by daubing them with cornicle droplets. This acts as a traveling signal, causing

aphids to disperse in response to an approaching predator (Mondor and Roitberg 2004). Recent results suggest that groups of aphids exposed to synthetic (*E*)-ß-farnesene (EBF), the main component of aphid alarm pheromone, (Bowers et al. 1972; Pickett and Griffiths 1980; Francis et al. 2005a), will be more likely to produce winged offspring (Kunert et al. 2005; Podjasek et al. 2005).

In addition to inducing defense-related behavioral changes in conspecifics, aphid alarm pheromone also induces behavioral changes in the predators and parasitoids that exploit them, acting as a kairomone used to home in on their aphid prey (Nakumuta 1991; Boo et al. 1998; Powell and Pickett 2003; Francis et al. 2004; Francis et al. 2005b).

Although the alarm pheromone, EBF, is used by many aphids of the family Aphididae, some species are more responsive to alarm pheromone than others (Losey and Denno 1998b), with variation in response to an alarm signal even among different clonal lines of the same species (Muller 1983; Braendle and Weisser 2001). In the pea aphid, *Acyrthosiphon pisum*, there is little variation in the amount of EBF emitted from different clonal lines in response to predation (Schwartzberg et al., unpublished); however, it has been shown that the concentration of EBF within cornicle droplets and the propensity to produce a cornicle droplet in response to an attack varies among instars (Mondor et al. 2000).

A number of studies have attempted to quantify the amounts of alarm pheromone produced by single aphids. Mondor et al. (2000) measured the EBF content within cornicle secretions of aphids disturbed by using a blunt probe. Schwartzberg et al. (unpublished) measured EBF in the headspace of aphid colonies attacked by predators, and the amount of EBF released by crushed aphids was measured by Francis et al. (2004) and Byers (2005). So far, however, no study has taken into consideration how natural predation may affect EBF emission from individual aphids, and how this may differ among aphid instars. Because the emission of EBF from a cornicle droplet is likely to be influenced by (1) the size and surface area of the cornicle droplet produced, (2) whether it is secreted as a single event, or continuously over a period of time, and (3) the concentration of EBF within the droplet, measuring the actual emission from single aphids is a much more direct and accurate method for comparing alarm signal among instars.

In this paper, we use a zNose™ (Electronic Sensor Technology, Newbury Park, CA, USA), which is an instrument for rapid gas chromatography that is capable of repeated quantitative sampling of headspace volatiles (Kunert et al. 2002; Tholl et al. 2006) to ask the following questions: (1) What is the temporal pattern of EBF volatization after attack by a predator? (2) Is there a time-lag between attack by the predator and EBF emission? (3) Do different instars differ in the amount of EBF emitted?

Materials and Methods

Pea aphids, *Acyrthosiphon pisum* (Hemiptera: Aphididae), used for alarm pheromone quantification were obtained from a naturally occurring pink pea aphid colony, "Jena Pink 1" (JP1), and were reared on 2-week-old dwarf broad bean plants, *Vicia faba* L. (The Sutton; Nickerson-Zwaan, UK) in 10-cm plastic pots with 16 h light: 8 h dark, 20°C, 75% relative humidity. Lacewing larvae, *Chrysoperla carnea* (Neuroptera: Chrysopidae), were obtained from a commercial supplier (Katz Biotech Services, Welzheim, Germany), and larvae were maintained on bean plants infested with pea aphids until they reached the second instar.

Aphid alarm pheromone emission was monitored from members of all instars, including the adult stage, by using a zNose™. Air was sampled from individual aphids and lacewing larvae within air entrainment vials (Fig. 1). The stainless steel inlet needle of the zNose™ was inserted through a small hole in the septum of a 4-ml glass vial. A clean air inlet was created by inserting a hypodermic syringe tip into the septum adjacent to the zNose™ inlet needle.

The zNose™ was programmed to sample air within the vial every 2 min with a flow rate of 30 ml min^{-1} for 20 s, drawing a total of 10 ml of air through the preconcentration trap during each 20 s sampling period. This quantity of air allowed the entrainment vial to be purged of most airborne volatiles prior to subsequent samples. The air was sampled repeatedly from the entrainment vial every 2 min for the duration of the bioassay.

For each replicate, a single aphid was introduced into a clean vial immediately after a baseline air entrainment. Once the aphid headspace was sampled, one second instar lacewing was introduced into the chamber with the aphid. Lacewing larvae did not attack aphids immediately so we were able to collect headspace volatile samples from aphid and lacewing larva before attack. Air within the vial was collected every 2 min from the introduction of the lacewing larva until 60 min after the beginning of lacewing attack (determined visually). Lacewing larvae feed by piercing their mouthparts into the soft bodies of their prey. The exoskeletons of prey are not consumed, and remain present even after feeding has finished. Therefore, it was not possible to discern exactly when the lacewing had stopped feeding. Because aphid alarm pheromone signals can exist beyond the life of an emitting aphid, the alarm signal was recorded even after the interior of the aphid was apparently fully consumed and the aphid was dead. We determined in preliminary tests that 60 min was a sufficient time period to measure all of the emitted alarm pheromone from an attacked aphid.

Air drawn from vials was collected on a Tenax™ absorbent trap during sampling. Trapped compounds were desorbed from the Tenax™ trap (300°C for 30 ms) and carried by helium (flow rate 3 ml min^{-1}) onto a GC column

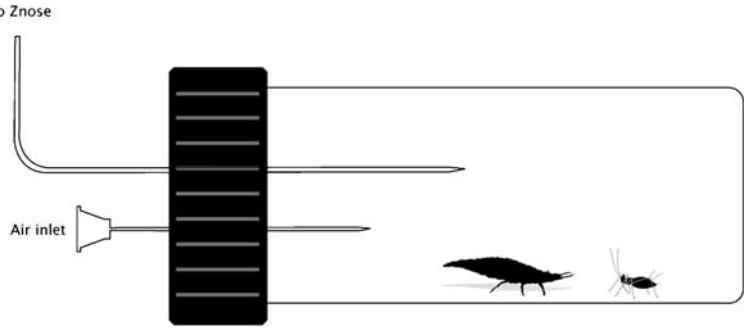

Fig. 1 Air entrainment setup showing 4 ml vial with inserted ZNose™ sampling needle and air inlet needle

(1 m, DB-5, film thickness 0.25 μm, ID 0.25 mm), which was programmed from 40 to 180°C at 5°C s^{-1}. As compounds exited the column, they were quantified as they pass over a temperature-controlled sensitive surface acoustic wave (SAW) quartz microbalance detector set at 40°C. The resonance frequency [Hz] of the SAW detector changes in a linear fashion as compounds from the column are attached to and heated off of the quartz detector. For quantification purposes, response factors were calculated by comparison with synthetic EBF (Bedoukian, Danbury, CT, USA) exposed to the zNose™ in known concentrations by using a heated desorber tube (glass, temperature controlled; 190°C; 3100 Vapor Calibrator; Electronic Sensor Technology, Newbury Park, CA, USA).

Alarm pheromone emission was quantified for nymphal stages L1 to L4 and for adult aphids (N=10 for each instar). The following variables were calculated from the data and used for the analysis: (1) total emission (calculated as the sum of all recordings after attack), (2) peak emission (the highest reading after attack), and (3) the lag time between initial attack and maximum emission (calculated as the time of attack subtracted from the time of maximum emission).

Because data were not normally distributed, we used a Kruskal–Wallis test for among-instar statistical comparisons.

Results

(*E*)-ß-farnesene was identified based on retention time comparison to a synthetic standard. There was only one peak detected in samples from JP1-aphids, and this peak was not present in control samples without aphids. Previous collections of volatiles from entire JP1-aphid colonies and analysis by GC-MS identified this peak as EBF (Schwarzberg et al., unpublished). The calibration curve for the SAW detector response to EBF was linear (y=0.230+0.000255x; y=ng of EBF, x=SAW detector response in hertz).

EBF volatization after an attack showed a typical pattern: after an initial burst it declined exponentially (Fig. 2). For the 46 cases where emission continued for more than 30 min,

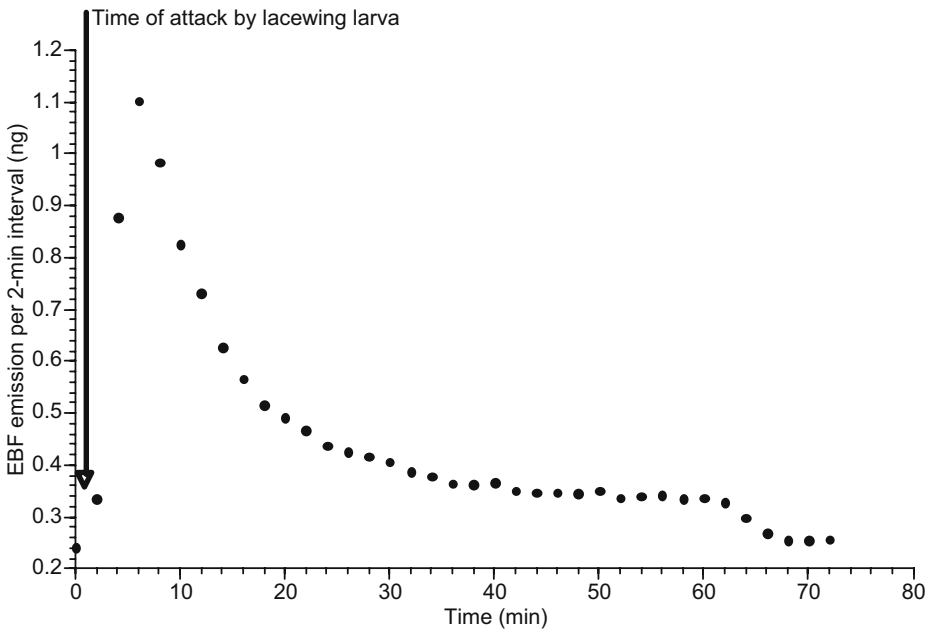

Fig. 2 Typical time course of (*E*)-ß-farnesene emission in the experiment. This example is from a first instar aphid (L1) attacked by a lacewing larva

amounts of over 0.3 ng per 2 min interval were measured in 30 replicates.

Total EBF emission over the entire 60 min collection period averaged 16.33±1.54 ng and ranged from 1.18 and 48.85 ng. Emission was different between first and second instar nymphs (L1 and L2) as compared to adults (χ^2= 13.34, *df*=4, *P*=0.01) with adult aphids emitting the least amount of EBF over the entire collection period (Fig. 3).

Peak EBF emission, measured as the maximum EBF emission for a 2 min interval within the total 60 min sampling period, had a mean of 1.98±0.32 ng per 2 min and ranged from 0.12 to 16.26 ng per 2 min. Mean peak emission varied among instars (χ^2=14.34, *df*=4, *P*=0.006, Fig. 4). While there was no significant difference in peak EBF emission among instars, adult peak emission was significantly lower.

The time lag between onset of attack by a lacewing larva and peak EBF emission was calculated to determine if different instars vary in their speed of alarm signal production. It is interesting to note that mean lag time was 10.7± 1.7 min and ranged from 2 to 50 min (*N*=48). Even if outliers (time-lag>13 min) were excluded, the mean was still 5.1± 0.4 min (*N*=36). Inspection of the 12 values with a time lag of 14 or more minutes revealed that in 10 cases (one for L1, five for L3, one for L4, and two for adults) there was no real burst of emission but rather a slow build up, associated with a low maximum emission value. In the other two cases (one L1, one L4), the observational determination of time of attack may have been wrong or there was a second burst of emission, possibly associated with a second attack by the predator. As a consequence of the variability, there was no statistical difference among instars (χ^2=3.98, *df*=4, *P*=0.409, Kruskal–Wallis, Fig. 5).

Discussion

All life stages of pea aphids can be stimulated to produce a cornicle droplet when prodded, but adults do so less consistently (Mondor et al. 2000). This was also reflected in our results that show both total EBF emission and peak emission were lower in adults than in the younger instars. In addition to the differences among instars, our analysis showed that variability of EBF emission within instars was high and that detectable amounts of alarm pheromone were still present in the headspace of aphids for a considerable time after the initiation of attack.

The zNose™ was able to illustrate the temporal patterns of alarm pheromone emission from individual aphids. In addition to total emission over a 60-min time period, we were

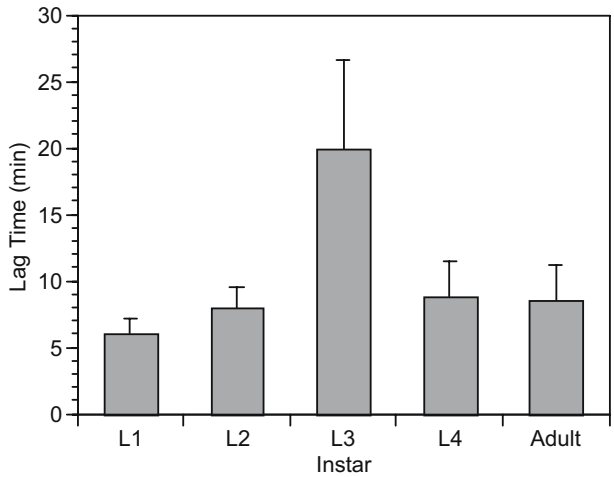

Fig. 5 Lag time between initial attack by lacewing larvae and peak emission of (*E*)-ß-farnesene in minutes±SE. There was no statistical difference in lag time among instars; *P*>0.05, Kruskal–Wallis test, *N*=10

able to record the initial peak of alarm signal production and latency of the alarm signal at 2 min intervals. The initial burst of alarm pheromone emission was relatively consistent among nymphal instars, but much lower in adults. The initial burst of alarm signal production is likely the most important, because aphids react within the first few seconds of perceiving the signal. Nevertheless, there was variability in peak emission from less than 1 ng up to 16 ng emitted in a single 2-min interval. Whereas we were able to determine visually when a lacewing larva grabbed an aphid, it was not possible to visually rate the strength of the attack and the time when the aphid died. The variability in peak emission may, therefore, reflect both the strength of initial attack and individual variability in cornicle secretion.

Aphid predators differ greatly in their handling time of prey, depending on their mode of feeding and the relative size of the predator compared to the prey. While we were not able to determine exactly the feeding time of the lacewing larvae in the vials, results from a separate experiment showed that feeding time of similar-sized lacewing larvae was 35.6± 4.8 min min after attack for adult pea aphids (N=12 larvae; Weisser, unpublished). In contrast, adult ladybirds consume an adult pea aphid within a few seconds. Handling times of ladybird larvae or hoverfly larvae are likely to be intermediate. Although most of the EBF that aphids produced during a lacewing larva attack volatilized during the first 15 min in our closed system, they continued to emit measurable quantities for 60 min. It is not known how EBF is synthesized, stored, and released by aphids during predation events, and it is possible that the larvae continually replenished their cornicle droplets while they were still not entirely eaten. Whereas our collection method was limited to a confined space with limited natural airflow in contrast to an open, natural system, where air currents may result in a faster rate of volatile emission from cornicle droplets, we believe that the EBF volatilization dynamics observed reflect natural dynamics. In experiments with adult ladybirds, a single flush of air after predation was in almost all cases enough to capture the entire EBF released (Hatano, personal communication). Regardless of whether natural dynamics may be slightly different, our design allowed for nonbiased comparison of signal strength and duration between nymphal and adult instars. It is interesting to note that these two temporally different signals were quantitatively similar among all nymphal instars.

Our results are consistent with those of other studies that attempt to measure alarm pheromone production from multiple life stages of aphids (Mondor et al. 2000; Byers 2005). In an elegant study, Mondor et al. (2000) determined the amounts of EBF in cornicle droplets after manual stimulation. Second to fourth instars contained on average between 11 and 13 ng, about five times higher than average peak emission in our study and slightly less than the 16 to 21 ng we found to be released over 60 min. In adults, Mondor et al. (2000) found on average 3–4 ng EBF in a cornicle droplet, about half of what we measured over the 60-min period, whereas EBF in adult cornicle droplets measured by Mondor et al. (2000) was four times as high as the mean peak emission in our study. The major difference between our and Mondor et al. (2000) results was for first instars, which emitted about 2 ng in their study, in contrast to 17 ng in ours. It is interesting to note that the 2 ng corresponded to what we measured as peak emission in our study. As mentioned above, it is conceivable that as the predator continues to feed on the aphid more EBF is released, either from a reservoir or by de novo synthesis, which would explain the higher amounts detected in summed headspace collections in our study. However, one thing to consider is that different predators feed differently, and this may have an effect on the duration and strength of the signal. For instance, a larger predator that completely consumes its prey may effectively quench the alarm signal of an aphid by consuming it.

Production of alarm pheromone, although altruistic in principle, is thought to be adaptive among groups of closely related individuals such as clones within aphid colonies because it allows related individuals to disperse and avoid predation or parasitization. However, alarm pheromone production comes at a cost (Mondor and Roitberg 2003; Byers 2005). This cost can be in terms of reproduction (Mondor and Roitberg 2003) or through the attraction of natural enemies (e.g., Francis et al. 2005a). Little is known about the emission dynamics of EBF in aphid colonies and how aphids may adjust alarm pheromone release to the actual ecological situation. An understanding of the temporal dynamics of EBF is necessary to further elucidate the role of aphid alarm pheromone in aphid–natural enemy interactions.

An Antiaphrodisiac in *Heliconius melpomene* Butterflies

Stefan Schulz · Catalina Estrada · Selma Yildizhan · Michael Boppré · Lawrence E. Gilbert

Received: 2 March 2007 / Revised: 19 September 2007 / Accepted: 19 September 2007 / Published online: 12 December 2007

Abstract Gilbert (1976) suggested that male-contributed odors of mated females of *Heliconius erato* could enforce monogamy. We investigated the pheromone system of a relative, *Heliconius melpomene*, using chemical analysis, behavioral experiments, and feeding experiments with labeled biosynthetic pheromone precursors. The abdominal scent glands of males contained a complex odor bouquet, consisting of the volatile compound (*E*)-β-ocimene together with some trace components and a less volatile matrix made up predominately of esters of common C_{16}- and C_{18}-fatty acids with the alcohols ethanol, 2-propanol, 1-butanol, isobutanol, 1-hexanol, and (*Z*)-3-hexenol. This bouquet is formed during the first days after eclosion, and transferred during copulation to the females. Virgin female scent glands do not contain these compounds. The transfer of ocimene and the esters was shown by analysis of butterflies of both sexes before and after copulation. Additional proof was obtained by males fed with labeled D-$^{13}C_6$– glucose. They produced ^{13}C-labeled ocimene and transferred it to females during copulation. Behavioral tests with ocimene applied to unmated females showed its repellency to males. The esters did not show such activity, but they moderated the evaporation rate of ocimene. Our investigation showed that β-ocimene is an antiaphrodisiac pheromone of *H. melpomene*.

Introduction

Male insects may use morphological, behavioral, or physiological adaptations that reduce the probability of female remating (Simmons 2001; Wedell 2005). One of these adaptations consists of male pheromones, transferred during mating, that make mated females repellent to subsequent males (Happ 1969; Gilbert 1976; Kukuk 1985; Andersson et al. 2000). These pheromones, known as antiaphrodisiacs (Happ 1969), confer direct selective advantage for the donor male by reducing sperm competition. However, there are also indirect advantages for other males and the females themselves, as courtship behavior and male harassment may result in reduced longevity and increased predation risk (Thornhill and Alcock 1983; Cook et al. 1994; Clutton-Block and Langley 1997; Bateman et al. 2006). Although antiaphrodisiac pheromones have been found in a wide range of insects, such as mealworm beetles, sweat bees, fruit flies, and butterflies (Happ 1969; Gilbert 1976; Kukuk 1985; Scott 1986), the chemical structures have been identified only for few species (Scott 1986; Andersson et al. 2000, 2003).

In butterflies, antiaphrodisiac pheromones were first found in the genus *Heliconius* (Lepidoptera: Nymphalidae). Gilbert (1976) suggested that the strong odor of *H. erato* mated females could inhibit further mating. He concluded

that the odor would repel courting males, as males waiting on female pupae rapidly left when exposed to the abdomen of mated females. All species of *Heliconius* and related genera, when handled, release strong odors that can be detected by humans (Eltringham 1925). These are produced in glands located in the last abdominal segments on both sexes. In females, it is a large yellow gland, which, when extruded, exposes a pair of club-shaped structures that probably serve to distribute the volatiles. Male glands, on the other hand, are located inside the two highly chitinized claspers that grasp the female abdomen during copulation (Eltringham 1925; Emsley 1963; Simonsen 2006).

In addition to their possible role in sexual communication, odors from abdominal glands may serve as warning signals about the toxicity of these butterflies (Eltringham 1925). Fritz Müller described the odors as strong and nauseous, and suggested they are also distasteful to enemies because they are released only after handling the butterflies (Eltringham 1925). The major volatile released from the abdominal scent glands of males and females of the heliconiine *Agraulis vanillae* is 6-methyl-5-hepten-2-one (Ross et al. 2001). The authors proposed that this ketone has a protective function, as it is a known defensive allomone of ants and cockroaches (Tomalsky et al. 1987; Ross et al. 2001). Their conclusions were based on observations of bird predation, but their experiments did not discriminate between protection due to gland constituents and those resulting from the wing warning coloration and toxicity (Nahrstedt and Davis 1983, 1985; Engler-Chaouat and Gilbert 2007). The idea of a male antiaphrodisiac, already reported in pierid butterflies and *Heliconius* (Gilbert 1976; Andersson et al. 2000, 2003), was not discussed by Ross et al. (2001).

Although *Heliconius* butterflies have been extensively studied and their characteristic odors described subjectively more than one century ago, few attempts have been made to elucidate their function and chemical composition (Eltringham 1925; Gilbert 1976; Miyakado et al. 1989; Ross et al. 2001). Here, we report work on the chemical composition of abdominal scent glands of *H. melpomene* and their role as an antiaphrodisiac pheromone. We show that the chemicals from abdominal scent glands are synthesized by the males only, are transferred to the females during copulation, and repel other courting males from mated females.

Methods and Materials

Chemicals Ocimene was prepared according to the method of Matsushita and Negishi (1982), resulting in a 7:3 mixture of (*Z*)- and (*E*)-ocimene. The amount of the (*E*)-isomer was increased to a 4:6 *Z*/*E* ratio by argentation-chromatography with AgNO3-treated silica (Williams and Mander 2001). We were unable to obtain a higher ratio, as no convenient and reproducible synthetic route to pure (*E*)-ocimene currently exists.

The ester mixture was prepared in a combinatorial way by using a mixture of fatty acids (ratios, see Table 1). The acids were converted into their acid chlorides by reaction with oxalyl chloride (Drutu et al. 2001). The acid chloride mixture was treated with an equimolar amount of an alcohol mixture (ratios, see Table 1) according to standard methods (Franklin et al. 2003). This ensured that every acid present in the mixture was esterified with each alcohol, resulting in a mixture of 25 esters. The analysis of the purified reaction product revealed that this ester mixture (hereafter called esters) was similar in composition and relative abundance of each component to the ester bouquet produced by male *H. melpomene*.

Analytical Procedures Chemical analyses were carried out on individual butterflies from a colony of *H. melpomene rosina* held in a greenhouse at Freiburg (Germany). The culture, originating from butterflies collected in Corcovado, Osa Peninsula, Costa Rica, was reared for about five generations with *Passiflora caerulea* as host plant and *Lantana camara* as source of pollen. The butterflies also had access to sucrose solution supplemented with pollen. Additional samples were obtained by a colony of *H. melpomene rosina* held at the University of Texas at Austin, originating from individuals brought from Costa Rica. They were reared in greenhouses at about 32°C and high humidity (>80%). Butterflies had access to *P. oerstedi* (larval host plant), sugar, and honey water, and sources of

Table 1 Relative proportion of acids and alcohols used in the synthesis of the ester mixture used in bioassays

Acid	Percent	Alcohol	Percent

Oleic	68	1-Butanol	18
Linoleic	13	1-Hexanol	52
Linolenic	9	(*Z*)-3-Hexenol	5

This mixture has similar composition and relative abundance to that produced by male *H. melpomene* butterflies.

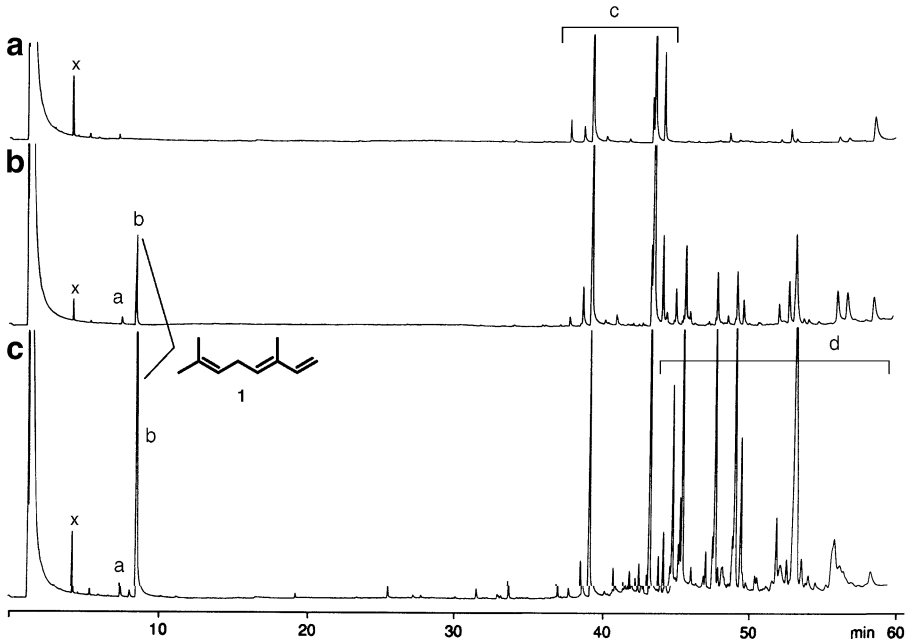

Fig. 1 Gas chromatogram of an extract of the scent glands of virgin females (**a**), mated females (**b**), and males (**c**) of *Heliconius melpomene*. *a*: (*Z*)-β-ocimene, *b*: (*E*)-β-ocimene, *c*: fatty acids, *d*: esters, *x*: internal standard (nonane)

pollen from *Psiguria* sp., *Psychotria poeppigiana* and *L. camara* flowers.

Butterflies were analyzed individually. The extracts were prepared either immediately after emergence from pupae or 5 d later. Some 5-d-old males were allowed to mate, and their glands were analyzed either directly after copulation or 3 d later.

Claspers of males and the last abdominal segment of females were dissected from bodies of freshly killed butterflies and placed individually in vials with approximately 100 µl of pentane. The lower tips of the abdomens were also cut and stored in vials with pentane. Analyses of the latter served to identify compounds found in tissues surrounding scent glands. Samples were kept at −70°C until analyzed.

Gas chromatography and mass spectrometry (GC-MS) of pentane extracts were performed with a Hewlett-Packard model 5973 mass selective detector connected to a Hewlett-Packard model 6890 gas chromatograph with a BPX5-fused silica capillary column (SGE, 30 m×0.25 mm, 0.25-µm film thickness). Injection was performed in splitless mode (250°C injector temperature) with helium as the carrier gas (constant flow of 1 ml/min). The temperature program started at 50°C, was held for 1 min, and then rose to 320°C with a heating rate of 5°C/min. All compounds were identified by comparison of the mass spectra and retention times with those of authentic reference samples in the different compound classes as well as by analysis of mass spectral fragmentation patterns.

The quantification of individual components was difficult because of many overlapping peaks, therefore peak areas of several compound classes were combined, and the sum of this area determined against an internal standard (hecadecanenitril). Results in Table 3 show individual variation of the scent gland composition. These data and results of the analysis of additional individuals were combined to examine the proportion of compounds transferred during copulation (Fig. 3).

Odors released by mated females or females of treatment 3 (see below) were analyzed by using headspace Solid

25 mg of 99% D-$^{13}C_6$-glucose, 5 mg of 99% $^{13}C_2$-sodium acetate, and 10 mg of 4,4,6,6,6-D_5-mevalolactone (Dickschat et al. 2005), all in 5 ml of honey water. Each group of males was enclosed in a 2×2×2 m insectary with access to sugar water and one of the feeding mixtures added to an artificial flower. Males were also fed by gently holding the butterfly and placing drops of solution directly onto the proboscis with a syringe until satiation (ca. 25 μl). This was done daily during 10 d or more, until they mated to a virgin female. After mating, terminal abdominal segments of both sexes containing putative pheromone glands were dissected and analyzed by GC-MS as described in the analytical procedures.

Behavioral Bioassays The experiment were also conducted in greenhouses at the University of Texas at Austin. Abdomens of 1- to 5-d-old virgin females were painted with 2 μl of one of three chemical mixtures: (1) analytical grade hexane used as control; (2) a 1:1 solution of the synthetic ester mixture (Table 1) and hexane (1 mg/individual of ester mixture); and (3) a 0.1:1:1 solution of 6:4 (*E*/*Z*)-β-ocimene, ester mixture, and hexane (100 μg/individual of β-ocimene).

Males, randomly chosen from a population held in a separate greenhouse and never exposed to females, were tested individually for their behavior in the presence of treated virgin females. Only males more than 3 d old were used in the experiments. Each test consisted of two phases. The male was first exposed to a virgin female for 10 min, during which time the number and duration of courtship bouts were recorded. Once the male grasped the female abdomen with his claspers, the couple was immediately separated, and the male was allowed to rest for 10 min. The immediate separation after males initiated copulation assured that there was no transfer of spermatophore or scents from males. The aim of this phase was to verify the sexual receptivity of both butterflies; therefore, only males that succeeded on grasping female abdomens were used in the second phase of the test. In the second phase, the same female was transferred back to the male insectary after applying on the top of her abdomen 2 μl of one of the test solutions. Here, number and duration of courtship bouts were measured for 10 min or until the male grasped the female's abdomen again. A total of 30 test were carried out, 10 for each treatment of virgin females. Females were used once and 4 out of 26 males were used in more than one test. Whenever males were reused, tests were done at least 2 d apart, and different chemical mixtures were used in the experimental phase.

We tested whether the proportion of matings in experiments done with females painted with test mixtures that contained possible repellents was lower than those with control females by using *Fisher's exact test* (Sokal and Rohlf 1969). Mean courtship events and courtship times between the two phases of tests were compared with a nonparametric *Wilcoxon Matched Pairs Test*. We also compared these variables between experiments with females painted either control or test mixtures using nonparametric *Mann–Whitney U Tests* (STATISTICA for Windows 1999).

Results

Chemical Analyses The GC-MS analyses of abdominal gland extracts of males showed a bouquet made up of more than 100 components belonging to different chemical classes (Figs. 1 and 2, Table 2). The extracts of mated

females showed a similar chemical composition, albeit in lower concentrations (Fig. 1, Table 2), whereas those of unmated female glands exhibited a markedly reduced composition (Fig. 1, Table 2). It is clear from the total ion chromatogram (TIC, Fig. 1) that the male blend consisted of early and late eluting parts. The early eluting compounds are made up of several volatile components clustered in the TIC mostly around the major constituent, (*E*)-β-ocimene (**1**). Minor amounts of the terpenes (*Z*)-β-ocimene, allo-ocimene, β-cyclocitral, (*E*,*E*)-α-farnesene, and traces of the alcohols hexanol and (*Z*)-3-hexenol were detected. Additional trace compounds include three pyrazines (e.g., **2**), as well as guaiacol (**3**).

The later eluting (and thus higher boiling) fraction was dominated by a complex ester mixture (Table 2) of common C_{16}- and C_{18}-fatty acids with the alcohols tabulated in Table 1 (**6**–**11**). A range of macrolides derived from a bishomolog series of C_{12}- to C_{20}-acids, oxidized at the ω or ω-1 position, were also present in trace amounts (**4** and **5**). Along with esters, this fraction also contained typical cuticular components of insects as unbranched and methyl-branched alkanes, together with small amounts of 2,5-dialkyltetrahydrofurans (Schulz et al. 1998). The fatty acid content was variable (ranging from major to minor constituents of the bouquet). However, analyses of abdominal samples without the scent glands showed that fatty acids, alkanes, cholesterol, squalene, and dialkyltetrahydrofurans are not specific to the scent glands, so their presence probably reflects more the quality of the sample preparation than the physiological state of an individual. Consequently, we excluded these compounds from the bioassays. The composition of the male scent glands was remarkably similar among individual butterflies raised at the different locations and on different host plants, showing only slight variations in the trace components and the proportions of esters and alkanes.

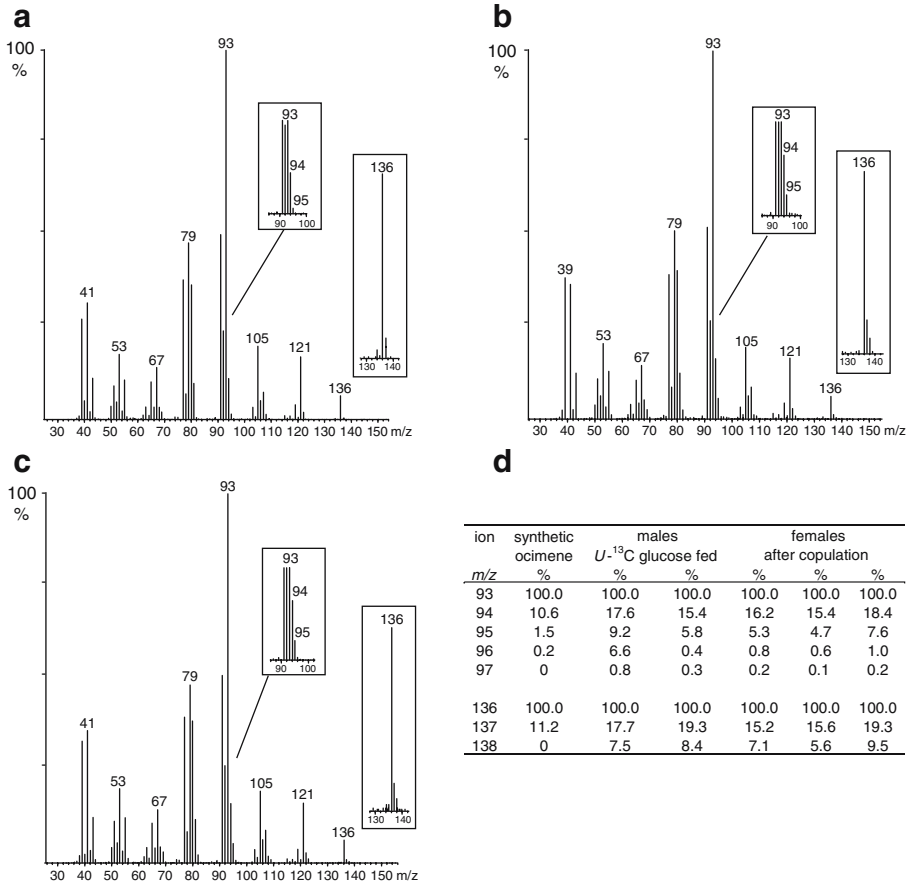
An obvious difference between the two parts of the blend is volatility. The calculated vapor pressure of **1**, the most prominent volatile component, is 1.56 Torr, whereas a major late eluting compound, hexyl octadecenoate, has a value of 4.94×10^{-8} Torr. One of the earliest eluting, and thus more volatile esters, ethyl hexadecanoate, has a value of 7.63×10^{-5} Torr (Scifinder database, ACS 2007). We, therefore, designate the ester part of the mixture as a matrix. Furthermore, because of their vapor pressures, macrolides, alkanes, tetrahydrofuranes, ketones, fatty acids, and cholesterol were all considered to belong to the matrix.

Abdominal glands from individuals of different age were also analyzed (Table 3). Freshly emerged males and females lacked volatile compounds, except for small amounts of guaiacol (**3**) in their scent glands. The only other compounds identified were the common C_{16}- and C_{18}-fatty acids together with hydrocarbons, cholesterol, and squalene, which are not gland-specific compounds. Five days after eclosion, males had developed the whole bouquet of compounds with **1** reaching up to 75 μg/individual. In males, bouquets before and after mating did not change significantly. Unmated females only produced **3**, but had a bouquet similar to that of males after mating. Even 3 d after mating, bouquet components were detectable. A quantitative analysis of a limited number of individual butterflies is found in Table 3. Occurrence of **1** and the esters in individuals of different physiological state is shown in Fig. 3.

Feeding Experiments with Labeled Percursors Deuterated mevalolactone, often incorporated by plants and bacteria into terpenes, was incorporated into **1** in males, but at a low rate (0.5%). ^{13}C-labeled acetate also gave low incorporation into **1**, but proved to be toxic, and surviving males did not mate. The best results were obtained by using uniformly labeled U-^{13}C-glucose. Glucose can be converted by butterflies into doubly labeled acetate via the citric acid cycle. This acetate can enter the mevalonate pathway of terpene synthesis. Together with two additional unlabeled acetate units, present in excess in experimental butterflies, it is transformed into isopentenyl pyrophosphate building blocks that contain one or two ^{13}C-atoms. This labeling pattern is expected because one carbon from the three acetate units is lost during this process, being either a ^{12}C- or ^{13}C-atom (Cane 1999). Indeed, **1** labeled with one or two ^{13}C-atoms was observed in the experiments. The possibility of glucose entering into terpene biosynthesis by the novel desoxyxylulose pathway (Eisenreich et al. 2004) was tested, but there was no evidence that this occurred.

The incorporation rate was determined by the relative abundance of the ions *m*/*z* 136/137/138 and *m*/*z* 93/94/95 in the mass spectrum of **1**, taking into account the natural abundance of ^{13}C (Fig. 4). The obtained values of 6 to 10% showed that males indeed biosynthesized **1** *de novo*. Females contained labeled **1** after mating with U-^{13}C-glucose fed males. Labeled esters, hydrocarbons, and tetrahydrofurans were also found in those females. These findings confirm that not only **1**, but also the esters and hydrocarbons, are transferred from males to females during mating.

Laboratory Bioassays In preliminary tests, β-ocimene showed a repellent effect on males, but its effect vanished quickly. We, therefore, choose to test this compound in combination with an artificial mixture of esters, similar in proportion to those found in the abdominal scent glands. Our assumption was that the esters might serve as a matrix, reducing the rate of evaporation of β-ocimene, so that the signal would stay longer on the females. We used the synthetic ester mixture because the esters are the most important compound class of the low boiling constituents of



ion	synthetic ocimene	males		females after copulation

the secretion. The other compounds were present only in low concentration or were part of the cuticule, as stated above. The odor emitted from females painted with the β-ocimene/ester solution was similar to the odor sampled from recently mated females when compared by GC-MS.

Males did not significantly change their behaviors toward females painted with hexane (control) as neither the mean number of courtship bouts (Z=1.069, P=0.285, Wilcoxon matched pair test, N=10) nor the mean courtship duration (Z=0.815, P=0.451, Wilcoxon matched pair test, N=10)

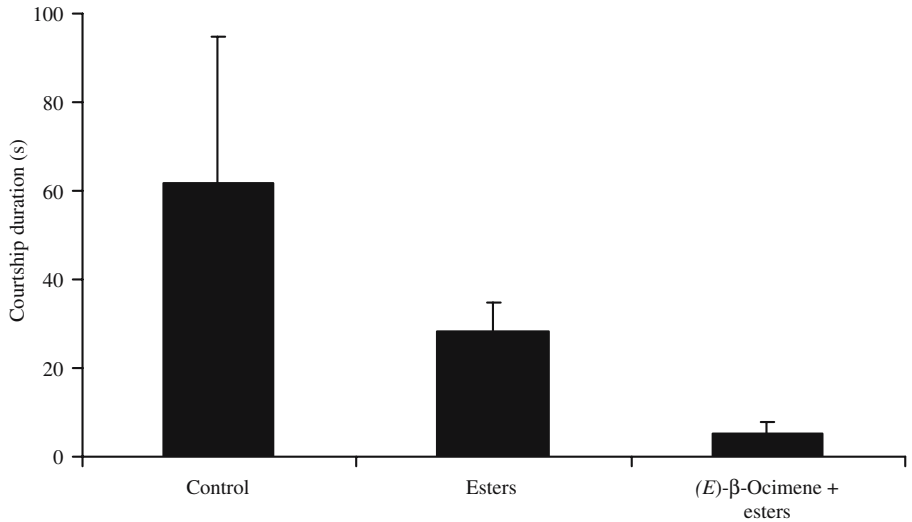

Fig. 5 Mean courtship duration in experiments where female abdomens were painted with 2 μl of control (hexane) or test mixtures to assess their effect on male sexual behavior. Test mixtures contained 1 mg of esters or a combination of 100 μg of 1:1 (*E*/*Z*)-β-ocimene plus esters

differed in the two experimental phases. Moreover, in 8 out of 10 tests males initiated copulation by grasping female abdomens after hexane was added to their abdomens.

Similarly, the ester mixture alone did not make females less attractive to courting males, as courtships were as long as those directed to control females (Mann–Whitney Test, $P=0.705$, $N=10$, Fig. 5). Furthermore, 70% of the couples engaged in copulation after painting females with esters, a percentage comparable to the one observed in control experiments (Fisher's exact test, $P=1$, $N=10$). Male behavior toward control or ester-painted females was similar to that observed in the first experimental phase. In all cases, males quickly approached and courted females, and in more than 90% of these tests, they grasped female abdomens within the first 2 min of the experiment.

In contrast to esters, β-ocimene strongly reduced female attractiveness. Although males exposed to females with β-ocimene plus esters quickly and repeatedly approached them, they courted them only for a few seconds and then left. The courtship duration was in average significantly shorter than in control experiments (Mann–Whitney Test, $P=0.002$, $N=10$, Fig. 5). In addition, only one of the 10 couples engaged in copulation in the second experimental phase, a lower proportion compared to that in control tests (*Fisher's exact test*, $P=0.006$, $N=10$).

Discussion

Our results show that male *H. melpomene* produce a complex odor profile that consists of volatile components as **1**, and a matrix of low-boiling-point components dominated by esters and hydrocarbons. This mixture is transferred to females during copulation, and the volatile component β-ocimene (**1**) makes females unattractive to courting males. As both ocimene isomers occur naturally and our synthetic sample also contained both, we cannot determine their relative strengths as repellents at this time. However, the prevalence of the (*E*)-isomer suggests this isomer to be active. The semivolatile ester matrix does not repel males, but in our experiments it reduced the evaporation rate of the ocimene, thus suggesting that this could be, at least in part, its function in female glands. Because the abdominal scent glands in this butterfly produce a bouquet that contains many different compounds, the possibility that other constituents of the scent gland also have antiaphrodisiac activity cannot be excluded. Such components might also provide other kinds of information to conspecifics, as in insects, even trace compounds of extracts can be important cues (e.g., Danci et al. 2006).

Interestingly, (*E*)-β-ocimene is one of the most prominent plant semiochemicals. It is commonly released by leaves in response to insect feeding or by flowers to attract pollinators (Pare and Tumlinson 1999; Andersson et al. 2002). Although the presence of this volatile has not been investigated in natural host plants or preferred pollen sources of *H. melpomene* (Boggs et al. 1981; Estrada and Jiggins 2002), **1** has been found in larval and adult host plants that are common in disturbed areas or that are frequently used to keep these butterflies in captivity, e.g. *L. camara* and *P. caerulea* (Piel et al. 1998; Andersson et al. 2002; Andersson and Dobson 2003b). Therefore, even if our experiments with labeled precursors show that *H. melpomene* has the capacity to synthesize **1** *de novo*, the additional contribution of **1** obtained from flowers or larval host plants cannot be ruled out.

Andersson and Dobson (2003a) showed that male and female *H. melpomene* antennae detect **1** and, in combination with other flower volatiles and color cues, was attractive to both sexes of butterflies. Taking into account the acute vision of *Heliconius* (Swihart 1972; Stavenga 2002; Zaccardi et al. 2006), the attractive or repellent activity of **1** might be explained by context specificity. In combination with other flower volatiles and visual flower cues, ocimene might be attractive, whereas with other conspecific gland constituents and visual signals, **1** could be repellent. This model points to further functions of the other male bouquet components besides the matrix effect discussed above. It also supports the observation that the antiaphrodisiac acts only over a short range.

Male behavior of *H. melpomene* toward mated females was similar to that described for pierid butterflies (Andersson et al. 2000) and *Drosophila melanogaster* (Scott 1986). Males approach mated females as often as unmated ones, clearly attracted by visual cues (Jiggins et al. 2004). When males come into close range to the mated females, the latter take mate-refusal posture by exposing their scent glands and release previously transferred compounds. Males immediately leave, so they spend less time courting mated than virgin females. In *Heliconius*, wing color patterns of females and males are identical, and males are visually attracted to both sexes. Males also release β-ocimene from their genitalia (claspers, unpublished data), which might serve for recognition of males and terminate male–male encounters. Therefore, it does appear that the antiaphrodisiac(s) of *H. melpomene* make mated females unattractive because they smell like males, as suggested earlier in *Heliconius* (Gilbert 1976) and found in *Pieris brassicae* and *D. melanogaster* (Scott 1986; Andersson et al. 2003).

Although antiaphrodisiac pheromones have been found in other groups of butterflies (Andersson et al. 2003), only the females of the Heliconiinae expose abdominal scent glands when they are courted or disturbed (Emsley 1963). This suggests that these odor mixtures might serve both as

antiaphrodisiac and protection. In fact, defense mechanism and sexual communication are tightly linked in unpalatable butterflies and moths (Boppré 1978, 1984; Weller et al. 1999; Conner et al. 2000; Schulz et al. 2004). The Lepidopteran scent glands studied so far show that the bouquets contain many different compounds (Miyakado et al. 1989; Ross et al. 2001; Schulz et al. 2007). Hence, it is possible that such odors provide conspecifics and predators with information. For example, the odor bouquet of *H. melpomene* contains three pyrazines, e.g., 3-isopropyl-2-methoxypyrazine (**2**), which are general warning odors of chemically defended insects and deter rats and birds (Kaye et al. 1989; Moore et al. 1990; Lindström et al. 2001). Unpalatable insects often use combinations of warning signals that target different sensory modalities (Lindström et al. 2001; Jetz et al. 2001). There is no evidence, other than the response to rough handling, that *Heliconius* females expose glands during attacks by predators. However, components in Heliconiinae odors, together with visual signals from the yellow glands, could alert, remind, and discourage predators.

Our findings that semiochemicals with evidence of antiaphrodisiac function are transferred from male to female *H. melpomene* support the observations published earlier by Gilbert (1976) for *H. erato*. Furthermore, we have similar results for other *Heliconius* and two other Heliconiinae in the genus *Argynnis* (Schulz, Yildizhan, Boppré, Estrada, Gilbert, unpublished; Schulz et al. 2007). Although the composition of these bouquets varies widely, male secretions of most Heliconiinae consists of more volatile compounds and a complex matrix of semivolatile components. This suggests a similar function of the scent glands in other Heliconiinae.

Acknowledgments We thank A. Wartenberg, R. Watkins, S. Marout, and K. Busby for assisting rearing butterflies; the United States Department of Agriculture for import and rearing permits, and Costa Rica's Ministerio del Ambiente y Energía for collection and exportation permits. This work was funded by the Deutsche Forschungsgemeinschaft and the University of Texas at Austin graduate program in Ecology, Evolution, and Behavior. Ethyl 4-Methyl Heptanoate: A Male-Produced Pheromone of *Nicrophorus vespilloides*

Wolf Haberer · Thomas Schmitt · Klaus Peschke · Peter Schreier · Josef K. Müller

Received: 11 June 2007 / Revised: 15 October 2007 / Accepted: 16 November 2007 / Published online: 13 December 2007

Abstract Sexually mature male beetles of the genus *Nicrophorus* (Coleoptera: Silphidae) exhibit a conspicuous behavior, recognized as pheromone-releasing activity. Laboratory and field studies demonstrated that females are attracted to males that exhibit this behavior, both on or off reproductive resources. Here, we report the results of a study in which volatile chemicals released by calling *Nicrophorus vespilloides* were collected by solid-phase microextraction and analyzed by using coupled gas chromatography–mass spectrometry. These analyses revealed that ethyl 4-methyl heptanoate and (*E*)-geranylacetone are emitted by males that engage in the behavior. In the field, traps baited with racemic ethyl 4-methyl heptanoate caught roughly equal numbers of male and female *N. vespilloides*. Some male and female *Nicrophorus vespillo* and male *Nicrophorus humator* were also caught in traps baited with this compound. Traps baited with (*E*)-geranylacetone did not catch significant numbers of beetles.

Introduction

In the past few decades, the chemical signals and defenses produced by Coleoptera have been the subject of numerous studies that focus on occurrence, biosynthesis, and biological significance (Francke and Dettner 2005). However, some coleopteran families have received relatively little investigation. In particular, there have been few studies on the chemical ecology of the Silphidae. In *Necrodes surinamensis*, several terpenes (necrodols) with a repellent function have been identified (Eisner and Meinwald 1982; Eisner et al. 1986; Roach et al. 1990). *Silpha americana* (Meinwald et al. 1985) and *Silpha novaboracensis* (Meinwald et al. 1987) utilize steroids that act as defensive chemicals. A recent study analyzed the composition of anal secretions in *Nicrophorus marginatus* (Woodard 2006).

Beetles of the genus *Nicrophorus* (Coleoptera, Silphidae) search for small vertebrate carcasses that are suitable as a reproductive resource. Once a suitable carcass has been found, the beetles drive away intra- and interspecific competitors and bury the carrion, thus hiding it from other potential competitors. Although fights over the carcass often result between competing *Nicrophorus* beetles, various breeding associations may also form on the carcass, from monogamous pairs to polygynandrous groups (reviewed in Eggert and Müller 1997).

Males of most, if not all, *Nicrophorus* species engage in pheromone emission during a species-specific time of day (Pukowski 1933; Eggert and Müller 1989a, 1997; Scott 1998). Males select elevated sites and assume a headstand-like posture, pointing the head down and raising the tip of the abdomen. Males differ from females morphologically in that they have an additional distal abdominal segment, presumably the site of the pheromone gland (Mosebach 1936). Since Pukowski's (1933) detailed study of burying

beetles provided the first accurate description of this behavior, numerous studies have attempted to elucidate its biological implications. Pukowski (1933) called the behavior "sterzeln," stating that *Nicrophorus* males exhibit sterzeln only when they have discovered a reproductive resource on which no female is present. Later observations revealed that male pheromone emission is not contingent on the presence of reproductive resources, at least in some species (Müller and Eggert 1987; Eggert and Müller 1989a; Beeler et al. 1999), with pheromone emission in the absence of carrion being interpreted as an alternative mate-finding behavior (Eggert 1992).

The time of day and the extent to which pheromone emission occurs is known for several *Nicrophorus* species (Müller and Eggert 1987). Furthermore, Müller and Eggert (1987) have demonstrated that individuals of congeneric species may also be attracted to pheromone-emitting males, although the ecological significance of such interspecific attraction is unclear. Beeler et al. (2002) proposed that females discriminate among potential mates by assessing pheromone signals, which would require that the signals contain information about the calling individual beyond sex and species. In this study, we report the identification of the male-produced pheromone of *Nicrophorus vespilloides*, the most abundant *Nicrophorus* species in Central Europe.

Methods and Materials

Beetles Nicrophorus vespilloides males used for headspace analysis were first- or second-generation offspring of beetles caught in pitfall traps baited with pieces of pigs' lung in a field near Freiburg, Germany (48°02′14″N, 7°50′52″E). The traps used were identical to those used in the experiment that tested the attractiveness of synthetic chemicals in the field (Fig. 1). Individual beetles were kept in transparent plastic boxes (100×100×65 mm) filled with moist peat under a 16:8 light/dark photoperiod. Some male beetles were provided with a small mouse carcass, whereas others were given decapitated mealworms.

Headspace Sampling Headspace chemicals were obtained from 15 individual males, in separate plastic boxes, by using solid-phase microextraction fibers (SPME, coating polydimethylsiloxane/divinylbenzene, Supelco, Bellefonte, PA, USA) and analyzed by gas chromatography–mass spectrometry (GC-MS). GC-MS analysis was performed on a Hewlett Packard (Palo Alto, CA, USA) 6890-5973 system equipped with a DB-1 column (30 m×0.25 mm ID; *df*=0.25 μm; J & W, Folsom, CA, USA). Conditions were as follows: injector temperature 250°C, splitless mode, oven temperature 50–250°C at 10°C min^{-1}. The electron impact mass spectra (EI-MS) were recorded with an ionization voltage of 70 eV and a source temperature of 230°C.

For collection of volatile chemicals, small holes were bored into the lids of boxes such that fibers could be placed close to the male during pheromone emission. Sampling took place from just before to the end of a beetle assuming the headstand posture typical of "sterzeln." Pheromone emission typically occurred between 1 hr before and 3 hr after lights off. After lights off, sampling continued under red light. We sampled the headspace of males with or without access to a carcass.

Chemicals Synthesis of racemic ethyl 4-methyl heptanoate was carried out by the method of Joung et al. (1998). The product was purified by liquid chromatography. (*E*)-geranylacetone was purchased from Fluka (Deisenhofen, Germany).

Field Experiment The field experiment was carried out in the oak-dominated mixed forest near Freiburg, southwestern Germany, from which our laboratory colonies originated. Five pitfall traps (Fig. 1) were arranged in a circle equidistant (ca. 50 m) from each other. A dispenser consisted of a 1.5 ml glass vial filled with silica gel (Merck, Darmstadt, Germany), 0.7 ml distilled water for wetting, and a 50-μl solution of the test chemicals. Vials were secured inside a tea ball with a small amount of liquid plaster. Each trap was baited with a tea ball placed above the center of the trap opening (Fig. 1). The vial remained closed until the bait was placed above a trap, at which point

D = Days (out of ten) on which beetles were trapped with the respective bait.

the cap was removed. The following treatments were tested: bait 1, ethyl 4-methyl heptanoate (34 nmol); bait 2 (control A), silica gel with distilled water; bait 3 (control B), same as control A but with 50 µl of *n*-pentane/dichloromethane (9:1); bait 4, (*E*)-geranylacetone (2.6 nmol); and bait 5, ethyl 4-methyl heptanoate and (*E*)-geranylacetone (34 and 2.6 nmol, respectively). The ratio of methyl heptanoate to geranylacetone in bait 5 was similar to that observed in the SPME analyses.

Fresh baits were placed above the traps an hour before sunset and left for 24 hr, after which the baits and the trapping containers were removed. Each trap was left without bait for 1 d before adding a new bait and trapping container. The position of each treatment was moved to the next trap in a clockwise direction. This procedure was repeated until the dispensers had rotated through all the traps twice; i.e., a total of 10 d of trapping, alternating with a total of 10 d without baits. The field trial was carried out between June 26 and July 14, 2006.

Results

Gas Chromatography–Mass Spectrometry SPME GC-MS analysis of the SPME samples revealed two volatile compounds that were detectable only when *Nicrophorus* males assumed the typical "sterzeln" posture. Based on mass spectra and retention times of the two compounds, and comparison with those of the synthetic versions, we concluded that the compounds were ethyl 4-methyl heptanoate {m/z (relative abundance): 172 [M+] (<1), 143 (6), 129 (13), 127 (28), 115(15), 109 (26), 101 (100), 88 (88), 73 (30); RT 7.99 min} and (*E*)-geranylacetone {m/z (relative abundance): 194 [M+] (2), 176 (2), 161 (3), 151 (28), 136 (24), 125 (12), 107 (22), 93 (13), 69 (64), 43 (100); RT 11.91 min}, in a ratio of approximately 1:13. No differences were detected in the composition of pheromone blends of males with and without carcasses.

Attractiveness of Compounds In the field, the number of *N. vespilloides* captured (Table 1) differed significantly among bait types (Friedman test, $P<0.0001$), as did the number of successful vs. unsuccessful trapping days ($\chi^2=26.3$, $df=4$, $P<0.001$). Traps baited with either ethyl 4-methyl heptanoate or a mixture of ethyl 4-methyl heptanoate and geranylacetone caught the greatest number of beetles (Wilcoxon–Wilcox-test, $P<0.05$); both of these treatments caught *N. vespilloides* on all but one of the trapping days (Table 1). The catches in traps baited with either of these two treatments did not differ (Wilcoxon–Wilcox-test, $P>0.1$). Traps with treatments that lacked ethyl 4-methyl heptanoate (i.e., the two controls and geranylacetone) caught few beetles. Comparison of the daily catches of *N. vespilloides* showed similar numbers of males and females trapped (Wilcoxon MPSR, $P>0.3$, Table 2). Most of the beetles caught in the trial (80.5%) were *N. vespilloides*, but some *Nicrophorus vespillo* (17.1% of total) and *Nicrophorus humator* (2.4%) were also caught in traps that contained ethyl 4-methyl heptanoate (Table 2). There was no effect of

Discussion

The data from both the headspace analysis and the field experiment suggest that ethyl 4-methyl heptanoate is a male-produced pheromone of *N. vespilloides*. The role of geranylacetone, also released by male *N. vespilloides*, remains unclear; catches with this compound alone were not different from those of the controls. Furthermore, addition of this compound to ethyl 4-methyl heptanoate did not yield increased catches compared to those with ethyl 4-methyl heptanoate alone. Interestingly, ethyl 4-methyl heptanoate has also been found as a minor component of volatile emissions from the beetle *Oryctes rhinoceros* (Coleoptera: Scarabaeidae), a widespread coconut pest in Asia. The principal pheromone component of *O. rhinoceros* is, however, ethyl 4-methyl octanoate (Hallett et al. 1995). Behavioral data suggest that the beetles produce a mix of both enantiomers of ethyl 4-methyl octanoate (Hallett et al. 1995). We did not determine the stereochemistry of ethyl 4-methyl heptanoate in *N. vespilloides*, but will do so in future studies.

Following the definition of Wertheim et al. (2005), ethyl 4-methyl heptanoate should be classified as an aggregation pheromone, rather than as a sex pheromone, of *N. vespilloides* because beetles of both sexes are attracted to this compound. Interestingly, in the field, males appear to attract primarily females (Müller and Eggert 1987). Males of the rove beetle *Aleochara curtula* also release a pheromone that attracts both sexes (Peschke et al. 1999).

Pheromone emission without carrion has been interpreted as an alternative to the primary mate-finding tactic of searching for carcasses (Eggert 1992; Beeler et al. 1999; Müller et al. 2007). According to Eggert (1992), pheromone emission benefits males irrespective of the presence of a reproductive resource. Males that have access to a suitable carcass can attempt copulation once a female arrives, and males without such a resource can secure matings with attracted females. In a field study of *N. vespilloides*, males that had buried a carcass prior to pheromone emission attracted equal numbers of females as males that had not (Eggert and Müller 1989b). Responding to the pheromone also benefits females by allowing them access to a carcass and/or a mate. Benefits for males that are attracted to males are less clear, especially if the pheromone-emitting male does not have a carcass. One possibility is that the attracted male could mate with surplus females that the pheromone emitter attracts. If the calling male has a carcass, then presumably the attracted male would fight the caller for the resource.

In the field trial, two other *Nicrophorus* species were attracted to ethyl 4-methyl heptanoate, consistent with earlier findings that calling male *Nicrophorus* attract members of other congeneric species (Müller and Eggert 1987). There is some evidence (Haberer, Schmitt, and Müller, unpublished) that the attracted *Nicrophorus* species use similar (i.e., 4-methyl branched heptanoate and octanoate) esters for their own sex pheromones. Müller and Eggert (1987) suggested that the response of larger congeners to the pheromones of a smaller species might be adaptive. If the pheromone-emitting male has access to a carcass, members of larger species would be able to displace the original owner and utilize the resource for their own reproduction. The two additional species, *N. vespillo* and *N. humator*, that were attracted to ethyl 4-methyl heptanoate are both larger than and competitively superior to *N. vespilloides* (Pukowski 1933; Otronen 1988). Future investigations of other *Nicrophorus* pheromones will aid our understanding of cross-attraction within the genus.

Acknowledgments We thank Anne-Katrin Eggert and Stephen Ellis for valuable comments on the manuscript.

RAPID COMMUNICATION

4-Methylquinazoline is a Minor Component of the Male Sex Pheromone in *Nasonia vitripennis*

Joachim Ruther · Sven Steiner · Leif-Alexander Garbe

Received: 11 October 2007 / Revised: 16 November 2007 / Accepted: 28 November 2007 / Published online: 18 December 2007

Abstract We identified 4-methylquinazoline (4-MeQ) as a minor component of the male sex pheromone of the parasitoid *Nasonia vitripennis*. Like the major components (4*R*,5*R*)- and (4*R*,5*S*)-5-hydroxy-4-decanolide (HDL), 4-MeQ is synthesized in the abdomen of males. At doses of 6 or 1 ng, 4-MeQ synergized the response of virgin females to the HDL-diastereomers in a still-air olfactometer, but was not attractive as a single component. 4-MeQ is also responsible for the characteristic medicinal odor of *N. vitripennis* males.

Keywords *Nasonia vitripennis* · Parasitoid · Pteromalidae · Sex pheromone · 4-methylquinazoline

Introduction

There is increasing evidence that with parasitic wasps, for some species, females attract mates with volatile sex pheromones, whereas in other species, males release the attractive chemicals (Cônsoli et al. 2002; Ruther et al. 2007). Males of the jewel wasp *Nasonia vitripennis*, a pupal parasitoid of cyclorraphous flies, release from their abdomen a mixture of (4*R*,5*R*)- and (4*R*,5*S*)-5-hydroxy-4-decanolides (HDL) that is attractive to virgin but not mated females (Ruther et al. 2007). Sample containers used for the storage of live *N. vitripennis* males and abdomen extracts from males possess a characteristic medicinal odor. However, the HDL-diastereomers smell fruity, reminiscent of peaches, suggesting that *N. vitripennis* males release another volatile chemical responsible for the characteristic odor. Here, we report identification of 4-methylquinazoline (4-MeQ) as a minor component of the male sex attractant of *N. vitripennis*, which synergizes the response of virgin females to HDL and which is responsible for the characteristic odor of *N. vitripennis* males as sensed by the human nose.

Methods and Materials

Insects N. vitripennis were reared on puparia of the green bottle fly *Lucilia caesar* as described elsewhere (Ruther et al. 2007). Three-day-old unmated male and female wasps were used for the experiments.

Preparation of Abdomen Extracts The abdomens of individual freeze-killed males were dissected under a stereomicroscope with a scalpel and transferred to 100-µl vial inserts filled with 20 µl dichloromethane that contained 20 ng/µl methyl undecanoate (Sigma-Aldrich) as an internal standard (N = 10). Each abdomen was extracted for 30 min.

Chemical Analysis Extracts (1 µl) were analyzed by gas chromatography-mass spectrometry (GC-MS) on a Fisons 8060 GC coupled to a Fisons MD800 quadrupole MS (EI, 70eV). The GC was equipped with (a) a nonpolar 30 m × 0.32 mm i.d. DB-5MS column, film thickness 0.25 µm or (b) a polar 30 m × 0.32 mm i.d. DB-WAX column, film

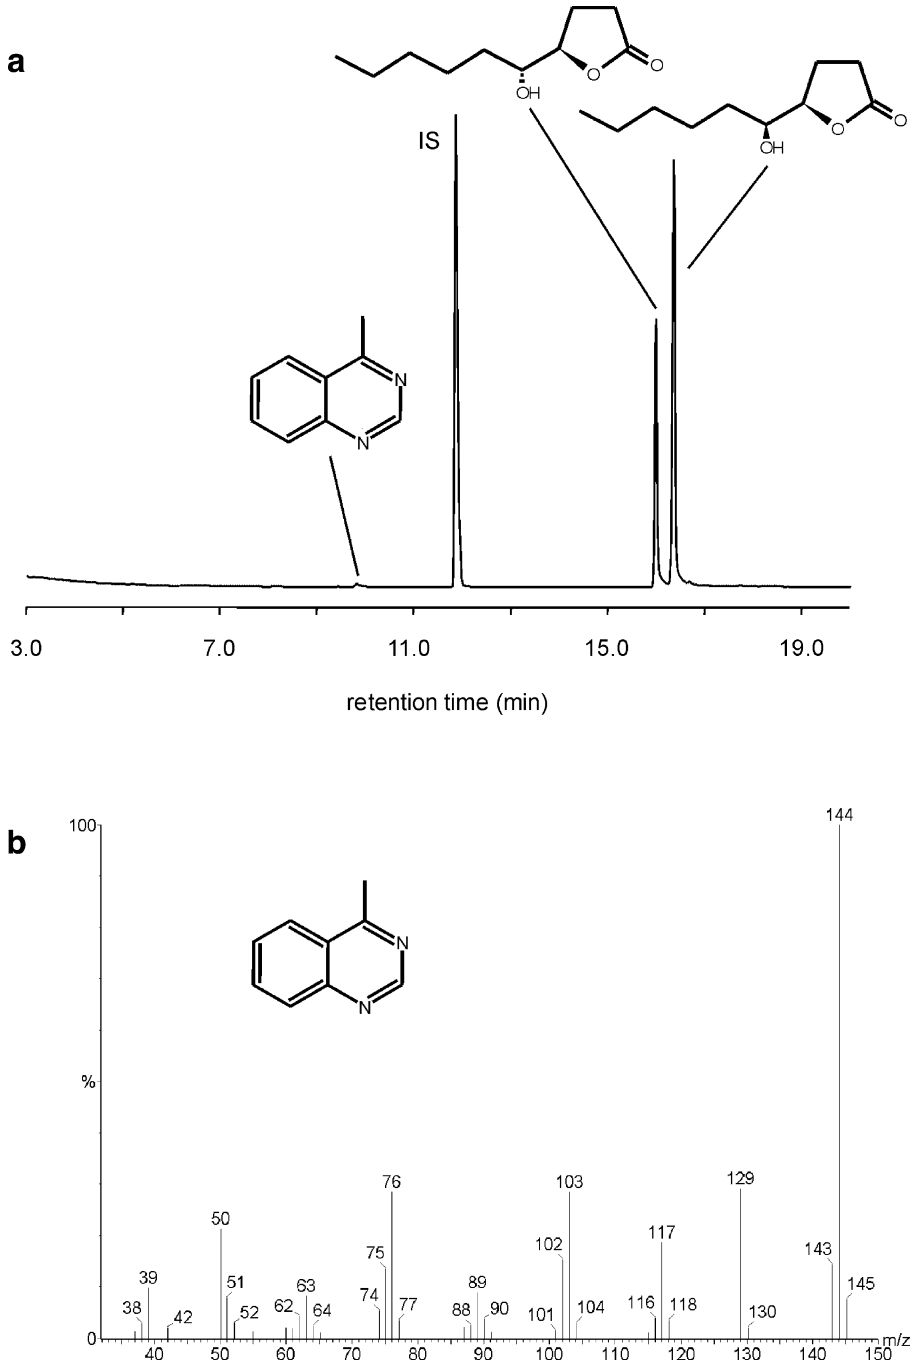

Fig. 1 **a** Total ion current chromatogram (nonpolar DB-5MS stationary phase) of a dichloromethane extract of the abdomen of a 3-d-old *N. vitripennis* male. Elution profile of higher boiling cuticular hydrocarbons not shown. (IS=20 ng of methyl undecanoate as internal standard). **b** Mass spectrum (EI, 70 eV) of the minor compound identified as 4-methylquinazoline

thickness 0.50 μm (J&W Scientific, Folsom, CA, USA) with helium as carrier gas (2 ml/min). Initial oven temperature was 80°C for both columns, increased at 5°C/min to 280°C (DB-5MS) and 240°C (DB-WAX), respectively. The maximum temperature was held for 30 min. 4-MeQ was identified by comparison of its mass spectrum and retention indices (in relation to co-injected *n*-alkanes) on nonpolar and polar stationary phases with those of a synthetic reference compound synthesized by reaction of 2-aminobenzonitrile with methylmagnesium iodide and subsequent treatment with ethyl formate as described by Bergmann et al. (1986). (4*R*,5*R*)- and (4*R*,5*S*)-HDL were identified as described previously by GC-MS and enantioselective GC (Ruther et al. 2007) with reference chemicals synthesized by published methods (Garbe and Tressl 2003). Volatiles were quantified by relating peak areas to the internal standard.

Table 1 Residence time (mean±SE) of virgin *N. vitripennis* females in test and control zones of a linear still-air olfactometer during a 5-min observation period

[a] (4*R*,5*R*)- and (4*R*,5*S*)-HDL in equal amounts

Bioassays Behavioral responses of *N. vitripennis* females were investigated in a linear still-air olfactometer that consisted of an angular clear acrylic tube (14 × 1 × 1 cm) divided into three zones, i.e., 4-cm test and control zones at both ends of the tube and a 6-cm neutral zone in the center. The tube had an open base, and the ends were sealed with perforated Parafilm. Centrally, the olfactometer had a cylindrical entry adapter (5 mm length × 1 cm i.d.) to which 1 ml microcentrifuge tubes with the parasitoids could be connected. Test and control solutions of synthetic volatiles were applied to filter paper disks (5 mm diameter), and the solvent was allowed to evaporate for 120 sec. Subsequently, the disks were placed at the end of the test and control zones for 60 sec, enabling the formation of an odor gradient, and the parasitoid females were allowed to enter the olfactometer tube. Residence times of females in test and control zones were recorded for 5 min (N = 21 per test). The following treatments were tested: (1) 40 ng of a 1:1 mixture of (4*R*,5*R*)- and (4*R*,5*S*)-HDL vs solvent control, (2) 6 ng 4-MeQ vs solvent control, (3) 6 ng 4-MeQ + 40 ng HDL vs HDL only, and (4) 1 ng 4-MeQ + 40 ng HDL vs HDL only. Mean residence times in test and control zones were compared by a *t*-test for dependent data by using Statistica 4.5 scientific software (StatSoft, Hamburg, Germany).

Results and Discussion

GC-MS analysis of the extracts from male abdomens revealed the presence of (4*R*,5*R*)-HDL and (4*R*,5*S*)-HDL as major components (100 ± 13 and 190 ± 23 ng per abdomen, mean ± SE) (Fig. 1a). These values are higher than previously reported for whole body extracts (Ruther et al. 2007) probably because of a more effective penetration of solvent into the dissected abdomen. In addition to HDL, there was a minor component in male abdomen extracts with retention indices of 1,337 (DB-5MS) and 2,111 (DB-WAX), respectively. The mass spectrum of this compound showed *m/z* 144 as both molecular ion and base peak, thus suggesting an aromatic compound (Fig. 1b). Losses of a methyl radical (*m/z* 129, M-15), hydrogen cyanide (*m/z* 117, M-27), and methyl cyanide (*m/z* 103, M-41) together with the even-numbered molecular ion (nitrogen rule) pointed to a methylated nitrogen-containing heterocycle with an even number of nitrogen atoms. The mass spectrum and retention indices on both nonpolar and polar stationary phases matched exactly those of synthetic 4-MeQ, which also had the characteristic medicinal odor of *N. vitripennis* males even at very low doses (1 ng). 4-MeQ occurred in abdomen extracts in amounts between 1 and 6 ng (mean value 3 ± 0.5 ng) but was not detectable in extracts from the head or thorax (data not shown). When applied alone to filter paper disks at a dose of 6 ng, 4-MeQ did not influence the behavior of female wasps in the olfactometer (Table 1). However, when applied at doses of 6 or 1 ng together with 40 ng of a 1:1 mixture of (4*R*,5*R*)- and (4*R*,5*S*)-HDL, females significantly preferred the combined odor over HDL alone. We conclude from these results that 4-MeQ is a minor component of the male sex attractant used by *N. vitripennis* males to attract receptive females. In addition, the sexual communication system of *N. vitripennis* comprises a still unknown aphrodisiac released by males from an oral gland that elicits receptivity in females (van den Assem et al. 1980) and a female contact pheromone that consists of cuticular hydrocarbons (Steiner et al. 2006). Quinazoline alkaloids are widespread in nature with 4-MeQ occurring in some *Pseudomonas* bacteria (D'yakonov and Teleszhenetskaya 1997) and in the feces of *Triatoma* bugs (Cruz-López and Morgan 1995). Furthermore, the compound is a putative semiochemical of ferrets (Zhang et al. 2005) and has been shown to interfere with the host-finding ability of the salmon louse *Lepeophtheirus salmonis* (Bailey et al. 2006). The structural differences between the primary pheromone components of *N. vitripennis* (lactones) and the synergist (nitrogen containing heterocycle) are striking and point to different biosynthetic pathways. These are the subject of ongoing research including investigation of endosymbiotic microorganisms as a possible source of 4-MeQ in *N. vitripennis*.

Identification of the Sex Pheromone of *Sesamia cretica* Lederer

Arman Avand-Faghih · Brigitte Frérot

Received: 1 June 2007 / Revised: 25 September 2007 / Accepted: 7 November 2007 / Published online: 19 December 2007

Abstract By using solid phase micro-extraction and gas chromatography–mass spectrometry analyses, a sex pheromone blend for the stem borer, *Sesamia cretica* Lederer (Lepidoptera, Noctuidae), was identified as consisting of (*Z*)-9-tetradecen-1-ol (80%), (*Z*)-9-tetradecen-1-yl acetate (10%), and (*Z*)-11-hexadecen-1-ol (10%). The first two components had previously been discovered as attractants for *S. cretica* in field tests, but had not been identified in the female's sex pheromone gland. A field-trapping trial showed that the three-component blend gave the highest catches of male *S. cretica*. This blend, in a sticky trap, was used to monitor a population of *S. cretica* in Iran, allowing the seasonal flight activity of this insect to be compared with that of a sympatric population of *S. nonagrioides*. The role of pheromones in the reproductive isolation of these species is discussed.

Keywords *Sesamia cretica* · Stem borer · Sex pheromone · SPME · (*Z*)-11-hexadecen-1-ol · Trapping · Sympatric species · Lepidoptera · Noctuidae

Introduction

The stem borer, *Sesamia cretica* Lederer (Lepidoptera, Noctuidae, Amphipyrinae), is one of the main insect pests of sorghum, maize, sugarcane, and cereal crops in the Mediterranean area (Anglade 1972). In certain regions, the species occurs sympatrically with other lepidopterans, including *Sesamia nonagrioides* (Lef), *Sesamia inferens* (Walk), *Ostrinia nubilalis* (Hüb), *Chilo agamemnon* (Bleszynski), and *Chilo partellus* (Swinhoe). *S. cretica* can be difficult to control on crops because the larvae develop inside the stem of host plants. Insecticidal control of this pest is, thus, most effective when the insecticide is applied when the eggs are on the leaves of the host plant and before the first instars bore into the plant stem.

Synthetic sex pheromones of moths have proven to be useful tools in integrated pest management (Cardé and Minks 1996). As baits in traps, they are used for monitoring moth flight activity, and hence, for timing control methods, such as insecticide sprays or the release of natural enemies. A synthetic sex pheromone could greatly aid control of *S. cretica* on agricultural crops by allowing precise timing of insecticidal treatments. During attractant field-screening experiments in Sudan, Arsura et al. (1977) found that *S. cretica* males were attracted to a 75:25 mixture of (*Z*)-9-tetradecen-1-ol (Z9-14:OH) and (*Z*)-9-tetradecen-1-yl acetate. Subsequently, this formulation was tested in various Mediterranean countries but failed to catch significant numbers of male moths (P. Moyal and G. Fédière, personal communication). In this paper, we report the results of the chemical analysis of the pheromone gland of female *S. cretica* and the field testing of an attractive three-component blend for males.

Methods and Materials

Insect Collection Insects were collected from maize in Iran (Mazandaran province) and in Egypt (near Cairo). After

emergence, females were placed in individual plastic containers and maintained at 24°C in 50% R.H. and with a reverse-phase L16:D8 photoperiod.

Pheromone Collection and Identification Sex pheromone was collected from 2-3-d-old females exhibiting the characteristic calling posture. The pheromone gland of each female was extruded by gentle pressure on the abdomen and kept in this position with forceps while the adsorbent part of a solid-phase microextraction (SPME) fiber (CW/DVB, 65 μm, Supelco Inc., Bellefonte, PA, USA) was gently rubbed on the gland surface according to the method of Frérot et al. (1997). The fiber was then desorbed in the heated injector (245°C) of a Varian 3400 gas chromatograph (GC) coupled with a Varian Saturn II ion trap (mass spectrometry, MS). Mass spectra were recorded in electronic ionization mode over a mass range of 40–300 amu. A 30 m×0.32 id, 0.5-μm film thickness, RTX-5MS column (Restek, Bellefonte, PA, USA) was used for the mass spectral analyses. The oven temperature was programmed from 50°C (held for 1 min) to 300°C at 8°C min^{-1} with helium as carrier gas. GC analyses were also conducted on a polar RTX-Wax column, (30 m×0.32 id, 0.5-μm film thickness, Restek) with the oven temperature programmed from 50°C (held for 1 min) to 100°C at 15°C min^{-1}, held for 1 min, and increased to 245°C at 5°C min^{-1}. The carrier gas was helium. Pheromone components were identified by comparison of mass spectra, and retention times on both columns, with the same parameters of authentic compounds.

Field Trapping Field trapping was carried out in a maize farm at Safi-Abad Agriculture and Natural Resources Research Center, near Dezful (Khouzestan Province) in Southwest Iran. The first experiment was performed between the 10th August and 31st November 2003 and the second from 12th September to 14th November 2004. Sticky Delta traps (NPP, France) were used in the experiments. All traps were deployed at the border of the field on wooden stakes at the height of the maize canopy. Traps were checked twice a week (every 3 or 4 days) and the trap sticky cards renewed each week.

Each chemical was dissolved in hexane (2 μg/μl) and the appropriate amount deposited onto a red rubber septum (Sigma-Aldrich). Septa were replaced every 4 wk of the trials. The different mixtures (1, 2, 3) tested in the *S. cretica* field experiment are given in Table 1. Traps for *S. nonagrioides* were also set up in the maize farm so as to compare the phenology of the two *Sesamia* species. The pheromone blend used for *S. nonagrioides* was: (*Z*)-11-hexadecen-1-yl acetate (Z11-16:Ac), (*Z*)-11-hexadecenal (Z11-16: Al), and (*Z*)-11-hexadecen-1-ol (Z11-16:OH) (850:100:50 μg; Ameline and Frérot 2001). All compounds tested were available in the laboratory and were >99% isomerically pure as determined by GC analysis.

Field trials were conducted as complete randomized block designs with four replicates of each treatment. Traps were placed approximately 30 m apart in each block, with blocks at least 100 m apart. In field trial 1, mixture 1 (the three component blend) was formulated based on our initial GC analyses, whereas mixture 2 was similar to the two-component blend reported by Arsura et al. (1977). In the second field trial, mixture 1 was again tested along with mixture 3, which lacked Z9-14:Ac. Blank traps, without any bait, were used as a control in both field trials.

Statistical Analysis Numbers of male *S. cretica* caught were transformed by $\ln(X+1)$ and subjected to analysis of variance (ANOVA; generalized linear model procedure). The mean values for different treatments were compared by using Tukey–Kramer tests. Statistical differences are reported at $P<0.05$.

Results

Pheromone Identification SPME collections were performed from glands of five females originating from Egypt and

glands of nine females from Iran. GC–MS analysis revealed the presence of a monounsaturated tetradecenol [*m/z*= 41:77%, 55:88%, 81:100%, 95:57%, 194 (M^+ −18):7%]; a monounsaturated tetradecenyl acetate [*m/z*=43:55%, 55:58%, 67:86%, 81:100%, 95:57%, 194 (M^+ −60):16%], and a monounsaturated hexadecenol [m/z=41:57%, 55:75%, 81:100%, 95:63%, 222 (M^+ −18):7%]. On the polar, RTX-Wax column, *Z* and *E* isomers, as well as various positional isomers, were separated clearly. Comparison of retention times of the unknown compounds with those of various synthetic standards led to the identification of Z9-14:OH, Z9-14:Ac, and Z11-16:OH in a ratio of roughly 80:10:10. The compounds and their relative ratio did not differ significantly between the Egyptian and Iranian populations.

Field Trapping Three different mixtures of the chemicals identified in female *S. cretica* were tested in field trials in 2003 and 2004. Across both trials, traps baited with mixture 1, containing the three components, caught significantly more males than traps baited with mixture 2, lacking Z11-16:OH, or mixture 3, lacking Z9-14:Ac. Traps baited with mixtures 2 and 3, however, caught significantly more insects than the control traps (Table 1).

Traps baited with synthetic *S. nonagrioides* pheromone were also used in the second trial in order to compare the phenologies of the two insects. Reasonably high numbers of male *S. cretica* were caught throughout the entire duration (approximately 2 mo.) of the field trial. However, *S. nonagrioides* males were caught in substantial numbers only during the latter half of the trial (Fig. 1). No males of either species were caught in traps baited with pheromone of the other species.

Discussion

We identified three chemicals, Z11-14:OH, Z11-14:Ac and Z11-16:OH, in the sex pheromone gland of female *S. cretica*. Two of these (Z11-14:OH and Z11-14:Ac) had previously been reported to be attractants for *S. cretica* males (Arsura et al. 1977). Our field trials showed that the most attractive blend tested was the one containing all three compounds; removal of either Z9-14:Ac or Z11-16:OH from the blend resulted in a significant decrease in catch of male *S. cretica*. Mixtures of 14-carbon and 16-carbon compounds have been reported as comprising pheromones of other *Sesamia* species, e.g., *Sesamia calamistis* (Zagatti et al. 1988).

Our comparison of the flight phenologies of *S. cretica* and *S. nonagrioides* in the second field trial showed that in the area of study, the two congeneric species have different but overlapping flight periods. Although these two species are found in the same geographical location and have overlapping flight periods, their reproductive isolation is probably maintained by their distinct pheromone systems, as evidenced by the lack of cross-attraction of the respective pheromone blends, i.e., traps baited with the *S. nonagrioides* blend did not catch *S. cretica* males and traps baited with the *S. cretica* blend did not catch *S. nonagrioides* males. The chemical compositions of the respective sex pheromones of the two species are distinct. Although they have the component, Z11-16:OH, in common, the pheromone of *S. nonagrioides* consists entirely of 16-carbon compounds (Z11-16:Ac and Z11-16:Al in addition to Z11-16:OH) (Sreng et al. 1985), whereas the pheromone of *S. cretica* contains two 14-carbon compounds.

To farmers, the two species are difficult to differentiate because of their similar appearance and similar damage they cause. Monitoring with the respective pheromones will

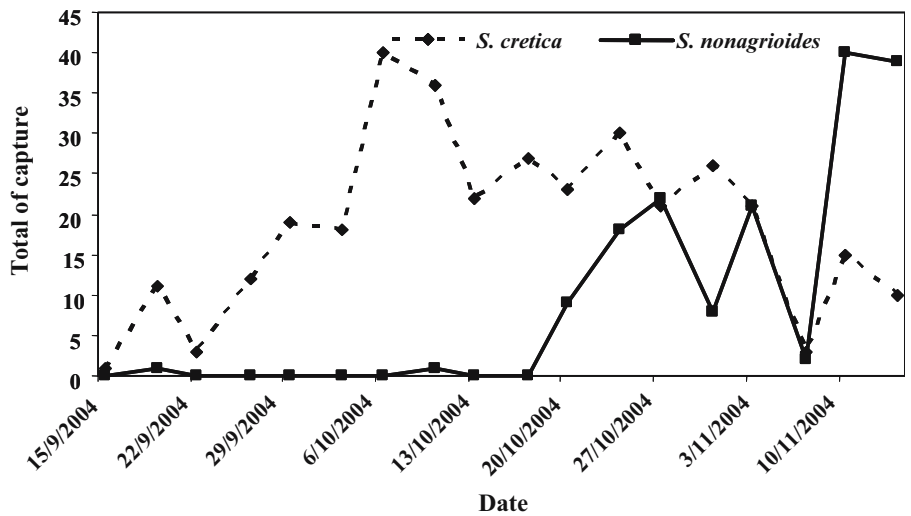

Fig. 1 Weekly catches of male *Sesamia cretica* (mixture 1) and *Sesamia nonagrioides* in sticky Traps baited with their respective sex pheromones, from September to November 2004 in Safi-Abad, Dezful, Khuzestan Province, Iran

allow easy detection and identification of which of the species is present, and therefore attacking the crop, in different regions.

Acknowledgments We thank Mohammad-Reza Malekzadeh from the IRIPP, Rahim Eslamizadeh and Mansour Reza-Gharib of the Safi-Abad Agriculture and Natural Resources Research Center for helping us with the field work. We are grateful to C. Malosse for obtaining the GC–MS spectra. This work was supported by the French Embassy in Tehran and by the Center for International Research and Collaboration (ISMO).

New Sex Attractant Composition for the Click Beetle *Agriotes proximus*: Similarity to the Pheromone of *Agriotes lineatus*

Miklós Tóth · Lorenzo Furlan · Amália Xavier · József Vuts · Teodora Toshova · Mitko Subchev · István Szarukán · Venyamin Yatsynin

Received: 2 June 2007 / Accepted: 2 November 2007 / Published online: 7 December 2007

Abstract While testing traps baited with a blend of geranyl octanoate and geranyl butanoate (pheromone components previously identified for *Agriotes lineatus*, Coleoptera, Elateridae) in Portugal and Bulgaria, large numbers of the closely related *Agriotes proximus* were captured. In the literature, two different compounds, (*E*,*E*)-farnesyl acetate and neryl isovalerate had previously been identified as pheromone components of *A. proximus*. Subsequent field tests, conducted in several European countries, revealed that *A. proximus* was weakly attracted to geranyl butanoate on its own, while *A. lineatus* was weakly attracted to geranyl octanoate on its own. However, the largest catches for both species were observed with a blend of both compounds. No *A. proximus* was caught in traps baited with the blend of (*E*,*E*)-farnesyl acetate and neryl isovalerate at any of the test sites. In electroantennographic studies, antennae of male *A. proximus* and *A. lineatus* both gave greater responses to geranyl butanoate than to geranyl octanoate, suggesting that the perception of these two compounds was similar for both species. A 1:1 blend of geranyl octanoate and geranyl butanoate can be used as a bait in traps for the detection and monitoring of both *A. lineatus* and *A. proximus* in many European countries.

Introduction

Pheromone gland extracts of *Agriotes lineatus* L. (Coleoptera, Elateridae) contain large amounts of geranyl octanoate (Borg-Karlson et al. 1988; Kudryavtsev et al. 1993; Siirde et al. 1993) and much smaller amounts of the related geranyl butanoate (Yatsynin et al. 1991, 1996; Tóth et al. 2003). A blend of 10:1 geranyl octanoate/geranyl butanoate was found to be optimal for field trapping *A. lineatus* (Tóth et al. 2003). In the course of a Europe-wide testing of click beetle pheromone baits, traps baited with the above composition captured *A. lineatus* in many European countries. However, in Portugal and Bulgaria, traps with this bait also caught beetles of the closely related species, *Agriotes proximus* Schwarz (Subchev et al. 2005, 2006; Tóth and Furlan 2005). Catches of *A. proximus* were

unexpected because two different compounds, (*E*,*E*)-farnesyl acetate and neryl isovalerate, had previously been identified as pheromone components of a Russian population of *A. proximus* (Yatsynin et al. 1980, 1996).

The objective of the work here was to conduct a study on the field and electrophysiological responses of *A. proximus* and *A. lineatus* to the above compounds, with a practical aim of defining a sex pheromone bait for trapping *A. proximus* populations across Europe.

Materials and Methods

Field-Trapping Tests

Synthetic geranyl butanoate and geranyl octanoate were purchased from Bedoukian (Danbury, CT, USA) and were >99% pure as determined by gas chromatography (GC). (*E*,*E*)-farnesyl acetate was obtained from Sigma-Aldrich Kft, (Budapest, Hungary) and was certified by the supplier to be >95% geometrically pure. Neryl isovalerate was synthesized as described in Tóth et al. (2003) and was >95% pure as determined by GC. The compounds were formulated in polyethylene dispensers (for details, see Tóth et al. 2003). Yf click beetle traps (Furlan et al. 2004; produced by RO-SA Micromecanica, San Doną di Piave, Venice, Veneto, Italy) were used in field tests.

Field tests were conducted at several sites in Hungary, Portugal, Bulgaria, and the European part of Russia. For details of single tests, refer to the description of a particular experiment. Traps were arranged in a randomized complete block design. Traps within blocks were separated by 8–10 m, with blocks at least 30 m apart.

Capture data were transformed to $(x+0.5)^{1/2}$ and were analyzed by analysis of variance (ANOVA). If the ANOVA was significant ($P<0.05$), then treatment means were separated by a Games–Howell test (Games and Howell 1976; Jaccard et al. 1984). All statistical procedures were conducted with the software packages StatView® v4.01 and SuperANOVA® v1.11 (Abacus Concepts, Berkeley, CA, USA).

Experiment 1 This compared the attractancy of blends of geranyl octanoate and geranyl butanoate, single compounds, and unbaited controls. Parallel tests (with five replicate blocks each) were conducted at: Vairao, Portugal, 30 March–20 July, 2004; Hajdúböszörmény, Hungary, 6 May–21 June, 2005; Krasnodar, Russia, 25 April–27 June, 2005; Brenitsa, Bulgaria, 12 May–26 July, 2005.

Experiment 2 This compared a range of dosages of a 1:1 blend of geranyl octanoate and geranyl butanoate and of geranyl butanoate on its own and was conducted at Koshava, Bulgaria, 11 May–20 June, 2005, with five replicate blocks.

Electroantennography

For recording electroantennograms (EAGs), a stainless-steel tube (Teflon-coated inside) with a constant humidified airflow of ca. 0.7 l/min was used. An antenna, freshly amputated at the base, from a live adult male click beetle was mounted between two glass capillaries that contained 0.1 M KCl solution, with the mounted antenna ca. 3 mm from the end of the steel tube. One electrode was grounded, while the other was connected to a high-impedance DC amplifier (AM-02, Syntech, Hilversum, The Netherlands). Test compounds (10 μg each) were administered in hexane to a 10×10 mm piece of filter paper inside a Pasteur pipette. A stimulus consisted of pushing 1 ml of air through the Pasteur pipette into the airstream flowing over the antenna. Response amplitudes were normalized against the means of responses to (*E*,*E*)-farnesyl butanoate (that elicited medium–high responses from antennae of both species), which was administered before and after the test compounds. Stimuli were delivered at ca. 20–30 s intervals. Experimental insects were collected from the field in Portugal (*A. proximus*) or in Hungary (*A. lineatus*). Thirty male specimens of each species were tested.

Results

Field-Trapping Tests

In experiment 1, in Portugal, traps baited with binary blends caught significantly more *A. proximus* than traps baited with single compounds (Fig. 1a). Traps containing only geranyl butanoate caught significantly more *A. proximus* than traps with geranyl octanoate alone. Traps with a 100:1 blend of (*E*,*E*)-farnesyl acetate/neryl isovalerate (the optimal ratio for *A. proximus* determined by Yatsynin et al. 1980) did not catch any *A. proximus*. In Bulgaria, few *A. proximus* were caught (Fig. 1b). Ratios of 10:1 and 1:1 (octanoate/butanoate) caught significantly more than the single components or traps with (*E*,*E*)-farnesyl acetate plus neryl isovalerate (Fig. 1b). Catches of the other treatments did not differ from each other.

In both tests, randomly selected specimens from the traps were inspected and all found to be males. No *A. lineatus* was caught in the Portuguese and Bulgarian trials.

Catches of *A. lineatus* in Hungary and Russia (Krasnodar region) showed a similar tendency, with catches to the

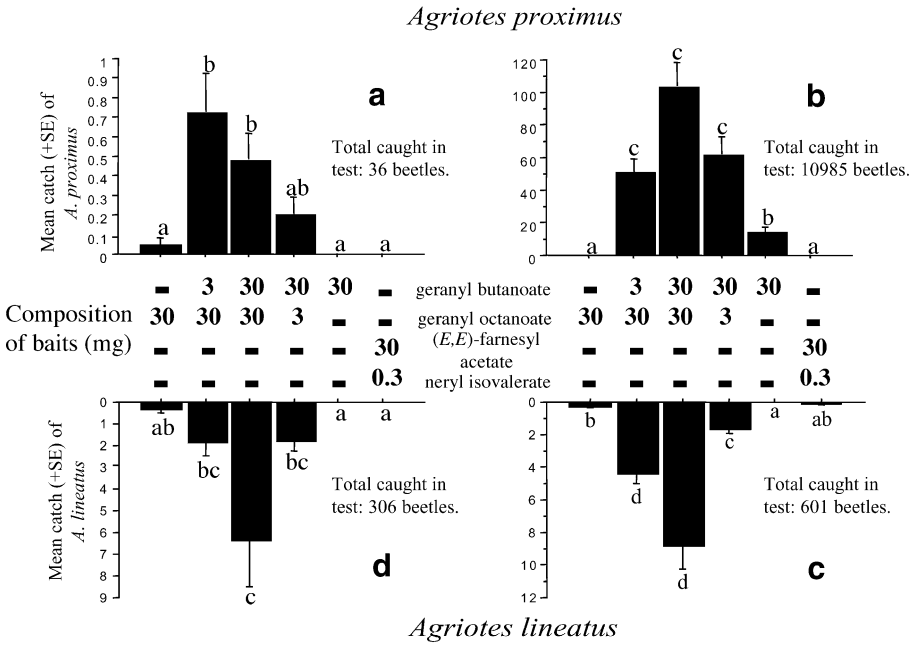

Fig. 1 Catches of *A. proximus* and *A. lineatus* in traps baited with mixtures of geranyl octanoate and geranyl butanoate, a 100:1 blend of (*E*,*E*)-farnesyl acetate and neryl isovalerate, and unbaited control traps (experiment 1). **a** Portugal, **b** Bulgaria, **c** Russia, **d** Hungary (for details of each test, please refer to "Materials and Methods"). Columns with same letter within one diagram not different at $P=5\%$ by ANOVA, Games–Howell

binary blends generally being greater than catches to the single compounds (Fig. 1c, d). At both sites, some specimens were caught in traps baited only with geranyl octanoate. Only at the Russian site was the number of *A. lineatus* caught in traps baited with geranyl octanoate significantly greater than the number caught in traps baited with geranyl butanoate (Fig. 1c). No *A. lineatus* was caught in traps baited with the (*E*,*E*)-farnesyl acetate and neryl isovalerate blend. No *A. proximus* was caught in the Hungarian and Russian trials.

Other click beetle species were captured during these tests. In Hungary and Russia, traps baited with only geranyl butanoate caught 3.3±0.9 and 3.6±0.9 (mean+SE) *Agriotes sputator* L., respectively, significantly higher than in other treatments which caught few or zero *A. sputator*. In Bulgaria, traps baited with (*E*,*E*)-farnesyl acetate and neryl isovalerate caught 134.8±22.3 (mean±SE) of *Agriotes ustulatus* Schwarz.

In a trial testing the effect of different dosages on *A. proximus* catch, binary blends of geranyl butanoate and geranyl octanoate caught significantly more *A. proximus* than geranyl butanoate alone at all dosages tested (Table 1). There was no significant difference in the catches of beetles among dosages of the binary blend tested. The only other click beetle species caught in the test was *A. sputator*; catches to the 100 and 30 mg geranyl butanoate treatments were significantly greater than to the corresponding binary blends that contained the same amount of geranyl butanoate (Table 1). Traps baited with the binary mixtures caught similar numbers of *A. sputator* as the unbaited control.

Electroantennograms

Antennae of male *A. proximus* exhibited greater EAG responses to geranyl butanoate than to geranyl octanoate at a dose of 0.001 μg and higher (Fig. 2). *A. lineatus* antennae also exhibited higher EAG responses to geranyl butanoate than to geranyl octanoate, but the difference was significant only at doses of 0.01 μg and greater (Fig. 2).

Even at a 10 μg dose, (*E*,*E*)-farnesyl acetate and neryl isovalerate elicited very low EAG responses from the antennae of both species (data not shown).

Table 1 Mean captures of *Agriotes* spp. in traps baited with different dosages of geranyl butanoate and its 1:1 mixture with geranyl octanote (experiment 2)

Bait composition (mg)		Mean number of beetles caught (per trap per inspection)	
Geranyl butanoate	Geranyl octanote	*A. proximus*	*A. sputator*
100	100	9.73b	0.53abc
30	30	8.46b	0.40ab
10	10	5.42b	0.60abcd
100	–	0.17a	2.15d
30	–	0.83a	1.80cd
10	–	0.25a	0.85bcd
–	–	0.00a	0.05a
Total number caught in test		297	126

Means with same letter not significantly different at $P=5\%$ by ANOVA, Games–Howell. Traps were inspected weekly.

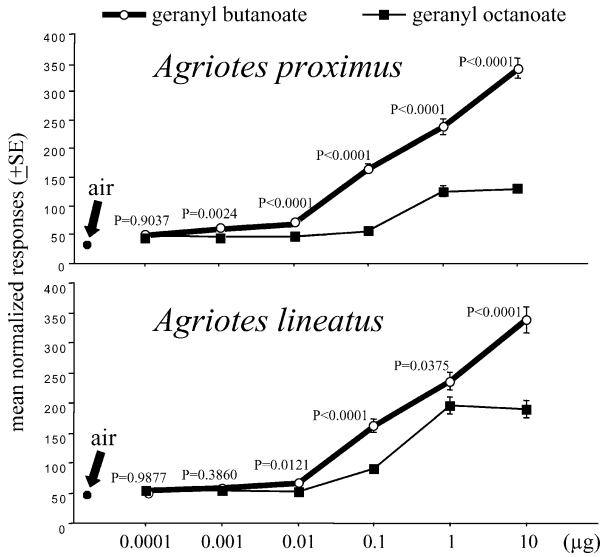

Fig. 2 Normalized EAG responses of male *A. proximus* and *A. lineatus* to a dosage series of geranyl butanoate and geranyl octanoate. Responses were normalized against the response to (*E*,*E*)-farnesyl butanoate. *P* values derive from Student's *t* test comparing mean responses to the two compounds at the given dose level

Discussion

Our field-trapping data show that a mixture of geranyl butanoate and geranyl octanoate attracted males of *A. proximus* at sites in southwestern and southeastern Europe, thus confirming our preliminary findings from Portugal (Tóth and Furlan 2005) and Bulgaria (Subchev et al. 2005, 2006). *A proximus* responded to a wide range of ratios (1:10 to 10:1) of the binary blend. Based on this work, practical application trials with geranyl butanoate and geranyl octanote blends were conducted and were successful for detecting the appearance and the flight dynamics of *A. proximus* in both Portugal (Tóth et al., unpublished) and Bulgaria (Subchev et al. 2005, 2006).

The inability of the previously described pheromone blend of (*E*,*E*)-farnesyl acetate and neryl isovalerate (Yatsynin et al. 1980, 1996) to attract *A. proximus* in our studies was surprising. Further studies, particularly looking at the production of pheromone components by *A. proximus* females from different locations (notably Portugal and Bulgaria), are needed to elucidate the reasons for this lack of response.

It is interesting to note that a similar inter-populational difference has been noted for *A. lineatus*. While geranyl octanoate is the main pheromone component used by populations in Eastern Europe (Russia), a mixture of (*E*,*E*)-farnesyl acetate and neryl isovalerate has been reported to attract *A. lineatus* populations in Western Ukraine (Kudryavtsev et al. 1993; Siirde et al. 1993). However, populations of *A. lineatus* respond to blends with geranyl octanoate as the main component all over Europe, even in areas (Hungary, Romania, and Bulgaria) neighboring Western Ukraine (Tóth and Furlan 2005; Furlan et al. 2007). *A. lineatus* populations in Canada (introduced from Europe in the past) also respond to the geranyl octanoate and geranyl butanoate blend (Vernon and Tóth 2007).

In the field trials that tested different ratios of geranyl butanoate and geranyl octanoate, *A. lineatus* showed similar responses to those of *A. proximus*. That the greatest catches of *A. lineatus* were obtained to a blend relatively high in geranyl butanoate (ratio of 1:1) was unexpected, since, in chemical studies, this compound was detected only in trace amounts in female pheromone glands (Siirde et al. 1993; Yatsynin et al. 1996; Tóth et al. 2003). One possible explanation is that compounds extracted by direct solvent extraction of pheromone glands (Siirde et al. 1993; Yatsynin et al. 1996; Tóth et al. 2003) do not reflect the ratio of components emitted into the air by a calling female. The analysis of volatiles emitted by *A. lineatus* and *A. proximus* females is underway in our laboratory in order to test this hypothesis.

In our study, *A. proximus* showed a low response to geranyl butanoate alone, whereas *A. lineatus* did not appear to respond to this compound. Furthermore, *A. lineatus* has been reported as being attracted (albeit in low numbers) to geranyl octanoate alone (Kudryavtsev et al. 1993; Siirde et al. 1993; Tóth et al. 2003). This suggested to us that there may be a difference between the two species in their respective sensitivity to these compounds. However, our EAG studies showed no difference in antennal responses: geranyl butanoate evoked higher EAG antennal responses than geranyl octanoate for both species.

The similarity in both field and antennal responses between the two species raises the question of whether *A. proximus* and *A. lineatus* are distinct species. Taxonomically, the two species are considered clearly separated, primarily because of one morphological difference: the ratio of the length and the width of the prothorax. However, there are no data that demonstrate separation at a biological level. Genetic or classical biological studies are needed to address this issue.

For pest-management purposes, a 1:1 blend of geranyl octanoate and geranyl butanoate can be used as bait in traps for the detection and monitoring of both *A. lineatus* and *A. proximus* in most parts of Europe. Although in most cases, insect species produce and respond to unique pheromone blends, there is precedent for similarity in pheromone composition between closely related species of click beetles. *Agriotes sordidus* Illiger and *Agriotes rufipalpis* Brullé both use geranyl hexanoate in their sex pheromones (Tóth et al. 2002, 2003; Furlan et al. 2004). For both pairs of *A. sordidus–A. rufipalpis* and *A. proximus–A. lineatus*, we have yet to find both species of a pair at the same site

(Tóth and Furlan 2005; Furlan et al. 2007). However, when traps baited with geranyl butanoate and geranyl octanoate are used for monitoring *A. lineatus* or *A. proximus* across Europe, the possibility of the presence of both species at a site should be considered.

Catches of other click beetle species in this study corresponded well with their respective sex-pheromone compositions. The main pheromone component of *A. sputator* is geranyl butanoate (Yatsynin et al. 1986, 1996; Siirde et al. 1993; Tóth et al. 2003). Lower catches of *A. sputator* in traps baited with blends that contain geranyl octanoate, compared to traps baited with geranyl butanoate alone, suggest that geranyl octanoate may act as a behavioral antagonist to *A. sputator*. Catches of *A. ustulatus* in traps baited with the blend of (*E*,*E*)-farnesyl acetate and neryl isovalerate are explained by the presence of the farnesyl compound, which is the main pheromone component of this species (Kudryavtsev et al. 1993; Siirde et al. 1993; Yatsynin et al. 1996; Tóth et al. 2003).

Production and Bioactivity of Common Lichen Metabolites as Exemplified by *Heterodea muelleri* (Hampe) Nyl.

Armin Hager · Georg Brunauer · Roman Türk · Elfie Stocker-Wörgötter

Received: 21 August 2007 / Revised: 4 October 2007 / Accepted: 12 November 2007 / Published online: 13 December 2007

Abstract Based on results of a former study in 2005, this investigation aimed at quantifying UV- and cold temperature stress-induced changes within the secondary metabolite production of the cultured mycobiont of the lichen *Heterodea muelleri* (Hampe) Nyl. The chemical profiles of the mycobiont cultures and the lichen thallus were determined by high-performance liquid chromatography (HPLC) and thin layer chromatography (TLC) analyses. The voucher specimen of *H. muelleri* produced diffractaic acid as a major polyketide and barbatic acid as a satellite compound, whereas the untreated mycobiont did not contain any detectable secondary metabolites. While UV-C stress caused a general increase in substance formation, cold temperature stress resulted in a strong activation of barbatic acid biosynthesis. A further series of experiments focused on the effect of diffractaic and barbatic acids on the growth of the symbiotic photobiont *Trebouxia jamesii*; usnic acid was similarly tested. Pure substances were obtained from mycobiont cultures by performing preparative TLC. A determined quantity of algae was incubated on BBM plates that contained three different concentrations of the pure lichen metabolites. The growth of the photobionts was monitored over a period of 1 mo to evaluate the impact of each substance on the cultured algae. While diffractaic and usnic acid had no noticeable effect, barbatic acid strongly inhibited algal growth and resulted in cell death.

Introduction

Lichen secondary metabolites, especially polymalonyl-derived polyketides, have been found to exhibit manifold biological activities in various screenings (Huneck 1999, 2001; Dayan and Romagni 2001; Müller 2001). Although the biological activities of lichen substances are well known, the biological and ecological functions of these compounds for the lichen symbiosis and the lichen itself are poorly understood. Although more than 800 lichen substances are known and their structures have been elucidated (Huneck 2001), many others remain to be characterized. In general, lichen secondary metabolites can be grouped into three classes according to their biosynthetic origin; polymalonate, mevalonate, and shikimate derivatives (Asahina and Shibata 1954; Culberson 1969, 1970). Lichens, like other ascomycetous fungi, form chemically heterogenous polyketides that comprise aliphatic and aromatic structural motifs. The orcinol and β-orcinol derivatives (depsides, depsidones, dibenzofurans) are especially interesting as they presumably play a role in the establishment of the lichen symbiosis and probably also in the interaction between the symbionts and with their environment (Armaleo 1995). A few of the structurally simple depsides have been found in non-lichenized fungi, such as lecanoric acid in the genus *Pyricularia* (Umezawa et al. 1974), a plant pathogenic fungus. In former studies, this group of organisms has been considered as the possible origin of the establishment of fungal symbioses that result in the lichen symbiosis (Ahmadjian 1970; Gargas et al. 1995). More

recent and extensive studies by Lutzoni et al. (2004) and James et al. (2006) have superseded the former speculations, indicating that many pathogens are derived from lichen-forming fungi.

The over-riding interest in these compounds has been in respect to their potential source as prospective pharmacophores (González-Tejero et al. 1995; Huneck 1999), but it is difficult to produce and isolate large quantities. To obtain rare compounds in large quantities without endangering the natural populations of the source organisms, optimized cultures of lichen fungi are desirable. It is, therefore, relevant to investigate what the ecological implications are in producing particular substances and what factors trigger the fungus to express a certain chemical profile (Culberson and Armaleo 1992; Armaleo 1995; Hamada and Miyagawa 1995).

The secondary metabolites of *Heterodea muelleri* (Hampe) Nyl. were previously analyzed by high-performance liquid chromatography (HPLC) and thin layer chromatography (TLC) and described by Hager and Stocker-Wörgötter (2005). Under particular stress conditions (e.g., exposure to UV light), cultured mycobionts produced the typical depsides, diffractaic and barbatic acids. In another screening experiment, Nishitoba et al. (1987) showed that diffractaic and barbatic acids strongly inhibited the growth of lettuce seedlings, and Takahagi et al. (2006) reported an inhibition of photosystem II in tobacco cells by barbatic acid.

Inspired by these results, we investigated whether these metabolites have any effect on the photobionts of *H. muelleri*. For this reason, we tested whether lichen substances protect the lichen photobiont against environmental stress and control its photosynthesis and growth. The major aim was to test the effects of typical lichen metabolites, diffractaic and barbatic acids, formed both by natural thalli and by cultured mycobionts on the growth of the cultured algal symbionts. A further experiment studied the effects of usnic acid extracted from *Heterodea beaugleholei*, the closest relative of *H. muelleri*.

Methods and Materials

Voucher Specimens The voucher specimens, fruticose thalli of *H. muelleri*, were collected from the hills of Canberra (Mt. Ainslie, S 35°20′57″, E 149°07′32″) in the Australian Capital Territory (Fig. 1a). The collected material is kept and preserved in the Herbarium of the University of Salzburg (Herbarium SZU L 23035).

Culture Method Single spore isolation was performed according to Ahmadjian (1973). Apothecia were cut off the thallus and transferred to 10 ml of water in a beaker (for 10 min.). After removal of the water film with filter paper, the apothecia were fixed to the top cover of a petri dish with petroleum jelly. Spores were discharged onto a sterile S2% medium in a petri dish [Sabouraud-2%–Glucose–Agar (Fluka 84086)]. After 2 d, several groups of spores were present on the surface of the agar plate. The cover that contained the apothecia was then removed to avoid further contamination. Germinated, single spore isolates were transferred to tubes containing S2%. Mycelia that developed from these spores (incubated for 4–6 mo) were gently homogenized to obtain subcultures.

Culture Media for Photobionts Algal symbionts were isolated and subcultured on Bold's basal medium(BBM; Deason and Bold 1960). For the growth experiment, petri dishes with BBM+b (BBM, as a solid medium impregnated by barbatic acid), BBM+d (BBM with diffractaic acid), and BBM+u (BBM with usnic acid) were used.

Culture Conditions Cultures were maintained in a culture chamber under a changing 12 hr/27°C:12 hr/24°C L:D regime, and a light intensity of 50–100 μmol m^{-2} s^{-1} (=standard conditions).

Stress Parameters (1) Well-developed subcultures (spore isolates, 4 mo old) of *H. muelleri* were subjected to a low temperature stress of 4°C for 6 wk. A control was kept

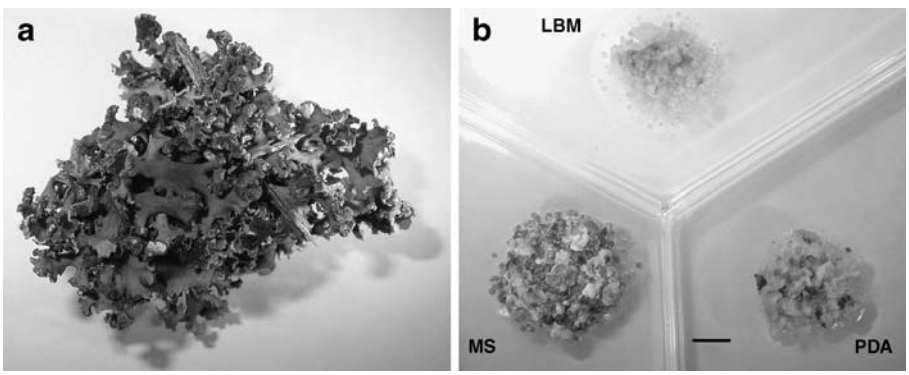

Fig. 1 **a** *Heterodea muelleri* thallus from Mt. Ainslie (Canberra, Australia). **b** Nutrient media growth experiment; mycobiont cultures on three different media after 5 mo (showing strong pigmentation on MS); *bar*=5 mm

under standard conditions. Methanol extracts of the freeze–dried cultures were analyzed by HPLC. (2) Four-month-old subcultures of the lichen fungus were exposed to UV-C (254 nm; 300 μW cm^{-2}) for 1 hr each day at room temperature (under a sterile hood with deactivated airflow to avoid dryness) over a period of 2 wk. Cultures were maintained under standard conditions (as described above) for the remaining time. A control culture was kept as a reference. Methanol extracts of freeze–dried cultures were analyzed by HPLC.

Preparation of Specimens, DNA and Chemical Analyses

Preparation Circular plugs (ca 1 cm in diameter) were cut from each agar plate overgrown by the mycobiont, and the origin of each subculture was recorded. To prevent contamination, the plugs for chemical testing were prepared in a hood under sterile conditions. Samples were vacuum freeze–dried at −42°C for 24 hr by using an ice condenser connected to a vacuum pump. The dried discs were transferred to glass tubes and extracted with methanol for 4 hr. Extracts were then transferred to HPLC vials, and an aliquot of 20 μl from every sample was injected.

DNA Extraction Total DNA was extracted from cultured mycobionts and for the comparisons from the voucher specimens (Armaleo and Clerc 1995).

DNA Amplification and Purification The ITS-regions, the 5.8 region, and the flanking parts of the small and large subunits (SSU 18S and LSU 28S) of the rDNA were amplified by using a GeneAmp polymerase chain reaction (PCR) system thermal cycler. Primers for the PCR were ITS1F (Gardes and Bruns 1993), ITS2, and ITS4 (White et al. 1990) designed for the lichen fungus. The PCR mix contained 1.25 U of Dynazyme Taq polymerase (Finnzymes), 0.2 mM of each of the 4 dNTPs, 0.5 μM of each primer, and 10–50 ng genomic DNA. The PCR products were cleaned by using a Quiaquick PCR product purification kit. Sequences were run on an ABI 310 automated sequencer. For the alignments of sequences, a Pile-up Programme was used, and the adjustments were done manually. For the photobionts, special *Trebouxia* primers (ITS1T and ITS4T, Kroken and Taylor 2000) were used.

Chromatographic Analysis Lichen thalli (100 mg dry weight) and vacuum-dried mycobionts (removed from the medium; 100 mg dry weight) were extracted for 4 hr with methanol at room temperature for HPLC. HPLC analysis was performed following Stocker-Wörgötter and Elix (2002) by using a Hitachi/Merck HPLC system that included two pumps, a Photodiode array detector (190–800 nm wavelength range), a Beckman 5C18 column (4.6× 250 mm, 5 μm), and a computer system with an integration package based on Windows NT.

Extraction of Pure Metabolites To obtain pure barbatic and diffractaic acids (Fig. 2a,b), a preparative TLC was performed: the yield of ten mycobiont subcultures was collected and vacuum freeze–dried for 12 hr. Dried cultured material (ca 5–10 g) was extracted with acetone for 4 hr at room temperature. The mixture was transferred to a silica plate (as one continuous line, 160×5 mm). As the two substances are closely related, the separation was achieved by using solvent B (120 ml hexane, 90 ml methyl tertiary-butyl ether, 230 ml formic acid) and on TLC plates (20× 20 cm). The substance bands were scraped from the silica plate and redissolved in acetone. The supernatant that contained the pure lichen compound was carefully separated from the silica gel, and the remaining acetone was evaporated in a hood. Finally, the purity of the substance was checked by HPLC.

Algal Growth Experiments and Effect of Biologically Active Metabolites Growth experiments with *Trebouxia jamesii* (photobiont) were done on BBM agar plates over a period

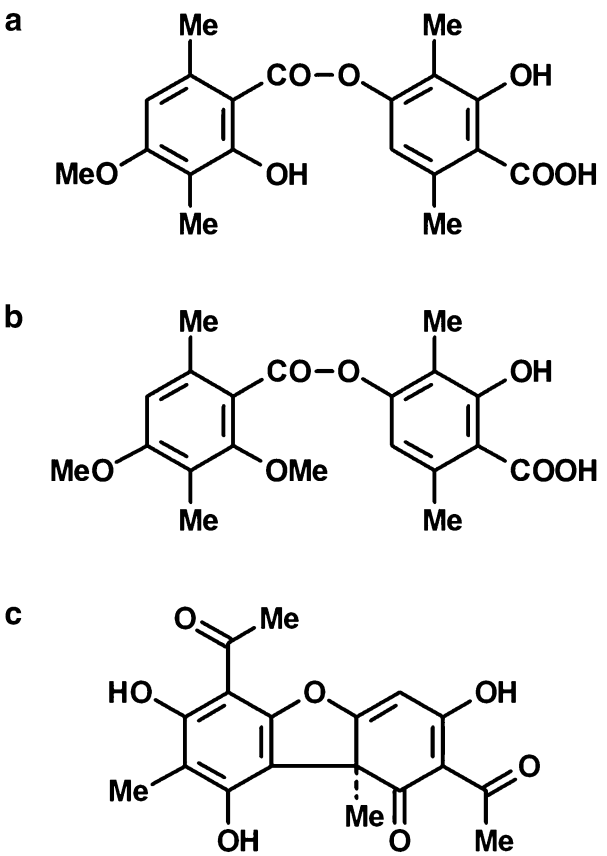

Fig. 2 Molecular structures of barbatic acid (**a**), diffractaic acid (**b**), and usnic acid (**c**)

of 1 mo in three different, independent experiments. In each, a layer of pure diffractaic or barbatic acid—extracted from metabolite-forming *Heterodea* mycobiont—was superimposed onto the nutrient media by using three different concentrations (0.5, 2, and 4 mg cm^{-2}; the quantity was chosen considering the overall thallus contents). The effect on the growth of the algae (starting with algal colonies, ca 3 mg fresh weight) was documented by a weekly analysis of images taken by a digital camera fixed to a light microscope. In another study, the effect of usnic acid (extracted from *H. beaugleholei*, Fig. 2c) on photobiont division rates was tested in a similar way. After 1 mo, the algal cells were harvested, weighed, and the obtained values were statistically evaluated by considering mean values and SDs.

Statistical Analyses Statistics were calculated by using ANOVA procedure of SigmaStat 3.11 for Windows; SigmaPlot 9.01 for Windows was used for figure preparation (Systat Software, Inc. 2004).

Results

HPLC analyses demonstrated that the voucher samples produce diffractaic acid as a major substance, whereas barbatic acid was detected as a minor satellite compound (Fig. 2a,b). Mycobiont cultures showed the highest growth rates on Murashige and Skoog (MS) medium (Stocker-Wörgötter 2001); development was accompanied by a more intense pigmentation than was found in cultures from other tested media (Fig. 1b).

Mycobiont cultures only began secondary metabolite production when they had been exposed to cold temperature stress (4°C for 6 wk) or UV-C light (254 nm, 1 hr per d over 2 wk). As a consequence of this treatment, cultures produced diffractaic acid, barbatic acid, and probably their precursors and intermediates. UV-C treatment doubled the proportion of produced substances and provoked a strong pigmentation.

In the UV-C experiment, diffractaic acid was the major substance, but cold temperature exposure resulted in large amounts of barbatic acid; overall values increased more than 60 times compared with voucher specimens (Fig. 3). In both experiments, the overall secondary metabolite contents were significantly higher than those of the voucher specimen. Based on the quantities of lichen acids in the thallus (4.80 mg cm^{-2} diffractaic acid and 0.36 mg cm^{-2} barbatic acid), the concentrations used for the algal test series were calculated as 0.5, 2, and 4 mg cm^{-2} on the surface of the agar plate.

After 3 d of incubation, algal growth was reduced considerably on the plates with barbatic acid. However, the algal biomass in the dishes that contained diffractaic and usnic acids and in the negative control, algal growth increased from 550 to 650% after 1 mo in culture (Table 1, Fig. 4). No significant differences were recognized between the diffractaic and usnic acid treatment and the control culture with no lichen metabolites. *Trebouxia* colonies were able to double their biomass at low barbatic acid concentrations (0.5 mg cm^{-2}), whereas the algal cells were seriously damaged at higher concentrations (2 mg cm^{-2}). Most of the cells died at the highest test concentration of 4 mg cm^{-2} (Figs. 5, and 6).

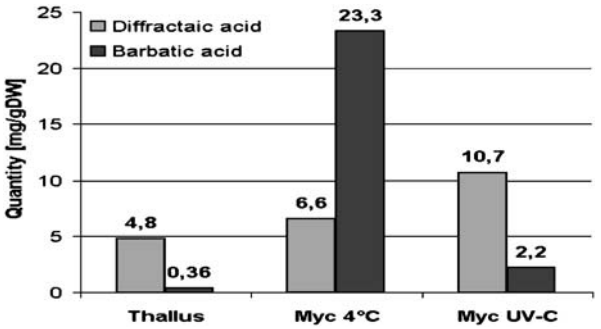

Fig. 3 Changes in lichen acid production of the cultures mycobionts (myc) due to temperature and UV-C stress in comparison with the thallus content

Discussion

As former studies have shown (Stocker-Wörgötter 2001; Hager and Stocker-Wörgötter 2005, Brunauer et al. 2006, 2007), the culturing of lichen mycobionts requires long-term experiments; numerous "case" studies have demonstrated that every "new" lichen fungus prefers a different composition of nutrient medium and specially adapted culture conditions. Many culture experiments are necessary to trigger the aposymbiotically grown mycobiont to produce specific secondary metabolites.

Table 1 Biomass increase of algal colonies on control and test-media after 1 mo (starting from 3 mg algal cells, N=3)

Medium (BBM)	Concentration (mg cm⁻2)	Mean (mg)	Increase (%)	SD
Control		19.13	537.66	18.23
+Barbatic acid	0.5	6.60	120.00	7.39
	2.0	2.58	−14.00	5.01
	4.0	1.95	−35.00	7.83
+Diffractaic acid	0.5	19.66	555.33	23.36
	2.0	20.65	588.33	28.47
	4.0	21.39	613.00	33.69
+Usnic acid	0.5	20.21	573.66	12.45
	2.0	20.44	581.33	37.51
	4.0	21.33	611.00	28.22

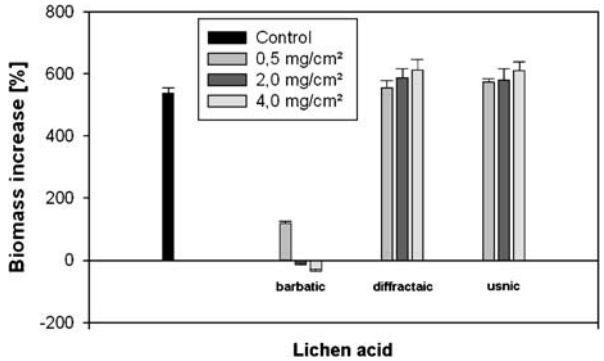

Fig. 4 Increase of algal colony biomass on the different lichen acid layers after 1 mo. *Error bars* represent SE

In some cases, lichen culturing is further complicated by the isolation of epi- and endolichenic fungi and algae. To identify the lichen mycobiont and to distinguish it from occasionally isolated, lichenicolous fungi, DNA canalyses of the ITS region have been performed. If the mycobiont produces lichen substances in culture, the fungus can be identified by its chemical profile, and the produced lichen substances can be used as chemical markers. Chemical analyses by HPLC, TLC, and microcrystallization tests cannot screen contaminations by other fungi.

Culture of *H. muelleri* mycobionts on MS medium enriched with sugars resulted in increased and optimized growth rates. The characteristic brown pigmentation found in cultures grown on MS is probably correlated with the brown pigment that is normally formed by the apothecia of the voucher specimens (Miyagawa et al. 1994).

Stress experiments with *H. muelleri* mycobiont cultures yielded surprising results, especially the more than 60-fold increase of barbatic acid that resulted from cold temperature treatment. Low temperatures can set off an increased production of secondary metabolites, as reported by Stocker-Wörgötter (2001) for *Umbilicaria mammulata*. The question as to why stress due to UV-C exposure resulted in an increased biosynthesis of medullary lichen acids (in the intact lichen formed by medullary hyphae) remains open. Further experiments, using different types of UV irradiations (A, B, and C) have to be performed, as different wavelengths may play a crucial role in secondary compound synthesis. According to Swanson and Fahselt (1997) and BeGora and Fahselt (2001), UV-A irradiation alone caused the production of higher contents of phenolic compounds in lichens than exposure to both UV-A and UV-B. A definite correlation between production of lichen acids and the effects of UV-light was recently reported by

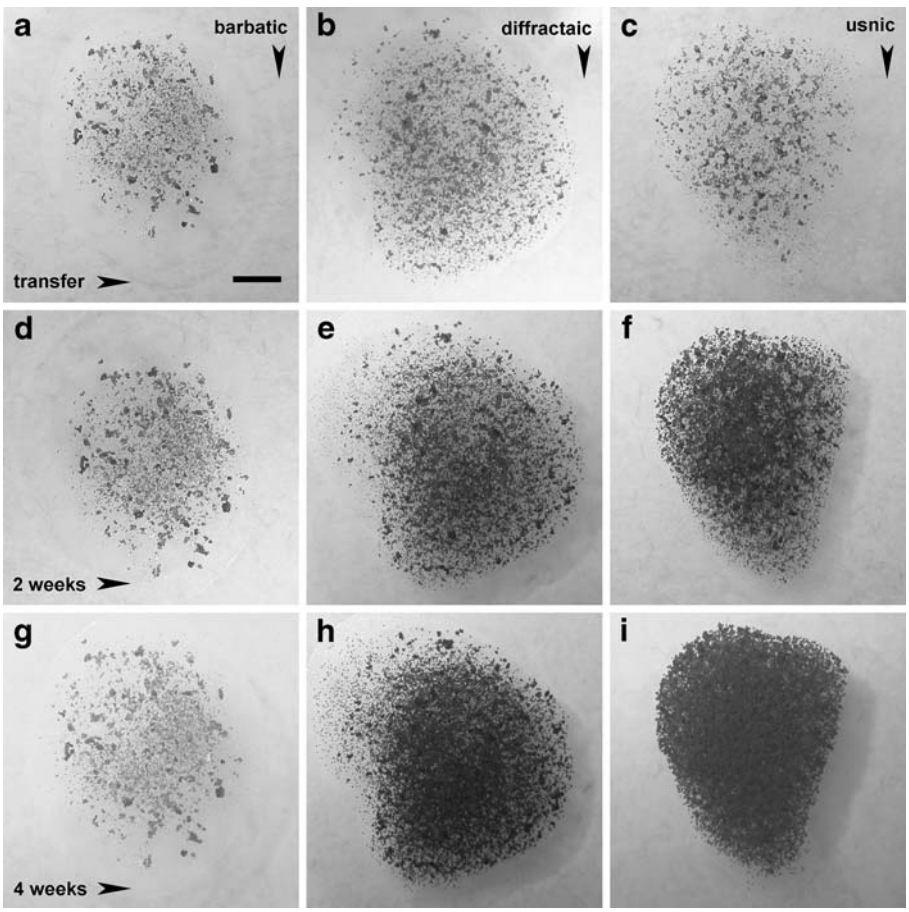

Fig. 5 Algal growth experiment example: growth over 1 mo of algal colonies on different lichen acid layers, concentration 2 mg cm^{-2}; *top*: algae on barbatic (**a**), diffractaic (**b**), and usnic acid (**c**) layer after transfer; middle: colonies on barbatic (**d**), diffractaic (**e**), and usnic acid (**f**) layer after 2 weeks; *bottom*: colonies on barbatic (**g**), diffractaic (**h**), and usnic acid (**i**) layer after 1 mo; *bar*=3 mm

Solhaug et al. (2003) for parietin, an anthraquinone that is known to act as an UV-protecting agent in the cortex of *Xanthoria parietina*.

While barbatic and diffractaic acids are known to be biologically active metabolites that act as inhibitors of specific functions such as cell division and growth, usnic acid is a molecule with manifold activities (Table 2; Ingólfsdóttir 2002). Although the molecules are closely related, our experiments and those of others indicate that barbatic and diffractaic acids exhibit diverging biological activities. Barbatic acid, for example, impairs the function of photosystem II in higher plants, whereas diffractaic acid has fungicidal properties (Nishitoba et al. 1987; Dayan and Romagni 2001, 2002; Takahagi et al. 2006). In agreement with these experiments, our test series showed that the growth of photobionts exposed to barbatic acid concentrations higher than 0.5 mg.cm^{-2} was inhibited, and a significant loss of vitality and cell-bleaching was observed. At such high concentrations, algae were killed depending on the lengths of exposure times. Whether cell death of the algae was caused by barbatic acid inhibiting photosystem II or due to another mode of action remains to be determined. The concentration of 0.5 mg.cm^{-2}, which corresponds to the quantity present in the *H. muelleri* thallus, slowed down cell division rates of the *Trebouxia* photobionts. This result clearly shows that barbatic acid acts as a regulating agent for algal growth and mitosis in the lichen.

Photobionts incubated on BBM+d and BBM+u were not affected in comparison to the negative control. Although Schimmer and Lehner (1973) reported that usnic acid inhibited the growth of the free-living unicellular green alga *Chlamydomonas reinhardii*, it had no impact on the growth of *Trebouxia jamesii* in our experiments. The increase in algal biomass on BBM+u was similar to that of the negative control. As usnic acid is accumulated solely in the thallus cortex, this outcome was expected. Effects of usnic acid on

Table 2 Overview of known activity of the lichen acids tested in this study

Metabolite	Activity	Publication
Barbatic acid	Inhibition of EBV activation	Yamamoto et al. 1995
	Non-redox inhibitors of Leukotriene B4 biosynthesis	Kumar and Müller 1999b,c
	PS II inhibitor	Dayan and Romagni 2001

	anticancer properties	Mayer et al. 2005

epibiontic algae that grow on the lichen have to be tested. Usnic acid has various biological activities in several plants and even humans. According to Swanson and Fahselt (1997) it also has important functions in the lichen itself, e.g., as UV protection. While usnic acid located in the cortex could act against uncontrolled propagation of epibiontic algae without having any impact on the photobiont, compounds such as diffractaic acid, deposited and accumulated by medullary hyphae, could effectively restrict the growth of endolichenic fungi (Dayan and Romagni 2001).

It has to be emphasized that the two depsides tested, diffractaic and barbatic acids, exhibit two fundamentally different biological activities, although the molecules differ merely in one functional unit (diffractaic acid has a CH_3-group at the side chain of C2, barbatic acid has a hydrogen), a phenomenon often observed by closely related biologically active substances. Further investigations are planned to identify the effects of barbatic acid on functional aspects of the lichen symbioses The investigated substances and their derivatives will be tested also on the photobionts of other lichens and on free-living algae, and their influence on the photosynthesis will be evaluated.

Acknowledgements We thank Prof. Jack Elix (ANU, Canberra, Australia) for help with the determination of the investigated lichens. ESt-W is appreciative of the opportunity to work in the cryptogamic herbarium of the Australian National Botanical Gardens in Canberra and expresses her thanks to Dr. Chris Cargill, curator of the lichen collections. During several stays in Canberra, the specimens of *Heterodea muelleri* and *H. beaugleholei* were collected for the culture experiments. We are grateful to the Austrian Science Foundation (grants P15328-B06 and P18210-B06) for support.

Barbarea vulgaris Glucosinolate Phenotypes Differentially Affect Performance and Preference of Two Different Species of Lepidopteran Herbivores

Hanneke van Leur · Louise E. M. Vet · Wim H. van der Putten · Nicole M. van Dam

Received: 19 October 2007 / Revised: 5 December 2007 / Accepted: 21 December 2007 / Published online: 23 January 2008

Abstract The composition of secondary metabolites and the nutritional value of a plant both determine herbivore preference and performance. The genetically determined glucosinolate pattern of *Barbarea vulgaris* can be dominated by either glucobarbarin (BAR-type) or by gluconasturtiin (NAS-type). Because of the structural differences, these glucosinolates may have different effects on herbivores. We compared the two *Barbarea* chemotypes with regards to the preference and performance of two lepidopteran herbivores, using *Mamestra brassicae* as a generalist and *Pieris rapae* as a specialist. The generalist and specialist herbivores did not prefer either chemotype for oviposition. However, larvae of the generalist *M. brassicae* preferred to feed and performed best on NAS-type plants. On NAS-type plants, 100% of the *M. brassicae* larvae survived while growing exponentially, whereas on BAR-type plants, *M. brassicae* larvae showed little growth and a mortality of 37.5%. In contrast to *M. brassicae*, the larval preference and performance of the specialist *P. rapae* was unaffected by plant chemotype. Total levels of glucosinolates, water soluble sugars, and amino acids of *B. vulgaris* could not explain the poor preference and performance of *M. brassicae* on BAR-type plants. Our results suggest that difference in glucosinolate chemical structure is responsible for the differential effects of the *B. vulgaris* chemotypes on the generalist herbivore.

Introduction

Glucosinolates and their breakdown products are involved in plant defense against a wide variety of potential plant enemies. They can also serve as feeding and oviposition stimulants for specialist herbivores (Chew 1988; Louda and Mole 1991; Wittstock et al. 2003). The composition of glucosinolates is genetically variable within plant species, and influences the feeding choices of insect herbivores (Kroymann et al. 2001; Lambrix et al. 2001). A heritable glucosinolate polymorphism in *Barbarea vulgaris* results in two discrete chemotypes (Van Leur et al. 2006). In this study, we investigate the effect of these two chemotypes on the preference and performance of two lepidopterans.

The most common and genetically dominant chemotype of *B. vulgaris* forms mainly (*S*)-2-hydroxy-2-phenylethyl glucosinolate (glucobarbarin, BAR-type). Although depending on the presence of cofactors like ESP, pH, or metal ions (Burow et al. 2006), the most likely initial hydrolysis product of glucobarbarin is an isothiocyanate. Due to the 2-hydroxylation of the glucosinolate side chain,

it spontaneously cyclizes to 5-phenyloxazolidine-2-thione (Kjaer and Gmelin 1957). This glucosinolate breakdown product is known to reduce infection by the soil fungus *Plasmodiophora brassicae* (Ludwig-Müller et al. 1999). Hardly anything is known about other ecological activities of oxazolidine-2-thiones (Wittstock et al. 2003).

The less abundant and genetically recessive chemotype of *B. vulgaris* contains mainly 2-phenylethyl glucosinolate (gluconasturtiin, NAS-type). 2-Phenylethyl glucosinolate is also present in *Arabidopsis thaliana* and other *Brassicaceae* (Reichelt et al. 2002), predominantly in root tissues (Sang et al. 1984). Its most likely breakdown product is 2-phenylethyl isothiocyanate. Isothiocyanates are the predominant breakdown products of glucosinolates and are generally toxic to various herbivores (Wittstock et al. 2003). 2-Phenylethyl isothiocyanate negatively affects a broad range of phytophages, e.g., nematodes (Potter et al. 1999, 2000; Serra et al. 2002; Lazzeri et al. 2004), snails (Kerfoot et al. 1998), flies, aphids, mites (Lichtenstein et al. 1962), fungi (Sarwar and Kirkegaard 1998), and several generalist and specialist Lepidoptera (Wadleigh and Yu 1988; Borek et al. 1998). Despite counter-adaptations of specialists to reduce or circumvent negative effects of glucosinolates (Ratzka et al. 2002; Wittstock et al. 2003), isothiocyanates can still reduce survival and growth, and increase development time of specialists (Agrawal and Kurashige 2003). In contrast to the oxazolidine-2-thiones formed in BAR-type plants, which can increase the incidence of goiter in mammals, the 2-phenylethyl isothiocyanate formed in NAS-type plants has chemopreventive effects against tumorigenesis in mammalian organisms (Canistro et al. 2004).

Based on the specific biological effects of the expected breakdown products of glucobarbarin and gluconasturtiin, we hypothesized that NAS-type and BAR-type *B. vulgaris* plants have differential effects on insect herbivores. Generally, it is expected that chemical plant defenses are more effective against generalist herbivores than against specialists (Cornell and Hawkins 2003). Therefore, we compared the preference and performance on the two chemotypes of a generalist (*Mamestra brassicae*) and a specialist (*Pieris rapae*) herbivore, which are both well-studied, important crucifer pests (Theunissen et al. 1985; Finch and Kienegger 1997).

M. brassicae is a generalist feeding on plants in 70 species and 22 families, of which Brassicaceae are among the most preferred (Rojas et al. 2000). Even though *M. brassicae* can detect glucosinolates by receptor cells on the sensilla (Wieczorek 1976), and its oviposition is stimulated by damaged cabbage plants (Rojas 1999), no physiological adaptations of this species to glucosinolates have been yet described. The larvae of *P. rapae*, on the other hand, can detoxify glucosinolates by shifting hydrolysis products from isothiocyanates to less toxic nitriles by using the myrosinase directing nitrile-specifier protein (NSP). This enables *P. rapae* to consume foliage that is otherwise well defended (Wittstock et al. 2003, 2004). Female adults of *P. rapae* can detect intact glucosinolates in leaves of Brassicaceae with specialized receptor cells, and are stimulated to lay eggs on glucosinolate containing plants.

We assessed herbivore preference on the level of adult oviposition and larval feeding. Female oviposition preference initially determines the host of the larvae (Akhtar and Isman 2003). As the isothiocyanates from NAS-type plants are expected to be more toxic than the oxazolidine-2-thiones produced by BAR-type plants, we expected *M. brassicae* to be repelled by NAS-type plants and to prefer BAR-type plants for oviposition. Oviposition of *P. rapae* is affected by glucosinolates at the leaf surface (Renwick et al. 1992; Van Loon et al. 1992) and known to be stimulated by glucobarbarin as well as by gluconasturtiin in a dose-dependent way (Chew 1988; Huang and Renwick 1994; Huang et al. 1994a, b).

As larvae can eventually leave their initial host (van Dam et al. 2000), we also assessed larval preference. If the *B. vulgaris* chemotypes differ in toxicity or palatability, we expect to see the largest effect on larval preference and larval performance for the unadapted generalist *M. brassicae* and no or minor effects on the glucosinolate specialist *P. rapae*.

Although we observed no differences in morphology, growth, or germination between the chemotypes (van Leur and van Dam, unpublished results), pleiotropic effects or close linkages could possibly cause other genes and metabolites to be consistently different between the chemotypes. As the nutritional value of plants is important for herbivore performance and preference (Simpson and Simpson 1990; Berenbaum 1995), additionally, we analyzed the sugar content and amino acid level of the tissue on which the herbivores were feeding.

Materials and Methods

Plant Material B. vulgaris seeds were collected from 10 individual BAR and their nearest neighbor NAS-type maternal plants, which were freely cross pollinated in a natural population of *B. vulgaris*. The population was located in Elderveld, The Netherlands (51.95°N; 5.87°E) and consisted of 22% NAS-type plants (Van Leur et al. 2006). We selected offspring of maternal NAS-type plants "EL44" (68% BAR-type offspring) and "EL13" (62% BAR-type offspring). Plants were grown in a glasshouse, at 21°C (day) and 16°C (night), with 60% relative humidity and natural daylight supplemented with sodium lamps to maintain the minimum PAR at 225 μmol m^{-2} s^{-1} with a photoperiod of 16:8 (L:D). One week after germination on glass beads, seedlings were transplanted to a mixture of

peat soil (Potgrond 4, Lentse Potgrond BV., Lent, The Netherlands) and 20% sand. After 2 weeks, the seedlings were transplanted to 1.1-l pots, watered, and fertilized regularly with half strength Hoagland's nutrient solution with a doubled KH_2PO_4 content.

Chemical Analysis For quantification of glucosinolates, soluble sugars, and amino acids, one global extraction was used. In a 2-ml Eppendorf tube, 50.0 mg of lyophilized finely ground plant material were dissolved in 1.0 ml 70% MeOH in water (*v*/*v*), vortexed, and immediately boiled for 5 min to kill the remaining myrosinase activity. Tubes were placed in an ultrasonic bath for 15 min and centrifuged (10 min 10,000 rpm). The extraction was repeated for the pellet omitting the boiling step. For each sample, both supernatants were combined in a new 2-ml Eppendorf tube and supplemented individually with 70% MeOH to attain the average mass (N=3) of a 2-ml Eppendorf tube that contained 2.0 ml 70% MeOH. This "stock" extract was stored at −20°C until further analysis.

Half (1.0 ml) of the stock extract was used for glucosinolate analysis and applied to a DEAE-Sephadex A 25 column (EC 1990), desulfated with arylsulfatase (Sigma, St. Louis, MO, USA) and separated on a reversed phase C-18 column on HPLC with a CH_3CN–H_2O gradient as described in van Dam et al. (2004). Glucosinolate analysis was performed with a PDA detector (200–350 nm) with 229 nm as the integration wavelength. Desulfoglucosinolate peaks were identified by comparison of HPLC retention times and UV spectra with authentic standards isolated from *B. vulgaris* as previously described (Agerbirk et al. 2001), as well as standards kindly provided by M. Reichelt, MPI Chemical Ecology, and a certified rape seed standard (Community Bureau of Reference, Brussels, code BCR-367R). The same response factor was used for glucobarbarin as for gluconasturtiin (Buchner 1987). To calculate glucosinolate concentrations in the plant tissue, the obtained values were multiplied by two and divided by dry mass.

To analyze soluble sugar content, a 10-µl aliquot of the stock extract was diluted with 990 µl MilliQ water. Soluble sugars were analyzed by injecting 5 µl of the diluted extract on Dionex HPLC system, equipped with a Carbopac PA1 column (2×250 mm) and a Carbopac PA1 guard column (2×50 mm, Dionex, Sunnyvale, CA, USA). An isocratic gradient mixture of 10% 1 M NaOH and 90% MilliQ water was used to separate sugars at a flow rate of 0.25 ml/min. Column temperature was kept at 20°C. A "10-ppm" reference solution that contained 54.9 µM sorbitol and manitol, 29.21 µM trehalose, sucrose, and melbiose, and 55.51 µM glucose and fructose, was diluted to obtain 7.5, 5, and 2.5 ppm calibration standards to obtain a reference curve. After every 10 samples, an additional standard was injected to check for deviations of retention times and the calibration curve. To calculate the molar concentration of sugars in the plant tissue, the concentration values were multiplied by 200 and divided by dry mass.

Amino acids were analyzed on a Dionex HPLC system by integrated pulsed amperometric detection. An aliquot of 20 µl of the stock extract was diluted with 980 µl MilliQ. Of this diluted extract, 25 µl were injected, and amino acids were separated with a ternary gradient (see DIONEX application update 152, Method 1, standard AAA gradient; condition 60/2 in Hanko and Rohrer 2004) on a 2×250 mm AminoPac© PA10 column with a 2×50 mm AminoPac© PA10 Guard column (Dionex, Sunnyvale, CA, USA). Eluents, flow rates, waveform, and working electrode conditions were all as specified under Method 1 in Dionex application update 152 and in Hanko and Rohrer (2004). The Sigma AA-S-18 amino acid standard (Sigma, St Louis, MO, USA) that contained 17 amino acids was supplemented with asparagine, glutamine, and tryptophane (2.5 µmol/ml each) to obtain a reference sample that contained the 20 most common amino acids. This reference solution was diluted to obtain calibration standard ranging from 1–8 µM for each amino acid, except for cysteine, which had a range of 0.5–4 µM. After every 10 samples, an additional standard was injected to check for deviations of retention times and the calibration curve. To calculate the molar concentration of the amino acids in the plant tissue, the concentration values were multiplied by 200 and divided by dry mass.

To determine the chemotype of each plant, glucosinolates were extracted from the first full grown leaf and analyzed on HPLC as described above. When the peak area of glucobarbarin divided by the peak area of gluconasturtiin was >10, the plant was considered a BAR-type. When this ratio was <0.1, it was considered a NAS-type.

Oviposition Insects were obtained from the Laboratory of Entomology of Wageningen University the Netherlands. Stock colonies of *P. rapae* and *M. brassicae* were maintained on *Brassica oleracea* var. *gemnifera* L., cultivar Cyrus, in a climatized room at 20–22°C, 50–70% relative humidity, and a photoperiod of 16:8 (L:D). We used ca. 4-month-old half-sib plants of family EL44 that were clipped 1 month before use to ensure abundant fresh leaf material. At the start of the experiment, plants were moved from the glasshouse to a climatized room at 21°C (day) 16°C (night), 60% relative humidity, illuminated to 200 PAR at plant height (Philips Master TLD 50W/840 HF and 60 W lights) and a photoperiod of 16:8 (L:D). In the same room, 1- to 3-day-old adult insects were held in a mesh cage (40×45×65 cm^3) provided with sugar solution. Males and females were held together to mate for at least 24 h. Oviposition preference was assessed by introducing individual pairs into one of the 11 oviposition mesh cages (40×45×65 cm^3) each containing one BAR-type and one NAS-type plant and

a source of sugar. Oviposition was checked every day at 10.30 and 15.30 h. *M. brassicae* oviposition was recorded 24 h after the first egg up to 7 days after introduction (N=68). *P. rapae* oviposition was recorded for at least 5 h after the first egg and up to a maximum of 24 h in total (N=35). Eggs deposited on the cage, pot, or on the label were not included in the analyses. To obtain sufficient replicates, four randomly chosen plants were used twice for *M. brassicae*, but oviposition preference was never tested on the same combination of plants.

Larval Preference For *P. rapae* as well as for *M. brassicae*, we used plants from EL44 and EL13 half sibs (one plant per chemotype per half-sib family and per herbivore). Two 0.9 cm diameter discs of each chemotype were cut from fully expanded leaves and placed in a circle (in an alternated design) in a 12 cm diameter Petri dish. We tested neonate larvae and 5-day-old larvae, which, until use, were feeding on *Brassica oleracea* var. *gemnifera* L., cultivar Cyrus leaves. The larvae were released individually at the center of the Petri dish with equal distance to all leaf discs (N=20 per species per age). After 4 h, the amount of leaf material consumed was recorded visually and categorized as follows: 0 = no damage, 1 = only consumption of the lower leaf layers, 2 = less then 10% was consumed, 3 = between 10% and 50% of the leaf disc was consumed, and 4 = more than 50% was consumed. We were not able to assign consumption categories in the experiment with neonates because they caused so little damage, but 5-day-old larvae showed distinct feeding patterns.

Larval Performance Larval performance was tested by forcing neonate larvae to stay on selected plants and measuring larval biomass and survival every other day. We selected forty 6-week-old plants (20 EL44 half sibs and 20 EL13 half sibs; 10 of each chemotype per half-sib family). To obtain a total of 80 plants, every plant was multiplied by cutting it into two halves and growing each plant in fresh pots. After 3 weeks, the plants were used to test performance of *M. brassicae.* Larvae were kept on the plant using 25 mm diameter meshed clip cages. After 4 days, these clip cages were replaced by 55 mm diameter meshed clip cages. After 8 days, *M. brassicae* larvae had consumed such large amounts of leaf tissue that the experiment had to be stopped. The remaining larvae were removed and weighed. All plants were clipped and after 3 weeks of regrowth used to asses performance of *Pieris* in the same way as we did for *M. brassicae*. However, *P. rapae* larvae were kept on the plants till day 18 when most larvae had pupated. Until day 4, each larva was feeding on a single leaf that we harvested to measure the consumed leaf area and sugar, glucosinolate, and amino acid content. These samples were considered to provide an estimate for the chemotype differences over the first 8 days of feeding.

The long-term performance of *M. brassicae* larvae was studied in a second experiment, in which three neonate larvae were placed on one plant (15 BAR and 15 NAS-type plants of EL 13). The larvae could freely move on the plant, but could not move to other plants due to a plastic cylinder and a water barrier around each plant. After 8 and 13 days, we determined larval mass and the number of dead or lost larvae. After 13 days on BAR-type plants, all but five larvae had died or were lost, so that we stopped the experiment. As dead larvae had often dried out, we excluded their biomass from all calculations.

Statistical Analysis In the oviposition preference experiments, total egg load may differ among individuals. Therefore, the number of eggs on each chemotype per individual female was treated as a paired sample. Per paired sample, we considered the chemotype with the highest egg load as the preferred type. Overall preference was tested with a Sign test. The number of eggs per plant and number of clusters per plant were not normally distributed, and were analyzed with the Wilcoxon matched-pair signed-ranks test. As there were no paired observations for cluster size, these data were analyzed with the Mann–Whitney U test.

To analyze larval preference, we compared the average food consumption category between the two chemotypes by using the Wilcoxon matched-pair signed-ranks test.

In the larval performance experiments, the larval masses were not normally distributed and therefore analyzed for differences between the chemotypes with separate Mann–Whitney U tests for each day followed by Bonferroni correction for multiple comparisons (for *M. brassicae* α=0.05/4=0.0125; for *P. rapae* α=0.05/8=0.0062). Data on the leaf consumption of each herbivore on the two chemotypes were also tested with the Mann–Whitney U test. The relationships between larval biomass and leaf consumption and between larval biomass and total glucosinolate concentration were tested by using Pearson product–moment correlations. The data were log-transformed to get a normal distribution. Before analysis of variance (ANOVA) total glucosinolate, sugar, and amino acid content data were log-transformed to meet the assumptions of ANOVA. Statistical analyses were performed with STATISTICA (data analysis software system), version 7.1. (StatSoft (2005); http://www.statsoft.com).

Results

Oviposition Preference Generalist and specialist adult herbivores did not prefer one chemotype over the other. Of the 68 *M. brassicae* females tested, 33.8% oviposited on the plants, 47.1% preferred to oviposit on the cage, whereas

19.1% did not oviposit at all within 1 week. The chemotypes did not receive significantly different numbers of eggs (Table 1). *M. brassicae*, which is a gregarious species, deposited a total of 19 clusters on BAR-type and 19 on NAS-type plants. The number of clusters per plant and the average cluster size, ranging from 6 to 465 eggs per cluster, were not significantly different between chemotypes (Table 1).

Of the 35 *P. rapae* pairs tested, 32 females oviposited on plants, two females did not oviposit at all, and one female died. With an average of 53.5±5.1 eggs per female, 61% deposited most eggs on NAS-type plants, and one deposited an equal amount of eggs on both chemotypes. The average numbers of eggs deposited on each chemotype did not significantly differ between chemotypes (Table 1). In total, BAR-type plants received 861 eggs and NAS-type plants 850 (Table 1).

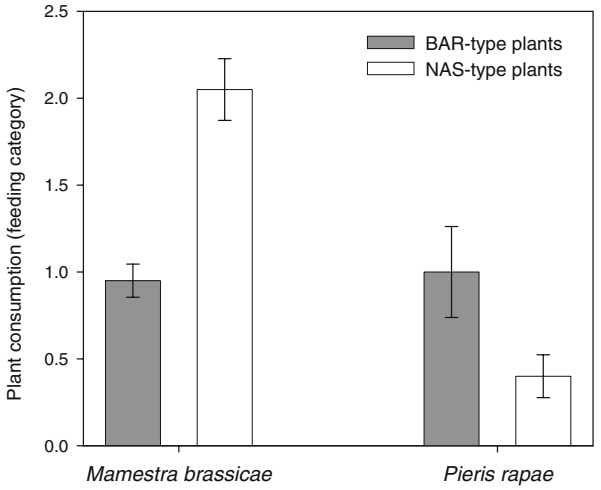

Fig. 1 Consumption of BAR-type (*grey bars*) and NAS-type (*white bars*) leaf discs by 5-day-old larvae of *Mamestra brasscicae* and *Pieris rapae* (feeding category averaged per Petri dish ± SE)

Larval Preference Of the 20 5-day-old *M. Brassicae* larvae tested, only one preferred to feed on BAR-type leaf discs, whereas 19 preferred the NAS-type (Sign test: $Z=3.67$, $P<0.001$). This preference for NAS-type leaf discs was confirmed when corrected for the consumed quantity (feeding categories). *M. brassicae* larvae consumed more from NAS-type leaf discs than from BAR-type (Fig. 1; Wilcoxon matched-pairs test on feeding categories: *M. brassicae* $N=20$, $Z=3.743$, $P<0.001$). In contrast, the 20 5-day-old *P. rapae* larvae did not show a significant preference. Five larvae preferred NAS-type, 11 BAR-type, and four consumed from BAR-type as well as NAS-type leaf discs (Sign test: $Z=1.25$, $P=0.211$). Although *P. rapae* larvae consumed more from BAR-type leaves, the difference in feeding categories was not significant (Fig. 1; Wilcoxon matched-pairs test on feeding categories: *P. rapae N=20,* $Z=1.629$, $P=0.103$). Consequently, we found no significant preference of *P. rapae* larvae for either chemotype.

Larval Performance and Chemotypes Over the first 8 days, the larval biomass accumulation of the generalist *M. brassicae* was affected by chemotype (Mann–Whitney *U* test: $P<0.001$ for each day of recording). When forced to stay on NAS-type plants, *M. brassicae* larvae grew exponentially (Fig. 2a). On BAR-type plants, however, *M. brassicae* larvae hardly increased in biomass and were moribund. This difference in performance was positively correlated to the difference in leaf consumption after 4 days of feeding (correlation analysis: $r=0.942$, $r^2=0.887$, $P<0.01$). Consequently, *M. brassicae* larvae caused more damage to NAS-type leaves than to BAR-type (Fig. 3a; Mann–Whitney *U* test: $U=12$, $Z=-7.583$, $P<0.001$). Larval survival after 8 days on the plants was in line with these results. On NAS-type plants, all larvae were still alive, whereas on BAR-type plants 37.5% of the *M. brassicae* larvae had died. The results of the second experiment, in which the larvae could move freely on the plants, confirmed the results of the clip cage experiment. After 13 days, 89% ±10 of the larvae had stayed and survived on

NAS-type plants and weighed 42.13±2.69 mg, whereas only 20% ±10 of the larvae had stayed and survived on BAR-type plants and weighed only 4.11±0.02 mg.

In contrast to *M. brassicae* larvae, *P. rapae* larvae grew and survived equally well on both chemotypes. *P. rapae* larval biomass accumulation over time showed no significant difference between chemotypes over the first 18 days (Fig. 2b; Mann–Whitney *U* test: $P>0.05$ for each day of recording) and was positively correlated to leaf consumption after 4 days (correlation: $r=0.768$, $r^2=0.589$, $P<0.01$). Leaf damage due to *P. rapae* feeding was not different between the chemotypes (Fig. 3b; Mann–Whitney *U* test: $U=673$, $Z=-1.217$, $P=0.223$). After 8 days, larval mortality was 7.5% on NAS-type and 12.5% on BAR-type plants. On day 14, the first *P. rapae* larvae started pupating. After 16 days on BAR-type plants, 45% had pupated, and on NAS-type plants this was 47.5%. At the end of the experiment, after 18 days, larval weights were still not significantly different on the chemotypes (on BAR-type: 161.9±7.37 mg, on NAS-type: 175.24±5.63 mg; Mann–Whitney *U* test: $U=238$, $Z=-1.131$, $P=0.265$).

Larval Performance and Total Glucosinolate Content The leaves on which larvae were feeding differed in glucosinolate composition (glucobarbarin vs. gluconasturtiin) and in total glucosinolate content (Fig. 3c,d). In both chemotypes, we detected glucobarbarin, gluconasturtiin, glucosibarin, glucobrassicin, 4-methoxyglucobrassicin, and neoglucobrassicin. In both families, BAR-type leaves had on average 1.5 times higher total glucosinolate levels than NAS-type leaves (Fig. 3c; ANOVA type effect: $F_{1,143}=22.831$, $P<0.001$). Because *M. brassicae* fed more on NAS plants, overall a negative—but weak—correlation of total glucosinolate content with the consumed leaf area was observed (correlation: $r(X,Y)=-0.26$, $r^2=0.065$, $P<0.05$). To analyze in more detail whether total glucosinolate level determines larval consumption and performance, we also examined the correlation *within* each chemotype. Within chemotypes, the range of glucosinolate concentrations was substantial (factor 6–7), but there was no negative correlation between glucosinolate level and larval biomass (Fig. 4; Correlation: within BAR, $r(X,Y)=0.15$, $r^2=0.024$, $P=0.932$; within NAS, $r(X,Y)=0.28$, $r^2=0.078$, $P=0.090$). Moreover, larvae on BAR-type leaves with similar low levels of glucosinolates as NAS-types consumed and performed considerably worse (Fig. 4; glucosinolate levels <35 μmol g^{-1} dry mass). There was also no difference in total glucosinolate level from BAR-type leaves on which the larvae survived or died (with living larvae: 31.32±2.95 μmol g^{-1}, with dead larvae: 32.81±6.49 μmol g^{-1}; ANOVA: $F_{1,29}=0.059$, $P>0.05$; Fig. 4). As the performance of *P. rapae* larvae was similar among chemotypes and families, there was no correlation of larval biomass with total glucosinolate level.

Larval Performance and Nutritional Value Total sugar content of both chemotypes was composed of five consistently detected sugars, which were glucose, sucrose, sorbitol, fructose, and trehalose (from high to low average concentration). Total amino acid content of both chemotypes was composed of 11 consistently detected amino acids, which were threonine, isoleucine, arginine, serine, glutamate, aspartate, glutamine, asparagine, phenylalanine, tyrosine, and histidine (from high to low average concentration). Because the individual sugars and amino acids showed effects similar to the total levels (results not shown), we only present data on total levels.

In contrast to the total glucosinolate level, sugar and amino acid content did not differ between the chemotypes (Fig. 3e–h). Although in the *M. brassicae* experiment the total sugar content was overall higher in BAR-type plants, there was a significant interaction between chemotype and family (Fig. 3e; ANOVA type effect: $F_{1,\ 75}=12.014$, $P<0.001$; type × family $F_{1,\ 75}=10.252$, $P<0.05$). Similar interactions between chemotype and family were shown for amino acid content of the plants in the *M. brassicae*

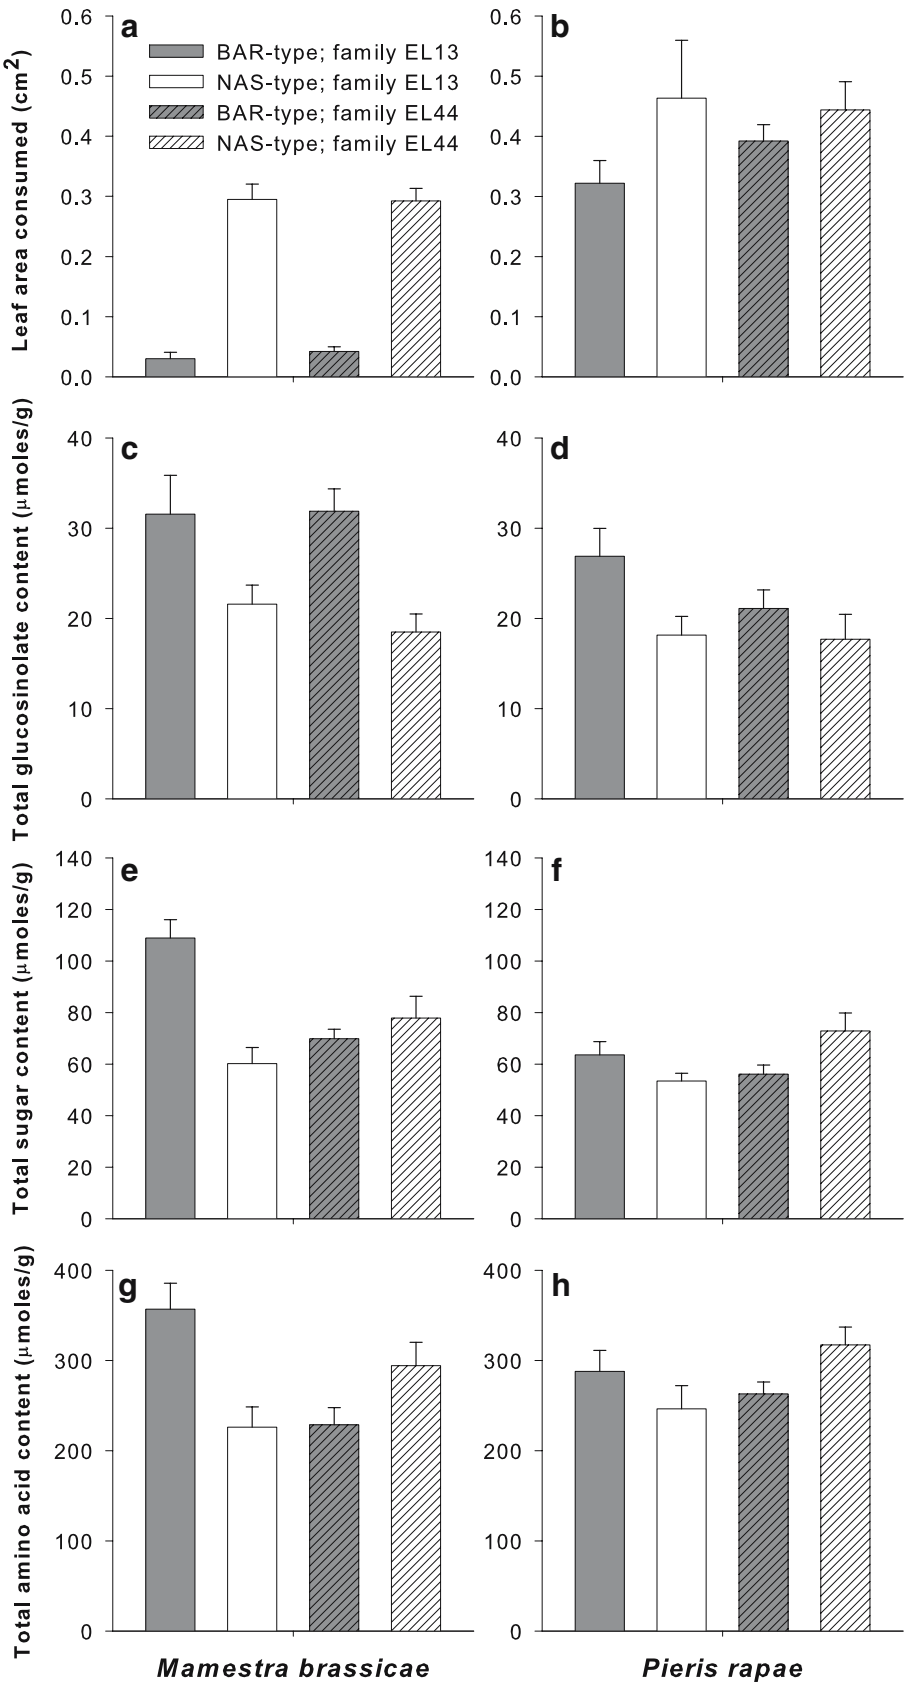

Fig. 3 Leaf characteristics after 4 days of larval feeding of *Mamestra brassicae* (*left graphs*) or *Pieris rapae* (*right graphs*) on *Barbarea vulgaris* ± SEM: **a** and **b** consumed leaf area (cm^2), **c** and **d** total glucosinolate content, **e** and **f** total sugar content, **g** and **h** total amino acid content. Results are depicted per chemotype (*grey bars* BAR-type plants; *white bars* NAS-type plants) and per half-sib family (*no hatching* EL13, *hatching* EL44)

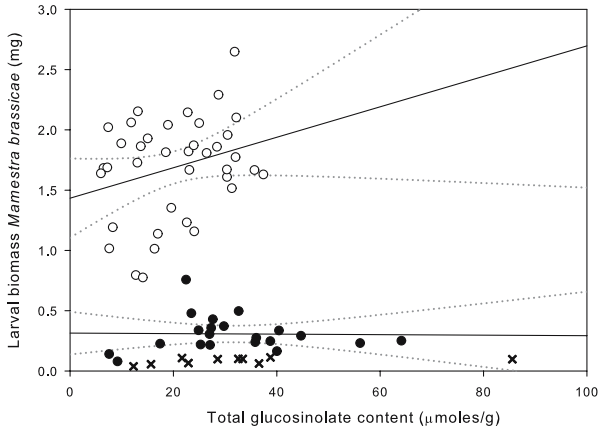

Fig. 4 Correlation of total glucosinolate content and the larval biomass after 4 days feeding of *Mamestra brassicae* experiment on NAS-type (*white dots*), BAR-type (*black dots*), and dead larvae of on BAR-type (*black crosses*) *Barbarea vulgaris* plants with their correlations per chemotype (*black line*) and their 95% confidence intervals (*dotted lines*)

experiment and for sugars and amino acid content of plants in the *P. rapae* experiment. In all chemotype × family interactions, the BAR-type of the EL13 half-sib family had higher levels of primary metabolites than the NAS-type of that family (Fig. 3e–h). In the EL44 half-sib family, the sugar and amino acid level differences of the chemotypes were negligible in plants during the *M. brassicae* experiment or even opposite to those of the EL13 during the *P. rapae* experiment. As sugar and amino acid content did not vary consistently with chemotype, these cannot explain the differences in larval performance and preference between the chemotypes.

Discussion

NAS and BAR chemotypes of *B. vulgaris* differentially affected preference and performance of the generalist herbivore *M. brassicae* but not the specialist *P. rapae*. Larvae of *M. brassicae* grew exponentially and had 100% survival on NAS-type leaves, but hardly grew and had a high mortality when feeding on BAR-type plants. As the dose-dependent effect of total glucosinolate content on herbivores is well-known (Li et al. 2000; Agrawal and Kurashige 2003; Mewis et al. 2006), the poor performance of *M. brassicae* could have been caused by the on average 1.5 times higher total glucosinolate content of BAR-type plants compared to NAS-type plants (Van Leur et al. 2006). However, we did not observe any dose-dependent effect *within* the chemotypes. Moreover, *M. brassicae* larvae on BAR-type plants with total glucosinolate levels similar to NAS-type plants still performed significantly worse. Hence, we exclude total glucosinolate level as explanatory factor for the differences found between chemotypes on larval biomass and leaf consumption.

In addition to total glucosinolate content, sugar and amino acid contents differed between chemotypes, but the pattern was inconsistent among half-sib families. The statistical interaction between chemotype and family found for sugar and amino acid levels was not found for herbivore performance and preference (Fig. 3). Therefore, total sugar content and total amino acid content can not explain the observed effects on *M. brassicae*.

In a different *B. vulgaris* polymorphism, described by Agerbirk et al. (2003b), there were P- and G-type plants that differed in resistance to *Plutella xylostella*. Other than our BAR/NAS polymorphism, the P-type and G-types also differed in trichome density, did not co-occur in natural populations, were hard to cross, and neither of the Danish types had a high content of gluconasturtiin in the leaves (Agerbirk, personal communication).The resistance of the G-type to *P. xylostella* was due to a difference in saponin content (Agerbirk et al. 2003a). Based on these findings, we compared saponin levels between BAR and NAS-type plants by using LC-TOF-MS (see supplemental data). This analysis revealed that the levels of the saponin described by Agerbirk et al. (2003a) and a saponin described by Shinoda et al. (2002) did not differ between the NAS and BAR chemotypes (supplemental data). Therefore, we exclude these saponins as an explanatory factor for the poor performance of *M. brassicae* on BAR-type plants.

The observed effects are likely caused by difference in glucosinolate structures and their break-down products. BAR-type plants were more toxic and deterrent to *M. brassicae* than the NAS-type plants. This suggests that *M. brassicae* can deal effectively with gluconasturtiin and isothiocyanates, but not with glucobarbarin and resulting oxazolidine-2-thiones. The latter compounds have received hardly any attention in chemical–ecological literature. Generalist herbivores possess broad-spectrum detoxification enzymes such as P450 enzymes and mixed-function oxidases (MFO) that enable them to deal with a wide range of allelochemicals, including glucosinolates (Schoonhoven et al. 1998; Li et al. 2000). Which detoxification mechanism is present in *M. brassicae* and why it can handle the presumably more toxic isothiocyanates, but not the oxazolidine thiones is unknown. The non-different performance of *P. rapae* on the chemotypes may indicate that NSP enzymes are equally effective in redirecting the hydrolysis pathways of both chemotypes towards the generally less toxic nitriles (Wittstock et al. 2004). Identification of the bioactive compounds could be acquired by using bioassay-guided fractionation.

Neither herbivore species significantly preferred one of the chemotypes as a host plant for oviposition. Even though isothiocyanates are known to elicit anemotaxis in herbi-

vores at extremely low concentrations (Finch and Skinner 1982), the concentrations of volatile cues emitted by our undamaged plants may have been below the detection limit (Finch et al. 1978). Upon damage or induction by herbivores, volatile levels may rise and affect oviposition preference (Rothschild and Schoonhoven 1977; Bruinsma et al. 2007). Next to chemical suitability, the surface on which to oviposit can be an important factor (Renwick and Chew 1994). In our experiment, however, leaf surface structure was unlikely to affect oviposition preference between chemotypes because the chemotypes did not have apparent differences in leaf surface (e.g., trichomes) in contrast to the completely different *B. vulgaris* polymorphism reported by Agerbirk et al. (2003b).

As *M. brassicae* larvae performed poorly on BAR-type plants, the lack of oviposition preference of adults seems to be non-adaptive. The discrepancy between larval performance and oviposition preference on *B. vulgaris* has also been shown for the Diamondback moth (*Plutella xylostella*) (Serizawa et al. 2001; Badenes-Perez et al. 2006). It may occur when insects or plants are new to an area and there has not been enough time for evolutionary adaptation (Agosta 2006). Whether this is the case for *M. brassicae* and the *B. vulgaris* chemotypes is unknown.

Co-evolutionary theory suggests that the variation of plant defense compounds is maintained by sequential adaptations of specialist herbivores and plants (Agrawal et al. 1999; Cornell and Hawkins 2003). The good performance of *P. rapae* on both chemotypes suggests that neither chemotype is effectively defended against this specialist. On the contrary, BAR-type plants are defended against the generalist *M. brassicae.* Although we have no experimental evidence indicating which chemotype is the newest form, the effective defense of BAR-type plants against *M. brassicae* suggests an evolutionary adaptive step in which BAR-type evolved from NAS-type. This matches with the biosynthetic origin of these glucosinolates. Gluconasturtiin is presumably the precursor that is hydroxylated to produce glucobarbarin. Moreover, gluconasturtiin occurs in five times more genera than glucobarbarin (Fahey et al. 2001). This does not preclude, however, that the NAS-types found locally in the Netherlands are due to a loss-of-function mutation from the BAR-type. In natural populations of *B. vulgaris*, there are only 0–22% NAS-type plants (Van Leur et al. 2006). This results in a potentially limited genetic basis for NAS-type plants compared to BAR-type plants, which could contribute to linkage disequilibrium between the BAR/NAS locus and other loci (for instance closely linked loci). However, the natural population from which we selected seed batches for these experiments had a phenotype frequency close to a Hardy–Weinberg equilibrium (22% potential NAS-type fathers observed instead of 25% expected). We estimate the chance of linkage disequilibrium effects in our experiments to be relatively small. Additionally, there are no *a priori* indications of closely linked loci that affect herbivore performance.

For the plant, the benefit of increasing its defense against *M. brassicae* will be larger than increasing its defense against *P. rapae*. Being gregarious and larger, *M. brassicae* larvae are more harmful to the chosen individual (many larvae feeding from one plant) and will more strongly reduce plant fitness than the solitary *P. rapae* (only one or few larvae feeding on a plant). Therefore, irrespective of the degree of specialization of the herbivores, it will be more important for *B. vulgaris* to be defended against *M. brassicae* than against *P. rapae.*

Based on our results, we would expect BAR-type plants in the field to suffer less from herbivory than NAS-type plants. Besides being the chemotype that is most severely damaged by *M. brassicae* larvae, the NAS chemotype is also the recessive genotype. Therefore, if herbivorous insects are the only selective force, we expect that natural selection will drive natural populations towards 100% BAR-types. European populations of *B. vulgaris* indeed are mainly dominated by BAR-type plants, but a minority number of populations has still up to 22% NAS-type plants. This indicates that in these populations there may be other factors that play a role in maintaining this chemical polymorphism. Other factors that may differ between the two types and that determine plant fitness, e.g., belowground herbivory, higher trophic level interactions, and inter- and intraspecific competition, need to be included in future studies.

Performance of Generalist and Specialist Herbivores and their Endoparasitoids Differs on Cultivated and Wild *Brassica* Populations

Received: 6 March 2007 / Revised: 26 December 2007 / Accepted: 7 January 2008 / Published online: 30 January 2008

Abstract Through artificial selection, domesticated plants often contain modified levels of primary and secondary metabolites compared to their wild progenitors. It is hypothesized that the changed chemistry of cultivated plants will affect the performance of insects associated with these plants. In this paper, the development of several specialist and generalist herbivores and their endoparasitoids were compared when reared on a wild and cultivated population of cabbage, *Brassica oleracea*, and a recently established feral *Brassica* species. Irrespective of insect species or the degree of dietary specialization, herbivores and parasitoids developed most poorly on the wild population. For the specialists, plant population influenced only development time and adult body mass, whereas for the generalists, plant populations also affected egg-to-adult survival. Two parasitoid species, a generalist (*Diadegma fenestrale*) and a specialist (*D. semiclausum*), were reared from the same host (*Plutella xylostella*). Performance of *D. semiclausum* was closely linked to that of its host, whereas the correlation between survival of *D. fenestrale* and host performance was less clear. Plants in the Brassicaceae characteristically produce defense-related glucosinolates (GS). Levels of GS in leaves of undamaged plants were significantly higher in plants from the wild population than from the domesticated populations. Moreover, total GS concentrations increased significantly in wild plants after herbivory, but not in domesticated or feral plants. The results of this study reveal that a cabbage cultivar and plants from a wild cabbage population exhibit significant differences in quality in terms of their effects on the growth and development of insect herbivores and their natural enemies. Although cultivated plants have proved to be model systems in agroecology, we argue that some caution should be applied to evolutionary explanations derived from studies on domesticated plants, unless some knowledge exists on the history of the system under investigation.

Introduction

The occurrence of pests in agroecosystems has long promoted the study of insect–plant interactions in crop plants, such as cabbage, lima bean, maize, cotton, and tomato (Takabayashi et al. 1994; Turlings et al. 1995; De Moraes et al. 1998; Geervliet et al. 2000; Thaler et al. 2001). Studies with crop plants have generated a wealth of data, highlighting a number of important mechanisms that influence the structure and function of multitrophic interactions and communities (Root 1973; Sheehan 1986; Khan et al. 1997; Gols et al. 2005). However, critics have argued that the biology and ecology of crop plants is often dramatically different from wild populations, thus bringing

into some question the evolutionary relevance of the conclusions generated from data that rely on crop plants (Benrey et al. 1998; van der Meijden and Klinkhamer 2000). For instance, plant breeding programs have been reported to disrupt the original plant defense strategies that were present in the wild progenitors of cultivated species (Evans 1993). Artificial selection of some crop plants, aimed at accentuating a specific plant trait or group of traits (e.g., the production of edible structures), has been shown to reduce the level of undesired constituents, such as defense compounds, while enhancing others (such as primary metabolites including proteins and sugars). Many of the undesired secondary plant compounds (SPC) are known to have evolved and function as putative defenses against herbivores, whereas the desired primary plant compounds act as nutrients and thus may actually enhance the performance of herbivores (Schoonhoven et al. 2005).

Levels of SPC are dynamic and vary with such factors as season, soil conditions, and leaf age (reviewed by Schoonhoven et al. 2005). Moreover, plants may increase their levels of defenses in response to feeding damage (Karban and Baldwin 1997; Agrawal 1999a), which may reduce the costs of defenses by avoiding the allocation of resources to defense when the attacker is absent. Secondary plant compounds have also been shown to affect negatively the development of higher trophic levels that attack these herbivores, such as predators, parasitoids, and even hyperparasitoids (Barbosa et al. 1986, 1991; Francis et al. 2001; Harvey et al. 2003, 2005, 2007; Ode et al. 2004). Consequently, changes in plant chemistry, mediated by artificial selection, may influence the behavior and development of consumers over several trophic levels, and this may ultimately lead to broader effects on the communities associated with these plants (Harvey et al. 2003; Ode 2006). Most importantly, in wild plants, defense mechanisms have not been constrained by the "directional selection" that characterizes many crop plants. Therefore, to understand the evolution of plant defenses against insect herbivores, multitrophic interactions should also be studied in wild conspecifics of the cultivated plant species where plant defenses are the likely result of a range of biotic and abiotic selection pressures.

One appropriate plant family for studying the effects of artificial *versus* natural selection on multitrophic interactions is the Brassicaceae, which contains such important crops as cabbages and various types of mustard (Gómez-Campo and Prakash 1999). Of all plants that have been domesticated, few have been manipulated to produce so many different cultivars as *Brassica oleracea* L. (e.g., cabbage, broccoli, cauliflower, and Brussels sprout; Gómez-Campo and Prakash 1999). Wild types of *B. oleracea* grow naturally along rocky coastlines of Britain and France (Mitchell and Richards 1979). It has been speculated that the wild populations in the UK are derived from plants that were cultivated by the Greeks and Romans in the Mediterranean region between 1,000 and 2,000 BC (Mitchell 1976). These early cultivated forms were introduced to Britain, but have been naturalized for centuries (Mitchell 1976). However, more recent evidence points also at an Atlantic origin of domestication (Song et al. 1990).

Plants in the Brassicaceae characteristically produce secondary metabolites called glucosinolates (hereafter GS) (Fahey et al. 2002). After tissue damage, myrosinases catalyze the hydrolysis of GS into (iso)thiocyanates and nitriles (Mithen 2001; Fahey et al. 2002), which play a role in defense against insect herbivores (Rask et al. 2000). Generalist herbivores produce enzymes that can detoxify a wide range of substrates (Krieger et al. 1971), whereas specialists have evolved enzyme systems that can detoxify specific plant compounds that are associated with herbivore diet (e.g., Johnson 1999; Ratzka et al. 2002). Thus, generalist herbivores are usually more sensitive to high levels of specific allelochemicals compared to specialists. (see e.g., Blau et al. 1978; Giamoustaris and Mithen 1995).

Specialist feeding on brassicaceous plants are adapted to plants containing GS, and they detoxify, excrete, or even sequester these harmful metabolites (Müller et al. 2001; Ratzka et al. 2002; Wittstock et al. 2004). Moreover, some insects use these compounds as indicators of food plant suitability (Nayar and Thorsteinson 1963; Renwick and Lopez 1999). Not all GS are equally effective as stimulants, and high levels of GS can reduce the performance of herbivores that are specialized on brassicaceous species (Stowe 1998; Li et al. 2000; Traw and Dawson 2002; Agrawal and Kurashige 2003). In addition, GS concentrations can increase in response to herbivore feeding damage (Bodnaryk 1992; Agrawal 1999b) and negatively affect subsequent herbivory by both generalists and specialists (Agrawal 1999b; Bartlet et al. 1999; Traw and Dawson 2002).

This study compares the development of several species of herbivores and endoparasitoids when reared on three *Brassica* populations that differ in their degree of domestication. Insects were reared on a cultivated and a wild population of *B. oleracea*, and a recently escaped (feral) *Brassica* species. Levels of GS were measured as indicators of direct plant defense. Initially, the development of two specialists on Brassicaceae, *Plutella xylostella* L. (Lepidoptera: Plutellidae) and *Pieris rapae* L. (Lepidoptera: Pieridae), and a generalist herbivore, *Mamestra brassicae* L. (Lepidoptera: Noctuidae), were examined when reared on the three populations. Finally, the development of a specialist and generalist parasitoid reared on the same host, *P. xylostella, were compared. Separate cohorts of P. xylostella were parasitized by two species of endoparasitoids, Diadegma semiclausum Hellén (Hymenoptera: Ich-*

neumonidae) and a related species, D. fenestrale Holmgren (Hymenoptera: Ichneumonidae). These two parasitoids differ in host specialization, with D. semiclausum restricted to P. xylostella and D. fenestrale attacking several other hosts that feed on non-brassicaceous species (Legaspi 1986; Azidah et al. 2000).

The following hypothesis was tested: specialist herbivores and parasitoids are less affected than generalists by differences in host plant chemistry between various *Brassica* populations that differ in their degree of domestication. It is proposed that changes in plant biology via domestication have significant effects on community level interactions and processes.

Methods and Materials

Plants The *B. oleracea* variety gemmifera (Brussels sprout) cv. Cyrus was used. Compared to other vegetable crops of *B. oleracea*, Brussels sprout cultivars contain relatively high levels of GS (Kushad et al. 1999; Rosa 1999), but considerably lower levels than the wild *B. oleracea* populations in Dorset, Great Britain (Moyes et al. 2000; Gols et al. 2008). Seeds from several plants (>10) were collected from a wild population of *B. oleracea* growing on chalk cliffs along the south coast of Great Britain, near Swanage, Dorset ("Old Harry," 50°38′N, 1°55′E). This population contains intermediate levels of GS compared to other Dorset wild populations (Moyes et al. 2000). A feral *Brassica* population, which was found in a roadside hollow about 15 km east of Wageningen (51°95′N, 5°78′E, The Netherlands), was also included.

In addition to comparing the development of different herbivores, we also compared the development of a specialist and generalist parasitoid reared on the same host (see section on *Plutella xylostella* and *Diadegma* species). To discriminate between food-plant quality mediated through the host and host quality itself, a second closely related wild brassicaceous plant species, black mustard, *Brassica nigra* L., was included in one of the experiments. Seeds of *B. nigra* were collected from a natural population growing in a small patch along the River Rhine, near Wageningen, The Netherlands (51°94′N, 5°62′E).

Seeds from the different populations were germinated in the first week of March 2005. Seedlings were transferred to 1.1 l pots filled with potting soil ("Lentse potgrond" no. 4, Lent, The Netherlands). Plants were grown in a greenhouse at 20–30°C, 40–80% r.h, with a photoperiod of at least 16 hr. If the light dropped below 500 μmol photons/m^2/sec during the 16-hr photoperiod, supplementary illumination was supplied by high-pressure mercury lamps. Plants were watered daily. After the plants were 4 wk old, they were fertilized once a week with Kristalon Blauw (N–P–K) 19–6–20–3 micro (2.5 mg/l), which was applied to the soil. *B. oleracea* plants were 7 wk old when they were used in experiments and attained similar amounts of biomass (25–30 g per plant). Plants from all three populations were in the vegetative state and developed new leaves during the experiments. Fertilization and watering continued during the experiments. *Brassica nigra* plants were 5 wk old and were not fertilized because the soil still contained enough nutrients for optimal growth. *B. nigra* matures much faster than *B. oleracea*.

Insects All insects used originated from cabbage fields in the vicinity of Wageningen. Cultures of all the herbivores have been maintained in the laboratory on Brussels sprouts cv. Cyrus for many years in climate rooms at 22±2°C, 40–80% r.h, with a light regime of 16:8 L/D. The two parasitoid species were collected in the summer of 2004 and were thereafter reared on plants heavily infested with *P. xylostella* larvae for several generations. After pupation on the walls of the rearing cage, parasitoid cocoons were carefully removed and transferred to a clean cage. Emerged adult wasps were provided with water and honey *ad libitum*. For parasitism, we used females that were 5 to 10 d old after adult emergence.

Glucosinolate Analyses As an indicator of direct defense, GS concentrations in leaf tissues of *B. oleracea* were measured. Leaf samples were taken during the performance experiments (see below) from three treatment groups: plants that were undamaged, plants damaged by unparasitized *P. xylostella*, and plants damaged by larvae that had been parasitized by *D. semiclausum*. When leaf samples were taken, the damaged plant groups had been exposed to herbivore feeding for 7 d. Undamaged control plants were maintained in the same greenhouse, but were physically separated from the plants with caterpillars. Larvae, feces, and pupae were removed from leaves. All fully developed leaves were harvested with the exception of the oldest leaves, which had turned yellow and did not contain feeding damage. Leaves were removed with a razor blade, pooled per plant, and stored at −80°C. Samples were later freeze-dried and pulverized with a mortar and pestle. Fifty milligram aliquots of freeze-dried material were weighed in 2-ml centrifuge tubes. GS were extracted and purified as described in van Dam et al. (2004) and were separated on a reverse phase C-18 column (Alltima C-18, 3 μm,150× 4.6 mm, Alltech, Deerfield, IL, USA) on HPLC (Dionex, Sunnyvale, CA, USA) with an acetonitrile water gradient. Detection was performed with a DIONEX PDA-100 Photodiode array detector set to scan from 200 to 350 nm. For quantification, sinigrin (Sigma, St. Louis, MO, USA) was used as an external standard. Peaks were integrated at

229 nm, for which standard response factors have been defined (EC 1990). The different GS were identified based on their retention times, and UV spectra were compared to those of pure compounds (sinigrin, Sigma, St. Louis, MO, USA; glucotropaeolin and glucobrassicin were kindly provided by M. Reichelt, Max Planck Institute for Chemical Ecology, Jena, Germany), or compared to a certified oil seed reference (EC Community Bureau of Reference BCR-367R, Fluka, Buchs, Switzerland).

Insect Performance To investigate the effect of domestication on plant direct defenses, the different herbivores and parasitoids (see below) were reared on the three plant populations. For all insects, egg-to-adult development time, adult dry mass, and survival (to adult) were determined when reared on the different populations. Adult dry mass was obtained by weighing adults on a Cahn C-33 microbalance (Cahn Instruments, Cerritos, CA, USA) that had been dried to constant weight at 80°C (3 d). Plants with insects were maintained in a greenhouse under the same conditions as described in the *Plant* section. Plants of the same population that received the same insect treatment were placed together, and caterpillars were allowed to develop and move around freely on plants until they reached the final instar. Different herbivore treatments were randomly positioned in a greenhouse, but were all placed in a similar position relative to the light sources to minimize microclimatic differences among plant populations and treatments.

Plutella xylostella and Diadegma Species To obtain eggs of *P. xylostella*, more than 150 adult moths were released with a 50:50 sex ratio in a plastic cage (37×40×30 cm). Folded strips of Parafilm served as substrate for females to lay eggs on. Females were allowed to oviposit on the Parafilm overnight. Subsequently, the strips with eggs were incubated for 4 d at 22°C until the eggs hatched. Pieces of Parafilm with neonate larvae were placed on top of individual plants of each of the three plant populations. Larvae were allowed to feed on these plants until they reached the third instar (L3).

For each plant population, one cohort of 60 larvae was transferred to new plants and served as an unparasitized control. A second cohort of 130 larvae was parasitized by *D. semiclausum*, and a third cohort of 180 larvae was parasitized by *D. fenestrale*. For parasitism, individual female wasps of both species were presented with a L3 *P. xylostella* host. A host was considered as parasitized when the female wasp was observed to insert into and remove her ovipositor from the larva. Individual female wasps were allowed to oviposit in up to 10 separate hosts. After this, they were removed. Parasitized larvae were transferred to new plants of the same population on which the larvae had fed previously. Five plants were used for the unparasitized controls and nine for each of the parasitoid treatments. The number of plants provided ample food for all larvae to complete their development.

When caterpillars molted into L4, strips of corrugated cardboard were placed on top of the plants, as *P. xylostella* prefers to pupate in secluded areas. After pupation, cocoons were collected and stored in labeled vials until adult emergence. When the moths or wasps emerged, the time of eclosion and sex were recorded. Individuals were killed by freezing at −20°C and stored for dry mass determination. Vials with cocoons ready to emerge were checked every 2 hr. Development time for *P. xylostella* was measured in full days, as the exact time of oviposition had not been recorded. In the case of the two *Diadegma* species, the median time point of the period needed to parasitize the hosts (3–4 hr) was used as the time of oviposition.

To further investigate whether food plant quality or host quality was a more important factor in the development of *D. fenestrale*, the experiments described above with *P. xylostella* were repeated on a second (and closely related) wild brassicaceous species, *B. nigra*. A separate study (Gols et al. unpublished) has shown that *B. nigra* is a qualitatively superior plant for the development of *P. xylostella*, compared with *B. oleracea*. We reared 33 unparasitized larvae on three *B. nigra* plants, and 180 larvae parasitized by *D. fenestrale* on 10 plants. We recorded egg-to-adult development time, adult biomass, and survival as before. The plants provided ample food for all the larvae to complete their development.

Pieris rapae Neonate larvae were obtained from the general culture and transferred to seven plants of each population with a distribution of six larvae per plant. When larvae had developed into L5, they were transferred to plastic containers that contained some leaf material from the plants they had fed on previously. After pupation, pupae were collected and placed in new plastic containers lined with filter paper. At adult emergence, the time of eclosion and sex were recorded, and the individuals were killed by freezing, followed by dry mass determination (as above). Containers with pupae ready to emerge were checked every 2 hr. Development time was measured in full days, as the exact time of oviposition had not been recorded.

Mamestra brassicae Like *P. xylostella*, adult *M. brassicae* are primarily nocturnal. Females do not need plants as an oviposition substrate and readily lay batches of eggs onto the surface of paper. From the general culture, we obtained paper sheets with *M. brassicae* eggs that were laid the previous night. These sheets were incubated at 22±2°C (5 d) until the eggs hatched. Neonate larvae were transferred to 10 plants of each population, with a density

of five larvae per plant. Once they had reached late L5, *M. brassicae* larvae were collected from the three populations, counted, and transferred to plastic containers (15×12×6 cm) that contained 2 cm of potting soil mixed with vermiculite (1:1) and some leaf material from the plant on which they had been feeding previously. After the larvae had pupated, they were collected and placed in new plastic containers filled with a layer of vermiculite. At moth emergence, the date of eclosion was recorded, and the individuals were killed by freezing, followed by dry mass determination. Containers with pupae ready to emerge were checked every 2 h. Development was measured in full days as the exact time of oviposition had not been recorded.

Statistical Analysis Data on adult dry mass and development time were analyzed by using ANOVA with plant population and sex and their interaction as factors. All larvae within one plant population were considered as independent samples. The Tukey–Kramer method was used for multiple comparisons of the means. For each insect species, a *G* test for heterogeneity was performed on survival rates of the three plant populations with H_0: survival on each of the three plant populations is equal.

Concentrations of individual GS compounds were log (x+1) transformed to meet assumptions of normality. To examine differences in GS content, a Mixed Model was used with plant population and plant treatment (intact, damaged by unparasitized *Plutella*, damaged by parasitized *Plutella*) as the fixed factors in the model. There was no random factor in the analysis, and the estimation of effects in the model was based on restricted likelihood maximization. When the main factors or their interactions were significant, specific linear contrasts were applied to separate further factor levels. When necessary, correction for unbalanced sample sizes was carried out by using the Satterthwaite correction. Analysis was carried out with SAS 8.02 (1999–2001 ©SAS Institute, Inc).

Results

Glucosinolate Analyses GS analyses of leaf tissues revealed considerable quantitative and some qualitative variation among the different *Brassica* populations (Fig. 1). Three pentyl-derived (C5) GS, glucoalyssin, gluconapoleiferin, and glucobrassicanapin were only detected in the feral population, whereas the other 10 compounds were present in all three populations (Fig. 1). Total GS concentrations in undamaged plants were 3.2 and 1.4 times higher in plants of the wild population than in the cultivated and feral populations, respectively (Fig. 1). Furthermore, concentrations of all individual compounds were significantly different among the three populations (statistics not shown, but all significance levels were lower than 0.05).

Differences between the cultivated and feral populations on the one side, and the wild population on the other side, became even more pronounced after the plants were induced by larval *P. xylostella* feeding (Fig. 1). In the cultivated and feral plants, total levels of GS remained at similar levels before and after induction by *P. xylostella* feeding (cultivar: t_{50}=0.82, P=0.42; feral population: t_{50}=0.39, P=0.70), whereas in the wild population, concentrations were 1.5–2 times higher after herbivore feeding (t_{50}=3.11, P<0.001). Levels of individual GS changed differentially in response to herbivore feeding. The indole GS, glucobrassicin, was induced by *P. xylostella* feeding in all the plant populations (t_{50}=6.90, P<0.001). Moreover, glucobrassicin accounted for almost 70% of the GS composition in the wild population after induction, and for only 53% and 35% in the cultivated and feral population, respectively. In contrast, the relative amount of glucobrassicin in undamaged plants was only 21%, 5%, and 25% in the cultivated, feral, and wild populations, respectively. A second indole GS, neoglucobrassicin, was also induced in response to herbivory in the feral (t_{50}=2.55, P=0.01) and the wild population (t_{50}=4.76, P<0.001), but not in the cultivated population (t_{50}=0.37, P=0.71) in which levels of this compound were very low.

Not all GS concentrations increased after herbivory. Sinigrin was reduced after *P. xylostella* larval feeding in the cultivated (t_{50}=2.4, P=0.02) and the wild population (t_{50}=3.67, P<0.001), but not in the feral population (t_{50}=0.07, P=0.95). Similarly, levels of glucoiberin decreased in response to *P. xylostella* feeding in the cultivar (t_{50}=2.79, P=0.007) and the wild population (t_{50}=4.22, P<0.001), but not in the feral population (t_{50}=0.02, P=0.99). In the feral population, both sinigrin and glucoiberin were present in much lower concentrations than in the other two populations (Fig. 1). In plants damaged by parasitized and unparasitized larvae of *P. xylostella*, concentrations of individual GS were not significantly different (statistics not shown, but all significance levels were lower than 0.05).

Insect Performance: Herbivores In *P. xylostella,* plant population and sex had an effect on egg-to-adult development time (plant population: $F_{2,\ 131}$=5.95, P=0.003; sex: $F_{1,\ 131}$=5.52, P=0.02; Fig. 2a). Female *P. xylostella* developed faster than males; the fastest development time was observed for females reared on the cultivated and the feral population. For adult biomass, the interaction between plant population and sex was significant ($F_{2,\ 132}$=11.1, P<0.001). Plant population had a strong effect on female but not on male biomass (Fig. 2b). The heaviest females were

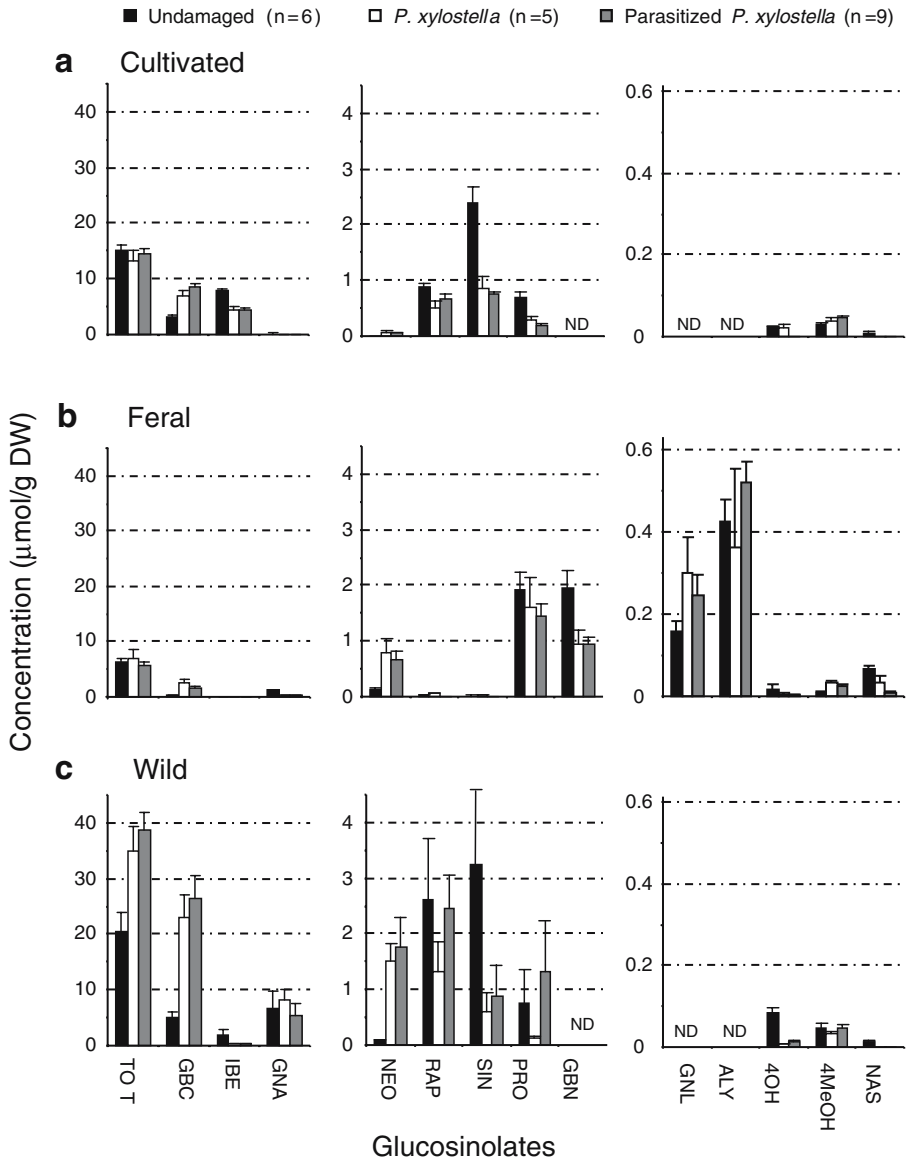

Fig. 1 Glucosinolate (GS) concentrations (mean ± SE) in leaf tissues of a cultivated (**a**), feral (**b**), and wild (**c**) *Brassica* population. Concentrations were measured in leaf tissue from plants that were undamaged (black bars), damaged by unparasitized *P. xylostella* larvae (white bars) and damaged by parasitized (*D. semiclausum*) larvae (gray bars). GS abbreviations and scientific names: *TOT* total GS concentration, *GBC* glucobrassicin (= indol-3-ylmethyl GS), *IBE* glucoiberin (= 3-methylsulfinyl propyl GS), *GNA* gluconapin (= 3-butenyl GS), *NEO* neoglucobrassicin (= 1-methoxyindol-3-ylmethyl GS), *RAP* glucoraphanin (= 4-methylsulfinyl butyl GS), *SIN* sinigrin (= 2-propenyl GS), *PRO* progoitrin (= 2(*R*)-2-hydroxy-3-butenyl GS), *GBN* glucobrassicanapin (= 4-pentenyl GS), *GNL* gluconapoleiferin (= 2-hydroxy-4-pentenyl GS), *ALY* glucoallyssin (= 5-methylsulfinyl pentyl GS), *4OH* 4-hydroxyglucobrassicin (= 4-hydoxyindol-3-ylmethyl GS), *4MeOH*, 4-methoxyglucobrassicin (= 4-methoxyindol-3-ylmethyl GS), and *NAS* gluconasturcin (= 2-phenylethyl GS). *ND* not detectable

recovered from the cultivar, and the lightest from the wild population. In contrast, males were significantly lighter than females ($F_{1,\ 132}$=317, P<0.001) and obtained similar biomasses on all three plant populations (Fig. 2b). For *P. xylostella*, plant population did not affect larval survival to the adult stage (χ^2=0.96, df=2, P=0.62, Fig. 3).

Development time also varied with the population on which the *P. rapae* larvae had been reared ($F_{2,\ 105}$=7.8, P< 0.001, Fig. 4a). Egg-to-adult development time of males was shortest on the cultivar, longer on the feral, and longest on the wild population (Fig. 4a). Males took longer to complete their development than females ($F_{1,\ 105}$=7.5, P= 0.007). Plant population also had a significant effect on adult biomass ($F_{2,\ 101}$=17.5, P<0.001, Fig. 4b). Whereas adult biomass in *P. rapae* did not differ between the cultivated and the feral line, biomass of butterflies reared on the wild population was lower (Fig. 4b). On average, females were marginally heavier than males ($F_{1,\ 101}$=3.2, P=0.08). Irrespective of plant population, more than 92%

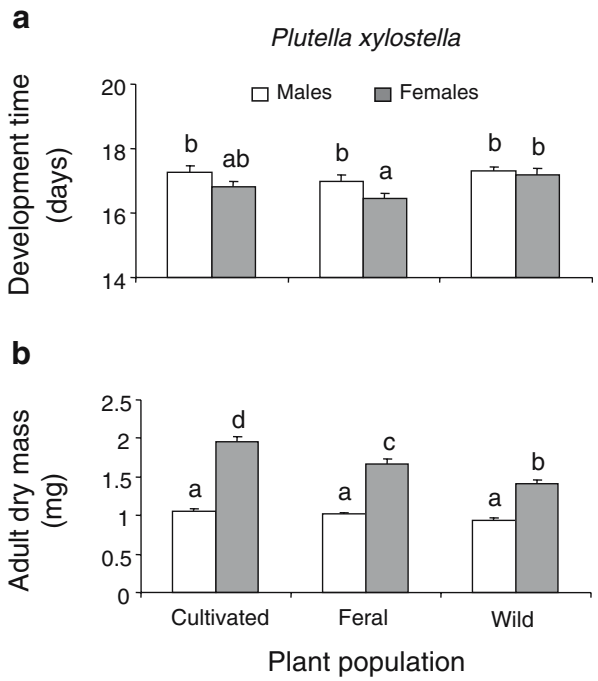

Fig. 2 Egg-to-adult development time (**a**) and adult dry mass (**b**) of *P. xylostella* males (white bars) and females (gray bars) reared on either a cultivated, a feral, or wild *Brassica* population. Bars (mean ± SE) with different letters are significantly different from each other (Tukey multiple comparisons, α=0.05). Numbers of individuals (*N*) were on the cultivar, escape, and wild population, respectively: males, 21, 22, and 31; females 23, 22, 18

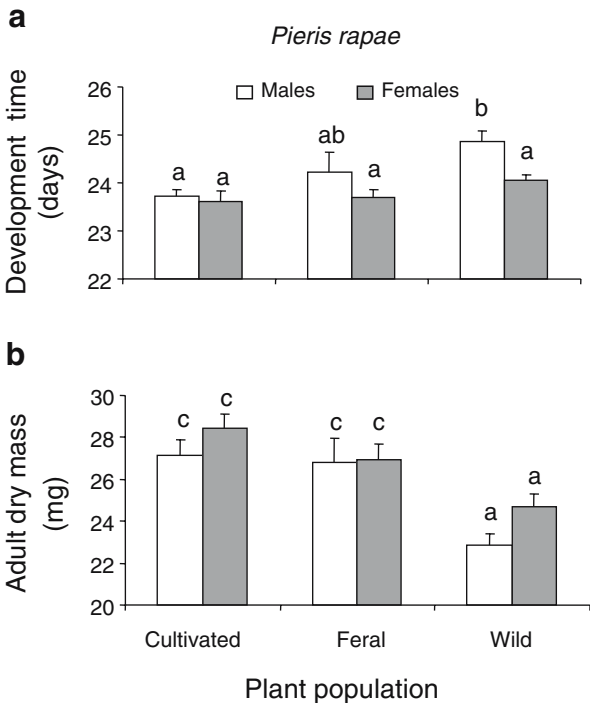

Fig. 4 Egg-to-adult development time (**a**) and adult dry mass (**b**) of *P. rapae* males (white bars) and females (gray bars) reared on either a cultivated, feral, or wild *Brassica* population. Bars (mean ± SE) with different letters are significantly different from each other (Tukey multiple comparisons, α=0.05). Numbers of individuals (*N*) were on the cultivated, feral, and wild population, respectively: males, 22, 10, and 19; females 16, 20, 20

of all *P. rapae* larvae successfully developed into adults, and survival rates were not significantly different (χ^2=0.22, *df*=2, *P*=0.90, Fig. 3).

In the case of the generalist herbivore, *M. brassicae*, the effect of host-plant population on adult biomass was more pronounced compared to the two specialists. It is difficult to determine the sex of adult moths, therefore, the data were pooled. Adult mass on the cultivated line was twice as high, compared to the wild population, and was also significantly higher on the feral population ($F_{2,\ 49}$=8.28, *P*<0.001, Fig. 5b). Plant population did not affect development time ($F_{2,\ 49}$=0.33, *P*=0.72, Fig. 5a). Unlike the two specialists, survival of *M. brassicae* was affected by plant population (χ^2=20.4, *df*=2, *P*<0.001, Fig. 3). The percentage of *M. brassicae* larvae that developed successfully into adults was highest on the cultivated population (58%), slightly lower on the feral population (42%), and the smallest (4%) on the wild population.

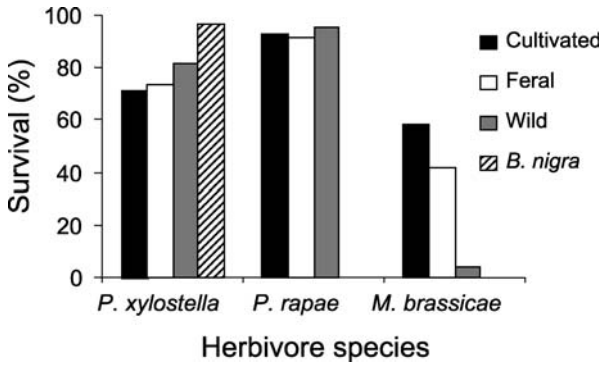

Fig. 3 Larval to adult survival of two specialist herbivores, *P. xylostella* and *P. rapae*, and one generalist, *Mamestra brassica*, when reared on either a cultivated, feral or wild *Brassica* population. *P. xylostella* was also reared on a wild population of *B. nigra*

Insect Performance: Parasitoids In the specialist parasitoid, *D. semiclausum*, plant population had an effect on egg-to-adult development time ($F_{2,\ 275}$=6.49, *P*=0.002, Fig. 6a). The parasitoid developed fastest on the feral population and developed more slowly on the cultivated and wild populations of *B. oleracea* (Fig. 6a). Egg-to-adult development time was longer in females than in males ($F_{1,\ 275}$=13.0, *P*<0.001). Furthermore, plant population had an effect on adult biomass in *D. semiclausum*, ($F_{2,\ 277}$= 11.3, *P*<0.001, Fig. 6b). The heaviest *D. semiclausum* wasps emerged from hosts that were reared on the cultivated population, whereas the lightest emerged from host reared on the wild and feral populations. *D. semiclausum* females were heavier than males ($F_{1,\ 277}$=57.4,

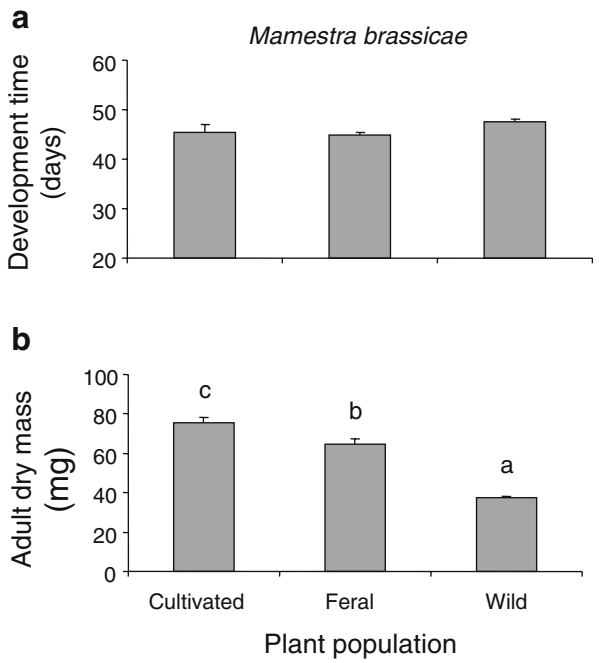

Fig. 5 Egg-to-adult development time (**a**) and adult dry mass (**b**) of *M. brassicae* reared on either a cultivated, feral, or wild *Brassica* population. Bars (mean ± SE) with different letters are significantly different from each other (Tukey multiple comparisons, α=0.05). Numbers of individuals (*N*) were on the cultivated, feral, and wild population, respectively: 21, 29, and 2

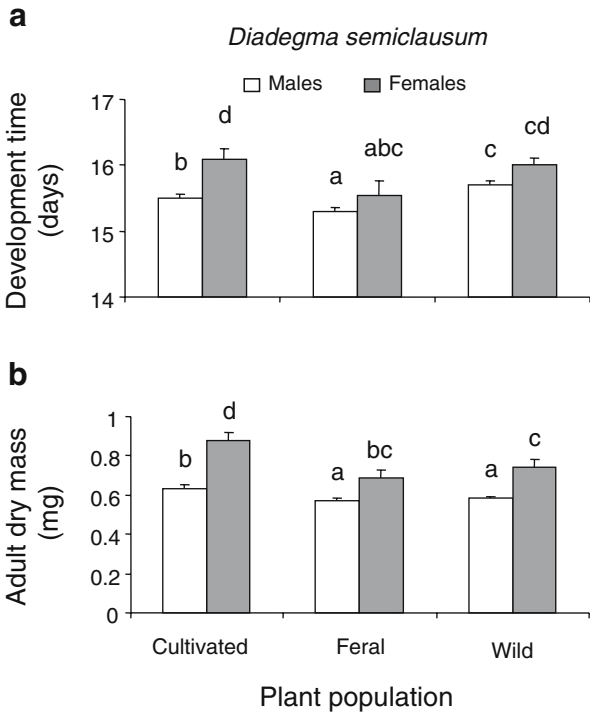

Fig. 6 Egg-to-adult development time (**a**) and adult dry mass (**b**) of *D. semiclausum* males (white bars) and females (gray bars) reared on *P. xylostella* feeding on either a cultivated, feral, or wild *Brassica* population. Bars (mean ± SE) with different letters are significantly different from each other (Tukey multiple comparisons, α=0.05). Numbers of individuals (*N*) were on the cultivated, feral, and wild population, respectively: 87, 69, and 81 for males and 11, 12, 10 for females

P<0.001). Between 67 and 80% *D. semiclausum* successfully completed development to eclosion on the three *Brassica* populations (Fig. 7). Survival rates were not significantly different on the three plant populations (χ^2= 3.77, *df*=2, *P*=0.15).

As with *D. semiclausum*, egg-to-adult development time in *D. fenestrale* varied with plant population ($F_{2,\ 69}$=5.27, *P*=0.007, Fig. 8a). However, dry mass in male *D. fenestrale* wasps did not vary significantly with the population on which the hosts had been reared ($F_{2,\ 69}$=0.25, *P*=0.78, Fig. 8b). As only thirteen *D. fenestrale* females in total successfully developed, data on females were excluded from the analysis and are not presented in the figures. The most dramatic effect of plant population was on the survival of *D. fenestrale* (Fig. 7), which was significantly different for the three plant populations (χ^2=12.2, *df*=2, *P*=0.002). Only 9% of the parasitized hosts reared on the wild population successfully produced *D. fenestrale* wasps. By contrast, 33% survived on the cultivar and 16% on the feral population. Moreover, the lowest number of surviving *D. fenestrale* parasitoids, eight out of 172 (or 4.6%), was obtained on *B. nigra*. Male wasps (*N*=5) developing in hosts reared on *B. nigra* plants were lighter (0.432± 0.033 mg, mean ± SE) and developed slower (17.8±0.37 d) than males reared from hosts on *B. oleracea* (see Fig. 6).

In contrast, healthy *P. xylostella* moths performed better on *B. nigra* than on *B. oleracea,* in terms of survival (97%, Fig. 3) and adult mass, 1.985±0.068 mg (*N*=16) and 1.104± 0.068 mg (*N*=16), for females and males, respectively (see also Fig. 2b). However, development time, 17.8±0.26 d for both female and male moths, was slightly longer (see also Fig. 2a).

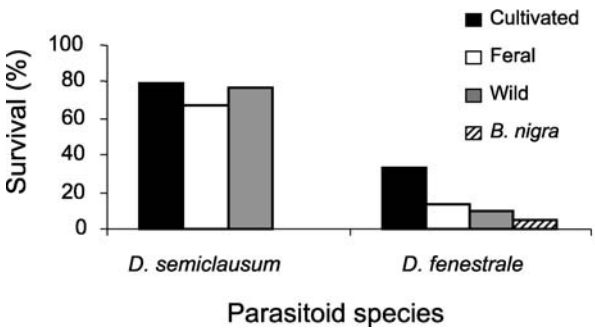

Fig. 7 Egg-to-adult survival of a specialist parasitoid, *D. semiclausum*, and a generalist parasitoid, *D. fenestrale*, when reared from the host, *P. xylostella,* on either a cultivated, feral, or wild *Brassica* population. *D. fenestrale* was also reared from *P. xylostella* on a wild population of *B. nigra*

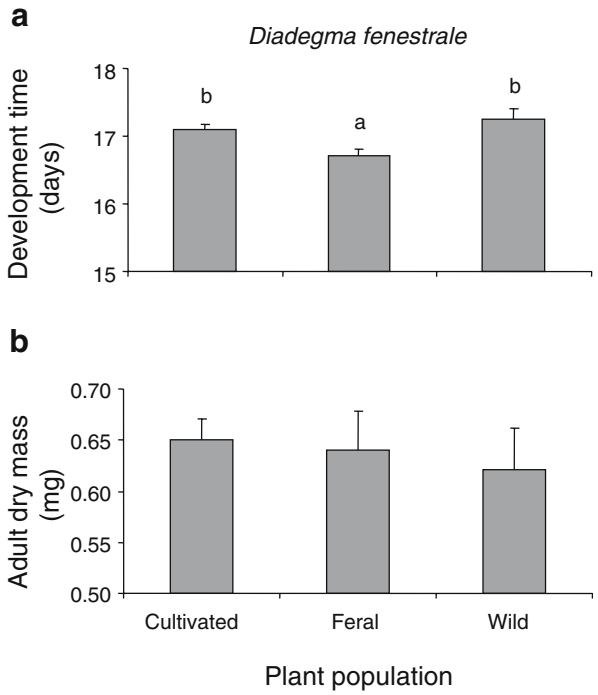

Fig. 8 Egg-to-adult development time (**a**) and adult dry mass (**b**) of *D. fenestrale* males reared on *P. xylostella* feeding on either a cultivated, feral, or wild *Brassica* population. Bars (mean ± SE) with different letters are significantly different from each other (Tukey multiple comparisons, α=0.05). Numbers of individuals (*N*) were on the cultivar, escape, and wild population, respectively: 44, 18, and 14

Discussion

Through artificial selection via domestication, levels of primary and secondary compounds in domesticated plants are often altered compared with their progenitors. The results of this study revealed that GS concentrations in leaf tissue varied significantly among the three different plant populations. Much higher concentrations of GS were recorded in wild *B. oleracea* than in cultivated and feral population. GS levels in the wild population studied in this paper were similar to concentrations reported earlier in other wild populations of *B. oleracea* (Mithen et al. 1995; Moyes et al. 2000). The most striking differences in GS concentrations were observed after induction by herbivore feeding, especially in the wild population. In wild plants, total GS concentrations were 1.7 times higher in induced plants than in uninduced conspecific plants, and were 2.7 and 4.9 times higher after herbivory than in induced plants of the cultivated and feral population, respectively. By contrast, the total GS concentrations in induced plants remained at the same level as in undamaged plants in the cultivated and feral populations, although differences were found for levels of individual compounds.

The feral population differed from the other two populations with respect to pentyl-derived GS, which were absent in the cultivated and wild population. These C5 GS usually are not found in *B. oleracea* crops (Rosa 1999), indicating that this population may have crossed with a closely related species such as *B. napus* or *B. rapa*, both of which contain pentyl GS (Giamoustaris and Mithen 1995). Moreover, both *B. napus* and *B. rapa* are cultivated and grow naturally in the Netherlands. In all plant populations, concentrations of the indole GS, glucobrassicin, increased the most after herbivore feeding, but this compound was dominant only in the wild population, accounting for 70% of the GS content. Several studies have reported on herbivore-induced changes in GS concentrations in both cultivated and wild brassicaceous species. In line with our results, previous studies have shown that levels of indole GS increase in response to insect wounding (Bodnaryk 1992; Agrawal et al. 1999; Bartlet et al. 1999; Gols et al. 2008). We found that concentrations of some of the aliphatic GS were lower in plants that had been damaged by *P. xylostella* than in undamaged plants. Previous studies that used different herbivores reported that levels of aliphatic GS were either unaffected (Bodnaryk 1992; Bartlet et al. 1999; Traw and Dawson 2002; Gols et al. 2008) or even increased (Traw and Dawson 2002) in response to insect wounding. These results suggest differential induction of aliphatic GS by different herbivores (see also Traw and Dawson 2002).

Glucosinolates also play a major role in determining a plant's nutritional quality, not only for humans and livestock but also for pathogens and insect herbivores (Chew 1988; Mithen 1992). This study shows that plants from a wild population of *B. oleracea* are less suitable for the development of several herbivores than plants from a cultivated and a feral population. However, the severity of these effects differed between the specialists *P. rapae* and *P. xylostella* on one hand, and the generalist *M. brassicae* on the other. In *P. rapae*, emerging adult butterflies were smaller and took longer to complete development when reared on wild plants than on the other two populations. These effects were less pronounced in *P. xylostella*; however, where adult body mass was more negatively affected than development time. Importantly, in both of the specialist herbivores, survival was high, irrespective of the plant population on which the larvae had been reared. By contrast, adult body mass and survival in the generalist herbivore, *M. brassicae*, were significantly lower when reared on the wild *B. oleracea* strain. This reveals that costs in terms of reduced fitness are higher for generalist herbivores than for specialists when they feed on the more toxic wild plants. Similarly, Giamoustaris and Mithen (1995) found a negative relationship between GS content in oilseed rape (*B. napus*) and the amount of leaf damage by generalist herbivores, but a positive relationship for specialists. Levels of GS, especially indole GS, were higher in the wild population of *B. oleracea* than levels of GS found in *B. napus* by Giamoustaris and Mithen (1995). These results suggest that indole GS,

especially neoglucobrassicin, which is present in very low concentrations in the cultivar, may play a role in reducing the performance of insect herbivores.

Specialist insect herbivores, in contrast with generalists, may use GS as indicators of host plant suitability. For example, GS serve as feeding stimulants for insect herbivores specialized on plants belonging to the Brassicaceae (Nayar and Thorsteinson 1963; David and Gardiner 1966; Renwick and Lopez 1999). However, not all GS are equally active as feeding stimulants (e.g., Nayar and Thorsteinson 1963), and high levels of GS can even be toxic for specialists (Agrawal and Kurashige 2003). As such, high levels of specific GS may be responsible for the reduced performance of the specialists *P. xylostella* and *P. rapae* when reared on the wild population. Furthermore, levels of the enzyme myrosinase, which catalyzes hydrolysis of GS into the more toxic (iso)thiocyanates and nitriles (Rask et al. 2000; Mithen 2001), may also have differed among the populations. In addition, host plant quality is not determined only by the presence of allelochemicals. Nutrients, such as proteins and carbohydrates, as well as digestibility reducers, also play a role (Slansky 1993). It is possible that levels of limiting nutrients such as nitrogen and other defense-related compounds also vary across the three populations and thus amplify differences in performance caused by GS (Slansky and Feeny 1977).

The performance of the two parasitoid species reared on *P. xylostella* also varied with the plant population on which the host had been reared. However, there were also significant differences in performance between the specialist parasitoid, *D. semiclausum*, and the congeneric generalist parasitoid, *D. fenestrale*. The development of *D. semiclausum* was directly affected by the development of the host. Adult body mass was reduced when developing on wild *B. oleracea* plants, whereas development time and survival were unaffected, revealing that *D. semiclausum* ontogeny is affected by quantitative changes in host quality as mediated through the diet of their host. Alternatively, the development of *D. fenestrale* was characterized less by direct differences in host quality than by indirect population-related variations in plant quality. Although *P. xylostella* survival was high (>80%) on all *B. oleracea* populations, as well as on *B. nigra* plants, mortality in *D. fenestrale* was much higher on the wild *Brassica* populations.

As in most endoparasitoids, larvae of *D. fenestrale* primarily consume host hemolymph and fat body during early development. They only begin to indiscriminately attack other tissues later during development (the so-called "destructive feeding phase"). In this way, they do not kill the host until the last possible moment. Larvae of *P. xylostella* are known to utilize enzymes that convert GS into desulfo-GS in their gut, which are then excreted with their feces (Ratzka et al. 2002). Because of their polarity, GS presumably do not permeate the host-gut membrane but effectively remain in the gut before they are excreted. Consequently, the larvae of *D. fenestrale* probably ingest little, if any, GS when feeding on hemolymph. However, during the destructive feeding phase, the parasitoid larvae undoubtedly consume the host gut and its contents, and this is when the toxic effects of plant allelochemicals on non-adapted parasitoids may be realized. In hosts parasitized by *D. fenestrale,* mortality mainly occurred just before the parasitoids would have been expected to pupate (personal observation) supporting this argument. Furthermore, the gut of endoparasitoid larvae is not externally connected until after emergence from the host. The excretion of wastes into internal host tissues would facilitate bacterial infection and precocious death of both the host and the developing parasitoid (Harvey et al. 2003). Thus, low concentrations of allelochemicals that are ingested by parasitoid larvae are stored and presumably accumulate in their tissues. This may account for the high mortality recorded here with *D. fenestrale* that developed in *P. xylostella* caterpillars reared on mustard and wild cabbage plants, which contain high levels of GS.

All insects used in this study have been reared on the Cyrus cultivar for many generations and may have adapted to this plant population. However, *P. xylostella* developed more successfully on *B. nigra* plants than on the cultivar, with moths enjoying higher survival and larger body mass. Furthermore, the performance of *Mamestra brassicae* and *Pieris rapae* was almost similar on the feral and the cultivated population. We cannot exclude that the observed differences are the result of rearing history rather than true plant effects, but the fact that the insects have no history with the recently cultivated feral population of *B. oleracea* and developed with equal success as on the cultivar suggests that plant quality is affected by domestication. Moreover, the development of the insects was more strongly negatively affected on the wild "Old Harry" population than on the feral population.

In summary, this study has shown that plant quality in terms of development of herbivores and their natural enemies differs significantly between wild and cultivated populations of *B. oleracea*. The identity of the food plant and the degree of specialization exhibited by the herbivores and their parasitoids influenced the degree to which plant population affected performance. Most importantly, these results demonstrate that artificial selection in which certain plant traits are accentuated at the expense of others can alter a significant part of a plant's evolved physiology. This may in turn have large impacts on insect communities that are associated with these plants. In wild plants, defense mechanisms have evolved under natural selection pressures from herbivores and pathogens and by the effects of natural enemies on herbivore populations. The reduction of the levels of direct defenses in cultivated plants could partly

explain why these plants have often become more susceptible to attack from a wide range of herbivores and pathogens. To better understand the relative contribution of insect herbivory as a selective agent on the evolution of plant defenses, these traits should be studied in wild populations in which defense mechanisms have not been constrained by the "directional selection" that characterizes many species of crop plants. Future studies should examine insect communities associated with plant populations, including cultivars that differ in resistance against insect herbivores in plots in which the structural heterogeneity is also manipulated. This will facilitate a better understanding of the role that artificial selection has played in shaping the structure of communities associated with cropping systems.

Acknowledgments The authors thank André Gidding and Leo Koopman for rearing the insects and Unifarm for rearing the plants. Ciska Raaijmakers from the Netherlands Institute of Ecology is acknowledged for her assistance in the GS analyses.

Phenolic Metabolites in Leaves of the Invasive Shrub, *Lonicera maackii*, and Their Potential Phytotoxic and Anti-Herbivore Effects

Don Cipollini · Randall Stevenson · Stephanie Enright · Alieta Eyles · Pierluigi Bonello

Received: 12 November 2007 / Revised: 5 December 2007 / Accepted: 28 December 2007 / Published online: 23 January 2008

Abstract *Lonicera maackii* is an invasive shrub in North America for which allelopathic effects toward other plants or herbivores have been suspected. We characterized the major phenolic metabolites present in methanol extracts of *L. maackii* leaves. In addition, we examined the effects of methanol–water extracts of *L. maackii* leaves on seed germination of a target plant species and on feeding preference and growth rate of a generalist insect herbivore. A total of 13 individual major and minor compounds were detected in crude leaf extracts by high-performance liquid chromatography coupled to electronspray ionization-tandem mass spectrometry (ESI-MS/MS). Extracts were dominated by two major flavones, apigenin and luteolin, and their glucoside derivatives, apigenin-7-glucoside and luteolin-7-glucoside. Quantities of these compounds, along with chlorogenic acid, varied between two sampling points. Leaf extracts that contained these compounds were inhibitory to seed germination of *Arabidopsis thaliana*. In addition, treatment of artificial diet with leaf extracts deterred feeding of the generalist herbivore, *Spodoptera exigua*, in choice experiments but had no effect on growth rate in short-term no-choice bioassays. Purified apigenin tended to deter feeding by *S. exigua* and inhibited seed germination of *A. thaliana*. We conclude that leaves of *L. maackii* contain phenolic compounds, including apigenin and chlorogenic acid, capable of having biological effects on other plants and insects.

Introduction

After receiving a great deal of scrutiny in the 1970s and 1980s, allelopathy has received renewed attention in part because of its potential to explain the dramatic success of some invasive plants (Hierro and Callaway 2003). Allelochemicals produced by invasive plants can contribute to their success and spread in several ways. For example, allelochemicals can inhibit growth of competing vegetation through direct or indirect means, thus providing the invader with a competitive advantage (Callaway and Aschehoug 2000; Ridenour and Callaway 2001). In addition to effects on other plants, allelochemicals produced by invasive plants can also contribute to insect and disease resistance and thus confer a competitive advantage to the invader in the introduced range (e.g., Haribal and Renwick 1998). In some cases, the same compound (or closely related structures) can have effects on multiple receiver species (Bais et al. 2002).

Lonicera maackii (Amur honeysuckle, Caprifoliaceae) is a Eurasian shrub that is invasive in eastern North America. The plant has devastating effects on forest understory

vegetation, which is due in large part to the intense shading this shrub imposes, along with competition for soil resources (e.g., Collier et al. 2002). Some of its effects may be mediated by allelopathic chemicals, but this phenomenon has been little studied. Trisel (1997) showed that both whole leaves and aqueous leaf extracts of *L. maackii* could inhibit germination of *Fraxinus* seeds and survival of *Acer* seedlings. Dorning and Cipollini (2006) showed negative effects of aqueous leaf and root extracts on germination of several wild herbaceous species, while Cipollini et al. (2008) showed negative effects of aqueous leaf extracts on growth and reproduction of *Arabidopsis thaliana*. While none of these studies addressed allelopathy in an ecological context, they demonstrated the potential phytotoxic effects of *L. maackii*. In addition to its effects on plants, *L. maackii* is relatively unaffected by herbivores and disease in North America (Trisel 1997; D. Cipollini, personal observation). These observations suggest that *L. maackii* contains compounds in its leaves (and other tissues) that are capable of negatively affecting other organisms. To date, no studies on the chemistry of *L. maackii* leaves or other tissues have been published, but tissues of other *Lonicera* species are known to contain a variety of flavonoids and their glucoside derivatives, phenolic acids, and iridoids (e.g., Flamini et al. 1997; Skulman et al. 2004).

In this study, we characterized and quantified the major phenolic metabolites present in methanol extracts of *L. maackii* leaves by high-performance liquid chromatography (HPLC)-electronspray ionization-tandem mass spectrometry (ESI-MS/MS). We also examined the effects of methanol–water fractions of *L. maackii* leaves on seed germination of a target plant species and on feeding preference and growth rate of a generalist insect herbivore. Finally, we examined the effect of selected flavonoids identified in methanol extracts on seed germination and insect feeding preference.

Materials and Methods

Chemicals and Reagents Methanol (HPLC grade) and acetic acid (HPLC grade) were purchased from Fisher (Pittsburgh, PA, USA). Ultrapure water was prepared with a Milli-Q water system (Millipore, Bedford, MA, USA). Standards of chlorogenic acid, apigenin-7-glucoside, luteolin, and luteolin-7-glucoside were purchased from Extrasynthese (Genay, France). Apigenin was purchased from Sigma-Aldrich (St. Louis, MO, USA).

Leaf Extraction Leaves were randomly collected from three shrubs growing in the Wright State University Woods, Dayton, Ohio on September 2005 and again on July 2006. For HPLC-ultraviolet (UV) and HPLC-MS analyses, three 0.100 g leaf samples were extracted twice with 0.500 ml of 100% methanol over 48 h in the dark at 4°C. In the extraction of plant secondary metabolites, methanol is commonly used to successfully extract a wide range of polar metabolites, many of which should also be present in aqueous extracts (e.g., Eyles et al. 2007). Extracts were transferred to a 1.5-ml microcentrifuge tube and centrifuged (13,000 rpm for 5 min) to remove solids. Samples were stored at −20°C.

Analysis of Phenolics with HPLC-UV and HPLC-ESI-MS/MS HPLC with UV detection and HPLC-ESI-MS were used to analyze the phenolic compounds present in the crude extracts (e.g., Eyles et al. 2007). LC-MS analyses were conducted on a Hewlett Packard HPLC system (Palo Alto, CA, USA) model HP 1100 equipped with a HP DAD G1315A detector coupled to a Q-tof I (Micromass). The same column and gradient program as detailed by Bonello and Blodgett (2003) was used; however, the mobile phase consisted of water/acetic acid (A; 98:2, *v*/*v*) and methanol/acetic acid (B; 98:2, *v*/*v*), and the flow rate was set at 1 ml/min. Detailed description of the operating conditions for HPLC-ESI-MS can be found in Eyles et al. (2007). Concentrations were determined for the five dominant phenolics in three independent samples from September 2005 and in three independent samples from July 2006. Concentrations were determined in relation to standard curves generated with relevant standards. Mean concentrations of each compound during each sampling period were compared statistically by using *t* tests for unequal variances.

Insect Bioassay Leaves from *L. maackii* were randomly collected from a single shrub from the same population used for chemical analysis then lyophilized and ground in a Wiley mill. An extract was prepared in 33% methanol using a tissue/solvent ratio of 1 g:15 ml. This mixture was stirred at room temperature for 24 h then filtered through several layers of cheesecloth and filter paper with a vacuum system. The liquid was evaporated under vacuum, and the residue was reconstituted in distilled water at a tissue/water ratio of 3 g:5 ml. This extract [0.6 g dry weight leaf equivalent per milliliter (referred to hereafter as gle/ml)] was stored at −20°C until further use.

Spodoptera exigua (beet armyworm, Noctuidae), was used as a model for the response of generalist insect herbivores to *L. maackii* allelochemicals. This species has a broad host range and overlaps in distribution across much of the native and introduced ranges of *L. maackii* (distribution maps of plant pests, 1972, CAB International, Map 302). Eggs of *S. exigua* were obtained from Benzon Research (Carlisle, PA, USA), and larvae were raised on an

artificial *S. exigua* diet (Southland Products, Lake Village, AR, USA) in an incubator at 22°C with a 16:8 light/dark period until they were 7 days old. Insects were starved for 3 h before starting the bioassay.

The original honeysuckle extract (0.6 gle/ml) was serially diluted by half with water to make a total of six extract concentrations. Artificial diet was prepared using a 1:10 ratio of diet to boiling water. Immediately after mixing, the diet was poured into 96-well microplates (with 0.300 ml wells) then leveled with a spatula. Once the diet plugs were cool, several were placed in each of the six extract concentrations in 15 ml Falcon tubes (enough to submerge all plugs) and were allowed to absorb the extract at 4°C for 24 h. An additional set of plugs was placed in distilled water to serve as the control. After 24 h, diet plugs were lightly blotted then weighed. Each 0.25 g diet plug absorbed 0.025 ml of extract with this procedure. Thus, the concentration in the diet that received the initial 0.6 gle/ml extract was 0.042 gle/g of diet.

No-Choice Bioassay For each extract concentration, one treated diet plug was placed in a 3.5 cm Petri dish along with a preweighed *S. exigua* larva. There were eight replicate plates for each extract concentration. Petri dishes were sealed with Parafilm, and insects were allowed to feed for 24 h in the incubator. After that time, diet plugs and insects were reweighed to calculate a relative growth rate (RGR; milligram mass gained per milligram insect mass per day) of larvae and a relative consumption rate (RCR; milligram diet eaten per milligram insect mass per day). A separate set of diet plugs from the 0.6 gle/ml extract and from the distilled water treatment was set up as above, except without an insect, to measure diet mass lost due to evaporation. The average mass loss was 0.010 g, which was accounted for in the final mass of all diet plugs. RGR and RCR were compared among extract concentrations with one-way analysis of variance (ANOVA) of log-transformed data on SAS version 9.1 (SAS Institute, Cary, NC, USA).

Choice Bioassay One diet plug containing 0.042 gle/g of diet was placed in a 3.5 cm Petri dish, along with a control diet plug and a pre-weighed *S. exigua* larva. Diet plugs were placed so they were not touching, and the insect was placed at an equal distance from each plug. There were eight replicate plates in this bioassay. Petri dishes were sealed with Parafilm, and insects were allowed to choose diet plugs and feed for 24 h in the incubator. Each diet plug in each dish was weighed after 24 h to calculate an antifeedant index $(AI)=[(C-E)/(C+E)]\times 100$, where C equals the amount of control diet consumed and E equals the amount of extract-treated diet consumed (Rodriguez et al. 1999). This index reveals the amount of the control diet consumed relative to the treated diet standardized by the total amount of feeding done by the insect. Negative values indicate stimulation of feeding, while positive values indicate deterrence of feeding. A value of zero would indicate no effect of the extract on feeding behavior. Mass lost to drying was accounted for in the calculations. A one-sided t test was used to examine whether the AI for this experiment differed significantly from zero.

Seed Germination Bioassay We used *A. thaliana* (Ecotype Col-0) as a representative target species, since its germination, growth, and reproduction were greatly inhibited by aqueous extracts of *L. maackii* leaves (Dorning and Cipollini 2006; Cipollini et al. 2008). Its seed-germination response to aqueous extracts of *L. maackii* also paralleled that of the native annual *Impatiens capensis* (Dorning and Cipollini 2006). Although it possesses general allelochemical detoxification mechanisms like most plants (Baerson et al. 2005), *A. thaliana* has been used as a model in several studies of phytotoxicity because of its general sensitivity to allelochemicals (e.g., Bais et al. 2003; Pennacchio et al. 2005). Wild *A. thaliana* also interacts with *L. maackii* in nature. Its range overlaps with that of *L. maackii* throughout North America, Europe, and Asia (USDA, NRCS 2007), and both species can be found growing in close proximity in the same field sites in North America (D. Cipollini, personal observation). Methanol–water extracts were prepared from *L. maackii* leaves as for the insect bioassay. The extract (0.6 gle/ml) was serially diluted by half with water to make a total of six extract concentrations. For each concentration, ten seeds (Col-0) were placed in a Petri dish (3.5 cm diameter) lined with Whatman® filter paper, along with 0.5 ml of extract. Three replicate Petri dishes were set up for each extract concentration, plus three replicates with distilled water. Seed germination was recorded at 4 and 7 days, and distilled water was added daily to each dish as needed. Numbers of seeds germinated on day 7 were compared among extract concentrations with one-way ANOVA.

Bioassays with Selected Flavones After confirming that apigenin and luteolin were major components of the phenolic metabolites present in *L. maackii* leaves, we conducted a bioassay of feeding deterrence and seed germination inhibition by using commercial standards. In addition, given that the concentration of luteolin in fresh leaves was tenfold higher than apigenin in our July samples, the bioassays were conducted to reflect the in situ relative proportion of apigenin and luteolin. Flavones were dissolved in methanol and diluted in water before their introduction in the diet. In the bioassay of feeding deterrence, a set of diet plugs containing apigenin (0.02 mg/g diet), a set containing luteolin (0.2 mg/g diet),

and a set containing both apigenin (0.01 mg/g diet) and luteolin (0.1 mg/g diet) were prepared. These concentrations are near but lower than those recorded for fresh leaves on a mass basis (see Table 2), thus, effects should be conservative. Concentration of methanol in the diet plugs was 1.3%. Each flavone-treated diet plug was presented to a *S. exigua* caterpillar along with a solvent-only diet plug, and feeding choice bioassays were conducted and analyzed as above. There were eight replicates of each flavone treatment in this experiment. One-sided *t* tests were used to examine whether the AI for each flavone treatment differed significantly from zero.

For the seed germination experiment, we placed 0.015 ml of 0.05% methanol or solutions of apigenin (0.063 mg/ml), luteolin (0.63 mg/ml) and apigenin (0.031 mg/ml) + luteolin (0.31 mg/ml) in 0.05% methanol in separate 2 ml centrifuge tubes. Relevant levels of flavones in soils under *L. maackii* where seeds may contact them are unknown. The amount of flavone present in each ml of these solutions is slightly less than that expected to be found in 1 g of fresh leaf, on average (see Table 2). Five *A. thaliana* seeds were placed in each tube, and the number of seeds germinated (showing radicle emergence from the seed coat) in each tube was examined after 4 and 7 days. There were three replicate tubes for each solution, and the experiment was repeated once. We analyzed numbers of seeds germinated on day 7 with a three-way ANOVA, with trial, apigenin (+ or −), luteolin (+ or −), and their interaction as effects.

Results

A total of 13 individual compounds were detected in honeysuckle crude extracts by HPLC-ESI-MS (Fig. 1, Table 1). Among them, five compounds were characterized (4, 9, 10, 12, and 13), initially on the basis of their MS and MS/MS (MS^2) data and by comparison of their UV spectra with literature data. Their identities were unambiguously confirmed by spiking samples with their respective standards, which were also used to construct standard curves for quantification purposes. Another four compounds (1, 2, 7, and 8) were tentatively characterized on the basis of their UV, MS, and mass spectrometry fragmentation behavior with literature data. The sensitive MS system also detected many smaller peaks that have yet to be analyzed. In general, however, honeysuckle crude extract was dominated strongly by two major flavones, apigenin (13) and luteolin (12), and their glucoside derivatives, apigenin-7-glucoside (10) and luteolin-7-glucoside (9), respectively (Fig. 1).

These compounds displayed UV spectra that were characteristic of flavones (Markham 1982). Furthermore, MS experiments of compound 10 showed a dominant fragment at *m/z* 269, indicating an apigenin derivative, while compounds 8 and 9 yielded an intense ion at *m/z* 285, indicating luteolin derivatives. The neutral loss of 162 Da indicates a hexoside for compounds 9 and 10. Compound 8 exhibited a loss of 294 Da, which most likely results from a disaccharide moiety composed of a hexose and a xylose unit. In a similar manner, compound 7 was tentatively identified as eriodictyol hexoside (Table 1). Samples collected at different times of the year generally contained the same major metabolites, although there was quantitative variation among samples (Table 2). Namely, higher concentrations of chlorogenic acid, luteolin, and luteolin-7-glucoside were detected in the July 2006 sample than in the September 2005 sample, while the inverse was true for apigenin.

In the no-choice bioassay of insect feeding and growth, the *S. exigua* larvae consumed at least some of the diet plug that they were offered in all cases. However, there were no

significant differences in RCR or RGR among concentrations of *L. maackii* extract ($F_{6,49}$=0.44, P=0.849; $F_{6,49}$=1.16, P=0.342, data not shown). In the choice bioassay of insect feeding and growth, most insects had sampled the *L. maackii* extract-treated diet plugs but had a clear preference for the control diet plugs. The AI for this experiment was 55.56 (±8.56 SE), which differed significantly from zero (t=6.54, P<0.001), indicating strong feeding preference for the control diet relative to the treated diet.

In the seed germination bioassay, *L. maackii* extracts strongly inhibited *A. thaliana* germination. After 4 days of incubation, all seeds in the water control had germinated, while the only seeds to germinate in the *L. maackii* extracts were those at the lowest concentration (0.019 gle/ml; $F_{6,14}$=125.1, P<0.001). By 7 days, this number rose slightly, and only one other seed germinated in the next highest extract concentration (0.038 gle/ml; $F_{6,14}$=111.0, P<0.001; Fig. 2).

The diets containing apigenin alone [AI=7.25 (±6.67 SEM)] or apigenin + luteolin [AI=5.29 (±6.41 SEM)] tended to deter feeding by *S. exigua*, but neither AI differed significantly from zero (t=1.09, P=0.156; t=0.823, P=0.218, respectively). The diet that contained luteolin alone [AI=−7.32 (±4.11 SEM)] marginally stimulated feeding (t=1.70, P=0.059). Across two trials, solutions that contained apigenin had only about half as much seed germination by day 7 as solutions without apigenin (apigenin, $F_{1,17}$=15.30, P=0.001, Fig. 3), a pattern that emerged by day 4 (data not shown). Luteolin had no significant independent or interactive effect.

Discussion

L. maackii is an invasive shrub in North America for which allelopathic effects have been suspected but little studied. Here, we identified several phenolic metabolites in methanol extracts of leaves of this plant and showed that methanol–water extracts substantially inhibited germination of a target plant, in accordance with studies that use aqueous extracts (Dorning and Cipollini 2006). In addition, feeding by a generalist insect herbivore was deterred by the presence of methanol–water extracts in an artificial diet. One flavone identified in crude extracts tended to deter herbivore feeding and inhibited seed germination on its own.

Methanol extracts were dominated by two major flavones, apigenin and luteolin, and their glucoside deriv-

Table 2 Concentration (mg/g FW) of major phenolic compounds from methanol extracts of *L. maackii* leaves collected during two sampling periods

Sample Date	Chlorogenic Acid	Apigenin	Apigenin-7-Glucoside	Luteolin	Luteolin-7-Glucoside
July 2006	0.737 (0.348)a	0.109 (0.013)a	0.652 (0.112)	1.044 (0.127)a	7.036 (1.863)a
September 2005	0.0595 (0.034)b	0.263 (0.030)b	0.695 (0.152)	0.239 (0.028)b	1.762 (0.435)b

Numbers represent means (±SE) of three samples. Means with different letters are significantly different at α=0.05.

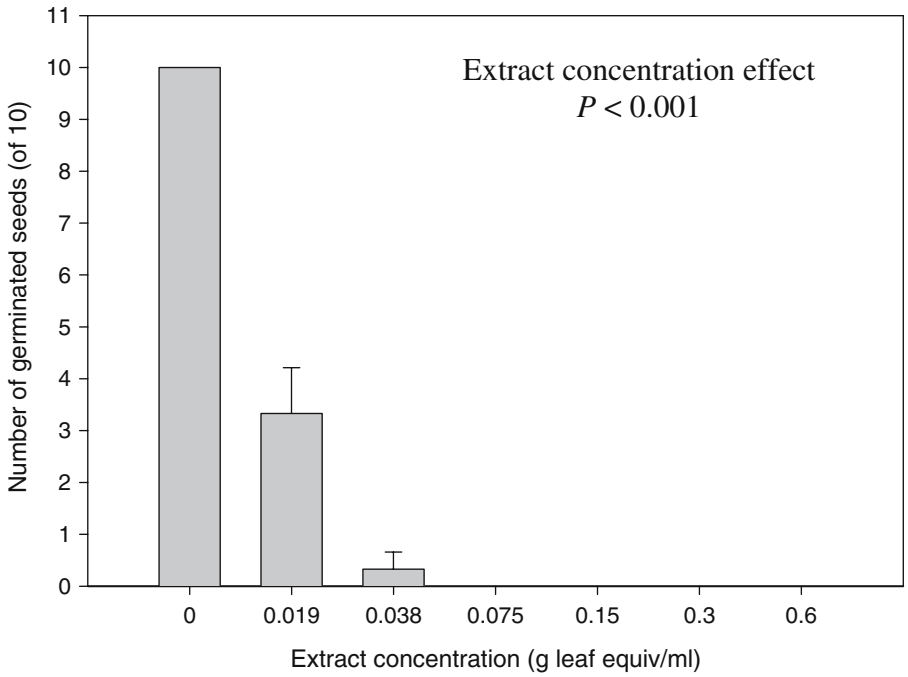

Fig. 2 Effects of methanol–water extracts of *L. Maackii* leaves on germination of *A. thaliana* seeds after 7 days of incubation. *Bars* are means (±SE) of three replicates, each containing ten seeds at each extract concentration. $p<0.001$

atives. These compounds are widespread in the plant kingdom and are well known to be bioactive (Iwashina 2003). These flavones have been studied extensively in the human health literature and possess anti-inflammatory, anti-tumor, and a variety of other health benefits (Verbeek et al. 2004; Graf et al. 2005). They have been less studied in the context of allelopathy, but there is some evidence that apigenin derivatives from *Cistus ladanifer* can reduce growth rate of target plant species and are detected in soils around *C. ladanifer* plants (Chaves et al. 2001). In this paper, we showed that apigenin alone inhibited the germination of *A. thaliana* seeds, while luteolin had no effect. Because these flavones are poorly soluble in water in their crystalline form, they are likely underrepresented in aqueous extracts of *L. maackii* previously noted for their phytotoxicity (Trisel 1997; Dorning and Cipollini 2006; Cipollini et al. 2008). As the results of Chaves et al. (2001) indicate, however, similar flavones do accumulate in soils

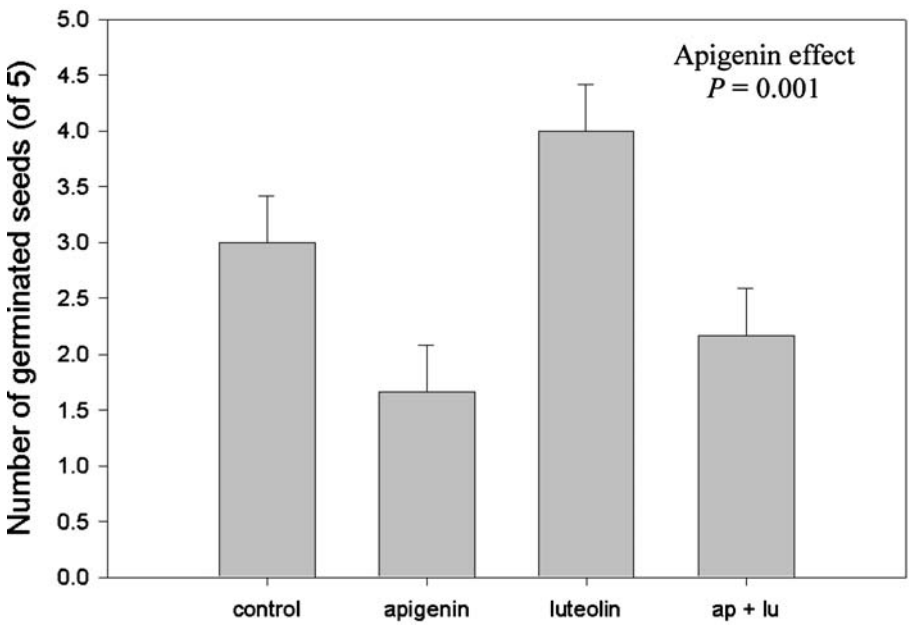

Fig. 3 Effects of purified apigenin, luteolin, and their combination on germination of *A. thaliana* seeds. *Bars* are means (±SE) of two trials, with three replicates of each treatment in each trial and with each replicate containing five seeds. $p<0.001$

around producing plants, so they may be relevant in the field. As for effects on insect performance, both apigenin and luteolin have been noted as phytoestrogens with the ability to disrupt molting cycles (Oberdorster et al. 2001). Although preferring to feed on them, *Spodoptera littoralis* larvae and pupae were smaller when continuously fed alfalfa plants in which apigenin concentrations were increased by herbivore feeding (Agrell et al. 2003). We saw no effect of extracts on relative growth rates of *S. exigua* in our 24-h no-choice bioassay, but longer-term effects on insect growth and development could be important. In contrast, extracts markedly deterred feeding on treated diets relative to a control diet in our choice bioassay. When offered in diet plugs, apigenin alone tended to deter feeding by *S. exigua*, while luteolin tended to stimulate it. While plant resistance to feeding will depend upon the overall balance of stimulants and deterrents, feeding deterrent effects of apigenin and other compounds could be partly responsible for the strong deterrence of crude extracts and for the relative lack of herbivory on *L. maackii* observed in the field in North America (Trisel 1997). A related flavone glycoside derived from apigenin, isovitexin 6″-*O*-β-D-glucopyranoside, significantly deters feeding and performance of *Pieris napi oleraceae* larvae on *Alliaria petiolata*, another invasive plant in North America (Haribal and Renwick 1998).

The July sample of *L. maackii* leaves contained substantial amounts of chlorogenic acid, and coumaric acid hexoside may have been present in our samples. Chlorogenic acid is highly extractable from plant tissues in water or methanol–water mixtures but poorly extractable by 100% methanol (Sripad et al. 1982), so levels found in our crude methanol extracts probably underestimated the actual amount in fresh tissue. There is a wide literature on both the phytotoxic and anti-insect effects of chlorogenic acid and coumaric acid (e.g., Dowd and Vega 1996; Blum and Gerig 2006), so we assume that these compounds contributed to the phytotoxic and feeding-deterrent effects of crude extracts demonstrated in this study.

Levels of chlorogenic acid displayed temporal variation in concentration with July samples reaching much higher concentration than September samples. This suggests that effects of this compound on either plants or herbivores may be more evident in summer months when maximum levels are present in leaves. Likewise, concentrations of luteolin and lueolin-7-glucoside were higher in July samples than in September samples, while concentrations of apigenin-7-glucoside were similar, and apigenin samples were higher in September than in July. Although yearly environmental variation could contribute to this pattern, such temporal variation is consistent with the role of selected flavones in UV light protection in plants, which would presumably be of greater importance during July. Tegelberg and Julkunen-Titto (2001) showed that concentrations of luteolin-7-glucoside in *Salix myrsifolia* leaves were significantly increased by UV-B light exposure, while concentrations of apigenin-7-glucoside were unaffected, a pattern that matches the temporal pattern seen in our study.

While the major effects of *L. maackii* on understory plant communities are likely driven by resource competition, we conclude that leaves of *L. maackii* contain phenolic compounds capable of having biological effects on other plants and herbivorous insects. Our implication of phenolics does not preclude the involvement of other metabolites of *L. maackii* in species interactions, including iridoids known to be produced by *Lonicera* species (Flamini et al. 1997) or other compounds (some of which may be novel) that would not be detected by our extraction and analytical techniques. In turn, while the major phenolic compounds identified here are not novel in the North American flora, nor is the genus *Lonicera* (USDA, NRCS 2007), the quantity introduced to the environment by *L. maackii* may depart from that of the North American flora for several reasons. *L. maackii* has a much longer leafing season than almost any other North American deciduous woody shrub (Harrington et al. 1989); thus, the length of time that it is physiologically active and capable of producing putative allelochemicals in growing leaves (or other tissues) is extended for this plant. In addition, *L. maackii* can reach a very high density and leaf-area index in moderate to high light environments (Hutchinson and Vankat 1997), which is not the case for the more sparsely distributed North American *Lonicera* species. Thus, the input of putative allelochemicals into the environment is likely high in dense patches of *L. maackii*.

Allelochemical levels vary temporally and likely among individual leaves and shrubs of *L. maackii*. Thus, the relative phytotoxicity and anti-insect properties of leaves or extracts of this plant likely vary throughout the season and in different habitats. In turn, recipient plant and herbivore communities vary in composition throughout the season and may be differentially exposed and/or sensitive to *L. maackii* allelochemicals. Along with seeds of *A. thaliana*, aqueous extracts of *L. maackii* leaves and roots inhibited germination of the herbaceous annual, *I. capensis*, and the herbaceous biennial, *A. petiolata*, while having no effect on seeds of *L. maackii* itself (Dorning and Cipollini 2006). However, many of the herbaceous plants that interact with *L. maackii* in North America are perennial, so it will be important to examine a wide range of native plants for their response to *L. maackii* allelochemicals. Variation must certainly exist in the response of herbivores to *L. maackii*, which have not yet been widely surveyed. While allelochemical levels in leaves may be related quantitatively to the preference and performance of leaf-associated herbivores and pathogens, allelopathic effects on other plants in

the field will depend on concentrations and stability of putative allelochemicals reaching the understory. Phenolics are readily metabolized by soil microbes which can greatly alter their bioactivity (Blum 1998). Nothing is yet known about levels or degradation rates of putative allelochemicals in soils around *L. maackii* plants, which is important to know to implicate them in allelopathic interactions where soil exposure is required.

Acknowledgments We thank the Ohio Plant Biotechnology Consortium and Wright State University for funding. Comments by two anonymous reviewers substantially improved the manuscript.

Causes and Consequences of Host Expansion by *Mnesampela privata*

Fredrik Östrand · Ian R. Wallis · Noel W. Davies · Mamoru Matsuki · Martin J. Steinbauer

Received: 24 September 2007 / Revised: 3 December 2007 / Accepted: 13 December 2007 / Published online: 23 January 2008

Abstract The autumn gum moth, *Mnesampela privata*, utilizes several species of *Eucalyptus* planted outside regions of endemism within Australia. We investigated whether foliar monoterpene composition influenced oviposition in the field on the natural primary host (*E. globulus*) and a novel host (*E. rubida*), both characterized by nonstructural epicuticular waxes. In the laboratory, oviposition preferences of females for species and families of known host, novel hosts, and non-hosts that were characterized by both nonstructural and structural waxes but also varied in foliar concentrations of the purportedly toxic plant secondary metabolite (sideroxylonal) were studied. Although *M. privata* laid as many eggs on trees of two families of *E. rubida* as they did on trees of two families of *E. globulus*, there were significant differences in the numbers of clutches of eggs laid. When combined with data for oviposition on another five families of *E. globulus*, we found a negative relationship between mean numbers of eggs and foliar concentration of α-pinene but a positive relationship between egg numbers and the concentration of α-terpineol. The field data suggest that female *M. privata* are just as willing to lay eggs on novel hosts with comparable foliar monoterpene compositions to those of the primary host, especially if they produce

nonstructural epicuticular waxes. Oviposition assays in the laboratory endorse this mechanism of host plant hierarchy and support the long-held assumption of the host primacy of *E. globulus*. In laboratory assays, some larvae pupated on all hosts (except *Corymbia eximia*) but the number completing larval development was greater on hosts with softer leaves. Larval survival was also reduced on hosts with high concentrations of sideroxylonal but only if those hosts also had modest to high concentrations of monoterpenes. Larval survival was high on a host (*E. macarthurii*) with a high concentration of sideroxylonal but with virtually zero monoterpene content. This suggests that the monoterpene content of a host could antagonize the effect on *M. privata* larvae of its sideroxylonal content. The larval food plant most affected the fitness of female rather than male pupae. Of the known host expansion events, all have occurred in mixed species plantations. The co-occurrence in these plantations of either the primary host or other highly ranked species probably explains the eventual expansion onto the neighboring species of *Eucalyptus* and *Corymbia*.

Introduction

The evolution of insect host specificity and host plant hierarchies depends on the suite of plant and insect species that coincided at a particular time and place (Janz and Nylin 1998; Janz et al. 2001; Braby and Trueman 2006). Typically, insect herbivores expand onto novel plant species that are taxonomically related and/or possess similar suites of plant secondary metabolites (PSMs). For example, the native Brazilian geometrid, *Thyrinteina arnorbia*, now exploits eucalypts (Grosman et al. 2005), whereas its natural hosts were a suite of endemic Myrtaceae. Hence, the expansion of *T. arnorbia* onto *Eucalyptus* provides an example of a host shift between related plant species. Perhaps rarer are instances when insects use unrelated plant families that possess similar PSMs to those of their natural hosts. Murphy and Feeny (2006) found that chemically similar extracts from both the ancestral host (family Apiaceae) as well as from three novel hosts (family Asteraceae) stimulated oviposition in two species of butterfly that belong to the *Papilio machaon* group. Steinbauer and Wanjura (2002) observed normally eucalypt-feeding species of *Anoplognathus* (Coleoptera: Scarabaeidae) eating the leaves of *Schinus molle* (family Anacardiaceae) and suggested that they were attracted by a similar monoterpene signal.

Mnesampela privata (Guenée) (Lepidoptera: Geometridae, Ennominae) is endemic to forests in south-eastern and south-western Australia. Before being called the "autumn gum moth," it was the "blue gum moth" because the only larval host then known was juvenile blue gum, *Eucalyptus globulus* (French 1900; Froggatt 1923; Evans 1943). Studies with *E. globulus* by Steinbauer (2002) and Steinbauer et al. (2004) revealed that females prefer to oviposit on the waxiest types (i.e., juvenile) and sides of leaves. The advent of plantation forestry has led to a reappraisal of the host status of *Eucalyptus* species that *M. privata* uses. One of the first cases of host expansion involved shining gum (*Eucalyptus nitens*), soon after its introduction to Tasmania (D. W. de Little, unpubl.). Other plantation and amenity eucalypts that *M. privata* now uses include *E. botryoides, E. camaldulensis, E. grandis, E. macarthurii, E. rubida, E. viminalis*, and *Corymbia maculata* (see Steinbauer and Matsuki 2004, and references cited therein). One expansion, onto *E. grandis*, in north-western Victoria, is particularly interesting because earlier records of *M. privata* that use this eucalypt are only from regions where the tree was endemic (Moore 1972). Less surprising are infestations of plantation *E. globulus* in southwest Western Australia (Loch and Floyd 2001; Hobbs et al. 2003), where *E. globulus* is far from its endemic region (Tasmania and south-eastern Australia). Because expansion and utilization of novel hosts by *M. privata* is not always documented, the phenomenon has seemed random and inexplicable to some. For example, *M. privata* had little effect on *E. macarthurii* in two mixed species plantations (Roberts and Sawtell 1981; Stone and Urquhart 1992), but it completely defoliated the species in another (E. G. Neumann and N. G. Collett, unpubl.). The events mentioned above show that this insect has successfully utilized species of eucalypt that either did not occur in a given region or were scarce in that location before plantations.

Eucalypt taxonomy is in a state of flux. In this work, the classification of Chippendale (1988) is followed, although Brooker (2000) proposes a more recent classification (but see Ladiges and Udovicic 2000). Much of the debate revolves around the status of *Corymbia*—whether it is a subgenus of *Eucalyptus* or has full genus status (Hill and Johnson 1995; Ladiges et al. 1995; Udovicic et al. 1995). Regardless of classification, *Corymbia* is still a taxon somewhat removed from the subgenera *Monocalyptus* and *Symphyomyrtus*, which explains our reason for studying it. None of the aforementioned authors disputes the subgeneric status of *Monocalyptus* or *Symphyomyrtus*. We know of no

published work that collates patterns of host tree utilization by native insects based on eucalypt PSMs.

The genus *Eucalyptus* provides an ideal group in which to study host shifts. Although there are more than 900 species, they rarely form single species forests of more than a few hectares and usually grow in close association with individuals of two, three, or more other species (Wardell-Johnson et al. 1997). Furthermore, different species of *Eucalyptus*, especially those belonging to the same subgenera, share many foliar PSMs, notably epicuticular waxes, monoterpenes, and formylated phloroglucinol compounds (FPCs; Boland et al. 1991; Li et al. 1995, 1996, 1997; Eschler et al. 2000). Hence, native eucalypt-eating insects are commonly exposed to a mosaic of volatile stimuli. Because the antennae of female *M. privata* respond to a number of ubiquitous eucalypt monoterpenes, Steinbauer et al. (2004) suggested that they are used as host location and assessment cues. These authors have also shown that the odors of the epicuticular waxes of new leaves stimulate the antennae of female moths more than do the odors of waxes from old leaves or the wax odors of glossy leaves. Steinbauer et al. (2004) have suggested that waxes provide host assessment/acceptance cues for female *M. privata*. When female *M. privata* mistakenly oviposit on *E. melliodora* or *E. sideroxylon* (both of which produce waxy leaves), their larvae suffer high neonate mortality. Steinbauer and Matsuki (2004) suggested that high neonate mortality on trees of these two species was because of high concentrations of sideroxylonal. Sideroxylonal is an FPC common to *Symphyomyrtus* species but present in some in much higher concentrations than in others. If it is possible to explain past host expansion events and oviposition mistakes by *M. privata*, then it may be possible to foresee future events.

Methods and Materials

Field Investigations of Oviposition Preferences for Novel and Natural Hosts The field investigations were conducted

Table 1 The eucalypts studied, their host utilization by *Mnesampela privata* and the characteristics of their epicuticular waxes

Species	Family Name and Code	Host Status and Wax Type (latter from Hallam and Chambers 1970)	Ontogeny and Distribution of Waxes
Field investigations GES2

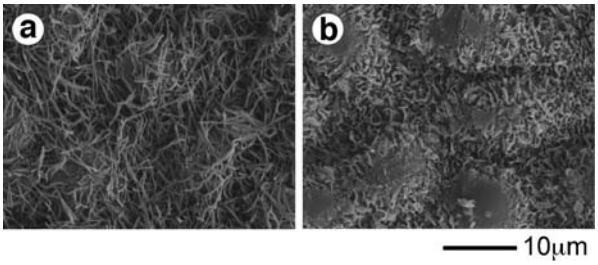

Fig. 1 Scanning electron micrographs of the epicuticular waxes of two hosts used in the laboratory investigations. **a** Abaxial surface of leaf of *E. nitens* family N66 showing nonstructural waxes and **b** leaf of *C. eximia* showing structural waxes. Nonstructural waxes can be removed by abrasion, whereas structural waxes cannot

in two common arboreta, i.e., Ginninderra Experiment Stations 2 and 1, hereafter referred to as GES2 and GES1. Our objective was to compare the oviposition preferences of *M. privata* for trees belonging to five families of *E. globulus* with those for two families of *E. rubida* (a novel host). Both species have waxy leaves, the chemical composition of which relates them to other species that possess nonstructural waxes (Table 1. Fig. 1). Because of their close taxonomic affinity (both subgenus *Symphyomyrtus*, series Viminales), it was thought that differences in oviposition according to species and family would indicate the influence of foliar monoterpenes on female preference. We surveyed 54 trees of each species in GES2 and 100 of each in GES1 for egg clutches for 1 min on at least 11 separate occasions that spanned two moth seasons. At the end of a survey, the numbers of eggs in each previously located clutch was counted. Data are expressed as the mean number of clutches or eggs per target tree per minute per survey.

Our interest was the influence of tree genotype on oviposition rather than the timescale of oviposition, so we ignored the repeated measures aspect of the data. Observations of "nil oviposition" were also ignored, which caused the oviposition data to be unbalanced. Therefore, general linear modeling (GLM) using the data for clutches and square root transformed egg data were used to assess oviposition preferences according to species and families of trees. The number of leaves examined during each 1-min survey and the number of clutches found were included as covariates, but were dropped from later models if statistically insignificant. A post hoc one-way analysis of variance (ANOVA) of transformed data was used to compare individual means.

Laboratory Investigations of Oviposition Preferences for Novel and Natural Hosts The attractiveness of natural and novel hosts was compared by using binary choice assays with groups of females and also by using multiple choice assays with individual females (details given in Table 2). With the exception of *C. eximia*, the two novel host species (*E. nitens* and *E. macarthurii*) belong to the subgenus *Symphyomyrtus* (series Viminales). Furthermore, the four *E. nitens* showed considerable variation in the waxiness of their leaves, all of which have nonstructural waxes, whereas *C. eximia* and *E. macarthurii* have structural epicuticular waxes that cannot be abraded. *Eucalyptus globulus* had waxier leaves than the waxiest *E. nitens* studied. The foliage of the four *E. nitens* came from another common arboretum, i.e., GES3. Of the other two trees, leaves of *C. eximia* were taken from a specimen growing in the grounds of Commonwealth Scientific and Industrial Research Organisation, whereas leaves of *E. globulus* came from a specimen growing in the garden of MJS (specimen belonged to same family as that planted in GES1).

Table 2 Laboratory investigations used to assay responses of *Mnesampela privata* to novel and natural hosts as well as hosts of unknown host status (F = female and M = male)

Assay	Branchlets (moths) and Leaves (larvae) Per Assay	Number of Insects Per Assay	Number of Cages (moths) or Dishes (larvae) Per Assay
Oviposition preference			
Binary choice	N66, G76	3–4 f, 3–6 m	9
As above	N64, N66	4 f, 4–5 m	7
As above	Mac, N64	4 f, 3–5 m	5
As above	Cor, N64	4 f, 3 m	5
As above	N64, N66	1 f, 1–3 m	11
Multiple choice	N63, N64, N65, N66	1 f, 1–3 m	13
Larval survival and performance			
	Cor, Mac, N66, G76	5 eggs per leaf	6 per tree
	N63, N64, N65, N66	5 eggs per leaf	6 per tree

To ensure that test females were host novices, male and female pupae were allowed to ecdyse in the cages that housed the test foliage. Assays were conducted in cages (54×37×28 cm) with gauze sides housed in a controlled temperature room (range 20–21°C) under a 12:12 h reverse-cycle lighting regimen with a fan circulating air. Branchlets were pruned so that they had either the same number of leaves or about the same leaf area before placing them upright in containers of moistened floral foam in diagonally opposite corners of cages. Moths were given 5% sugar water for sustenance. Branchlets were left for 7 days before removing them, counting the eggs, and measuring the total leaf area (i.e., leaf area multiplied by 2), with an AM100 portable leaf area meter (ADC Bioscientific Ltd., Herts).

Two-tailed paired-sample *t*-tests were used to analyze the results from binary choice assays after first transforming the data—square root (eggs+0.5)—to account for zero values. Paired *t*-tests cannot incorporate covariates, such as leaf area, and so these were compared separately. There were significant differences in total leaf area per cage only for *E. macarthurii* vs. *E. nitens* N64 (P=0.001). The juvenile leaves of *E. macarthurii* were a third the size of those of *E. nitens* N64, so it was difficult to match leaf area per cage. Nevertheless, the preference of females for *E. nitens* N64 over *E. macarthurii* could be because of differences in the leaf areas.

A GLM was used to analyze the results of the multiple choice assays, with leaf area as a covariate, after transforming the data [square root (eggs+0.5)]. The total leaf area did not explain significant variation (P=0.57) and was dropped from later models. A post hoc one-way ANOVA of the transformed data was used to separate the treatment means.

Laboratory Investigations of Larval Survival and Performance on Novel and Natural Hosts In two sets of assays, the survival and performance of larvae, from hatching to pupation, was assayed by using leaves of all the trees used in the oviposition experiments. In the first set of assays, the survival of six groups of five larvae on each of *E. globulus*, *E. nitens* N66, *E. macarthurii*, and *C. eximia* was followed by recording the number of dead larvae twice weekly. The second set of assays was the same, except larvae were reared on leaves of the four *E. nitens*. Groups of larvae were reared in individual 15-cm Petri dishes (same temperature and lighting regime as used for the oviposition assays) with saturated plaster of Paris bases until the third instar and then transferred them to 750-ml plastic containers each half filled with moist vermiculite as a pupation substrate. Fresh leaves were supplied to all groups of larvae at the same time when needed. Individuals that pupated were sexed, oven dried at 40°C, and weighed.

Log-rank tests were used to compare pairs of Kaplan–Meier survival curves. Because there were six pairs of comparisons per survival assay, the test statistic was compared against critical values of the chi-square distribution with df=1, but adjusted P values used the Bonferroni method because there were more comparisons than there were trees in each assay. This adjustment was also applied to the regression results of female pupal weight vs. leaf traits because they met the same condition. The dry weights of male and female pupae were log transformed and compared with one-way ANOVA.

Analyses of Foliage The concentration [given as milligrams tridecane (i.e., the internal-standard)] equivalents per gram of leaf dry mass (DM) of α-pinene, limonene, 1,8-cineole, γ-terpinene, and α-terpineol in fresh leaves from two representative trees of each family in GES2 and GES1 were measured according to Steinbauer et al. (2004). The extraction procedure entails immersion of 100 mg of fresh leaf slivers in 400 μl of high-performance liquid chromatography grade hexane (containing 100 ppm tridecane as an internal standard) in sealed glass tubes followed by heating to 100°C for 1 h. One microliter volume of the solvent extract was subjected to gas chromatography/mass spectrometry analysis, and quantities of each monoterpene were calculated based on reference to the response factor for the internal standard.

FÖ and MJS independently examined the same eight branchlets (each with six leaves) of each of the four *E. nitens* and ranked them on abundance of epicuticular waxes. The two sets of rankings were the same, i.e., *E. nitens* N66, N65, N64, to N63, with N66 the waxiest and N63 the least waxy.

Freeze-dried leaves were used in chemical analyses of nitrogen and sideroxylonal (an FPC), respectively. Leaves were ground in a Tecator Cyclotec 1093 mill to pass through a 1-mm sieve, and nitrogen content was measured by using 0.35 g of leaf powder and a semi-micro Kjeldahl technique with a Tecator 2012 digester, selenium catalyst (3.5 g of K_2SO_4, 3.5 mg Se) and a Gerhardt Vapodest-5 distillation and titration apparatus. The method was standardized by using ammonium sulfate. The sideroxylonal content of ten individual leaves of each host used in the laboratory investigations was measured following Wallis et al. (2003). However, to ensure the extraction of all the sideroxylonal, the leaves were finely chopped, sonicated in solvent, and then extracted in solvent for 8 rather than 5 h.

Specific leaf weight (SLW) was measured as an indicator of leaf toughness because leaf toughness is the only foliar trait known to link oviposition preference and neonate performance in *M. privata* (Steinbauer 2002; Steinbauer and Matsuki 2004). Foliar water content is inversely correlated with SLW (as is nitrogen; Steinbauer and Matsuki 2004) and can be measured coincident with SLW. Consequently, it was also measured (as a percentage of leaf mass) and arcsine transformed for use in statistical tests.

The physical and chemical characteristics of the trees were also characterized to help differentiate them from one another. Global nonmetric multidimensional scaling (GNMDS), an ordination procedure, using PC-ORD was used to compare the traits of the trees. The settings used for the analyses were 40 runs with real data, 100 runs with randomized data, 500 maximum iterations, 5 (for GES2 and GES1 data; i.e., 5 monoterpenes) or 9 (for laboratory data; i.e., 5 monoterpenes, sideroxylonal A and C, toughness and water content) starting dimensions, and <0.001 minimum instability threshold. The results of these analyses are provided as Supplementary Material.

Results

Field Investigations of Oviposition Preferences for Novel and Natural Hosts In GES2, there was no significant difference in the mean numbers of eggs on the families of *E. globulus* and *E. rubida*. There were, however, different

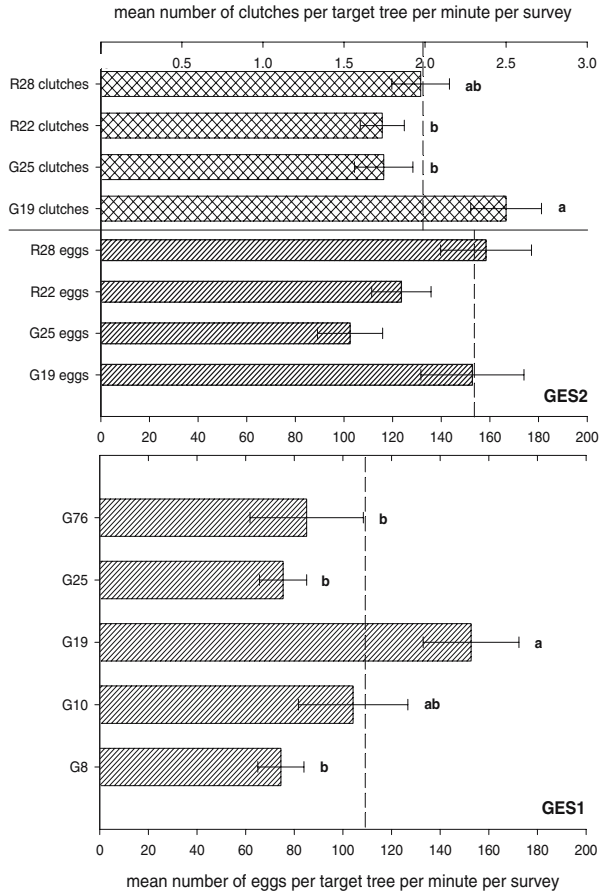

Fig. 2 Field observations of oviposition by *M. privata* on novel and natural hosts. (*GES2*) oviposition (mean number of clutches as well as mean number of eggs) on two families of *E. globulus* (*G19* and *G25*) and two families of *E. rubida* (*R28* and *R22*). *GES1* oviposition on five families of *E. globulus* (*G8*, *G10*, *G19*, *G25*, and *G76*). Data are means±SE *Dashed vertical lines* indicate mean overall oviposition. *Letters alongside bars* indicate statistical similarity of means

numbers of clutches laid on the different families of *E. globulus* and *E. rubida* (Table 3, Fig. 2). Specifically, *M. privata* laid most clutches on *E. globulus* family G19 with only slightly fewer clutches on *E. rubida* family R28. Female moths laid almost identical numbers of clutches on *E. globulus* family G25 and *E. rubida* family R22, but the numbers did not differ significantly from the number laid on *E. rubida* family R28.

In GES1, the family of tree as well as the number of clutches significantly influenced the number of eggs on individual *E. globulus* (Table 3). Of the five families of primary hosts, *M. privata* preferred to lay on *E. globulus* family G19, followed by family G10 with equal preference for the remaining three families (Fig. 2).

There were two statistically significant relationships between oviposition on the nine genotypes of tree in both arboreta and the concentrations of monoterpenes in their leaves. Oviposition was negatively related to the concentration of α-pinene but positively related to the concentration of α-terpineol (Fig. 3). Appendix 1 shows the monoterpene concentrations. An ordination of the genotypes from both arboreta is provided in Supplementary Material, Fig. 1.

Laboratory Investigations of Oviposition Preferences for Novel and Natural Hosts Despite the leaves of *E. nitens* N66 being equally waxy on both surfaces, whereas those of *E. globulus* are most waxy on the abaxial surface, *M. privata* preferred laying on branchlets of *E. globulus* than on branchlets of *E. nitens* N66 (Table 3, Fig. 4a). The moths preferred ovipositing on leaves of the waxiest *E.*

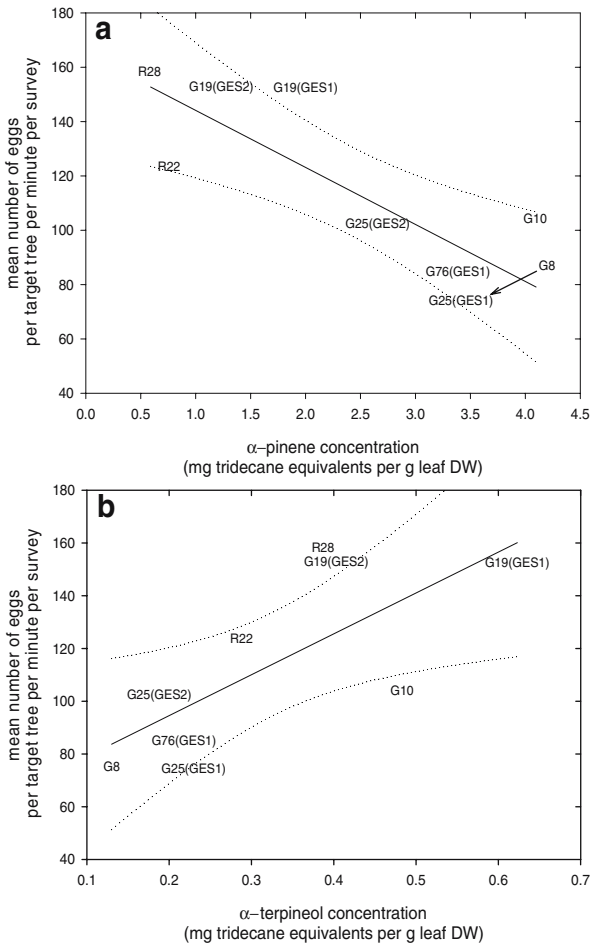

Fig. 3 Oviposition on families of *E. globulus* and *E. rubida* growing in GES2 and GES1 relative to monoterpene content. **a** Oviposition in relation to the concentration of α-pinene (location of G8 offset for clarity; number of eggs=−20.987×α-pinene concentration+165.092; r^2=66.8%, $F_{1,\ 7}$ =14.109, P=0.007; SE slope=5.6, P=0.007; SE intercept=15.2, P=0.001). **b** Oviposition in relation to the concentration of α-terpineol (number of eggs=154.984×α-terpineol concentration+63.560; r^2=52.9%, $F_{1,\ 7}$=7.866, P=0.026; SE slope=55.3, P=0.026; SE intercept=19.9, P=0.015)

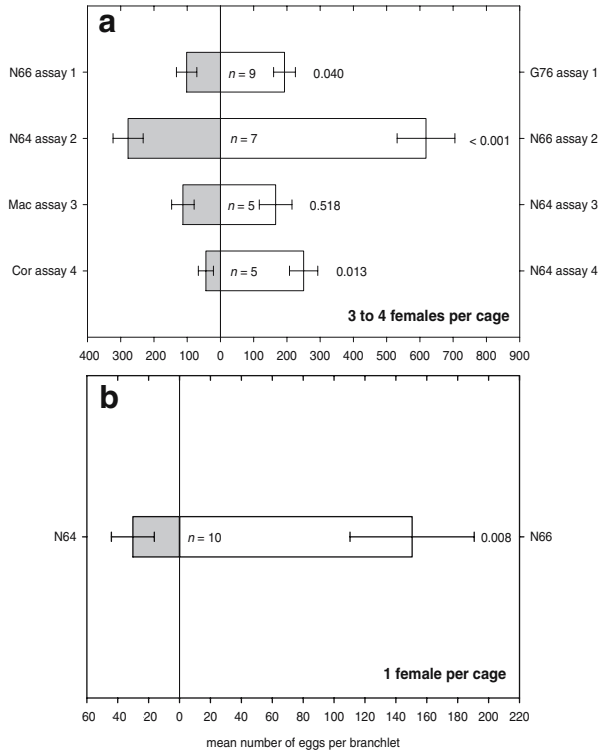

Fig. 4 Results of binary choice assays. **a** Oviposition by groups of three to four females per cage on branchlets of *E. nitens* N66 or *E. globulus* G76, *E. nitens* N64 or *E. nitens* N66, *E. macarthurii* (Mac) or *E. nitens* N64, and *C. eximia* (Cor) or *E. nitens* N64. **b** Oviposition by individual females on branchlets of *E. nitens* N64 or *E. nitens* N66. Data are means±SE. Two-tail probabilities, from paired-sample *t*-tests, given at RHS of bars

nitens, namely N66, to the third waxiest leaves, *E. nitens* N64. There was no difference in oviposition rates on the leaves of *E. macarthurii*, which possess structural waxes, compared to those of *E. nitens* N64 that produce nonstructural waxes. Least preferred were the leaves of *C. eximia*. Assays with 11 individual female moths offered *E. nitens* N64 and N66 tended to confirm the preferences obtained with groups of females. Ten females laid more eggs on leaves of *E. nitens* N66 than on leaves of N64 (P=0.008; Fig. 4b), but the other female laid 337 eggs on *E. nitens* N64 and only 51 eggs on N66 and reduced the probability of the preference response to P=0.061.

When individual *M. privata* were given a choice of four *E. nitens* on which to lay, they tended to choose them from most (N66) to least waxy (N63 then N64) (P=0.028; Fig. 5). Not surprisingly, the post hoc ANOVA indicated there were significant differences in the fecundities of the 13 females used in these assays.

Laboratory Investigations of Larval Survival and Performance on Novel and Natural Hosts All larvae reared on *C. eximia* died before completing the second instar (Fig. 6a). Not surprisingly, the survival curves for larvae on *C. eximia* differed significantly from those chosen for comparison (*E. globulus, E. nitens* N66, and *E. macarthurii*). Survival curves for these latter three did not differ (Table 4). Interestingly, larval survival was high and time to pupation short on *E. macarthurii*, although its leaves had the highest concentration of sideroxylonal (Fig. 6a and Appendix 1). In contrast, the leaves of *C. eximia* were devoid of sideroxylonal. The leaves of *C. eximia*, however, were the toughest of those in this set of assays, i.e., mean SLW of 0.124 mg per mm^2 compared to 0.079, 0.082, and 0.104 mg per mm^2 for the leaves of *E. nitens* N66, *E. globulus*, and *E. macarthurii*, respectively (Appendix 2).

Larvae survived significantly better on the leaves of *E. nitens* N66 and N63 than on those of N65 (Fig. 6b and

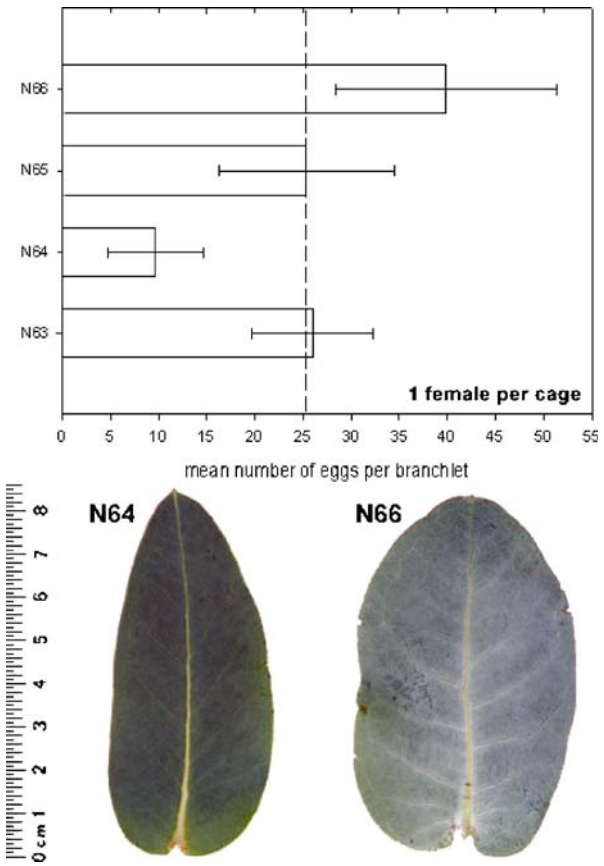

Fig. 5 Results of multiple choice assays with four *E. nitens*. Data are means±SE. *Dashed vertical line* indicates mean overall oviposition. The *bottom two images* are of the leaves of *E. nitens* N64 (least preferred) and of *E. nitens* N66 (most preferred) illustrating the relative abundance of epicuticular waxes. Epicuticular waxes are evenly distributed on both sides of juvenile *E. nitens* leaves

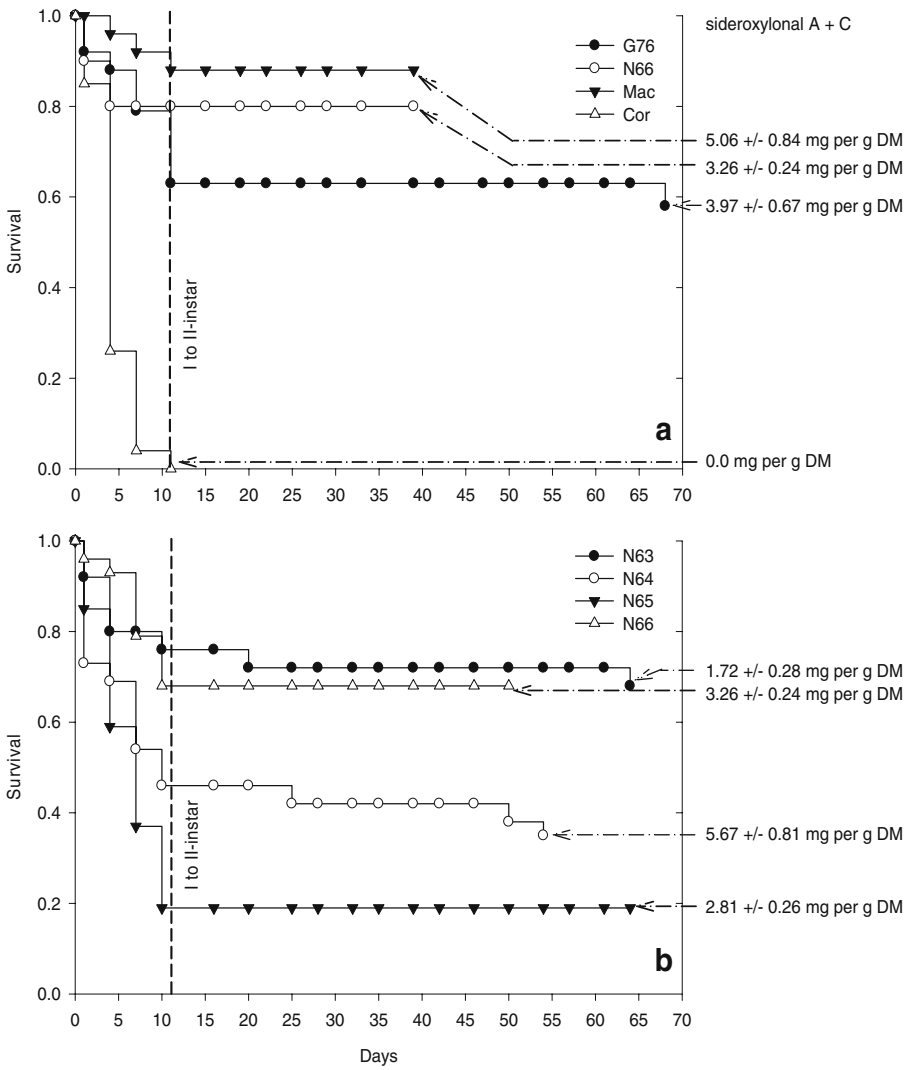

Fig. 6 Survival of larvae on novel and natural species of *Eucalyptus* and *Corymbia*. **a** Survival on leaves of *E. globulus* G76, *E. nitens* N66, *E. macarthurii* (Mac), and *C. eximia* (Cor). **b** Survival on leaves of *E. nitens* N63, N64, N65, and N66. Larval survival is shown relative to the total sideroxylonal content of leaves. Period to day 11 (indicated by *dashed vertical line*) encompasses larval development to end of the second instar

Table 4). As in the case of *C. eximia*, the higher mortality on leaves of *E. nitens* N65 was likely due in part to leaf toughness (Appendix 2). It is interesting to note that final larval survival on *E. nitens* N66 and N63 (both 0.68) as well as N64 (0.35) roughly matched the total sideroxylonal contents of the leaves of those trees (see Fig. 6b).

The dry weights of male pupae were less variable than those of female pupae (Fig. 7). With the exception of individuals fed *E. nitens* N63, male pupae tended to weigh the same irrespective of their larval diet (Table 4). In contrast, the weight of female pupae was less predictable. For example, there was little variation in the weight of female pupae reared on *E. globulus, E. macarthurii*, and *E. nitens* N66 in the first set of assays. There was, however, more variation in the weight of pupae reared on the four *E. nitens*. In particular, pupae reared on *E. nitens* N66 were significantly heavier than pupae reared on the leaves of *E. nitens* N64, whereas those fed *E. nitens* N63 were of intermediate weight. Thus, the results for larval performance exhibit a linkage to female oviposition preferences on these four *E. nitens*.

After a Bonferroni adjustment, there was only a single significant relationship ($P \leq 0.003$) between female pupal weight and one of the eight leaf traits measured. Female pupal weight was negatively related to the toughness of the leaves used to rear larvae (pupal weight=−1069.5×leaf toughness+354.6; r^2=95.1%, $F_{1,\ 6}$=76.9, P<0.001; SE slope=122.0, P<0.001; SE intercept=14.8, P<0.001). There was a trend toward a positive relationship between the weight of female pupae and foliar nitrogen (P=0.010). Leaf toughness and nitrogen were negatively related to one another (nitrogen content=−101.5×leaf toughness+25.7;

Discussion

There were three main findings of this study. First, the laboratory assays confirmed the long-held assumption that the juvenile leaves of *E. globulus* are the primary host of *M. privata*. Second, the field observations and laboratory assays showed that female *M. privata* base their oviposition decisions on both nonstructural epicuticular wax and foliar monoterpene cues. Thus, they are as likely to lay their eggs on novel hosts as on a known host if the foliar chemistry resembles that of the primary host. Finally, tough leaves and high concentrations of PSMs decrease larval survival, with the fitness of female survivors apparently more likely to be adversely affected by natal host than male fitness. Importantly, these conclusions were reached by studying female oviposition preference and larval performance simultaneously and by using closely related species and families of eucalypts and a less closely related taxon within Myrtaceae, namely *C. eximia*.

By studying the oviposition preferences of *M. privata* for two members of the series Viminales (*E. macarthurii* with structural waxes and *E. nitens* with nonstructural waxes), our assays are the first to show that wax structural type can influence insect host assessment and oviposition. For some unknown reason, female *M. privata* preferred to lay more eggs on the least waxy family of *E. nitens* than on *E. macarthurii* that is characterized by structural waxes. The identity of the waxes that influence female oviposition remains unknown. However, because the chemical composition of a species' epicuticular waxes, as well as their method of crystallization, determines the physical structure of its wax layer, we can narrow the potential suite of biologically active wax compounds (Hallam and Chambers 1970; Carr et al. 1985). Specifically, Hallam and Chambers (1970) suggested that the presence or absence of β-diketones determined whether a eucalypt had tube or platelet type waxes, the presence of β-diketones being associated with the formation of tubes (nonstructural waxes) and the absence of β-diketones with the formation of platelets (structural waxes). Jones et al. (2002) and Rapley et al. (2004) found that reduced defoliation of certain families of *E. globulus* was correlated with high concentrations of benzyl *n*-tetracosanoate in the epicuticular waxes of those trees and suggested that this wax ester was an oviposition repellent. Steinbauer et al. (2004) argued that the epicuticular waxes of eucalypts were likely to be oviposition stimulants. Because, according to Hallam and Chambers (1970), wax esters are associated with both tube and platelet waxes, benzyl *n*-tetracosanoate seems even less likely to be the biologically active component responsible

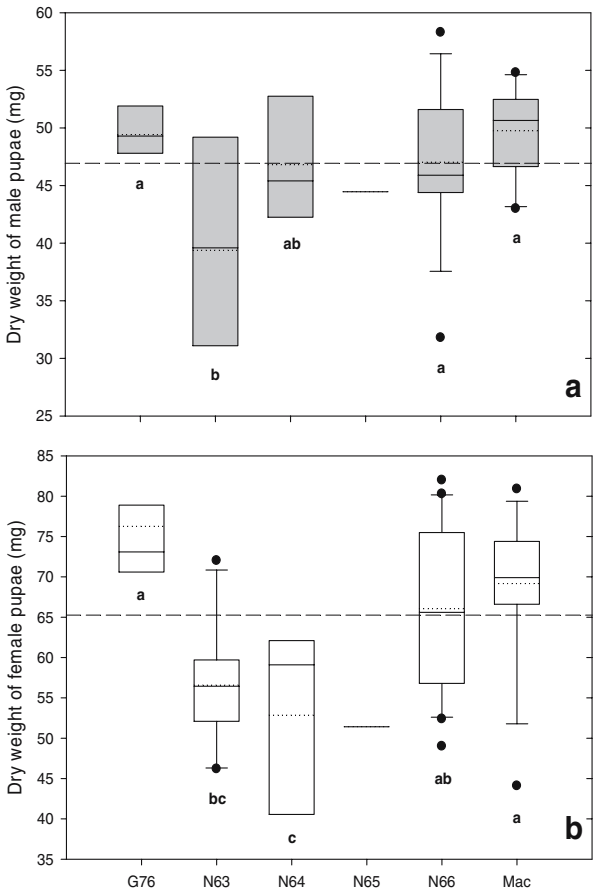

Fig. 7 Dry weights of pupae reared during survival assays. **a** Male pupae. **b** Female pupae. No larvae survived to pupation on *C. eximia*. *Figures* are box plots with standard error bars (if $N \geq 10$); the boundary of the *box nearest the x-axis* represents the 25th percentile, the *solid line within the box* marks the median, the *dotted line within the box* marks the mean, the *boundary of the box furthest from the x-axis* represents the 75th percentile and *solid circles* are outlying pupae. The *dashed horizontal lines* extending across each individual figure mark mean overall pupal weight. *Letters beneath boxes* indicate statistical similarity of means. Two male and two female pupae only were reared on *E. nitens* N65

for the repellence of oviposition by female *M. privata*. Final elucidation of the biological activity of particular wax compounds will require "boutique" synthesis and assay in choice experiments, perhaps with supplementary electrophysiological studies.

The possibility that host attractiveness for oviposition may be influenced by the concentrations of α-pinene and α-terpineol is of interest because there is apparently only one other parallel in insect–Myrtaceae relationships. Specifically, Wheeler and Ordung (2005) reported that the psyllid *Boreioglycaspis melaleuca* (Hemiptera: Psyllidae) laid more than twice as many eggs on a viridiflorol chemotype of its host (*Melaleuca quinquenervia*) than it did on a *E*-nerolidol chemotype. The families of *E. globulus* and *E. rubida* in GES2 and GES1 were best differentiated by their concentrations of 1,8-cineole (100%), followed by α-pinene (98.0%), and least differentiated by γ-terpinene (38.0%; see GNMDS analysis in Supplementary Material, Fig. 1). The leaves of *E. globulus* had two to three times more 1,8-cineole than did those of *E. rubida*, but *M. privata* laid a similar number of eggs on each species or family. Therefore, if female *M. privata* prefer hosts with high concentrations of 1,8-cineole, they should not choose *E. rubida* when there are ample *E. globulus* nearby. Our results, however, suggest that *M. privata* do not discriminate hosts so simply. In exploratory analyses not presented here, there was a negative relationship (r^2=94.6%) between oviposition and the ratio of the concentrations of α-pinene to 1,8-cineole. There was, however, a close positive correlation between the concentrations of α-pinene and 1,8-cineole (r^2=65.4%), which illustrates how difficult it is to separate the influences on oviposition of individual monoterpenes. Finally, terpenes that occur in lower concentrations than 1,8-cineole or α-pinene should not be ignored because the antennae of female moths responded to several of these aromatics, e.g., terpinolene, α-campholene aldehyde, α-terpineol, and possibly also *trans*-pinocarveol (see Steinbauer et al. 2004).

Exaptation of *M. privata* larvae enables them to eat the leaves of more species of eucalypt (notably those with glossy leaves) than females would choose to oviposit upon. Irrespective of this, high leaf toughness is universally detrimental to neonates because their small size and gape constrains the physical forces they can exert on leaf surfaces. Steinbauer and Matsuki (2004) reported that small groups of neonate *M. privata* larvae (e.g., ≤5 larvae) were unable to create a feeding scar when leaf toughness exceeded 0.20 mg per mm^2. High leaf toughness may partly explain the deaths of all the larvae on *C. eximia* before the completion of the second instar. However, there were probably additional reasons for the demise of the larvae fed *Corymbia*, although sideroxylonal could not have been among them because the species is devoid of this compound. For example, *C. eximia* differed notably from others used in the laboratory investigations by its high concentrations of α-pinene and γ-terpinene (Supplementary Material, Fig. 2). Exactly how sideroxylonal might be detrimental to neonate *M. privata* is a mystery. Research by Moore and Evertz (2006, unpubl.) has shown that sideroxylonal is most likely synthesized by the cells surrounding the oil glands and may be stored within the oil glands. However, neonate and second instars typically

feed on young, expanding leaves and, even then, around oil glands (Steinbauer and Matsuki 2004). Because oil glands are not fully formed until leaf expansion is complete (Carr and Carr 1970), it seems probable that young larvae ingest sideroxylonal by rupturing or swallowing oil gland progenitor cells. Oil gland progenitor cells synthesize sideroxylonal and monoterpenes before the maturation of the oil glands and are densely packed in expanding leaves (Moore, pers. comm.). When larvae are large enough to ingest whole leaf fragments (i.e., from the third instar onward), they are exposed to the sideroxylonal in the leaves of their hosts because they disrupt and swallow mature oil glands.

The lower larval survival on hosts that produce both sideroxylonal and modest to high concentrations of monoterpenes vs. the higher survival of larvae on a host that produces high concentrations of sideroxylonal but virtually no monoterpenes (namely *E. macarthurii*) could suggest that variations in sideroxylonal concentration alone do not determine survival. [According to Boland et al. (1991), *E. macarthurii* has a total oil content between 0.8 and 1.1% (fresh weight), but its main component is geranyl acetate, followed by β-, α-, and γ-eudesmol, respectively]. The severity of defoliation by adult Christmas beetles of trees of six species of eucalypt was negatively correlated with the concentration of 1,8-cineole in leaves (Edwards et al. 1993). Edwards et al. (1993) did not attribute this reduction in feeding solely to cineole. It has subsequently been shown in folivorous marsupials of eucalypts only (although a similar interaction is considered likely to occur in insects also) that high cineole odors act as a cue for the presence of high concentrations of sideroxylonal, which is actually the compound that the animals appear to avoid (Lawler et al. 2000). McLean et al. (2004) have shown that the biological activity of jensenone and sideroxylonal arises because the functional aldehyde groups of both compounds bind with the natural amines on the animal's gut wall (again, a similar mechanism is thought likely to also occur in insect herbivores). Hence, there is some evidence for interactive effects between monoterpenes and FPCs—albeit pre-ingestion. Because a number of species of insects metabolize certain foliar monoterpenes (Ohmart and Larsson 1989; Fletcher et al. 2000; Schmidt et al. 2000; Southwell et al. 1995, 2003), perhaps, the addition of high concentrations of sideroxylonal to the ingesta overwhelms the capacity of the insect gut to degrade all the compounds, and it is via this mode of action that sideroxylonal affects larval survival. If high oil content alone antagonized the toxicity of moderate concentrations of sideroxylonal, such an interaction should have been noted sooner than now because the relationship would hold across different *Eucalyptus* species that synthesize it. Because *E. nitens* N64 (the family least preferred by female and least suitable for larvae) can be only partially differentiated from trees of the three other families of *E. nitens* by its concentrations of α-terpineol, 1,8-cineole, and limonene (Supplementary Material, Fig. 3), perhaps attention should be given to the interactions of these monoterpenes and sideroxylonal.

The phenomenon surrounding the occurrence of outbreaks of *M. privata* in mixed plantations of *E. globulus* and other eucalypts may be a consequence of the insect experiencing a variety of primary host and other eucalypt monoterpene odors. Liu et al. (2005) reported that *Plutella xylostella* (Lepidoptera: Plutellidae) could be attracted to non-host volatiles on a preferred host plant if they had previously experienced the odor. By this scenario, *M. privata* that develop on *E. globulus* might acquire an induced preference for the neighboring species of eucalypt, thus increasing the chance that they might later oviposit on them. The results of Linn et al. (2005) that showed that most *Rhagoletis pomonella* (Diptera: Tephritidae) fly toward the odor of their developmental host suggest that such a change would happen slowly. Likewise, the similarity of the natal host and the non-host is likely to influence the extent to which slight alterations of preference result in expansion onto the novel species (Bengtsson et al. 2006). Perhaps, given this background, outbreaks of *M. privata* in single species plantations of novel species of eucalypt are as yet unknown.

We suggest that our findings demonstrate how similarities between novel and preferred eucalypt species, both in terms of their epicuticular wax and monoterpene compositions, may have facilitated the host expansions by *M. privata* that have been observed in the past couple of decades. From an applied perspective, an important question to address would be whether host races of *M. privata* now exist. Future studies should examine whether females prefer to oviposit on the species on which they develop and whether they prefer to mate with males that have developed on that same host. It would also be important to know whether the limits to the detoxification capacity of larvae have prevented the occurrence of a greater number of host expansion events than have already been witnessed.

Acknowledgments We thank Nick Collett, John Connors, David de Little, Jane Elek, Kirsten Evertz, William "Bill" Foley, Anne Hastings, Ken Hill, Ben Moore, Jan Scheirs, and Rex Sutherland for their assistance/advice. Colleagues Caroline Müller, Helen Nahrung, and Sören Nylin provided useful comments on an early draft of the manuscript. This study was conducted while FÖ was a visiting Postdoctoral Fellow supported by funding from the Hellmuth Hertz Foundation and CF Lundströms Stiftelse.

	N63	N64	N65	N66
Toughness	$0.137±0.0041^{a}$	$0.132±0.0034^{ab}$	$0.150±0.0078^{a}$	$0.115±0.0045^{b}$
Water	$49.5±0.34^{a}$	$48.1±0.40^{b}$	$46.0±0.27^{c}$	$50.3±0.30^{a}$

[†] These means are the same as those measured for leaves used in binary choice assays 3 and 4. The leaves used in the choice assays were harvested on 31 January and 7 February, respectively, whereas the survival assay was begun on 6 March. Therefore, the toughness of the leaves of *C. eximia* and *E. macarthurii* that were used in this assay was not thought necessary to measure because they were likely to be comparable to those of leaves harvested earlier

Data are means±SE, N=10 leaves unless otherwise stated. Superscripted letters along rows indicate mean difference at $P \leq 0.05$

Received: 21 August 2007 / Revised: 6 December 2007 / Accepted: 7 December 2007 / Published online: 10 January 2008

Abstract The larva of the hoverfly *Microdon mutabilis* is a specialist social parasite of the ant *Formica lemani* that is adapted to local groups of *F. lemani* colonies but maladapted to colonies of the same species situated only a few hundred meters away. At a study site in Ireland, *F. lemani* shares its habitat with four other ant species. All nest under stones, making the oviposition choice by *M. mutabilis* females crucial to offspring survival. In this study, we tested the hypothesis that, as an extreme specialist, *M. mutabilis* should respond to cues derived from its host rather than from its microenvironment, a phenomenon that has hitherto only been addressed in the context of herbivorous insects and their parasitoids. In behavioral assays, *M. mutabilis* females reacted to volatiles from *F. lemani* colonies by extending their ovipositors, presumably probing for an oviposition substrate. This behavior was not observed toward negative controls or volatiles from colonies of *Myrmica scabrinodis*, the host ant of the closely related *Microdon myrmicae*. Coupled gas chromatography-electroantennography (GC-EAG) that used antennal preparations of *M. mutabilis* located a single physiologically active compound within an extract of heads of *F. lemani* workers. Coupled GC-mass spectrometry (GC-MS) tentatively identified the compound as a methylated methylsalicylate. GC co-injection of the extract with authentic samples showed that of the four possible isomers (methyl 3-, 4-, 5-, and 6-methylsalicylate), only methyl 6-methylsalicylate co-eluted with the EAG-active peak. Furthermore, the response to methyl 6-methylsalicylate was four times higher than to those of the other isomers. Coupled GC-EAG and GC-MS also revealed physiological responses to two constituents, 3-octanone and 3-octanol, of the *M. scabrinodis* alarm pheromone. However, the behavioral trials did not reveal any behavior that could be attributed to these compounds. Results are discussed in the context of four phases of host location behavior, and of the characteristics, which volatile cues should provide to be useful for an extreme specialist such as *M. mutabilis*.

Introduction

Host localization and recognition is crucial in the lives of female parasites and parasitoids (Godfray 1994), particularly when the larval stages do not disperse and are unlikely to detect a host themselves (Sadeghi and Gilbert 2000). In these situations, an ovipositing female has to locate suitable hosts, which may be hidden in a complex environment, widely dispersed or rare, making detection difficult (Morehead and Feener 2000; Morehead et al. 2001).

There are typically four stages to host localization: (1) finding a suitable habitat for the host, (2) locating the host

within that habitat, (3) accepting the host, and finally (4) ovipositing (Godfray 1994; Sutherland et al. 2001). Throughout these stages, parasites rely on a range of cues, including olfactory, visual, and/or acoustic signals. These may come directly from the host animal or plant, or in combination from the host and the microenvironment (Godfray 1994). The response of females to cues can be genetically fixed, although an increasing number of studies show that cues can also be acquired by conditioning and possibly by learning (Godfray 1994).

Whether parasites and parasitoids use habitat or host-derived cues is thought to reflect their level of host specificity (Vet and Dicke 1992; Vet et al. 1993; Cortesero et al. 1997; De Moraes and Mescher 2005). Although habitat-derived cues may be adaptive for generalists, host-derived cues are used for host location and recognition by parasitoids that attack one or a few species (van Alphen and Visser 1990; Godfray 1994). However, aphid attack also can cause host plants to produce different chemical signals, depending on the species of aphid, and thereby attract a specialized parasitoid (Du et al. 1998). Host pheromones provide useful host recognition cues. Because of their consistency and volatility, they provide easily detectable and reliable cues both for intraspecific communication and for use as kairomones (Feener et al. 1996; Orr et al. 2003; Powell and Pickett 2003). As the compounds are fundamental to host communication, there may be a cost in reducing pheromone production to avoid parasitoid attack (Godfray 1994). Of course, different cues may be utilized through the four stages of host location (Dicke et al. 1985). Although volatile chemicals are long-range indicators of the presence of a host, these may be shared by several co-existing species; less volatile, species-specific compounds might then be used for host acceptance (Morehead 2001).

The larvae of the syrphid fly *Microdon mutabilis* live as predators of ant brood in colonies of their host ant *Formica lemani* (Elmes et al. 1999; Schönrogge et al. 2006). Like many hosts of social parasites, *F. lemani* is moderately polygyne, at least in populations infested by *Microdon* (Gardner et al. 2007). *M. mutabilis* has a short free-living adult stage of up to 10 d in the laboratory but probably <5 d in the wild, and females oviposit in the environment of *F. lemani* (Schönrogge et al. 2006). The larvae apparently develop for 2 yr before pupation in the ant nest, from which the emerging adult has to escape (Schönrogge et al. 2000). The distinctive feature of *M. mutabilis*' relationship with *F. lemani* is its extreme host specificity, in which a hoverfly population is specific not only to *F. lemani* as a species, but to certain *F. lemani* nests within a host ant population (Elmes et al. 1999; Schönrogge et al. 2006). The exact mechanism by which *M. mutabilis* infiltrates host colonies is unknown, although there are indications that it relates to chemical compounds deposited by the females on the eggs (Elmes et al. 1999; Schönrogge et al. 2006). One consequence of host specificity at this level is the limited dispersal by *M. mutabilis* females of just a few meters from the natal nest (Schönrogge et al. 2006). Even over such short distances, however, the female would improve survival chances of her offspring if she could recognize colonies of *F. lemani* for oviposition.

This study was carried out on The Burren, Ireland, the largest outcrop of limestone pavement in Europe where *F. lemani*, like other ant species, builds nests under loose stones. We characterized the environment in which *M. mutabilis* females identify suitable ant nests for oviposition. Then, by using a combination of behavioral assays, electrophysiological studies, and chemical analysis, we identified olfactory host location and/or oviposition cues, thus testing the hypothesis that the extreme specificity of *M. mutabilis* originates from the host directly, rather than from the environment.

Methods and Materials

Distribution of Ant Nests within Sites All species of ants were mapped in three sites (1,000–1,500 m^2 and 6–24 km apart) on the Burren, Co. Claire, Ireland in May 2000, and the position of every nest was determined by triangulation by using a Laser Range Finder (Laser Technologies, Inc.). The Burren represents a roughly circular area of limestone, about 25 km in diameter. Both *F. lemani* and *M. mutabilis* were found locally throughout the Burren, although valleys with dense hazel undergrowth may be barriers to dispersal, and little is known about the population structure across this large area (Schönrogge et al. 2006). At three sites, all ant species were recorded.

Collection and Maintenance of Microdon and Host Ants One hundred *M. mutabilis* pupae were collected from *F. lemani* nests on Mull, Scotland, in 2001 and on the Burren in 2003. Emerging males and females were mated and the females left at 16°C for 24–72 hr, and then acclimatized at 20°C for 1 hr before being used in experiments. Five females from Mull were used in electrophysiological studies, and 44 females from the Burren were used in the olfactometer experiments.

Samples of at least 150 workers were taken from each of six *F. lemani* nests on the Burren and from six colonies of *Myrmica scabrinodis*, in Dorset, UK, which until recently was thought to be an alternative host for *M. mutabilis* and is host to the closely related hoverfly *Microdon myrmicae* (Schönrogge et al. 2002). Laboratory colonies of 100 workers from each colony were established in nest boxes comprising two small plastic arenas, with a 3-cm^2 piece of

sponge cloth covered in glass and secured with an elastic band (Fig. 1) (Elmes et al. 1991). All workers were introduced to the laboratory colonies at least 24 hr before olfactometer experiments began. A second set of nest boxes without ants was used as a control. All experimental and control nest boxes contained 0.1 g of *Drosophila melanogaster* larvae and 0.2 g sugar granules as ant food, and the sponge cloth was kept moist.

Olfactometer Set-up and Behaviors Scored A four-way olfactometer, comprising a square Perspex arena with treatment arms at each corner, was used (Fig. 1). This design was chosen because *M. mutabilis* females did not acclimatize well in the traditional Pettersson four-way olfactometer (Al Abassi et al. 2001), and the additional depth of our olfactometer allowed females to display a larger range of behaviors (Fig. 1). Four test areas of equal size were designated, each containing a treatment arm at the center. A nest box was connected to each treatment arm, containing either *F. lemani* or *M. scabrinodis* workers (treatment), or no ants (control). Olfactometers were set up with two treatment and two control arms, with like arms opposite.

All *M. mutabilis* females were mated to ensure that they were motivated to find ant colonies in which to lay eggs (virgin females were not tested). Also, the females had no contact with ants after pupation. Females were placed individually into the olfactometer, which was closed with a glass lid. An airflow of 500 ml/min was established by using a pump attached to a hole in the base of the olfactometer. The airflow drew air from the treatment and control arms into the arena, but was low enough to ensure that the fly was not disturbed. Ant nests were obscured from the females' view by using black screens to eliminate visual cues. All trials were conducted under natural light.

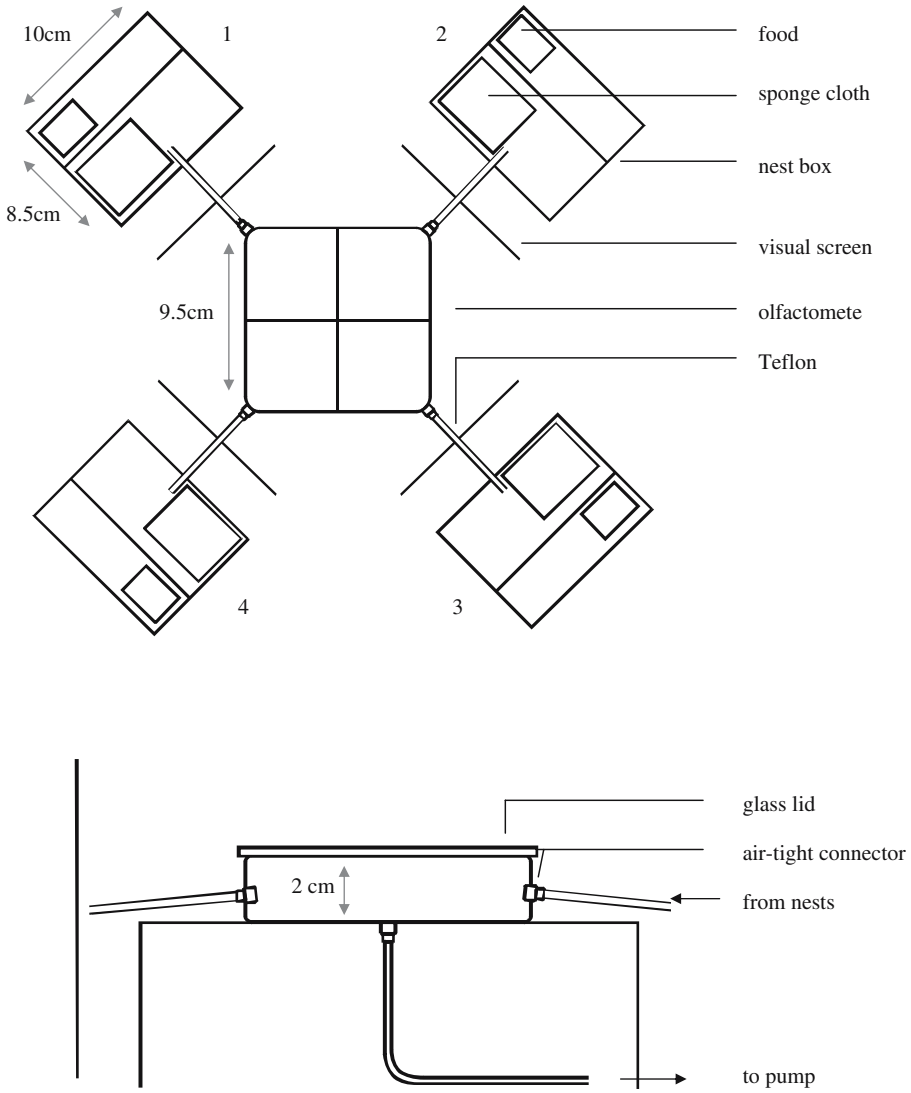

Fig. 1 Olfactometer used to examine the response of mated *M. mutabilis* females to nest boxes containing test ant colonies (100 workers of either their host ant or a non-host ant) compared with control nest boxes containing no ants. Two test ant colonies and two control boxes were used in each experiment with like arms opposite (e.g., test colony on *1* and *3*, control boxes on *2* and *4*)

We recorded the amount of time the *M. mutabilis* female spent in each of the four sections and how often and where she rested, cleaned herself, or displayed oviposition behavior, i.e., the extension of the ovipositor (although no eggs were laid in any of the trials). The latter was scored when the female extended her ovipositor and curled it under her abdomen, as observed when females oviposit onto soil (see also Sutherland et al. 2001). Resting periods were recorded when females remained motionless for more than 10 sec.

Olfactometer Trials Fifteen *M. mutabilis* females were used to assess the response to *F. lemani* workers (host ant) relative to negative controls. Two *F. lemani* colonies were randomly chosen from the six test nests before the start of each bioassay (nests were numbered 1–6 and lots were drawn). Females were allowed to acclimatize for 15 min before recording began. After 30 min, trials were terminated and the female removed. The whole chamber was cleaned with warm water and detergent (Decon) and then rinsed with distilled water and allowed to dry. The olfactometer was rotated 90° before the start of the next trial to eliminate any effect of the direction of light. Each *M. mutabilis* female was used only once. Another 16 *M. mutabilis* females were used to assess their response to the non-host *M. scabrinodis* by using the same procedure described above, but replacing the *F. lemani* nests with those of randomly chosen *M. scabrinodis* nests.

To test for significance, we calculated the difference in frequency of the behaviors in the treatment and control areas of the arena and tested for a difference from 0 by using the Exact Wilcoxon signed-rank test. Similarly, the time spent in the treatment sections of the arena was tested for significant differences from 50%.

Identification of Olfactory Cues

Insects Two hundred and fifty *M. scabrinodis* workers and 20 *F. lemani* frozen workers (−70°C for 5 min) were extracted in diethylether by submerging them for 2 min. The *M. scabrinodis* extract was vacuum distilled to remove high molecular weight impurities (Griffiths and Pickett 1980). In addition, 20 *F. lemani* workers were snap-frozen and the cadavers separated into head, thorax, and abdomen. Three samples that contained heads, thoraxes, and abdomens, respectively, were extracted in diethylether. All ant samples were concentrated under N_2 to 0.1 ant/μl equivalents.

Gas Chromatography (GC) Volatiles were analyzed on a Hewlett-Packard 5890A gas chromatograph equipped with a cold on-column injector, a flame ionization detector (FID), and a 50 m×0.32 mm i.d. HP-1 bonded phase-fused silica capillary column. The oven temperature was maintained at 40°C for 2 min and then programmed at 10°/min to 250°C. The carrier gas was hydrogen.

Electrophysiology Electroantennogram (EAG) recordings were made by using Ag-AgCl glass electrodes filled with saline solution (composition as in, but without glucose; Maddrell 1969). Mated *M. mutabilis* females were immobilized by chilling, and one antenna was removed as close to the head as possible. The cut base of the antenna was inserted into the indifferent electrode. The tip of the arista was excised, and the recording electrode was slipped over the cut surface. The signals produced by the antenna were passed through a high impedance amplifier (UN-06, Syntech, The Netherlands) and recorded by using a customized software package (EAG for Windows, Syntech).

Stimulus Delivery The delivery system employed a filter paper in a disposable Pasteur pipette cartridge, as described by Wadhams et al. (1982). The stimulus (2 sec duration) was delivered into a purified air stream (1 l/min) flowing continuously over the preparation. Samples (10 μl) of extracts or standard solutions of test compounds (10^{-6} g/10 μl were applied to filter paper strips, and the solvent was allowed to evaporate (30 sec) before the strip was placed in the cartridge. The control stimulus was hexane (10 μl). Fresh cartridges were prepared immediately before each stimulation.

M. mutabilis female antennae were tested for responses to *F. lemani* workers (whole), *F. lemani* worker heads, abdomens, and thoraxes, and *M. scabrinodis* whole workers before coupled GC-EAG experiments (see below). Synthetic standards of compounds tentatively identified by GC-MS (see below) were tested for EAG activity. Responses to a solvent control and solutions of the synthetic standards (N=5–6) were normalized to the response to (4a*S*,7*S*,7a*R*)-nepetalactone, a compound known to have activity in other Syrphidae (C. Woodcock, pers. obs.) but not found in either *F. lemani* or *M. scabrinodis* workers. The responses were compared for significant differences by using Student's t test.

Coupled Gas Chromatography-Electroantennography (GC-EAG) The coupled GC-electrophysiology system in which the effluent from the GC column is simultaneously directed to the antennal preparation and the GC detector has been described previously (Wadhams 1990). Separation of the volatiles was achieved on an AI 93 GC equipped with a cold on-column injector and an FID. Two columns were used, a 50 m×0.32 mm i.d. HP-1 column and a 30 m×0.3 mm i.d. HP-WAX column. For the HP-1 column, the oven temperature was maintained at 30°C for 2 min and then programmed at 5°/min to 100°C and then at 10°/min to

Table 1 Geographical location of three sites on the Burren, Co. Clare, Ireland, the area sampled and number of nests found for each of five ant species recorded

	Coordinates	Area sampled (m^2)	*F. lemani*	*L. flavus*	*L. niger*	*M. sabuleti*	*M. schencki*

250°C. For the HP-WAX column, the oven temperature was maintained at 30°C for 1 min and then programmed at 10°/min to 220°C. The carrier gas was hydrogen. The outputs from the EAG amplifier and the FID were monitored simultaneously and recorded with a customized software package (GC/EAD for Windows, Syntech, The Netherlands).

Coupled Gas Chromatography-Mass Spectrometry (GC-MS) A capillary GC column (50 m×0.32 mm i.d. HP-1) fitted with an on-column injector was directly coupled to a mass spectrometer (VG Autospec, Fisons Instruments). Ionization was by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min and then programmed at 5°/min to 250°C. Tentative identification by GC-MS was confirmed by peak enhancement with authentic samples (Pickett 1990).

Chemicals Methyl 5-methylsalicylate, 3-octanone, and (±)-3-octanol were purchased from Sigma-Aldrich (Gillingham, UK). Methyl 3-methylsalicylate and methyl 4-methylsalicylate were synthesized in high purity (>99% pure by GC) by esterification of 3-methylsalicylic acid (Aldrich) and 4-methylsalicylic acid (Aldrich), respectively. Methyl 6-methylsalicylate was synthesized in high purity (>99% pure by GC) in two steps, via diazotization of 2-amino-6-methylbenzoic acid (Aldrich) to generate 6-methylsalicylic acid, and subsequent esterification. Confirmation of the identity of synthesized materials was obtained by ^{1}H and ^{13}C NMR spectroscopy (Bruker 500 MH_z).

Results

Ant Communities on the Burren We identified nests of five ant species on three *M. mutabilis* sites in the Burren: *Lasius flavus*, *L. niger*, *F. lemani*, *Myrmica sabuleti*, and *M. schencki*. Table 1 gives the location and area of each site and the number of nests of each ant species. We found no evidence of *M. mutabilis* in the nests of any species other than *F. lemani*. Figure 2 shows, as an example, the distribution of ant nests occupied by the five species at site 1 (Table 1). *F. lemani* was found throughout the site, although most were concentrated toward the bottom parts of the square. Nests of the other ant species are found mostly to the top and left of the plot, although there is much overlap. There was no obvious visual difference between the stones covering *F. lemani* nests and those of the other ant species.

Olfactometer Trials Ovipositor extensions were observed only in trials where *M. mutabilis* females were exposed to

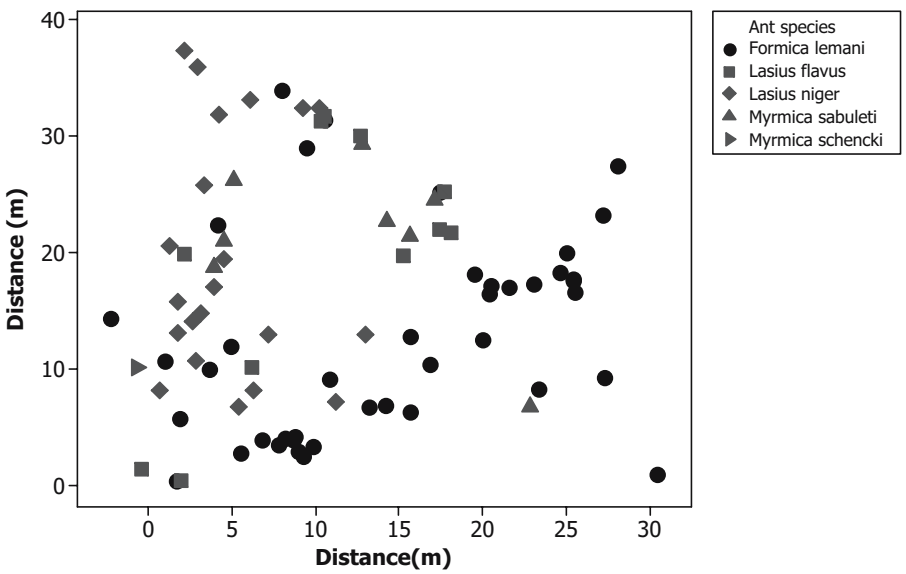

Fig. 2 Spatial distribution of colonies of five ant species recorded at site 1 (Table 1) on the Burren, Ireland

odors from their host ant, *F. lemani*. There were no ovipositor extensions in trials with the non-host *M. scabrinodis*, although cleaning and resting were observed in both sets. In the 16 trials of *M. mutabilis* females with *F. lemani* nests vs. empty control nests, ovipositor extension was observed in nine, cleaning in six, and resting in 12 trials.

There were no significant differences in the frequency of cleaning or resting behavior in either sets of trials with treatments of either the host *F. lemani* (cleaning: v=12, N=6, P=0.834; resting: v=45, N=12, P=0.666), or the non-host *M. scabrinodis* (cleaning events were too few to be analyzed; resting: v=23, N=10, P=0.683) (Fig. 3). The average percentage time spent in front of the ant inlet in *F. lemani* trials was 51.3%±5.73% (Exact Wilcoxon: v=77, N=16, P=0.66) and in *M. scabrinodis* trials 52.9%±4.69% (Exact Wilcoxon: v=62, N=15, P=0.932). However, females extended the ovipositor more often in front of the inlet from *F. lemani* colonies compared to the controls (v=45, N=9, P< 0.01; Fig. 3a), whereas no oviposition attempts were recorded in trials with the non-host *M. scabrinodis* (Fig. 3b).

Electrophysiology and Identification of Active Compounds In contrast to the behavioral trials, *M. mutabilis* responded to extracts of both *F. lemani* and *M. scabrinodis* workers in the EAG. With the extracts of *F. lemani* heads, thoraxes, and abdomens, *M. mutabilis* responded only to the head extracts (Fig. 4).

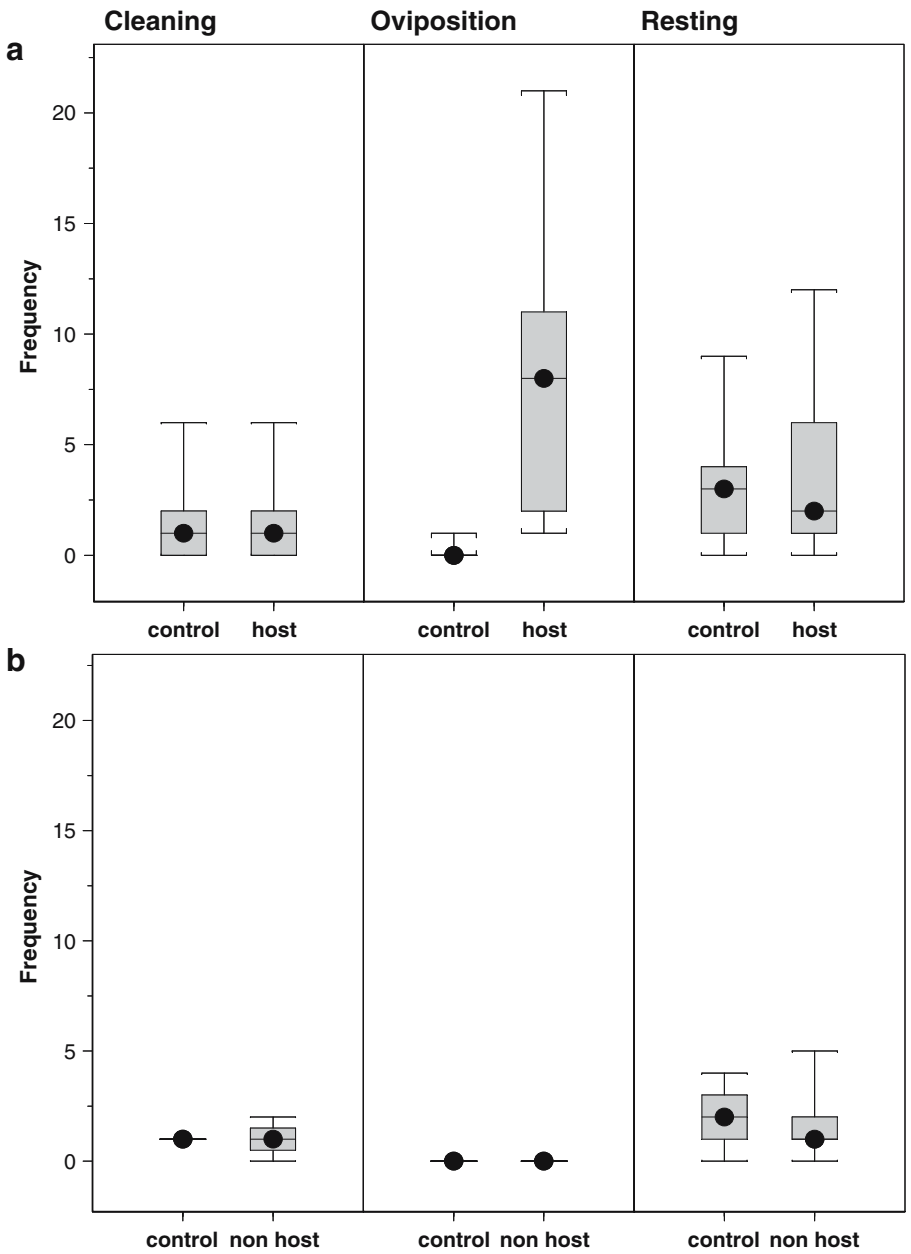

Fig. 3 Frequencies of cleaning, oviposition, and resting behavior using (**a**) the host ant *F. lemani* and (**b**) the non-host *M. scabrinodis* as treatments against negative controls. The dot and horizontal bar marks the median, the top and bottom of the box the 25% and 75% quartiles, and the whiskers indicate the range. The frequency in oviposition behavior in front of *F. lemani* nests differed significantly (Exact Wilcoxon sign-rank test: v=45, N=9, P<0.01)

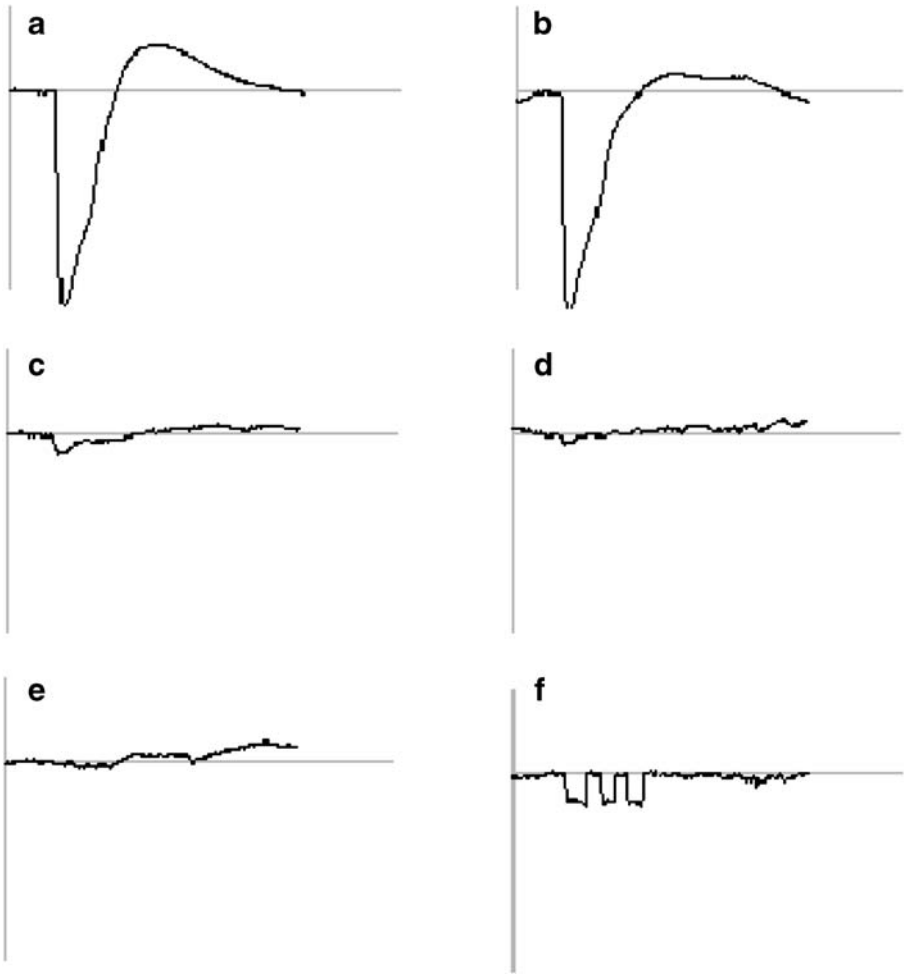

Fig. 4 EAG responses of female *Microdon mutabilis* females to ant samples. **a**=*Formica lemani* heads; **b**=*Myrmica scabrinodis* whole bodies; **c**=*F. lemani* thoraxes; **d**=*F. lemani* abdomens; **e**=hexane; **f**= 0.1 mV signal

Coupled GC-EAG analysis located a single active component in the *F. lemani* whole workers extract (Fig. 5a). Further GC-EAG on *M. mutabilis* confirmed that this compound was found only in the heads of *F. lemani* workers. The active compound was tentatively identified by coupled GC-MS as a methylated analogue of methyl salicylate. The identity of the peak as methyl 6-methylsalicylate was confirmed by GC coinjection of the *F. lemani* extract with an authentic sample, resulting in successful peak enhancement. GC coinjection of the extract with the other isomers (methyl 3-methylsalicylate, methyl 4-methylsalicylate, methyl 5-methylsalicylate) showed no peak enhancement. All four synthetic isomers were presented to five *M. mutabilis* antennae, and gave significantly larger EAG responses than that of the solvent (Table 2). However, the response to methyl 6-methylsalicylate was significantly (four times) higher than the other isomers (Table 2)

There were also two compounds in the sample of *M. scabrinodis* workers to which *M. mutabilis* antennae responded (Fig. 5b). Mass spectra indicated that the active compounds were 3-octanone and (±)-3-octanol, and their identities were confirmed with GC by coinjecting the synthetic compounds with ant extract. The stereochemistry of the 3-octanol was not determined. Synthetic 3-octanone and 3-octanol (racemic) were presented to the antennae of *M. mutabilis*, and both gave a significant response relative to the solvent (Table 2).

Discussion

Female *M. mutabilis* hoverflies exposed to volatile odors from colonies of the ant species *F. lemani* extend the ovipositor, suggesting that they use a volatile cue to identify nest sites of suitable hosts. Subsequent electrophysiological studies identified only a single compound in the mixture of volatiles that is recognized by *M. mutabilis*. MS and additional GC and EAG studies confirm that this is methyl 6-methylsalicylate. However, by also responding to 3-octanol and 3-octanone from *M. scabrinodis*, *M. mutabilis* may also be able to avoid nests of this non-host species.

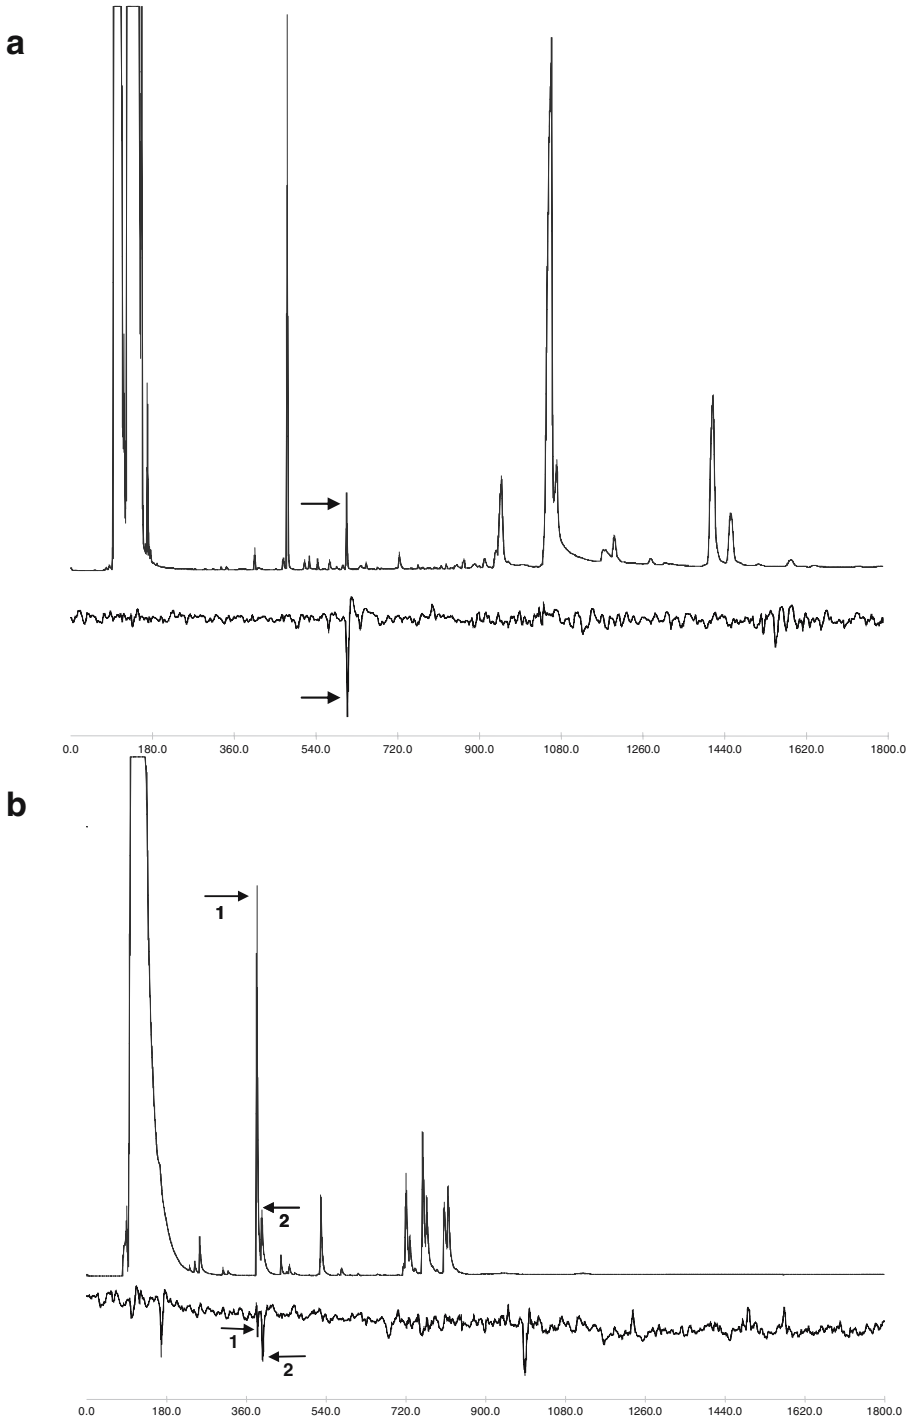

Fig. 5 *Microdon mutabilis* female excised antennae tested in coupled GC-electroantennograms with (**a**) extract of whole *F. lemani* workers and (**b**) extract of whole *M. scabrinodis* workers (vacuum distilled, 0.1 worker equivalents). The upper lines in (**a**) and (**b**) show the output from the GC detector and the lower lines that from the excised antennae. Active compounds are indicated by arrows. In (**a**), the peaks refer to methyl 6-methylsalicylate and in (**b**), to *1*) 3-octanone and *2*) 3-octanol

The use of volatile cues that originate from host ant colonies has been suggested as a mechanism for oviposition patterns in other social parasites such as the myrmecophilous butterflies in the genus *Maculinea* (van Dyck et al. 2000). However, in this system, eggs are laid on host plants and not in ant colonies directly, and subsequent analyses indicate that the developmental stage and niche of the plants determine the spatial patterns of butterfly oviposition, rather than ant-derived cues (Thomas and Elmes 2001; Musche et al. 2006). The myrmecophilous beetle *Lomechusa* (=*Atemeles*) *pubicollis*, however, has been shown to use volatile cues for orientation when changing from the summer host (*Formica* spp. ants) to the winter host (*Myrmica* spp. ants) (Hölldobler 1969, 1970; Hölldobler and Wilson 1990). Whereas the orientation behavior of *L. pubicollis* has been established, the nature of the volatile cue(s) has not been identified. Also, in contrast to the observed behavior by *L. pubicollis*, the extension of the

ovipositor in *M. mutabilis* is likely to reflect host acceptance in reference to the four stages of host location (Godfray 1994; Sutherland et al. 2001). In our studies, the time spent in front of the ant colonies (host or non-host) or the empty control nests did not differ significantly. It is possible that the olfactometer was too small to investigate orientation behavior in *M. mutabilis* females. Casual observations in the field, when a stone is lifted from above a *F. lemani* nest, suggest that escaping odors are attractive to adult females in the vicinity (G.W. Elmes, pers. obs.). As methyl 6-methylsalicylate was the only physiologically active volatile compound in the *F. lemani* extracts, it could also be responsible for attraction; additional studies are needed to establish whether *M. mutabilis* uses methyl 6-methylsalicylate for orientation.

To be useful as a cue for either orientation or host acceptance, a volatile compound or mixture needs to distinguish the correct host from a non-host. We identified methyl 6-methylsalicylate as a constituent of the *F. lemani* head extract. The same compound has been reported as a constituent of the mandibular gland in other Formicidae, including males of several *Camponotus* species, where it acts as a swarming pheromone (Torres et al. 2001), and in the ponerine ant *Gnaptogenys pleurodon*, where it functions as an alarm pheromone (Duffield and Blum 1975). It has also been identified in the poison gland of *Tetramorium impurum,* where it acts as a major component of the trail pheromone (Attygalle et al. 1990). The function of this compound in intraspecific communication of *F. lemani* is as yet unclear, but while it has been found in several other ant species, none of them lives sympatrically with *F. lemani*. Although our knowledge about the occurrence of methyl 6-methylsalicylate in other ant species is limited, it appears that within the communities where *F. lemani*, *M. scabrinodis*, and *M. mutabilis* co-occur, methyl 6-methylsalicylate provides a mechanism for the hoverfly to identify *F. lemani* reliably. The purity of methyl 6-methylsalicylate could be a criterion associated with *F. lemani.*

3-Octanone and 3-octanol, found in the extracts of *M. scabrinodis* ants, elicited a response from *M. mutabilis* antennae. Both compounds are known constituents of the alarm pheromone of most European *Myrmica* species (Morgan et al. 1978; Cammerts et al. 1981, 1982, 1983, 1985). In the olfactometer experiments, we observed no behavior of *M. mutabilis* females toward *M. scabrinodis* that could be attributed to the recognition of volatile cues, but the same argument regarding the limitations of our experimental set-up to study orientation might apply. Nevertheless, we suggest that these chemicals may provide cues that allow female *M. mutabilis* to identify and reject this unsuitable species of host ant in the field.

As predicted by Cortesero et al. (1997), it appears that *M. mutabilis*, as an extreme specialist, may use a host-derived, rather than a microenvironment-derived cue to identify *F. lemani* colonies. Whereas the hypothesis was formulated in the context of parasitoid host specificity, it appears to be applicable equally to parasites and social parasites. It seems unlikely that the extreme host specificity shown by *M. mutabilis* to particular groups of *F. lemani* colonies could be based on a single compound (Elmes et al. 1999; Schönrogge et al. 2006), although this work suggests a mechanism by which *M. scabrinodis* nests might be avoided. The contents of ant mandibular glands, which are often involved in alarm responses, have also been suggested as having a role in nest mate recognition (Jaffe and Sanchez 1984). However, the argument generally refers to mixtures of chemicals, where colony-specific ratios of compounds might confer sufficient information to distinguish among colonies. It is difficult to imagine how this could be achieved with one compound. However, colonies in the behavioral trials included only workers, and it is possible that other members of the colony (brood, queens) could be sources of additional volatile cues.

Acknowledgments We thank Judith Wardlaw for help with rearing and maintenance of ant colonies, and two anonymous referees for helpful comments. This work was partly funded by NERC (GR3/12662) and partly by the EU FP V project MacMan (EVK2-CT-2001-00126). Protected by Fumigants: Beetle Perfumes in Antimicrobial Defense

Jürgen Gross · Kerstin Schumacher · Henrike Schmidtberg · Andreas Vilcinskas

Received: 16 August 2007 / Revised: 30 November 2007 / Accepted: 11 December 2007 / Published online: 31 January 2008

Abstract Beetles share with other eukaryotes an innate immune system that mediates endogenous defense against pathogens. In addition, larvae of some taxa produce fluid exocrine secretions that contain antimicrobial compounds. In this paper, we provide evidence that larvae of the brassy willow leaf beetle *Phratora vitellinae* constitutively release volatile glandular secretions that combat pathogens in their microenvironment. We identified salicylaldehyde as the major component of their enveloping perfume cloud, which is emitted by furrow-shaped openings of larval glandular reservoirs and which inhibits *in vitro* the growth of the bacterial entomopathogen *Bacillus thuringiensis*. The suggested role of salicylaldehyde as a fumigant in exogenous antimicrobial defense was confirmed *in vivo* by its removal from glandular reservoirs. This resulted in an enhanced susceptibility of the larvae to infection with the fungal entomopathogens *Beauveria bassiana* and *Metarhizium anisopliae.* Consequently, we established the hypothesis that antimicrobial defense in beetles can be expanded beyond innate immunity to include external disinfection of their microenvironment, and we report for the first time the contribution of fumigants to antimicrobial defense in animals.

Introduction

Larvae of the leaf beetle taxon Chrysomelina possess nine pairs of dorsal exocrine glands, which are inserted in the body surface and contain reservoirs of glandular secretions. In case of predator attack, the larvae evert their glandular reservoirs to present the fluid secretions toward the exterior. The secreted toxins vary both in structure and biosynthetic origin. The major components secreted by leaf beetle larvae belonging to the taxa *Phaedon*, *Gastrophysa*, *Linaeidea*, and most *Phratora* species are iridoid monoterpenes, which are produced *de novo* via the acetate-mevalonate pathway. In contrast, larvae of *Chrysomela* spp. and *Phratora vitellinae* emit secretions in which salicylaldehyde is the major component (Wain 1943; Oldham et al. 1996; Pasteels et al. 1982, 1988). When feeding upon willows (Salicaceae), larvae of the latter species sequester phenolic glycosides (e.g., salicin) from their host plants as precursors to produce salicylaldehyde (Wallace and Blum 1969; Pasteels et al. 1988; Gross and Hilker 1995). Different biological functions have been reported for larval glandular secretions from beetles: Some prevent intraspecific competition (Gross and Hilker 1995), whereas others show insecticidal activities (Dettner et al. 1992) or act as allomones in defense against predators. Although salicylaldehyde has repellent activity against some generalist predators (Blum et al. 1972; Hilker and Schulz 1994; Pasteels et al. 1986; Gross et al. 2004), it also has detrimental effects for the larvae by attracting specialized predators and parasitoids (Köpf et al. 1997;

Gross et al. 2004; Zvereva and Rank 2004). This raises the question: Why do leaf beetle larvae permanently produce salicylaldehyde?

Beetles are of the order with the highest number of species among eukaryotes. Like other eukaryotes, they have evolved an innate immune system that provides protection against intruding pathogens. The first representative genome, that of the red flour beetle *Tribolium castaneum*, has recently been sequenced (Tribolium Genome Sequencing Consortium 2008). The innate immunity of this species bears similarities to that of other insects. For example, numerous homologous molecules have been identified in *Tribolium* that are known to mediate perception of infection and immune-related signaling, or represent antimicrobial peptides such as defensins or thaumatins (Altincicek et al. 2007). Studies provide evidence that the larval secretions of some Chrysomelina species possess antimicrobial activity against bacteria and entomopathogenic fungi *in vitro* (Gross et al. 1998, 2002). However, the biological impact of these secretions was unclear, because the contact of the larval surface with fungal conidia did not elicit secretion discharge.

Hence, in the present study, we addressed the following questions to find out how an antimicrobial secretion can protect its producer against infection with entomopathogenic microorganisms: (1) Do larvae of the brassy willow beetle *P. vitellinae* permanently emit volatile compounds in their secretions, and by means of which morphological structure? (2) Do larvae benefit from these fumigants in case of an infestation by conidia of entomopathogenic fungi? To answer these questions, we collected the headspace of undisturbed larvae, analyzed it by GC-MS, and examined the surface of the glandular reservoirs by scanning electron microscopy. Further, we artificially emptied the glandular reservoirs of larvae and applied conidia of several entomopathogenous fungi onto their body surface, followed by monitoring the mortality of larvae with full and empty glandular reservoirs. Finally, the effect of the main component of larval headspace, salicylaldehyde, was tested against entomopathogenic bacteria in bioassays.

Methods and Materials

Insects Larvae of *P. vitellinae* were collected on willows (mainly *Salix fragilis* and *S. rubens*) at Berlin, Germany, transferred to a climate chamber, and reared on the willow *S. fragilis* at 20°C with a natural light/dark cycle.

Fungi Four strains of entomopathogenous fungi, isolated and provided by the Biological Research Centre for Agriculture and Forestry (BBA), Darmstadt, Germany, were used: *Beauveria bassiana* strain 135 (isolated from *Ips typographus* [Coleoptera], 1994) and strain 138 (isolated from Boverol© [Fytovita, Czech Republic], 1995); *Metarhizium anisopliae* strain 140 (isolated from *Ips typographus* [Coleoptera], 1994) and strain 79 (isolated from *Agrotis segetum* [Lepidoptera], 1982).

Bacteria Two subspecies of *Bacillus thuringiensis* were used: *B. thuringiensis tenebrionis* strain 10 BI 256-82, isolated from *Tenebrio molitor* (Coleoptera: Tenebrionidae), and *B. thuringiensis kurstaki* strain HD 1.

Analysis of Larval Headspace

Sampling. Five larvae with filled glandular reservoirs were cooled to 4 °C and transferred to a closed silanisized glass vial, taking care that they did not evert their glandular reservoirs. A continuous flow of purified air was passed for 3 hr through the vial and subsequently through a small carbon filter (5 mg; Graenicher/Quartero, Daumazan, France). The airflow was regulated by a flowmeter (Supelco, Bellefonte, PA, USA) and sucked through the system by a membrane vacuum pump (Vakuubrand, Germany). The filter was then eluted with 20 µl dichloromethane that contained tridecane as internal standard (50 ng/µl; Aldrich, Germany), and the sample was analyzed by gas chromatography mass spectrometry (GC-MS) as described below. For sampling the emission of larvae that had everted their glandular reservoirs, the same procedure was used; however, two artificial stimuli were given during the sampling period: a magnet inside the glass vial was gently moved by a second one outside the system, until all larvae had everted their glandular reservoirs. This was performed after 1 and after 2 hr during the sampling period. For measuring the time-dependent regeneration of the volatiles, the same procedure as described above was carried out with minor modifications: During the sampling period, a leaf of *S. fragilis* was added as food. After sampling of untreated larvae, their glandular reservoirs were artificially emptied (as described below) and the sampling procedure was repeated after 3, 6, 9, 24, and 48 hr. For each treatment, six replications were conducted.

Identification and Quantification of Salicylaldehyde in Larval Headspace One microliter of each sample was injected splitless into a gas chromatograph (Fisons GC 8060, Thermoquest, Germany, injector temperature 240°C) equipped with a 30 m×0.32 mm×0.25 µm db-5 column (Fisons). The temperature program started at 40°C, was held for 4 min, then raised by 10°C/min to 280°C. Helium (Air Liquide, Germany) was used as carrier gas (inlet pressure 10 kPa). The gas chromatograph was coupled to a quadrupole mass spectrometer (Fisons MD 800, Thermoquest, Germany), and EI mass spectra were recorded at

70 eV. The antimicrobial active compound (salicylaldehyde) was identified as described earlier (Gross et al. 2002). The relative amount of salicylaldehyde (ng/µl solvent) compared to the internal standard was calculated with the following formula:

$$\frac{\text{peak area of salicylaldehyde} \times 50\,[\text{ng}/\mu\text{l}]}{\text{peak area of internal standard}}$$

Scanning Electron Microscopy (SEM) Larvae were fixed with 2.5% glutardialdehyde in 0.1 M phosphate-buffered saline (PBS; pH 7.4) for 1 hr at room temperature under moderate shaking. After washing several times in PBS, the animals were dehydrated in a graded series of ethanol. Subsequently, they were dried at critical point with CO_2 in a Balzers CPD 030 and sputtered with gold with a sputter coater 0712 B (Balzer/Leitz). Microscopic investigations were carried out on a Philips XL 20 scanning electron microscope.

Bioassay for Testing Antifungal Activity *In Vivo*

Cultivation of Fungi and Preparation of Conidia Suspensions Conidia from the stock cultures were inoculated into nutrient broth (25 g Standard I, 20 g glucose (Merck, Germany), dissolved in 1,000 ml distilled water) on a gyratory shaker (200 rpm). After 6 d of incubation, 1 ml of the suspension was transferred to malt peptone agar plates (90 mm diam; MPA, LAB 37, UK) and spread with a Drygalsky spatula. After complete sporulation at room temperature for a number of days, the conidia were harvested and mixed for 1 min on a vortex (Vibrofix VF1, Germany) with 2 ml of sterile saline, adjusted to pH 6.1, and 1 µl Tween 20. The conidia were counted in a Neubauer chamber and adjusted to different concentrations (5×10^3, 10^4, 10^5, 10^6 conidia/ml). Fresh spore suspensions were prepared for every experiment.

Removal of Larval Secretion Larvae of the third stage (and in one experiment also of the second stage) were randomly selected and fixed on an ice-block. Under gentle pressure from a needle, the glandular reservoirs were everted by the larva, and the secretion from every individual reservoir was sucked onto a small disk of filter paper (5-mm diameter). After this, the larva was washed in ice-cold deionized water for 2 sec and placed on a filter paper for drying. No food was supplied until the larvae were used for headspace sampling, or until conidia were applied.

Application of Conidia Four groups of larvae were used in the biotests. The first and second groups were "milked" as described above, whereas the third and fourth groups retained their full glandular reservoirs. One test larva each from the first and third group was set on an ice-cold Petri dish to prevent eversion of its glandular reservoirs, and 1 µl of the corresponding spore suspension (1×10^4, 1×10^5, 1×10^6 conidia/ml) was applied to its back. For comparison of the temporal dependent survival of two larval stages, 0.5 µl of spore suspension (1×10^4 conidia/ml; L_2) or 1 µl (5×10^3 conidia/ml; L_3) was applied, corresponding to an application of five conidia/larva. The control larvae for the second and fourth groups were treated with 1 µl of sterile saline. After a short drying period, all 10 larvae from the same treatment were put in a Petri dish (53-mm diameter) lined with moistened filter paper and supplied with leaves of *S. fragilis*. The mortality was controlled every 24 hr until all surviving beetles had hatched to adults. Each experiment was repeated at least 40 times.

Inhibition Zone Assays Suspensions of *Bacillus thuringiensis tenebrionis* and *B. thuringiensis kurstaki* were grown up at 29°C in sterile nutrient bouillon (Standard I, Merck, Germany) to a density of 0.50–0.54, measured at a wavelength of 546 nm. Two hundred and twenty microliters of this suspension were transferred to a 45°C temperate agar suspension comprising 4.07 g Standard I nutrient agar (Merck, Germany) dissolved in 110 ml deionized water. Sterile Petri dishes (Falcon, 8.7-cm diameter) were filled with 5 ml each of this agar suspension and stored at 6 °C for a maximum of 4 d until use. Salicylaldehyde (Roth, Germany) was added either undiluted, with one sample per test plate (located in the middle of the test plate), or diluted (1:10 and 1:100), with one or six samples evenly spaced on the same test plate. Three microliters of each salicylaldehyde sample were applied directly into a hole (2.3-mm diameter), which was punched into the agar beforehand, or indirectly on a piece of filter paper fixed with glue to the middle of the Petri dish lid. For control, the solvent dichloromethane was also tested in the same manner.

Statistical Analysis Comparisons between the amounts of salicylaldehyde emitted by the larvae before and after artificial emptying of their glandular reservoirs was performed by *Wilcoxon matched pairs tests*. The time-dependent headspace sampling of emptied glandular reservoirs was compared to controls (filled reservoirs) by *Friedman* tests. Differences in survival between the controls and the test groups in the bioassays were evaluated by χ^2 *tests*. Comparison of time-dependent survival between two larval stages was analyzed by χ^2 *tests* followed by *sequential Bonferroni correction* (Holm 1979; Bärlocher 1999). Differences between one and six samples per test plate in the inhibition zone tests with *Bt* were analyzed by Mann–Whitney *U* test. All statistical tests were done by using the Statistica 5.5 software (StatSoft 1999).

Results

Headspace samples taken from *P. vitellinae* larvae that did not evert their glandular reservoirs were analyzed by GC-MS, revealing that volatile salicylaldehyde was permanently present as the main component in headspace (average relative concentration compared to internal standard 29.7±28 ng/µl, N=6). When two artificial stimuli were given to trigger an eversion of the glandular reservoirs during the sampling period, the concentration of salicylaldehyde increased to 119.2±99 ng/µl (N=6). Permanent emission of salicylaldehyde was measured during a 48-hr experiment in which the larvae were provided with food. Between 3 and 24 hr after artificial removal of glandular secretion, the content of salicylaldehyde in the larval headspace was reduced. After 48 hr, the relative amount of salicylaldehyde was as high as before the removal (Fig. 1). Typical GC-MS total ion chromatograms before and 6 hr after removal of the secretion are provided in Fig. 2. The peaks of internal standard and salicylaldehyde are indicated. The other peaks represent volatiles emitted from plant leaf, larval frass, and feces.

We examined the body surface of third instars of *P. vitellinae* by SEM (Fig. 3). When the glandular reservoirs are everted (Fig. 3a,c), the secretion is presented on top of the reservoirs. In case the reservoirs are not everted, furrow-shaped openings of glandular reservoirs are visible above the glandular reservoirs (Fig 3b, indicated by arrow).

Artificial draining of glandular secretions did not affect the survival of untreated larvae, but significantly reduced survival after treatment with conidia from both strains of *B. bassiana* or *M. anisopliae*, respectively (conidia concentration 10^4 conidia/ml, Table 1, χ^2 test, P<0.05). By increasing the concentration of the applied conidia, statistically significant differences in survival were measured in one *M. anisopliae* strain (Ma 140) and both *B. bassiana* strains at 10^5 conidia/ml, and in *B. bassiana* strain 135 at 10^6 conidia/ml (Table 1, χ^2 *test*, P<0.05). Detailed analysis of the time-dependent survival, i.e., survival of larvae treated with *M. anisopliae* strain 79 conidia (Fig. 4), revealed a significant reduction in larvae with emptied reservoirs compared to larvae with full reservoirs from the 15th day until the end of the experiment with 5×10^3 conidia/ml (P<0.05), and from the 5th day with 10^4 conidia/ml (P<0.001), respectively. Further increase of conidia dose (10^5 conidia/ml) broke the fumigant defense line, and more than 80% larvae of both test groups died 16 d after the treatment (Fig. 4).

To investigate the differences between two different larval stages, another experiment was conducted that used a concentration corresponding to an application of 5 *M. anisopliae* (Ma 79) conidia on each larva (Fig. 5). While there were no statistically significant differences between the two groups of both larval stages after 5 d, 95% of the second-stage larvae with full glandular reservoirs were still surviving after 10 d compared to only 55% of those with artificially drained reservoirs. These differences lasted until the end of experiment (χ^2 *test* followed by *sequential Bonferroni correction*, P<0.01). In contrast, differences between groups of third-stage larvae were detected only at the end of the experiment (85% vs. 57.5% for the two groups, respectively; P<0.01). Comparison of time-dependent survival between the two larval stages revealed differences between 5 and 10 d (χ^2 tests followed by *sequential Bonferroni correction*, P<0.01).

showed that growth of this entomopathogenous bacterium was inhibited, regardless of whether the main component of the beetle's perfume was applied undiluted or in a 1:10 dilution. The inhibition increased when six samples were tested simultaneously on the same plate, indicating that salicylaldehyde samples act additionally over the gas phase. A dilution of 1:100 showed no inhibition of bacterial growth. When salicylaldehyde was applied on the Petri dish lids, it also inhibited the growth of *B. thuringiensis tenebrionis* in both the undiluted and 1:10 dilution treatments (five samples simultaneously tested). The solvent dichloromethane did not affect the growth of *B. thuringiensis* (Table 2).

Discussion

Insects are threatened by pathogenous microorganisms throughout their whole life. Their sclerotized chitinous exoskeleton provides an efficient primary barrier against microbial invasion, which can only be directly penetrated by entomopathogenic fungi such as *B. bassiana* or *M. anisopliae.* On the other hand, viral and bacterial pathogens usually gain entry into their insect hosts via the intestinal tract (Clarkson and Charnley 1996; Gillespie et al. 2000). Once microorganisms have entered the insect hemocoel they are exposed to the host innate immune system, which is responsible for sensing of infections (Royet et al. 2005)

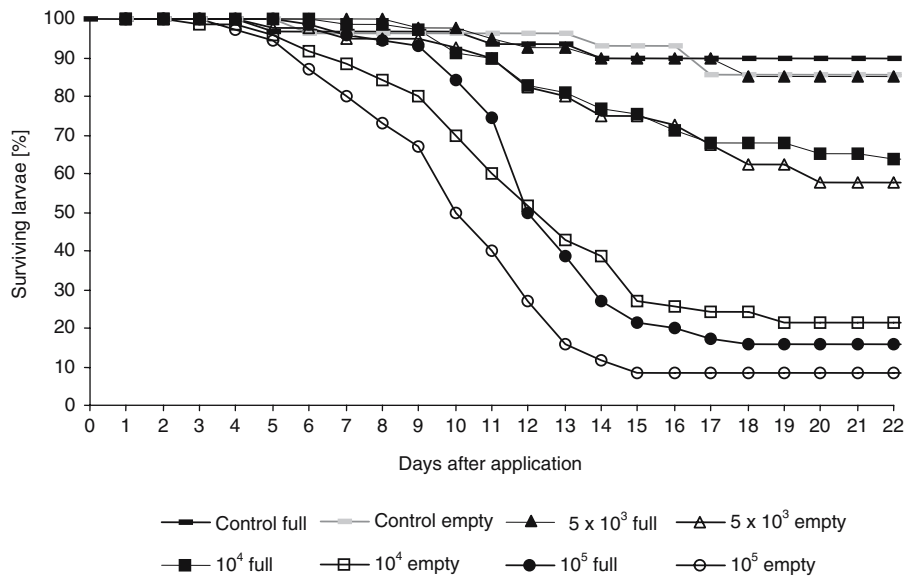

Fig. 4 Temporally dependent cumulative mortality of *Phratora vitellinae* larvae (L_3) with full or emptied glandular reservoirs after application of different conidia concentrations from *Metarhizium anisopliae* strain 79 (controls and 5×103 conidia/ml: $N=40$; 1×10^4 and 1×10^5 conidia/ml: $N=70$)

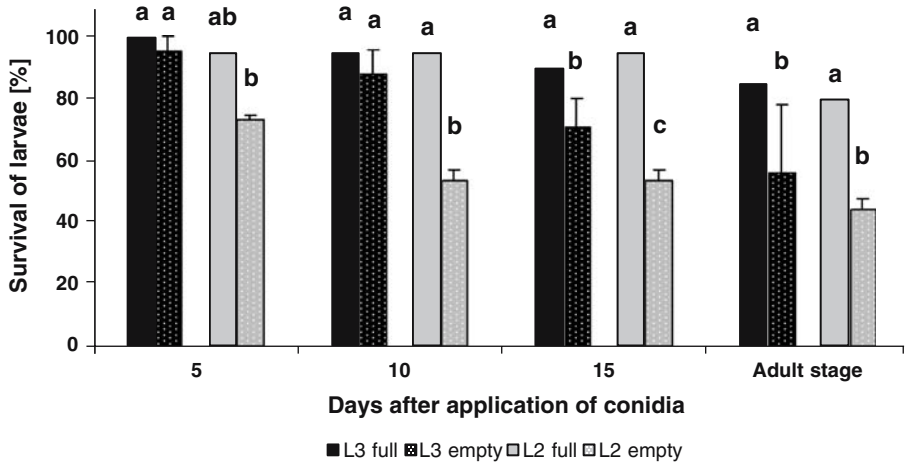

Fig. 5 Comparison of temporally dependent survival of two larval stages (L_2 gray bars, N=20; L_3 black bars, N=40) after dorsal application of five conidia (*M. anisopliae*, strain 79) each. The glandular reservoirs of two groups (dotted bars) were emptied artificially. Different letters indicate statistically significant differences ($\chi 2$ *test* followed by *sequential Bonferroni correction*, $P<0.025$)

and mounting of complex cellular and humoral defense reactions (Vilcinskas and Götz 1999). The latter encompass the rapid synthesis of a diverse array of powerful antimicrobial peptides (Hoffmann 2003).

Although the endogenous innate immunity in insects has been intensively studied for decades, our knowledge about exogenous antimicrobial defense mechanisms nevertheless remains fragmentary. The contribution of fluid secretions in antimicrobial defense was studied in some insect species. For example, water beetles have glandular secretions that inhibit the growth of bacteria on their integument (Dettner 1985; Kovac and Maschwitz 1990), whereas in other insects they are effective at combating microorganisms in their nests or stored food (Rosengaus et al. 2000; Traniello et al. 2002; Herzner et al. 2007; Herzner and Strohm 2007). However, the role of insect antimicrobial secretions in defense against entomopathogens has not been established. Based on our observation that main components of leaf beetles' glandular secretions exert *in vitro* antimicrobial activity against bacteria and entomopathogenic fungi (Gross et al. 1998, 2002), we hypothesized that antimicrobial defense in beetles can be expanded beyond innate immunity to include external disinfection of the microenvironment. In support of this, we discovered in this study that leaf beetles also produce volatiles that exhibit antimicrobial activity. These were shown to form a disinfecting cloud that prevents germination of entomopathogenic fungi on their cuticle. Consequently, we analyzed whether the leaf beetle fumigants are permanently produced and whether this perfume provides protection against entomopathogenic fungi *in vivo*.

The larvae of the leaf beetle *P. vitellinae*, like others of taxon Chrysomelina, possess nine pairs of exocrine glands, which are everted in case of a predator attack, presenting their secretion at the top of the everted reservoir (Fig. 3c). After 1–2 sec, they are subsequently reinverted with the help of specialized retractor muscles (Garb 1915; Hinton 1951). The reservoirs are filled with different chemical compounds, which are at least partly volatiles (Pasteels et al. 1988). In the present study, investigations of the

Mean values and standard deviations of inhibition zones are provided. Different letters indicate significant differences between one sample and six samples per test plate (*Mann–Whitney U* test, $P<0.05$). The solvent (DCM) and higher dilutions (1:100) caused no inhibition of bacterial growth.

morphological structure of the cuticle of *P. vitellinae* larvae revealed furrow-shaped openings above glandular reservoirs, allowing the volatile components to emit continuously (Fig. 3b). The openings are distributed segmentally and pairwise on the larval body from the mesothorax to the seventh abdominal segment (Fig. 3a), allowing a perfect distribution of the fumigant cloud all over the larval body. By analyzing the chemical composition of the headspace of undisturbed larvae of *P. vitellinae*, salicylaldehyde was revealed as the main component (Figs. 1 and 2). This component is known to show antimicrobial activity against both bacteria and fungi (Gross et al. 2002). After detecting the conditions required for protection by a permanently produced fumigant, we conducted *in vivo* bioassays to test our hypothesis.

The removal of glandular secretion from larval reservoirs of *P. vitellinae* decreased their survival after external exposure with conidia of the fungal entomopathogens *B. bassiana* and *M. anisopliae* compared to that of untreated larvae (Table 1, Fig. 4). These two species are known as the most frequently occurring fungal pathogens of Chrysomelidae (Humber 1996). Successful removal of the fumigants was confirmed by GC-MS analysis of headspace samples from larvae with full or emptied glandular reservoirs (Figs. 1 and 2). Beyond this, we determined that *P. vitellinae* larvae need approximately 48 hr to emit the same amount of salicylaldehyde from their glandular reservoirs (Fig. 1). The higher amount of salicylaldehyde in the headspace 3 hr after emptying the reservoirs compared to 6 hr later was caused by an unavoidable contamination of the beetles' surface with secretion during the draining, which continued to emit during the first 3 hr. The reduced amounts of salicylaldehyde in the headspace seen in the second experiment compared to the first may be caused by addition of a leaf during headspace sampling, on whose surface a portion of the volatile salicylaldehyde may have been adsorbed. Such an effect was shown previously for volatile secretion of the closely related leaf beetle *Phaedon cochleariae*, which adsorbed to the surface of Chinese cabbage leaves (Rostás and Hilker 2002). Emptying the glandular reservoirs 48 hr after application of conidia, no significant differences in mortality were revealed compared to the mortality of larvae with full reservoirs (data not shown). Thus, transient reduction in fumigant concentration around the larvae by a single removal of the content from their dorsal glands is sufficient to result in increased mortality when exposed to fungal pathogens. The determined *in vivo* effect, in combination with reported morphological and chemical structures, lends some support to our hypothesis that leaf beetles use volatile glandular secretions that prevent germination of conidia from fungal pathogens on their cuticle. Fungal pathogens can directly infect their insect hosts via the integument (Gillespie et al. 2000). Consequently, fumigation of fungal conidia before germination on the exoskeleton is a plausible explanation for the prevention of infection.

Until now, the activity of salicylaldehyde has not been tested for the detrimental effects against entomopathogenic bacteria. Thus, we tested the effects of this compound against two different subspecies of *Bacillus thuringiensis* in concentrations that occur naturally in leaf beetle secretions (Gross et al. 2002). When the bacteria were treated directly or indirectly (via the gas phase) with salicylaldehyde, their growth and development was inhibited (Table 2). Pathogenic bacteria invade the larval body by oral uptake or via injuries. Hence, salicylaldehyde may act additionally against entomopathogenic bacteria, if the fumigant cloud also exerts its activity at contaminated feeding sites, killing the bacteria before they are ingested by food.

Recently, it has been reported that phytophagous insects that consume bacteria within their diet suffer immune responses that negatively affect their fitness costs in terms of pupation time and pupal mass (Freitak et al. 2007). Hence, activation of the indigenous immune system causes costly life history trade-offs. The synthesis of salicylaldehyde takes place by sequestration and catabolization of the plant-borne precursors salicin and saligenin (Kuhn et al. 2004), causing no additional costs for the larvae (Rowell-Rahier and Pasteels 1986). The investigated cloud of salicylaldehyde putatively reduces such immune-related fitness costs, if fumigation of the microenvironment prevents both ingestion of living bacteria and infection with parasitic fungi, such as *B. bassiana* and *M. anisopliae*, that can directly enter the insect host via the cuticle.

This effect could be strengthened by a special behavior known as cycloalexy that is displayed by many leaf beetle larvae (Grégoire 1988), whereby Chrysomelina larvae feed close together in groups of 10 to 30 larvae. This behavior is explained as better protection against enemy attack, but in leaf feeding insects it is also related to overcoming plant defenses, especially with respect to feeding establishment (Nahrung et al. 2001; Wilson et al. 2003). We modeled this behavior by applying different numbers of volatile secretions on test plates, and detected a statistically significant increase in the diameter of every inhibition zone when six samples were applied per test plate instead of only one sample (Table 2, Mann–Whitney U test, $P<0.05$). Whereas predator attack will cause a loss of fluid and volatile secretions and deteriorate the individual antimicrobial protection, cycloalexy may increase the efficacy of antimicrobial defense through synergistic enlargement of the mutual fumigant cloud. Further studies will be necessary to prove this hypothesis.

Insect bodily fluids represent a promising reservoir for new antimicrobial active compounds (Vilcinskas and Gross 2005). If disinfection of the microenvironment by insect perfumes is widespread in nature, a targeted analysis of

volatile glandular secretions from other insects may result in identification of novel fumigants that could be used as a source of innovative pesticides for pathogen control, e.g., for disinfection of stored food or decontamination in hospitals. Overall, our results provide evidence that beetles made use of volatiles that disinfect their microenvironment. As far as we are aware, this is the first report on the principle of fumigation in antimicrobial defense of animals.

Acknowledgments We thank Gisbert Zimmermann (BBA Darmstadt, Germany) for providing the different strains of entomopathogenic bacteria and fungi and Monika Hilker (Berlin, Germany) for providing the GC-MS for analysis of headspace samples. The authors are indebted to Rod Snowdon (Giessen, Germany) for editing the manuscript.

Enantiomeric Specificity in a Pheromone–Kairomone System of Two Threatened Saproxylic Beetles, *Osmoderma eremita* and *Elater ferrugineus*

Glenn P. Svensson · Mattias C. Larsson

Received: 5 October 2007 / Revised: 3 December 2007 / Accepted: 21 December 2007 / Published online: 31 January 2008

Abstract The scarab beetle *Osmoderma eremita* and its larval predator, the click beetle *Elater ferrugineus*, are threatened saproxylic beetles regarded as indicators of the species-richness of insect fauna of hollow deciduous trees. Male *O. eremita* produce the pheromone (*R*)-(+)-γ-decalactone to attract conspecific females, and this compound is also utilized by *E. ferrugineus* as a kairomone, presumably for detection of tree hollows containing prey. We have investigated enantiomeric specificity to γ-decalactone in this pheromone–kairomone system by electrophysiological and field trapping experiments. In single-sensillum recordings from male and female *O. eremita*, which used the (*R*)-enantiomer and the racemic mixture of γ-decalactone as odor stimuli, numerous olfactory receptor neurons (ORNs) responding to both stimuli were found. No neurons responded preferentially to the racemic mixture, showing that these beetles seem to lack receptors specific for the (*S*)-enantiomer. The enantiomeric specificity of ORNs was confirmed by gas chromatography-linked single-sensillum recordings where the two enantiomers in a racemic mixture were separated on a chiral column. Furthermore, in field experiments that used the (*R*)-enantiomer and the racemic mixture as lures, the attraction of *O. eremita* females corresponded to the amount of (*R*)-enantiomer released from lures with the (*S*)-enantiomer displaying no antagonistic effects. Trap catch data also suggested that the (*S*)-enantiomer is not a behavioral antagonist for *E. ferrugineus*. The odor-based system can be highly efficient in attracting the larval predator where trap catch in 1 yr almost equaled the total number of specimens collected in Sweden until 1993. Our study shows that racemic γ-decalactone could be used for cost-effective monitoring of both beetles.

Introduction

Ever since the first insect pheromone was identified half a century ago (Butenandt et al. 1959), the ultimate practical goal of research on insect chemical ecology has been the development of semiochemical-based strategies to control populations of agricultural and forest pests (e.g., Cardé and Minks 1995; Borden 1997; Foster and Harris 1997). In contrast, surprisingly little effort has gone into the exploration of the chemical ecology of threatened insects and the potential to use infochemicals in conservation biology. Monitoring with volatile attractants could be more efficient than traditional survey methods in gathering ecological data on focal species for conservation and in assessing species diversity of threatened insect communities. Priority should be given to assemblages that are difficult to detect and monitor with currently available methods. One such group is saproxylic beetles that live in hollow deciduous trees. The severe fragmentation and isolation of this habitat in recent centuries (Hannah et al. 1995) has resulted in the associated insect fauna being endangered all over Europe. Surveys of beetles that live inside tree trunks are often both

labor-intensive and time-consuming, and in many cases, only a small fraction of suitable trees in an area can be surveyed.

We recently initiated a research program to integrate chemical ecology and conservation biology of saproxylic beetles by using *Osmoderma eremita* Scopoli (Coleoptera: Scarabaeidae) as a model. This beetle is strongly associated with hollow deciduous trees (Luce 1996; Ranius and Nilsson 1997) and it has become a major model for ecological research on insects associated with this habitat in Europe (e.g., Ranius 2001; Ranius and Hedin 2001). Because of its role as an indicator for the species-rich fauna of saproxylic insects, *O. eremita* has high conservation priority according to the European Union's Habitat Directive (Anonymous 1992), and it has recently been intensively surveyed in Europe (Ranius et al. 2005). The most well-known feature of *O. eremita* is its fruity, plum-like or peach-like odor, which is emitted exclusively by males. We identified the odor as (*R*)-(+)-γ-decalactone and demonstrated its function as a sex pheromone used to attract conspecific females (Larsson et al. 2003). We have also shown that the likewise-threatened click beetle *Elater ferrugineus* L. (Coleoptera: Elateridae), whose larvae prey upon the larvae of *O. eremita*, utilizes (*R*)-(+)-γ-decalactone as a kairomone to locate its prey (Svensson et al. 2004). The *Osmoderma* pheromone is produced in exceptionally large amounts and can even be detected inside tree hollows by using traditional headspace sampling techniques (Svensson et al. 2003).

Sexual communication in beetles is often achieved by chiral pheromone compounds (e.g., Birch et al. 1980; Mori et al. 1986; Leal 1991). When one enantiomer of a chiral molecule is used for intraspecific communication, its antipode may function as a behavioral antagonist to avoid cross-species attraction, if the antipode is used by a closely related species. For example, the sympatric scarabs *Popillia japonica* Newman and *Anomala osakana* Sawada utilize the (*R*)- and (*S*)-configuration of japonilure, respectively, as sex pheromones, and strong reciprocal behavioral antagonism to the opposite enantiomer has been observed (Tumlinson et al. 1977; Leal 1996). Similar stereochemical discrimination has also been documented in insect predators that eavesdrop on the pheromone communication systems of their prey (Aldrich 1999), such as the clerid beetle *Thanasimus dubius* F., which only responds to the (*S*)-enantiomer of frontalin, the major enantiomer of the pheromone of its prey *Dendroctonus frontalis* Zimmerman (Payne et al. 1982, 1984).

However, behavioral effects of nonpheromonal enantiomers vary considerably among different insect species (Mori 1998; Leal 1999), and more studies are needed to understand the adaptive significance of these effects, including mechanisms of enantiomeric perception and behavioral data. From an applied perspective, evaluating the enantiomeric specificity in insect pheromone or kairomone systems is important for efficient semiochemical-based monitoring. Because pure enantiomers are usually more expensive than racemic mixtures (in the case of commercially available (*R*)-(+)-γ-decalactone, currently about 15 times as expensive, see the "Methods and Materials" section), use of the latter could significantly reduce the cost for monitoring. We, therefore, conducted electrophysiological analyses and field experiments to evaluate the effects of the (*S*)-enantiomer of γ-decalactone on the behaviors of *O. eremita* and *E. ferrugineus*.

Methods and Materials

Insects *O. eremita* is a large (25–35 mm) scarab beetle living exclusively in hollow deciduous trees, mainly oaks (Luce 1996). It is dependent on hollows with large amounts of wood mold, i.e., a mixture of loose, rotten wood, fragments of insects, fungi, and old bird nests. The development time is normally 3 yrs (Ranius et al. 2005). The species is distributed in most parts of Europe, but a recent survey that included 33 countries indicated that it has decreased in all areas (Ranius et al. 2005). Today, it has a relict distribution and only occurs in isolated populations in, e.g., woodland pastures. In Sweden, it is currently known from only 130 sites (Antonsson et al. 2003), and many populations occupy single isolated trees with few or no suitable trees nearby, and may, therefore, be doomed to extinction. *E. ferrugineus* is a large (15–25 mm) click beetle and larval predator on several saproxylic beetles associated with hollow trees, including *O. eremita* (Hansen 1966; Dajoz 2000). In Sweden, it is currently known from only 25+ sites (Nilsson and Baranowski 1994). Ranius (2002) found a strong correlation of occupancy between *E. ferrugineus* and *O. eremita* with fragments of the predator found almost exclusively in trees with fragments of its prey. The development time is several years (Palm 1959). According to Hansen (1966) and T. Tolasch (personal communication) this species swarms during evenings and nights, and its female-produced sex pheromone was recently identified (Tolasch et al. 2007). The species is rare in Sweden with only 147 adult specimens collected from about 25 localities until 1993 (Nilsson and Baranowski 1994). It is considered endangered in the Swedish Red List of threatened species (Gärdenfors 2005).

Chemicals and Dispensers (*R*)-(+)-γ-Decalactone (97% enantiomeric purity) was purchased from Sigma-Aldrich, Sweden (catalog no.: W236012). Because the (*S*)-enantiomer of the compound is not commercially available, we used a racemic mixture of γ-decalactone (catalog no.:

W236004) to study the electrophysiological and behavioral effects of the (*S*)-enantiomer. Dispensers for traps were made from 2 ml glass vials loaded with 600 µl of neat (*R*)-(+)-γ-decalactone or the neat racemic mixture. Cut strings of cotton dental rolls (Celluron, Paul Hartmann, S.A., France) were inserted as wicks into the glass vials, and dispensers were attached to traps via a metal hook.

Electrophysiology Single-sensillum recordings were performed on both female and male *O. eremita*, but not on *E. ferrugineus*, which is rare in Sweden. To restrain a beetle, it was wrapped with parafilm, placed on a microscope slide, and fixed with dental wax. To get access to olfactory receptor neurons (ORNs), the three lamellae on the antenna were held apart with thin metal pins. A tungsten microelectrode or a thin silver wire was inserted into the abdomen of the insect, serving as a ground electrode, and a second tungsten microelectrode (electrolytically sharpened in KNO_2 solution) was inserted into an olfactory sensillum to establish contact with ORNs. The recording electrode was connected to a ×2 gain probe (Syntech, Hilversum, The Netherlands). A microscope with up to ×500 magnification and a DC-3K micromanipulator with a Piezo translator (PM10) (Märzhauser, Wetzlar-Steindorf, Germany) were used to position the electrode. Charcoal-filtered and humified air passed over the antenna from a glass tube outlet at 10 mm distance from the preparation. Odor stimulation of an ORN was achieved by inserting the tip of a Pasteur pipette, containing defined amounts of a stimulus, into a hole in the glass tube 10 cm before the outlet. The pipette was linked to an air control system (Syntech, Hilversum, The Netherlands), which generated 0.5 sec air puffs through the pipette into the air stream of the glass tube.

Odor Stimuli Neat (*R*)-(+)-γ-decalactone and the racemic mixture were diluted in hexane in decadic steps down to concentrations to be used in electrophysiological experiments. A test stimulus was then applied to a small piece of filter paper inserted into the test pipette, and the solvent was allowed to evaporate. Each pipette was loaded with 10 µl of a stimulus solution, and the amount of compound loaded into a pipette ranged from 100 ng to 100 µg. Pipettes loaded with 10 µl of hexane served as controls. After establishing contact with an ORN, it was stimulated with both test odorants at the highest dose (100 µg) and the control. If responses to the test odorants were not greater than to the control, the neuron was classified as non-responding. If the neuron responded to any of the test odorants, a dose–response trial was often performed by using the test stimuli at increasing concentrations. To enable the receptor neuron to recover after odor stimulation, at least 20 sec passed between each stimulation event. Responses from ORNs were calculated as the total number of spikes during 0.5 sec after the onset of stimulation minus the number of spikes during 0.5 sec before the onset of stimulation. The net response to an odor stimulus was calculated by subtracting the response generated by the control stimulation. In dose–response trials, net responses for females and males were compared for stimulations with the (*R*)-enantiomer and the racemic mixture at each dose using paired *t* tests, and net responses for stimulations with (*R*)-enantiomer were compared between the sexes at each dose using unpaired *t* tests.

Coupled Gas Chromatography and Single-sensillum Recordings To further test for the enantiomeric specificity of ORNs to γ-decalactone in *O. eremita*, gas chromatography linked to single-sensillum recordings (GC–SSR) was performed with a chiral column to resolve the enantiomers in the racemic mixture. A Hewlett-Packard 5890 Series II Plus gas chromatograph was used, equipped with a Cyclosil-B chiral column (30 m×0.25 mm i.d., 0.25 µm film; J&W Scientific, USA). Hydrogen was used as carrier gas (40 cm/sec), injector temperature was 220°C, and the following temperature program was used: 60°C for 2 min, 10°C/min to 170°C, followed by 2°C/min to 200°C, and then 10°C/min increase to 225°C. The transfer line temperature was maintained at 225°C. As stimulus, 100 ng of the racemic mixture were injected into the GC.

Field Trapping Field bioassays were conducted in Bjärka-Säby (58°16′N, 15°46°E) and Brokind (58°12′N, 15°40′E), southeast Sweden, during July–August, 2006 and 2007. The study area included five large stands of old hollow oaks housing some of the largest populations of *O. eremita* and *E. ferrugineus* in Sweden (Nilsson and Baranowski 1994; Ranius 2001; Antonsson et al. 2003). In 2006, two different nondestructive trapping systems were used, allowing beetles to be released alive after examination: Lindgren funnel traps (Phero Tech, Delta, BC, Canada), and custom-built traps consisting of two black plastic sheets (25 cm height×30 cm width, 3 mm thickness) arranged in a cross and attached perpendicular to a black plastic funnel (upper diameter, 27 cm) leading down to a 5-l white plastic container [for a picture of a trap with the same general design, see Ruther et al. (2000)]. In 2006, 20 replicates of 4 traps were used. Each replicate contained two traps of each type, baited with either 600 µl of the (*R*)-enantiomer or 600 µl of the racemic mixture. Custom-built traps were about 1.5 times more efficient than Lindgren traps in catching *O. eremita* (191 vs. 141 catches, $\chi^2=7.53$; $df=1$; $P<0.01$) and *E. ferrugineus* (88 vs. 55 catches, $\chi^2=7.62$; $df=1$; $P<0.01$). Thus, only custom-built traps were used in 2007. Twelve replicates were used, each containing 2 traps baited with either 600 µl of (*R*)-enantiomer or 2×600 µl of racemic

mixture, and a control trap without odorants. Traps were suspended from oak branches at 2–4 m height and at least 10 m apart, and they were checked for the presence of beetles every second day. The relative positions of traps within replicates were changed every eighth day.

In 2006 (but not in 2007), captured *O. eremita* were marked with shallow marks drilled in the elytra (Ranius 2001), and *E. ferrugineus* were marked on the elytra with a permanent marker pen to estimate the proportion of recaptures, which comprised <10% of the total number of captures in *O. eremita* and <4% in *E. ferrugineus*. Statistical analyses on trapping data were based on the total number of captures, including recaptures. For male and female *O. eremita* and *E. ferrugineus*, χ^2 analyses were performed to check for the difference in trap catch among treatments. We found no published information allowing the sex of *E. ferrugineus* individuals to be distinguished easily without genital examination, and to avoid killing them, we did not determine the sex of most captured individuals in 2006, except for a subset of 23 individuals, mostly consisting of individuals found dead in the traps.

Results

Electrophysiology Recordings were performed only from sensilla on the inner lamella of the *O. eremita* antenna. High-quality recordings were obtained from 234 sensilla of 30 females and 101 sensilla of 21 males. Based on their spike amplitude, most sensilla appeared to contain two ORNs, but odor stimulation always affected only one of these neurons, whereas the other was nonresponsive to both stimuli. In 88% of the recordings from both females and males, the ORNs in the sensillum did not respond to the (*R*)-enantiomer or racemic mixture of γ-decalactone. The remaining sensilla (29 in females and 10 in males)

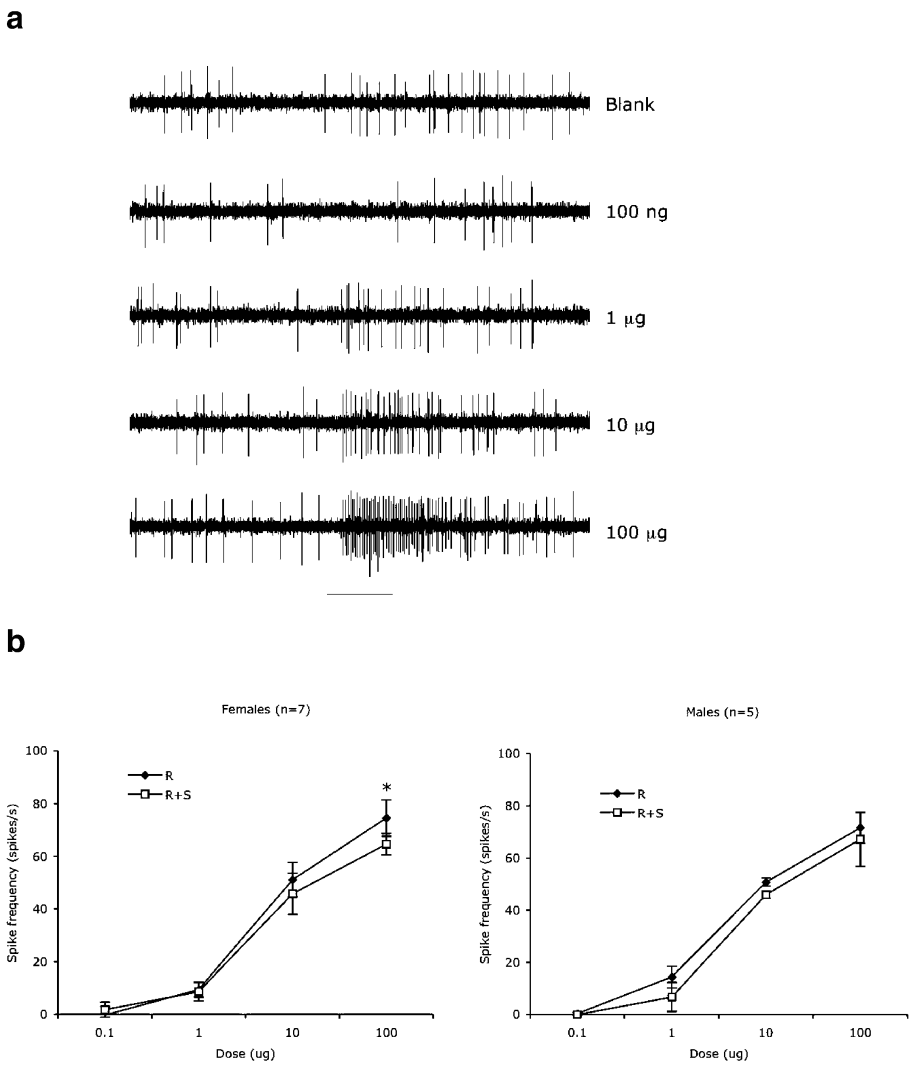

Fig. 1 **a** Single-sensillum recordings from the antenna of a female *O. eremita* showing the response of an ORN to the blank control and to increased doses of (*R*)-(+)-γ-decalactone. The *bar below* the recordings indicates the stimulus duration (0.5 sec). **b** Dose–response relationships of ORNs of female and male *O. eremita* stimulated with the (*R*)-enantiomer (*R*) or a racemic mixture (*R*+*S*) of γ-decalactone. For each dose, the same amount of (*R*)-enantiomer was used in both test stimuli. The response to a stimulus is quantified as the net number of spikes (number of spikes during 0.5 sec after the stimulation minus the number of spikes during 0.5 sec before the stimulation) minus the net blank response. *Error bars* show the standard error of the mean. The *asterisk* indicates a significant difference in spike activity between stimuli within the dose (paired *t* test, $P<0.05$)

contained a receptor neuron that responded to both test odorants (Fig. 1a). No neurons were found that responded primarily to the racemate, which would have indicated specificity to the (*S*)-enantiomer. The electrophysiological recordings revealed that γ-decalactone-sensitive ORNs were sparsely distributed over the whole inner antennal lamella of both sexes, but mainly found in the smooth area close to the ventral edge of the lamella (cf. Larsson et al. 2001, 2003). In dose–response trials, ORNs of females and males showed equal sensitivity to (*R*)-(+)-γ-decalactone (for all doses, $P>0.05$; Fig. 1b). However, a small but significant difference in spike frequency was observed for ORNs of females when stimulated with the (*R*)-enantiomer compared to the racemic mixture at the highest dose ($t=2.96$, $df=6$, $P<0.05$; Fig. 1b). Single-sensillum recordings coupled with gas chromatography confirmed that the γ-decalactone-sensitive ORNs indeed only responded to the (*R*)-enantiomer (Fig. 2). There was a clear separation of the two compounds on the chiral column with the (*R*)-enantiomer eluting 8.5 sec earlier than its antipode, which allowed the γ-decalactone-sensitive receptors to recover between stimulation events.

Trap Catch O. eremita: In 2006, 332 females were caught in odor-baited traps with significantly more caught in traps baited with the (*R*)-enantiomer compared to those baited with the racemic mixture (with half the amount of (*R*)-enantiomer) (200 vs. 132; $\chi^2=13.93$; $df=1$; $P<0.001$; Fig. 3a). Also, 87 captures of males were observed, but no difference was observed in the number of captures between odor treatments (51 vs. 36 for *R* and *R*+*S*, respectively; $\chi^2=2.59$; $df=1$; $P>0.05$; Fig. 3a). In 2007, 122 captures of females in odor-baited traps were observed (Fig. 3b). No significant difference in trap catch was observed between traps baited with the (*R*)-enantiomer and those baited with the racemic mixture (with the same amount of (*R*)-enantiomer) (56 vs. 66; $\chi^2=0.82$; $df=1$; $P>0.05$; Fig. 3b). Seven and three males were captured in attractant-baited traps with (*R*)-enantiomer and the racemic mixture, respectively, and three females were found in control traps.

E. ferrugineus: In 2006, 143 captures of 139 individuals were observed (Fig. 3a). The majority of trapping events (60%) included single individuals, whereas up to six beetles were found in a trap on other occasions. Similar to *O. eremita* females, significantly more insects were caught in traps baited with the (*R*)-enantiomer compared to those baited with the racemic mixture with half the amount of (*R*)-enantiomer (88 vs. 55; $\chi^2=7.62$; $df=1$; $P<0.01$). The subset of 23 beetles used for sex determination contained 22 females and only 1 male. In 2007, only six females were trapped (three for each treatment, data not shown in Fig. 3b).

Discussion

In this study, we show both electrophysiological and behavioral evidence for enantiomeric anosmia in the pheromone communication system of *O. eremita*. Recordings from single sensilla showed that both sexes have

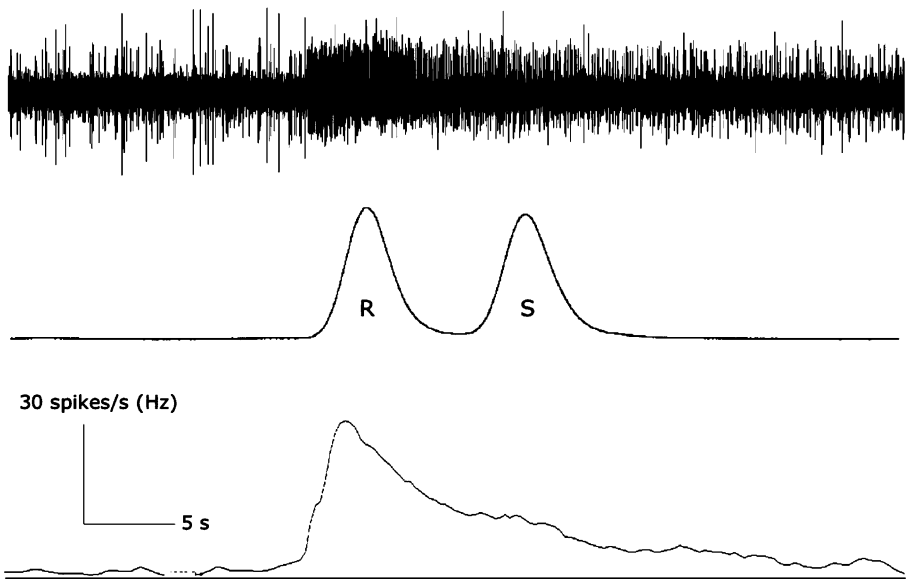

Fig. 2 Example of enantiomer-specific response to γ-decalactone in the ORN of a female *O. eremita* using GC–SSR. The *upper* trace shows the spike activity of the ORN, the *middle* trace shows the FID response to the two enantiomers separated on a chiral column, and the *lower* trace shows the spike activity of the ORN calculated as the number of spikes per second. After responding to the (*R*)-enantiomer, the ORN recovers almost completely and no second activity peak is observed during stimulation with the (*S*)-enantiomer

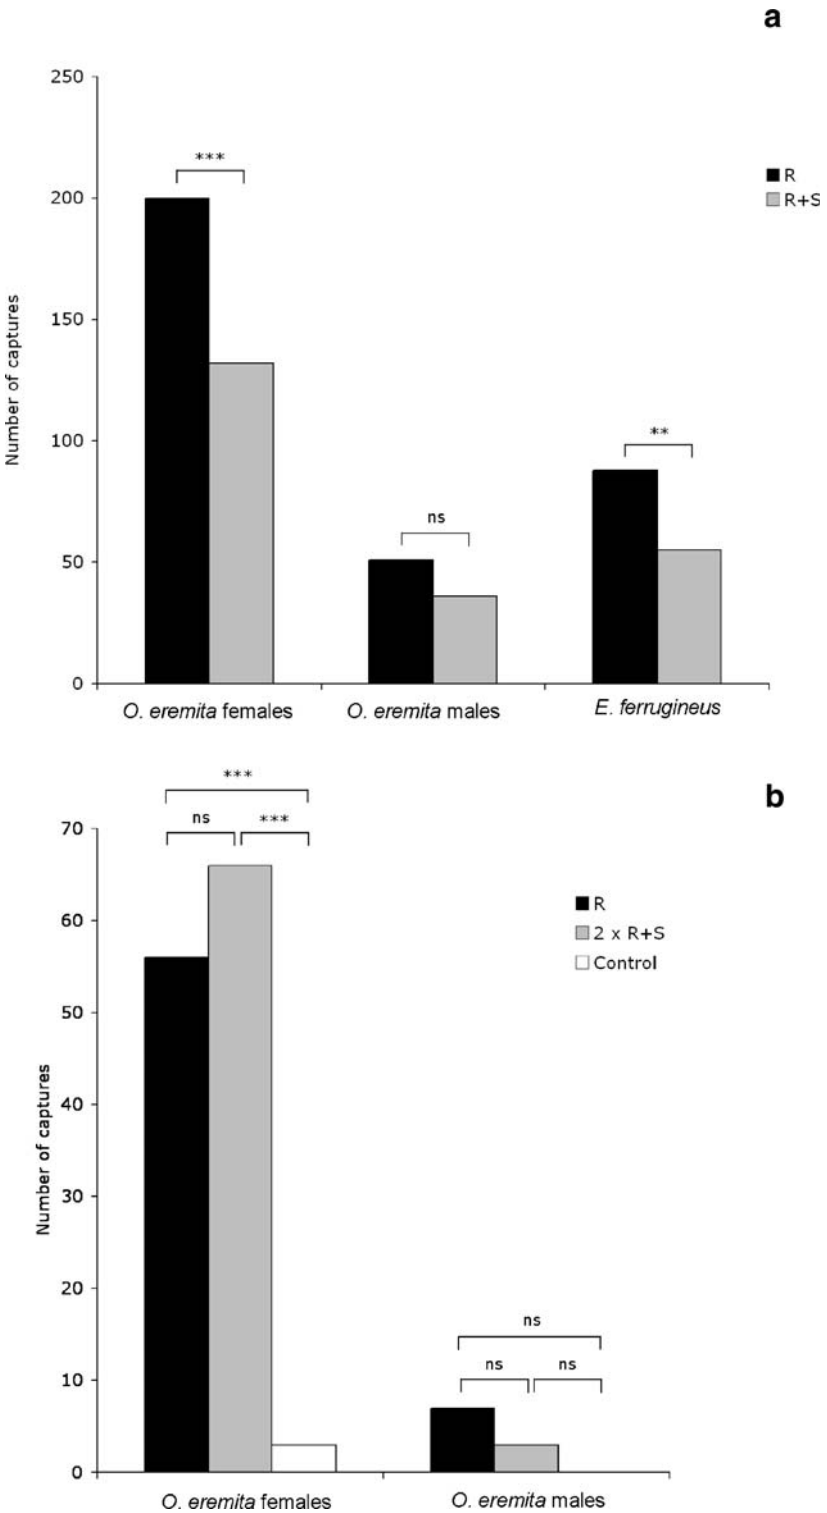

Fig. 3 **a** Trap catch of *O. eremita* and *E. ferrugineus* in 2006 using traps baited with 600 µl of (*R*)-enantiomer (*R*) or 600 µl of the racemic mixture (*R*+*S*) of γ-decalactone (χ^2 test: ***P*<0.01, ****P*<0.001). **b** Trap catch of *O. eremita* in 2007 using traps baited with 600 µl of (*R*)-enantiomer (*R*) or 2×600 µl of the racemic mixture (2×*R*+*S*) of γ-decalactone, and control traps (χ^2 test: ****P*<0.001)

ORNs specific to the (*R*)-enantiomer of γ-decalactone, the compound produced by conspecific males. No neurons tuned to the opposite enantiomer were found in the sensilla investigated. In dose–response trials that used the (*R*)-enantiomer and the racemic mixture as stimuli, the spike frequency of female ORNs was significantly higher for the pure (*R*)-enantiomer than for the mixture (with half the amount of (*R*)-enantiomer) at the highest dose (100 µg), also indicating that those neurons do not respond to the (*S*)-enantiomer (Fig. 1b). These observations were confirmed by using coupled gas chromatography and single-sensillum recordings where the two enantiomers were resolved on a

chiral column: the neurons always responded to the first-eluting (*R*)-enantiomer and never to the later-eluting (*S*)-enantiomer (Fig. 2).

Field trapping data were in concordance with electrophysiological data, and the attraction of both *O. eremita* females and its predator *E. ferrugineus* to attractant-baited traps was correlated with the amount of (*R*)-enantiomer released from lures. In 2006, significantly more captures of *O. eremita* females and *E. ferrugineus* were observed in traps with pure (*R*)-enantiomer compared to the racemic mixture, releasing half the amount of (*R*)-enantiomer. In 2007, no difference in trap catch of *O. eremita* females was observed when both treatments released the same amount of (*R*)-enantiomer. Thus, there is no inhibitory effect of adding the (*S*)-enantiomer to the *O. eremita* pheromone. From a practical point of view, the choice of lure is not critical, and the much cheaper racemic mixture can be used if the lure constitutes a significant part of the trap costs.

Effects of nonpheromonal enantiomers on insect pheromone attraction range from attractive to neutral to strong antagonistic effects (Mori 1998). The lack of inhibitory effects on the attraction of *O. eremita* and *E. ferrugineus* by the antipode of their pheromone/kairomone is in stark contrast to many other cases where the presence of the wrong enantiomer, sometimes at concentrations of only a few percent, results in strong inhibition of response to the pheromone. This phenomenon is common in many insect groups that use chiral pheromones, including scarab (Tumlinson et al. 1977; Leal 1996; Tolasch et al. 2003) and other beetles (Birch et al. 1980; Levinson and Levinson 1999; Lacey et al. 2004), gall midges (Hillbur et al. 2001), and moths (Szöcs et al. 1993; Larsson et al. 2002). The generally accepted explanation for this strong antagonistic effect is that it prevents cross-attraction of sympatric, usually congeneric, species that use the antipode as a pheromone component. Electrophysiological investigations of insect olfactory receptor neurons have demonstrated special sensory adaptations for avoiding enantiomers produced by heterospecifics. Species that use chiral pheromones often possess dedicated olfactory receptor neurons that respond selectively to each enantiomer, also when only one of these constitutes a pheromone component (Okada et al. 1992; Larsson and Hansson 1998; Larsson et al. 2002; Wojtasek et al. 1998).

In several scarab species, racemic mixtures do attract significant numbers of beetles, indicating that these species are indifferent to the presence of nonpheromonal enantiomers (Leal 1999). Absence of biological activity to nonpheromonal enantiomers has been demonstrated in the scarabs *Anomala octiescostata* Burmeister and *A. cuprea* Hope, for which the racemic mixture and pure enantiomer are equally attractive (Leal 1999). Electrophysiological investigations have shown that both species appear to be anosmic to the nonpheromonal enantiomers, entirely lacking receptors for their detection (Larsson et al. 1999, 2001; Leal 1999), which seems to be the case also for *O. eremita*. When the nonpheromonal enantiomer in a racemic mixture cannot be detected, the expected outcome might be a slightly lower attraction to the racemate than to the pure pheromone, considering that the release rate of the attractant is only 50% as high in the racemic mixture.

The high numbers of *E. ferrugineus* observed in attractant-baited traps in 2006 suggest that this click beetle may have higher populations than previously recognized. Scientists used to dealing with pest insects may not consider 139 beetles impressive, but it is close to the total of 147 specimens documented in Swedish collections until 1993 (Nilsson and Baranowski 1994) and is certainly many times more than entomologists have previously encountered during a lifetime. Earlier investigations of only eight *E. ferrugineus* individuals found in attractant-baited traps indicated that both males and females might be attracted to the *O. eremita* pheromone (Svensson et al. 2004). This study, with a larger sample analyzed, showed that the pheromonal signal is exploited almost exclusively by females, presumably to find trees containing *O. eremita*. The much lower number of *E. ferrugineus* captured per trap in 2007 suggests that populations of this predator fluctuate much more than populations of its prey.

Many trees suitable for saproxylic beetles cannot be analyzed with traditional methods, such as wood mold sampling or pitfall trapping, because of the characteristics of their hollows. For example, only about 25% of the oaks in the current study areas that potentially harbor *O. eremita* and *E. ferrugineus* have been investigated because other hollows have been too far up in a tree to be reached by a ladder or the cavity has been too deep to place a trap in the wood mold (Hedin and Mellbrand 2003). With a majority of suitable habitat patches not investigated, estimates of population sizes of focal species may be severely biased, which may in turn affect conservation strategies. With efficient nondestructive trapping systems available, we can now gather detailed ecological data about these species that have not been possible with previously available methods. Attractant-baited traps placed outside tree hollows will only catch those individuals that have left their natal tree and should be used as a complementary method to pitfall traps and other methods to increase the accuracy of population size estimates and analyses of dispersal rates and dispersal distances. Odor traps may also be used for targeted efforts to rediscover species at localities where they have not been observed for sometime. Our data show that attractant-based monitoring could be a powerful tool for conservation purposes, and more research should be focused on the chemical ecology of threatened insects to develop new strategies for their preservation.

Acknowledgment We thank Björn Brage, Marie Garstad, Therese Lindström, and Niclas Berg for the field assistance, and Fredrik Schlyter for lending the Lindgren funnel traps. Identification and Characterization of Cuticular Hydrocarbons from a Rapid Species Radiation of Hawaiian Swordtailed Crickets (Gryllidae: Trigonidiinae: *Laupala*)

Sean P. Mullen · Jocelyn G. Millar · Coby Schal · Kerry L. Shaw

Received: 2 July 2007 / Revised: 17 October 2007 / Accepted: 3 December 2007 / Published online: 19 January 2008

Abstract A previous investigation of cuticular hydrocarbon variation among Hawaiian swordtail crickets (genus *Laupala*) revealed that these species differ dramatically in composition of cuticular lipids. Cuticular lipid extracts of *Laupala* species sampled from the Big Island of Hawaii also possess a greatly reduced number of chemicals (as evidenced by number of gas chromatography peaks) relative to ancestral taxa sampled from the geologically older island of Maui. One possible explanation for this biogeographic pattern is that reduction in chemical diversity observed among the Big Island taxa represents the loss of ancestral hydrocarbons found on Maui. To test this hypothesis, we characterized and identified the structures of cuticular hydrocarbons for seven species of Hawaiian *Laupala*, two from Maui (ancestral) and five from the Big Island of Hawaii (derived) by using gas chromatography-mass spectrometry. Big Island *Laupala* possessed a reduced number of alkenes as well as a reduction in the diversity of methyl-branch positions relative to species sampled from Maui (ancestral), thus supporting our hypothesis of a founder-induced loss of chemical diversity. The reduction in diversity of ancestral hydrocarbons was more severe within one of the two sister lineages on the Big Island, suggesting that post-colonizing processes, such as drift or selection, also have influenced hydrocarbon evolution in this group.

Introduction

Endemic Hawaiian swordtail crickets of the genus *Laupala* are a well-characterized species radiation that has been intensively studied as a model system for the evolution of acoustic communication and speciation (Otte 1994; Shaw 1996, 1999, 2000; Shaw and Herlihy 2000; Mendelson and Shaw 2002; Shaw et al. 2007). Phylogenetic evidence suggests that speciation in *Laupala* has proceeded by colonization of newly emerged volcanic islands and subsequent rapid intra-island radiations (Mendelson and Shaw 2005). Unlike examples of ecologically-driven speciation (Funk 1998; Via 1999; Rundle et al. 2000; Nosil et al. 2002), closely related species of *Laupala* have diversified in secondary sexual traits but remain morphologically and ecologically similar.

Species boundaries in *Laupala* have been hypothesized based on differences in acoustic signaling and, to some extent, small metric differences in male genitalia (Otte 1994; Shaw 2000). Molecular evidence supports these delineations (Shaw 1999, 2002; Parsons and Shaw 2001;

Mendelson and Shaw 2002, 2005). Multiple species often occur sympatrically (Otte 1994; Shaw 2000), but males of sympatric species always call with distinct pulse rates (Otte 1994; Shaw 1999, 2000; Parsons and Shaw 2001). Evidence from phonotaxis trials has established that females are preferentially attracted to conspecific pulse rates (Shaw 2000; Shaw and Herlihy 2000; Mendelson and Shaw 2002), thereby contributing to the maintenance of barriers to gene flow in sympatry.

These data suggest that divergence among species of *Laupala* is driven by evolution of male calling songs and that sexual selection on this trait may be responsible for the rapid speciation rates observed among these crickets. Although recent behavioral work suggests that female preference for conspecific pulse rates operates as a long-range signal, females that are not given an opportunity to choose males based on long-range acoustics evidently rely upon additional sexual recognition signals during close-range courtship (Mendelson and Shaw 2006). Reliance upon multiple mate-recognition signals during sexual communication is widespread among animals (Johnstone 1996; Rowe 1999; Candolin 2003), and therefore, it is possible that *Laupala* utilize diverse chemical, tactile, or vibratory cues during courtship and mating (e.g., *Drosophila*, Boake 2005). Specifically, the use of chemical mate-recognition signals has been demonstrated in other cricket species (Balakrishnan and Pollack 1997; Treganza and Wedell 1997), and cuticular compounds may function as close-range sex pheromones in the *Laupala* system as well.

To investigate the possible importance of contact pheromones in *Laupala*, Mullen et al. (2007) examined patterns of chemical variation in cuticular lipids among species of *Laupala* from Maui and the Big Island of Hawaii. Their results demonstrated that (1) significant differences in cuticular lipids exist between males and females, (2) there has been rapid and dramatic evolution of cuticular lipid composition among species in this genus, and (3) there has been a significant reduction in the complexity of cuticular lipid profiles among closely related species from the Big Island of Hawaii, as compared to two outgroup species from Maui. Detailed knowledge of the chemical differences between these two island faunas is important to our understanding of the evolution of cuticular hydrocarbon (CHC) biosynthesis in these and other insects and, furthermore, may provide insights into the evolutionary processes that shape patterns of lipid diversity among species. Specifically, chemical identification will determine whether the reduced number of gas chromatography peaks observed for species on the Big Island, relative to outgroup taxa on Maui (Mullen et al. 2007), reflects a reduction in the chain-length diversity of saturated or unsaturated hydrocarbons, differences in methylation patterns for specific hydrocarbons, or both. This would allow us to test the hypothesis that Big Island *Laupala* species have experienced a founder-induced loss of ancestral cuticular lipid variation.

Methods

Sampling To identify the major cuticular lipid components identified by Mullen et al. (2007) and to test biogeographic hypotheses about patterns of chemical variation, extracts of cuticular lipids of males and females of seven *Laupala* species ($N=14$) were analyzed by coupled gas chromatography-mass spectrometry (GC-MS). Specifically, we sampled two ancestral species of these crickets from the island of Maui (*Laupala makaio* and *Laupala orientalis*) and five derived species from two distinct clades on the Big island of Hawaii (*Laupala pruna* and *Laupala kohalensis* vs *Laupala nigra*, *Laupala paranigra*, and *Laupala kona*; see Mendelson and Shaw 2005). Individual crickets used for GC-MS analysis were collected during 2005 and stored frozen until used for sample preparation.

Extraction and Analysis of Cuticular Lipids Lipids were extracted with high-performance liquid chromatography-grade hexane. All glassware was pre-rinsed three times with hexane to remove possible contaminants and allowed to dry in a fume hood for 5–10 min before beginning extractions. Between each extraction, forceps were rinsed in three separate containers of hexane to avoid cross-contamination of samples. Each cricket carcass was wiped with a wet Kimwipe® to remove any external debris and then submerged in 1 ml hexane for 5 min in a glass vial with a Teflon-lined cap. Extracts were concentrated to ~200 µl under a stream of nitrogen, and 1 µl aliquots were analyzed by GC-MS with an Agilent 6890 GC interfaced to an Agilent 5973 mass selective detector operated in electron impact ionization mode (70 eV). The GC was fitted with a 30 m×0.25 mm I.D. DB-5MS column (J &W Scientific, Folsom, CA, USA), programmed from 100°C for 1 min, 10°C/min to 280°C and held for 20 min. Helium was the carrier gas. The injector and transfer line temperature was 280°C, the ion source temperature was 250°C, and the quadrupole temperature 200°C. Injections were made in splitless mode, with purge on at 0.5 min.

Straight-chain saturated alkanes were identified by their molecular ions and from comparisons of retention times and mass spectra with those of authentic standards. Methyl-branched compounds were identified from their Kovat's retention indices relative to straight chain hydrocarbons, in combination with diagnostic ions from enhanced fragmentations at methyl branch points (Nelson 1993; Nelson and Blomquist 1995; Carlson et al. 1998). Unsaturated alkenes were identified by molecular weight, from retention times

slightly shorter than those of the corresponding straight-chain saturated alkanes, and their characteristic patterns of ions with masses 2, 4, or 6 mass units less than the corresponding ions in the spectra of straight-chain alkanes, for monoenes, dienes, and trienes, respectively. The positions and geometries of double bonds were not determined.

Results

Mass spectral analyses indicated that the cuticular lipids of *Laupala* species consisted of a relatively small number of saturated and unsaturated hydrocarbons (c.f., other insects; Howard and Blomquist 2005), varying in chain length from C_{22} to C_{33}. We found considerable variability among species (Table 1, Fig. 1), with the greatest diversity in chain length observed for *L. orientalis* (Maui). In particular, this species possessed a large variety of differentially methylated pentacosanes as well as several different unsaturated C_{27} and C_{29} alkenes. *L. makaio*, the other species sampled from Maui and the sister taxon to *L. orientalis* (Mendelson and Shaw 2005), similarly showed a large variety of hydrocarbons but differed from *L. orientalis* in possessing longer-chain alkenes (C_{29} and C_{31}), and lacking C_{22}–C_{24} alkanes. These two species also showed radically different relative abundances of particular hydrocarbons, with the CHC profile of *L. orientalis* predominantly (~66%) composed of C_{27} dienes.

Patterns of hydrocarbon diversity among the Big Island species were similar to *L. makaio* but typically displayed a marked reduction in hydrocarbon diversity. We found fairly similar hydrocarbon compositions for *L. kohalensis* and *L. pruna*, but these two species varied in the relative compositions of C_{31}–C_{33} tri- and tetraenes. In contrast, the remaining three species, *L. kona*, *L. paranigra*, and *L. nigra*, each showed a drastic reduction in both the number of hydrocarbon-chain lengths and the variety of unsaturated alkenes. The two most closely related species, *L. paranigra* and *L. nigra*, differed mainly in the relative abundance of C_{31} vs C_{33}. C_{33} alkenes made up ~70% of the CHC abundance for *L. nigra*, whereas a single C_{31} triene represented ~65% of the CHC observed for *L. paranigra*. A slightly larger number of *n*-alkenes were observed for *L. kona*, with no single-hydrocarbon type comprising more than 30% of the total.

Differences between Males and Females Our previous GC analyses of CHC variation (Mullen et al. 2007) demonstrated that significant qualitative differences existed among all species sampled. In addition, we showed that males and females of *L. makaio* had different cuticular lipid compositions. One of the goals of the current study was to assay each species for both qualitative and quantitative differences in individual hydrocarbons between males and females. In line with our expectations, we found that *L. makaio* males possessed more C_{31} tetraene than females (Fig. 2; males=48% total abundance vs 5% in females; $P<0.001$). Males and females of this species also appeared

to differ in the relative ratios of C_{27} alkenes. Surprisingly, males and females of the other species sampled showed little qualitative variation (Fig. 2), even though our previous statistical analysis found significant quantitative variation between males and females when grouped by sex (Mullen et al. 2007).

Discussion

We tested our a priori hypothesis about hydrocarbon evolution in this group, namely, that the reduction in chemical diversity among the Big Island taxa represents the loss of modifications to the ancestral hydrocarbons found on the Maui taxa rather than the de novo origin of chain-length diversity. The chemical identifications supported this hypothesis and indicated that the differences between these two island faunas were due primarily to a decrease in the number of dienic and trienic hydrocarbons on the Big Island taxa compared to the crickets on Maui (Figs. 1 and 2, Table 1). Furthermore, the two ancestral species from Maui also showed a greater diversity of methyl branch positions for a given chain-length hydrocarbon than did species from the Big Island. The differences among species are highlighted by the fact that we identified only two hydrocarbons in common for all the *Laupala* species: 2-Me-C_{26} and 2-Me-C_{28}.

The striking differences between these two lineages in their hydrocarbon composition must reflect modifications in the biosynthesis of hydrocarbon. Straight-chain alkanes and *n*-alkenes are formed via elongation of fatty acyl-CoAs, which are converted to hydrocarbons one carbon shorter in length by decarboxylation (Blomquist 2003; Howard and Blomquist 2005). Chain length is regulated by specific fatty acyl-CoA elongases. Furthermore, methyl-branched hydrocarbons are derived from substitution of methylmalonyl-CoA for malonyl-CoA at specific chain positions during

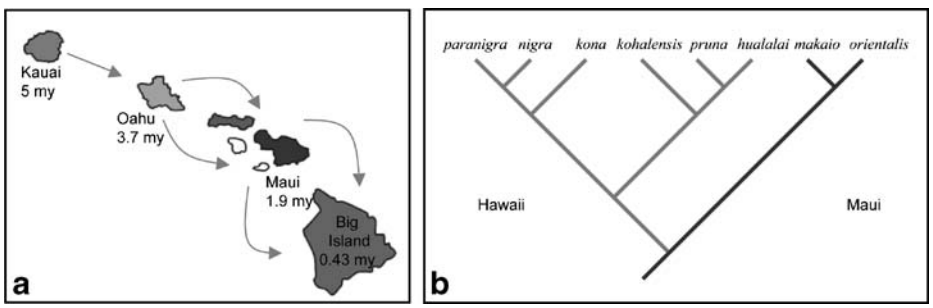

Fig. 3 **a** History of lineage splitting and intra-island radiations within the Hawaiian *Laupala* genus. **b** Simplified cladogram of the evolutionary relationships among the 'pacifica' group species sampled for this study based on Mendelson and Shaw's (2005) amplification fragment length polymorphism phylogeny

elongation (Howard and Blomquist 2005). Although it is unclear how the number and position of methyl-branching units is regulated, work on houseflies (*Musca domestica*, Gu et al. 1997) and the German cockroach (*Blattella germanica*, Gu et al. 1993) suggests that microsomal fatty-acid synthase (FAS) is involved in the production of methyl-branched fatty-acid precursors (Blomquist and Vogt 2003). Thus, the relatively greater diversity of methyl-branched alkanes and alkenes among the Maui species may involve differential regulation of FAS in this lineage.

Differences in Cuticular Composition among Laupala Species on the Big Island of Hawaii A previously unrecognized pattern that emerged as a result of the current analysis was the difference in the composition of cuticular hydrocarbons among the taxa of the Big Island '*pacifica*' species group. This lineage is the most rapidly diverging clade in a rapid species radiation (Mendelson and Shaw 2005). Previous phylogenetic work on these species supports close evolutionary relationships among *L. kohalensis*, *L. pruna*, and *L. hualalai* (Fig. 3). These three species form a recently diverged lineage that is most closely related to the remaining Big Island 'pacifica' group species (*L. kona*, *L. paranigra*, and *L. nigra*). Our results indicate that the *L. kohalensis–L. pruna* clade (*L. hualalai* was not sampled) is more diverse with respect to methyl-branch positions than the *L. kona–L. paranigra–L. nigra* clade. In fact, the former two species possess hydrocarbons that are similar to those found on *L. makaio* on Maui, although the relative amounts of each hydrocarbon vary considerably. The lesser hydrocarbon diversity in the latter species clade suggests that a dramatic reduction in the complexity and diversity of cuticular lipids has occurred in this lineage relative to the remaining Big Island species of the 'pacifica' group.

It is commonly thought that the primary function of insect cuticular hydrocarbons is to regulate water balance (Hadley 1984). Therefore, one possible explanation for the differences in cuticular lipid composition among species on the Big Island is natural selection acting in different environments (e.g., wet vs dry). However, this does not appear to be the case because each of these species occurs in a range of habitats on the Big Island. Furthermore, previous work suggested that closely related, allopatrically distributed species are more similar in their hydrocarbon profiles than are sympatric taxa that share overlapping habitats and ranges (Mullen et al. 2007). An alternative possibility for the variation in cuticular hydrocarbons is that some of these compounds serve as chemical mate-recognition signals and that differences among species reflect lineage-specific adaptations to sexual selection driven by female choice. It is well-recognized that cuticular hydrocarbons serve as recognition signals in arthropods (Howard and Blomquist 2005). While direct behavioral assays have not yet been completed, our preliminary behavioral observations (unpublished data) suggest that courtship between males and females of the species described here involves chemical communication.

Courtship in *Laupala* takes place over the course of several hours and involves a complex series of behavioral elements that are repeated multiple times (Shaw and Lugo 2001). Each courtship unit culminates in the passage of a spermless "microspermatophore" to the female, which is consumed by the female before the next courtship bout. Mating terminates only after the transfer of a much larger "macrospermatophore", that contains all of the sperm for a given mating (Shaw and Khine 2004; de Carvalho and Shaw 2005). Throughout courtship, males emit the same song used for long-range calling. Behaviorally, male singing during courtship is always preceded by antennal contact, and production of each spermatophore occurs while males and females "face" each other and engage in extensive antennal interactions (Shaw and Lugo 2001; Shaw and Khine 2004). Thus, chemical and/or tactile signals are likely exchanged during courtship, and mate choice may be a function of multiple mating signals, rather than simply a byproduct of long-range attraction of females to conspecific male songs.

In summary, the biogeographic differences in CHC diversity among lineages of Hawaiian *Laupala* is broadly consistent with a founder-induced loss of biochemical variation resulting from the colonization history of the Big Island taxa. However, the differences observed between the two major clades of these crickets on the Big Island suggest that post-colonization processes, such as drift or selection, have also played an important role in the evolution of CHC diversity in this system. Further work will focus on complete identification of the hydrocarbons along with behavioral assays to test whether these hydrocarbons function as mate-recognition cues.

Experimental Evidence for Three Pheromone Races of the Scarab Beetle *Phyllophaga anxia* (LeConte)

Paul S. Robbins · Daniel B. Cash · Charles E. Linn, Jr · Wendell L. Roelofs

Received: 7 December 2006 / Revised: 7 October 2007 / Accepted: 4 January 2008 / Published online: 24 January 2008

Abstract This study offers experimental evidence for the existence of three pheromone races of the northern genitalic form of *Phyllophaga anxia*: one race in which females produce and males respond mainly to L-valine methyl ester, a second producing and responding to L-isoleucine methyl ester, and a third producing and responding to an intermediate range of blends of the two compounds. At Franklinville, NY, pheromone gland contents of females were analyzed using coupled gas chromatography–electroantennogram detection. Two types of females were found, one that produced greater than 99% L-valine methyl ester and another that produced greater than 99% L-isoleucine methyl ester. Capture–mark–release–recapture field tests with males at Franklinville established that most males were recaptured in traps baited with the same blends with which they were originally captured. The populations characterized at Franklinville, NY, have also been found at numerous locations from eastern Canada and the northeast and north central USA, sometimes in allopatry and sometimes in sympatry. At a site in Carver, MA, *P. anxia* males responded to blends of the methyl esters of L-valine and L-isoleucine, and Carver females produced blends similar to those to which the males responded. Populations responding to blends have been identified only from southeastern Massachusetts and Rhode Island. At a field site near Waterloo, NY, the addition of small proportions of L-isoleucine methyl ester to lures containing L-valine methyl ester did not affect trap captures, but higher proportions of L-isoleucine methyl ester were inhibitory, decreasing trap captures.

Introduction

In a multiyear North American study involving the capture and identification of approximately 57,000 individuals in 61 species of scarab beetles in the genus *Phyllophaga*, Robbins et al. (2006) documented the existence of geographic variation of male response of the northern genitalic form of *Phyllophaga anxia* to various blends of the two sex attractant components of this species. *P. anxia* is described as having two distinctive genitalic types, commonly called northern or southern (see Luginbill and Painter 1953 or Woodruff and Beck 1989 for photographs or scanning electron micrographs of the two forms). *P. anxia* is perhaps the most widely distributed (Luginbill and Painter 1953; Woodruff and Beck 1989) of the approximately 215 species (Evans and Smith 2007) of *Phyllophaga* in the USA and Canada. The larval stages of *P. anxia* are serious root-feeding pests of commercial cranberry crops in Massachusetts and Wisconsin (Franklin 1950; Dittl and Kummer 1997).

In the study of Robbins et al. (2006), traps were baited with various blends of the methyl esters of L-valine and L-isoleucine, the sex pheromone components of this species (Zhang et al. 1997). Three types of *P. anxia* male responders were identified: males that were captured principally in the 100:0 or 90:10 L-valine methyl ester/L-

isoleucine methyl ester baited traps, those that were captured in the 0:100 L-valine methyl ester/L-isoleucine methyl ester baited traps, and those that were captured in traps baited with blends (90:10, 80:20, 60:40, 40:60, 20:80, 10:90) of the two compounds (Fig. 1). No morphological characters were found that delineated these populations (Robbins, personal observation). Males captured with intermediate blends of L-valine methyl ester/L-isoleucine methyl ester were found only in populations from southeastern Massachusetts and Rhode Island, whereas the groups responding to predominantly L-valine methyl ester or L-isoleucine methyl ester alone were captured over a much greater area (Fig. 2). In most locations, either the L-valine methyl ester population or the L-isoleucine methyl ester population dominated the male flight response profile, but at several sites, both populations occurred in large numbers flying on the same dates, producing a bimodal trap response profile (e.g., Fig. 3).

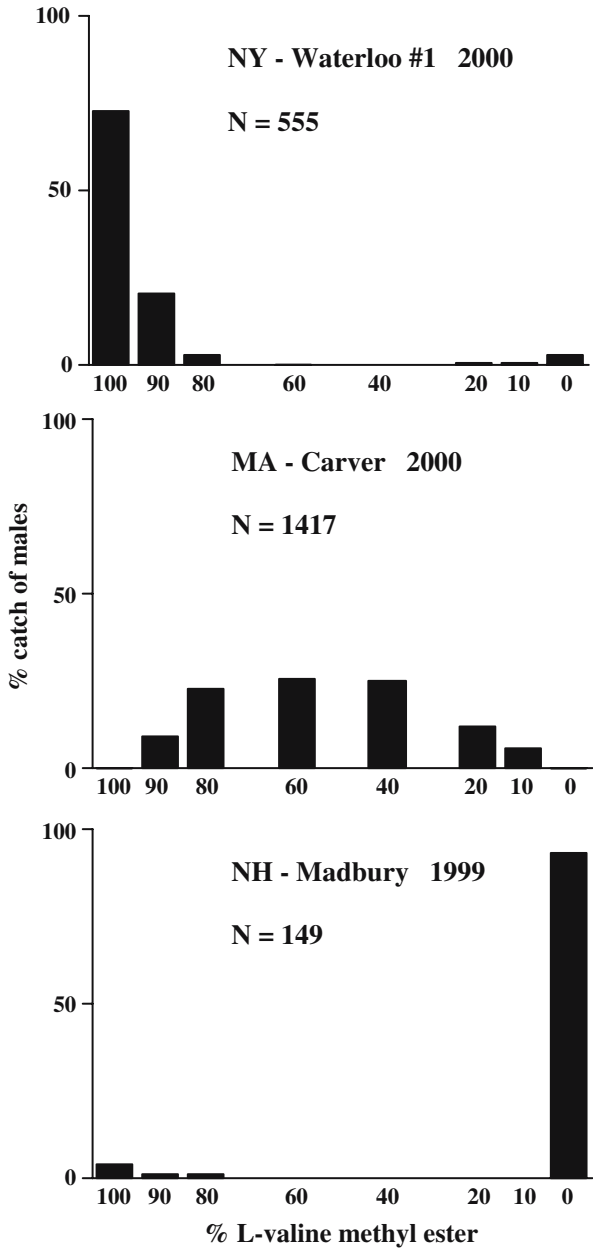

Fig. 1 Captures of male *P. anxia* in traps baited with various blends of the methyl esters of L-valine and L-isoleucine at three different sites. Captures for each lure blend are shown as a percentage of the total catch at that site

To investigate these populations in greater detail, experiments were conducted at three sites. At the first site, near Franklinville, NY, sex pheromone glands from individual females were analyzed to determine whether the female pheromone production curve was also bimodal. Male capture–mark–release–recapture studies were also conducted at Franklinville to determine repeatability of male preference. At the second site, near Carver in southeastern Massachusetts, where males responded to the various blend combinations, the range of ratios of L-valine methyl ester/L-isoleucine methyl ester produced by females was determined, to compare with the male response curves. The third site, Waterloo # 1 (Robbins et al. 2006), near Geneva, NY, was used to test the role of L-isoleucine methyl ester as a minor component in an L-valine methyl ester-responding *P. anxia* population.

Methods and Materials

Franklinville, NY—Single Female Pheromone Gland Analysis Female *P. anxia* were captured with UV light traps at the Franklinville site in 2000 to determine whether the ratios of L-valine methyl ester/L-isoleucine methyl ester produced by females mirrored the bimodal nature of the male response profile recorded in 1999 (Fig. 3). Five light traps were maintained at the site in 2000 from May 1 to June 30. Each day, insects captured in light traps were retrieved, and the sexes were separated. Females were stored individually in ~30-ml plastic cups in a 3:1 mix of greenhouse sand and screened peat moss raised to approximately 12% moisture. Each cup was marked with the date and light trap identification number. Cups containing females were held in a home refrigerator for 2–3 d and then at 10°C for up to 4 d until gland contents were extracted for analysis. Pheromone glands were everted by applying gentle pressure to the abdomen and then excised with iris scissors. Excised glands were soaked individually for 20 min in 200 µl of dichloromethane, removed, and the extract concentrated under a nitrogen stream to approximately 20 µl. Samples were stored at −80°C until analysis.

Single-gland analysis of the Franklinville females was carried out by using a coupled gas chromatograph–electroantennogram detector (GC-EAD). A Hewlett-Packard

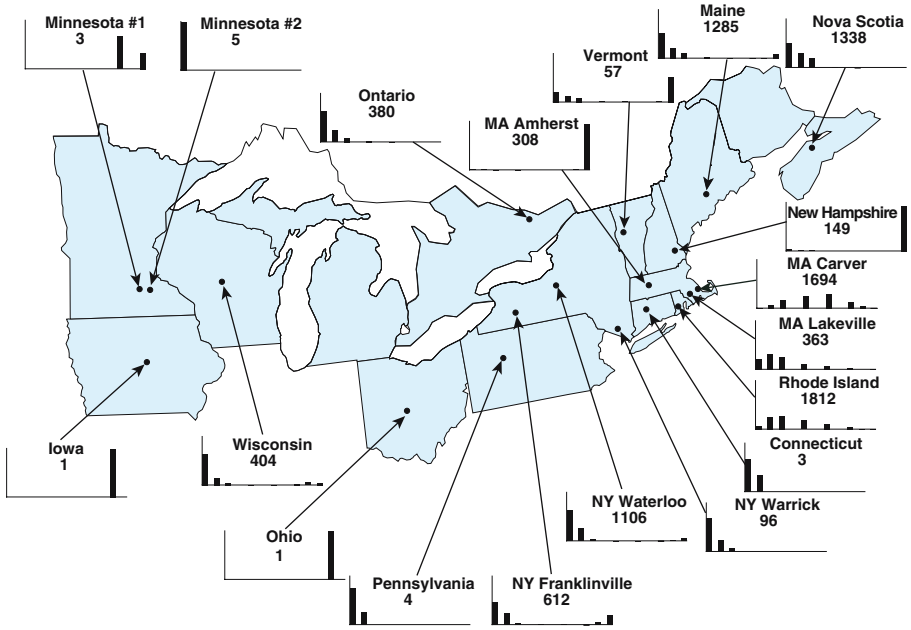

Fig. 2 Captures of male *P. anxia*, northern genitalic form, in traps baited with various blends of the methyl esters of L-valine and L-isoleucine. Total male capture=20,640. Catches from all years are not shown here. *X*- and *Y*-axes are the same as those shown in Fig. 1

5890 series II gas chromatograph equipped with a nonpolar EC-1 Econo-Cap column (30 m×0.25 mm inner diameter [ID], 0.25 μm film thickness; Alltech, Deerfield, IL) was used for the analyses. The carrier gas was N_2 at a head pressure of 138 kPa (flow rate, 2.0 ml/min). Injections were made in splitless mode (split valve opened at 1 min). The temperature program was 40°C for 5 min, then 15°C/min to 250°C, and held for 10 min. Injector, EAD outlet, and flame ionization detector (FID) temperatures were 250°C. The column effluent was combined with N_2 makeup gas (30 ml/min) and then split 1:1 to the FID and EAD.

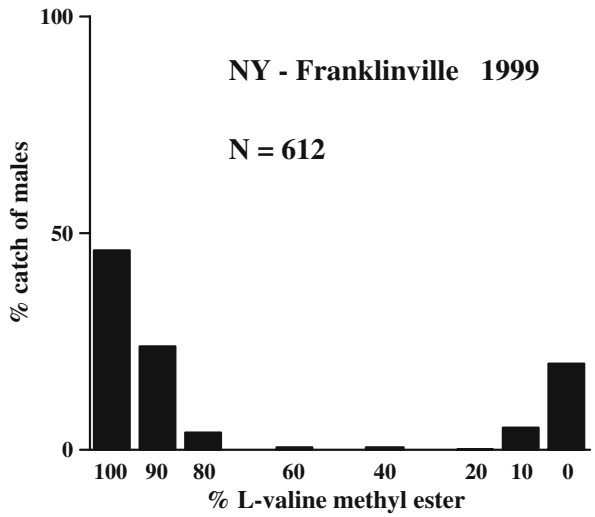

Fig. 3 Captures of male *P. anxia* in traps baited with various blends of the methyl esters of L-valine and L-isoleucine at a bimodal site. Captures for each lure blend are shown as a percentage of the total catch at that site

An extra FID port of the GC was modified and used for the EAD outlet. The EAD transfer line was terminated in a humidified, filtered air stream, which was cooled by a modified condenser flushed with 0°C water. The air stream carried the column effluent over the beetle antennal preparation. See Robbins et al. (2003) for a photograph of the beetle antennal preparation. The output signal from the antenna was amplified by a customized single-step high-input impedance DC amplifier. The resulting signal was recorded on a HP 3390 A integrator synchronized with the GC integrator. These methods were adapted from Nojima et al. (2003a) and Zhang et al. (1997).

Pheromone glands from 67 Franklinville females were extracted and analyzed by GC-EAD in 2000, using antennae from 11 different males. Preliminary work indicated no differences in antennal responses between the races when antennae from males of each of the two races were tested in the GC-EAD apparatus with 1 μl of a hexane solution containing 1 ng/μl of the methyl esters of L-valine and L-isoleucine.

Franklinville, NY—Male Capture–Mark–Release–Recapture

Males of populations in Franklinville, NY, were studied from 2000 to 2002 using capture–mark–release–recapture methods to evaluate blend response specificity. Traps were deployed on May 1, before *P. anxia* flights began, and checked each day until flight activity ceased at the end of June. In 2000 and 2001, the blends of L-valine methyl ester/L-isoleucine methyl ester were tested in the same ratios (100:0, 90:10, 80:20, 60:40, 40:60, 20:80, 10:90, and 0:100) and the same doses (4 mg per septum) as in the 1999 field test. A trap baited with a control septum treated with hexane was deployed in both years. A.C. Oehlschlager

(ChemTica Internacional S.A. [San Jose, Costa Rica]) kindly provided the lures for this study. The traps (see Robbins et al. 2006) were placed at the edge of a mature hardwood forest bordering a large field. Traps were hung on metal stakes ~15 m apart such that the trap bottom was ~30 cm from the ground. Traps were rerandomized each morning after collecting the beetles. In 2000 and 2001, male beetles were collected from each trap/blend combination and marked with a unique paint (Testor Corporation, Rockford, IL) code identifying the date captured and the blend to which the male responded. Marked individuals were distributed randomly among three release sites and allowed to burrow into the soil. The three release sites were 20 m from the trap line and equidistant from each other. Data from recaptured males were recorded, and males were frozen for later identification to species.

In 2002, eight traps were deployed at the same site, consisting of four traps baited with lures containing 4 mg of L-valine methyl ester and four containing 4 mg of L-isoleucine methyl ester. Positions of the L-valine methyl ester and L-isoleucine methyl ester traps were alternated within the trap line at initial placement. Beetles were collected, and trap positions were rotated each day during the flight period. Beetles captured were marked according to the compound to which they responded and released as in 2000 and 2001. Data from recaptured males were recorded, and males were frozen for later identification to species.

Carver, MA—Analysis of Female Pheromone Gland Contents Virgin females were dug from a cranberry bog in Carver, MA, in April of 2001 and 2002 before the beetle flight season. This was the same bog from which the individuals used to identify the *P. anxia* sex pheromone were acquired (Zhang et al. 1997). In the laboratory, females were housed in glass observation cages in a controlled environment room maintained at 25°C during the 16-hr photophase and 20°C during the 8-hr scotophase. Cages contained a 3:1 mix of greenhouse sand and screened peat moss raised to approximately 12% moisture in the bottom (approximately 10 cm deep) in which the females could burrow. A 6-mm mesh wire screening was available for the females to climb on and call from during scotophase. When females were observed calling (Leal et al. 1993; Nojima et al. 2003b) during scotophase, they were removed from the cages, the glands were excised and extracted, and the extracts were stored as described previously. Samples were analyzed on a Shimadzu GC17A in splitless mode, equipped with a nonpolar EC-1 Econo-Cap column (30 m×0.25 mm ID, 0.25 μm film thickness; Alltech). Nitrogen was used as the carrier gas. During the 1-min time for splitless injection, the column head pressure was kept at 150 kPa (flow rate, 2.2 ml/min) and then decreased to 78 kPa after the split valve was opened (flow rate, 1 ml/min). The oven temperature was kept at 40°C for 2 min, then programmed at 15°C/min to 150°C (0 min) and then at 30°C/min to 250°C (8 min). Injector and detector temperatures were 200 and 260°C, respectively. A 1:1 mix of L-valine methyl ester and L-isoleucine methyl ester at a concentration of 10 ng/μl each in hexane was used to calibrate the instrument and determine retention times of the two compounds. Ratios of the two compounds were determined by manual integration of the electronically stored peaks. Individuals were then ranked in 5% increments by percent of L-valine methyl ester from 0 to 100%. For example, an individual with 14.8% L-valine methyl ester was placed in the 10% rank, whereas an individual with 16.3% L-valine methyl ester was placed in the 15% rank.

Waterloo, NY—Role of L-Isoleucine Methyl Ester as a Minor Component The male flight response profile at Waterloo # 1 over several years (Robbins et al. 2006) indicated the presence of a large population that responded to lure blends containing a high percentage of L-valine methyl ester. This population provided an excellent site to test the effect on male capture of small amounts of L-isoleucine methyl ester added to the L-valine methyl ester. Traps were placed at the Waterloo no. 1 site, near Geneva, NY, on May 18, 2001 and removed on June 8, 2001. Treatments included L-valine methyl ester/L-isoleucine methyl ester blends of 100:0, 99.75:0.25, 99.5:0.5, 99:1, 97:3, 95:5, 90:10, and a solvent control-baited trap. Red rubber septa (5 mm Thomas Scientific, Swedesboro, NJ) were loaded with 4 mg each of the above blends by dissolving neat compounds in hexane, applying appropriate amounts to the septa, and allowing the hexane to evaporate in a fume hood. Three replications of the eight treatments were placed in three noncontiguous lines at the study site as described above. Traps were rerandomized each time they were checked, three times each week.

Statistics Data were tested for homogeneity of variance using Levene's test and log transformed ($x+1$) if necessary. Data were analyzed with a one-way analysis of variance, $P<0.05$. Fisher's least significant difference test was used for post-hoc comparisons.

Results

Franklinville, NY—Analysis of Pheromone Glands of Females Of the 67 glands analyzed from females caught in light traps at the Franklinville site in 2000, 63 glands contained enough material for GC analysis. The pheromone blend ratios were partitioned into two groups: those with L-valine

methyl ester/L-isoleucine methyl ester blends of approximately greater than 99:1 and those producing blends of approximately less than 1:99, yielding an unequivocal bimodal distribution (Fig. 4). In examining the coupled GC-EAD traces, it was found that in every instance, female glands contained both esters, regardless of the group to which they had been assigned. However, the amount of the lesser compound was often too small to be detected by the GC. Nevertheless, the EAD provided evidence of the presence of trace amounts of these compounds (Fig. 5).

Franklinville, NY—Capture–Mark–Release–Recapture of Males In capture–mark–release–recapture experiments of males, the rate of recapture for 2000 was 13.1% (39 of 297; Fig. 6a) and for 2001 was 10.9% (32 of 293; Fig. 6b). In both 2000 and 2001, males captured in traps baited with blends containing a high proportion of L-valine methyl ester were recaptured in traps baited with those blends. The shapes of the male recapture profiles are nearly identical to those of the capture profiles. In neither year were any males that were captured in the 100% L-isoleucine methyl ester-baited trap recaptured in that trap. In 2001, a single male captured using 100% L-isoleucine methyl ester returned to the 100% L-valine methyl ester-baited trap.

In 2002, the capture–mark–release–recapture field trial was redesigned. Because no males were recaptured in traps baited with the 100% L-isoleucine methyl ester in 2000 or 2001, we hypothesized that the sensitivity of the L-isoleucine methyl ester-responding population to the large amount of L-valine methyl ester emanating from the other blends present at the trapping site hindered their recapture in the single 100% L-isoleucine methyl ester-baited trap. The response curve of males from Franklinville in 1999

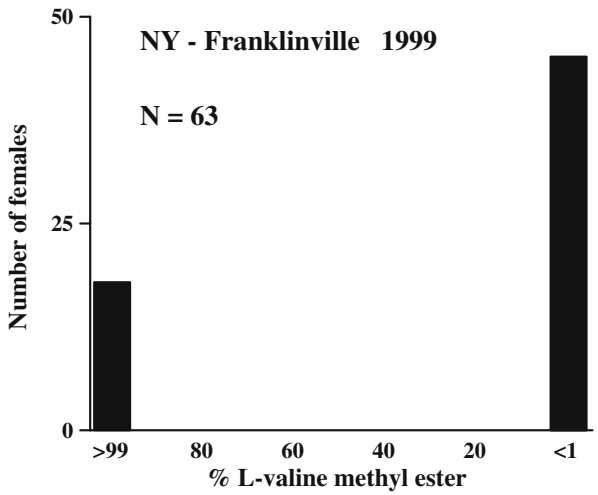

Fig. 4 Percentages of the methyl esters of L-valine and L-isoleucine extracted from pheromone glands of female *P. anxia*, Franklinville, NY, 2000

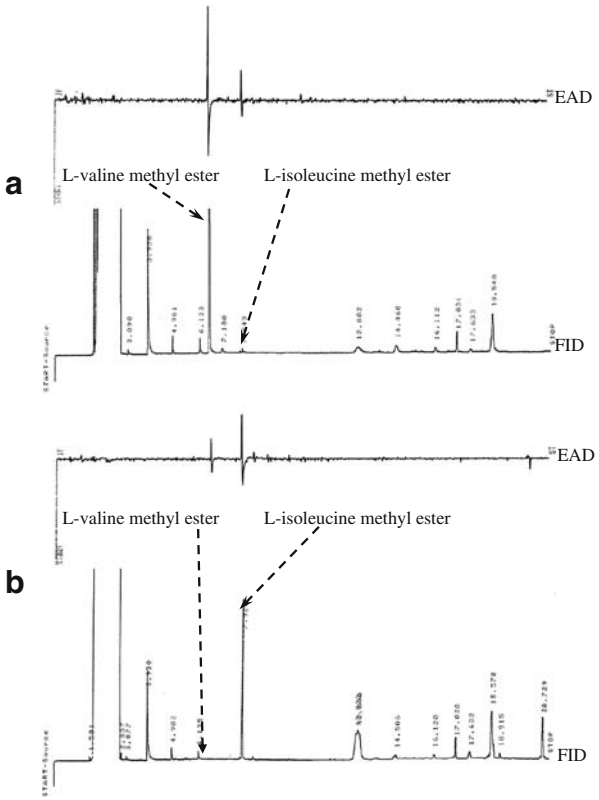

Fig. 5 Simultaneous EAD and FID traces illustrating male antennal responses to the gland contents of the two populations of female *P. anxia* found at Franklinville, NY, 2000. **a** L-Valine methyl ester population; **b** L-isoleucine methyl ester population

(Fig. 3) revealed that the population that responded to the high-percentage L-valine methyl ester blends was more tolerant of the presence of L-isoleucine methyl ester than was the L-isoleucine methyl ester-responding population to the presence of L-valine methyl ester. This phenomenon was also true for other *P. anxia* response profiles, whether or not both populations were present at a given site (Robbins et al. 2006). Bearing these observations in mind, males used for capture–mark–release–recapture in 2002 were presented with only the two pure compounds, 100% L-valine methyl ester and 100% L-isoleucine methyl ester. The capture profile of males in 2002 (Fig. 6c) indicated an increase in the number of beetles captured in the L-isoleucine methyl ester-baited traps relative to 2000 or 2001. The total rate of recapture for 2002 was 16.0% (212 of 1,320). The rate of recapture for the L-valine methyl ester-baited traps was 27.8% (199 of 717) and for the L-isoleucine methyl ester baited traps was 2.1% (13 of 603). A single male captured in a L-valine methyl ester-baited trap was recaptured in a L-isoleucine methyl ester-baited trap.

Carver, MA—Analysis of Pheromone Gland Contents of Females The contents of pheromone glands from 21 females were analyzed during 2001 and 2002. Of these, 17

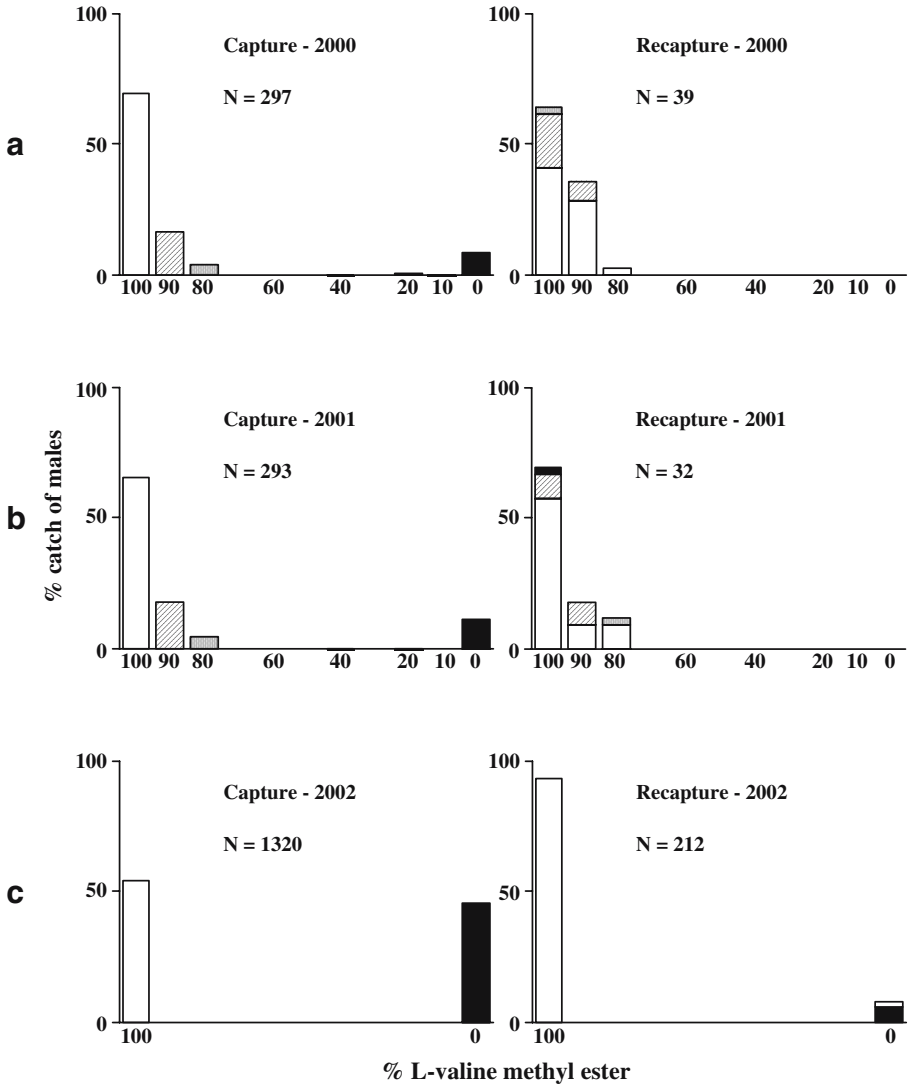

Fig. 6 *P. anxia* male capture–mark–release–recapture in traps baited with various blends of the methyl esters of L-valine and L-isoleucine. Franklinville, NY, **a** 2000, **b** 2001, **c** 2002. *Graph on the left* indicates percent male capture in each blend. *Graph on the right* indicates the percent female recapture in a given blend and the blend from which it was first captured in the graph on the left

extracts had sufficient amounts of the two components to calculate blend ratios. Single-gland analyses of females from the Carver site yielded a histogram of L-valine methyl ester/L-isoleucine methyl ester ratios (Fig. 7) similar to the male response curve found there in 1999 (Fig. 1) as well as other years (Robbins et al. 2006). No females from the Carver site produced blends of greater than 99:1 L-valine methyl ester/L-isoleucine methyl ester or less than 1:99, resembling those from Franklinville, NY. Of the 7,004 male *P. anxia* captured at Carver, MA, over 4 yr of trapping, only 33 were captured in the 100% L-valine methyl ester-baited traps and 22 in the 100% L-isoleucine methyl ester-baited traps. Thus, more than 99% of the males captured at Carver, MA, were captured using blends of the two compounds.

Waterloo, NY—Role of L-isoleucine Methyl Ester as a Minor Component All baited traps captured significantly ($F_{7,\ 16}$= 8.43; P<0.001) more males than the control (hexane only)

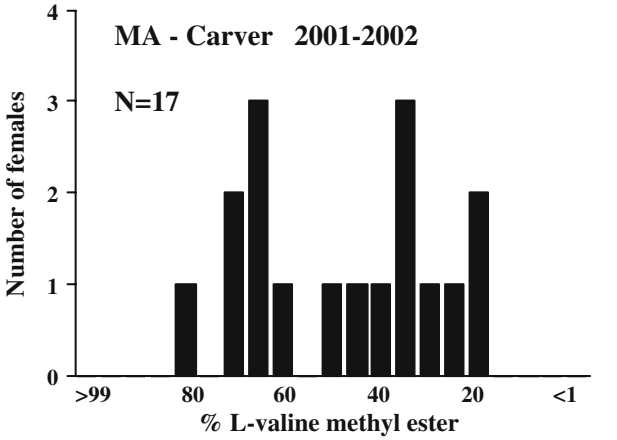

Fig. 7 Percentages of the methyl esters of L-valine and L-isoleucine extracted from pheromone glands of female *P. anxia*, Carver, MA, 2001 and 2002

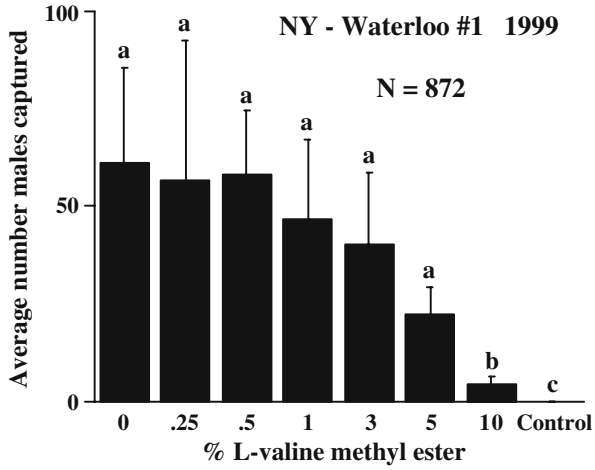

Fig. 8 Average capture/treatment (mean±SE) of male P. anxia in traps baited with various blends of the methyl esters of L-valine and L-isoleucine. Waterloo, NY, 2001. *Bars with the same letter* are not significantly different, $P<0.05$, Fisher's LSD test

traps (Fig. 8). There were no significant differences in numbers of males captured in traps baited with 0, 0.25, 0.5, 1.0, 3.0, and 5.0% L-isoleucine methyl ester (relative to the amount of L-valine methyl ester). The trap baited with 10% L-isoleucine methyl ester captured significantly fewer males than any of the traps baited with the other six blends with lower percentages of L-isoleucine methyl ester or no L-isoleucine methyl ester. Thus, we conclude that isoleucine did not function as a pheromone component at trace levels but rather was antagonistic at increasing doses.

Hand digging at Waterloo no. 1, NY, in April of 1999 yielded three virgin females. GC-EAD analysis of their pheromone gland contents showed a pattern identical to females from the Franklinville L-valine methyl ester group (Robbins, unpublished data), with large amounts of L-valine methyl ester and only trace amounts of L-isoleucine methyl ester.

Discussion

Evidence for Pheromone Races in P. anxia The results from analysis of female pheromone gland contents and capture–mark–release–recapture field tests with males offer experimental evidence for the existence of three pheromone races of the northern genitalic form of *P. anxia*: one in which females produce and males respond mainly to L-valine methyl ester, a second that employs L-isoleucine methyl ester, and a third that produces and responds to an intermediate range of blends of the two compounds. The variation in the sex pheromone system of *P. anxia* stands in direct contrast to the intraspecific uniformity of male pheromone response profiles found for 23 other *Phyllophaga* species captured at more than one geographical location (Robbins et al. 2006).

At Franklinville, NY, pheromone gland contents of females were analyzed by using GC coupled with EAD. One fraction of the population produced greater than 99% L-valine methyl ester, whereas the other fraction produced greater than 99% L-isoleucine methyl ester. Capture–mark–release–recapture field tests of males at Franklinville established that most but not all males were recaptured in traps baited with the same ratios of compounds in which they were originally captured. In 2000 and 2001, the trap lures were 100:0, 90:10, 80:20, 60:40, 40:60, 20:80, 10:90, and 0:100 L-valine methyl ester/L-isoleucine methyl ester. The results from those trapping tests revealed that 94% of the males captured in the 100:0 and 90:10 combinations were recaptured in traps baited with those same mixtures. In 2002, traps were baited with L-valine methyl ester or L-isoleucine methyl ester alone. In that test, of the males recaptured, 99.5% captured initially in traps baited with 100% L-valine methyl ester were recaptured in traps baited with the same source, whereas 100% captured in traps baited with 100% L-isoleucine methyl ester were recaptured in traps baited with 100% L-isoleucine methyl ester. Thus, the two *P. anxia* populations found at Franklinville, NY, are sympatric and synchronic, although it is unknown if they have different diel activity cycles.

Pheromone response curves of males resembling those of the two *P. anxia* pheromone races found at Franklinville, NY, are distributed from eastern Canada and the northeast USA to the north central USA (Fig. 2), sometimes in allopatry and sometimes in sympatry. Populations responding to blends have been found only in southeastern Massachusetts and Rhode Island. The blend responders appear as two groups. The first group, represented by a male capture profile generated from the Carver site (Fig. 9), was found at three locations (see the Carver, MA, and Plympton, MA, sites in Robbins et al. 2006) at which the overwhelming majority of males were captured in traps baited with blends of L-valine methyl ester/L-isoleucine methyl ester. Female *P. anxia* at Carver, MA, were found to produce blends of L-valine methyl ester/L-isoleucine methyl ester that ranged from 16:84 to 79:21 (Fig. 7). The male response profiles generated from capture data at the Carver site (Fig. 9) overlapped female production profiles by about 10% at each end, suggesting that the male response window was wider than the range of blends produced by the Carver females. In 4 yr of field testing at Carver, MA, and 1 yr each at Plympton no. 1, MA, and no. 2, MA, a total of 7,717 male *P. anxia* were captured. Of this total, only 53 (0.7%) were captured in traps baited with L-valine methyl ester alone, and 24 (0.3%) were captured in traps baited with L-isoleucine methyl ester alone.

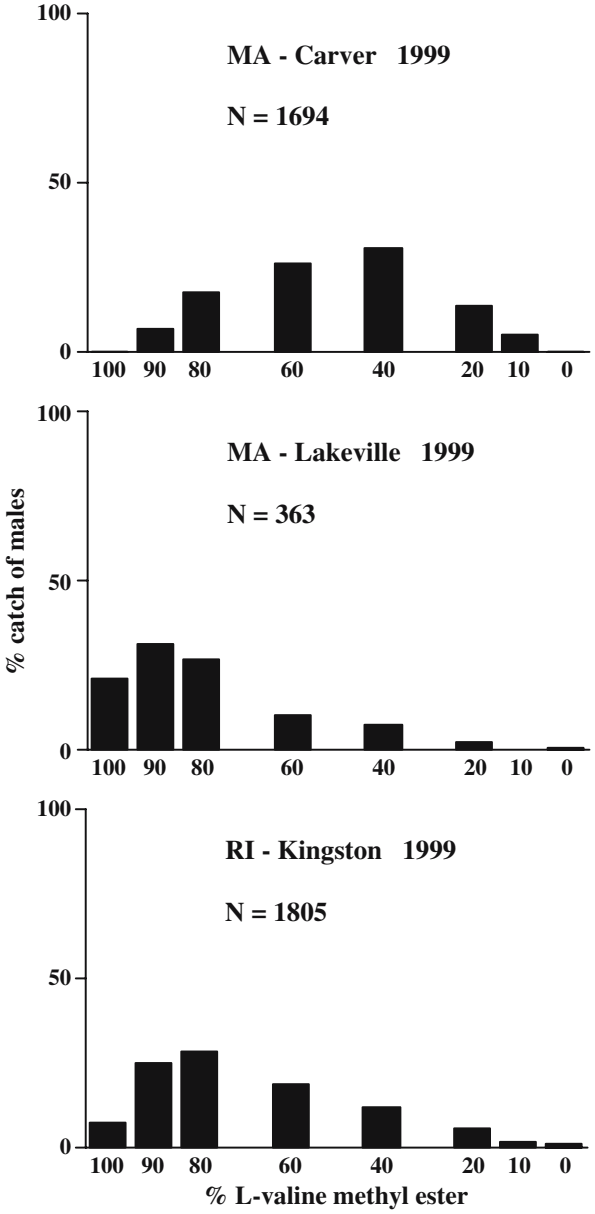

Fig. 9 Captures of male *P. anxia* in traps baited with various blends of the methyl esters of L-valine and L-isoleucine at test sites in southeast Massachusetts and Rhode Island. Captures for each lure blend are shown as a percentage of the total catch at that site

The second group responding to blends is represented by male capture profiles generated from 2 yr of field testing at Lakeville, MA, and Kingston, RI (Fig. 9). Although the majority of males at these sites were captured in traps baited with blends of L-valine methyl ester/L-isoleucine methyl ester, male capture curves were shifted to the L-valine methyl ester end of the blends presented, relative to those noted at Carver, MA. At the Carver and Plympton sites, an average of 0.7% of the males were captured in traps baited with 100% L-valine methyl ester, but in Lakeville, MA, and Kingston, RI, an average of 15.5% of the males were captured in traps baited with 100% L-valine methyl ester.

Intraspecific Variation in Insect Sex Pheromone Systems Sex pheromone variation is well documented in numerous insect species (Löfstedt 1990; Phelan 1997), particularly those in the order Lepidoptera. The turnip moth, *Agrotis segetum*, is widely distributed throughout Europe, the near East, and Africa. Various ratios of (*Z*)-5-decenyl acetate, (*Z*)-7-dodecenyl acetate, and (*Z*)-9-tetradecenyl acetate were required to attract males throughout Eurasia and North Africa, whereas in sub-Saharan Africa, (*Z*)-5-decenyl acetate alone attracted males (Arn et al. 1983; Löfstedt et al. 1986; Tóth et al. 1992; Wu et al. 1999). The larch budmoth, *Zeiraphera diniana*, consists of two host races that feed on larch and Cembran pine in the European Alps. The host races exist in both allopatry and sympatry, with each race producing and responding to its own pheromone. Cembran pine populations of *Z. diniana* utilize (*E*)-9-dodecenyl acetate as their pheromone, whereas the larch populations utilize (*E*)-11-tetradecenyl acetate (Baltensweiler et al. 1978; Baltensweiler and Priesner 1988). In contrast, analyses of populations of the pink bollworm moth, *Pectinophora gossypiella*, sampled in several areas of the world (Haynes and Baker 1988), and the cabbage looper moth, *Trichoplusia ni*, sampled across the USA (Haynes and Hunt 1990), demonstrated little variation in female produced pheromone blends.

The first case of intraspecific geographical variation in sex pheromone response was demonstrated in the Coleoptera. Lanier et al. (1972) utilized pine bolts infested with male pine engraver (*Ips pini*) from California, Idaho, and New York to perform reciprocal field tests at each of the three locations. In New York, beetles responded much more strongly to the infested bolts from New York than to either the infested bolts from California or Idaho. In both California and Idaho, the local populations preferred infested bolts from Idaho over bolts from California. In California, the local population showed only a small response to the New York bolts. Lanier et al. (1980) quantified ratios of (+)- and (−)-ipsdienol from *I. pini* males from Idaho and New York and field tested the two compounds in both locations. They concluded that the differences in production of and response to the enantiomers of ipsdienol in the populations at each of the locations explained their earlier work with infested bolts. Later, Miller et al. (1989) demonstrated that both chirality and quantity of the enantiomers of ipsdienol varied both between and within populations, even populations as close in proximity as southwestern and southeastern British Columbia.

The sex pheromone variation observed in *P. anxia* resembles none of the examples described above but rather

is reminiscent of the patterns seen in the European corn borer, *Ostrinia nubilalis*. In *O. nubilalis*, two pheromone races use blends of (*E*)-11-tetradecenyl acetate and (*Z*)-11-tetradecenyl acetate. The *E* race produces a 99:1 blend of *E*/*Z* isomers, whereas the *Z* race produces a 3:97 blend of *E*/*Z* isomers. In the field, these races occasionally mate, and hybrids are produced. Hybrid females produce intermediate blend ratios of approximately 35:65 *Z*/*E* (Roelofs et al. 1985; Glover et al. 1991), and hybrid male moths preferentially fly to blends of the *E*/*Z* isomers in the flight tunnel, although more hybrid males of either *E*×*Z* or *Z*×*E* crosses fly to the *Z* blend alone than to the *E* blend alone. Despite of the fact that natural hybridization between the *E* and *Z* pheromone races is well documented in the field, an in-depth genetic analysis of sex pheromone production and perception in this species predicts that no self-sustaining population of hybrids can exist (Roelofs et al. 1987). Therefore, the origin of the stable blend-responding populations of *P. anxia* is intriguing.

In *O. nubilalis*, the differences in the blend ratios of (*E*) and (*Z*)-11-tetradecenyl acetate are due to a single change in the activity of the reductase enzyme that determines the final blend ratio in pheromone production (Linn and Roelofs 1995). Roelofs et al. (1987) speculated that a few simple genetic substitutions could result in the *E* strain evolving from the *Z* strain. However, changes in the sex pheromone production system would have to evolve by a different mechanism in *P. anxia* because the raw materials are not synthesized *de novo*. L-Valine and L-isoleucine are essential amino acids (Chapman 1982) and must either be sequestered during larval feeding or produced by bacterial endosymbionts. Our results from Franklinville showed that both amino acid methyl esters were present in the female pheromone glands of females, one in large amounts and the other in very small amounts, whereas at Carver, the compounds were present in the pheromone glands of females in intermediate blends. Therefore, the titers of the amino acids before esterification or the formation of the methyl esters themselves must be regulated in some manner in all the pheromone races. If bacteria are involved in production of sex pheromones in *P. anxia*, as they are in *Costelytra zealandica*, another melolonthine scarab beetle (Henzell and Lowe 1970; Hoyt and Osborne 1971), their identification and coevolution with the many *Phyllophaga* species will be of interest.

Genitalic Morphology and Pheromone Races in P. anxia Although this study was undertaken to examine the sex pheromone variation encountered in the northern genitalic form of *P. anxia*, this discussion would not be complete without including mention of the southern genitalic form. Luginbill and Painter (1953) note that *P. anxia*, the most widely distributed *Phyllophaga* species in North America, is a variable species in both size and genitalic characters. In an examination of *P. anxia* from collections at Rutgers University, the University of Kentucky, and the University of Alabama, Robbins found both distinctly northern and southern forms of genitalia from each of the three states, as well as genitalic forms that can be regarded as intermediates (Robbins, unpublished data). Luginbill and Painter (1953) also record the presence of intermediate forms. The southern form has been captured only in traps baited with 100% L-isoleucine methyl ester (Robbins et al. 2006). Although little is known about close range courtship and mating behaviors in *Phyllophaga*, there is nothing that precludes a male of the southern genitalic form flying upwind to a female of the northern genitalic form producing L-isoleucine methyl ester or vice versa. Successful matings between northern and southern forms may explain the existence of intermediate genitalic phenotypes.

Acknowledgments P.S.R. thanks Satoshi Nojima and Bruce Morris for generously sharing their knowledge of GC-EAD and chemistry techniques. We thank Donna Boyce of Communication Services at Cornell University in Geneva, NY, for assistance with illustrations. P.S.R. also thanks Michael G. Villani, friend, mentor, and committee chair, who passed away on May 15, 2001.

E-2-Ethylhexenal, *E*-2-Ethyl-2-Hexenol, Mellein, and 4-Hydroxymellein in *Camponotus* Species from Brunei

Heather L. Voegtle · Tappey H. Jones · Diane W. Davidson · Roy R. Snelling

Received: 27 August 2007 / Revised: 14 November 2007 / Accepted: 7 January 2008 / Published online: 23 January 2008

Abstract *E*-2-ethyl-2-hexen-1-ol (**1**), mellein (**4**), and 4-hydroxymellein (**5**) were identified as the major volatile compounds in the head and/or thorax of *Camponotus quadrisectus*. Neither **1** nor **5** have been previously detected in insects. Also identified were small amounts of *m*-cresol (**2**) and 6-methyl salicylic acid (**3**). *E*-2-ethylhexenal (**6**) and small amounts of **3** were identified in heads of *Camponotus irritibilis* from Kuala Belalong, Brunei. Compounds **2**–**4** occur in other Bornean camponotines with hypertrophied mandibular glands, and **4** is widespread in the tribe. The possibility of semiochemical parsimony (multiple functions) for these mandibular gland compounds is reviewed in the context of existing data on mandibular gland products of other camponotines, reported biological activities of the compounds, and secondary loss of metapleural glands in this ant group.

Introduction

Mandibular gland products of hyperdiverse and ubiquitous carpenter ants (genus *Camponotus*) have been studied in relation to several different functions (Hölldobler and Wilson 1990). The economic importance of these ants drove early studies of compounds proposed as male sex pheromones (Brand et al. 1973a; Blum et al. 1987; Seidel et al. 1990; Torres et al. 2001). However, the few studies that included sterile workers and reproductive females identified similar products in those castes (Duffield and Blum 1975; Seidel 1988; Blum et al. 1988; but see Bellas and Hölldobler (1985) for a *Polyrhachis* species, also Camponotini). In workers of certain species, mandibular gland volatiles also function in nestmate recognition (Jaffe and Sánchez 1984) and alarm/defense. For example, in *Camponotus gigas*, mandibular gland secretions appear to be used in fighting; they flow prodigiously from mandibular gland orifices when majors are engaged in combat (D. W. Davidson, personal observations). Additionally, some members of the *Camponotus* (*Colobopsis*) *cylindricus* complex deploy secretions of hypertrophied mandibular gland reservoirs in suicidal fights over territory (Jones et al. 2004; D.W. Davidson, unpublished data).

This report describes the identification of three compounds not previously reported from insects, *E*-2-Ethyl-2-hexen-1-ol (**1**) and 4-hydroxymellein (**5**) are two of the major components of the mandibular glands of workers of *Camponotus quadrisectus* (F. Smith), and *E*-2-ethyl-2-hexenal (**6**) is a major component from workers of a coexisting species, *Camponotus irritibilis* (F. smith). In addition, the mandibular glands of *C. quadrisectus* contain mellein (**4**) as a major component.

Methods and Materials

Field Work Ants were collected and observed at various times of the year at the Kuala Belalong Field Studies Center (KBFSC), run by the Universiti Brunei Darussalam, and located in the Batu Apoi Forest Reserve, Temburong District, Brunei (4°32′N, 115°10′E). Workers from each of two *C. quadrisectus* nests, and one nest of *C. irritibilis*, were collected separately in vials containing small amounts of methanol. In one of two collections from a *C. quadrisectus* nest, several workers were trisected into head, thorax, and gaster, with replicates of each body segment stored independently in vials containing methanol. Both *C. quadrisectus* colonies nested in live trees, one at ∼1.5 m height and the second at an undetermined height. After feeding, workers of *C. irritibilis* climbed high into the trees, likely to a high canopy nest that we could not locate. Activities of one colony of each species were monitored sporadically for 5–6 weeks on each of three trips to KBFSC. Voucher specimens of both species were deposited in the entomological collections of both the Brunei Museum and the Los Angeles County Natural History Museum (DWD-KB series 05A-30 and 05A-42, respectively).

Chemical Analyses Gas chromatography-mass spectrometry (GC-MS) was carried out in the EI mode with a Shimadzu QP-5000 equipped with a 30 m×0.25 mm i.d. RTX-5 column. The instrument was programmed from 60 to 250°C at 10°C min^{-1}. Nuclear magnetic resonance spectrometry (NMR) was carried out in $CDCl_3$ solutions by using a Varian Mercury 400 MHz NMR spectrometer. For samples of less than 1 mg, a Shigemi tube was used (5 mm symmetrical microtube matched with $CDCl_3$, insert length 190 mm, bottom length 8.0 mm). Vapor phase Fourier Tranform-Infrared Spectrophotometry (FT-IR) spectra were obtained with a Hewlett-Packard model 5965B detector interfaced with a Hewlett-Packard 5890 gas chromatograph fitted with a 30 m×0.25 mm RTX-5 Amine column. Preparative HPLC was performed on a Waters machine equipped with a 1525EF Binary HPLC pump, a 2987 Dual λ Absorbance Detector set at 254 nm, and Empower software. A prepacked C_{18} reversed-phase (RP) column (Nova-Pak, 3.9×150 mm, 4 μm, 60 Å) was used for the analyses with a solvent system of 60% methanol/40% H_2O (both solvents HPLC grade) and a flow rate of 1.0 ml min^{-1}.

4-Hydroxymellein **(5)**: Methanol extracts from *C. quadrisectus* were purified by reversed-phase HPLC. The fraction containing the unknown with a molecular ion of *m/z*=194 was collected, and the solvent was removed *in vacuo* to provide an isomeric mixture of **5** as a white solid; GC-FTIR: ν_{max} 3636, 3159, 3074, 2994, 2916, 1709, 1615, 1587, 1465, 1368, 1336, 1300, 1224, 1163, 1107, 1047, 986, 954, 825, 884 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ *cis*: 10.98 (1H, s, 8-OH), 7.47 (1H, t, *J*=7.2 Hz, H-6), 6.96 (1H,d, *J*=8.4 Hz, H-7), 6.86 (1H, d, *J*=6.8 Hz, H-5), 4.64 (1H, dq, H-3), 4.52 (1H, bs, H-4), 1.53 (3H, d, *J*=6.8 Hz, 3-Me); *trans*: 10.94 (1H, s, 8-OH), 7.47 (1H, t, *J*=7.2 Hz, H-6), 6.96 (1H, d, *J*=8.4 Hz, H-7), 6.86 (1H, d, *J*=6.8 Hz, H-5), 4.64 (1-H, dq, H-3), 4.56 (1H, bs, H-4), 1.46 (3H, d, *J*=5.6 Hz, 3-Me); ^{13}C NMR data, see Table 2; EI-MS: *m/z* 194 [M^+] (33), 165 (2), 150 (66), 137 (2), 122 (50), 121 (100), 104 (5), 93 (20), 77 (5), 65 (25), 43 (20).

Results

Chemical Analyses GC-MS analysis of the methanol extracts from whole *C. quadrisectus* revealed three major components, *E*-2-ethyl-2-hexenol (**1**), mellein (**4**), and 4-hydroxymellein (**5**), along with small amounts of *m*-cresol (**2**) and 6-methylsalicylic acid (**3**) as its methyl ester (Fig. 1, Table 1). Straight chain alkanes, alkenes, and fatty acid methyl esters were frequently detected in smaller amounts. Extracts of heads and thoraxes had components **1**, **4**, and **5** as major compounds (92% in heads and 78% in thoraxes), while the gasters contained these compounds as minor components (ca. 16% of the total composition, with the remainder being the hydrocarbons listed in Table 1). *E*-2-Ethyl-2-hexenol (**1**) was suggested by its mass spectrum and confirmed by direct comparison with a synthetic sample (Iseki et al. 1992), while *m*-cresol (**2**) and 6-methylsalicylic acid (**3**) and its methyl ester, likely a consequence of storage in methanol, were suggested by

their mass spectra and confirmed by comparison with authentic samples. Mellein (**4**) was identified from its mass spectrum and direct comparison with published data (Dimitriadis et al. 1997).

The EI mass spectrum of **5** showed a parent ion at *m/z*= 194, 16 larger than the mass of mellein, indicating an additional oxygen, along with an ion at *m/z*=150 (M- CO_2) and analogous to the same fragmentation observed in the mass spectrum of mellein. The base peak at *m/z*=121/122 suggested that the second hydroxyl group must be somewhere other than the aromatic ring. The mass spectrum of **5** was similar to the published data for 4-hydroxymellein (Findlay et al. 1995). The C=O absorption at 1,709 cm^{-1} and the C–O absorptions at 1,224 and 1,105 cm^{-1} in the GC-FTIR spectrum of **5** corresponded to those (at 1,707, 1,220, and 1,101 cm^{-1}) observed in the spectrum of mellein obtained from the same sample. This strongly suggested a similar dihydroisocoumarin. Additionally, absorptions at 3,636 and 3,159 cm^{-1} in the spectrum of **5** indicated the presence of two hydroxyl groups. The latter matched the one at 3,157 cm^{-1} in the spectrum of mellein resulting from the hydrogen bonded phenolic hydroxyl group at C-8, while the absorption at 3,636 cm^{-1} indicated a non-hydrogen bonded OH.

To confirm the location of the second hydroxyl group on the non-aromatic ring, the ant extract was purified by RP HPLC to yield compound **5** as a white solid. The ^{1}H NMR spectrum of **5** resembled published spectra of 4-hydroxymellein (Findlay et al. 1995; Asha et al. 2004) and indicated the presence of both isomers of this compound. The presence of two distinct phenolic OH singlets at 10.98 and 10.94 ppm corresponded to the values reported for the *cis* and *trans* isomers, respectively, with the former being the major component (2.5:1 *cis:trans*). Doublets at 1.46 and 1.53 ppm for the methyl group on C-3 and broad singlets at 4.52 and 4.56 ppm for the hydrogen on C-4 also confirmed these assignments. Since the isomeric mixture broadened many signals throughout the ^{1}H NMR spectrum, the ^{13}C spectrum of **5** was obtained by using a low volume Shegimi tube. The intensities of the clearly observable pairs of signals for C-3, C-4, C-4a, and the methyl group, confirmed the 2.5:1 *cis/trans* isomeric ratio of **5**. With the exception of the signal for C-1, the ^{13}C NMR spectrum of the mixture of *cis* and *trans* **5** from *C. quadrisectus* corresponded to those previously reported for the separated isomers of 4-hydroxymellein (Table 2; Asha et al. 2004). On the other hand, the C-1 ^{13}C carbonyl signals of other dihydroisocoumarins, along with that of ethyl salicylate, are reported to appear from 170.2, to 173.0 ppm (Avantaggiato et al. 1999; Kongsaeree et al. 2003; Saito et al. 2007), more closely matching our observation of 169.4 ppm for C-1 than that reported by Asha et al. (2004). Some signals (C-1, C-8, and C-8a,) from the minor *trans* isomer of **5** were not apparent, possibly because of their long relaxation times and the predominance of the *cis* isomer.

The GC-MS analysis of the methanol extracts from *Camponotus irritibilis* revealed the presence of one major component, *E*-2-ethylhexenal (**6**), along with small amounts of 6-methylsalicylic acid (**3**) and its methyl ester, and smaller amounts of normal alkanes, alkenes, and fatty acid methyl esters frequently detected in the methanol extracts of ants (Table 1). The structure of **6**, was suggested by its mass spectrum (NIST/EPA/NIH 1999) and confirmed by direct comparison with an authentic sample (Häusermann 1951).

Discussion

This is the first report of *E*-2-ethyl-2-hexene-1-ol (**1**) and the analogous aldehyde (**6**) from insects. *C. quadrisectus*

Table 2 ^{13}C NMR DATA (δ) FOR *cis*- and *trans*-4-Hydroxymellein (**5**) Compared with literature values[a]

[a] From Asha et al. 2004

and *C. irritibilis* are distinctive morphologically, but the presence of **1** and **6** as major components in the respective taxa, together with the unusual nature of these compounds, suggest a close phylogenetic chemical relatedness. Similar hydrocarbon profiles in the two species (Table 1) also support this.

In *C. quadrisectus*, the hydrocarbons are localized to the gaster, and presumably, this is also the case for *C. irritibilis*, although only whole ants were analyzed.

In contrast to **1** and **6**, phenolic acetogenins **2**, **3**, and **4,** are widespread in camponotines. However, 4-hydroxymellein (**5**), a major component in *C. quadrisectus*, has not been reported previously from insect sources. The monocyclic aromatics **2** and **3** have been identified, respectively, from worker mandibular glands in eight taxa from the *Colobopsis cylindricus* complex in Borneo (Jones et al. 2004; T.H. Jones, unpublished data) and three such taxa, plus some phylogenetically distant *Camponotus* (Brand et al. 1973a, b; Duffield and Blum 1975; Torres et al. 2001; Jones et al. 2004 and unpublished data).

The more volatile of the major mandibular gland components in *C. quadrisectus* and *C. irritibilis*, *E*-2-ethyl-2-hexene-1-ol (**1**) and the analogous aldehyde (**6**), may function in alarm/defensive roles. Aldehyde **6** is the aldol condensation product of butanal, with **1** being its subsequent carbonyl reduction product. In the formicine ant *Oecophylla longinoda*, the four carbon homolog of **6**, *E*-2-butyl-2-octenal, the aldol condensation product of hexanal, has been shown, along with hexanal, to be an alarm pheromone (Bradshaw et al. 1979). Similar, but more highly branched enals, the aldol condensation products of branched chain aldehydes, have been detected in the heads of an Australian *Calomyrmex* species, although their function was not determined (Brown and Moore 1979). Additionally, unbranched, unsaturated aldehydes, functionally similar to **6,** along with their corresponding alcohols, are common defensive compounds in Hemiptera (Blum 1981). It should be noted that unsaturated alcohols homologous to **1,** found in *C. quadrisectus*, were not detected in either *Oecophylla longinoda* or in the *Calomyrmex* species, suggesting that **1** and **6** in the Brunei *Camponotus* are not merely minor artifacts from aldehyde self condensation.

With somewhat lower volatilities, dihydroisocoumarins, such as mellein (**4)** and its analogs, occur in many species of carpenter ants, in which functions likely differ by source organ or gland. Historically, mellein has been reported from male mandibular glands of various *Camponotus* species, and is thought to serve as a sex pheromone (Brand et al. 1973a; Blum et al. 1987; Seidel et al. 1990; Torres et al. 2001). However, in at least three *Camponotus* species, mellein in the worker rectal bladder functions as a trail pheromone (Bestmann et al. 1992, 1999; Übler et al. 1995; Kohl et al. 2003), and appears to be synthesized *de novo*, although microbial contributions have not been explicitly ruled out (Bestmann et al. 1997).

Despite these previously reported functions, the four major mandibular gland components described here also possess documented antiseptic activity, and could play an additional role in nest hygiene. Antifungal activity has been demonstrated for *E*-2-ethyl-2-hexene-1-ol (**1**) and the analogous aldehyde (**6**) (Lyr and Banasiak 1983; Casperson et al. 1986), while the dihydroisocoumarins **4** and **5** are well-known metabolites of diverse fungi (e.g., Sasaki et al. 1970) and display both antiseptic and phytotoxic activities (e.g., Berestetskii et al. 1979; Kansoh and El-Gindi 2004). Consistent with possible use of these compounds as antiseptics are observations of *C. quadrisectus* workers applying them to edges of nest entrances and swollen (possibly diseased) lenticels on the host trunk (D. W. Davidson, unpublished data).

Blum (1996) has suggested that ants and other arthropods may benefit from "semiochemical parsimony", in which exocrine products serve multiple roles simultaneously. As one of perhaps several functions of camponotine mandibular gland compounds, antisepsis would not be surprising, because other (metapleural) glands with antiseptic function have been lost secondarily in this group (Hölldobler and Engel-Siegel 1984). Whatever the combined functions of these compounds, the presence of substantial quantities of mandibular gland compounds in the thorax (above) could indicate that these functions have selected for production of larger amounts of the compounds and enlargement of glandular reservoirs into the anterior thorax, which is distinctly light colored (like the head) in contrast to the remainder of the mesosoma.

Acknowledgment HLV and THJ gratefully acknowledge the support of the Camille and Henry Dreyfus Foundation and thank Dr. Tom Spande (Laboratory of Bioorganic Chemistry, NIH/NIDDK) for the GC/ FTIR spectra and Dr. Judith Cain for her NMR assistance. We are grateful to Dr. J. A. Findlay for copies of the GC-MS and ^{1}H NMR spectra for 4-hydroxymellein for direct comparison with our data for compound **5**. DWD thanks the National Geographic Society and the University of Utah Research Committee for support of field studies.

Identification of a Sex Pheromone Produced by Sternal Glands in Females of the Caddisfly *Molanna angustata* Curtis

Christer Löfstedt · Jan Bergmann · Wittko Francke · Erling Jirle · Bill S. Hansson · Vladimir D. Ivanov

Received: 14 March 2007 / Revised: 17 November 2007 / Accepted: 25 November 2007 / Published online: 23 January 2008

Abstract In the caddisfly *Molanna angustata*, females produce a sex pheromone in glands with openings on the fifth sternite. Gas chromatographic analyses of pheromone gland extracts with electroantennographic detection revealed four major compounds that stimulated male antennae. These compounds were identified by means of gas chromatography–mass spectrometry and enantioselective gas chromatography as heptan-2-one, (*S*)-heptan-2-ol, nonan-2-one, and (*S*)-nonan-2-ol in the approximate ratio of 1:1:4:10, respectively. Field tests showed that the mixture of the two alcohols was attractive to males whereas addition of the corresponding ketones reduced trap catches. The sex pheromone of *M. angustata*, a species in the family Molannidae within the suborder Integripalpia, is similar to the pheromones or pheromone-like compounds previously reported from six other trichopteran families, including members of the basal suborder Annulipalpia. This suggests that minimal evolutionary change of the pheromone chemistry has taken place within the leptoceroid branch of integripalpian Trichoptera compared to the ancestral character state.

Keywords *Molanna angustata* · Molannidae · Trichoptera · Sex pheromone · Nonan-2-ol · Heptan-2-ol · Nonan-2-one · Heptan-2-one

Introduction

The insect order Trichoptera (caddisflies) comprises more than 12,000 described extant species distributed among 46 families (Morse 1997, 1999, 2003). Whereas sex pheromone communication has been thoroughly investigated in the sister order Lepidoptera (moths and butterflies) and hundreds of moth sex pheromones from all of the major lepidopteran families have been identified, the corresponding information on caddisfly pheromone is limited. So far, pheromones or compounds with putative pheromonal activity have been described from only a dozen caddisfly species. Improved knowledge about sex pheromone communication in caddisflies would contribute not only to a better understanding of the reproductive biology in Trichoptera, but would also help to reconstruct the evolution of pheromone communication systems within the superorder Amphiesmenoptera that comprise the two orders already mentioned.

Pheromones occur in various evolutionary lineages of Trichoptera (Kelner-Pillault 1975; Wood and Resh 1984;

Resh and Wood 1985; Solem 1985; Resh et al. 1987; Löfstedt et al. 1994; Bjostad et al. 1996). Attraction of males to sticky traps baited with insect extracts has established that the pheromones are produced in sternal glands situated ventrally on the fourth to fifth female abdominal segment (Resh and Wood 1985). Chemically, the trichopteran pheromones identified so far consist of short-chain secondary alcohols and the corresponding methyl ketones (Löfstedt et al. 1994; Bjostad et al. 1996). Other compounds identified from the sternum V glands have no known pheromonal function and may be defensive secretions rather than pheromones (Duffield et al. 1977; Ansteeg and Dettner 1991). Nevertheless, in some species, strong antennal responses to the compounds suggest that they could be pheromone components (Bergmann et al. 2001, 2002, 2004). The short-chain alcohols and corresponding methyl ketones identified from caddisflies are similar to the sex pheromone components identified from the archaic moth family Eriocraniidae (Zhu et al. 1995) and Nepticulidae (Tóth et al. 1995).

Caddisflies of the family Molannidae are advanced representatives of the leptoceroid branch within the suborder Integripalpia (Ross 1964; Weaver 1984). Field studies suggested the presence of both a swarming behavior (Solem 1984; Ivanov 1985, 1992; Solem and Petersson 1987) and female pheromone signaling (Solem and Petersson 1987) in the Molannidae, whereas no evidence for pheromone communication has been found in the family Leptoceridae, another family from the same evolutionary lineage (Petersson and Solem 1987).

Adults of the genus *Molanna* J. Curtis, 1834, show crepuscular activity at lakeshores. The experiments by Solem and Petersson (1987) on *Molanna angustata* J. Curtis, 1834, showed that whole body extracts of females attract conspecific males. The present study was performed to identify the structures of the sex pheromone components produced by female *M. angustata* and to confirm that they elicit electrophysiological responses and mediate reproductive behaviors in these insects.

Methods and Materials

Insects and Preparation of Extracts Males and females of *M. angustata* were collected manually or by sweep netting at lakeshores in south Sweden. The most abundant populations were found at the lakes Krageholmssjön and Snogeholmssjön situated about 60 km southeast of Lund. These populations were used as the source of material for chemical analyses. Only one species of *Molanna* occurred at these sites. Caddisflies of the genus *Molanna* are readily distinguishable from other local trichoptera by the shape of their wings and their pale coloration.

Adults were taken to the laboratory where females were separated from males based on their genitalia. Both sexes were placed in plastic containers with water droplets on the walls, and the containers were placed in a room with controlled climate (16–20°C, 60–70% relative humidity) and a reversed light/dark cycle (16L:8D) to invert the diurnal rhythm of the insects. Females spent about 40 h under these conditions before extraction of the pheromone glands. Early in the scotophase, insects to be dissected were freeze killed (−20°C, approximately 1 h) before dissection.

The fourth and fifth abdominal sternites from females were dissected and cleared from fat body components so that the glands situated in the anterodorsal part of the fifth and the posterodorsal part of the fourth sternite were exposed. Sternites with attached epithelial tissue and secretory glands were put into a micro-extraction vial that contained 100 µl of dichloromethane to produce composite extracts of several females. This vial was placed in a larger screw cap vial with solvent on the bottom to saturate the atmosphere and thereby reduce the loss of solvent from the actual extract. The sample was extracted for 12 h at room temperature. Then, the extract was transferred to a clean micro-vial that was sealed and stored in the freezer at −20°C. A similar protocol was used to obtain extracts from the female abdominal tips (seventh to ninth abdominal segments), female heads, and male fourth to fifth sternites. In total, approximately 70 µl of extract of fourth and fifth sternites were collected from 24 females; similar amounts of extracts were obtained from 24 female heads, 24 abdominal tips, and from 14 male fourth to fifth sternites. These extracts of females and males were analyzed by gas chromatography with electroantennographic detection (GC-EAD) and coupled gas chromatography–mass spectrometry (GC–MS). The female sternal extract was used also for field behavioral bioassays.

Electroantennography and Gas Chromatography with Electroantennographic Detection A freshly cut male antenna was placed with its basal end in a reference glass electrode that contained Beadle–Ephrussi Ringer solution (155 mM NaCl, 5 mM KCl, 3 mM $CaCl_2$). This electrode was grounded via an Ag/AgCl wire. The antennal tip was removed, and the apical end of the antenna was inserted into a recording electrode and connected through a Ag/AgCl wire to a high-impedance DC amplifier (Syntech, Hilversum, The Netherlands) with automatic baseline drift compensation. The DC potential was recorded on a computer using an IDAC A/D converter and software (Auto Spike v. 3.0; Syntech). Filtered and humidified air continuously flowed over the mounted antenna (approximately 0.5 m/s). Extracts of different parts of the insect bodies were tested for electroantennography (EAG) activity by depositing one insect equivalent inside the tip of a

Pasteur pipette and blowing 1 ml of air through the pipette and onto the antenna.

A Hewlett-Packard 5890 Series II Plus gas chromatograph equipped with an HP Innowax column (30 m× 0.25 mm i.d., Hewlett-Packard, Palo Alto, CA, USA) was used for chromatographic analyses. An effluent split allowed simultaneous flame ionization detection (FID) and EAD of the separated compounds. Hydrogen was used as carrier gas, and the effluent split ratio was approximately 1:1. Samples were injected splitless with injector temperature 225°C, and the split valve was opened 1 min after injection. The column temperature was generally maintained at 40°C for 5 min after injection and then linearly increased to 230°C at a rate of 10°C/min. The outlet for the EAD was placed in a purified humidified air stream flowing over the antennal preparation at a speed of 0.5 m/s. Two to five microliters of an extract containing two to three female equivalents were injected onto the column for analysis.

Structure Elucidation Preliminary GC–MS analysis of active extracts was performed with a Hewlett-Packard 5890 gas chromatograph linked to a 5972 mass spectrometer and equipped with a DB-Wax 30 m×0.25 mm column (J&W Scientific, Folsom, CA, USA), similar to the column used for GC-EAD analyses. Further analyses of the extracts were carried out by using a VG 70/70 mass spectrometer (Vacuum Generators, Manchester, UK) linked to an HP 5890GC (Hewlett-Packard) equipped with a 30 m× 0.25 mm i.d., 0.25 μm film thickness Optima 5MS column (Macherey-Nagel, Düren, Germany) or a 50 m×0.25 mm i.d., 0.25 μm film FFAP column (CS Chromatographic Service, Langenwehe, Germany). Identification of volatile compounds was carried out by means of GC–MS on the basis of comparison with known mass spectra (McLafferty and Stauffer 1989) and by gas chromatographic retention times upon coinjection of natural products and synthetic reference samples. Separation of enantiomers of the chiral secondary alcohols was achieved with a 25 m×0.25 mm i.d. fused silica column coated with a 60:40 mixture of octakis-(6-*O*-methyl-2,3-di-*O*-pentyl)-γ-cyclodextrin and OV1701 (custom-made by Prof. W. A. König, Univ. Hamburg, Germany) with hydrogen or helium as carrier gas and a mass spectrometer as detector. Experimental conditions were 50°C for 12 min, then to 120°C at 3°C/min.

Synthetic Compounds Heptan-2-one and nonan-2-one and the enantiomers of heptan-2-ol and nonan-2-ol were purchased from Aldrich. All compounds were ≥98% chemically pure. The optically active compounds had ee's of at least 98%.

Field Trapping Attraction to extracts and synthetic compounds was examined in the field at the lake Krageholmssjön in 1996 and at the lakes Snogeholmssjön and Sövdesjön in 2004. Lund type II traps with sticky bottoms (Anderbrant et al. 1989) were distributed along the water line. Traps within a replicate (four to seven traps depending on the experiment) were placed in a group, with individual traps separated by 2–3 m distance (1996) or approximately 10 m distance (2004). Distances between replicates were not less than 50 m. Traps were positioned with the bottom approximately 0.3 m above the water surface. Rubber septum dispensers (Arthur H. Thomas Co., 5×9 mm red rubber septa, Catalog No. 1780-J07) were loaded with different mixtures and doses of the test compounds dissolved in dichloromethane (500 μl in 1996 and 100 μl in 2004). The solvent was allowed to evaporate, and the baits were used the same day or stored in the freezer (−20°C) in aluminum bags until used. The dispensers were suspended 1–2 cm from the trap ceiling on an insect pin.

The dose of the synthetic pheromone blends refers to the amount of the major component nonan-2-ol. Thus, a 100 μg dose indicates 100 μg of nonan-2-ol, and other compounds were added as required in the relative amounts in which they occurred in extracts. The blank (control) dispensers were loaded with pure dichloromethane.

Five field-trapping experiments were carried out. The first took place July 18–29, 1996 and was designed to compare the activity of different doses of two alcohols to pheromone gland extracts of females and to a synthetic four-compound blend. The alcohol lures contained a mixture of (*S*)-nonan-2-ol and (*S*)-heptan-2-ol in the proportion found in female extracts wish doses of nonan-2-ol of 10, 100, or 1,000 μg per trap. The synthetic four-compound blend contained 100 μg (*S*)-nonan-2-ol and the corresponding amounts of (*S*)-heptan-2-ol, nonan-2-one, and heptan-2-one. The pheromone extracts originated from the same sample as was used for the GC-EAD experiments, and a septum was loaded with 1.7 female equivalents.

A second experiment, similar to the first, was carried out July 29–August 10, 1996, but in this experiment, pheromone extracts were exchanged for a bait that contained ketones only. A third trapping experiment was designed to examine the effects of the individual alcohols and their corresponding (*R*)-enantiomers. The experiment was performed August 14–22, 1996. The baits tested contained the individual compounds in amounts corresponding to 100 μg of nonan-2-ol. Baits were loaded with both (*S*)-alcohols, both corresponding (*R*)-alcohols, both corresponding ketones, only (*S*)-nonan-2-ol, or only (*S*)-heptan-2-ol.

A fourth experiment was carried out July 28–August 18, 2004 to confirm the attractiveness of (*S*)-nonan-2-ol and (*S*)-heptan-2-ol. Attraction to traps baited with the individual alcohols (100 and 10 μg, respectively, based on their relative abundance in gland extracts), and the mixture of the two compounds was examined. The final experiment was carried out August 23–September 17, 2004 to investigate

the influence of the ratio between (*S*)-nonan-2-ol and (*S*)-heptan-2-ol. Traps were baited with 100 μg of (*S*)-nonan-2-ol plus different amounts of (*S*)-heptan-2-ol (1, 3, 10, and 30 μg).

Traps were checked and re-randomized every 2–4 days during each experiment. Each reading of a trap catch was then treated as a replicate in the statistical analysis. The statistical significance of the trapping results was analyzed by generalized linear models assuming Poisson distribution and corrected for over-dispersion (SAS 9.1, proc Glimmix).

Results

EAG Recordings In preliminary tests that used insect extracts, the only distinct EAG responses recorded were those of antennae of males to extracts of females. Antennae of females were not receptive to any of the stimuli tested. Antennae of males responded strongly to extracts of the female fourth and fifth sternite, whereas head or abdominal tip extracts of females did not elicit significant EAG responses. Extracts obtained from fourth and fifth sternites of males also did not elicit any response from the antennae of males.

Gas Chromatography with Electroantennographic Detection Four EAD responses with matching peaks in the FID chromatogram (peaks 1–4) were observed consistently in the earlier part of the chromatogram during three separate analyses. In addition, in all of these analyses, three EAD responses at longer retention times (peaks 5–7) but without any visible matching FID peaks were also observed (Fig. 1). GC-EAD analyses with extracts of males and extracts from other parts of the female did not show any EAD-active peaks.

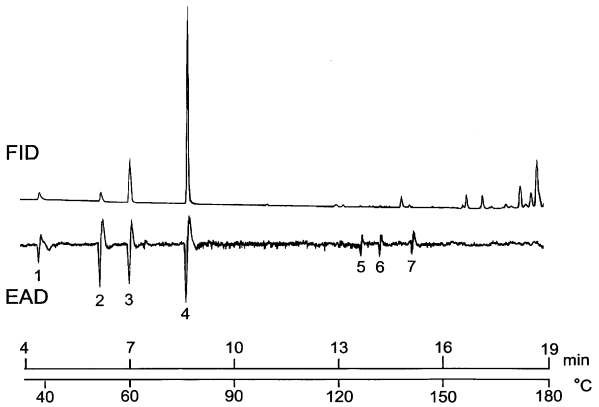

Fig. 1 Gas chromatographic analysis of an extract of female *M. angustata* fourth and fifth abdominal sternites. Simultaneous FID and EAD using a male antenna as detector. EAD-active compounds 1–4 were identified as heptan-2-one (1), (*S*)-heptan-2-ol (2), nonan-2-one (3), and (*S*)-nonan-2-ol (4)

Structure Elucidation Compounds 1–4 in the extracts of sternites IV–V of females were identified as simple methylketones and the corresponding secondary alcohols. Compound 1 was identified as heptan-2-one, characterized by a weak signal for the molecular ion at *m*/*z* 114, an intense signal at *m*/*z* 58 (as a result of a McLafferty rearrangement), and a base peak at *m*/*z* 43 caused by α-cleavage at the carbonyl group. Compound 2 was identified as heptan-2-ol, characterized by small signals at *m*/*z* 101 (M^+-methyl) and *m*/*z* 98 (M^+-water) and a dominant base peak at *m*/*z* 45 caused by α-cleavage at the alcohol group; the molecular ion at *m*/*z* 116 was not observed. The mass spectrometric fragmentations of the two compounds were identical with those reported in the literature (McLafferty and Stauffer 1989). The same was true for the homologs, nonan-2-one (3) and nonan-2-ol (4); the mass spectra of which showed fragmentation patterns similar to those of the C7 compounds. Diagnostic fragments were M^+142 and *m*/*z* 58 as well as *m*/*z* 43 for the ketone, and *m*/*z* 129 (M^+-15), *m*/*z* 126 (M^+-18), and *m*/*z* 45 for the alcohol (M^+=144, was not observed).

Enantioselective gas chromatography was carried out with a modified cyclodextrin as the stationary phase and pure stereoisomers of heptan-2-ol and nonan-2-ol as references revealed the natural products to be the (*S*)-enantiomers of high stereoisomeric purity. The enantiomers of heptan-2-ol and nonan-2-ol were almost baseline separated with α=1.010–1.013 [retention time of the later eluting (*R*)-enantiomer divided by retention time of the earlier eluting (*S*)-enantiomer] showing a valley down to 3% of the peak height. No traces of the (*R*)-enantiomers were detected in the natural products.

We were not able to identify the compounds that elicited the three EAG responses in the later part of the chromatogram (Fig. 1). None of the identified compounds were detected in extracts of males.

The amount of the major compound nonan-2-ol was estimated to be 100 ng or more per female. Based on total ion current counts, the approximate relative amounts (within parentheses) of the four identified compounds were heptan-2-one (1), heptan-2-ol (1), nonan-2-one (4), and nonan-2-ol (10).

Field Trapping In the first of five trapping experiments, the attractiveness of a female extract was compared to three different doses of a mixture of (*S*)-heptan-2-ol and (*S*)-nonan-2-ol, and a mixture of the alcohols plus heptan-2-one and nonan-2-one (Fig. 2). In total, 142 males were captured in this experiment. There was no overall, statistically significant treatment effect. Numerically, the traps baited

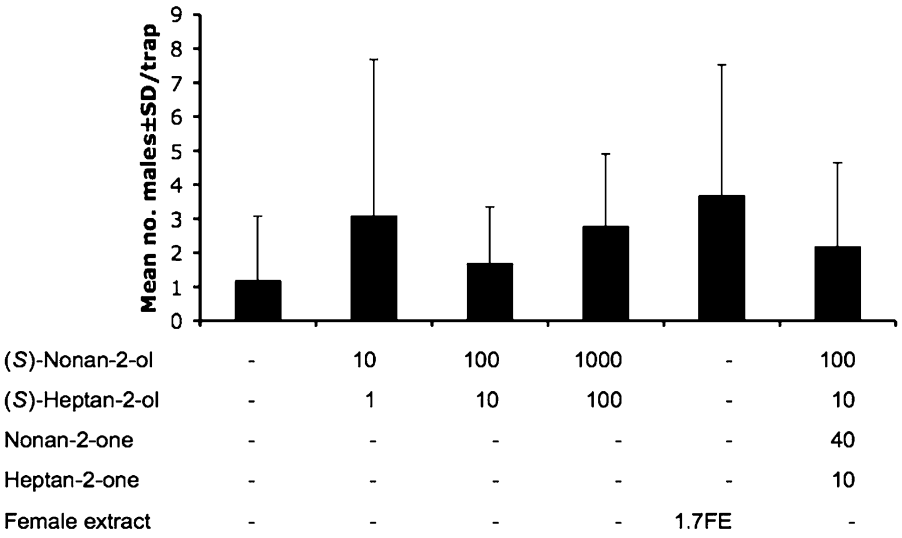

Fig. 2 Attraction of male *M. angustata* to female extracts, alcohols and alcohols, mixed with ketones (Experiment 1). Amounts of synthetic compounds in micrograms. *FE* Female equivalent. Statistical significance of treatment effects (least squares means) analyzed by generalized linear model assuming Poisson error: $F_{5,52}$= 1.04, P=0.403

with female extracts trapped the largest number of males followed by the alcohols in the 10 and 1,000 μg doses. In the second experiment (Fig. 3), the same synthetic baits and an additional bait that contained only the two ketones were tested. In this experiment, we observed a significant overall treatment effect. The three alcohol baits followed by the mixture of alcohols and ketones were the most attractive ones, significantly different from the control and the mixture of the ketones.

In experiment 3 (Fig. 4), the activities of (*S*)-heptan-2-ol and (*S*)-nonan-2-ol as single components were compared with the activity of the mixture of these two compounds, the activity of the mixture of the corresponding (*R*) enantiomers, and the activity of the mixture of heptan-2-one and nonan-2-one. The overall effect was statistically significant, and the mixture of the (*S*) alcohols and (*S*)-nonan-2-ol on its own were more attractive than (*S*)-heptan-2-ol, the mixture of the ketones, or the mixture of the (*R*) alcohols. Numerically, the alcohols showed the highest trap catches, but when tested for statistical significance, all treatments were not different from the blank.

Thus, high variation in trap catches confounded the results in experiments 1–3, carried out during the first field season. Only a few significant differences were found by using pairwise comparisons, and no pronounced differences were found between different baits or between baited traps and the control. Thus, we decided to perform two additional experiments several years later. Experiment 4 (Fig. 5) conclusively demonstrated that the mixture of (*S*)-heptan-2-ol and (*S*)-nonan-2-ol in their natural ratio was significantly attractive to male *M. angustata*. Traps baited with (*S*)-nonan-2-ol as a single component gave the second highest trap catch, but this treatment was not significantly different from the results obtained with (*S*)-heptan-2-ol (P=0.09) or the control. The final experiment (Fig. 6) demonstrated a significant effect of the relative amount of (*S*)-heptan-2-ol

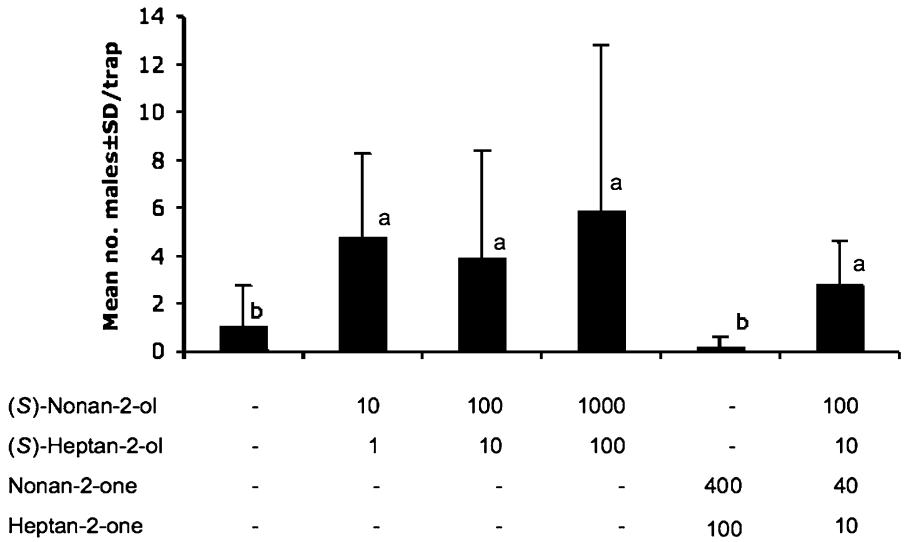

Fig. 3 Field trapping of *M. angustata*, comparing attractiveness of alcohols, ketones, and alcohols mixed with ketones (Experiment 2). Statistical significance of treatment effects (least squares means) analyzed by generalized linear model assuming Poisson error: $F_{5,54}$= 2.98, P=0.019. Values followed by the same letter are not significantly different (P> 0.05)

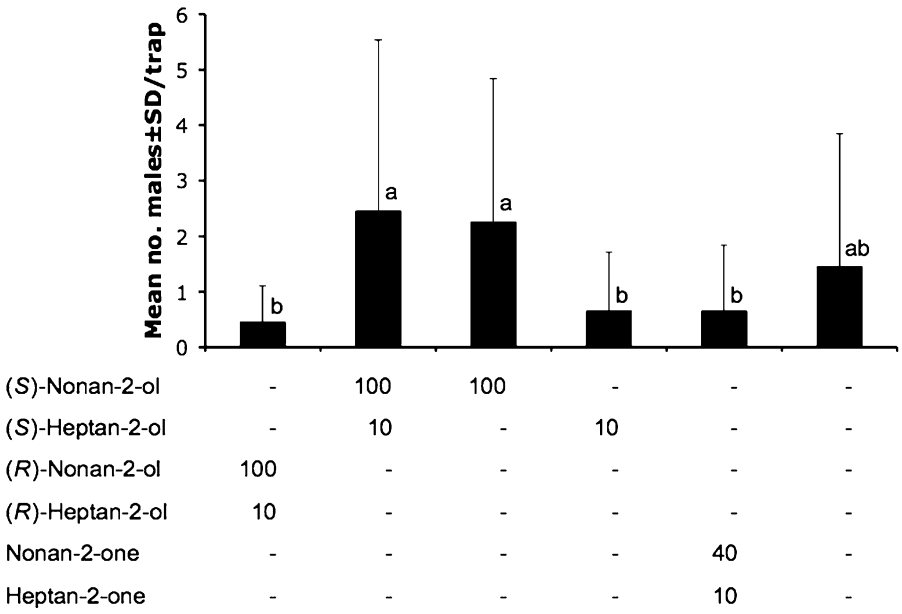

Fig. 4 Field trapping of *M. angustata*, comparing attractiveness of different alcohol baits and a mixture of ketones (Experiment 3). Statistical significance of treatment effects (least squares means) analyzed by generalized linear model assuming Poisson error: $F_{5,84}$= 2.93, P=0.017. Values followed by the same letter are not significantly different (P> 0.05)

added to a fixed amount of the major component (*S*)-nonan-2-ol. The highest trap catches were obtained with the 100:10 mixture, but this treatment was the only one that was significantly different from the 100:1 mixture that appeared to be least attractive.

Discussion

Our study showed that female *M. angustata* produce a mixture of (*S*)-nonan-2-ol and (*S*)-heptan-2-ol that attracts conspecific males. (*S*)-Nonan-2-ol is the major component both quantitatively and with respect to behavioral activity. The electroantennographic responses of male antennae to female extracts were strong and reproducible, and males were attracted to the synthetic pheromone in field bioassays.

We experienced problems in our studies of pheromone communication in *M. angustata*, similar to those reported in studies of other species of caddisflies. For example, (Löfstedt et al. 1994) obtained unexpectedly high catches in unbaited control traps, whereas catches in traps baited with synthetic pheromone or insect extracts were relatively low, albeit still significantly higher than in the controls. In many other species of caddisflies, we have identified pheromone component candidates with high electrophysiological activity but have failed to demonstrate any attraction to these compounds in field trapping experiments (J. Bergmann, W. Francke, V. D. Ivanov, and C. Löfstedt, unpublished). In contrast, in trapping experiments with similar compounds that target primitive moths, large numbers of moths were attracted, and unbaited traps never trapped more than a few insects, if any (Zhu et al. 1995; Kozlov et al. 1996). This suggests that the problem is not a general technical one, related to solvent

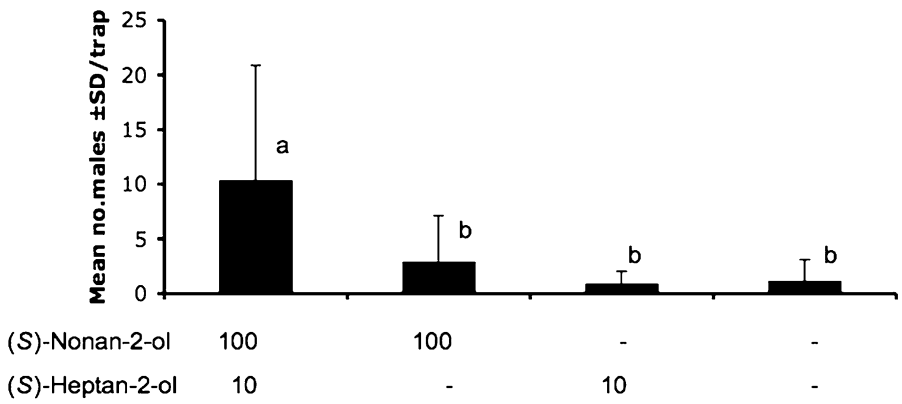

Fig. 5 Field trapping of *M. angustata*, comparing attractiveness of (*S*)-heptan-2-ol, (*S*)-nonan-2-ol, and their mixture (Experiment 4). Statistical significance of treatment effects (least squares means) analyzed by generalized linear model assuming Poisson error: $F_{3,54}$=10.06, P<0.001. Values followed by the same letter are not significantly different (P> 0.05)

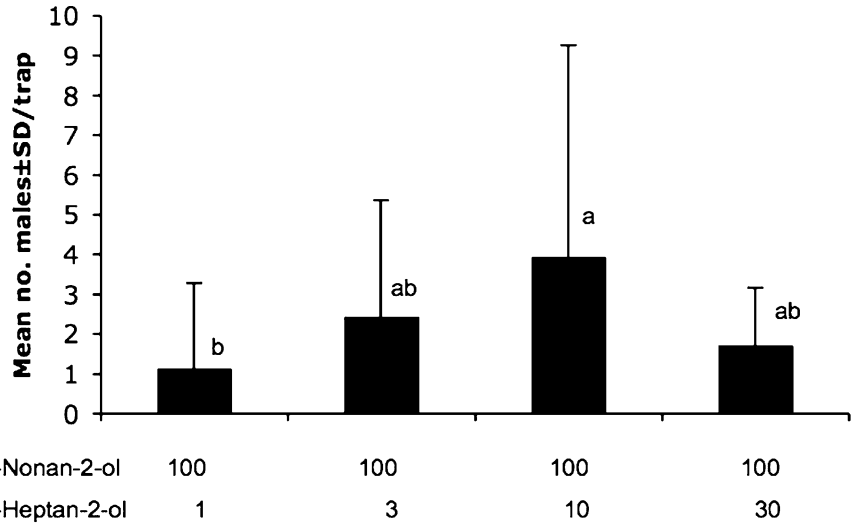

Fig. 6 Field trapping of *M. angustata*, comparing different amounts of (*S*)-heptan-2-ol added to (*S*)-nonan-2-ol (Experiment 5). Values followed by the same letter are not significantly different (P> 0.05)

impurities or the release of the alcohols and ketones from the dispensers, but rather a problem specific to trapping of caddisflies and related to the behavior, biology, or pheromone blend of these insects.

In southern Sweden, species of the genus *Molanna* are nocturnal or crepuscular, so their natural behavior is difficult to observe. Observations of adults of *Molanna* sp. at more northern latitudes during the polar day (when they perform mating behavior under conditions of full illumination) revealed the formation of aggregations near the shoreline, where part of the population exhibits characteristic flight patterns, whereas another part of the population crawls over the vegetation. These aggregations are loose, and their borders are not distinct. Thus, this is not a typical lekking (or swarming) formation, as has been observed in other Trichoptera from the families Hydropsychidae and Leptoceridae. On the Kola Peninsula (polar day) and in the Leningrad district (in the fading twilight), the females preferred to stay on the vegetation, and males were most abundant among the flying insects (V. D. Ivanov, personal observations). Possible reasons for the weak and uneven results in our trapping studies, thus, include both the short range of pheromone-mediated attraction in caddisflies ("weak pheromones") and the highly aggregated distribution of insects along the shoreline.

The mixture of (*S*)-nonan-2-ol and (*S*)-heptan-2-ol in the female-produced ratio was the most attractive bait in the field. Adding the ketones to the blend did not increase the attractiveness but rather the opposite. The alcohols and the ketones are biosynthetically related, and we do not know if the females release only the alcohols or the ketones as well. It is noteworthy that, in our GC-EAD analyses, three responses were observed at longer retention times, but no corresponding FID peaks could be detected, and no compounds responsible for this activity could be identified. These EAD peaks may represent biologically active trace components of the pheromone blend.

The four compounds that we identified from *M. angustata* females have been identified previously from several other caddisflies (Duffield 1981; Löfstedt et al. 1994; Bergmann et al. 2002). In *Rhyacophila fasciata*, a mixture of the racemates of heptan-2-ol and nonan-2-ol was attractive to males (Löfstedt et al. 1994). The enantiomeric composition of female extracts was not investigated, and the enantiomers were not tested in trapping experiments. In *R. nubila*, males have antennal receptors specific for the enantiomers of heptan-2-ol (Larsson and Hansson 1998), and male eriocraniid moths likewise have specific receptors for (*R*)- and (*S*)-enantiomers of methyl carbinols that have been identified as pheromone components in this moth genus (Zhu et al. 1995; Kozlov et al. 1996; Larsson et al. 2002). Females of *R. nubila* produce (*R*)-heptan-2-ol and (*R*)-nonan-2-ol of 99.5% ee and 90% ee, respectively (J. Bergmann, W. Francke, C. Löfstedt, and P. Valeur, unpublished). It is interesting to note that unbranched methylketones and the corresponding alcohols are widespread among Hymenoptera and that those methyl carbinols are components of the sex pheromone of the stingless eusocial bee *Scaptotrigona postica* (Engels et al. 1990, 1997). In Trichoptera, different combinations of alcohols and ketones or, similar to Lepidoptera and Coleoptera (Francke and Schulz 1999), the enantiomeric composition of chiral pheromone components may account for the species specificity of caddisfly pheromones. Caddisflies also use vibrational and acoustic signals for communication (Ivanov 1993, 1994), which may contribute to the species specificity of the communication systems. These signals have not been recorded for *M. angustata*, and the specific sternal structures that usually produce these signals are not present in this species. Males have been shown to perform

the zigzagging flight similar to that of searching moths and resembling the swarming flight of Leptoceridae (Ivanov 1985), with the exception that the *Molanna* males never form swarms, even at high population densities.

Three suborders are recognized within the Trichoptera. Annulipalpia is concluded to be the most basal suborder, and Spicipalpia and Integripalpia form a clade (Kjer et al. 2002). Both Annulipalpia and Integripalpia are monophyletic, but whether or not Spicipalpia is monophyletic remains equivocal. Methyl carbinols and methylketones, similar or identical to those found in *M. angustata*, have been reported in the families Philopotamidae, Polycentropodidae, and Hydropsychidae that belong to the Annulipalpia, as well as in Rhyacophilidae and Glossosomatidae that belong to the Spicipalpia. In addition to their occurrence in the Molannidae, such compounds also have been found in Phrygaenidae belonging to a different branch within the Integripalpia (Löfstedt et al. 1994, Bergmann et al. 2002). Thus, this type of pheromone component produced in the sternum V gland may be a basal character in both Trichoptera and Lepidoptera and, thus, of the superorder Amphiesmenoptera (Löfstedt and Kozlov 1996), a conclusion further corroborated by the present study. The alcohols and ketones produced by females were not found in extracts of male *M. angustata*, which resembles the typical situation in Lepidoptera. In contrast, most other species of caddisflies studied previously have male-produced pheromone-like compounds similar to those found in conspecific females (Löfstedt et al. 1994; Bergmann et al. 2002, 2004) that elicit electrophysiological responses from antennae of both females and males.

Acknowledgments Karin Johnson and Dr. Mattias Larsson helped in the initial field tests of the pheromone blends and also in the collection of insects for the pheromone extractions. Valuable suggestions by Peter Valeur and Dainius Plepys are acknowledged. Henrik Smith assisted with the statistical analysis. Funding for this project was obtained from the Swedish Research Council (NFR/VR), the Royal Swedish Academy of Sciences, the Swedish Institute and the Russian Foundation for Fundamental Studies (grant No. 97-04-49957). WF thanks the Fonds der chemischen Industrie, Germany, for financial support.

New Contact Sex Pheromone Components of the German Cockroach, *Blattella germanica*, Predicted from the Proposed Biosynthetic Pathway

Dorit Eliyahu · Satoshi Nojima · Kenji Mori · Coby Schal

Received: 5 July 2007 / Revised: 25 October 2007 / Accepted: 12 November 2007 / Published online: 23 January 2008

Abstract Upon contacting the cuticle of a sexually mature female, a male German cockroach exhibits a characteristic courtship behavior: he turns away from the female and raises his wings, thereby exposing tergal glands. The glandular secretion stimulates the female to mount the male and feed, thus positioning her appropriately for copulation. A multicomponent contact sex pheromone produced by females is responsible for eliciting courtship behavior. The most abundant pheromone components are 3,11-dimethylnonacosan-2-one and 3,11-dimethylheptacosan-2-one, oxidation products of the abundant hydrocarbon analogs 3,11-dimethylnonacosane and 3,11-dimethylheptacosane, respectively. The C_{29}-dimethyl ketone is thought to be further metabolized to two less abundant pheromone components, 29-hydroxy-3,11-dimethylnonacosan-2-one and 29-oxo-3,11-dimethylnonacosan-2-one. Based on this proposed biosynthetic pathway of pheromone production, we hypothesized that 3,11-dimethylheptacosan-2-one also would be oxidized to give two candidate pheromone components, 27-hydroxy-3,11-dimethylheptacosan-2-one, and 27-oxo-3,11-dimethylheptacosan-2-one. By using bioassay-guided fractionation and chemical analyses of cuticular extracts of virgin females and synthesis of the (3*S*,11*S*)-isomer of each of the two predicted pheromone components, we showed that the epicuticle of the German cockroach does indeed contain these two compounds. The contact sex pheromone of the female German cockroach, thus may consist of at least six biosynthetically related components.

Keywords 27-Oxo-3,11-dimethylheptacosan-2-one · 27-Hydroxy-3,11-dimethylheptacosan-2-one · Sex pheromone · *Blattella germanica* · German cockroach · Methyl ketone · Alcohol · Aldehyde

Introduction

Sex pheromones of insects are most often produced and emitted as blends of related chemicals rather than single components. Furthermore, in recent years, it has become apparent that many pheromone molecules are produced from the action of tissue-specific enzymes on intermediates of fatty acid metabolic pathways, giving rise, among other compounds, to related hydrocarbons, alcohols, ketones, epoxides, acetates, and aldehydes (reviewed by Howard and Blomquist 2005). In many cases, each of the pheromone components alone is relatively ineffective, but a blend of two or more components may act as a "minimal blend" that stimulates attraction and/or courtship behavior (McNeil 1991). Unlike the vast majority of volatile sex pheromones, however, each of the four known contact sex pheromone components of the German cockroach, *Blattella germanica*, can independently elicit courtship, and some "minor" less abundant components are far more active than the major most abundant components (reviewed by Gemeno and Schal 2004). Therefore, chemical communication in *B. germanica* is of interest not only because this species is a pest of medical and veterinary importance but also because the chemistry, biochemistry, and behavioral

ecology of its sexual communication system are relatively well understood.

The German cockroach lives in aggregations. Nevertheless, sexually receptive females release a volatile pheromone, blattellaquinone (Nojima et al. 2005), that attracts males from a distance. Upon contact with the antennae and mouth parts, the male perceives the female's contact sex pheromone on her cuticle and performs a characteristic courtship display. This behavior includes a rotation of the male's body, turning away from the female so as to orient his abdominal tip toward the female's head. Thus positioned, he raises the wings to almost 90°, exposing specialized glands on the seventh and eighth tergites. These glands secrete a mixture of lipids, proteins, and sugars that synergistically serve as feeding stimulants (Nojima et al. 1999a, b, 2002; Kugimiya et al. 2002). The female then mounts the male to feed on the tergal secretion, and this places her in the correct alignment for copulation (Roth and Willis 1952). Hence, the contact sex pheromone blend encodes sex- and species-specific information, and it triggers and mediates close-range sexual behavior. It is, therefore, imperative for mating.

The most abundant component of the female contact sex pheromone is (3*S*,11*S*)-dimethylnonacosan-2-one (**1**, Fig. 1; Nishida et al. 1974), which is derived through hydroxylation and subsequent oxidation of the abundant cuticular hydrocarbon 3,11-dimethylnonacosane (Chase et al. 1992). Based on the well-established biochemical scheme of conversion of hydrocarbons to methyl ketone pheromones in the housefly (reviewed by Blomquist 2003) and the presence of the hydrocarbon 3,11-dimethylheptacosane on the cuticular surface of females, we predicted and later confirmed through synthesis that 3,11-dimethylheptacosan-2-one (**4**) also served as a sex pheromone component in this cockroach (Jurenka et al. 1989; Schal et al. 1990; Eliyahu et al. 2004). This component is less abundant on the female's cuticular surface, and its biological activity is significantly lower in dose-response studies than that of its C_{29} homolog.

Two less abundant sex pheromone components have also been identified: the alcohol 29-hydroxy-3,11-dimethylnonacosan-2-one (**2**) and the aldehyde 29-oxo-3,11-dimethylnonacosan-2-one (**3**). Interestingly, the alcohol has been shown to be about tenfold more effective at eliciting behavioral responses than the C_{29}-dimethyl ketone (reviewed by Nishida and Fukami 1983). The biochemical pathway that gives rise to the alcohol and aldehyde components has not been elucidated, but Chase et al. (1992) proposed that female-specific hydroxylation and subsequent oxidation reactions that result in the dimethyl ketones might act at the C-29-position of the dimethyl ketone to produce the 29-hydroxy- and 29-oxo-dimethyl ketone pheromone components.

Although this hypothesis has yet to be tested with labeled precursors, it predicts that if the same mechanism converts 3,11-dimethylheptacosane to the corresponding dimethyl ketone pheromone, then its two oxidation analogs, 27-hydroxy- and 27-oxo-3,11-dimethylheptacosan-2-one, might also be present as pheromone components in the female German cockroach. We now report behavioral and analytical results that show that 27-hydroxy-3,11-dimethylheptacosan-2-one and 27-oxo-3,11-dimethylheptacosan-2-one (**5** and **6**, respectively, Fig. 1) are found on the cuticular surface of adult females, and we confirm their pheromonal activity by synthesis and bioassay of the synthetic compounds.

Methods and Materials

Insects Blattella germanica cockroaches, representing an insecticide-susceptible strain originally obtained from American Cyanamid in 1989, were kept in groups at 27°C under a 12:12 L/D photoperiod with continuous access to dry LabDiet rat chow (#5001; PMI Nutrition International, Brentwood, MO, USA) and water. Nymphs that hatched within 2–3 d were reared in synchronous cohorts, and newly emerged adult males and females were separated daily from cages containing late instar nymphs.

Behavioral Assay Male sexual response was tested by using a modification of the assay developed by Roth and Willis (1952). An antenna of a 14- to 21-d-old adult male *B. germanica* was excised, inserted into a small mass of

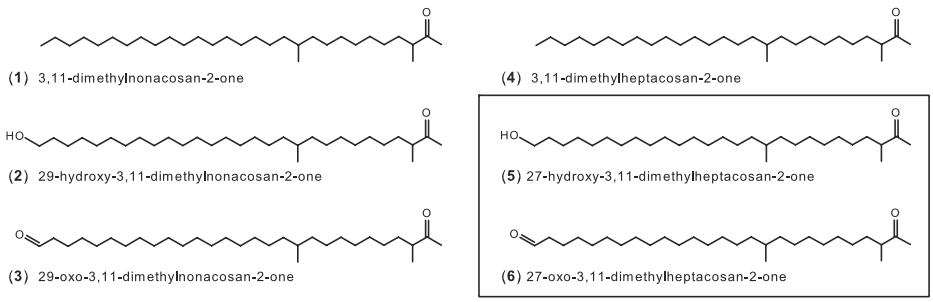

Fig. 1 Components of the contact sex pheromone of female *B. germanica*. Compounds **5** and **6**, *within the box*, are identified as new pheromone components in this paper

modeling clay at the end of a glass Pasteur pipette, and extracted for 1–2 sec in hexane to remove cuticular lipids. A test fraction or standard solution was applied with a 10-µl syringe (Hamilton, Reno, NV, USA) in 3 µl hexane to the distal 1 cm of the test antenna. The hexane was allowed to evaporate, and the antenna was used immediately to test the responses of at least 3 groups of 10 males, 14- to 21-d-old, that were housed individually in 9×9×7.5-cm plastic cages supplied with rat chow and water. All assays were conducted during mid-scotophase, avoiding the first and last 2 hr of the scotophase. The antennae of each male were gently stroked with the test antenna, and a positive response was recorded when the male executed a courtship response, rotating his body relative to the stimulus and raising his wings within 30 sec. This is an unmistakable response that occurs only in a sexual context and is never elicited by male test antennae either unfortified with female pheromone or treated with hexane alone.

This behavioral assay was used to identify chromatographic fractions that elicited behavioral responses, to conduct dose-response studies with synthetic compounds, and to test for synergistic interactions among the three C_{27} pheromone components.

Extraction and Fractionation Sexually mature virgin females, 6- to 7-d-old, were freeze-killed and extracted in groups of 50 females in a 20-ml vial with ~6 ml hexane (Optima; Fisher Scientific, Waltham, MA, USA) for 1 min. The extract was transferred to a clean vial, and the hexane was slowly reduced to 100 µl under a gentle stream of N_2. The extract was fractionated by flash column chromatography: 14.5-cm glass Pasteur pipettes loaded with 200 mg of silica gel (100–200 mesh; Fisher Scientific) were activated at 110°C for 30 min and washed with ~1 ml hexane. The extract was loaded and eluted successively with 4 ml hexane, 2 ml each of 1, 2, 5, 10, 20, and 40% diethyl ether (Optima; Fisher Scientific) in hexane, 2 ml diethyl ether, 2 ml ethyl acetate (Optima; Fisher Scientific), and 2 ml methanol (HPLC grade; Fisher Scientific). Each fraction was tested in the courtship behavioral assay, and active fractions were further fractionated on a normal phase

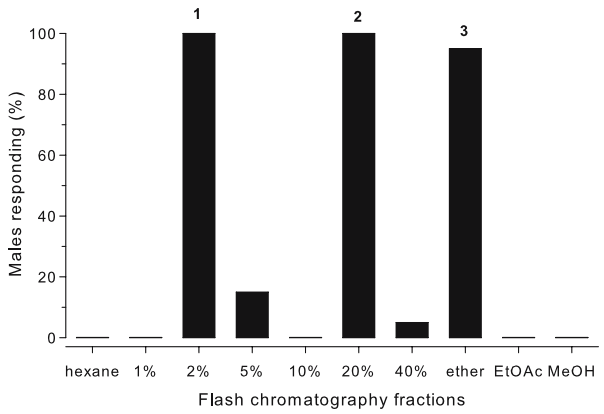

Fig. 2 Percentage of males (N>90 per fraction) responding to flash column chromatography fractions of female cuticular extract (0.05 female equivalents). The fractions in which synthetic compounds **1** (3,11-dimethylnonacosan-2-one), **2** (29-hydroxy-3,11-dimethylnonacosan-2-one), and **3** (29-oxo-3,11-dimethylnonacosan-2-one) would elute are indicated. Numbers (fractions) between hexane and ether represent percent ether in hexane. *EtOAc* Ethyl acetate, *MeOH* methanol

The fragment at *m*/*z* 72 is the result of McLafferty rearrangement of the 3-methyl-2-one-moiety

high performance liquid chromatography (HPLC) column (Econosphere, 5 μm silica, 250×4.6 mm; Alltech, Deerfield, IL, USA) on an HP1050 HPLC (Hewlett-Packard, Palo Alto, CA, USA). Supellapyrone (Charlton et al. 1993) was added as internal standard and monitored at 296 nm with an HP1050 diode array detector; the *B. germanica* sex pheromone components have no UV absorption. The sample was eluted isocratically at 1 ml min^{-1} with 99% hexane and 1% 2-propanol (HPLC grade; Fisher Scientific). One-minute fractions were collected and tested in behavioral bioassays on at least 30 males.

An Agilent 5975 mass selective detector, operated in electron impact ionization mode and coupled to an Agilent 6890 GC (Agilent, Santa Clara, CA, USA) was used for chemical structure determinations of compounds in active fractions. The GC was operated in splitless injection mode and fitted with a 30-m×0.25-mm ID DB-5MS column (Agilent). The oven was programmed from 60°C to 300°C at 15°C min^{-1} after an initial delay of 2 min and held at 300°C for 20 min. Injector temperature was 280°C, MS quadrupole 150°C, MS source 230°C, and transfer line 250°C.

Microchemical Reactions 1,1-Dimethylhydrazine (DMH, 98% pure; Sigma-Aldrich, St. Louis, MO, USA) derivatization was used to stabilize the thermally unstable oxo-dimethyl ketones (Nishida and Fukami 1983). The biologically active HPLC fraction was concentrated under N_2 to ~50 μl in a conical reaction vial, DMH (5 μl) was added, the vial was capped and incubated in a 60°C glass bead bath for 30 min, and the resulting solution immediately subjected to gas chromatography–mass spectrometry (GC-MS) analysis.

Silylation of the hydroxyl group was conducted before GC-MS analysis of the hydroxy-dimethyl ketones. The biologically active 100% ether fraction from flash chromatography of 120 females was concentrated under N_2 in a conical reaction vial, 80 μl *N*-methyl-*N*-trimethylsilyl trifluoroacetamide (MSTFA, Alltech) were added, the reaction mixture was incubated in an 80°C bead bath for 30 min, and the mixture was analyzed immediately by GC-MS.

Synthesis of 27-Hydroxy- and 27-Oxo-3,11-dimethylheptacosan-2-one (3*S*,11*S*)-27-Hydroxy-3,11-dimethylheptacosan-2-one and its oxidation product (3*S*,11*S*)-27-oxo-3,11-dimethylheptacosan-2-one were synthesized by K.M. The synthesis was executed based on an improved version of the previous synthesis of (3*S*,11*S*)-29-hydroxy-3,11-dimethylnonacosan-2-one (Mori et al. 1981). Oxidation of the alcohol to the aldehyde was carried out with Dess–Martin periodinane to avoid racemization at C-3. Details of the synthesis will be published separately by K.M. We used an enantioselective synthesis because the natural isomer of compound **1** is (3*S*,11*S*). We surmise that the natural isomers of compounds **4**, **5,** and **6** also have the (3*S*,11*S*) configuration, although this has not been shown analytically.

Statistical Analysis For dose-response studies, the probit and logistic procedures were used to estimate the dose to which 50% of the males would respond (RD_{50}) and to compare the RD_{50} values for the 3 components. The analysis was performed with SAS (SAS Institute 2003).

Results

Identification of New Components Three flash chromatography fractions (2, 20, and 100% ether fractions) elicited sexual responses from male cockroaches in behavioral bioassays (Fig. 2). These fractions corresponded to the synthetic pheromone components 3,11-dimethylnonacosan-2-one (**1**, Fig. 1), 29-oxo-3,11-dimethylnonacosan-2-one (**3**, Fig. 1), and 29-hydroxy-3,11-dimethylnonacosan-2-one (**2**, Fig. 1), respectively. The elution pattern of the components corresponded to that reported by Nishida and Fukami (1983).

Table 1 Amounts and ratios of 6 sex pheromone components on the cuticular surface of adult female *B. germanica*

Pheromone Component	C_{27} Components[d]		C_{29} Components[d]	
	Amount (ng)	Ratio	Amount (ng)	Ratio
Dimethylketone[a]	97	100	470	100
Hydroxy-dimethylketone[b]	5.3	5.5	25.6	5.4
Oxo-dimethylketone[c]	0.15	0.15	0.5	0.11

[a] 3,11-Dimethylheptacosan-2-one and 3,11-dimethylnonacosan-2-one, respectively
[b] 27-Hydroxy-3,11-dimethylheptacosan-2-one and 29-hydroxy-3,11-dimethylnonacosan-2-one, respectively
[c] 27-Oxo-3,11-dimethylheptacosan-2-one and 29-oxo-3,11-dimethylnonacosan-2-one, respectively
[d] Amounts and ratios of sex pheromone components determined from GC analyses of a composite extract of the cuticular surface of 100 virgin adult females, adjusted to nanogram per female. Ratios relative to 100% of the respective dimethyl ketone

To determine if the 100% ether fraction contained the predicted 27-hydroxy-3,11-dimethylheptacosan-2-one, hydroxylic components in this fraction were converted to silyl ethers and subjected to GC-MS analysis. The silyl ether of compound **2**, 29-hydroxy-(3*S*,11*S*)-dimethylnonacosan-2-one (Fig. 3a) was found at retention time 29.04 min, and its identity was confirmed by comparing the GC retention time and MS fragmentation pattern with those of the authentic compound (Fig. 3c). The silyl ether of the predicted candidate 27-hydroxy-3,11-dimethylheptacosan-2-one was found at retention time 25.14 min (Fig. 3b) by careful examination of the fragmentation patterns of all components. The mass spectrum of compound **5** was somewhat noisy because of its low abundance in the extract and other components eluting very close to it. However, it showed diagnostic fragments at *m*/*z* 510 (expected molecular weight, 0.08 intensity), *m*/*z* 495 (base peak, loss of a methyl group), an intense *m*/*z* 72 from McLafferty rearrangement of the 3-methyl-2-one-moiety, supporting the structure of a methylketone with a methyl group in the alpha position (Fig. 3d). Silylation also produced a fragment at *m*/*z* 144 in compounds **2** and **5**. The intense fragment at *m*/*z* 215 in the MS of the silylated heptacosanone derivative appears to be an artifact resulting from compounds that co-elute with **5**. The identity of compound **5** was confirmed by comparing both its GC retention time and MS fragmentation pattern with those of the authentic compound.

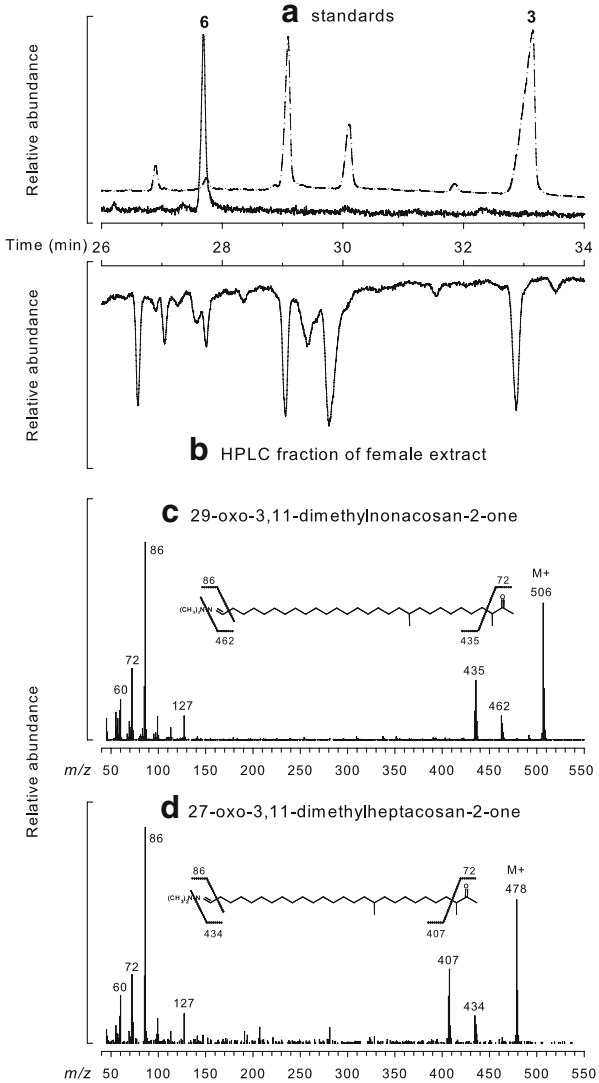

Fig. 4 Gas chromatograms and mass spectra of synthetic and natural aldehydes. **a** Two separate total ion chromatograms of 300 ng of the derivatized synthetic compound **3**, 29-oxo-3,11-dimethylnonacosan-2-one (*dotted line*), and 100 ng of the derivatized synthetic compound **6**, 27-oxo-3,11-dimethylheptacosan-2-one (*solid line*). **b** The similarly derivatized active HPLC fraction of the combined 20% ethyl ether fractions from a composite extract of 120 females fractionated by flash chromatography. **c** and **d** The electron impact mass spectra of peaks in the extract of females with retention times that corresponded with those of compounds **3** and **6**, respectively. The fragment at *m*/*z* 72 is the result of McLafferty rearrangement of the 3-methyl-2-one-moiety, and the intense fragment at *m*/*z* 86 represents McLafferty rearrangement of the 1,1-dimethylhydrazone moiety

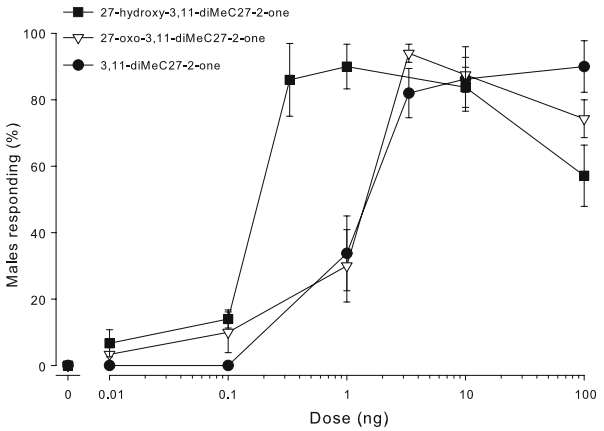

Fig. 5 Dose–response curves of 3 C_{27} sex pheromone components showing mean (±SE) percentage of males responding to 3,11-dimethylheptacosan-2-one (**4**), 27-hydroxy-3,11-dimethylheptacosan-2-one (**5**), and 27-oxo-3,11-dimethylheptacosan-2-one (**6**). (*N*=30–80 per compound/dose combination)

The amount of 27-hydroxy-3,11-dimethylheptacosan-2-one was estimated by comparison to authentic compound **2** to be ~5.3 ng per female, which is about fivefold less than the amount of 29-hydroxy-3,11-dimethylnonacosan-2-one found on the cuticular surface of sexually receptive females. Each of these alcohols is about 18-fold less abundant than the equivalent chain length dimethyl ketone from which the alcohol presumably arises (Table 1).

The 20% ether fraction was subjected to further bioassay-guided fractionation by HPLC. Two discrete fractions that elicited behavioral responses were obtained: the first 1-min fraction co-eluted with synthetic compound **3**, 29-oxo-3,11-dimethylnonacosan-2-one, whereas the second fraction

Table 2 Probit analysis of dose-response studies of 3 sex pheromone components

Sex Pheromone Component	Slope	Intercept	RD_{50} (ng)[a]	95% Fiducial Limits
3,11-Dimethylheptacosan-2-one (**4**)	0.590	−0.376	1.67 a	0.814, 2.818
27-Hydroxy-3,11-dimethylheptacosan-2-one (**5**)	0.763	0.664	0.18 b	0.042, 0.456
27-Oxo-3,11-dimethylheptacosan-2-one (**6**)	1.105	−0.093	1.18 a	0.567, 2.199

[a] Estimated dose to which 50% of males respond. Values followed by different letters are significantly different ($P<0.05$, Probit and logistic procedures, SAS Institute 2003).

eluted several minutes later (data not shown). To determine if the first fraction also contained the predicted 27-oxo-3,11-dimethylheptacosan-2-one, aldehyde components in this fraction were reacted with 1,1-dimethylhydrazine and subjected to GC-MS analysis. The hydrazone derivative of compound **3** (Fig. 4a) was found at retention time 32.87 min, and the identity was confirmed by comparing the GC retention time and MS fragmentation pattern with those of the authentic compound (Fig. 4b). The hydrazone derivative of the predicted candidate 27-oxo-3,11-dimethylheptacosan-2-one was found at retention time 27.74 min (Fig. 4a) by screening of the fragmentation patterns of all components. Compound **6** showed diagnostic fragments at *m/z* 72 (0.32 intensity relative to base peak) and 86, indicating McLafferty rearrangements of alpha-methyl ketone and 1,1-dimethylhydrazone moieties, $–CH_2–CH(CH_3)–CO–CH_3$ and $–CH=N–N(CH_3)_2$, respectively. In addition, it showed diagnostic fragments of the 1,1-dimethylhydrazone derivative at *m/z* 407, 434, and 478, from M^+-44 and M^+-86, and the expected molecular ion of the derivative, respectively (Fig. 4c). The identity of compound **6** was confirmed by comparing the GC retention time and MS fragmentation pattern with those of the authentic compound. Although DMH reacts with carbonyl groups in general, the proximity of the ketone group to the methyl branch in compounds **3** and **6** appears to hinder its reaction with the carbonyl group at position 2. Accordingly, derivatizations of compound **1** did not result in a hydrazone (data not shown), and we did not find products with 2-hydrazone moieties.

The amount of 27-oxo-3,11-dimethylheptacosan-2-one, estimated by comparison with known amounts of 29-oxo-3,11-dimethylnonacosan-2-one, was ~0.15 ng per female. Thus, the ratio of the C_{29} aldehyde to its C_{27} homolog is about 4:1. These oxo-dimethyl ketone components were about 40-fold less abundant than the respective alcohols (compounds **2** and **5**, Table 1).

The 20% ether fraction from flash column chromatography also contained a second active fraction that eluted several minutes after the 27-oxo- and 29-oxo-dimethyl ketones in normal phase HPLC. It may represent additional sex pheromone components whose compositions are currently under investigation.

Biological Activity of the Synthetic New Pheromone Components The biological activities of 3,11-dimethylheptacosan-2-one, 27-hydroxy-3,11-dimethylheptacosan-2-one, and 27-oxo-3,11-dimethylheptacosan-2-one were tested at various doses on 3–8 groups of 10 individually housed males. 27-Hydroxy-3,11-dimethylheptacosan-2-one (**5**) was about tenfold more active than the other two C_{27} components (Fig. 5). The estimated doses to which 50% of the males responded for each component (RD_{50}) are presented in Table 2. The RD_{50} values for compounds **4** and **6** were similar, but significantly higher than for compound **5**, as demonstrated by both logistic analysis and non-overlapping 95% fiducial limits.

The activity of 3,11-dimethylheptacosan-2-one was compared in a dose-response study to the activity of a blend of 3,11-dimethylheptacosan-2-one, 27-hydroxy-3,11-dimethylheptacosan-2-one, and 27-oxo-3,11-dimethylheptacosan-2-one in a 100:10:1 ratio. No synergism between the different C_{27} compounds was observed: the activity of a mixture of 100:10:1 methyl ketone/alcohol/aldehyde was not significantly different from that of the methyl ketone alone (Fig. 6).

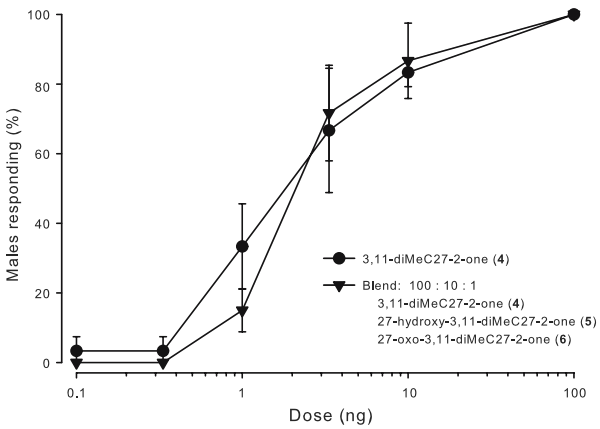

Fig. 6 Results of behavioral assays showing interaction among C_{27} sex pheromone components. 3,11-Dimethylheptacosan-2-one (**4**) was compared to a blend of 3,11-dimethylheptacosan-2-one, 27-hydroxy-3,11-dimethylheptacosan-2-one (**5**), and 27-oxo-3,11-dimethylheptacosan-2-one (**6**) in a ratio of 100:10:1, respectively. Data show mean percentage of males responding (±SE; N=30–60 per compound/dose combination)

Discussion

Semiochemicals are generally identified by the well-established approach of bioassay-guided sequential fractionation of extracts followed by chemical analysis, structure elucidation, and confirmation of biological activity with synthesized authentic compounds. A complementary approach predicts possible pheromone components based on an understanding of the chemistry and biochemistry of pheromone production coupled with knowledge of the evolutionary relationships among taxa. For example, Bjostad et al. (1984) predicted the structures of sex pheromone components of the cabbage looper, *Trichoplusia ni*, based on knowledge of biosynthetic pathways and fatty acid precursors. The pheromone gland of this noctuid moth utilizes acetate to produce octadecanoic and hexadecanoic acids which undergo Δ11-desaturation to produce Z11-18: acid and Z11-16:acid. However, the major component of the sex pheromone is (*Z*)-7-dodecen-1-yl acetate (Z7-12:OAc). When labeled Z11-16:acid was applied to glands, it was incorporated into both Z7-12:acid and the corresponding acetate ester pheromone. Because the main pheromone component was produced through a Δ11-desaturation followed by chain shortening, reduction, and acetylation to form the acetate ester, Bjostad et al. (1984) reasoned that other pheromone components would be produced from intermediates in the chain shortening sequence. Indeed, other acetate esters, including Z9-14:OAc, Z7-14:OAc, and Z5-12:OAc, were found to be pheromone components, the first derived from chain shortening of Z11-16:acid and the latter two from Z11-18:acid. In a similar manner, pheromone components of the spruce budworm (*Choristoneura fumiferana*) were predicted based on identification of fatty acids in the pheromone gland and their temporal variation in relation to pheromone production (Silk and Kuenen 1986), although in this case, the proposed components were not shown conclusively to be biologically active. Overall, few pheromone components have been identified from predictions based on biosynthetic pathways. In this paper, we confirmed that candidate compounds, predicted based on the biosynthetic pathways of related contact sex pheromone components, do indeed serve as pheromone components in the German cockroach.

In insects, cuticular hydrocarbons and hydrocarbon pheromones are formed through fatty acid elongation followed by decarboxylation (reviewed by Howard and Blomquist 2005). For example, in the housefly, the sex pheromone component (*Z*)-9-tricosene is first formed, and this alkene is then metabolized by a cytochrome-P450 enzyme to the corresponding epoxide and ketone, which also serve as sex pheromone components (reviewed by Blomquist 2003). This conversion of hydrocarbons to methyl ketone and epoxide pheromone components in the housefly served as a guide for our research on pheromone biosynthesis in the German cockroach.

The major cuticular lipids in all life stages of the German cockroach consist of an isomeric mixture of 3,7-, 3,9-, and 3,11-dimethylnonacosane (Jurenka et al. 1989). However, the dimethyl ketone fraction of cuticular extracts of adult females, which contains the pheromone 3,11-dimethylnonacosan-2-one, comprises only the 3,11-isomer. This led Jurenka et al. (1989) to propose a biosynthetic relationship between the hydrocarbon and its dimethyl ketone pheromone analog. Using radiolabeled compounds coupled with radio-GC, Chase et al. (1992) determined that the dimethyl ketone sex pheromone arises from the insertion of an oxygen into the preformed 3,11-dimethyl alkane. Radioactivity from the alkane was detected in both 3,11-dimethylnonacosan-2-ol and 3,11-dimethylnonacosan-2-one, but only in adult females, whereas when tritiated 3,11-dimethylnonacosan-2-ol was applied to the cuticle, it was readily and highly efficiently converted to the corresponding dimethyl ketone pheromone not only in females but also in males. These results confirmed that the dimethyl ketone sex pheromone of *B. germanica* arises via a female-specific hydroxylation of 3,11-dimethylnonacosane and a subsequent non-sex-specific oxidation to 3,11-dimethylnonacosan-2-one.

The same mechanism presumably converts 3,11-dimethylheptacosane, a component of the cuticular hydrocarbon profile of the German cockroach, to 3,11-dimethylheptacosan-2-one. Dose-response studies with both natural and synthetic 3,11-dimethylheptacosan-2-one confirmed its biological activity, although it was found to be approximately tenfold less active than its C_{29} homolog (Schal et al. 1990; Eliyahu et al. 2004).

Chase et al. (1992) previously proposed that a similar hydroxylation and oxidation at the C-29 position of 3,11-dimethylnonacosan-2-one might give rise to 29-hydroxy- and 29-oxo-3,11-dimethylnonacosan-2-one, the other components of the contact sex pheromone blend, and that the same mechanism might convert 3,11-dimethylheptacosan-2-one to its 27-hydroxy- and 27-oxo- analogs.

Identification of the C_{27} alcohol and aldehyde as sex pheromone components was fraught with difficulties, and it is not surprising that earlier studies with cuticular extracts of more than 200,000 females did not reveal these compounds. The two active homologs in each class (dimethyl ketones, alcohols, aldehydes) differ only in chain length and can only be separated by high performance fractionation methods, such as preparative GC. Furthermore, the aldehydes are thermally unstable, and derivatization is advisable before GC analysis. Also, silylation of the hydroxy group in the alcohols renders the analysis easier because the derivatives are less polar, and hence, less susceptible to adsorption by active sites on the column or in the injector. Moreover, both the C_{27} alcohol and aldehyde

occur in minute amounts that are largely obscured by other compounds in the extracts. Therefore, predictions based on the biosynthetic pathway of the C_{29} components were crucial for the location, recognition, and identification of the three C_{27} components.

Our finding of the predicted C_{27} compounds in the cuticular pheromone blend, and in a similar blend ratio to that of the C_{29} components, further corroborates the biosynthetic pathway proposed and partly demonstrated by Chase et al. (1992; reviewed by Schal et al. 2003). Furthermore, our results provide motivation for a reexamination of other hydrocarbons that might serve as precursors for methyl ketones and their oxidation derivatives that might also mediate behavioral responses. A prime candidate for consideration is 3,11-dimethylhentriacontane, which occurs on the cuticular surface in tiny amounts (Carlson and Brenner 1988). Structure–activity studies on 3,11-dimethylnonacosan-2-one indicate that the apparently promiscuous pheromone receptor of *B. germanica* males accepts chain lengths that are slightly shorter or longer than the optimal 29-carbon alkyl chain (Nishida and Fukami, 1983). Because the C_{27} homolog elicited behavioral responses, we predict that the C_{31} homolog will also show biological activity.

Although the 3,11-dimethyl structure is important for eliciting behavioral response, structure–activity studies have shown that both the 3-monomethyl and 11-monomethyl compounds are also biologically active, albeit at much higher doses (Nishida and Fukami 1983). The epicuticular lipids of *B. germanica* contain 11-methylheptacosane, 11-methylnonacosane, 11-methyltriacontane, 3-methylheptacosane, and 3-methylnonacosane, as well as dimethylalkanes that include an 11-methyl branch, including 11,15-dimethylheptacosane, 11,15-dimethylnonacosane, 5,11-dimethylheptacosane, and 5,11-dimethylnonacosane (Augustynowicz et al. 1987; Carlson and Brenner 1988; Jurenka et al. 1989). It is possible that the same mechanism that inserts a C-2 carbonyl into the preformed dimethylalkane might do the same with monomethyl alkanes of the proper chain length. We recently discovered that oxidation metabolites of 11-methylheptacosane are indeed biologically active. Nishida and Fukami (1983) found that when antennae of the Oriental cockroach, *Blatta orientalis*, stroked against the antennae of male German cockroaches, courtship was elicited in the latter species. Through fractionation and bioassays, we have recently identified two more active compounds: 11-methylheptacosan-2-one and 27-oxo-11-methylheptacosan-2-one (Eliyahu et al. 2008). 11-Methylheptacosane is abundant on the cuticular surface of the Oriental cockroach (Lockey and Dularay 1986), and it is likely that in this cockroach too, the methyl ketone and aldehyde are oxidation products of the hydrocarbon. 3-Methyl and 11-methyl hydrocarbons of the appropriate chain length are present in the cuticular lipids of German cockroach females, and they similarly could be converted to biologically active methyl ketones, alcohols, and aldehydes.

Our dose-response results with synthetic C_{27} components are in agreement with similar results from the C_{29} components (Nishida and Fukami 1983). Both the C_{29} and C_{27} primary alcohols were about tenfold more active than the respective methyl ketones, whereas the aldehydes were not significantly more active than the respective methyl ketones of the same chain length. Unlike most insect pheromone blends, especially in the case of volatile pheromones, each of the 6 contact sex pheromone components can independently elicit the complete repertoire of sexual responses. Schal et al. (1990) found that the 2 methyl ketone components of the pheromone interacted additively, not synergistically. We show here that there is also no synergism between different component classes. Therefore, it appears that the total semiochemical activity might be achieved by additive effects, with low amounts of the more polar compounds being compensated for by their lower thresholds for eliciting courtship responses.

Further studies are necessary to determine the definitive number of components in the contact sex pheromone blend of the female German cockroach. Two points of caution are worth mentioning. First, the sex pheromone reception system of the male German cockroach exhibits a highly promiscuous response, responding to compounds that deviate significantly from the native pheromone. Indeed, it represents one of the few cases where the native pheromone can be significantly improved upon, for example by changing the C-2 carbonyl to a C-2 hydroxy group. This might explain in part the frequent observations of interspecific courtship in cockroaches, as described above. It also highlights the important point that for a pheromone component to be considered as such, it must not only elicit a response from the receiver but also must be present on the producer.

Second, the relative behavioral value to the male of each female pheromone component must be considered. The dimethyl ketone generally constitutes 10% of the abundance of its precursor hydrocarbon analog (Chase et al. 1992), and the alcohol and aldehyde occur at ~5 and ~0.1% of the respective parent dimethyl ketone (Table 1). Assuming that other, yet to be identified, semiochemicals occur at similar ratios, it seems that if they arise from relatively poorly represented hydrocarbons, they might occur in subnanogram amounts. Moreover, these compounds are presumably spread over the total cuticular surface and possibly buried within hundreds of micrograms of cuticular hydrocarbons. It remains to be determined how much of each component is "operationally functional", that is, perceived by the male when he briefly strokes the female's antennae. We previously determined that each female antenna contains about 1 ng of 3,11-dimethylnonacosan-2-one and 0.4 ng of

3,11-dimethylheptacosan-2-one, closely matching the minimal amounts required to elicit courtship behavior from males as determined from dose-response studies (Eliyahu et al. 2004). It is conceivable that many minor components that could potentially act as pheromones at appropriate doses are represented on the female's cuticle and antennae at amounts substantially below the male's threshold of detection, and thus, they may represent "noise" arising from biosynthetic processes that are not completely selective. We suggest that such compounds should only be labeled as pheromone components if they elicit responses in dose ranges within which they are naturally found on the producer.

Acknowledgments We thank Ritsuo Nishida for providing synthetic 29-hydroxy-3,11-dimethylnonacosan-2-one, and Takuya Tashiro for helping with an earlier synthesis of 29-oxo-3,11-dimethylnonacosan-2-one. We appreciate Wittko Francke's assistance in interpreting MS data and his critique of the manuscript, and Cavell Brownie for help with statistical analyses. We thank Jinping Sun, Jeffrey Spontak, and Richard Santangelo for maintaining insect colonies, Edward Vargo, Charles Apperson, and Robert Anholt for useful comments on an early draft of this manuscript. This work was supported in part by the Blanton J. Whitmire Endowment at North Carolina State University.

Identification, Synthesis, and Bioassay of a Male-Specific Aggregation Pheromone from the Harlequin Bug, *Murgantia histrionica*

Deane K. Zahn · Jardel A. Moreira · Jocelyn G. Millar

Received: 15 January 2007 / Revised: 28 October 2007 / Accepted: 4 December 2007 / Published online: 19 January 2008

Abstract Sexually mature male harlequin bugs produced a sex-specific compound, identified as one of the stereoisomers of the sesquiterpene epoxyalcohol 4-[3-(3,3-dimethyloxiran-2-yl)-1-methylpropyl]-1-methylcyclohex-2-en-1-ol (henceforth murgantiol), a compound with four chiral centers and 16 possible stereoisomers. Production of the compound was highest during the middle of the day. Individual virgin male bugs in separate containers produced the compound at a higher rate than virgin males in groups. The carbon skeleton was verified by synthesis of several mixtures which, in total, contained all possible isomers, one of which matched the insect-produced compound. The relative and absolute configurations of the insect-produced compound remain to be determined. In laboratory bioassays, insect-produced and synthetic murgantiol attracted harlequin bugs of both sexes, suggesting that murgantiol is a male-produced aggregation pheromone, analogous to those found in a number of other phytophagous bug species.

Keywords Aggregation pheromone · Heteroptera · Hemiptera · 4-[3-(3,3-dimethyloxiran-2-yl)-1-methylpropyl]-1-methylcyclohex-2-en-1-ol · Murgantiol

Introduction

The harlequin bug, *Murgantia histrionica* (Hahn), is an important pest of cabbage, broccoli, and other cole crops in the United States (McPherson 1982). Methods for monitoring this and other stink bug species, such as sampling the crop by using a sweep net or a beating tray, or by visual inspection of damage or presence of insects, are typically labor-intensive. Sampling at frequent intervals may be required to detect immigration of bug populations into crops, so that control measures can be applied before significant damage occurs. Consequently, attractive sex or aggregation pheromones used as baits in monitoring traps could prove of value in integrated pest management programs.

To date, pheromones have been identified for only a few stink bug species. For all phytophagous pentatomids for which sex or aggregation pheromones have been identified, the compounds were produced by males (reviewed in McBrien and Millar 1999; Ho and Millar 2001a, b; Millar 2005). In addition to using sex-specific pheromones, phytophagous stink bugs use species- and sex-specific substrate-borne vibrations for intraspecific communication over relatively short distances (Čokl and Doberlet 2003). The vibrational signals of *M. histrionica* were recently described (Čokl et al. 2004), with males producing five different vibrational songs and females producing only one song. Contrary to those found for most stink bugs investigated, the vibrational signals did not seem to play a role in orientation toward the source of the vibration (i.e., mate location). Rather, the vibrational signals appeared to function in close-range mate recognition and courtship, suggesting that signals other than vibrational signals may be important in bringing the two sexes together over greater distances.

Harlequin bugs produce or sequester a variety of chemicals. For example, the metathoracic scent gland secretion of adult *M. histrionica* consists of (2*E*,6*E*)-octadienedial and (2*E*,6*E*)-octadiene-1,8-diol diacetate (Aldrich et al. 1996). Additionally, when adults are

squeezed, a sticky froth is expelled from the margins of the prothorax. This fluid contains aglycones of glucosinolates, *sec*-butyl isothiocyanate, methylthiopropyl nitrile, and methylthiobutyl nitrile, as well as two strong-smelling alkylmethoxypyrazines, 2-*sec*-butyl-3-methoxypyrazine and 2-isopropyl-3-methoxypyrazine, which have been hypothesized to serve as warning odors (Aldrich et al. 1996). These compounds are likely derived from glucosinolates sequestered from host plants, providing the vividly colored aposematic bugs with a formidable chemical defense against predation. The bugs can retain these compounds for an extended period of time (Aliabadi et al. 2002). However, none of these compounds has been reported to have a role as pheromones.

We describe herein the collection and analysis of volatile compounds released by live adult *M. histrionica* of both sexes. In addition to a number of compounds common to both sexes, one major sex-specific compound was found in the odors released by sexually mature adult males. This compound functions as an aggregation pheromone component for the harlequin bug.

Materials and Methods

Insect Colonies Adults and nymphs of *M. histrionica* were collected from bladderpod, *Isomeris arborea* Nutt. (Capparaceae), from one site each in Riverside and San Diego, CA, USA. A colony was started in the laboratory in 2003 and augmented every year since with approximately 100 males, females, and nymphs from each location. Voucher specimens were submitted to the University of California, Riverside Entomology Research Museum (UCRC 145863–145882). Insects were reared at 26±1°C, approximately 45% RH, with a photoperiod of 16:8 h (L:D) provided by fluorescent lights. Immature insects were held separately from adults in cylindrical plastic containers (20×15 cm), with two 4-cm holes on opposite sides of each container covered with brass screening. Adults were held in 30×17×18 cm glass-topped rearing cages. Insects were provided with Napa cabbage, cauliflower, and broccoli three times per week. Upon eclosion, adults were sexed and maintained for 14 d with florets of broccoli in 175 ml transparent plastic cups, or in groups in 3.8-l cardboard ice-cream cartons with ventilated lids, before use.

Collection of Insect-Produced Compounds from Live Bugs A system for collecting volatile compounds from live organisms was set up as previously described (Millar and Sims 1998). Ten to fifteen virgin adult bugs and two large cauliflower florets were put into a two-part, 400 ml cylindrical glass aeration chamber, lined with screen upon which bugs could perch. Humidified, charcoal-filtered air (6–14 mesh activated charcoal granules) was drawn through the chamber by vacuum at 250 ml per min. Volatile chemicals were collected overnight on activated charcoal traps made from 4 mm ID glass tubes loaded with a 0.4-cm bed of 50–200 mesh activated charcoal (Cat. # 05–690A, Fisher Scientific, Pittsburgh, PA, USA), precleaned by heating at 200°C under a flow of clean N_2 (~100 ml per minute). Aerations of groups of bugs were conducted continuously for 2–3 weeks at ~25°C and 50% RH with cohorts of male and female bugs of known age, changing the food and the collectors every other day. Aerations of individual bugs were conducted in the same way, but using smaller, 200-ml chambers. All aeration chambers were within the main colony rearing room. Additional cohorts of sexed virgin bugs, of the same age as those in the chamber, were maintained and used to replace any bugs in the chamber that died. As a control, two to three cauliflower florets were put in a 1-l aeration chamber and aerated for 20 h with an air flow rate of 1 l per minute. Trapped volatiles were stripped off the activated charcoal by elution with methylene chloride (500 µl; Optima grade, Cat. # D151–4, Fisher Scientific, Pittsburgh PA, USA), and the resulting extracts stored in glass vials with Teflon-lined screw caps at ~−20°C until needed.

Single-bug and group (5, 10, and 15) aerations were set up simultaneously to determine whether the male-specific compound was released at different rates by individuals or groups. For this, bugs were either held individually (N=20) or in groups (N=20 each group) for 2 weeks before use. Traps were changed every other day and eluted with 500 µl of CH_2Cl_2. The amounts of male-specific compound per bug hour were analyzed by one-way ANOVA and means were separated by Games–Howell tests.

To determine the diurnal cycle of release of the male-specific compound, five cohorts of five virgin, sexually mature, adult males (14–16 days old), and three florets of cauliflower were aerated in chambers as described above. After a cohort of bugs was confirmed to be producing the male-specific compound, the traps were changed every 2 h during the photophase. A single trap was used to collect volatiles produced between 23:00 and 07:00. An external standard of hexadecane in CH_2Cl_2 (1.6 µg/ml) was used to estimate the amount of male-specific compound present in each extract. The total amounts of the male-specific compound produced during each 24-h period were calculated along with the percentage of the total produced during each 2-h interval. For the 8-h period between 23:00 and 07:00, the average amount per 2 h was calculated. The percentage data from all cohorts were averaged, analyzed by ANOVA, and means were separated by Student–Newman–Keuls tests.

General Procedure for Y-tube Bioassays Bioassays were conducted with a vertical glass Y-tube (5 cm ID; bottom arm=18 cm long, top arms=15 cm long, Y angle=90°) with female ground glass joints, each fitted with male joints terminating in a hose nipple. The Y-tube was illuminated from above with a 1.2-m long light bank containing a Sylvania Octron 3500K F032/735 32 W fluorescent light and a GE F40PL/AQ Plant and Aquarium wide spectrum fluorescent light, providing light intensities of 350 lux at the bottom to 600 lux at the top of the Y-tube. Charcoal-purified air was pulled through the apparatus (2.5 liter per minute) by vacuum. Bugs were tested individually and used only once. Each bug was gently placed inside the bottom male joint of the Y-tube, which was then inserted into the female joint. *M. histrionica* are positively phototactic and negatively geotactic, and generally walked up toward the light. A positive response was classified as a bug crossing a line 12 cm up either arm from the junction. If a bug did not move within 10 min of the start of the bioassay, it was discarded. Each Y-tube and joint was used once, then washed, acetone rinsed, and oven-dried at 140°C. Bioassays were conducted in a temperature (22–25°C) and humidity (40–50% RH) controlled room, 4 to 8 h after the onset of photophase. Positions of treatments were alternated every second replicate. Choice data were analyzed with chi-square tests with one degree of freedom and $\alpha=0.05$.

The Y-tube olfactometer was also used to determine which sex of adult *M. histrionica* produced pheromone. The top joints of the Y-tube were connected to 200 ml glass aeration chambers that contained five sexually mature virgin bugs and two cauliflower florets, or two cauliflower florets alone. Chambers were positioned above the Y-tube, behind a cardboard screen so contents were not visible to the bugs in the Y-tube. Ten minutes after the chambers were set up, a test bug was introduced into the bottom of the Y-tube and its response recorded by an observer and on video tape (Panasonic high-density recording, time lapse video recorder, model AG-6740p). A fresh group of five unmated, sexually mature bugs was used as a pheromone source for each day of bioassay. Four separate experiments were conducted, testing the responses of females to odors from males, females to odors from females, males to odors from females, and males to odors from males. The responses of 40 bugs were tested in each experiment. Because females did not attract males, but males attracted females, only females were used as responders in the subsequent experiments, except where indicated otherwise.

The numbers of virgin female *M. histrionica* attracted to 5 bug-hour equivalents (1 bug-hour equivalent=the volatiles collected from 1 bug in 1 h) of crude extract in CH_2Cl_2 vs a CH_2Cl_2 blank were compared. Aliquots of extract or solvent were loaded on half-circular filter papers (1.5 cm in diameter) mounted on wires in the top of each arm of the Y-tube. Five bug-hours of extract contained ~30 ng of the major male-specific component, as determined by gas chromatography.

A pooled extract of male-produced odors was separated into eight fractions (see below), and the fraction containing the major male-specific compound (5 bug-hour equivalents) was bioassayed against a CH_2Cl_2 control. Equal aliquots of the remaining seven fractions were combined and tested against a CH_2Cl_2 control. Having determined that only the fraction containing the major male-specific compound was attractive to females, this fraction was then tested against an equivalent amount of crude extract.

Mixtures containing synthetic enantiomers (see below) of the major male-specific compound were tested using 14-day-old sexually mature adults of both sexes. The mixture derived from (*S*)-citronellal was tested vs a solvent control, and both synthetic mixtures were tested vs the crude extract. Finally, equal doses of the two synthetic mixtures were tested against each other. The mixtures (240 ng of each mixture of four stereoisomers, ~60 ng/isomer), in CH_2Cl_2, and solvent controls, were loaded onto filter paper discs as described above.

Gas Chromatography (GC) and Mass Spectrometry (MS) Analyses of Extracts Extracts were concentrated under a gentle stream of nitrogen, and analyzed by splitless gas chromatography with a Hewlett–Packard (H–P) 5890 GC fitted with a DB-5 column (30 m×0.32 mm ID×0.25 μm film, J&W Scientific, Folsom, CA, USA), using a temperature program of 40°C for 1 min, then 15°C min^{-1} to 250°C. The injector and detector temperatures were 250°C and 280°C, respectively, and helium was used as carrier gas. Extracts were also analyzed by GC-MS, using an HP 5890 GC, fitted with a DB5-MS column (20 m×0.2 mm ID×0.33 μm film), interfaced to an HP 5970B mass selective detector (electron impact ionization, 70 eV). The same temperature program described above was used, with injector and transfer line temperatures of 250 and 280°C, respectively. Injections (1 μl) were made in splitless mode. Previously known compounds were tentatively identified from their mass spectra, and from matches with the NBS-NIH mass spectral database. Identifications were confirmed by matching retention times and mass spectra with those of authentic standards (see below).

An aliquot of the purified male specific compound was also analyzed by chemical ionization mass spectrometry (NH_3 reagent gas) by direct insertion on a VG-7070B instrument.

Fractionation of Extracts of Volatiles Collected from Sexually Mature Male Bugs Thirty aeration extracts of

sexually mature male bugs, prepared from May 2003 to August 2005, were combined and concentrated to ~1 ml by fractional distillation of the solvent through an 8-cm long Vigreux column. The concentrated extract was transferred to a vial and the solvent removed under a gentle stream of nitrogen. The sample was reconstituted to ~250 µl with pentane, and then loaded onto a 2.8-ml solid phase extraction (SPE) cartridge (J.T. Baker silica gel SPE, stock #7086–01, precleaned by flushing with 3× 1 ml diethyl ether, then 3×1 ml pentane). The extract was rinsed onto the SPE bed with two to three drops of pentane, and eluted with 2×1 ml pentane, 2×1 ml 10% ether in pentane, and 4×1 ml ether, collecting each elution as a separate fraction.

Aliquots (100 µl) of crude extract were subjected to a series of microchemical tests to ascertain characteristics of the male-specific compound.

a) To test for the presence of a conjugated diene, an aliquot was treated with two drops of a solution of the dienophile, 4-methyl-1,2,4-triazolin-3,5-dione (MTAD; Young et al. 1990) in CH_2Cl_2 (2 mg/ml), producing a pale pink solution which was analyzed immediately by GC-MS.
b) To test for an ester function, an aliquot was concentrated just to dryness, and then treated with three drops of 1 M NaOH in ethanol to water (95:5). After standing at room temperature for 4 h, 200 µl of water were added and the mixture extracted with 500 µl pentane. The pentane extract was dried over Na_2SO_4, concentrated under a stream of nitrogen, and analyzed by GC-MS.
c) To test for an alcohol function, an aliquot was treated with one drop each of pyridine and acetyl chloride. The resulting mixture was stirred for 2 h, treated with 200 µl of saturated aqueous $NaHCO_3$, and extracted with 0.5 ml pentane. The pentane extract was concentrated and analyzed as above.
d) To test for reducible functional groups, an aliquot in diethyl ether was treated with ~1 mg of $LiAlH_4$, with stirring at room temperature for 2 h. The mixture was quenched with 1 M HCl and extracted with 0.5 ml pentane. The pentane extract was dried over Na_2SO_4, concentrated, and analyzed.
e) To test for unsaturation, an aliquot of extract and ~1 mg of 5% Pd on carbon were placed in a 1.5-ml screwcap vial with a Teflon-lined septum. The septum was punctured with a syringe needle attached to a balloon filled with hydrogen, the lid was loosened for 10 s to flush the vial with hydrogen and resealed, and the mixture stirred for 2 h. The reactant mixture was filtered through a small plug of Celite and analyzed.

NMR Analysis of the Male-Specific Compound Forty-two extracts were combined, concentrated, and fractionated as described above, and the fraction containing the male-specific was compound concentrated under a gentle stream of nitrogen, taking the solution just to dryness. Approximately 200 µl of CD_2Cl_2 were added, and the solution was concentrated just to dryness again to remove traces of non-deuterated solvent. The residue (estimated at >100 µg) was then taken up in CD_2Cl_2 and transferred to a 3-mm NMR tube. ^{13}C, ^{1}H, and ^{1}H-^{1}H COSY spectra were obtained with both a Varian INOVA-400 and a Brucker 600 MHz NMR spectrometer; the latter instrument was also used to obtain NOESY, ^{13}C-DEPT 135, HMBC, and HSQC spectra.

Chemicals Cineole, limonene, myrcene, dodecane, and dimethyldisulfide were purchased from Aldrich Chemical Co. (Milwaukee, WI, USA). Dimethyltrisulfide was obtained from Alfrebro (Monroe, OH, USA). The bisabolene epoxide pheromones of *Acrosternum hilare* were available from previous studies (McBrien et al. 2001). The sex-specific compound produced by male harlequin bugs was synthesized as described below.

For the syntheses, unless stated otherwise, all reactions were carried out under argon. Tetrahydrofuran (THF) used in the synthesis was distilled from sodium/benzophenone ketyl under argon. ^{1}H- and ^{13}C-NMR spectra were taken as $CDCl_3$ or CD_2Cl_2 solutions, recorded on a Varian INOVA-400 (400 and 100 MHz, respectively) spectrometer. Chemical shifts are expressed in parts per million (ppm) (δ-scale) relative to $CDCl_3$ (7.26 and 77.23 ppm) and CD_2Cl_2 (5.32 and 54.00 ppm) signals for ^{1}H and ^{13}C NMR, respectively. Routine GC analyses were performed with an HP 5890 series II GC, equipped with a DB-5 column (30 m×0.25 µm ID, 0.25 µm film thickness, J&W Scientific, programmed from 100°C for 1 min, then at 15° C min^{-1} to 250°C) or a DB-WAX column (30 m×0.25 µm ID, 0.25 µm film thickness, J&W Scientific), programmed from 40°C for 1 min, then at 5°C min^{-1} to 250°C).

*Preparation of (3S)-α-Methylene-3,7-dimethyl-6-octen-1-al (**2**)* Piperidine (5.39 g, 63.3 mmol) was added dropwise over ~5 min to a three-necked, round-bottomed flask, containing (*S*)-citronellal **1** (4.69 g, 30.4 mmol; Aldrich Chem. Co., Cat. #37375-3, 96%), attached to a condenser. The temperature was increased to 44°C and the mixture became cloudy, and then cleared again. Formaldehyde (37% aqueous solution, 7.8 ml) was added dropwise, keeping the temperature under 40°C, followed by glacial acetic acid (0.78 ml) dropwise. The mixture was stirred overnight at room temperature and then heated to 80°C for 1.5 h. The mixture was cooled to room temperature, diluted

with hexanes (80 ml), then washed sequentially with HCl (2 M in water, 2×30 ml), saturated aqueous $NaHCO_3$ (20 ml), and brine (20 ml). The organic phase was separated and dried with anhydrous Na_2SO_4 and concentrated under vacuum. The crude product was Kugelrohr distilled (64–67°C, 1.6 mm Hg), affording 4.01 g of aldehyde **2** (79.3% yield). ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.07 (d, 3H, J=7.2 Hz), 1.33–1.44 (m, 1H), 1.48–1.56 (m, 1H), 1.57 (s, 3H), 1.67 (s, 3H), 1.86–2.00 (m, 2H), 2.70 (sext, 1H, J=7.0 Hz), 5.08 (br t, 1H, J=7.0 Hz), 5.99 (s, 1H), 6.23 (s, 1H), 9.53 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.85, 19.75, 25.89, 25.96, 31.18, 35.79, 124.34, 131.88, 133.25, 155.71, 194.89. MS (*m/z*, rel. abundance): 166 (M^+, 8), 151 (8), 137 (2), 135 (3), 133 (4), 124 (4), 123 (8), 121 (1), 110 (8), 109 (41), 107 (3), 106 (2), 105 (4), 96 (3), 95 (18), 93 (9), 91 (5), 84 (10), 83 (15), 81 (18), 69 (28), 67 (26), 56 (12), 55 (51), 53 (16), 43 (16), 41 (100).

*Preparation of 4-[(1S)-1,5-Dimethylhex-4-enyl]cyclohex-2-en-1-one (**3**)* Sodium (177 mg, 7.7 mmol) was added to a 200-ml, three-necked, round-bottomed flask containing methanol (23 ml) and attached to a condenser. After the sodium had dissolved, a solution of methyl acetoacetate (2.74 g, 23.6 mmol) in methanol (35 ml) was slowly added (~20–25 min) and the mixture was stirred 30 min at room temperature. A solution of aldehyde 2 (3.92 g, 23.6 mmol) in methanol was added dropwise over 40 min. The resulting mixture was stirred 2 h at room temperature and then refluxed for 2 h. After cooling, the methanol was removed under vacuum, the residue diluted in hexanes (100 ml), washed with saturated aqueous NH_4Cl, water and brine, dried over anhydrous Na_2SO_4, and concentrated under vacuum. The crude product was purified by vacuum flash chromatography on silica gel, eluting with hexane/ethyl acetate (97:3). The resulting product was purified further by Kugelrohr distillation (112–117°C, 0.35 mm Hg), affording 2.19 g of cyclohexenone **3** (45.1% yield) as a ~1:1 mixture (estimated from ^{1}H and ^{13}C NMR spectra) of inseparable diastereomers. ^{1}H NMR ($CDCl_3$): δ 0.90 (d, 1.5H, J= 6.8 Hz), 0.94 (d, 1.5H, J=7.2 Hz), 1.20–1.32 (m, 1H), 1.38–1.48 (m, 1H), 1.62 (s, 3H), 1.70 (s, 3H), 1.90–2.15 (m, 4H), 2.30–2.56 (m, 4H), 5.06–5.14 (m, 1), 6.02 (dt, 1H, J=3.2 and 10.2 Hz), 6.82–6.90 (m, 1H). ^{13}C NMR ($CDCl_3$): d 16.23, 16.75, 17.91, 24.21, 25.92, 26.07, 34.14, 34.34, 36.29, 36.35, 37.74, 37.93, 41.30, 41.85, 124.34, 124.37, 129.91, 130.17, 132.03, 132.04, 154.54, 155.64, 200.34. Several of these peaks corresponded to composite signals from carbons in both diastereomers. MS (*m/z*, rel. abundance) 206 (M^+, 9), 191 (4), 177 (1), 163 (5), 149 (4), 136 (6), 135 (5), 124 (5), 123 (36), 122 (30), 121 (16), 109 (13), 107 (10), 96 (18), 95 (13), 94 (16), 91 (4), 79 (16), 77 (6), 69 (61), 67 (25), 55 (31), 53 (15), 43 (10), 41 (100).

*Preparation of 4-[(1S)-1,5-Dimethylhex-4-enyl)-1-methylcyclohex-2-en-1-ol (**4**)* A solution of cyclohexenone **3** (2.18 g, 10.6 mmol) in diethyl ether (20 ml) was cooled to −78°C, and methyl lithium (26.4 ml of a 1.2-M solution in hexanes, 31.7 mmol) added dropwise. The resulting mixture was stirred 4 h, warmed to room temperature, and stirred overnight. The reaction was quenched with dilute aqueous NH_4Cl and extracted with ethyl acetate (4×20 ml). The combined organic phase was washed with brine, dried over anhydrous Na_2SO_4, and concentrated by rotary evaporation. The residue was purified by flash chromatography on silica gel, eluting with 5% ethyl acetate in hexane, yielding alcohols **4** in two fractions (less polar fraction, higher Rf, 0.681 g; more polar fraction, lower Rf, 1.272 g; 83.1% yield). Each fraction consisted of mixtures of two diastereomers that were inseparable by flash chromatography; each mixture eluted as a single peak on a DB-5 GC column. Less polar diastereomers: ^{1}H NMR ($CDCl_3$): δ 0.84 (d, 1.5H, J=7.2 Hz), 0.89 (d, 1.5H, J=6.8 Hz), 1.28 (s, 3H), 1.61 (s, 3H), 1.69 (s, 3H), 1.14–1.60 (m, 7H), 1.80–2.08 (m, 4H), 5.07–5.14 (m, 1H), 5.59–5.70 (m, 2H). MS (*m/z*, rel. abundance): 222 (M^+, 3), 207 (10), 204 (M^+-18, 7), 189 (5), 179 (2), 161 (8), 151 (4), 148 (6), 147 (4), 138 (12), 137 (17), 133 (7), 123 (15), 121 (12), 119 (39), 109 (22), 108 (4), 107 (10), 105 (9), 95 (23), 94 (22), 93 (24), 91 (12), 82 (12), 81 (13), 79 (19), 77 (14), 69 (91), 67 (25), 55 (37), 53 (15), 43 (80), 41 (100). More polar diastereomers: ^{1}H NMR: ($CDCl_3$): δ 0.82 (d, 1.5H, J=6.4 Hz), 0.85 (d, 1.5H, J=7.2 Hz), 1.10–1.22 (m, 1H), 1.27 (s, 3H), 1.32–1.55 (m, 4H), 1.60 (s, 3H), 1.68 (s, 3H), 1.60–1.75 (m, 2H), 1.83–2.14 (m, 4H), 5.06–5.13 (m, 1H), 5.48–5.65 (m, 2H). MS (*m/z*, rel. abundance): 222 (M^+, 2), 207 (11), 204 (M^+-18, 10), 189 (3), 179 (2), 161 (8), 151 (4), 148 (3), 147 (3), 138 (14), 137 (20), 133 (6), 123 (20), 121 (14), 119 (38), 109 (19), 108 (4), 107 (10), 105 (9), 95 (23), 94 (11), 93 (23), 91 (12), 82 (13), 81 (13), 79 (14), 77 (14), 69 (86), 67 (24), 55 (37), 53 (15), 43 (83), 41 (100).

*Preparation of 4-[3S-(3,3-Dimethyloxiran-2-yl)-1-methylpropyl]-1-methylcyclohex-2-en-1-ol ((S)-murgantiol—**5**)* *m*-Chloroperbenzoic acid (ca. 70%, 0.333 g, ~1.35 mmol) was added in small portions over 30 min to a well-stirred suspension of the less polar, higher Rf, fraction of alcohols **4** (0.300 g, 1.35 mmol) in an aqueous solution of $NaHCO_3$ (0.5 M, 10 ml) in an ice-bath (Fringuelli et al. 1992). The mixture was stirred 3 h at 0°C, then brine (50 ml) added, and the mixture was extracted with hexanes (4×20 ml). The combined organic phases were dried with anhydrous Na_2SO_4 and concentrated by rotary evaporation. The residue was purified by vacuum flash chromatography (hexanes/ethyl acetate 5:1) to yield 0.240 g of epoxyalcohols **5** (74.5%) as an inseparable mixture of diastereomers. ^{1}H NMR (400 MHz, CD_2Cl_2): δ 0.86 (d, 1.5H, J=6.8 Hz),

0.90 (d, 1.5H, J=6.0 Hz), 1.24 (S, 6H), 1.27 (S, 3H), 1.35–1.70 (m, 9H), 1.76–1.87 (m, 1H), 1.99–2.10 (M, 1H), 2.63–2.70 (M, 1H), 5.58–5.70 (m, 2H). The ^{13}C spectrum was complex because of the mixture of stereoisomers, but contained peaks that matched those of insect-produced murgantiol. MS (m/z, rel. abundance) 205 (2), 165 (9), 147 (6), 138 (10), 135 (4), 134 (13), 132 (10), 123 (10), 122 (4), 121 (12), 119 (11), 109 (15), 107 (9), 106 (6), 105 (9), 95 (15), 94 (19), 93 (17), 91 (11), 81 (15), 79 (18), 77 (11), 71 (27), 69 (12), 67 (15), 59 (20), 55 (21), 43 (100), 41 (47).

*Preparation of 4-[3R-(3,3-Dimethyloxiran-2-yl)-1-methylpropyl]-1-methylcyclohex-2-en-1-ol ((R)-murgantiol—**5**)* An analogous mixture of diastereomers containing the other enantiomer of murgantiol was prepared in identical fashion, and in similar yield, using (*R*)-citronellal (Aldrich Chem. Co, technical grade, 90%) as the starting material.

Results

Y-tube Bioassays with Odors from Live Insects, or Insect Extracts Sexually mature females were significantly attracted to odors from live males in Y-tube bioassays (Fig. 1). Males were also significantly attracted to odors from other males. In contrast, odors from live females were not attractive to either sex (Fig. 1).

Crude extracts of male-produced odors were significantly more attractive to female *M. histrionica* than a solvent control (Fig. 2). Fractionation of the extract and bioassay of the fractions showed that the fraction containing the male-specific component (eluted from the silica gel cartridge with the first aliquot of 100% ether) was attractive to females (Fig. 2), whereas the recombination of the remaining seven fractions appeared to be repellent (Fig. 2). In a follow-up bioassay, the active fraction was as attractive as

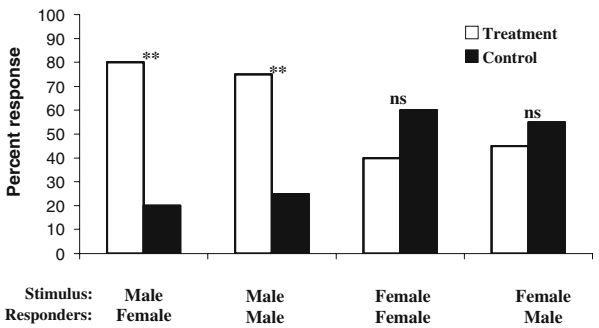

Fig. 1 Results of vertical Y-tube bioassays that tested attraction of sexually mature virgin *Murgantia histrionica* to odors from live, sexually mature virgin conspecifics on a cauliflower floret vs odors from a cauliflower floret control (N=24). Data were analyzed with χ^2 tests. **P<0.001; *ns* not significant, P>0.05

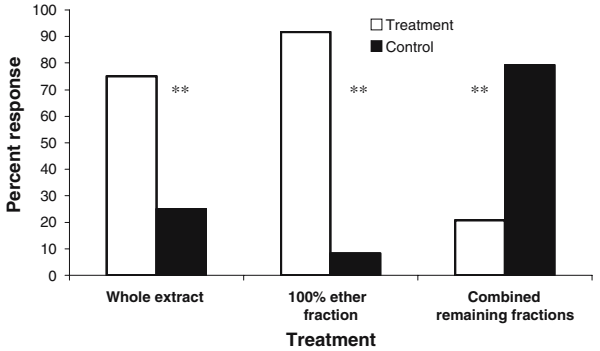

Fig. 2 Results of vertical Y-tube bioassays testing attraction of sexually mature, virgin female *Murgantia histrionica* to fractions of an extract of odors from *M. histrionica* males vs a solvent control (N=24). Each experiment was analyzed with χ^2 test. **P<0.001

the crude extract (N=24, χ^2=0.22, P>0.05), suggesting that the fraction containing the male-specific compound, and possibly the compound itself, may be responsible for all the attractiveness of the extract.

Production of the Male-Specific Compound by Individual Males or Males in Groups Males that were aerated individually, or in groups of only five, produced more murgantiol per bug than males aerated in groups of ten or more (Fig. 3). Individual bugs and bugs aerated in groups of five produced the male-specific compound at similar rates (Games–Howell test, P=0.41; Games and Howell 1976).

Diurnal Cycle of Pheromone Production The production of the male-specific compound followed a defined diurnal cycle (Fig. 4), with production increasing from midmorning and peaking in the early afternoon.

Analysis of Extracts of Odors from Adult Bugs Typical gas chromatograms of extracts of odors from groups of 10–15 sexually mature, virgin adult bugs of both sexes are shown in Fig. 5. Several compounds appeared in extracts from both females and males, including dodecane, dimethyldisulfide, dimethyltrisulfide, *S*-methylmethanethiosulfonate, myrcene, limonene, and cineole. With the exception of *S*-methylmethanethiosulfonate, for which a standard was not available, the identifications of these compounds were verified by comparison of their retention times and mass spectra with those of authentic standards. Myrcene, limonene, and cineole were also found in cauliflower odor controls, whereas the sulfur-containing compounds were only seen in the insect odor extracts.

Comparison of extracts collected from sexually mature virgin males and females (>14 day old) by gas chromatography (Fig. 5) revealed the presence of two male-specific compounds. The first was identified by retention time and

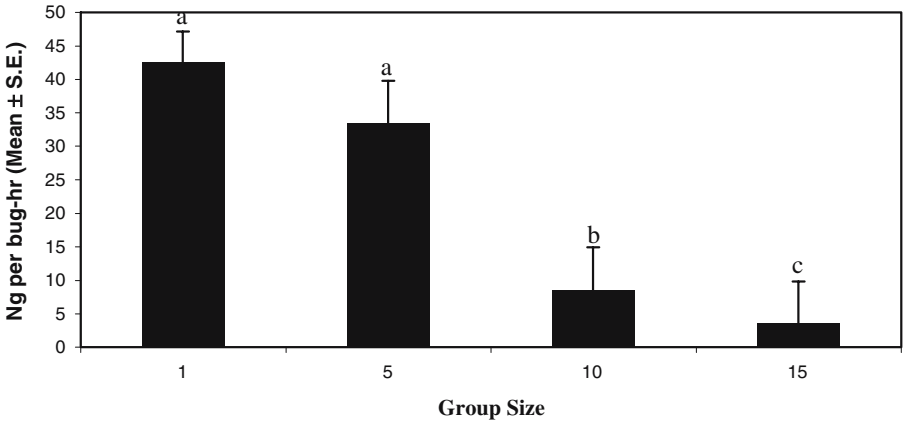

Fig. 3 Production of the male-specific compound by groups of different numbers of *Murgantia histrionica* virgin males. One-way ANOVA for group size, $F=11.48$, $df=3$, $P<0.001$. Bars surmounted by the same letter are not significantly different (Games–Howell test, $P<0.05$)

mass spectral matches as tridecane, a common component of stink bug odors (e.g., Ho and Millar 2001a, b). The second compound (Kovats index, KI, 1743 on DB-5 column; Kovats 1965) was not found in aerations of sexually immature males, nor was it a component of the frothy defensive emissions (2-*sec*-butyl-3-methoxypyrazine and 2-isopropyl-3-methoxy-pyrazine; (Aldrich et al. 1996)) or one of the two components reported from the metathoracic glands of male bugs ((2*E*,6*E*)-octadienedial and (2*E*,6*E*)-octadien-1,8-diol diacetate; Aldrich et al. 1996). The spectrum also gave no meaningful matches with any literature spectra in the NBS-NIH mass spectral database.

Electron impact ionization GC-MS analysis (70 eV) of the compound gave an apparent molecular ion at $m/z=220$, with an ion at $m/z=202$ probably due to loss of water (Fig. 6), for a possible molecular formula of $C_{15}H_{24}O$. The base peak at m/z 93 suggested a methylcyclohexadiene fragment. The spectrum bore some similarity to the mass spectra of sesquiterpenoids, and the overall complexity of the spectrum suggested that the compound was not aromatic. Based upon comparison of the retention indices of known compounds with the KI for the *Murgantia* compound, it seemed unlikely that the molecular weight was actually 220 amu. For example, the bisabolene epoxide pheromone components ($m/z=220$) of *Nezara viridula* and *Acrosternum hilare* had retention indices on a DB-5 GC column of 1609 (*trans* isomer) and 1616 (*cis* isomer) vs the *Murgantia* compound with KI 1743. Thus, we suspected that the loss of 18 amu from $m/z=220$ to give an ion at $m/z=202$ in the 70 eV EI mass spectrum of the *Murgantia* compound was not the first loss of water but the second, and that the actual molecular ion at m/z 238, corresponding to a molecular formula of $C_{15}H_{26}O_2$, was too unstable to be seen under EI-MS conditions. This molecular formula requires three rings or sites of unsaturation. A molecular ion at m/z 238 also was not observed with chemical ionization mass spectrometry (NH_3 reagent gas) using a direct insertion probe.

Microchemical tests provided further information. The compound did not react with the dienophile 4-methyl-1,2,4-triazoline-3,5-dione, ruling out the presence of a conjugated diene. The compound was not changed by treatment with NaOH in aqueous alcohol (ruling out an ester), by acetyl chloride and pyridine in ether (ruling out primary and

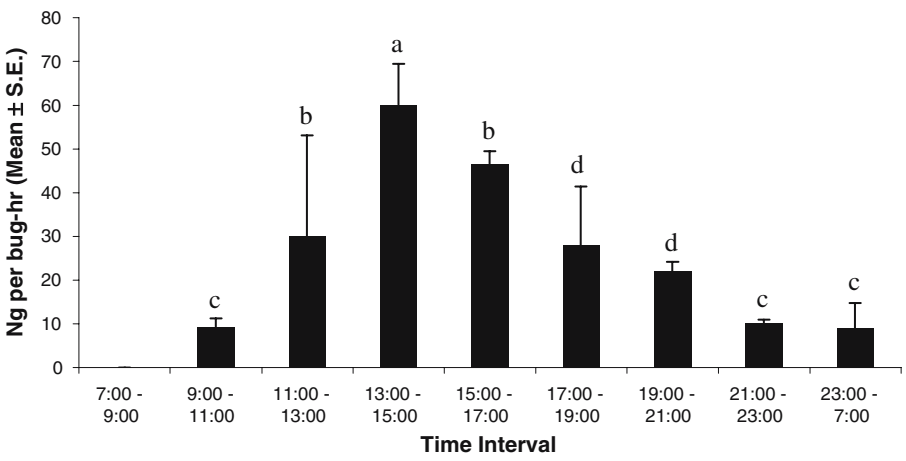

Fig. 4 Diurnal rhythm of release of the male-specific compound by *Murgantia histrionica* males ($N=5$ cohorts). Two-way ANOVA for cohort effect, $F=3.08$, $df=4, 39$, $P=.03$; for time interval effect $F=107.1$, $df=7, 39$, $P<0.001$. Bars surmounted by the same letter are not significantly different (Student–Newman–Keuls test, $P<0.05$)

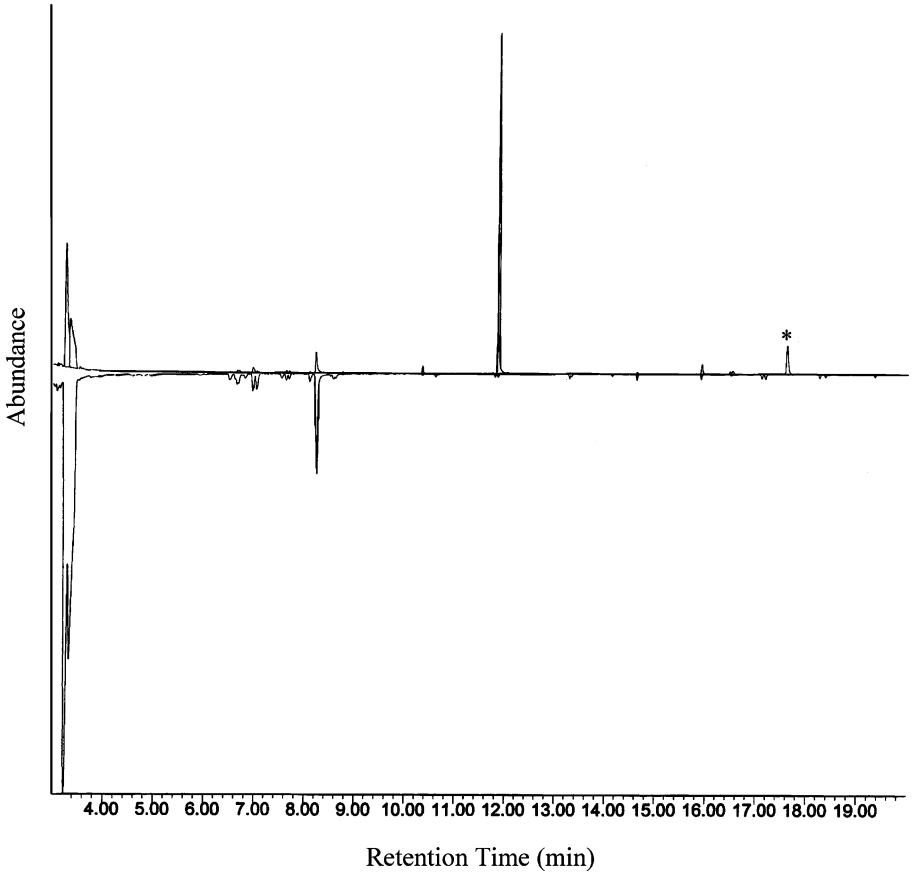

Fig. 5 Representative gas chromatograms of crude extracts (males on top, females on bottom) from sexually mature adult *Murgantia histrionica*. Murgantiol is indicated with an *asterisk*. The large peak in the male extract is tridecane

secondary alcohols), or by treatment with $LiAlH_4$ at room temperature (ruling out aldehydes, ketones, or esters). This suggested that the two postulated oxygen functionalities were probably present as ethers or tertiary alcohols. The presence of at least one polar functional group was suggested by fractionation of the crude extracts on silica gel: the compound appeared in the first fraction eluted with 100% diethyl ether.

Reduction of the compound by catalytic hydrogenation gave a mixture of compounds with apparent molecular

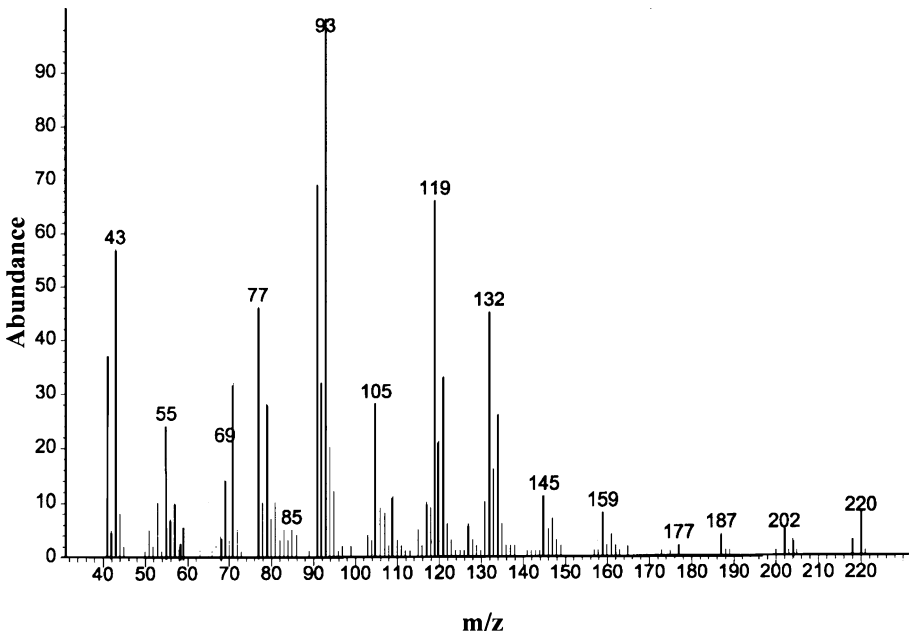

Fig. 6 Electron impact ionization (70 eV) mass spectrum of the *Murgantia histrionica* male-specific compound (murgantiol)

weights of 224 or 226 by EI GC-MS, corresponding to loss of water from the actual molecular ions, indicative of two or three double bonds or other functionalities susceptible to catalytic hydrogenation. Most of these derivatives had a base peak or large fragment at *m*/*z* 95 or 97, suggestive of a methylcyclohexane substructure, such as that found in bisabolane-type sesquiterpenoids. Furthermore, males of several stinkbug species are known to produce pheromones with bisabolene skeletons, such as the bisabolene epoxides from *Nezara viridula* (Aldrich et al. 1987; Baker et al. 1987) and *Acrosternum hilare* (McBrien et al. 2001), zingiberene and sesquiphellandrene from *Thyanta* spp. (McBrien et al. 2002), and zingiberenol from *Tibraca limbativentris* (Borges et al. 2006). In total, the evidence supported a bisabolene-type sesquiterpenoid structure, with two oxygens present as ethers or tertiary alcohols.

With this fragmentary information about the possible structure of the unknown, crude aeration extracts from multiple cohorts of virgin males were combined to obtain sufficient material (>100 μg) for NMR analysis, and fractionated by liquid chromatography. The fraction enriched in the male-specific compound was concentrated, and taken up in CD_2Cl_2 rather than the usual $CDCl_3$ solvent to avoid possible decomposition of the sample by the traces of DCl commonly found in $CDCl_3$.

The ^{13}C spectrum showed the expected fifteen carbons (Table 1). The three carbons with chemical shifts between δ 58.5 and 67.6 ppm were in the correct position for carbons with an attached oxygen, indicating that one of the two oxygens was bonded to two carbons as a straight-chain or cyclic ether. The two carbons at 134.2 and 134.3 ppm were in the correct range for alkene carbons, indicative of a single C–C double bond and, by default, indicating that there were two rings in the structure. The ten other carbons ranging from 16.1 to 41.2 ppm were within the expected range for aliphatic carbons with no directly attached heteroatoms (Table 1).

A DEPT experiment, in combination with HSQC data (see below) confirmed that there were four methyl carbons (δ 16.1, 19.0, 25.2, and 30.1), four methylene carbons (δ 20.7, 27.7, 31.3 and 37.8), five methine carbons (δ 37.1, 41.2, 64.9, 134.2, and 134.3), and two quaternary carbons (δ 58.5 and 67.6) (Table 1). The fact that both alkene carbons were methines showed that the single alkene present was 1,2-disubstituted. Combining the information from the ^{13}C and DEPT experiments suggested the presence of a tertiary alcohol (67.6 ppm) and a trisubstituted epoxide (δ 64.9 and 58.5), accounting for all three carbons bonded to oxygens and one ring. It was noteworthy that treatment with $LiAlH_4$ during the microchemical tests did not open

Table 1 Summary of ^{13}C and ^{1}H NMR spectral data from the male-specific compound from *Murgantia histrionica*

Carbon Number	^{13}C (ppm)	^{1}H, ppm (*J*)	^{1}H-^{1}H COSY	HMBC Correlations	NOESY Correlations

For the ^{13}C data, the number of protons attached to each carbon is indicated in parentheses. For the ^{1}H data, the splitting pattern and the coupling constants (*J*) in hertz are indicated in parentheses. The assignments of protons to specific carbons were confirmed with an HSQC experiment.
[a] Extensive overlap prevented conclusive assignment of signals.
[b] Four peaks instead of two were seen in the HSQC, at 1.56, 1.46, 1.35, and 1.25 ppm.

the epoxide ring, presumably due to the mild conditions used.

This also confirmed the presence of the two postulated oxygens and, with the evidence for 15 carbons, the likely molecular weight of 238 amu and molecular formula of $C_{15}H_{26}O_2$. Thus, the single remaining site of unsaturation had to be a second ring which, from the mass spectral and NMR data, was probably a methyl-substituted cyclohexene with one oxygen attached as a tertiary alcohol.

The ^1H spectrum corroborated much of the above information (Table 1). There were three, three-proton singlets at 1.23, 1.23, and 1.27 ppm, from three methyl groups attached to quaternary carbons. The fourth methyl group appeared as a doublet at 0.85 ppm, indicative of a methyl group attached to a tertiary carbon. There was a one-proton triplet at 2.66 ppm (J=6.6 Hz), consistent with a proton attached to an epoxide carbon, and a possible allylic hydrogen as a complex multiplet centered around 2.04 ppm. The alkene configuration was *Z*, based on the coupling constant (10.2 Hz) between the two broadened single-proton doublets at 5.65 and 5.61 ppm. The remaining protons were accounted for by overlapped multiplets between about 1.6 and 1.25 ppm.

The ^1H-^1H COSY spectrum indicated that the two alkene hydrogens (5.61 and 5.65 ppm) on C_2 and C_3, respectively, were coupled to each another, as expected. The possible allylic proton (2.04 ppm) on C_1 was coupled to one of the two protons on C_6 (~1.46 ppm). The single epoxide proton (2.66 ppm) on C_{10} was correlated with the two protons on C_9 in the overlapped multiplets between 1.47–1.60 ppm, and one of the two protons on C_5 (1.80 ppm) was coupled with multiple protons in the overlapped 1.47–1.60 ppm range.

Further information on connectivity through two and three bonds was obtained from the HMBC experiment (Table 1). The HMBC experiment showed correlations between the quaternary C_4 (67.6 ppm) and the alkene proton H_3 (5.65 ppm), the methyl protons at 1.23 ppm (H_{15}), and one of the protons (1.80 ppm) of the C_5 methylene carbon at 37.8 ppm, indicative of a tertiary allylic alcohol flanked by a CH_2 group. The H_5 proton at 1.80 ppm showed a further correlation to the C_6 methylene carbon at 20.7 ppm. To finish establishing the connectivity within the cyclohexene ring, the remaining olefin proton at 5.61 ppm on C_2 was correlated with the ring junction carbon C_1 at 41.2 ppm and with the methylene carbon at C_6.

The epoxide carbons at 64.9 and 58.5 ppm showed interactions with protons of two methyl groups (singlets) at 1.23 (H_{13}) and 1.26 (H_{12}) ppm, with the two methyl groups being directly bonded to the C_{11} quaternary carbon (58.5 ppm), confirming the trisubstituted epoxide fragment in the side chain. The epoxide proton H_{10} at 2.66 ppm was correlated with the C_9 methylene carbon at 27.7 ppm. The methyl protons at 0.85 ppm (H_{14}) showed correlations with C_1 (41.2 ppm), C_7 (37.1 ppm), and C_8 (31.3 ppm), establishing the rest of the connectivity in the side chain, and between the side chain and the ring junction.

The NOESY spectrum (summarized in Table 1) provided further corroboration of several parts of the structure, with correlations between the epoxide proton and the adjacent methylene protons and the C_{12} methyl, between one of the protons (1.80 ppm) on C_5 and the C_{15} methyl group, between the alkene proton H_2 at 5.61 ppm and the bridgehead proton on C_1 (2.04 ppm), and between the bridgehead proton H_1 and the C_{14} methyl.

In total, the evidence unequivocally supported the bisabolane-type skeleton shown in Fig. 7, with one double bond in the cyclohexene ring, a tertiary alcohol at position 4 of the ring, and a trisubstituted epoxide in the side chain. This structure has four chiral centers, for a total of 16 possible isomers. The gross structure was confirmed by synthesis as described below but, to date, we have not been able to assign unequivocally the relative and absolute configurations of the insect-produced compound, henceforth referred to as murgantiol.

Synthesis of Murgantiol (Scheme 1) Because it was not possible to determine the relative stereochemistry of the insect-produced murgantiol, a short synthetic route was developed that would produce all possible stereoisomers of the compound, one of which should then match the natural

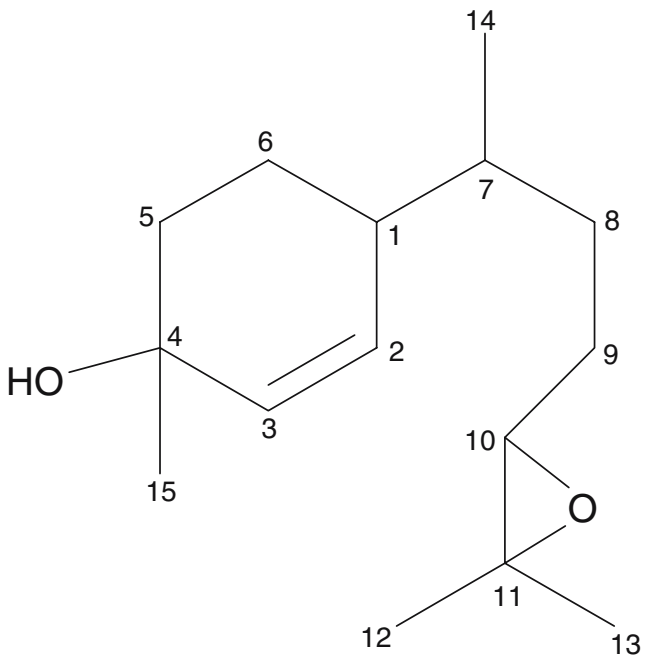

Fig. 7 Structure of murgantiol

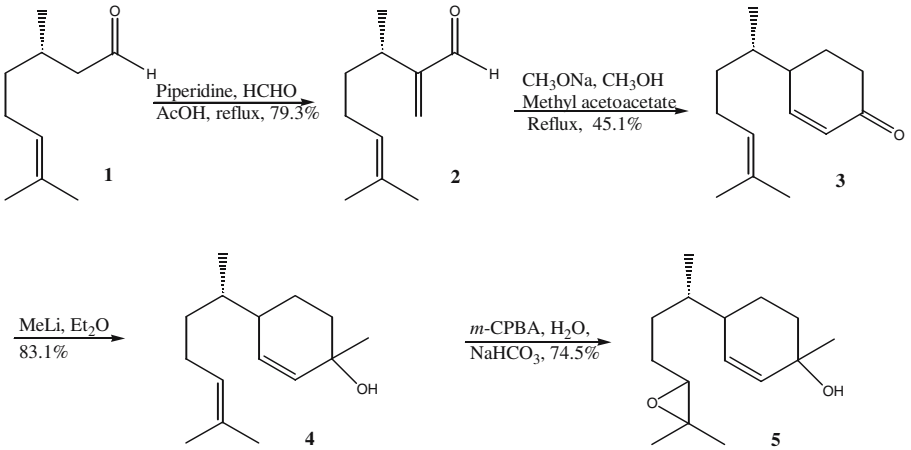

Scheme 1 Synthesis of murgantiol as a mixture of diastereomers, from (*S*)-citronellal

compound (Scheme 1). Citronellal, available in both enantiomeric forms, was chosen as the starting material, so that one chiral center in the molecule would be known. Two parallel syntheses were carried out, using (*R*)- and (*S*)-citronellal as starting materials, respectively, to ensure that all 16 possible stereoisomers would be represented. Thus, citronellal 1 was converted into α,ß-unsaturated aldehyde 2 by α-methylenation with formaldehyde (79.3% yield) (Chavan et al. 1997). Treatment with methyl acetoacetate and sodium methoxide then produced the 4-(1,5-dimethyl-hex-4-en-1-yl)cyclohex-2-en-1-one 3, presumably by conjugate addition followed by an aldol condensation, as a mixture of diastereomers (~1:1, determined by NMR) at the ring junction (Chavan et al. 1997). The mixture was not resolved on capillary GC (DB-5). Addition of methyl lithium to enone 3 afforded a mixture (38:62 – less/more polar isomer) of diastereomers of alcohol 4 in 83.1% yield (Hagiwara et al. 2002). The diastereoisomeric mixture was separated by flash chromatography into two fractions, and both were epoxidized individually with buffered *m*-chloroperbenzoic acid. Each diastereomeric mixture thus yielded a further mixture of diastereoisomeric epoxyalcohols 5. NMR and mass spectra, and GC retention times on two columns (DB-5 and DB-Wax) of the epoxidation products 5 were compared with those of the insect-produced compound. One of the stereoisomers in the product mixture 5, from epoxidation of the less polar, higher Rf diastereomer of 4, matched the retention times of the insect-produced compound on DB-5 and DB-Wax GC columns. Comparisons of the mass, ^{1}H, and ^{13}C NMR spectra of the synthetic mixture from the less polar alcohol 4 with the natural pheromone gave good agreement, confirming the gross structure of the insect-produced compound as one of the stereoisomers of 4-[3-(3,3-dimethyloxiran-2-yl)-1-methylpropyl]-1-methylcyclohex-2-en-1-ol (5). The relative and absolute stereochemistry of the insect-produced compound remain to be determined.

Bioassays of Synthetic Murgantiol The mixtures of murgantiol diastereomers prepared from (*R*)- and (*S*)-citronellal were both attractive to female bugs in Y-tube bioassays. Thus, 21 of the 24 females tested were attracted to murgantiol derived from (*S*)-citronellal vs three females attracted to the crude extract control (χ^2 test, $P<0.001$), whereas 18 of 24 females tested were attracted to murgantiol derived from (*R*)-citronellal vs the control (χ^2 test, $P<0.014$). When the mixtures of murgantiol diastereomers derived from (*R*)- and (*S*)-citronellal were tested against one another, 17 of 24 females tested were attracted to the mixture derived from (*S*)-citronellal (χ^2 test, $P<0.04$). Similarly, when these mixtures were tested against each other with sexually mature virgin males as the responding animals, 19 of 24 males tested were attracted to the mixture derived from (*S*)-citronellal (χ^2 test, $P<0.004$).

Discussion

Both female and male bugs were attracted to odors from live males in Y-tube bioassays, indicating that mature males produce an aggregation pheromone, as previously observed for other phytophagous stink bug species including *Nezara viridula* (Harris and Todd 1980), several *Euschistus* spp. (Aldrich et al. 1991), *Biprorulus bibax* (James et al. 1994), and *Plautia stali* (Moriya and Shiga 1984; Sugie et al. 1996). In contrast, two other pentatomid species [*Thyanta pallidovirens* (Millar 1997) and *Acrosternum hilare* (McBrien et al. 2001)] have been reported to produce compounds attractive to females only.

Single males released significantly more murgantiol than males aerated in groups of ten or more, suggesting that males in groups may detect each other's presence influencing their release of pheromone. An analogous situation was recently reported for the predatory stink bug *Eocanthecona furcellata*, with single individuals producing orders of

magnitude more pheromone than groups of bugs (Ho et al. 2005). Although the full biological significance of these results has not been determined, for practical purposes, they suggest that collection of pheromone from individual bugs or small groups of bugs will be most efficient for analysis or identification of the pheromone.

The quantity of pheromone released peaked between 13:00–15:00, mirroring the peak of reproductive activity of the bugs (Zahn et al. 2007). Murgantiol was detected throughout most of the 24 h-sampling period, but the pattern of release suggested that the compound was released primarily during the photophase. The small amounts of murgantiol detected during the scotophase may have been due to the slow release of murgantiol absorbed in the insects' cuticular lipids or on the glass walls of the aeration chamber. Insects of both sexes were dissected to look for possible pheromone glands, but no obvious macroscopic male-specific glands that may be the site of pheromone production were found. Other phytophagous pentatomid species produce pheromones from sex-specific unicellular glands on the ventral surface of the abdomen (Pavis and Malosse 1986; Lucchi 1994).

The diurnal peak in pheromone production also corresponded with the general activity cycle of the insect. *M. histrionica* are aposematic, with effective chemical defenses, which protect them from predation during daylight hours (Aliabadi et al. 2002). Unlike other stink bug species that are heavily parasitized by Diptera and Hymenoptera which use the bugs' pheromone for location, no parasitoids of nymphal and adult *M. histrionica* are known, although there are several egg parasitoids (Chittenden 1920; Mitchell and Mau 1971; Ludwig and Kok 1998; Amarasekare 2000; Millar et al. 2001). For other phytophagous pentatomids, the majority of reproductive activity occurs in the late afternoon or around dusk, which allows them to evade predation or parasitization, and to avoid unfavorable temperature conditions. In particular, the risk of desiccation may limit the activity period of bug species such as *Thyanta* spp., *Nezara viridula*, and *Chlorochroa* spp., that typically feed on seeds rich in oils and proteins but with little water content (Hall and Teetes 1982; Panizzi et al. 1995; Wang and Millar 1997; Zalom et al. 1997; Ho and Millar 2001a, b; Nuessly et al. 2004; Numata 2004). In contrast, *M. histrionica* typically feeds on a wide range of plant tissues that are high in water, and thus the risk of desiccation through being active during the hottest part of the day is probably low.

Murgantiol contains four chiral centers at carbons 1, 4, 7, and 10 (Fig. 7), for a total of 16 possible stereoisomers (eight diastereomeric pairs of enantiomers). Although we have been able to match the insect-produced compound to a component in a synthetic blend of stereoisomers, we have not yet determined which isomer this is. The difficulty in trying to determine exactly which stereoisomer the bugs produce was exacerbated by our synthesis of murgantiol not being stereoselective. We separated alcohol mixture 4 into two fractions, each containing two stereoisomers, with the alcohol in either the axial or the equatorial orientation. However, after epoxidation of each of these fractions, we were unable to separate the resulting mixtures, which may contain as many as four stereoisomers, varying in the configurations of C_1 at the ring junction and C_{10} in the side chain. Similar problems have been reported in the separation of diastereomers of less functionalized, but related, sesquiterpenes such as zingiberene and its ring junction epimer (Breeden and Coates 1994). Furthermore, because the epoxide in murgantiol is several carbons removed from the other chiral centers in the molecule, diastereomers differing only in the configuration of the chiral epoxide carbon might not be expected to separate easily by chromatographic methods. It is also noteworthy that epoxidation under buffered conditions at 0°C (Fringuelli et al. 1992) was highly selective for the trisubstituted double bond in the sidechain rather than the 1,2-disubstituted double bond in the cyclohexene ring.

The exact identification of the insect-produced compound was further complicated by the HSQC spectrum showing four, rather than two, signals from the protons on C_9, as well as several very close, paired signals from carbons in the 1D ^{13}C spectrum, suggesting that the molecule may exist as more than one conformer. It seems less likely that two isomers are present because of the clarity of the ^{1}H signals in the 1D proton spectrum, and only the protons on a single carbon gave an HSQC signal that appeared anomalous.

Several interesting points emerged from the bioassays of the insect extracts and of the synthetic murgantiol mixtures. First, the insect fraction containing murgantiol was as attractive as crude extract, whereas the mixture of the remaining fractions was repellent. This suggests that the crude extract may contain defensive compounds or other repellent stimuli, the effects of which are overcome when murgantiol is present. Second, test bugs responded to the synthetic mixtures of murgantiol isomers, indicating that the bugs were not deterred by the presence of stereoisomeric impurities in the blends. Remarkably, the insects also responded to synthetic murgantiol mixtures prepared from either enantiomer of citronellal. Whether this result was an artifact of testing mixtures of stereoisomers, some of which are attractive, or indicative of a general response to all stereoisomers, will only be resolved when the pure stereoisomers are available for testing.

The structural similarity between murgantiol and a number of other sesquiterpenoid pheromones isolated from various pentatomid species is noteworthy. For example, epoxides of bisabolene constitute the male-produced pher-

omone components of *Nezara viridula* (Aldrich et al. 1987; Baker et al. 1987) and *Acrosternum hilare* (McBrien et al. 2001), and zingiberene and sesquiphellandrene form part of the pheromone blend of several *Thyanta* spp. More recently, zingiberenol 4 (the penultimate intermediate in our syntheses of murgantiol, Scheme 1), has been identified from males of the rice stalk stink bug, *Tibraca limbativentris* (Borges et al. 2006). As with murgantiol, the relative configuration of this compound, which has three chiral centers and hence eight possible stereoisomers, has yet to be determined. Thus, the bisabolane skeleton is emerging as a recurring structural motif among pheromones of stink bugs.

Although we do not know which stereoisomer of murgantiol is produced by male harlequin bugs, for practical purposes, it is convenient that the bugs respond to mixtures of the murgantiol isomers, which are relatively easy to synthesize. Thus, it should be possible to proceed to field trials with the impure "technical grade" murgantiol, to determine the potential for use of this compound in developing pheromone-based monitoring methods for this pest.

Received: 28 June 2007 / Revised: 12 October 2007 / Accepted: 29 October 2007 / Published online: 15 January 2008

Abstract Alkaloid profiles for 81 individual mantellid frogs, *Mantella baroni* (Boulenger 1988) (*N*=19), *M. bernhardi* (*N*=51), and *M. madagascariensis* (Grandidier 1877) (*N*=11), from six different populations from Madagascar were examined. Marked individual differences in alkaloid composition (number, type, and amount) were observed between different species and between populations of the same species. Disjunct populations of each of the three species differed significantly in alkaloid composition. Sympatric populations of *M. baroni* and *M. madagascariensis* also differed significantly in alkaloid composition. In *M. bernhardi*, differences in alkaloid composition were marginally associated with different sexes. A total of 111 alkaloids, including isomers, were detected in analysis of the individuals from the three species. The majority (47%) appear likely to be obtained from dietary mites, whereas many of the others (18%) are presumed to be from ants, and a few (4%) are from millipedes. Putative dietary sources for the remaining alkaloids are generally unknown, but beetles are probably the source of at least some of the tricyclic alkaloids (6%). In addition, alkaloid compositions from extracts of groups of individuals from five additional populations of *M. baroni* and from one population of *M. bernhardi* (Vences et al. 1994) and one population of *M. cowanii* (Boulenger 1882) were examined. An additional 50 alkaloids, including isomers, were detected in the combined samples, bringing the total number of alkaloids identified from these four species of mantellid frogs to 161. Alkaloid compositions in mantellid poison frogs are diverse and highly dependent on geographic location that appear to be largely determined by the nature and availability of alkaloid-containing prey items.

Introduction

The wide variety of lipophilic alkaloids present in skin extracts of poison frogs of the Neotropics (Dendrobatidae), subtropical South America (Bufonidae, *Melanophryniscus*), and Madagascar (Mantellidae, *Mantella*) appears to be directly sequestered from dietary arthropods (Daly et al. 1994a, b, 1997; Daly 1998). The putative arthropod sources of such alkaloids are as follows: (1) The widespread pumiliotoxins (PTXs) appear to be derived from oribatid mites (Takada et al. 2005; Saporito et al. 2006, 2007a), although two such PTX alkaloids have been reported from Panamanian formicine ants (Saporito et al. 2004). (2) The several classes of izidines with branch points in their carbon skeleton also appear likely to be derived from oribatid mites (Takada et al. 2005; Saporito et al. 2006, 2007a). However, one such izidine, a 5,8-disubstituted indolizidine, has been reported from a Madagascan myrmicine ant (Clark et al. 2005). (3) The izidines without branch points in their carbon skeleton appear to be derived from myrmicine ants, as are (4) the unbranched pyrrolidines and piperidines (Jones et al. 1999). Recently, two unbranched 3,5-disubstituted pyrrolizidines were reported from a formicine ant, and a different 3,5-disubstituted pyrrolizidine was reported from a ponerine ant (Clark et al. 2006). A 2,5-disubstituted pyrrolidine also was reported from the same species of formicine ant (Clark et al. 2006). In addition, one unbranched 3,5-disubstituted indolizidine and two unbranched pyrrolidines have been detected in oribatid mites (Saporito et al. 2007a). It seems likely that the ultimate source of alkaloids with branching in the carbon skeletons will be oribatid mites and the source of those with unbranched structures will be myrmicine ants (Saporito et al. 2007a). (5) Spiropyrrolizidine alkaloids appear to be derived from siphonotid millipedes (Saporito et al. 2003; Clark et al. 2005); however, one such alkaloid was recently reported from an oribatid mite (Saporito et al. 2007a). (6) Tricyclic alkaloids, such as precoccinelline, appear to be derived from coccinellid beetles (Daloze et al. 1995); however, precoccinelline and other tricyclic alkaloids were also recently reported from oribatid mites (Takada et al. 2005; Saporito et al. 2007a).

Variation in alkaloid composition (the number, type, and amount) within and among species has been reported for Neotropical dendrobatid poison frogs (Myers and Daly 1976; Daly et al. 1987, 1992, 2000, 2002; Myers et al. 1995; Saporito et al. 2006, 2007b), bufonid poison frogs (Garraffo et al. 1993a; Mebs et al. 2005; Daly et al. 2007), and mantellid poison frogs (Garraffo et al. 1993b; Daly et al. 1996; Clark et al. 2005, 2006). Individual variability in alkaloid composition has been reported for dendrobatids (Daly et al. 1994a; Myers et al. 1995; Saporito et al. 2006), bufonids (Mebs et al. 2005; Daly et al. 2007), and mantellids (Clark et al. 2006). The literature indicates that alkaloid compositions are strongly dependent on geographic location and that compositions change with time. Differences in habitat among locations and changes in habitat over time (succession) are likely responsible for determining the availability of alkaloid-containing prey arthropods, which is reflected as geographic and temporal variation in alkaloid composition of poison frogs (Daly et al. 1987, 1996, 2002; Saporito et al. 2006, 2007b).

This study was designed to provide further insight into the factors that are involved in alkaloid composition variability within and among populations of poison frogs of the mantellid genus *Mantella*. The poison frogs of this genus consist currently of 16 described and, probably, at least one undescribed species that are found in a variety of habitats in Madagascar (Vences et al. 1999; Glaw and Vences 2006). All of these species are small, diurnal frogs that have aposematic coloration, practice microphagy, and accumulate dietary alkaloids that act as a defense against predators (Daly et al. 1996, 1997; Vences and Kniel 1998; Vences et al. 1998; Schaefer et al. 2002). Alkaloid compositions have been reported for 11 of the species (see Garraffo et al. 1993a; Daly et al. 1996; Clark et al. 2005, 2006). In this paper, we report our findings of individual alkaloid composition for 81 individuals, comprising six populations of three different species of *Mantella* from Madagascar (*Mantella baroni* of the *M. cowanii* group, *M. madagascariensis* of the *M. madagascariensis* group, and *M. bernhardi*, the sole member of the *M. bernhardi* group [Pintak et al. 1998; Vences et al. 1999, 2004]). Individuals were sampled from two sympatric populations of *M. baroni* and *M. madagascariensis* and from two geographically distant populations of *M. bernhardi*. Profiles of the major, minor, and trace alkaloids are presented for the 81 individuals. In addition, we also report on a number of extracts from groups of *M. baroni*, *M. bernhardi*, and *M. cowanii*. Alkaloid composition for mantellid frogs was examined for possible relationships with geographic location (habitat), species, size, and sex. Geographic location (and associated habitat) appears to be the primary determinant of variation in alkaloid composition; however, differences among sympatric species were also observed.

Methods and Materials

Mantellid Frog Collections—Individual Frog Analyses A total of 81 mantellid frogs of three species were collected: *M. baroni* (*N*=19), *M. bernhardi* (*N*=51), and *M. madagascariensis* (*N*=11). Each of the three species was collected at two different locations (Fig. 1), and therefore, a total of six different populations were examined. All frogs sampled from one site were usually collected during the same day, sometimes during a time span of 2–3 days, by opportunistic searching that involved observation and removal of leaf litter and low vegetation or by precisely targeting calling males, especially in the case of *M. baroni*. All frogs were collected on relatively small plots of a maximum of 0.5 ha, often much smaller. For instance, all *M. bernhardi* from Vevembe were found within an area of 20×20 m and all *M. madagascariensis* from Ranomafana within an area of 10×10 m, in a small degraded area under *Eucalyptus* trees near primary rainforest.

Individual frogs were sexed and measured for snout-to-vent length (SVL) to the nearest 0.1 mm. Collection localities included Ranomafana, a relatively large National Park in southeastern Madagascar, which contained several specific collecting localities for *Mantella* (e.g., Ranomafanakely, Mangevo, Vatoharanana, Vohiparara; Fig. 1). Individual skin extracts reported herein to originate from Ranomafana all came from a specific collection site, locally known as "Ranomafanakely," along National Road 45 from the village of Vohiparara toward the town of Fianarantsoa. The combined skin extracts reported herein to originate from Vohiparara came from the Kidonavo Bridge. Besariaka is located far to the north of Ranomafana, whereas Manombo and Vevembe are far to the south (Fig. 1). At two sites, *M. baroni* and *M. madagascariensis* were collected in syntopy. At Ranomafana, *M. madagascariensis* was found close to the road in a tiny patch of degraded forest dominated by *Eucalyptus* spp., whereas *M. baroni* was found at a distance of less than 50 m in primary rainforest. At Besariaka, the two species were fully mixed and, apparently, were using exactly the same microhabitat.

Collection dates and the total number of frogs sampled at each location are provided in table headings. The global positioning system (GPS) coordinates and nature of each site and voucher identification numbers are tabulated in the Supplementary Information. Voucher specimens are deposited at the Zoological Museum Amsterdam, the Université d'Antananarivo, Département de Biologie Animale (UADBA), and the Zoologische Staatssammlung München.

Mantellid Frog Collections—Combined Frog Analyses In January–February, 2003, 29 mantellid frogs from three species, *M. baroni* (*N*=19), *M. bernhardi* (*N*=8), and *M.*

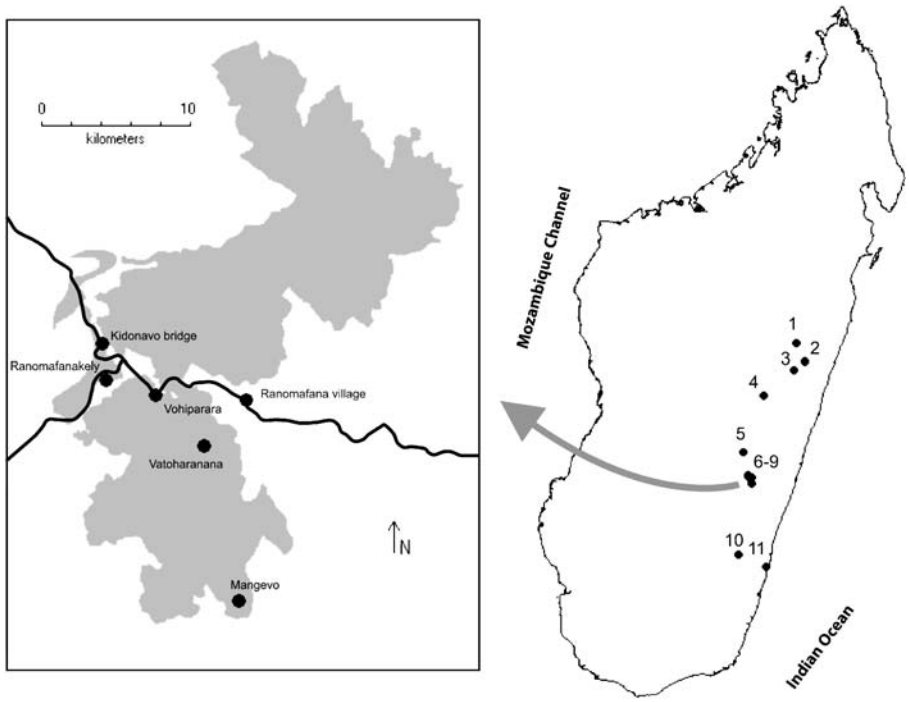

Fig. 1 Map of localities in Madagascar where *Mantella* frogs were collected including Andriabe (*1*), Vohindrazana (*2*), Besariaka (*3*), Tsinjoarivo (*4*), Antoetra (5), Vatoharanana (*6*), Vohiparara (*7*), Mangevo (*8*), Ranomafanakely (*9*), Vevembe (*10*), and Manombo (*11*). The *map on the left* shows detailed geographical location of localities 6–9. Ranomafana National Park is indicated in *gray*

cowanii (*N*=2), were also collected for extracting alkaloids from samples of pooled individuals. *M. baroni* was collected from five different populations, whereas *M. bernhardi* and *M. cowanii* were collected from one population each (Fig. 1). Individual frogs of the same species from each site were combined for alkaloid analyses, and therefore, alkaloid composition is based on combined skin samples. Collection dates and the total number of frogs sampled at each location are provided in table headings. The GPS coordinates and nature of each site are tabulated in the Supplementary Information. Voucher specimens are deposited as described above for the frogs that were extracted individually.

Spectral Analyses A Finnigan–Thermoelectron gas chromatography–mass spectrometry (GC–MS) (GCQ) was used to obtain all mass spectral data reported here. The GC was fitted with a Restek-5MS (Bellefonte, PA, USA) fused silica column (30 m×0.25 mm inside diameter [i.d.], 0.25-μm film thickness) and used a temperature program of 100 to 280°C at 10° per min with a final hold time of 5 min. The injector temperature was 280°C. The carrier (He) flow was controlled at 1 ml/min. The gas chromatography–Fourier transform infrared spectrometry (GC-FTIR) spectral analyses were obtained with an HP-5 (Hewlett-Packard, USA) fused silica-bonded capillary column (25 m× 0.32 mm i.d., ×0.17 μm film thickness) programmed from 100 to 280° at a rate of 10° per min, interfaced with an HP model 5971 Mass Selective Detector and an HP Model 5965B IRD detector (narrow band 4,000–750 cm^{-1}). An HP ChemStation was used to generate MS and FTIR spectra. For additional details of spectral analyses, see Saporito et al. 2006 and 2007b.

Individual Frog Skin Analyses Individual mantellids were examined for alkaloids by using GC–MS. In many cases, chemical ionization-mass spectrometry (ND_3) was used to confirm molecular ions and the number of exchangeable hydrogens. Alkaloids were identified by comparison of spectral and chromatographic properties to previously detected and identified poison frog alkaloids (see Supporting Information of Daly et al. 2005 for a complete listing). The single skin samples were stored in small plastic vials sealed with a silicone rubber O-ring with approximately 0.5–1.5 ml of methanol, which unfortunately led to contamination of each sample with a series of silicone polymers and dibutyl phthalate. Because of the large number of samples examined in this study and the length of time necessary for complete alkaloid partitioning (see below for combined skin analyses), we developed a fairly rapid "semi-purification" of the samples for GC–MS analysis. The method is as follows: To 50 μl of the methanolic frog skin extract, 50 μl of a 0.1 M solution of HCl in methanol was added and swirled well. Then, the methanol was immediately blown off with a stream of nitrogen gas. The HCl in methanol had been prepared by addition of acetyl chloride to methanol, to form a 1 M solution, which was then diluted 1:10 with additional methanol. After evaporation, the residue consisted of hydrochlorides of any frog skin alkaloid and nonvolatile contaminants. It was redissolved in a small volume of methanol, followed by re-evaporation. This process was repeated twice. Then, 50 μl of reagent grade octane was added. The octane was blown off with nitrogen to remove any residual methanol. Then, a small portion of octane was added, swirled with the sample residue, and removed with a pipette, thereby removing the neutral silicones, phthalates, and fatty acid methyl esters (FAMEs). This was repeated twice, and the final traces of octane were removed with a nitrogen stream leaving a whitish residue of amine hydrochlorides. The residue was dissolved in 50 μl of methanol and the vial tightly capped with a Teflon-lined APC (Alltech, Deerfield, IL, USA) cap for later alkaloid analysis. One microliter was injected for the GC–MS analysis (see above). The octane washes were occasionally combined from a group of samples and checked for any dissolved amine hydrochlorides. Traces of the lower molecular weight amine hydrochlorides were detected in some extracts, but the large majority of materials were silicone polymers, dibutyl phthalate, and FAMEs. Each sample could be prepared in less than 10 min. Only one sample was processed at a time to ensure minimum contact between the methanolic HCl and alkaloid mixtures to avoid any acid-catalyzed reactions. We cannot rule out the possibility that some GC peaks represent acid-catalyzed artifacts. To check for possible artifacts, aliquots from each set of individual methanolic skin extracts were combined, and an alkaloid fraction was obtained by the standard partitioning under mild conditions and analyzed (see below). The volumes of the skin extracts varied by a factor of two to three, and no attempt was made to apply a correction, as the weights of frog skin, while probably fairly uniform, were unknown. Thus, quantitation is an approximation, but there were large differences in the overall amounts, ranging in MS total ion currents by 10^2 (see legends to tables). Some samples had no detectable or barely detectable levels of alkaloids. Combined samples consisting of aliquots from all individuals of the same species and collection sites were also subjected to alkaloid partitioning. For example, 50 μl of each individual extract of *M. baroni* from the Ranomafana site was combined for standard alkaloid-partitioning as previously described (Daly et al. 1994a). Such combined samples, much more concentrated than the single skin samples, were used to help establish retention times and alkaloid compositions for the single skin samples as well as an aid in ruling out any

acid-catalyzed reactions potentially occurring during the individual skin protocols. Such artifacts, not detected in the partitioned alkaloid fraction, proved to be rare and minor and are not reported.

Despite the individual skin protocols having problems of not excluding completely neutrals like silicones, phthalates, and FAMEs and possibly generating artifacts arising from the inadvertent acid catalysis of unwanted reactions with methanol, there may be an advantage in retaining very volatile alkaloids by virtue of having converted them to hydrochlorides. Some extracts (no. 113 of Table 3) had low molecular weight alkaloids (e.g., **197D**, **199B**), not observed after using the standard partitioning protocol.

Combined Frog Skin Analyses An alkaloid fraction was prepared from the methanol extract of the combined skins by using the partitioning methodology as described in Daly et al. (1994a, b). The resultant alkaloid fractions were analyzed spectrally by GC–MS and, in some cases, by GC-FTIR [for details of the GC–MS and GC-FTIR spectral analysis, see Saporito et al. (2006, 2007b)].

Statistical Analyses—Individual Frogs Variation in alkaloid composition within and among mantellid populations was visualized graphically by using nonmetric multidimensional scaling (nMDS). In nMDS plots, individuals/populations that have greater similarity in alkaloid compositions will be plotted closer to each other than individuals/populations with very different alkaloid compositions [see Saporito et al. (2006, 2007b) for further examples and discussions on the use of these techniques]. Differences in alkaloid composition among these populations were analyzed with a one-way analysis of similarity (ANOSIM). Alkaloid composition is a simultaneous measure of the number, type, and amount of alkaloids, and therefore, the use of nMDS plots in association with ANOSIM provides a more biologically meaningful view of alkaloid variation in poison frogs as compared to individual analyses of the number and amount of alkaloids. Differences in alkaloid composition between sexes for *M. bernhardi* from Mandombo were also visualized by using nMDS, and differences were analyzed with a one-way ANOSIM. All nMDS plots and ANOSIM results are based on Bray–Curtis dissimilarity matrices. All nMDS and ANOSIM statistical analyses were performed by using the software program PRIMER (version 5; Clarke and Warwick 2001).

Linear regression was used to determine if the total number of alkaloids (a measure of alkaloid diversity) varied with size of the frog (measured as SVL) within and among the three different mantellid species. The statistical program SPSS (version 11.5 for Microsoft Windows) was used to perform these statistical analyses.

Results

A total of 111 alkaloids, including isomers, were identified from skin extracts of individuals of *M. baroni* (*N*=19; Tables 1 and 2), *M. bernhardi* (*N*=51; Tables 5 and 6), and *M. madagascariensis* (*N*=11; Tables 3 and 4). Representatives of all classes of alkaloids noted in "Introduction" were present in at least one species or population (Table 7). Twenty representative alkaloids were detected relatively frequently in this study [Fig. 2, see Daly et al. (2005) for details concerning structures of the more than 800 alkaloids reported to date from alkaloid-containing amphibians]. A total of 82 alkaloids, including isomers, were detected in skin extracts of the combined samples (ranging from one to eight skins per sample) of *M. baroni*, *M. bernhardi*, and *M. cowanii* (Tables 8, 9, 10, and 11). Representatives of all classes of alkaloids noted in "Introduction" were present in at least one species or population (Table 11). Fifty alkaloids that were detected in these combined frog samples, mainly 5,8-disubstituted indolizidines and alkaloids of undefined structure (unclassified alkaloids), were not detected in any of the individual frog samples (cf. Tables 7 and 11). Thus, 161 alkaloids were detected in this study of four mantellid species (Tables 7 and 11).

Previously unreported new alkaloids are indicated by asterisks within the text and tables. Their GC retention times, mass spectral data, and other data are presented in the Supplementary Information. Tentative structures for some of these previously unreported new alkaloids are proposed in the Supplementary Information.

Individual Skin Alkaloid Analyses—M. baroni from Ranomafana Many of the alkaloids identified in 15 skin extracts of *M. baroni* from Ranomafana were of the PTX group (Table 1). The dominant PTX alkaloids in most of the extracts were PTX **251D** and **309A** and homoPTX **265N**. Other alkaloids of the homoPTX class (**251R**, **281K**) were detected in trace amounts. Only one alloPTX was detected (**325A**), which also usually occurred in trace amounts. Several extracts had trace or minor levels of PTX **237A** (a C-15 analog of the C-16 PTX **251D**). A keto-PTX **307F′** (characterized by an enhanced *m*/*z* 194 ion) was detected in most of the extracts, but only as a trace or minor alkaloid. PTX **267C** and deoxyPTX **251H** occurred in skin extracts rarely and usually as trace alkaloids. In addition to alkaloids of the PTX group, many individuals of *M. baroni* from Ranomafana contained significant amounts of 1,4-disubstituted quinolizidines **217A** and **231A**, along with 5,8-disubstituted indolizidine **217B**. The 5,6,8-trisubstituted indolizidine **273A** was present in large amounts in nearly every extract, often accompanied by a minor diastereomer. The PTX group of alkaloids (PTX, alloPTX, and homoPTX) and the branched chain indolizidine and

Probable class and dietary source of each alkaloid are indicated in the headings (see abbreviations).
[a] Sex (*m* male; *f* female, *s* subadult) is indicated.
[b] Total content of alkaloids [major (+++), minor (++), trace (+)] are based upon total ion chromatogram intensities with 10^4 or greater = major, 10^3–10^4 = minor; $\leq 10^3$ = trace. The amounts of each alkaloid in the table are relative to one another in each sample with 3≥50% in relative ion intensity, 2=8–50% relative ion intensity, and 1<8% relative ion intensity. Where two or three intensities are tabulated, two or three isomers are noted, and the intensities are in the order of elution from the GC column. Blanks indicate the alkaloid was not detected.
[c] Alkaloids reported for the first time. See Supplementary Information for characterization.

quinolizidine alkaloids of *M. baroni* from Ranomafana are likely derived from oribatid mites (Saporito et al. 2007a). Izidines with unbranched carbon skeletons, which likely are sequestered from myrmicine ants (Jones et al. 1999), were rare in *M. baroni* from Ranomafana. The only exception was the presence of diastereomers of the 3,5-disubstituted indolizidine **275C**, which were present in all but one individual and often in large amounts. The spiropyrrolizidine **236** of millipede origin (Saporito et al. 2003; Clark et al. 2005) occurred in six of the 15 individuals of *M. baroni* from Ranomafana.

Individual Skin Alkaloid Analyses—M. baroni from Besariaka The skin extracts of four *M. baroni* from Besariaka (all adult males; Table 2) differed from the same species collected from Ranomafana (Table 1). However, alkaloid composition among individuals was again characterized by many alkaloids of the PTX group, including PTXs **251D**, **307F′**, **307G**, and **309A**, which were found in all frogs. No homoPTXs were detected. Two alloPTXs (**323J*** and **325A**) were identified in large amounts in most frogs. Keto-PTXs **307F″** and **307F‴** (characterized by an enhanced *m*/*z* 193 fragment ion) occurred in one extract along with the more common **307F′**. Similar to the *M. baroni* from Ranomafana, frogs from Besariaka contained large amounts of 1,4-disubstituted quinolizidine **217A**. Frogs from Besariaka had a somewhat greater diversity of putative mite izidine alkaloids (*N*=13), as compared to frogs from Ranomafana (*N*=11). The 5,6,8-trisubstituted indolizidine **223A** and dehydro-5,8-disubstituted indolizidine **245F**, both of which are putative mite alkaloids, occurred in three of the four Besariaka frogs. Neither of these two alkaloids was detected in Ranomafana frogs. Putative ant alkaloids in the Besariaka frogs were represented by trace amounts of the 3,5-disubstituted pyrrolizidine **223M** in one frog and by the 3,5-disubstituted indolizidine **251O** in two frogs. Interestingly, the 3,5-disubstituted indolizidine **275C**, common in *M. baroni* from Ranomafana, was not detected in *M. baroni* from Besariaka.

Alkaloid Variation Within and Among Populations of M. baroni As previously documented for *M. baroni* (Daly et al. 1996; Clark et al. 2006), alkaloid composition within and among populations of this species can differ markedly (see Tables 1 and 2 for extracts of individuals from two populations and Tables 8 and 9 for extracts of groups from five populations). Alkaloid compositions among the 15 individual frogs from Ranomafana were more similar to each other than were the compositions of the four individual frogs from Besariaka (see nMDS plot of Fig. 3a). Alkaloid composition of *M. baroni* was significantly different between Ranomafana and Besariaka (Global R=0.99; P<0.001; Fig. 3a).

Individual Skin Alkaloid Analyses—M. madagascariensis from Ranomafana Alkaloid composition of six extracts of *M. madagascariensis* from Ranomafana (Table 3) differed from that of *M. baroni* from Ranomafana (Table 1). However, it should be noted that the two species were not in exactly the same microhabitat at the Ranomafana site (see "Methods and Materials"). Most individuals of *M.*

madagascariensis had substantial amounts of homoPTX **265N**, as was the case for the *M. baroni*. However, in three of the six *M. madagascariensis*, homoPTX **281K** was present as a dominant or substantial alkaloid, whereas the same alkaloid was present in only one of the 15 *M. baroni* from Ranomafana and then only as a trace alkaloid. PTXs **237A** and **309A**, abundant in *M. baroni*, occurred only as trace alkaloids in *M. madagascariensis*. PTX **251D**, a dominant or substantial alkaloid in all but one of the 15 *M. baroni*, occurred in substantial amounts in only one of the six *M. madagascariensis* while being a trace alkaloid in another four. PTX **267C**, which was detected only twice as a trace alkaloid in 15 *M. baroni*, occurred in three of the six *M. madagascariensis*, once as a major alkaloid, once as a minor alkaloid, and once as a trace alkaloid. There were considerable differences between *M. madagascariensis* and *M. baroni* in the izidine alkaloids that are of putative mite origin. The 1,4-disubstituted quinolizidines **217A** and **231A**, common in large amounts in *M. baroni*, were less common in *M. madagascariensis*. Similarly, the 5,8-disubstituted indolizidine **217B** was much less common in *M. madagascariensis*. The six *M. madagascariensis* frogs contained eight 3,5-disubstituted pyrrolizidines and indolizidines, which are of probable ant origin. This is in marked

The probable class and dietary source of the alkaloid are indicated by the headings.

[a] Sex (*m* male; *f* female) is indicated.

[b] Total content of alkaloids [major (+++), trace (+)] is based upon total ion chromatogram intensities with 10^4 or greater = major, $\leq 10^3$ = trace; n. d. = none detected. The amounts of each alkaloid are relative to one another in each sample with 3≥50% in relative ion intensity, 2=8–50% relative ion intensity, and 1<8% relative ion intensity. Where two intensities are tabulated, two isomers are noted, and the intensities are in the order of elution from the GC column. Blanks indicate the alkaloid is not detected.

[c] Alkaloids reported for the first time. See Supplementary Information for characterization.

contrast to the 15 *M. baroni* frogs, where only four such alkaloids were detected. Both species had the presumed ant-derived 3,5-disubstituted indolizidine **275C** as a common constituent. In addition, the millipede alkaloid **236** was identified in 6 of the 15 *M. baroni* and in 5 of the 6 *M. madagascariensis*. Interestingly, in *M. madagascariensis*, a minor isomer of the spiropyrrolizidine **236** with a slightly longer retention time occurred in four of the frogs. Unfortunately, a GC-FTIR spectrum of this minor isomer could not be obtained. A minor isomer of **236** has been previously reported from *M. baroni* (Clark et al. 2005) and has been found to occur in siphonotid millipedes

(Clark et al. 2005; Saporito et al., unpublished data). One *M. madagascariensis* from Ranomafana had two additional millipede alkaloids, the spiropyrrolizidines **222** and **252B**.

Individual Skin Alkaloid Analyses—M. madagascariensis from Besariaka Alkaloid composition of five extracts of *M. madagascariensis* from Besariaka (Table 4) was markedly different than those from *M. baroni* (Table 2) of the same site and from the *M. madagascariensis* from Ranomafana (Table 3). Alkaloid composition in *M. madagascariensis* of Besariaka was dominated by a previously unreported 5,6,8-trisubstituted-indolizidine **239Z** presumed to be of mite origin. A GC-FTIR spectrum was obtained. The Bohlmann band pattern indicated an indolizidine of the 5*Z*,9*Z* configuration with a non-hydrogen-bonded hydroxyl group (3,666 cm^{-1}). A tentative structure is presented in the Supplementary Information. Two minor isomers also were detected. Other putative mite alkaloids that were present in three of the five *M. madagascariensis* from Besariaka were the 1,4-disubstituted quinolizidine **217A** and the 5,6,8-trisubstituted indolizidines **223A** and **239C**. The 5,6,8-trisubstituted indolizidine **239Z** was not detected in *M. baroni* of Besariaka; however, both **217A** and **223A** were present. Accompanying the "izidine" alkaloids in *M. madagascariensis* of Besariaka were alloPTXs **305A**, **321C**, **323B**, and **325A**. On the basis of differences in the pattern of mass spectral fragmentation, it appears that some of the alloPTXs may prove to be 16-hydroxyl isomers of the usual 15-hydroxyl alloPTXs. Methoxy alloPTX alkaloids of molecular weight 337 were detected in three extracts. However, upon further analysis, these compounds appear to be artifacts of a chemical reaction of certain alloPTXs (probably **323B**) with methanol during exposure to HCl-methanol in the fractionation process. These apparent methoxy alkaloids were not detected when combined skin extracts of the five *M. madagascariensis* were partitioned using the standard method of Daly et al. (1994a, b) to yield an alkaloid fraction. Two indolizidines, namely the 3-butyl-5-methylindolizidine **195B** and the 3-hydroxybutyl analog **211E**, were detected in *M. madagascariensis* from Besariaka. These alkaloids are likely derived from myrmicine ants. Neither of these indolizidines was detected in the *M. baroni* from Besariaka.

[d] *UABD* uncataloged

Alkaloid Variation within and among Populations of M. madagascariensis With the exception of the one individual that contained no detectable alkaloids, alkaloid compositions among the six *M. madagascariensis* from Ranomafana were quite similar (see nMDS plot of Fig. 3b). The alkaloid compositions among the five individuals of *M. madagascariensis* from Besariaka were also similar to each other (see nMDS plot of Fig. 3b). Indeed, the alkaloid composition for two of the individual frogs was identical. However, alkaloid composition of the *M. madagascariensis* was significantly different between Ranomafana and Besariaka (Global R=1.0; P<0.008; Fig. 3b).

Individual Skin Alkaloid Analyses—M. bernhardi from Manombo The skin extracts of 26 *M. bernhardi* frogs collected from Manombo (Table 5) contained remarkably few alkaloids of the PTX group, with PTX **251D** as a dominant alkaloid in only five extracts and with PTX **309A** as a dominant alkaloid in only one extract. The alloPTX **325A** occurred as a minor alkaloid in one extract. The presumed mite alkaloids 1,4-disubstituted quinolizidines **217A** and **231A** and dehydro-5,8-disubstituted indolizidine **245F** were dominant alkaloids in most extracts. In addition, the putative ant 3,5-disubstituted pyrrolizidine **251O** and the 3,5-disubstituted indolizidines **249A** and **275C** occurred frequently as dominant alkaloids in many of the extracts. Interestingly, only one isomer of **275C** (5*Z*,9*Z* relative configuration) was observed in the extracts. This is in contrast to *M. baroni* (see Table 1), where frequently two or three diastereomers of **275C** were detected, with the 5,9*Z*-isomer usually being minor or absent. A minor diastereomer, accompanying 1,4-disubstituted quinolizidine **217A**, was seen in several extracts of the *M. bernhardi* from Manombo. This isomer of **217A** also occurred rarely in extracts of *M. baroni* (Tables 1 and 2). An isomer of alkaloid **217A** that previously had been detected in an extract of *Mantella betsileo* and based on comparison with synthetic material was shown to be the C-1-epimer of **217A** (unpublished results, cited in Michel et al. 2000).

The present collection of *M. bernhardi* from Manombo consisted of 11 males, 14 females, and 1 juvenile. This represents the only site in which numbers were large enough to compare alkaloid composition between sexes (see below). The 1,4-disubstituted quinolizidine **231A** appeared in six males, but in only one female. PTX **251D** was seen in 7 of the 11 males and only 4 of the 14 females. In the females, **251D** occurred as a trace alkaloid in three of these four individuals and as a minor alkaloid in only one individual. The 3,5-disubstituted indolizidine **275C** was observed in six females and in only one male. Thus, there appears to be a clear relationship between the occurrence of the putative mite alkaloid **231A** and of the putative ant alkaloid **275C** and the sex of the frog.

Individual Skin Alkaloid Analyses—M. bernhardi from Vevembe In contrast to the izidine-dominated alkaloid compositions for the 26 *M. bernhardi* from Manombo (Table 5), the compositions for the 25 *M. bernhardi* of Vevembe were dominated by alkaloids of the PTX group (Table 6). Nearly all individuals had PTXs **251D** and **309A**

The probable class and dietary source of alkaloids are indicated (see abbreviations).

[a] Sex: *m* male; *f* female; *?* indicates uncertainty as to sex.

[b] Total content of alkaloids [major (+++), minor (++), trace (+)] is based upon total ion chromatogram intensities with 10^4 or greater = major, 10^3–10^4 = minor, $\leq 10^3$ = trace. The amounts of each alkaloid in the table are relative to one another in each sample with 3≥50% in relative ion intensity, 2=8–50% relative ion intensity, and 1<8% relative ion intensity. Where two intensities are tabulated, two isomers are noted, and the intensities are in the order of elution from the GC column. Blanks indicated that the alkaloid was not detected.

[c] Alkaloids reported for the first time. See Supplementary Information for characterization.

and alloPTX **325A** as significant or dominant alkaloids. However, three frogs had no PTX **251D**. HomoPTX **323E** was present in eight frogs as a significant alkaloid. A previously unreported alloPTX **323J** was present in trace amounts in 13 frogs. Another previously unreported alkaloid, deoxy-homoPTX **307K**, was found in two frogs. In contrast to the *M. bernhardi* from Manombo, "izidine" alkaloids that are proposed to be derived from dietary mites occurred rarely in *M. bernhardi* from Vevembe. Thus, the 1,4-disubstituted quinolizidine **217A** and the dehydro-5,8-

For detailed distribution and quantitation data, see Tables 1, 2, 3, 4, 5, and 6. Structures for selected alkaloids are shown in Fig. 2 (see also Daly et al. 2005). See abbreviations for alkaloid classes.
Ran. Ranomafama; *Bes.* Besariaka; *Man.* Manombo; *Vev.* Vevembe; *d-hPTX* deoxy-hPTX
[a] Previously undescribed alkaloids. Properties and tentative structures for some of these alkaloids are in the Supplementary Information.

disubstituted indolizidine **245F** were common and often dominant alkaloids in *M. bernhardi* from Manombo (Table 5), but these alkaloids occurred rarely in *M. bernhardi* from Vevembe, with **217A** being found as a trace alkaloid in one frog and **245F** being found in significant amounts in only two frogs (Table 6). "Izidine" alkaloids that are presumably derived from dietary ants were represented in the Vevembe frogs by four 3,5-disubstituted pyrrolizidines, namely **237R**, **239BB**, **251K**, and **251O** and by the 3,5-disubstituted indolizidine **249A** (diastereomers of these alkaloids were occasionally present). Of these 3,5-disubstituted pyrrolizidines, only **239BB**

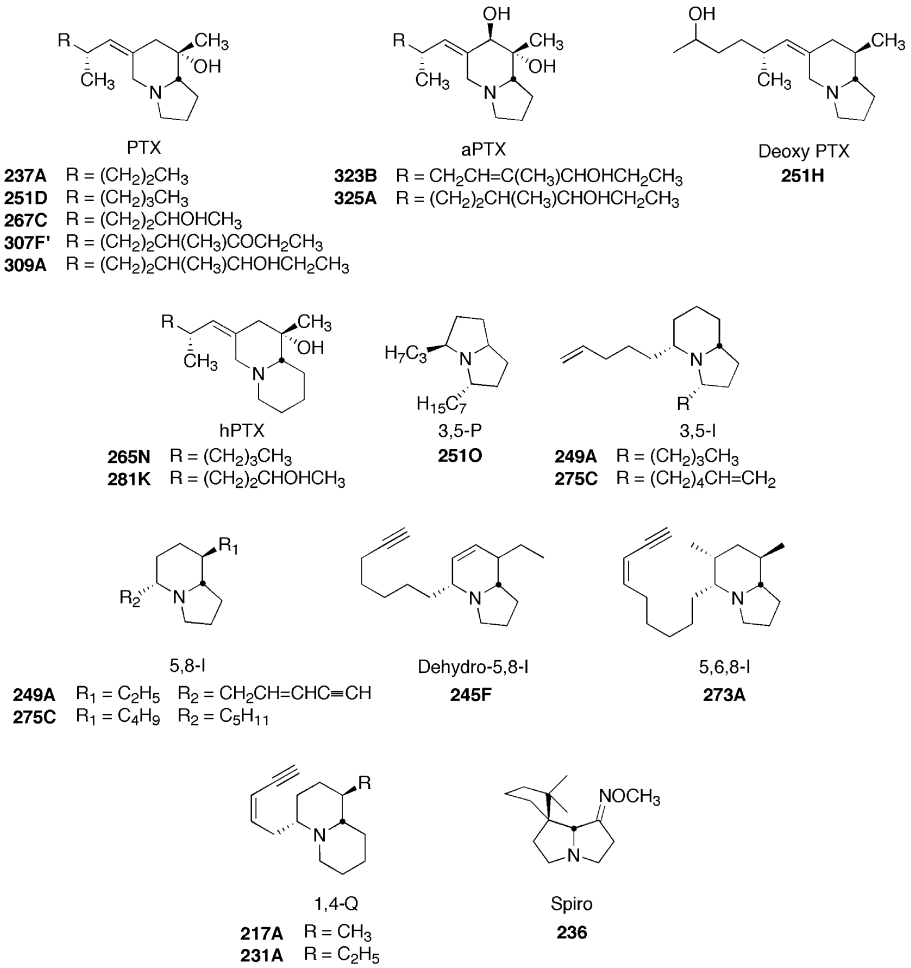

Fig. 2 Representative alkaloids of 11 of the structural classes detected in the present collections of mantellid species. These alkaloids occur relatively frequently or are major alkaloids in several extracts as are the following new alkaloids: deoxy-homoPTX **307K***, 3,5-disubstituted pyrrolizidine **239BB***, and 5,6,8-trisubstituted indolizidine **239Z*** (for tentative structures, see Supplementary Information)

and **251O** occurred in several frogs, and overall, such putative ant alkaloids were not very common in *M. bernhardi* from Vevembe. In the *M. bernhardi* from Manombo, the putative ant alkaloids **249A** and **251O** were present in almost all frogs (Table 5).

Alkaloid Variation Within and Among Populations of M. bernhardi There was a somewhat uniform variation in alkaloid composition among the 26 individuals of *M. bernhardi* from Manombo and also among the 25 individuals of *M. bernhardi* from Vevembe (see nMDS plot of Fig. 4a). There did appear to be a group of eight frogs from Vevembe (nos. 903 f to 910 m of Table 6) that were characterized by an alkaloid mix of PTX **309A** and izidines **239BB** and **251O** along with the very common PTX **251D** and alloPTX **325A**. The alkaloid composition of *M. bernhardi* was significantly different between Manombo and Vevembe (Global R=0.83; P<0.001; Fig. 4a). The alkaloid composition of *M. bernhardi* from Manombo was not significantly different between sexes (Global R=0.06; P= 0.20; Fig. 4b).

Alkaloid Variation among Species Alkaloid composition was significantly different between *M. baroni* and *M. madagascariensis* from Besariaka (Global R=1.0; P< 0.008; Fig. 5a). Alkaloid composition was also significantly different between *M. baroni* and *M. madagascariensis* from Ranomafana (Global R=0.96; P<0.001; Fig. 5b). A summary of variation is provided in Table 7.

Combined Skin Alkaloid Analyses—M. baroni A variety of PTXs (Table 8) and izidine alkaloids (Table 9) were detected among the five populations of *M. baroni*. The six combined skins from Mangevo (Fig. 1) and the one skin from Vohiparara (Kidonavo Bridge location of Fig. 1) are from the Ranomafana National Park. Alkaloid composition for the combined six skins of *M. baroni* from Mangevo was similar to those of the individual *M. baroni* frogs of

[a] Total content of alkaloids is major (+++) in each case (see definition in legend to Table 6). The amounts of each alkaloid in the table are relative to one another in each sample with 3≥50% in relative ion intensity, 2=8–50% relative ion intensity, and 1<8% relative ion intensity. Where two intensities are tabulated, two isomers are noted, and the intensities are in the order of elution from the GC column. Blanks indicate the alkaloid is not detected.

[b] Alkaloids reported for the first time. See Supplementary Information for characterization.

Ranomafana (Ranomafanakely location of Fig. 1). The presence of PTXs **237A**, **251D**, **307F′**, and **309A** and alloPTX **325A** in the combined skins from Mangevo (Table 8) and individual skins (Table 1) reflect similarities in alkaloid composition for these two populations of *M. baroni*. The absence of homoPTX **265N** and the presence of PTX **307G** in substantial amounts only in the combined skins represent differences for these two populations of *M. baroni*. The differences in alkaloids among the populations of combined skins from Mangevo and individual skins of *M. baroni* from Ranomafana, particularly the lack of detection of **307G** and **223B** in the 15 individual skins, likely reflect differences in the geographic location of the two frog populations (Fig. 1). The alkaloids from five populations of *M. baroni* in Tables 8 and 9 that seem most common were the putative mite alkaloids PTXs **251D**, **307F′**, **307G**, and **309A**, alloPTX **325A**, and 1,4-disubstituted quinolizidines **217A** and **231A**, whereas the most

et al. 2005), contained a variety of PTXs (Table 10). The dominant alkaloid was PTX **251D**. An earlier study of *M. cowanii*, frogs of which were presumably collected near Antoetra, reported PTX **251D** as the predominant alkaloid (Daly et al. 1996). The current *M. cowanii* had remarkably few izidines, consisting only of significant amounts of the 5,8-disubstituted indolizidine **217B** and trace amounts of the 5,8-disubstituted indolizidine **245A**.

Number of Alkaloids vs. Frog Size for Three Mantellid Species There was a positive significant relationship between the number of alkaloids and frog size (measured as

SVL), when all three species of mantellids were examined together (Fig. 6; $P<0.001$; $R^2=0.37$). However, when each species was examined independently, only *M. baroni* had a positive significant relationship between the number of alkaloids and frog size (Fig. 6; $P<0.02$; $R^2=0.27$). There was no relationship between the number of alkaloids and frog size for *M. madagascariensis* and *M. bernhardi* (Fig. 6; $P=0.838$ and $P=0.975$, respectively).

Discussion

Alkaloid composition varied within and among species of the mantellid frogs examined in this study (see MDS plots of Figs. 3, 4 and 5). Differences in alkaloid composition within species were largely related to geographic location, with the same species differing significantly in alkaloid composition between locations. These findings suggest that there are differences in the availability of alkaloid-containing arthropods based on geographic location, which are likely influenced by differences in habitat (i.e., vegetation, leaf litter, forest structure, etc.) at each location. Differences in alkaloid composition among locations have been reported previously for various poison frogs, including frogs of the genera *Mantella* (Garraffo et al. 1993a; Daly et al. 1996; Clark et al. 2005, 2006), *Melanophryniscus* (Garraffo et al. 1993b; Mebs et al. 2005; Daly et al. 2007), and *Pseudophryne* (Daly et al. 1990; Smith et al. 2002), as well as the dendrobatid frogs (Daly et al. 1987; Myers et al. 1995; Saporito et al. 2006, 2007b; and numerous references within). Within the same location, marked individual differences in alkaloid composition of the same species were also observed in the present study. Although these differences were not as great as differences between locations, they certainly suggest that location and availability of alkaloid-containing arthropods are also important on small spatial scales. Insights into the factors that result in differences in alkaloid composition among individuals from the same geographic location remain a challenge for further research.

The early studies on the alkaloid composition for collections of a mantellid species [e.g., *M. aurantiaca*, *M baroni*, *M. crocea*, and *M. pulchra*] at the same location indicated that there can be marked differences in alkaloid composition over time (Garraffo et al. 1993a; Daly et al. 1996). Recently, further examples of apparent temporal variation for populations of *M. baroni* from Sahavondrana and Vatoharanana locations in the Ranomafana region have been reported (Clark et al. 2006). Such findings indicate

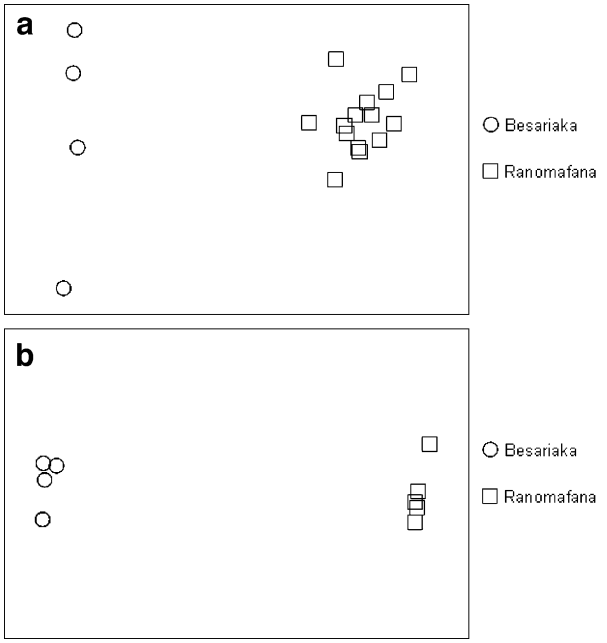

Fig. 3 **a** Multidimensional scaling plot of alkaloid composition in *M. baroni* from two different locations in Madagascar (stress=0.08). Alkaloid composition of *M. baroni* is significantly different between locations (Global R=0.99; P<0.001). *Each symbol* represents an individual frog from one of the two locations. The *distance between symbols* represents the difference in alkaloid composition. One subadult frog from Ranomafana (Table 1, no. 128s) was removed from the analysis due to the small number of alkaloids (only two in trace amounts) detected relative to other frogs. **b** Multidimensional scaling plot of alkaloid composition in *M. madagascariensis* from two different locations in Madagascar (stress=0.01). Alkaloid composition of *M. madagascariensis* is significantly different between locations (Global R=1.0; P<0.008). *Each symbol* represents an individual frog from one of the two locations. The *distance between symbols* represents the difference in alkaloid composition. One male frog from Ranomafana (Table 3, no. 112m) was removed from the analysis due to the absence of detectable alkaloids

that, in addition to geographic location, time also plays a prominent role in alkaloid variation of mantellid frogs. Temporal variation also has been reported for dendrobatid frogs (Daly et al. 1987, 2002; Saporito et al. 2006, 2007b) and bufonid toads (Daly et al. 2007). Such differences in alkaloid composition over time would likely be because of successional changes in habitat (i.e., vegetation, leaf-litter, forest structure, etc.), because of factors such as disturbance, which in turn lead to temporal shifts in alkaloid-containing arthropod availability (also see Daly et al. 2000; Saporito et al. 2006, 2007b).

Alkaloid profiles for three individuals of *M. baroni* collected in 2003 at Vatoharanana (see Fig. 1) were reported by Clark et al. (2005, 2006). Based on the GC–MS chromatograms in the Supplementary Information of Clark et al. (2006), the major alkaloids in all three frogs (in order of elution from the GC column) were as follows: quinolizidine **217A**, indolizidine **217B**, PTX **237A** and PTX **309A**. Other alkaloids, present as significant constituents in one or two individuals, were quinolizidines **233A** and **257D**, PTXs **251D** and **307G**, indolizidine **275C**, and pyrrolizidine **251O**. Except for the last two putative ant alkaloids, all the major alkaloids are of putative mite origin. It should be noted that, often, the alkaloid peaks in the GC–MS traces are listed incorrectly in Table 1 of Clark et al. (2006). For example, PTX **309A**, a major alkaloid in the GC–MS traces for all three individuals, is listed as minor or trace in the table. The alkaloid composition for a combined sample of ten skins of *M. baroni* collected in Ranomafana in November of 1989 probably at or near the same Vatoharanana site was reported to consist mainly of PTX **309A** and 1,4-disubstituted quinolizidine **217A**, with significant amounts of PTX **237A**, 1,4-disubstituted quinolizidines **231A** and **233A**, and 5,8-disubstituted indolizidines **217B**, **243D**, and **245C** (Daly et al. 1996; see also Clark et al. 2006). Thus, with respect to the major alkaloid components, there did not appear to be major temporal changes.

A significant variation in alkaloid composition was observed among sympatric species sampled at the same location (see nMDS plots of Fig. 5a, b and Tables 1, 2, 3, and 4). *M. madagascariensis* and *M. baroni* were collected together at two different locations (Ranomafana [Ranoma-

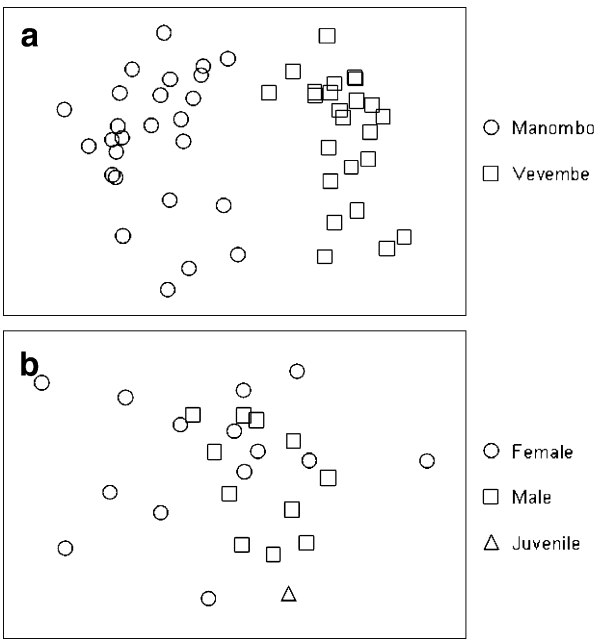

Fig. 4 **a** Multidimensional scaling plot of alkaloid composition in *M. bernhardi* from two different locations in Madagascar (stress=0.13). Alkaloid composition of *M. bernhardi* is significantly different between locations (Global R=0.83; P<0.001). *Each symbol* represents an individual frog from one of the two locations. The *distance between symbols* represents the difference in alkaloid composition. **b** Multidimensional scaling plot of alkaloid composition between sexes of *M. bernhardi* from Manombo (stress=0.17). Alkaloid composition is not significantly different between sexes (Global R=0.06; P=0.20). One of the frogs (Table 5, no. 413s) in the sample is a subadult. *Each symbol* represents an individual frog. The *distance between symbols* represents the difference in alkaloid composition

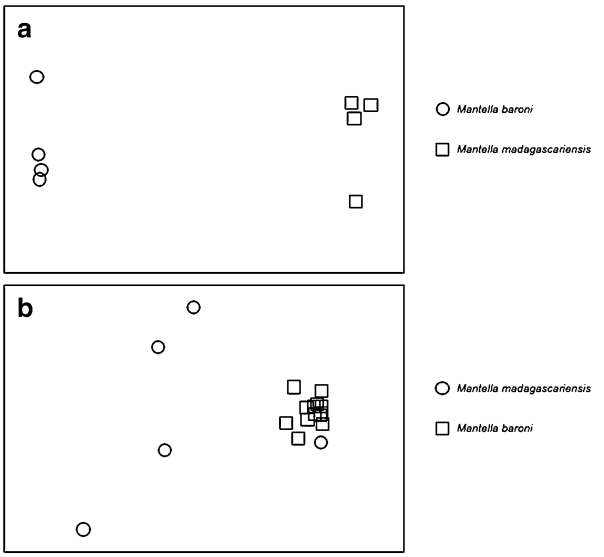

Fig. 5 **a** Multidimensional scaling plot of alkaloid composition in *Mantella baroni* and *M. madagascariensis* from Besariaka (stress= 0.01). Alkaloid composition is significantly different between *M. baroni* and *M. madagascariensis* (Global R=1.0; P<0.008). *Each symbol* represents an individual frog from one of the two species. The *distance between symbols* represents the difference in alkaloid composition. **b** Multidimensional scaling plot of alkaloid composition in *M. madagascariensis* and *M. baroni* from Ranomafana (stress= 0.1). Alkaloid composition is significantly different between *M. madagascariensis* and *M. baroni* (Global R=0.798, P<0.001). One male *M. madagascariensis* frog (Table 3, no. 112m) was removed from the analysis due to the absence of detectable alkaloids. One subadult *M. baroni* frog (Table 1, no. 128s) was removed from the analysis due to the small number of alkaloids (only two in trace amounts) detected relative to other frogs. *Each symbol* represents an individual frog from one of the two species. The *distance between symbols* represents the difference in alkaloid composition

fanakely] and Besariaka; see Fig. 1) and differed significantly between each other in alkaloid composition within each of the locations. As explained in "Materials and Methods," the two species may use partly different microhabitats at the Ranomafana site, but apparently not at the Besariaka site. Differences in alkaloid composition among these two sympatric species suggest that, at least in the case of Besariaka, there are either differences in feeding or in the sequestering systems responsible for uptake of alkaloids. Interestingly, these two sympatric species were originally considered different color morphs of the same species, but recent genetic analyses have suggested that they are separate, not even closely related species that belong to different species groups (Chiari et al. 2004, 2005). Certainly, the differences in alkaloid composition among these two sympatric species complement the findings that these are two different species. Future dietary analyses and alkaloid feeding experiments with these two species would provide more information as to whether or not alkaloid variation is because of differences in feeding or in the uptake system that sequesters dietary alkaloids. Whether there may also be changes in dietary habits with the age of the frogs is unknown.

Alkaloid composition for one individual of *M. madagascariensis*, which was collected in 2003 along with six *M. baroni* from Vohiparara (at Kidonavo bridge in Fig. 1), has been reported (Clark et al. 2005, 2006). Based on the GC–MS chromatograms in the Supplementary Information of Clark et al. (2006), the major alkaloids in the *M. madagascariensis* sample (in order of elution from the GC column) appear to be the following: indolizidines **203A**, **205A**, and **217B**; quinolizidine **217A**; an unidentified (not listed by Clark et al. 2006) alkaloid, which is likely the dehydro-5,8-disubstituted indolizidine **205L**, reported as a

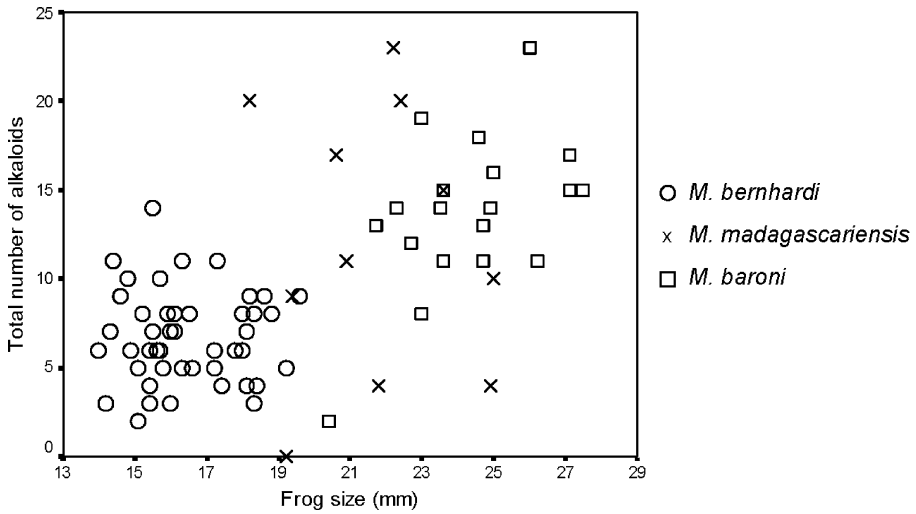

Fig. 6 The number of alkaloids versus frog size for all three mantellid species. When all three species are examined together, there is a positive significant relationship between number of alkaloids and frog size (P<0.001; R^2=0.37). However, when each species is examined independently, only *M. baroni* has a positive significant relationship between number of alkaloids and frog size (P value=0.02; R^2=0.27). There is no relationship between the number of alkaloids and frog size for *M. madagascariensis* and *M. bernhardi*

new alkaloid for the first time in the present study; homoPTX **265N**; indolizidine **275E**; and PTX **267C** (designated in error in the GC–MS legend of Clark et al. 2006 as deoxyPTX **267N**). All of these major alkaloids are probably of mite origin. The profiles of alkaloids in the six *M. baroni* from the same site were quite different from the one *M. madagascariensis* frog, based on the GC–MS chromatograms in the Supplementary Information of Clark et al. (2006). The dominant alkaloids were PTXs **251D**, **307G**, and **309A**, homoPTX **265N**, and for certain individuals pyrrolizidine **251O** and indolizidine **273A**. It should be noted that, often, minor or trace peaks in the GC–MS traces are listed in Table 1 of Clark et al. (2006) as major alkaloids (see critical comments on the Clark data in the Supplementary Information for the present report).

Differences in alkaloid composition between sexes have been suggested for other poison frogs (see Saporito et al. 2006, 2007b); however, because of small sample sizes and the confounding effects of location, this has not been specifically examined for any species. In the present study, an examination of alkaloid profiles in *M. bernhardi* from Manombo (Table 5: 11 males, 14 females) provided an opportunity to examine alkaloid composition between sexes. Alkaloid composition was not found to be significantly different between sexes (see nMDS plot in Fig. 4b; $P=0.20$), and therefore, males and females could not be distinguished on the basis of their alkaloid composition. However, although overall alkaloid composition was not significantly different between sexes, there do appear to be certain alkaloids that are related to sex in *M. bernhardi*. These alkaloids include the 1,4-disubstituted quinolizidine **231A** (present in six males in minor amounts, but in only one female and only in a trace amount), the 3,5-disubstituted indolizidine **249A** (present in 11 females, but in only 4 males), and the 3,5-disubstituted indolizidine **275C** (present in six females, but in only one male). The presence of **249A** and **275C** (mainly in females) is presumably because of sequestration from myrmicine ants, whereas the presence of **231A** (mainly in males) presumably is because of sequestration from oribatid mites. The differences in the presence of certain alkaloids observed between sexes of *M. bernhardi* may be explained by differences in diet (preference or availability based on behavior) between sexes. Breeding of this species occurs in swamps or near ponds in the forest, where males call from particular positions on the ground, close to the water, probably delimiting at least short-term territories. Consequently, females probably have larger home ranges than males, at least during the reproductive season, and are therefore presumably encountering a more diverse array of alkaloid-containing arthropods, whereas males are more subject to local availability of alkaloid-containing arthropods. In addition, female *Mantella* frogs are typically larger (SVL) than male frogs, which may suggest that they would consume more prey and/or have a larger capacity for storage of alkaloids. The tendency for larger females is particularly clear in *M. bernhardi*, where in the populations from Manombo and Vevembe, the males can be quite small (indeed being the smallest adult *Mantella* known) and the females distinctly larger (males 14–18 vs. females 17–20 mm SVL). In *M. bernhardi* from Manombo (Table 5), none of the 11 males had total alkaloid amounts classified as major (+++), whereas 11 of the 14 females did. However, the importance of location with respect to total amount of alkaloids is clear from a comparison to the *M. bernhardi* from Vevembe (Table 6), where of the 25 frogs (mostly males), all but one male and one female had alkaloid amounts classified as major (+++). Unfortunately, nothing is known as to whether any of the mantellid frogs have reached the maximum alkaloid storage capacity of the cutaneous (poison) glands. Furthermore, it should be noted that any general conclusions as to sex differences should be treated as tentative, because of the preponderance of males in all collections except *M. bernhardi* from Manombo, in which differences between sexes were detected with respect to certain alkaloids and perhaps with respect to amounts.

Poison glands are known to increase in diameter with increases in size of a poison frog, as has been shown for the dendrobatid poison frog *Oophaga pumilio* (Saporito et al., unpublished data), suggesting that larger frogs might have a larger storage capacity for alkaloids. The total amount of alkaloids is one measure of capacity, whereas the total number of alkaloids present in an individual frog can be thought of as a rough measure of the diversity of alkaloid-containing arthropods consumed by an individual over a lifetime. Within a species, larger poison frogs can be presumed to be older than smaller frogs. On the basis of these presumptions, it might be expected that the number of alkaloids (diversity) would be greater in larger mantellid frogs, both within and among species. When the three mantellid species were examined together, the number of alkaloids (including trace alkaloids) was positively correlated with frog size (Fig. 6; $P<0.001$; $R^2=0.37$), and in general, larger frog species tended to have a larger number of alkaloids. Clark et al. (2006) also reported a positive relationship between frog size (*M. baroni* vs. *M. bernhardi*) and the total number of alkaloids. However, in the present study, when each mantellid species is examined separately, size is related to the number of alkaloids only in *M. baroni* (Fig. 6; $P=0.002$; $R^2=0.27$). The lack of a strong relationship between frog size and the number of alkaloids within a mantellid species suggests that frog size (and probably age) is not the main determinant of total alkaloid number (alkaloid diversity). However, the differences between species may be at least partly explained by their different sizes and ages. Data on the age of specimens in

wild *Mantella* populations are needed to test this hypothesis. Inclusion of additional species and increased sample sizes are necessary to determine the extent by which size influences the diversity of alkaloids within a mantellid species. Analyses of alkaloids in individuals of two relatively small mantellid frogs, namely, *M. aurantiaca* and *M. milotympanum* are in progress.

The report by Clark et al. (2006) proposed that mantellid frogs from relatively pristine sites have a greater number of alkaloids than those from disturbed sites, suggesting that levels of disturbance are directly related to alkaloid diversity in poison frogs. Although differences in disturbance likely play a role in the abundance and distribution of alkaloid-containing arthropods, which likely influences alkaloid compositions in frogs, we do not think that the data presented in Clark et al. (2006) are compelling enough to make the claim that disturbance negatively influences alkaloid diversity in poison frogs. The proposal by Clark et al. (2006) is based on a comparison of the total number of alkaloids among very limited numbers of individuals of *M. baroni* from three different geographic locations (ranked as pristine, slightly disturbed, and disturbed). Given the amount of alkaloid variation within populations of poison frogs (illustrated in this study; also see Saporito et al. 2006), it is not clear what conclusions can accurately be made with such small sample sizes. In addition, Clark et al. 2006 were not justified in including four individuals from a disturbed site in which alkaloids were not obtained by extraction of the skin but solely by electrical stimulation of the skin (transcutaneous amphibian stimulation). Other critical comments on the data of Clark et al. (2006) are included in the present Supplementary Information.

Alkaloid compositions for *M. baroni* from seven sites, some relatively undisturbed and some disturbed, had been previously reported (Daly et al. 1996). A discussion of that study was neglected by Clark et al. (2006). The *M. baroni* from four disturbed areas had an average of 20 alkaloids per site, whereas those from three relatively undisturbed areas had an average of 17 alkaloids per site (Daly et al. 1996). Analyses were of combined skin samples from each site. In addition, the gas chromatograms presented in Daly et al. (1996) and Garraffo et al. (1993a) do not show any clear relationship between the amounts of alkaloids for *M. baroni* and the disturbance of a collection site. Of the four disturbed sites, two show major amounts of alkaloids, and two show minor amounts. Of the three relatively undisturbed sites, one shows major amounts, the other two, minor (Garraffo et al. 1993a; Daly et al. 1996) Thus, neither the number of alkaloids nor the amounts of alkaloids appeared to correlate with the degree of disturbance at a location.

The present alkaloid analyses of *M. baroni* also do not support the conclusion that frogs from an undisturbed collection site will have a larger number or a greater diversity of alkaloids. However, it should be noted that sample sizes in the present study also were small and, therefore, any conclusion should be treated as tentative. For the sites of the five combined skin collections of *M. baroni*, Mangevo and Vohiparara in the Ranomafana National Park are considered relatively undisturbed sites, whereas Andriabe, Tsinjoarivo, and Vohindrazana are considered disturbed sites (see Table 7). The two relatively undisturbed sites have, respectively, a total of 17 alkaloids (of which ten are major/minor) and 19 alkaloids (of which four are major/minor). The total number of alkaloids for the disturbed sites, in the order listed above, is as follows: 24 alkaloids (of which 17 are major/minor), 22 alkaloids (of which 12 are major/minor); and 30 alkaloids (of which 12 are major/minor). A comparison of the number of alkaloids in *M. baroni* between these sites clearly demonstrates that there are not significantly more alkaloids in frogs from the undisturbed sites. Furthermore, in the present study, the 15 individual skins of *M. baroni* from Ranomafana (an undisturbed site) contained an average of 7.0 major/minor alkaloids per frog (average including trace alkaloids, 16), whereas the four individuals from Besariaka (a disturbed site) contained an average of 8.3 major/minor alkaloids (average including trace alkaloids, 13). Once again, there is no marked difference in the number of alkaloids (a measure of alkaloid diversity) between an undisturbed and a disturbed site for *M. baroni*. At the present time, the generalization by Clark et al. (2006) that a pristine site will yield frogs with either a greater diversity or amount of alkaloids cannot be supported with the available data.

The current study resulted in the detection of 46 alkaloids (including isomers) in 19 individuals of *M. baroni* from two different populations, 56 alkaloids (including isomers) in 11 individuals of *M. madagascariensis* from two different populations, and 48 alkaloids (including isomers) in 51 individuals of *M. bernhardi* from two different populations (Tables 1, 2, 3, 4, 5, and 6). Summaries of alkaloid composition of extracts of individuals from six populations (Table 7) and of extracts from combined skins (Table 11) indicate the marked dependence of alkaloid compositions on the geographic location of the collections.

A variety of factors undoubtedly affect the complex differences in alkaloid composition detected in mantellid frogs. The geographic location of mantellid species and associated differences in habitat between locations, as well as the availability of alkaloid-containing arthropod prey items within each habitat are likely the most important factors in explaining variation in alkaloid composition. Temporal differences in alkaloid composition are likely because of successional changes in habitat and the associated shifts in alkaloid-containing prey availability. In addition, difference in prey electivity and/or foraging

behavior, which may be correlated in some cases with certain species, sexes, age, and/or size of mantellids, may also play a role in mantellid alkaloid variation. Finally, it is possible that some of the variation in alkaloid composition is because of differences in the alkaloid uptake systems among different species, which are presumably involved in sequestration and retention of alkaloids. A simplistic analysis of the factors involved in explaining variation in alkaloid composition is clearly not possible, but the various confounding factors are amenable to further study.

There is currently no information on whether or not there is a preference for sequestration and/or storage of one alkaloid structural class over another in mantellid frogs. A series of controlled and extensive feeding experiments will be required to clarify these points. However, as yet, the resources, which include a large number of captive-raised frogs, have not been available. Several of the mantellid species are now at risk (Andreone et al. 2005; Vieites et al. 2006), which may preclude extensive studies of mantellids similar to the present study. The wide range of amounts of alkaloids present in individual frogs from a single collection site is perhaps the most important current observation and has required these extensive single skin analyses to verify. The rare complete absence of alkaloids or the presence of only a trace amount of alkaloids in individual frogs is somewhat puzzling. It is possible that such frogs have expelled most of their alkaloids just before capture; however, it is unlikely that all of the alkaloids are expelled as a defensive strategy. Therefore, a deficient or possibly absent uptake system for these rare individuals is the most likely explanation at the moment. Those frogs without alkaloids or with only trace amounts of alkaloids appear to occur randomly in every collection.

Further research is clearly needed to understand the complex trophic relationships between alkaloid-containing mites, ants, millipedes, and beetles and chemical defense in poison frogs. Crucial to such an understanding will be (1) the distribution and composition of alkaloids within oribatid mites and myrmicine ants, which appear likely to be the principal dietary sources of poison frog alkaloids, (2) the factors that affect abundance/availability of such prey, and (3) the electivity of frogs toward such alkaloid-containing prey. Multiple classes of alkaloids do occur together in mites, but can also occur alone (Saporito et al. 2007b). In ants, alkaloid composition differs not only with species, but also with caste and age (Deslippe and Guo 2000; Torres et al. 2001; Saporito et al. 2004). Studies of alkaloid composition in different species of Madagascan mites, the occurrence of such mites in stomach contents of mantellid frogs, and correlations between alkaloids of mites, ants, and frogs from the same site are required.

Analyses of alkaloid profiles in more than 80 individual frogs of the *M. milotympanum* group (Vences et al. 1999), namely, *M. aurantiaca*, *M. milotympanum*, and *M. crocea*, are in progress (Daly and Vences et al., unpublished data). In parallel studies, alkaloid profiles have been obtained for extracts of combined frogs of 13 species of *Mantella* from more than 40 different sites in Madagascar (N. R. Andriamaharavo, M. Andriantsiferana et al., unpublished data), and the profiles are being analyzed for further insights into the factors that determine alkaloid compositions in these poison frogs.

Acknowledgments We are grateful to numerous students, guides, and colleagues for their assistance during fieldwork, in particular to Parfait Bora, Euan Edwards, Falitiana Rabemananjara, Emile Rajeriarison, Theo Rajaofiarison, Edouard Randriamitso, Tokihery Razafindrabe, and Cindy Woodhead. Olga Ramilijaona and Noromalala Raminosoa provided valuable assistance. We are indebted to MICET/ICTE for logistical support. The Tsinjoarivo samples were kindly provided by Franco Andreone in January of 2003. The work was carried out in the framework of collaboration accords of the authors' institutions with the Département de Biologie Animale, Université d'Antananarivo and the Association Nationale pour la Gestion des Aires Protegées, ANGAP. We are grateful to the Malagasy authorities, in particular the Ministère de l'Environnement, des Eaux et Forêts and the ANGAP, for research and export permits. Fieldwork was supported by the Volkswagen Foundation and the BIOPAT foundation. One of the authors (R.A.S.) was the recipient of an NIH Courtesy Associates appointment. The support of the NIH undergraduate Scholarship Program for author L.-A.G. is gratefully acknowledged. D.R.V. was supported by the NSF AmphibiaTree Grant EF-0334939. The research at NIH was supported by intramural funds of the National Institute of Diabetes and Digestive and Kidney Diseases.

Received: 5 June 2007 / Revised: 1 November 2007 / Accepted: 14 November 2007 / Published online: 10 January 2008

Abstract It is well established that plants infested with a single herbivore species can attract specific natural enemies through the emission of herbivore-induced volatiles. However, it is less clear what happens when plants are simultaneously attacked by more than one species. We analyzed volatile emissions of lima bean and cucumber plants upon multi-species herbivory by spider mites (*Tetranychus urticae*) and caterpillars (*Spodoptera exigua*) in comparison to single-species herbivory. Upon herbivory by single or multiple species, lima bean and cucumber plants emitted volatile blends that comprised mostly the same compounds. To detect additive, synergistic, or antagonistic effects, we compared the multi-species herbivory volatile blend with the sum of the volatile blends induced by each of the herbivore species feeding alone. In lima bean, the majority of compounds were more strongly induced by multi-species herbivory than expected based on the sum of volatile emissions by each of the herbivores separately, potentially caused by synergistic effects. In contrast, in cucumber, two compounds were suppressed by multi-species herbivory, suggesting the potential for antagonistic effects. We also studied the behavioral responses of the predatory mite *Phytoseiulus persimilis*, a specialized natural enemy of spider mites. Olfactometer experiments showed that *P. persimilis* preferred volatiles induced by multi-species herbivory to volatiles induced by *S. exigua* alone or by prey mites alone. We conclude that both lima bean and cucumber plants effectively attract predatory mites upon multi-species herbivory, but the underlying mechanisms appear different between these species.

Introduction

Plants can employ arthropod natural enemies and defend themselves against herbivorous insects and mites. Such arthropod natural enemies can have an impact on local herbivore populations and thereby also on plant fitness (Sabelis and van der Meer 1986; Dicke and Sabelis 1989; Pels and Sabelis 1999; van Loon et al. 2000; Fritzsche Hoballah and Turlings 2001; Kessler and Baldwin 2001). Plants can promote the effectiveness of natural enemies by providing alternative food, shelter, or volatiles (Price et al. 1980; Dicke and Sabelis 1988). The emission of herbivore-induced plant volatiles (HIPV) has been demonstrated in several families (e.g., Dicke et al. 1990a; Turlings et al.

1990; van den Boom et al. 2004; van Poecke and Dicke 2004). Many parasitoid wasps, predatory mites, and predatory insects use HIPV to locate their prey or hosts (reviewed in Dicke 1999; Dicke and Vet 1999; Sabelis et al. 1999). HIPV are thus thought to have an important influence on the interactions between plants, herbivores, and natural enemies in food webs (Turlings et al. 1995; Dicke and Vet 1999).

To date, studies on the production of HIPV by plants and the responses of natural enemies to these have been carried out mostly for systems with one species of plant, herbivore, and natural enemy. Yet, in the field, most plants are likely to be attacked by several herbivore species, or by herbivores and pathogens, at the same time. It is difficult to predict whether or not changes in HIPV blends upon multi-species herbivory affect attraction of natural enemies, and in what direction. Several studies have attempted to fill this gap by analyzing the chemical composition of volatile blends upon multi-species infestation of plants (Shiojiri et al. 2001; Cardoza et al. 2002; Rodriguez-Saona et al. 2003; Rostás et al. 2006; Moayeri et al. 2007; Rasmann and Turlings 2007; Soler et al. 2007). For instance, Shiojiri et al. (2000) showed that the parasitoid wasp *Cotesia plutellae* prefers the HIPV blend induced by its host *Plutella xylostella* to the blend induced by multi-species herbivory by its host and the non-host caterpillar *Pieris rapae* although volatile blends are similar (Shiojiri et al. 2001). *Cotesia glomerata*, on the other hand, prefers HIPV blends induced by its host *P. rapae* and non-host caterpillars to blends induced by one caterpillar species feeding alone (Shiojiri et al. 2000; Vos et al. 2001). *Cotesia marginiventris* and *Microplitis rufiventris* do not discriminate between the multi-species-induced HIPV blend of plants infested with their host (beet armyworm caterpillars) and a plant pathogen or plants infested with their host alone, although the pathogen significantly suppresses volatile induction (Rostás et al. 2006). Similarly, *C. glomerata* does not discriminate between mustard plants infested with a root herbivore and its host, or plants infested with its host alone (Soler et al. 2007). The parasitoid *C. marginiventris* and the entomopathogenic nematode *Heterorhabditis megidis* exhibited a reduced attraction to volatiles from maize plants that were infested by a non-host in addition to their host, although the non-host was feeding on different tissues from the host, i.e., leaves vs. roots (Rasmann and Turlings 2007).

In this study, we investigated the effects of multi-species herbivory by spider mites (*Tetranychus urticae*) and beet armyworm caterpillars (*Spodoptera exigua*) on volatile emissions by two different plant species: lima bean (*Phaseolus lunatus*) and cucumber (*Cucumis sativus*), and evaluated the responses of *Phytoseiulus persimilis*, a specialist natural enemy of spider mites. Both herbivore species are known to induce volatile emission in several plant species, and remarkable differences in HIPV blend composition have been found in lima bean infested by either of these herbivores (e.g., Ozawa et al. 2000; Schmelz et al. 2003; de Boer et al. 2004). We statistically compared volatile emission by multi-species-infested plants with the sum of volatile emissions of plants infested with either herbivore species alone to evaluate the presence of potentially antagonistic or synergistic effects among signal transduction pathways (e.g., Engelberth et al. 2001). Plant responses to multi-species herbivory may depend on feeding modes of the herbivore species involved (Walling 2000), but whether or not plant species differ in these responses is unknown. Therefore, we compared two plant species in their relative responses to multi-species vs. single-species herbivory by using the same two herbivore species to attack both plant species. We also studied the olfactory responses of predatory mites (*P. persimilis*). In nature, plants are commonly attacked by more than one herbivore. Knowledge on natural enemy responses to volatile blends induced by multi-species vs. single-species herbivory is essential to understand whether differences in volatile composition are relevant in an ecological context.

Methods and Materials

Plants, Herbivores, and Predators Lima bean plants (*Phaseolus lunatus* L. cv Sieva) and cucumber plants (*C. sativus* L. cv Lange Groene Giganten) were grown in a greenhouse at 20–30°C, 50–70% R.H. and 16 hr of light. Bean plants were used when their primary leaves had unfolded (and were about 8–12 cm wide), which was 10–15 d after sowing. Cucumber plants were used when their first two leaves were about 8–12 cm wide, which was 15–35 d after sowing.

Two-spotted spider mites, *Tetranychus urticae* Koch (Acari: Tetranychidae), were reared on lima bean plants in a greenhouse under the same conditions as uninfested plants. Eggs of the beet armyworm *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae) were obtained from a colony reared on artificial diet in the laboratory of Virology, Wageningen University, The Netherlands (Smits et al. 1986). Two to three batches of eggs were placed in a Petri dish together with a lima bean or cucumber leaf in a growth chamber at 23±1°C. Larvae were used in experiments within 24 hr of hatching.

A colony of predatory mites, *Phytoseiulus persimilis* Athias-Henriot (Acari: Phytoseiidae), was kept on spider mite-infested lima bean leaves in a growth chamber at 23±1°C, 50–70% R.H. and continuous light. To obtain females of the same age for olfactometer experiments, gravid females were allowed to oviposit on a spider mite-infested bean leaf for 2 d. The female offspring were used

in experiments 9 d after initiation of the colonies, i.e., 1–2 d after their final molt. Before the experiments, females were kept individually in 1.5-ml microcentrifuge tubes with a small droplet of water, for 24±2 hr at 23±1°C.

Plant Treatments Treatments were applied to the two oldest leaves of lima bean or cucumber plants 3 d before an experiment. Plants were incubated in plastic cages in a climate-controlled chamber at 24±1°C, 50–70% R.H. and 16L:8D, each treatment in a separate cage. We used the following four treatments:

(1) *T. urticae*: Adult female spider mites were transferred to experimental plants. Twenty mites per leaf were used on lima bean, and 100 mites per leaf were used on cucumber because the same number of spider mites leads to lower attraction of *P. persimilis* to cucumber than to lima bean plants (Dicke et al. 1990b).
(2) *S. exigua*: Newly hatched *S. exigua* larvae were placed in clip cages to keep caterpillars on the leaves (clip cages were made of two plastic cylinders, 2.5 cm diam., and a hairpin; the upper side was covered with gauze and the underside with Parafilm). Two larvae in one clip cage were used per leaf. Clip cages were moved daily to a new position on the same leaf, and any missing larvae were replaced. The clip cages were supported by sticks to prevent the leaves from bending and incurring damage due to the weight of the cages.
(3) Multi-species herbivory: Two newly hatched *S. exigua* larvae in a clip cage and 20 (lima bean) or 100 (cucumber) *T. urticae* females were placed on each leaf.
(4) Uninfested: Plants without herbivores were treated in the same way as plants of the other treatments. This treatment was only used for volatile collections of cucumber. We did not analyze volatile emission from uninfested lima bean plants because it is documented that they emit low amounts of volatiles (e.g., de Boer et al. 2004).

When clip cages were used to keep caterpillars in place, *T. urticae*-infested or uninfested plants were treated in the same way with empty clip cages to avoid any cage effects.

Volatile Collections and Analyses Just before volatile collections, plants were cut above the soil line. Stems of individual plants were wrapped in moist cotton and aluminum foil to prevent them from wilting during volatile collection, which lasted at most 4 hr. All clip cages, caterpillars, and their products were removed. Five plants of one treatment were transferred to a 5-l glass vessel. A viton O-ring and a metal clamp were used to attach the glass lid to the vessel to make it airtight. Purified air (filtered through silica, a molecular sieve, activated charcoal, and 90 mg Tenax) was split into two air streams of about 100 ml/min each and led into the vessels through teflon tubing. Volatiles from two treatments were collected simultaneously in parallel. The system was purged for 30 min before attaching a collection tube with Tenax (90 mg for bean samples, 200 mg for cucumber samples) to the air outlet in the lid of the vessel. Bean volatiles were collected for 25 min, cucumber volatiles were collected for 3 hr. For lima bean, volatile collection was repeated four times for each treatment, except for uninfested from which volatiles were not sampled. For cucumber, volatile collections were replicated seven times for the uninfested, six times for *T. urticae*, and five times for *S. exigua* and multi-species herbivory each. One sample of the *T. urticae* and one of the *S. exigua* treatments of cucumber were lost during the analysis.

Volatiles from lima bean and cucumber were analyzed on two different gas chromatography-mass spectrometry (GC-MS) systems.

Lima bean Volatiles were released from Tenax traps with a thermodesorption cold trap setup (Chrompack, Middelburg, The Netherlands) by heating at 250°C for 10 min, with a He-flow of 12 ml/min. Desorbed compounds were collected in the cold trap at −90°C. Volatiles were injected in splitless mode into the DB5 column (60 m×0.25 mm ID, 0.25 μm film thickness) by heating the cold trap to 220°C. After an initial column temperature of 40°C for 4 min, the temperature was raised to 280°C at 4°C/min. The column was directly coupled to the ion source of a Finnigan MAT 95 mass spectrometer, which was operating in the 70-eV electron impact (EI) ionization mode with scanning from mass 24 to 300 at 0.5 scan/sec. Compounds were identified by comparison of mass spectra with those in the NIST 98 library and in the Wageningen Mass Spectral Database of Natural Products, and by checking the retention indices.

Cucumber Volatiles were released from Tenax traps with a thermodesorption cold trap setup (Markes, UK) by heating at 200°C for 10 min, with a He-flow of 30 ml/min. The desorbed volatiles were collected in the cold trap at −10°C. Volatiles were injected in splitless mode into the RTX-5Silms column (Restec, 30 m×0.32 mm ID, 0.33 μm film thickness) by heating of the coldtrap to 270°C. After an initial column temperature of 40°C for 2 min, the temperature was raised to 95°C at 3°C/min, then to 165°C at 2°C/min, and subsequently to 250°C at 15°C/min. The column was directly coupled to the ion source of a Finnigan quadrupole mass spectrometer, which was operated in the 70-eV EI ionization mode and scanned from mass 33 to 300 at three scans/sec. Compounds were identified by comparison of mass spectra with those in the NIST 98 and

Wiley 7th edition spectral libraries, and by checking the retention indices.

Analyses Not all compounds were detected in every replicate of every treatment. We therefore added one peak area unit to all measurements for lima bean and 10 units to all measurements for cucumber. These were the lowest recorded non-zero values for bean and cucumber, respectively. This enabled us to plot volatile emission on a log scale (Figs. 1a and 2a), and to determine ratios among treatments (see below).

For cucumber, we first determined which volatile compounds were induced by herbivory by using Kruskal–Wallis tests per compound. Variation in volatile emission levels of uninfested plants was low, indicating that other types of inducing factors (e.g., general stress) were absent or had only minor effects. Only herbivore-induced volatiles were used in subsequent analyses. We assumed that all

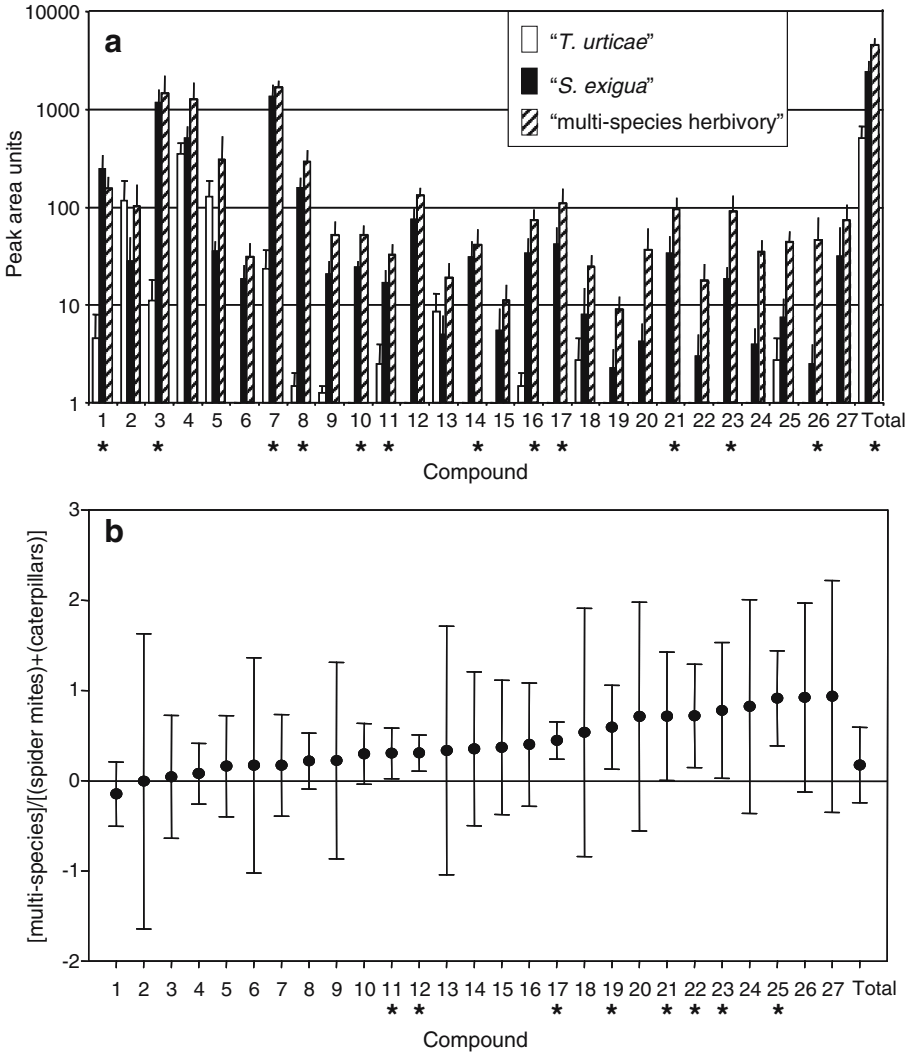

Fig. 1 Effect of multi-species herbivory on volatile emission by lima bean plants. (**a**) Volatile emission (mean + SE peak area units) upon single herbivory by *Tetranychus urticae* (20 mites per leaf) (open bars), single herbivory by *Spodoptera exigua* (two larvae per leaf) (filled bars), or multi-species herbivory (hatched bars). Asterisks indicate compounds that were significantly affected by herbivore treatment ($P<0.05$, Kruskal–Wallis tests). (**b**) Ratio of emission rates upon multi-species herbivory to the sum per volatile emitted by the two single herbivore treatments (see "Methods and Materials" for detailed explanation). Symbols indicate mean ratio, and error bars indicate upper and lower 95% confidence limits. Asterisks indicate compounds that were significantly more strongly induced by multi-species herbivory than by the sum of *T. urticae* and *S. exigua* (lower 95% confidence limit larger than 0). $N=4$ for all treatments. Compound numbers: (1) (*Z*)-3-hexen-1-ol, (2) methyl salicylate, (3) (*E*)-β-ocimene, (4) (*E*)-4,8-dimethyl-1,3,7-nonatriene, (5) (*3E,7E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, (6) *p*-mentha-1,3,8-triene, (7) (*Z*)-3-hexen-1-ol acetate, (8) 2-methylbutanal-*O*-methyl oxime, (9) 3-methylbutanal-*O*-methyl oxime, (10) linalool, (11) 1-octen-3-ol, (12) hexyl acetate, (13) limonene, (14) β-caryophyllene, (15) nonanal, (16) indole, (17) (*E*)-2-hexen-1-ol acetate, (18) 3-pentanone, (19) 3-octanone, (20) 2-methylbutanal nitrile, (21) (*Z*)-β-ocimene, (22) rose furan, (23) unknown 95B, 150, (24) 3-methylbutanal nitrile, (25) unknown 91B, 148, (26) unknown 41, 69B, 164, (27) 2-methylpropanal-*O*-methyl oxime

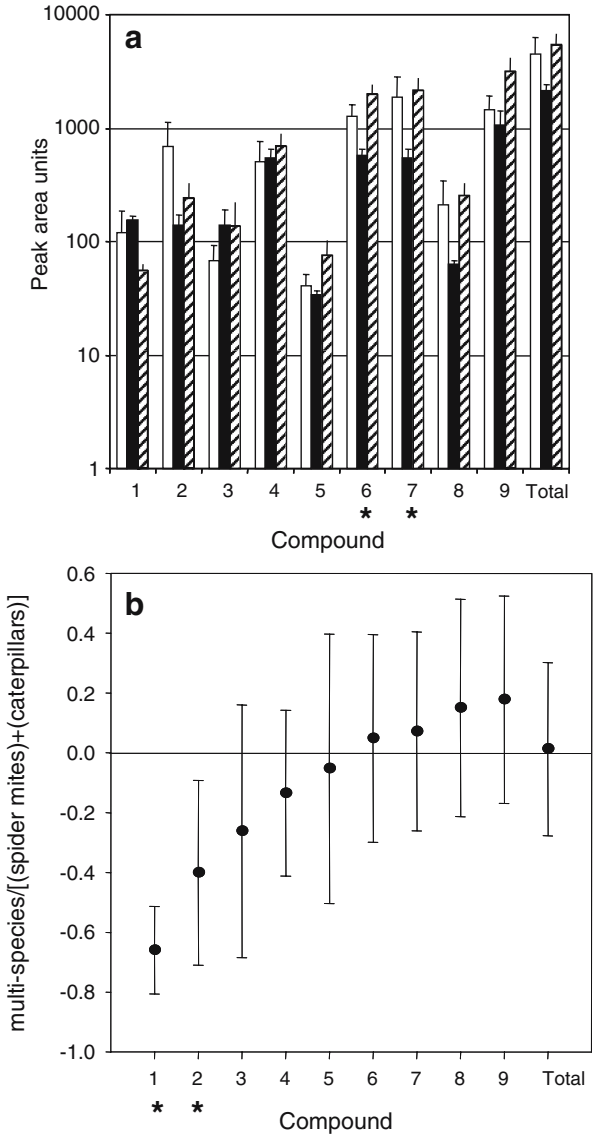

Fig. 2 Effect of multi-species herbivory on volatile emission by cucumber plants. (**a**) Volatile emission (mean ± SE peak area units) upon single herbivory by *Tetranychus urticae* (100 mites per leaf, N=5, open bars), single herbivory by *Spodoptera exigua* (2 larvae per leaf, N=4, filled bars), or multi-species herbivory (N=4, hatched bars). Asterisks indicate compounds that are significantly affected by herbivore treatment (P<0.05, Kruskal–Wallis tests). (**b**) Ratio of emission rates upon multi-species herbivory to the sum per volatile emitted by the two single herbivore treatments (see "Methods and Materials" and for detailed explanation). Symbols indicate mean ratio, and error bars indicate upper and lower 95% confidence limits. Asterisks indicate compounds that were significantly less induced by multi-species herbivory than by the sum of *T. urticae* and *S. exigua* (upper 95% confidence limit smaller than 0) (N=4) Compound numbers: (1) (*E*)-2-hexenal + (*Z*)-3-hexanal, (2) (*Z*)-3-hexen-1-ol acetate, (3) indole, (4) (*E,E*)-α-farnesene, (5) butyl aldoxime, (6) 3-methylbutanal-*O*-methyl oxime, (7) (*E*)-4,8-dimethyl-1,3,7-nonatriene, (8) (*3E,7E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, (9) (*E*)-β-ocimene. Note that peak area units in Fig. 2a cannot be compared with Fig. 1a because measurements were done on a different GC-MS system

compounds emitted by infested lima bean plants were induced by herbivores based on previous measurements of volatile emissions by uninfested lima bean plants (e.g., de Boer et al. 2004). Per plant species, we then used Kruskal–Wallis tests to analyze which compounds were differentially induced by the three herbivore treatments (*T. urticae*, *S. exigua*, or multi-species herbivory) (α=0.05). Note that we did not statistically compare absolute levels of volatile emission across plant species because volatiles were collected for different periods of time, and analyses were run on two different GC-MS systems.

We also tested whether the effect on HIPV of multi-species herbivory was the same as the combined effect of the two herbivores feeding alone, i.e., *T. urticae* + *S. exigua*. Per replicate, the amount of each volatile compound of the multi-species herbivory treatment was divided by the sum of the amounts emitted by *T. urticae* and *S. exigua*. The ratios were log-transformed before taking their averages. An average ratio of 0 means the effect of multi-species herbivory and the sum of *T. urticae* and *S. exigua* is equal. We concluded that a compound was significantly more strongly induced by multi-species herbivory than by the sum of *T. urticae* and *S. exigua* if the lower 95% confidence limit was larger than 0. Similarly, we concluded a significantly weaker effect of multi-species herbivory if the upper 95% confidence limit was smaller than 0 (see Figs. 1 and 2). We also used a χ^2 test to test whether the number of compounds with a ratio >0 and a ratio <0 differed from a 50:50 distribution. A 50:50 distribution would be expected if the effect of multi-species herbivory and the sum of *T. urticae* and *S. exigua* is equal. One replicate of the *T. urticae* treatment in cucumber was excluded from this analysis because we had no corresponding replicates of the *S. exigua* and multi-species herbivory treatments. Note that these tests reflect volatile responses to multi-species herbivory relative to responses to single-species herbivory. This allows us to compare these data between lima bean and cucumber because the data no longer depend on the absolute levels of volatiles detected by the different GC-MS systems.

Y-tube Olfactometer Experiments A closed system Y-tube olfactometer setup was used to test the responses of predatory mites to volatiles induced by multi-species herbivory (Takabayashi and Dicke 1992; de Boer et al. 2004). Odor sources consisted of four leaves of the same treatment that were cut from the plant just before an experiment; the petioles were wrapped in wet cotton wool and aluminum foil. Individual female predators were observed for a maximum of 5 min. A choice was recorded when the finish line, halfway one of the olfactometer arms, was reached within this period. Otherwise, it was recorded as "no-choice". Sixteen to 23 predators were tested per

experimental day, and each experiment was repeated on 4 different days. Per replicate, new groups of predatory mites and new sets of leaves were used. We tested the responses of predatory mites to volatiles from bean or cucumber plants of the multi-species herbivory treatment vs. volatiles from plants of the *T. urticae* or *S. exigua* treatments.

The choices of predatory mites between two odor sources in the Y-tube olfactometer were analyzed with two-sided binomial tests to investigate whether the distribution of the predators differed from 50:50. Predators that did not make a choice were excluded from statistical analyses.

Results

Volatile Emission by Lima Bean Plants The main compounds emitted by *T. urticae*-infested bean plants were methyl salicylate (MeSA; compound number 2 in Fig. 1a), (3*E*)-4,8-dimethyl-1,3,7-nonatriene [(*E*)-DMNT] (4), and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene [(*E,E*)-TMTT] (5). Herbivory by *S. exigua* alone resulted in the emission of similar amounts of (*E*)-DMNT (4), but amounts of MeSA (2) and (*E,E*)-TMTT (5) were small. Instead, *S. exigua*-infested bean leaves emitted large amounts of (*E*)-β-ocimene (3) and (*Z*)-3-hexen-1-ol acetate (7). Multi-species herbivory on bean plants induced the same volatile compounds as *S. exigua* feeding alone. Multi-species-infested plants emitted larger amounts of all volatile compounds than plants infested with a single herbivore species, except for (*Z*)-3-hexen-1-ol (1) that was emitted in larger amounts by *S. exigua*-infested plants, and MeSA (2) that was emitted in somewhat larger absolute amounts by *T. urticae*-infested plants.

In lima bean, herbivore treatment had a significant effect on the emission of (*Z*)-3-hexen-1-ol (1), (*E*)-β-ocimene (3), (*Z*)-3-hexen-1-ol acetate (7), 2-methylbutanal-*O*-methyl oxime (8), linalool (10), 1-octen-3-ol (11), hexyl acetate (12), β-caryophyllene (14), indole (16), (*E*)-2-hexen-1-ol acetate (17), (*Z*)-β-ocimene (21), and two unknown compounds (23 and 26) (all $P<0.05$, Kruskal–Wallis tests, Fig. 1a). These compounds were all induced in larger amounts by *S. exigua* and/or multi-species herbivory than by *T. urticae*. Total volatile emission was also significantly affected by treatment ($P<0.006$, Kruskal–Wallis test, Fig. 1a).

We compared the ratio of volatiles emitted in the multi-species herbivory treatment to the sum of volatiles emitted by the *T. urticae* and *S. exigua* treatments to determine whether infestation by two herbivore species simultaneously had additive, synergistic or antagonistic effects. Figure 1b shows the average ratio of multi-species herbivory to the sum of *T. urticae* and *S. exigua* for lima bean. Eight of 27 compounds were significantly more strongly induced by multi-species herbivory than by the sum of the two herbivore species feeding alone, suggesting synergistic effects (Fig. 1b). These compounds included members of various groups of chemicals, for example, (*E*)-2-hexen-1-ol acetate (17) and (*Z*)-β-ocimene (21). In addition, more compounds had a ratio >0 than expected ($\chi^2=9.80$, $P=0.002$). None of the compounds was significantly less induced by multi-species herbivory, suggesting the absence of antagonistic effects of *T. urticae* and *S. exigua* feeding simultaneously on lima bean.

Volatile Emission by Cucumber Plants Nine compounds were induced by herbivory on cucumber (all $P<0.10$, Kruskal–Wallis tests; data not shown). The main compounds emitted by *T. urticae*-infested cucumber plants were (*Z*)-3-hexen-1-ol acetate (compound number 2 in Fig. 2a), (*E,E*)-α-farnesene (4), 3-methylbutanal-*O*-methyl oxime (6), (*E*)-DMNT (7), and (*E*)-β-ocimene (9) (Fig. 2a). Similar compounds were emitted in the largest amounts by *S. exigua*-infested cucumber plants. Multi-species herbivory resulted in a volatile blend that consisted of the same compounds as the blends induced upon herbivory by each of the herbivore species alone. The multi-species herbivory treatment resulted in the strongest induction of 3-methylbutanal-*O*-methyloxime (6) and (*E*)-β-ocimene (9), while *T. urticae*-infested plants emitted the largest amounts of (*Z*)-3-hexen-1-ol acetate (2). Herbivory by *T. urticae* alone and multi-species herbivory induced larger amounts of (*E,E*)-TMTT (8) than single herbivory by *S. exigua* alone. No MeSA was detected in any of the cucumber samples.

In cucumber, herbivore treatment had an effect on the emission of 3-methylbutanal-*O*-methyloxime (6) and (*E*)-DMNT (9) ($P<0.05$, Kruskal–Wallis tests, Fig. 2a). Both compounds were induced in larger amounts by *T. urticae* or multi-species herbivory than by *S. exigua*. Total volatile emission was not affected by herbivore treatment in cucumber ($P>0.10$, Kruskal–Wallis test, Fig. 2a).

Two volatile compounds [(*E*)-2-hexanal/(*Z*)-3-hexenal (1) and (*Z*)-3-hexen-1-ol acetate (2)] were induced significantly less by multi-species herbivory than by the sum of *T. urticae* and *S. exigua* (Fig. 2b), suggesting the presence of antagonistic effects of the two herbivore species feeding on cucumber. The seven other compounds were equally induced by multispecies herbivory and the sum of the two herbivores feeding alone, indicating an additive effect of *T. urticae* and *S. exigua*. The distribution of compounds with a ratio >0 or <0 did not differ from 50:50 ($\chi^2=0.06$, $P=0.81$).

Responses of P. persimilis We tested the preferences of the predatory mite *P. persimilis* for the volatile blends analyzed above in a Y-tube olfactometer. On bean and cucumber plants, predatory mites preferred HIPV induced by multi-

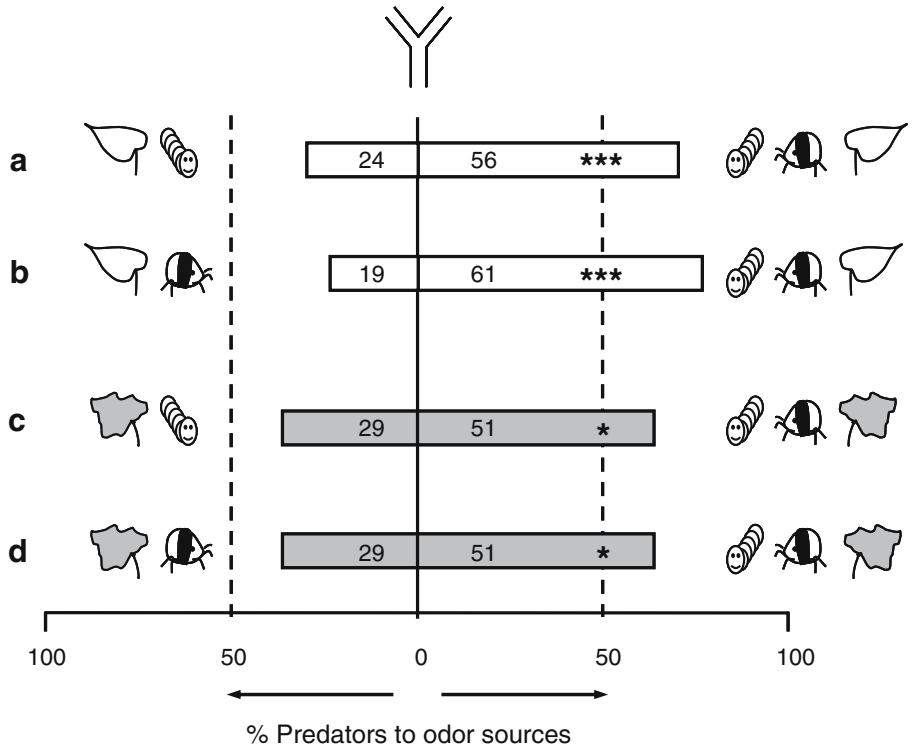

Fig. 3 Responses of *P. persimilis* to volatile blends in the Y-tube olfactometer. Odor sources consisted of four leaves from lima bean (**a** and **b**) or cucumber plant (**c** and **d**) simultaneously infested by *Tetranychus urticae* and *Spodoptera exigua* or infested by one of the herbivore species alone (*S. exigua*: **a** and **c**, *T. urticae*: **b** and **d**). Bars present the overall percentages of predators choosing for each odor source. Numbers in bars are the total numbers of predators responding to each odor source. Choices between odor sources were analyzed with a two-sided binomial test (*$P<0.05$; ***$P<0.001$)

species herbivory to blends induced by either *T. urticae* or *S. exigua* alone (Fig. 3, $P \leq 0.02$, binomial tests).

Discussion

We investigated volatile emissions by lima bean and cucumber plants upon single and multi-species herbivory by *T. urticae* and *S. exigua*. In lima bean, we found that most compounds were more strongly induced by multi-species herbivory than by the sum of each of the herbivores feeding separately (Fig. 1b). This suggests that the two herbivores feeding together on the same plant have more than an additive effect on volatile emission, potentially indicating that biosynthetic pathways may act synergistically. It is also possible that one or both herbivore species inflicted more damage on multi-species-infested plants than on plants with conspecifics only. However, it is unlikely that spider mite feeding was affected by the presence of *S. exigua* because in a preliminary experiment oviposition rates of mites, which are correlated with food intake rates, were similar on leaf discs with or without *S. exigua* damage (de Boer et al., unpublished). Some studies have observed that feeding by *S. exigua* is enhanced by the presence of aphids or a fungal pathogen (Rodriguez-Saona et al. 2005; Cardoza and Tumlinson 2006), but other studies have found no effect of the presence of whiteflies or a fungus (Rodriguez-Saona et al. 2003; Rostás et al. 2006).

In contrast to bean, we found that in cucumber plants, two volatile compounds were induced less by multi-species herbivory than by the sum of the two herbivores feeding separately, suggesting that their induction was suppressed by simultaneous feeding of *T. urticae* and *S. exigua*. Whether this reduction is caused by a negative interaction between the signal transduction pathways induced by spider mites and beet armyworms, or to reduced feeding of one or both herbivore species as a result of feeding on the same plant, remains to be investigated. From our data, it appears that plant species is an important determinant in the way in which herbivore-induced defense pathways interact upon multispecies herbivory.

The plant hormones salicylic acid (SA) and jasmonic acid (JA) play important roles in plant defense pathways and the production of HIPV (e.g., Kessler and Baldwin 2002; van Poecke and Dicke 2004). Interaction between these pathways may occur, for example, when SA inhibits JA-dependent defense pathways (e.g., Doares et al. 1995; Niki et al. 1998; Engelberth et al. 2001). To determine whether

synergistic (lima bean) and antagonistic (cucumber) interactions between biosynthetic defense pathways caused the changes in HIPV blends that we observed, endogenous levels of JA and SA should be determined in future studies. Arimura et al. (2002) showed that both JA and SA levels are significantly elevated in lima bean after 3 d of spider mite feeding, whereas several *Spodoptera* species are known to increase JA levels in corn and broad bean (Blechert et al. 1995; Schmelz et al. 2003). We are not aware of analyses of SA levels in response to *Spodoptera* feeding. No studies of JA and SA levels in plants upon multi-species herbivory are known to us either.

Another important question that needs to be addressed is the effect of herbivore sequence on volatile emission patterns, since in nature two herbivore species may infest an individual plant sequentially. In fact, some herbivore species are known to be attracted to HIPV themselves (e.g., Bolter et al. 1997; Kalberer et al. 2001), but spider mites are not attracted to *S. exigua*-infested lima bean plants (Horiuchi et al. 2003).

To determine whether the differences in volatile profiles upon multi-species herbivory and single-species herbivory are relevant in an ecological context, we investigated the behavior of the predatory mite *P. persimilis*, a specialist natural enemy of spider mites. Our results show that *P. persimilis* prefers volatiles induced by multi-species herbivory by spider mites and the non-prey caterpillar *S. exigua* to volatiles induced by one of the herbivore species feeding alone (Fig. 3). The strong preference of *P. persimilis* for the volatiles induced by multi-species herbivory may be explained by the relatively large amount of some specific compounds. Of the three major compounds emitted by spider mite-infested lima bean, two, namely (*E,E*)-TMTT and especially (*E*)-DMNT, were induced more strongly by multi-species herbivory, whereas induction of the third, MeSA, was somewhat reduced (Fig. 1a). Of the five major compounds emitted by spider mite-infested cucumber, four were induced more strongly by multi-species herbivory: (*E*)-DMNT, (*E*)-β-ocimene, (*E,E*)-α-farnesene, and 3-methylbutanal-*O*-methyl oxime, while (*Z*)-3-hexen-1-ol acetate emission was reduced (Fig. 2a). (*E*)-DMNT, (*E,E*)-TMTT, and (*E*)-β-ocimene are known attractants for *P. persimilis* (Dicke et al. 1990a, de Boer et al. 2004), and (*E,E*)-TMTT can be used by *P. persimilis* to discriminate between complex blends of HIPV (de Boer et al. 2004). Similarly, when *S. exigua*-induced volatiles are compared to the blend induced by multi-species herbivory, all of these compounds are produced in larger amounts in the latter. This suggests that a greater emission of (the sum of) attractive compounds may be the main determinant in attracting the predatory mite *P. persimilis.*

Previous studies on the responses of parasitoid wasps to HIPV also demonstrated a preference for HIPV induced by multi-species herbivory compared to single-species herbivory (Shiojiri et al. 2000; Vos et al. 2001; Cardoza et al. 2003; Moayeri et al. 2007). Rodriguez-Saona et al. (2005) even showed that naïve *Cotesia marginiventris* females were only attracted to tomato plants infested with their host *S. exigua* when the same plant was also infested with aphids. The presence of aphids thus made the host-infested plants more detectable. The opposite, i.e., multi-species herbivory-induced volatiles being less attractive than volatiles induced by only the host has been found in two cases: *C. plutellae* wasps preferred volatiles induced by their host, *P. xylostella*, to volatiles induced by their host and the non-host caterpillar *P. rapae* (Shiojiri et al. 2000), and *C. marginiventris* as well as the entomopathogenic nematode *H. megidis* were less attracted to volatiles from maize plants that were infested by a non-host in addition to their host (Rasmann and Turlings 2007). In such cases, the presence of non-host or non-prey herbivores may decrease the detectability or reliability of HIPV cues for natural enemies. For example, feeding by a non-prey or non-host herbivore may suppress the induction of volatile compounds used by natural enemies. Multi-species herbivory thus adds a new dimension to the trade-off between reliability and detectability of searching cues used by natural enemies of herbivorous arthropods (Vet and Dicke 1992).

Acknowledgments We thank Wouter Tigges, Leo Koopman, Frans van Aggelen, André Gidding, and Bert Essenstam for rearing plants and spider mites, Els Roode and Magda Usmany from the department of Virology, Wageningen University for providing *Spodoptera* eggs, and Saskia Burgers for statistical advice. We are grateful to Chris Kulhanek, Remco van Poecke, and Maurice Sabelis for comments on a previous version of this manuscript. The Attraction of *Spodoptera frugiperda* Neonates to Cowpea Seedlings is Mediated by Volatiles Induced by Conspecific Herbivory and the Elicitor Inceptin

Mark J. Carroll · Eric A. Schmelz · Peter E. A. Teal

Received: 30 December 2006 / Accepted: 4 December 2007 / Published online: 7 February 2008

Abstract Neonate fall armyworms [FAW; *Spodoptera frugiperda* (Smith)] often encounter conspecific herbivore damage as they disperse from an egg mass to an initial feeding site. We investigated the orientation responses of dispersing neonates to herbivore damage in cowpea seedlings, specifically examining whether neonate behaviors were affected by inceptin, the primary elicitor of FAW-induced defenses in cowpea leaves. We focused on responses to damage caused by conspecific first instars, as might occur during the dispersal of siblings from an egg mass. Inceptin contents of damaging first instar FAW were controlled through their diets, with leaf-fed FAW producing inceptins in their oral secretions, and root-fed or starved FAW lacking these elicitors. In a bioassay designed to evaluate neonate dispersal off a host plant, a higher percentage of neonates remained on herbivore-induced or inceptin-treated plants than on undamaged plants, mechanically damaged plants, freshly damaged plants, or on plants damaged by FAW lacking inceptins. Further investigations of neonate responses to plant odors with a four-arm olfactometer demonstrated that neonate attraction to odors from 4-h old FAW damage was strongly dependent on previous diet of the damaging larvae. Neonates were attracted to odors from 4-h old FAW damage over odors from undamaged plants or fresh FAW damage, provided that the damaging larvae had previously ingested leaf material. In a direct comparison of odors from induced plants, plants damaged by leaf-fed FAW were as attractive as plants treated with synthetic inceptin. GC-MS analysis confirmed that (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) was the major volatile induced by FAW herbivory. While both DMNT and undamaged plant odors were more attractive than air, neonates preferred DMNT-supplemented plant odors. These results suggest that neonate FAW exploit herbivore-induced plant volatiles as host plant location and recognition cues.

Introduction

Plants respond to herbivore feeding through increased biosynthesis and emission of volatile compounds from the damaged tissues (Paré and Tumlinson 1997, 1999). While these volatiles often benefit the plant through enhanced attraction of natural enemies (i.e., parasitoids and predators; Dicke and Sabelis 1988; Kessler and Baldwin 2001; Turlings et al. 1990, 1995), the same volatiles can potentially serve as olfactory cues to the herbivores themselves by making the damaged tissues more apparent (Bolter et al. 1997; Dicke and Vet 1999; Carroll et al. 2006). Such enhanced detectability of host plant tissue may be particularly useful to herbivores with limited search capacities (Ward 1987; Stamps and Krishnan 2005), such as neonate caterpillars (Zalucki et al. 2002). Despite their

greatly restricted mobility, neonates must locate and establish feeding sites on appropriate host tissues within a limited amount of time, or they will starve to death due to minimal energy reserves (Zalucki et al. 2002). In many species, location of an initial neonate feeding site is accomplished largely by female oviposition choice (Thompson 1988). However, the oviposition site may be inappropriate or insufficient for neonate development for a variety of reasons. Females may oviposit off the plant or on tissues that are not consumed by the neonate (Harris et al. 1999; Zalucki et al. 2002). Ovipositing females may be phenologically displaced from the tissues that their offspring will consume, particularly in rapidly developing tissues, and therefore, they are often unable to assess host quality or to lay eggs in an appropriate location (Zangerl and Berenbaum 1992). Females may also lay more offspring on the natal plant than can be supported by the available resources (Chapman et al. 1999; Prokopy and Roitberg 2001). In such cases, neonates may compensate for suboptimal conditions at the oviposition site by dispersing to other host tissues via ballooning or crawling (Roitberg and Mangel 1993; Harris et al. 1999; Doak 2000; Zalucki et al. 2002). Since location and recognition of appropriate host plant tissue by neonates involves chemosensory and tactile inputs (del Campo et al. 2001; Schoonhoven and van Loon 2002), herbivore damage may affect dispersal behavior and eventual recruitment of neonates to damaged tissues.

The fall armyworm (FAW) *Spodoptera frugiperda* (Smith) is a highly mobile lepidopteran that disperses as a neonate from its oviposition site (Yang et al. 1993), thus escaping from the frequent and negative effects of overcrowding (Chapman et al. 1999). Larval overcrowding can be limited through the use of larval frass as an oviposition deterrent, as in the related noctuid *S. littoralis* (Hilker and Klein 1989); however, an ovipositing FAW female lays up to 200 eggs in a single egg mass on a host plant, often exceeding the resources available (Sparks 1979; Pitre et al. 1983; Chapman et al. 1999). Larvae that remain in proximity to conspecifics face not only depletion of host plant material, but the threat of cannibalism (Chapman et al. 1999). To compensate for unfavorable conditions at the oviposition site, neonates disperse *en masse* several hours after hatching from the egg mass before initiating feeding on the natal host plant and on neighboring ones (Sparks 1979).

During dispersal from the egg mass, neonates often encounter various phases of herbivore damage caused by feeding conspecifics, from fresh damage inflicted at new feeding sites to older damage at abandoned feeding sites, to a combination of fresh and older damage at feeding sites established by actively feeding (often older) conspecifics. Eventually, the neonate will experience the whole phenological sequence of damage volatiles as it establishes its own feeding site. The volatile compositions emitted during these various damage phases change considerably over time as individual volatile components are induced at different rates (Turlings et al. 1998). In many plants, fresh damage volatiles that consist of lipoxygenase products (i.e., green leaf volatiles) rapidly released by mechanical damage differ from older damage volatiles consisting of terpenoids and other compounds slowly synthesized by the attacked plant (Hoballah and Turlings 2005). As such, the damage-induced volatiles encountered by dispersing neonates may convey information not only about host tissue location, but also the presence of other herbivores (Landolt 1993; Prokopy and Roitberg 2001; Carroll et al. 2006), host tissue quality *vis-à-vis* damage phenology (Bernasconi et al. 1998), and eventually the location of the larva's own feeding site.

We examined the responses of dispersing neonate FAW to herbivore damage in cowpea [*Vigna unguiculata* (L.) Walp.], an occasional, yet marginal, host of the fall armyworm (Meagher et al. 2004). We compared neonate responses to both fresh damage and older damage separately. We also evaluated neonate responses to damage-induced volatiles alone. While host location, recognition, and eventual acceptance of host tissues involves several sensory inputs, the initial opportunity for interactions with damaged host tissues are likely to occur through long distance modalities such as olfaction and vision (Harris et al. 1999; Schoonhoven and van Loon 2002).

We also asked whether neonate responses to herbivore damage could be mediated by elicitor-induced defensive responses in cowpea. Inceptin, a peptide formed by the partial proteolysis of chloroplastic ATPase, is the primary elicitor of induced volatile responses to sixth instar FAW in cowpea leaves (Schmelz et al. 2006). We examined whether neonate responses to older damage were dependent on full induction of herbivore-induced responses (*sensu* Dicke et al. 1999 and Turlings et al. 2000), both through the application of synthetic inceptin to wounded plant tissues and the use of damaging FAW with different predicted inceptin contents. Since only FAW larvae that have previously ingested chloroplast-containing tissues produce inceptin in their oral secretions, the inceptin contents of damaging larvae, and therefore the extent of herbivore-induced responses in cowpea leaves, can be readily manipulated through the larval diet (Schmelz et al. 2006). We also examined whether neonate responses to whole plant odors could be altered by a single induced volatile. The terpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) is a major constituent of induced volatiles in many plants, not only in cowpea but also in preferred graminaceous hosts such as maize (Turlings et al. 1998; D'Alessandro and Turlings 2005; Carroll et al. 2006). Given the prominence

of DMNT in the induced volatile profile of such unrelated host plants, we investigated the orientation responses of dispersing neonates to DMNT volatiles.

Methods and Materials

Plants Seeds of cowpea [*Vigna unguiculata* (L.) Walp. var. Cal 5] were planted in professional growers mix potting soil (Metro Mix 300, SunGro Horticulture, Vancouver, British Columbia) in 4 in. square pots and initially maintained for the first 7 days under 350 μmol m^{-2} s^{-1} photosynthetic active radiation under a 12:12 h (L/D) photoperiod. On the eighth day, plants were transferred and maintained at 25 °C under ambient greenhouse light supplemented with high-pressure sodium lamps under a 12:12 h (L/D) photoperiod. Supplemental lighting was used from 6:00 A.M. to 6:00 P.M. Seedlings (14–17 days old) with two fully expanded V2 leaves were used in all experiments.

Insects Fall armyworm eggs and neonates used in the behavioral bioassays were obtained from a colony maintained on an agar-based artificial diet at CMAVE, USDA-ARS (Gainesville, FL, USA). All insects were reared at 25° C under a 14:10 h (L/D) photoperiod.

Damage Treatments of Cowpea Seedlings Herbivore damage was inflicted by first instar FAW that either contained or lacked inceptins in their oral secretions. Because inceptins are formed by the partial proteolysis of chloroplastic ATP synthase, only larvae that have previously ingested and partially digested chloroplast-containing plant material produce inceptins (Schmelz et al. 2006). To obtain damaging first instars with inceptins, neonates were prefed on cowpea leaves (LF-FAW) for 10 h before their use in the damage treatments. Larvae without inceptins in their oral secretions were acquired by prefeeding neonates on cowpea roots [which lack chloroplasts (RF-FAW)] for 10 h or starving the larvae (unfed; UF-FAW) before their use in the damage treatments (Schmelz et al. 2006). We also specifically included a treatment that stimulates fresh damage by unfed [UF-FAW (fresh)] first instars, as this type of herbivore damage is commonly encountered by dispersing neonates near the initial feeding sites of their neonate siblings. Herbivore damage to leaves was initiated by transferring 120 first instar FAW to the V2 leaves of each plant. To minimize the production of inceptin-related peptides from recently ingested foliage during the damage treatments, we restricted the time period that damaging larvae were allowed to feed on the plants to 60 min or less. In cowpea leaves, emissions of damage volatiles induced by FAW herbivory or inceptin treatment increase substantially 4 h after the initial attack (Schmelz et al. 2006). To obtain cowpea seedlings that emitted only fresh damage or older damage odor phenologies, bioassays or volatile collections were conducted on plants either 1 h (fresh) or 4 h (old) after feeding damage had been inflicted.

Artificial damage treatments were initiated by superficially scratching three small wound patches (about 2 cm^2 each) with repeated shallow swipes of a razor blade on the adaxial side of a newly expanded V2 trifoliate. Each trifoliate was treated by applying either inceptin [2.5 ng synthetic inceptin in 10 μl 50 mM sodium phosphate pH 8.0 buffer, inceptin-treated (INC)] or a buffer solution [10 μl buffer, mechanically-damaged (MD)] across its wounds. To obtain cowpea seedlings that emitted older damage odors, all artificial damage treatments were conducted 4 h before use in bioassays or volatile collections. All damage treatments were inflicted under normal light conditions (previously described) to obtain maximal induction of photosynthesis-dependent volatiles (Turlings et al. 1995).

Plant Volatile Collections Collections of headspace volatiles emitted by cowpea plants were performed in glass chambers with a push–pull system (Analytical Research Systems, Gainesville, FL, USA) modified after Heath and Manukian (1994). An excess of pre-humidified, carbon-filtered air was added to the top of the chamber at 3 l/min to ensure that outside air did not enter the chamber. Volatiles were sampled by pulling air over the plants and through a Super Q absorbent (80–100 mesh, Alltech Associates, Deerfield, IL, USA) filter at 600 ml/min for 1 h. Adsorbed volatiles were eluted from the filter with 200 μl dichloromethane that contained 400 ng nonyl acetate as an internal standard.

Identification of Plant Volatiles Volatile analysis was performed by positive ion electron impact gas chromatography-mass spectrometry (EI GS-MS) on an HP 6890 gas chromatograph coupled to an HP 5973 MS detector. 1 μl of the sample was injected (240°C) onto an Agilent HP-5MS dimethylpolysiloxane column (30 m×250 μm (i.d.)× 0.25 μm, Agilent Technologies, Palo Alto, CA, USA) and separated by temperatures programmed from 35°C (1.0 min hold) to 230°C at 10°C/min. Helium was used as a carrier gas at 1.2 ml/min. Volatiles were identified by comparison of mass spectra (a) with mass spectra libraries (NIST and Department of Chemical Ecology, Göteborg University, Sweden) and (b) with mass spectra and retention times of authentic standards.

Chemicals Inceptin (ICDINGVCVDA) was synthesized and purified at the Protein Core Chemistry Facility (University of Florida, Gainesville, FL) as previously

described by Schmelz et al. (2006). Synthetic stocks of 4,8-dimethyl-1,3,7-nonatriene were acquired as a gift from Robert J. Bartlett (Crop Bioprotection Research Unit, USDA-ARS, Peoria, IL, USA). To enrich the content of the naturally emitted (*E*) isomer over the (*Z*) isomer, the mixture was separated three times sequentially by normal phase HPLC on a $AgNO_3$-coated (25%) silica gel column with benzene as an eluent (Heath and Sonnet 1980). Although we were unable to completely separate the isomers, the ratio of (*E*):(*Z*) DMNT was improved from 1:2 to approximately 20:1. The benzene was carefully removed under gentle N_2 flow.

Neonate Dispersal Bioassay To assess the effects of plant damage on neonate dispersal, we recorded the number of first instars remaining on a plant 24 h after transfer to leaves as dispersing neonates. We compared first instar retention on plants induced by inceptin [LF-FAW (old) and INC (old)] with retention on plants that were not induced by inceptin [CON (undamaged control), MD (old), UF-FAW (fresh), RF-FAW (old)]. The bioassay was conducted in a walk-in incubator (2.4×2.4×2.4 m, Aminco, Silver Springs, MD) maintained at 30°C and 80% RH under a 12:12 h (L/D) photoperiod. The ambient vibration and airflow within this incubator was minimal, thereby reducing the chance of disturbance or successful ballooning off the plant in a strong airflow. A group of 20 newly dispersing neonates were transferred by a camel hair brush to the adaxial side of V2 leaflets on each plant at 8:00 P.M. (2 h after the onset of scotophase). Retention of larvae was tested on three plants per treatment. One replicate set of plants containing one plant from each treatment (six plants total) was placed in the walk-in incubator at a time. Three replicate sets total were performed during separate overnight periods. To limit the exposure of neonates to volatiles from adjacent plants, the plants were placed in a single, staggered line that ran perpendicular to the reduced air flow. The order of plants in the linear array was randomly assigned by treatment in each replicate. Each plant was isolated from other plants by at least 50 cm and placed on a water-filled plastic saucer (25 cm diameter) to ensure that neonates that left the plant could not return. Larvae observed attempting to silk off the plant were unable to become aloft and simply lowered to the ground or returned to the plant above. The number of first instars left alive on each plant was recorded 24 h after introduction. No dead larvae were observed on any of the plants at the end of the bioassay.

Four-Arm Olfactometer Bioassays Orientation responses of neonate FAW to plant and synthetic volatile odors were evaluated with a four-arm olfactometer (Suazo et al. 2003). The olfactometer consisted of a quadrilateral-shaped choice arena with an arm at each corner and a 3 cm diameter base for air outflow at the center. Air flow from distal odors sources through the olfactometer was maintained with a push–pull system. Volatiles were obtained in distal volatile collection systems (previously described, Heath and Manukian 1994) by passing 3 l/min of pre-humidified, carbon-filtered air over the odor source. A portion of these volatiles were relayed from the distal odor source to an arm by 1/4" OD corrugated Teflon tubing. Air was then pulled through the olfactometer and out of the bottom at 2.4 l/min (600 ml/min per arm) by a vacuum line attached to the central base. Neonates were prevented from entering the vacuum line by a fine nylon mesh screen and the odor source lines by a glass trap placed at the distal end of each arm.

We evaluated neonate responses to odors in the olfactometer by using groups of neonates rather than individuals, since neonate FAW disperse from egg masses containing many siblings. A group of 120–200 neonates was transferred by a camel hairbrush to a 10 ml glass scintillation vial. Each group of neonates was placed in the center of the olfactometer by rapidly inverting the vial directly over the base and gently tapping the larvae off the glass vial. To minimize phenological changes in odors from damaged plants, the neonates were given a limited amount of time (up to 1 h) to move toward an odor source in the arena. A choice preference for an odor source was scored only if a neonate entered an arm. Larvae that did not enter an arm (up to 65%) within the allotted time were scored as neutrals and excluded from the statistical analysis.

Whole plant odors were sampled by the methods previously described for volatile collection. Synthetic DMNT was introduced into the odor source airstream by capillary release, a method that allows for the predictable and stable release of volatile compounds from a capillary tube based on their physiochemical characteristics (Weatherston et al. 1985). We based our protocol on the modifications of D'Alessandro et al. (2006), who greatly improved handling ease and conservation of volatile compounds by creating a volatile-saturated atmosphere in an auxillary container rather than the capillary tube itself. A DMNT-saturated atmosphere was created within a 4 ml glass vial by placing 5 µl DMNT inside a 250 µl glass GC vial insert and sealing the vial with a GC septum. A defined capillary release of DMNT (80 ng/h) was achieved by inserting one end of a 50 µl capillary tube (Drummond Scientific Company, Broomall, PA, USA) through the vial septum and projecting the other end into the odor source airstream. The released DMNT was thoroughly mixed with the airstream through the use of multiple nylon mesh baffles.

The capillary-release rate of DMNT in odor source airstreams was estimated by analysis of SuperQ filter-trapped volatiles following the methods of Schmelz et al.

(2001). Quantification of DMNT was performed on an Agilent 6890 gas chromatograph coupled to a flame ionization detector (250°C). One microliter of the sample was injected (splitless, 220°C) onto an Agilent DB-1 dimethylpolysiloxane column (15 m×250 μm (i.d.)× 0.25 μm, Agilent Technologies, Palo Alto, CA, USA) and separated with temperatures programmed from 40°C (0.50 min hold) to 180°C at 12°C/min followed by a 220° C post run (2 min). Helium was used as a carrier gas at 1.2 ml/min.

Statistics In both the neonate dispersal bioassay and the olfactometer bioassays, the proportion of neonates remaining on the plant or selecting the source were arcsin-transformed and compared either across treatments or odor sources by a one-way ANOVA (JMP 4.0.4, SAS Institute, Cary, NC, USA). In all bioassays, proportion means were compared by Tukey-Kramer HSD tests (JMP 4.0.4, SAS Institute, Cary, NC, USA).

Results

Retention of Dispersing Neonates on Herbivore-Induced Plants The percentage of dispersing neonates remaining on induced plants (plants damaged by leaf-fed first instar FAW or inceptin-treatment) was significantly higher than on undamaged plants or plants that experienced other forms of damage (Fig. 1). The retention of first instars on these plants could not be attributed to feeding damage alone, as plants that experienced fresh damage or damage by root-fed first instar FAW retained first instars in proportions similar to undamaged or mechanically damaged plants. These results are consistent with the hypothesis that neonate retention on damaged cowpea plants is largely mediated by inceptin-induced plant responses. Of all the damaging larvae, only leaf-fed first instar FAW would be expected to produce inceptins from previously ingested chloroplast-containing plant material. Curiously, we observed that the majority of first instars retained on the damaged plants established feeding sites in pre-existing wound sites, despite the fact that these tissues comprised less than 5% of the total leaf area.

Neonate Attraction to Herbivore-Induced Odors in Olfactometer Bioassays In the olfactometry bioassays, dispersing neonates were strongly attracted to odors emitted by herbivore-induced plants (plants damaged by leaf-fed FAW), but not to odors from undamaged plants, plants with fresh damage, or plants damaged by larvae lacking inceptins (starved or root-fed FAW; Figs. 2 and 3). These results support the hypothesis that neonate attraction to cowpea volatiles induced by plant damage, like neonate retention, is strongly mediated by inceptin-induced plant responses. A direct comparison of the larval response to volatiles released from plants with old feeding damage and to odors from inceptin-treated plants revealed that neonates do not distinguish between these odor sources (Fig. 4).

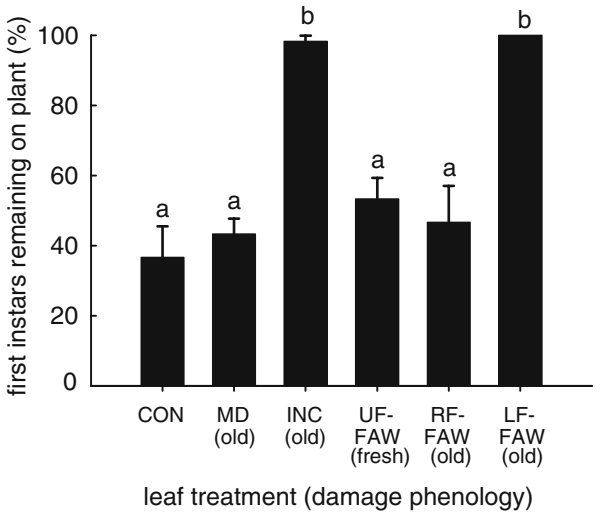

Fig. 1 Retention of *Spodoptera frugiperda* neonates on cowpea plants subjected to different leaf damage treatments: undamaged (*CON*), mechanically damaged (*MD*), inceptin-treated (*INC*), or FAW-damaged [unfed (*UF-FAW*), root-fed (*RF-FAW*), or leaf-fed (*LF-FAW*) first instars] plants. Mean percentage(±SE) of first instars represents the number of FAW remaining (out of 20 dispersing neonates introduced) on a plant 24 h after placement on the upper foliage (N=3 plants per treatment). To obtain only fresh or older damage odor phenologies, FAW-damaged plants were attacked by damaging larvae either 1 h (fresh) or 4 h (old) before use in the bioassay. Treatments not sharing the same letter are significantly different by *Tukey-Kramer HSD* ($P<0.05$; *one-way ANOVA*; $P<0.001$, $F=32.55$, $df=5$)

Herbivore-Induced Plants Emit DMNT In a comparison of volatiles from FAW-damaged, inceptin-treated, and undamaged cowpea seedlings during the early afternoon, the homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) was the major induced volatile produced by cowpea foliage (Fig. 5). DMNT emissions were strongly induced by inceptin-treatment or feeding damage by leaf-fed first instar FAW after 4 h, but only moderately by mechanical damage, feeding damage from unfed FAW, or fresh feeding damage. The greater induction of DMNT in inceptin-treated plants was likely due to the large amount of inceptin (2.2 pmol/trifoliate) applied, which equates to 4 μl of oral secretions by a 6th instar, a quantity that probably exceeds the amount contributed by leaf-fed first instars (Schmelz et al. 2006). Other volatiles commonly encountered in damaged leaf tissues, including lipoxygenase products (green leaf volatiles) from freshly damaged plants, were not detected by the methods used.

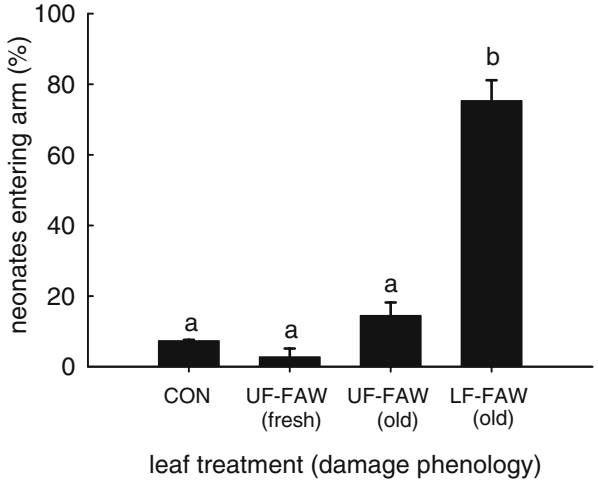

Fig. 2 Response of *Spodoptera frugiperda* neonates to different odor sources offered simultaneously in a four-arm olfactometer: undamaged cowpea plants (*CON*), or cowpea plants attacked by FAW [unfed (*UF-FAW*) or leaf-fed (*LF-FAW*) first instars]. Mean percentage (±SE) of neonates is the proportion of neonates entering a respective olfactometer arm out of the total number that responded positively (entered arms; $N=2$ replicates, a total of 93 and 179 larvae responded in each replicate). To obtain only fresh or older damage odor phenologies, FAW-damaged plants were attacked by damaging larvae either 1 h (fresh) or 4 h (old) before use in the bioassay. Treatments not sharing the same letter are significantly different by *Tukey-Kramer HSD* ($P<0.05$; *one-way ANOVA*; $P<0.001$, $F=27.60$, $df=3$)

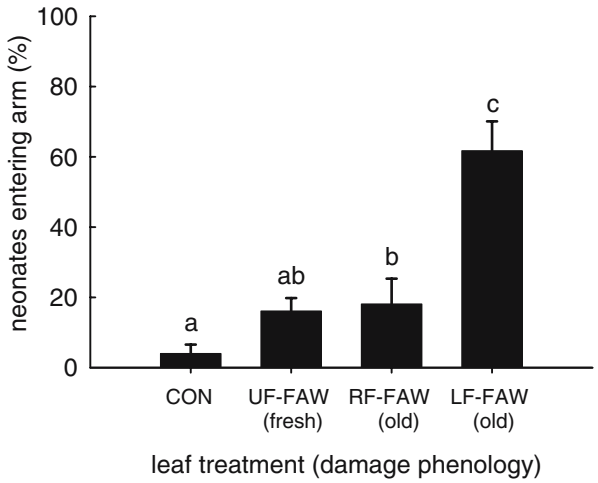

Fig. 3 Response of *Spodoptera frugiperda* neonates to different odor sources offered simultaneously in a four-arm olfactometer: undamaged cowpea plants (*CON*), or cowpea plants attacked by FAW [unfed (*UF-FAW*), root-fed (*RF-FAW*), or leaf-fed (*LF-FAW*) first instars]. Mean percentage (±SE) of neonates is the proportion of neonates entering a respective olfactometer arm out of the total number that responded positively (entered arms; $N=3$ replicates, a total of 95, 109, and 149 larvae responded in each replicate). To obtain only fresh or older damage odor phenologies, FAW-damaged plants were attacked by damaging larvae either 1 h (fresh) or 4 h (old) before use in the bioassay. Treatments not sharing the same letter are significantly different by *Tukey-Kramer HSD* ($P<0.05$; *one-way ANOVA*; $P=0.003$, $F=34.81$, $df=3$)

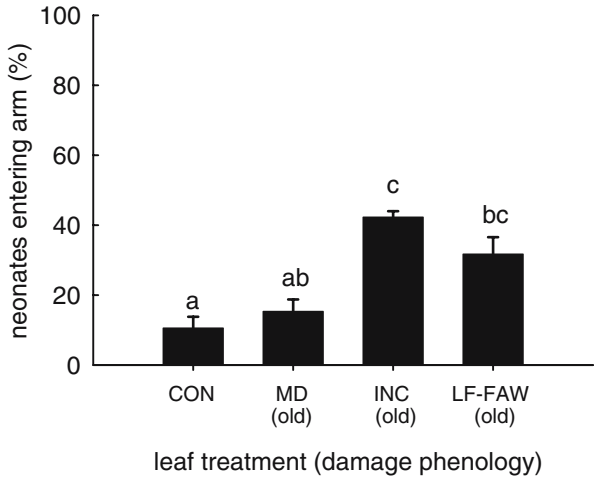

Fig. 4 Response of *Spodoptera frugiperda* neonates to different odor sources offered simultaneously in a four-arm olfactometer: undamaged cowpea plants (*CON*), mechanically damaged cowpea plants (*MD*), inceptin-treated cowpea plants (*INC*), or cowpea plants damaged by leaf-fed first instar FAW (*LF-FAW*). Mean percentage (±SE) of neonates is the proportion of neonates entering a respective olfactometer arm out of the total number that responded positively (entered arms; $N=2$ replicates, a total of 104 and 112 larvae responded in each replicate). To obtain only older damage odor phenologies, FAW-damaged plants were attacked by damaging larvae 4 h before use in the bioassay. Treatments not sharing the same letter are significantly different by *Tukey-Kramer HSD* ($P<0.05$; *one-way ANOVA*; $P=0.014$, $F=14.14$, $df=3$)

Attraction of Neonates to DMNT DMNT was an attractant to dispersing neonates in the four-arm olfactometer, both by itself and as a supplement to undamaged cowpea plant odors (Fig. 6). The combination of supplementary DMNT and undamaged plant odors was significantly more attractive than either odor source alone. This observation, combined with the equivalent response of neonates to DMNT or undamaged plant odors (which contain much lower amounts of DMNT than damaged plants), indicates that undamaged leaves may emit volatiles other than DMNT that are also attractive to dispersing neonates.

Discussion

Neonate FAW are attracted to volatiles released from herbivore-damaged cowpea leaves. In cowpea leaves, inceptin induces both volatile and nonvolatile anti-herbivore defenses against FAW larvae, as implicated by phenylpropanoid markers and protease inhibitor transcripts (Schmelz et al. 2006). Sixth instar FAW fed on inceptin-induced cowpea leaves endure a significant reduction in growth rate (17%) compared to larvae given undamaged leaves (Schmelz et al. 2006). Furthermore, herbivore-induced volatiles are well-known to serve as signals to

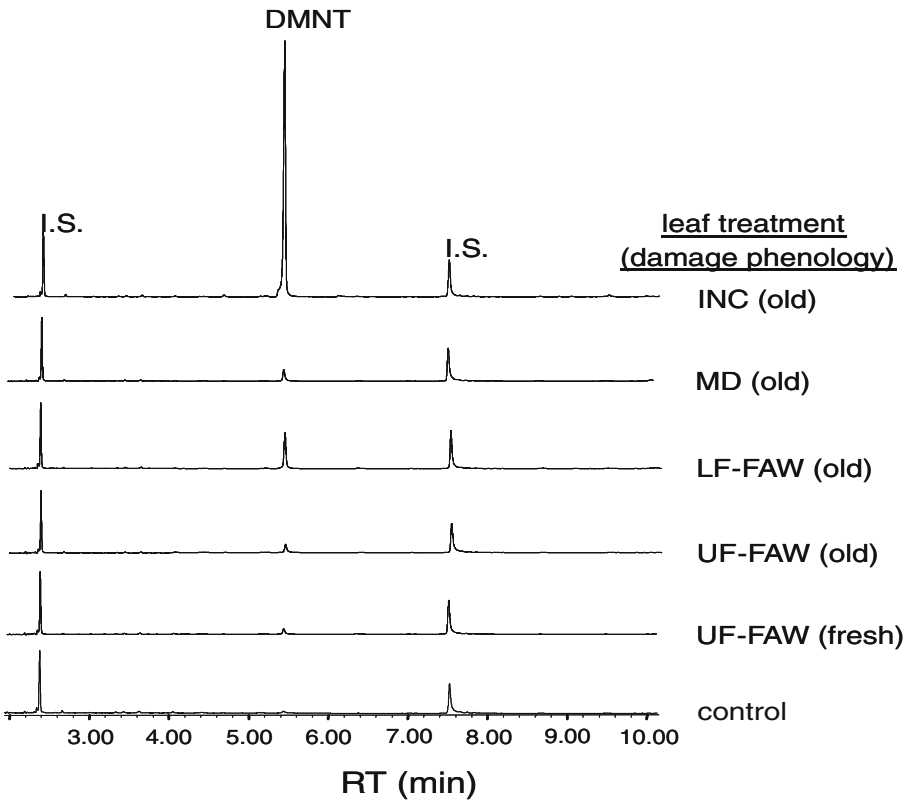

Fig. 5 Representative GC-FID chromatographic profiles of headspace volatiles collected in the early afternoon from cowpea plants subjected to different leaf damage treatments: inceptin-treated (*INC*), mechanically damaged (*MD*), FAW-damaged [unfed (*UF-FAW*) or leaf-fed FAW (*LF-FAW*)], or undamaged (*control*) plants. The homoterpene [*E*]-4,8-dimethyl-1,3,7-nonatriene (DMNT, RT 5.22 min) is the most abundant volatile emitted by both the induced and uninduced cowpea plants used in the bioassays. Samples represent 1/5× the total headspace emissions collected over 60 min. Octane (280 ng, RT 2.38 min) and nonyl acetate (400 ng, RT 7.53 min) were added separately as internal standards (I.S.). To obtain only fresh damage or older damage odor phenologies, FAW-damaged plants were attacked by damaging larvae either 1 h (fresh) or 4 h (old) before the volatile collections

natural enemies that forage for plants infested with herbivores (Kessler and Baldwin 2001).

Despite the role of herbivore-induced plant volatiles as cues for natural enemies, some lepidopteran neonates orient to herbivore-damaged hosts during the search for an initial feeding site. Many neonates are not positioned on preferred host tissues during oviposition, but move within the plant to an appropriate feeding site after hatching (Zalucki et al. 2002). Movement of codling moth (*Cydia pomonella*; Lepidoptera: Tortricidae) neonates from oviposition sites on foliage to feeding sites on apple fruit is enhanced by conspecific damage and induction of the fruit volatile [*E, E*]-α-farnesene (Landolt et al. 2000), despite the fact that herbivore damage attracts the larval parasitoid *Hyssopus pallidus* (Hymenoptera: Eulophidae; Rott et al. 2005). In this case, the utility of induced volatiles as olfactory attractants to appropriate host tissue may outweigh secondary consequences of induced defenses or enhanced recruitment of natural enemies.

Noticeably, dispersing FAW neonates are more attracted to odors from plants with old (4 h) neonate feeding damage than to odors from plants with fresh (1 h) neonate feeding damage. These olfactory preferences occur despite an absence of prior feeding experience. Unlike older instars, neonates have not yet been exposed to plant odors during feeding. Experience-based olfactory preferences are thought to be an important component in the development of host preferences in related polyphagous noctuids, such as *Spodoptera littoralis* (Anderson et al. 1995; Carlsson et al. 1999). However, an innate lack of attraction to fresh damage volatiles would enhance dispersal of FAW neonates away from the egg mass and limit orientation to new feeding sites established by neonate siblings. Neonate attraction might also be targeted toward host plant volatiles induced by oviposition itself. Recent studies indicate that some plants respond to insect oviposition by emitting volatiles that attract egg parasitoids to the oviposition site (Meiners and Hilker 1997, 2000; Colazza et al. 2004). Although induction of volatiles by oviposition has not been examined in either cowpea or the grasses preferred by FAW, the large size of the egg mass and the female's preference for readily inducible leaf tissue (leaf vein creases) as a preferred oviposition site (Sparks 1979) are factors that merit further investigation.

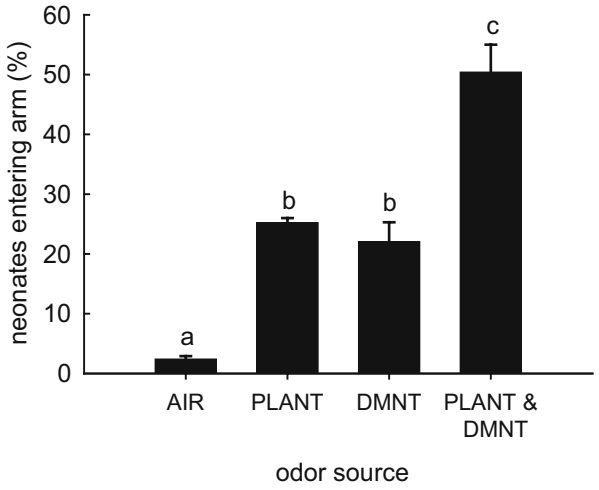

Fig. 6 Response of *Spodoptera frugiperda* neonates to different odor sources offered simultaneously in a four-arm olfactometer: filtered air (AIR), undamaged cowpea plant (PLANT), DMNT-supplemented filtered air (DMNT), or a DMNT-supplemented air stream from an undamaged cowpea plant (PLANT & DMNT). Mean percentage (±SE) of neonates is the proportion of neonates entering a respective olfactometer arm out of the total number that responded positively (entered arms; $N=3$ replicates, a total of 97, 107, and 123 larvae responded in each replicate). For the DMNT supplemented odor sources, 80 ng/h of synthetic DMNT was introduced into the air stream by capillary release. Treatments not sharing the same letter are significantly different by *Tukey-Kramer HSD* ($P<0.05$; *one-way ANOVA*; $P<0.001$, $F=27.60$, $df=3$)

The use of herbivore-induced plant volatiles as neonate orientation cues may facilitate and reinforce a broad host range in polyphagous herbivores such as FAW. Although FAW has been reported from over 80 plant species, the preferred oviposition hosts are overwhelmingly grasses (Luginbill 1928; Sparks 1979; Meagher et al. 2004). On grasses, FAW neonates feed preferentially and performed better on younger tissues, especially leaf whorls (Yang et al. 1993; Davis et al. 1999), developing tissues that usually emit higher levels of constitutive and induced volatiles than comparable mature tissues (Hoballah et al. 2004). While unrelated hosts such as cowpea and maize differ considerably in plant architecture and overall secondary chemistry, these plants share some similarities in damage odors derived from a relatively restricted pool of volatiles (Gouinguené et al. 2003; D'Alessandro and Turlings 2005). DMNT is one of the few major induced volatiles emitted by both cowpea and maize (Carroll et al. 2006). FAW attraction to the major induced volatile emitted by a marginal host (cowpea) may reflect its co-occurrence in the preferred tissues of a major host (maize). A polyphagous caterpillar therefore may exploit induced volatile odors, not only because of their high emission rates, but also because qualitatively these compounds are fairly ubiquitous components of diverse host volatile profiles. The use of induced volatiles as cues may be further promoted by their familiar presence around actively feeding FAW at their own feeding sites, as larvae routinely encounter induced volatiles emitted by host tissues damaged by themselves.

Compared with other hosts of FAW, herbivore-damaged cowpea releases relatively few major volatile components, yet is readily detected by both feeding herbivores and parasitoids (Hoballah et al. 2002). It is unclear if herbivores and parasitoids are attracted to exactly the same induced volatiles. FAW neonates orient toward herbivore-induced volatiles that may be poorly perceived by some parasitoids (Gouinguené et al. 2005) but used as cues by others (Pickett et al. 2006). For example, DMNT, the major volatile induced in cowpea leaves, is readily detected (as measured by GC-EAG) in *Spodoptera littoralis*-damaged cowpea leaves by the parasitoid *Campoletis sonerensis* (Hymenoptera: Ichneumonidae) but not *Cotesia marginiventris* (Hymenoptera: Braconidae) or *Microplitis rufiventris* (Hymenoptera: Braconidae; Gouinguené et al. 2005). Other induced volatile components from cowpea leaves may be used as olfactory cues by both herbivores and parasitoids. For example, the monoterpene linalool, which has been detected as a minor component of herbivore-damaged cowpea leaves by several authors (Hoballah et al. 2002; D'Alessandro and Turlings 2005) but not in one of our previous studies (Schmelz et al. 2006), is highly attractive to both sixth instar FAW (Carroll et al. 2006) and several noctuid parasitoids (Hoballah et al. 2002; Gouinguené et al. 2005). Neonates and parasitoids have likely converged on a limited subset of induced plant volatiles as olfactory cues based on their functionality (Stamps and Krishnan 2005)—as ubiquitous and reliable markers of herbivore damage, induced volatiles are among the most apparent indicators of host plant location available to a forager. The extent of overlap and exclusion between herbivores and parasitoids in their use of particular volatiles as cues remains to be determined.

While much research has focused on how plants respond to herbivory and how natural enemies react to induced plant volatiles (Kessler and Baldwin 2002; Dicke et al. 2003; Paré et al. 2005), little is known about responses of feeding herbivores themselves. The few studies that have been performed on generalist responses to induced volatiles have focused primarily on ovipositing females for the simple reason that oviposition is often a critical determinant of host plant selection (De Moraes et al. 2001; Kessler and Baldwin 2001). However, we should not ignore the fact that it is neonate establishment of an initial feeding site on a host, rather than oviposition alone, that is the *sine qua non* of host acceptance by herbivores. Paradoxically, it is often the limited and unspectacular search capabilities and acceptance behaviors of neonates that determine whether host acceptance or rejection occurs after oviposition (del Campo et al. 2001; Renwick 2001). Despite their underlying simplicity (Bernays et al. 2004), caterpillar feeding

behaviors can be readily influenced by host plant volatiles (Shiojiri et al. 2006a).

Given that the induced volatile profiles of herbivore-damaged plants often differ considerably from undamaged plants and change rapidly over time, it is necessary to consider both the role of volatile induction in herbivore host plant acceptance as well as the reciprocal impact of herbivore behavioral responses on the plant. Recent studies with parasitoids demonstrate a surprising complexity in the functions attributed to individual components of an attractive herbivore-induced plant odor, with some compounds being attractive, others repellent, some potentially masking the effects of others, and some inaffectably neutral (D'Alessandro et al. 2006). Comparable studies need to be conducted to determine to what extent these volatiles are directed against herbivores. In particular, the potential of induced volatile components to mask or alter the attractive qualities of a host plant to an herbivore should be further explored. Future attempts to improve plant resistance through alteration of induced volatiles must take into account the different roles of individual components, not only for natural enemies but also for direct mediation of herbivore behavior (Zangerl 2003; Shiojiri et al. 2006a, b).

Acknowledgment We thank Sean Collins and Art Zangerl for comments that improved the manuscript. We especially thank Rob Meagher, Charlie Dillard, and Nancy Lowman for providing the insects used in these experiments. We also thank Julia Meredith and Mary Searle for assistance in the maintenance of plants used in this experiment.

Aphid and Plant Volatiles Induce Oviposition in an Aphidophagous Hoverfly

Francois J. Verheggen · Ludovic Arnaud · Stefan Bartram · Marie Gohy · Eric Haubruge

Received: 17 September 2007 / Revised: 16 November 2007 / Accepted: 16 January 2008 / Published online: 6 February 2008

Abstract *Episyrphus balteatus* DeGeer (Diptera, Syrphidae) is an abundant and efficient aphid-specific predator. We tested the electroantennographic (EAG) response of this syrphid fly to the common aphid alarm pheromone, (E)-β-farnesene (EβF), and to several plant volatiles, including terpenoids (mono- and sesquiterpenes) and green leaf volatiles (C6 and C9 alcohols and aldehydes). Monoterpenes evoked significant EAG responses, whereas sesquiterpenes were inactive, except for the aphid alarm pheromone (EβF). The most pronounced antennal responses were elicited by six and nine carbon green leaf alcohols and aldehydes [i.e., (*Z*)-3-hexenol, (*E*)-2-hexenol, (*E*)-2-hexenal, and hexanal]. To investigate the behavioral activity of some of these EAG-active compounds, *E. balteatus* females were exposed to *R*-(+)-limonene (monoterpene), (*Z*)-3-hexenol (green leaf alcohol), and EβF (sesquiterpene, common aphid alarm pheromone). A single *E. balteatus* gravid female was exposed for 10 min to an aphid-free *Vicia faba* plant that was co-located with a semiochemical dispenser. Without additional semiochemical, hoverfly females were not attracted to this plant, and no oviposition was observed. The monoterpene *R*-(+)-limonene did not affect the females' foraging behavior, whereas (*Z*)-3-hexenol and EβF increased the time of flight and acceptance of the host plant. Moreover, these two chemicals induced oviposition on aphid-free plants, suggesting that selection of the oviposition site by predatory hoverflies relies on the perception of a volatile blend composed of prey pheromone and typical plant green leaf volatiles.

Introduction

Episyrphus balteatus DeGeer (Diptera: Syrphidae) is the most frequently encountered syrphid species at aphid-infested sites in temperate regions (Schneider 1969), and one of the most efficient aphid-specific predators (Entwistle and Dixon 1989; Tenhumberg and Poehling 1991). Because syrphid larvae have limited dispersal abilities (Chandler 1969), oviposition site selection has an important impact on offspring performance. Several studies have addressed a wide range of parameters that influence the foraging and oviposition behavior of aphid natural enemies. Those studied so far are (1) aphid species and their associated chemicals (Budenberg and Powell 1992; Bargen et al. 1998; Sadeghi and Gilbert 2000a, b; Zhu et al. 2005; Almohamad et al. 2007; Verheggen et al. 2007a), (2) physical and chemical characteristics of plants associated with aphid species (Chandler 1968; Sanders 1983; Vanhaelen et al. 2001, 2002; Tumlinson et al. 1992; Zhu et al. 2005; Videla et al. 2006; Almohamad et al. 2007; Harmel et al. 2007), (3) aphid colony size and density (Bargen et al. 1998; Scholz and

Poehling 2000; Sutherland et al. 2001), (4) age of the hoverfly female (Sadeghi and Gilbert 2000c; Frechette et al. 2004) and (5) floral characters (Sutherland et al. 1999).

Location of herbivorous prey by carnivorous arthropods is known to be mediated by many semiochemicals emitted by the prey or its host plants (Dicke and Sabelis 1988; Vet and Dicke 1992; Harmel et al. 2007). Many studies on tritrophic interactions between plants, herbivorous insects, and natural enemies have demonstrated that attack-induced plant volatiles (synomones) may attract carnivorous species (Nordlund and Lewis 1976; Turlings et al. 1990; Vet and Dicke 1992; Tumlinson et al. 1992; Turlings and Tumlinson 1992; De Moraes et al. 2001). Plants infested by herbivores can qualitatively and/or quantitatively change their volatile emissions. These emissions usually consist of terpenoids (monoterpenes and sesquiterpenes) and green leaf volatiles (GLVs; alcohols, aldehydes, or esters), the latter being specifically released just upon tissue damage (Paré and Tumlinson 1997; Farag and Paré 2002; Tholl et al. 2006).

Compared to the large body of information on parasitoids, less information is available on those chemical cues that guide predators during location and acceptance of oviposition sites (Steidle and van Loon 2002). Hoverflies are subjected to various chemical blends when searching for an oviposition site. These blends consist of plant and insect semiochemicals such as (*E*)-β-farnesene (EβF), the main component of the alarm pheromone of most aphid species (Nault et al. 1973; Francis et al. 2005a). This sesquiterpene has been found to act as a kairomone for several aphid predators, including *E. balteatus* larvae, *Harmonia axyridis* adults, and *Adalia bipunctata* larvae and adults (Francis et al. 2004, 2005b; Verheggen et al. 2007a). More than 20 additional chemicals, including α- and β-pinene, cymene, α-phellandrene, or limonene, were found by Francis et al. (2005a) to be released by some aphid species. These volatiles are also commonly found in the headspace of many plant families, such as the Solanaceae, Fabaceae, or Brassicaceae (Agelopoulos et al. 1999; Farag and Paré 2002; Verheggen et al. 2005; Harmel et al. 2007). Terpenoids and GLVs are potential semiochemicals that are used by aphid predators, such as syrphids, lady beetles, or lacewings, to locate their prey (Zhu et al. 1999; Steidle and van Loon 2002; Harmel et al. 2007).

In this study, we investigated the olfactory perception and behavioral activity of various plant volatiles and the common aphid alarm pheromone (EβF) to highlight those that may act on the prey-seeking behavior of *E. balteatus*.

Methods and Materials

Chemicals All chemicals, except EβF, were purchased from Sigma-Aldrich (Chemie Gmbh, Steinheim, Germany) and had chemical purity >97% [determined by gas chromatography (GC)]. EβF was synthesized from farnesol (Tanaka et al. 1975) and had a chemical purity of 98% (also determined by GC).

Biological Material All plants, aphids, and hoverflies were reared in climate-controlled rooms (16 hrs light photoperiod; 70% RH; 20±2°C). Broad beans (*Vicia faba* L.) were grown in plastic pots (9×8 cm) filled with a mixture of vermiculite and perlite (1/1) and were used as host plants for the pea aphid, *Acyrthosiphon pisum* Harris. Adult *E. balteatus* were reared in cages (75×60×90 cm) and fed with pollen, sugar, and water *ad libitum*. Hoverfly oviposition was induced by placing broad beans in the cage for 3 hrs. *E. balteatus* larvae were fed with *A. pisum* and pupae were placed in aerated plastic boxes (14×11×4 cm) until hatching. Experiments were carried out with 2- to 4-wk-old adults.

Electroantennography The hoverfly was immobilized by covering its abdomen and thorax with modeling clay. This setup enabled the recording of electroantennograms for a longer time period than if the antenna was excised (Verheggen et al. 2007b). Two glass Ag-AgCl electrodes (Harvard Apparatus; 1.5 mm OD×1.17 mm ID) filled with saline solution (NaCl, 7.5 g/l; $CaCl_2$, 0.21 g/l; KCl, 0.35 g/l; $NaHCO_3$, 0.2 g/l) and in contact with a silver wire were placed on the insect antennae. The ground glass electrode entirely covered one antenna, whereas the recording electrode that was linked to an amplifier (IDAC-4, Syntech®, Hilversum, The Netherlands) with a ×100 amplification was placed on the bottom of the last segment of the other antenna. A 0.5-cm^2 piece of filter paper that was impregnated with 10 µl of the chemical under examination was placed in a Pasteur pipette. This was then used to puff an air sample in a constant 1.5 l/min airstream. Paraffin oil was used to make chemical solutions with seven concentrations ranging from 10^{-1} to 10^5 ng/µl (by 10× increments). Electroantennograms were collected by using Autospike 3.0 (Syntech, Hilversum, The Netherlands). Stimulation with paraffin oil was used as a negative control before and after the stimulations with the seven concentrations. Time between stimulations was 30 sec. Preliminary results indicated that this length of time was adequate to allow the antenna to recover and regain its full reactivity to stimuli. Five insects from both sexes were tested with each chemical.

Behavioral Observations A single female hoverfly was placed in a cage (30×30×60 cm) with a *V. faba* plant (height, 20 cm). As a positive control, the hoverflies were offered a *V. faba* plant that was infested with 1 g of the pea aphid *A. pisum* 24 hrs before the experiment started. A non-

infested *V. faba* plant was offered to the hoverfly as negative control. A rubber septum was used as dispenser to test the behavioral activity of *(R)*-(+)-limonene (monoterpene), *(Z)*-3-hexenol (GLV), and EβF (sesquiterpene). The dispenser was placed on the first pair of true leaves of a non-infested plant and contained a 100-µl paraffin oil solution (400 ng/µl) of the test chemical. The solution was changed after each replication. Paraffin oil was chosen because of its chemical inertness and ability to continuously release chemicals that are diluted within it. The foraging behavior was recorded for 10 min by using the software The Observer5.0® (Noldus information Technology, version 5.0, Wageningen, The Netherlands). This allows hoverfly behavior to be easily observed, subdivided, and recorded (Harmel et al. 2007). Descriptions of the four observed behavioral subdivisions are presented in Table 1. The number of eggs laid by each female was counted at the end of each observation. Experiments were conducted in a climate-controlled room at 22±1°C. The *E. balteatus* females were 15- to 30-d old, and no aphid-infested plant was offered for 24 hrs before the experiment. Ten replications were performed for each tested chemical.

Statistical Analyses One-way analysis of variance (ANOVA) followed by Tukey's test (pairwise comparisons) was used to evaluate the EAG results. Two sample *t* tests were used to compare EAG responses by males and females. A one-way ANOVA followed by Dunnett's test (comparison with a control) was used to compare the behavioral data observed for the four treatments compared to the control. The one sample *t* test was applied to compare the mean number of eggs laid in behavioral assays to the "0" value observed with the control. All statistical tests were conducted by using Minitab v.14 for Windows®.

Table 1 Description of the behavioral sequences recorded for aphidophagous hoverfly *Episyrphus balteatus* exposed to *Vicia faba*

Observed Behavioral Sequences	Descriptions
Immobility	Predator immobilized on the cage
Searching	
Fly/cage	Predator flies in the cage
Fly/plant	Predator flies near the plant
Acceptance	
Immobile/plant	Predator lands on the plant
Walking/plant	Predator moves on the plant
Proboscis/plant	Predator extends its proboscis and identifies the stimulatory substrate to accept the host
Oviposition	
Immobile abdomen/plant	Predator exhibits an abdominal protraction
Walking abdomen/plant	
Egg laying	Oviposition

Results

Electroantennography Antennal responses increased significantly in both sexes with the concentration of the tested compound (that ranged from 0.1 ng/µl to 0.1 mg/µl). No saturation of the antenna was observed for any tested chemical. The three lowest concentrations (0.1, 1, and 10 ng/µl) did not elicit antennal response, regardless of the tested compound. Because we aimed to compare EAG data to results previously obtained when similar chemicals were tested on other aphid predators, we did not correct our EAG responses by taking into account their differences of volatility, as stated by Brockerhoff and Grant (1999).

EAG responses were significantly different among the five tested chemical families ($F_{4,152}$=117.82, P<0.001), namely, monoterpenes, monoterpenes with an alcohol function, sesquiterpenes, and C6 and C9 green leaf chemicals (Fig. 1). The eight tested monoterpenes elicited electrical depolarization that ranged from −400 to −800 µV, and they were all equally perceived by both sexes. Linalool induced an average depolarization of −1,300 µV. This monoterpene was similarly perceived by males and females (t_{obs}=0.95, P=0.372). The sesquiterpene EβF was the only chemical to be perceived differently by males and females (t_{obs}=2.62, P=0.031). The two other sesquiterpenes (α-humulene and β-caryophyllene) did not elicit electrical depolarization in either sex. The green leaf alcohols and aldehydes tested elicited high EAG responses, statistically equal in both males and females, ranging from −1,750 to −2,250 µV for the six-carbon chain GLV and from −600 to −1,400 µV for the nine-carbons chain GLV.

Behavioral Observations Hoverfly gravid females were not activated by a non-infested *V. faba* and stayed immobile during 80% of the observation time (Fig. 2). However, when an aphid-infested plant was presented, the duration of immobility was significantly reduced, and the time spent on the plant (acceptance) increased. Moreover, the number of eggs laid increased compared to non-infested plants (7.4 eggs/female; t_{obs}=7.38, P<0.001; Fig. 3). *(R)*-(+)-Limonene did not significantly attract the predatory hoverflies to the non-infested plant and did not increase the number of eggs laid, when compared with a non-infested semiochemical-free plant (0.2 egg/female; t_{obs}= 1.50, P=0.084). *(Z)*-3-Hexenol presented on a non-infested plant significantly increased the mobility of females and plant acceptance. Furthermore, this GLV induced oviposition on the non-infested plant compared to oviposition on

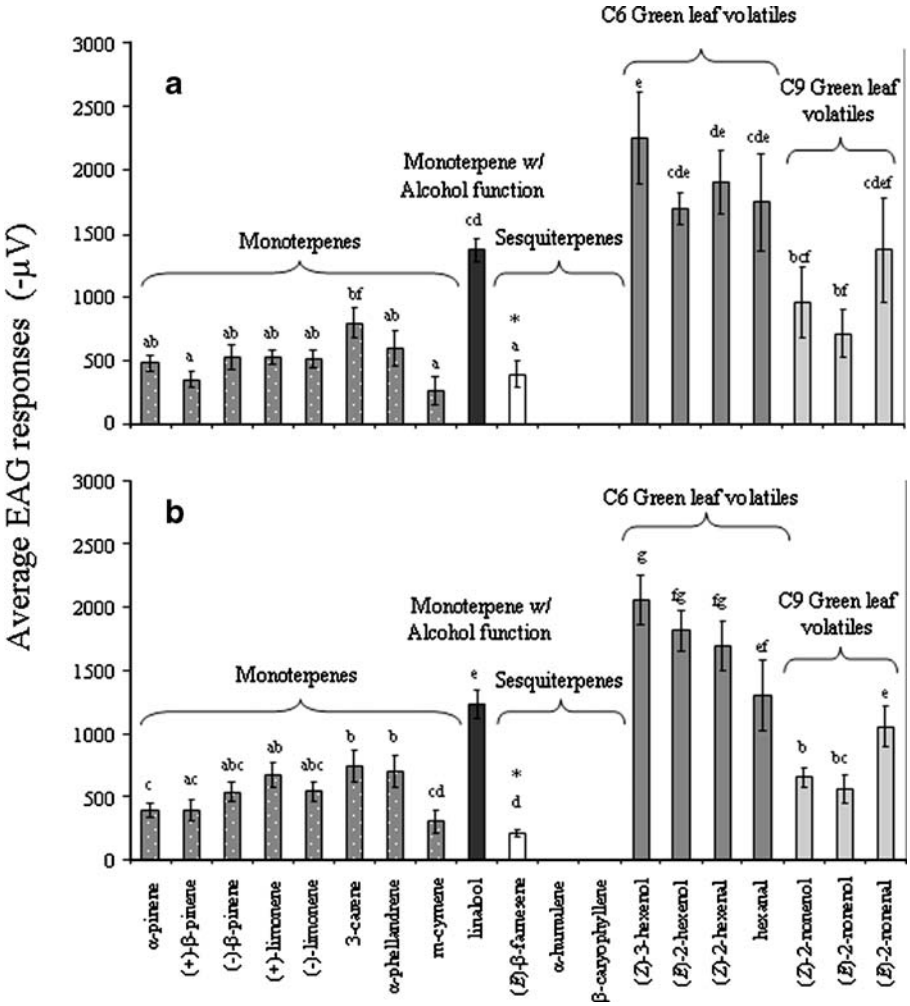

Fig. 1 EAG activity of female (**a**) and male (**b**) *Episyrphus balteatus* antennae to aphid and plant volatiles (100 μg/μl). Means (±SE) with no letter in common are significantly different (ANOVA followed by Tukey's test, $P<0.05$). An *asterisk* indicates significant difference in EAG activity between male and female antennae (two-sample Student's *t* test, $P<0.05$). $N=5$ for both sexes and each chemical

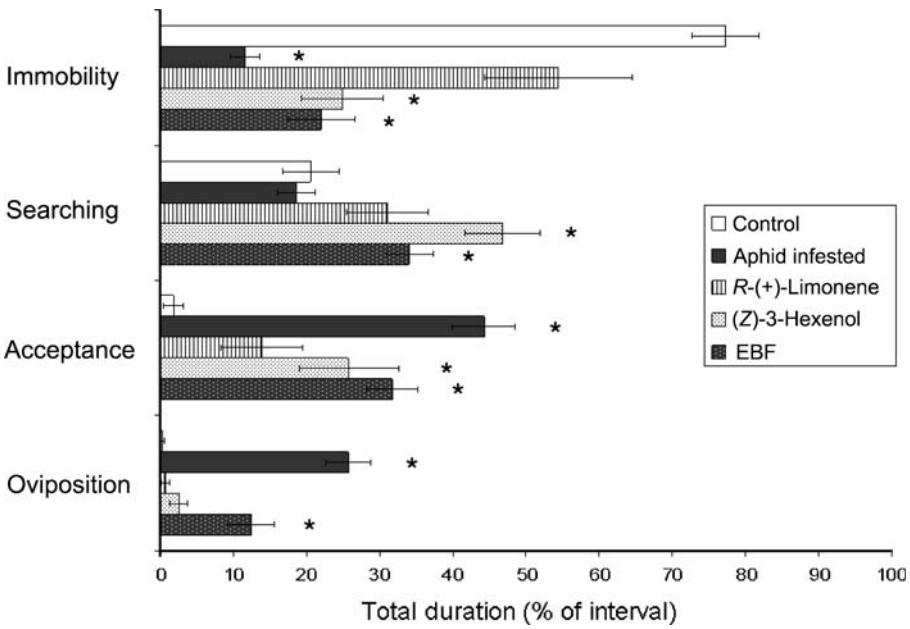

Fig. 2 Effect of plant and aphid volatiles on different sequences of the foraging behavior of *Episyrphus balteatus* females (mean duration in percent of interval, ±SE). Volatiles [*R*-(+)-limonene, (*Z*)-3-hexenol, and (*E*)-β-farnesene (EBF)] were offered on a non-infested plant. *Stars* indicate significant differences from the non-infested semiochemical-free plant (=Control) for the respective behavioral sequence (ANOVA followed by Dunnett's test, $P<0.05$). $N=10$ for each treatment

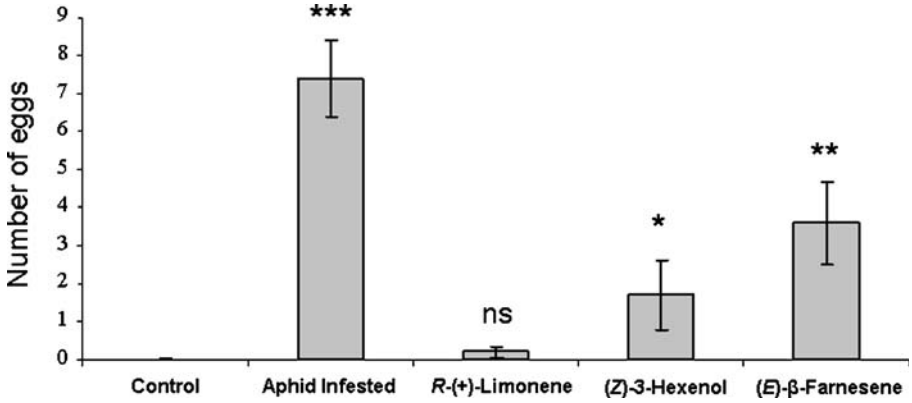

Fig. 3 Effect of plant and aphid semiochemicals on oviposition of *Episyrphus balteatus* females (mean number of eggs ±SE). *ns* No significant differences from control; **P*<0.05, ***P*<0.01, and ****P*<0.001 significant differences from control (one-sample Student's *t* test). *N*=10 for each treatment

semiochemical-free, non-infested plants (1.7 eggs/female; t_{obs}=1.85, *P*=0.049). The main compound of the aphid alarm pheromone (EβF) significantly increased hoverfly mobility on non-infested plants, searching duration, acceptance of the host plant, and oviposition. The mean number of eggs laid per female was 3.6. This was significantly higher than the control (t_{obs}=3.31, *P*=0.005) and lower than the number of eggs laid on an aphid-infested *V. faba* plant ($F_{1,18}$=6.60, *P*=0.019).

Discussion

Tritrophic interactions among infested plants, herbivorous arthropods, and their natural enemies are complex because of the many semiochemicals typically involved. In addition to the semiochemicals emitted by herbivorous insects, most plant species respond to insect infestation by synthesizing and releasing complex blends of volatiles. These can be used by predators and parasitoids as foraging cues, thereby enhancing the plants' defense ability (Dicke et al. 1990; Dicke 1994; Turlings et al. 1995). There are several previous electrophysiological studies of antennal responses by aphid natural enemies to prey and host plant semiochemicals that include lady beetles (Coleoptera, Coccinellidae) (Zhu et al. 1999; Al Abassi et al. 2000; Verheggen et al. 2007a) and lacewings (Nevroptera, Chrysopidae) (Zhu et al. 1999; 2005). Some chemicals attract predators, but no information is available about their impact on predator foraging behavior and oviposition (Zhu et al. 1999, 2005). However, several species respond with oviposition to aphid-produced honeydew alone, whereas in others, the aphid prey itself is needed for oviposition (Steidle and van Loon 2002).

Syrphid larvae do not use semiochemicals to locate aphids, or exclusively at short distances (Bargen et al. 1998; Francis et al. 2005b). Because of their limited dispersal abilities (Chandler 1969), the choice of the oviposition site by adult females has an impact on offspring performance. Volatile organic compounds are therefore presumed to guide their foraging behavior. To the best of our knowledge, this is the first published report of successful EAG recordings from *E. balteatus* antennae, and we found that adult hoverflies are able to sense their environment by odors. Generalists may need to invest less time in searching particular host and prey species than specialists. Therefore, the use of infochemicals to reduce searching time should be less important (Vet and Dicke 1992). However, previous studies have indicated that the use of infochemicals for foraging is an adaptive strategy regardless of dietary specialization and that physiological constraints on sensory processing in generalists might be less severe than previously supposed (Steidle and van Loon 2003). We demonstrated in this paper that some EAG-active compounds play a key role in foraging behavior of the generalist *E. balteatus*. Plant and prey volatiles activate this predatory species and induce oviposition, even in absence of aphids. Additionally, we have confirmed that *E. balteatus* females do not lay eggs on a non-infested plant (Scholz and Poehling 2000).

The electrophysiologically tested terpenoids α-pinene, β-pinene, α-phellandrene, and limonene are not only common plant volatiles (Farag and Paré 2002; Tholl et al. 2006) but are also emitted by some aphid species such as *Megoura viciae* Buckton or *Drepanosiphum platanoides* Schrank (Francis et al. 2005a). It is not surprising that they, like other monoterpenes, elicited EAG responses in both male and female *E. balteatus*. *(R)*-(+)-Limonene did not attract the hoverflies and that the number of eggs laid by females exposed to *(R)*-(+)-limonene on a non-infested plant was not significantly different from a non-infested plant. This monoterpene is commonly found in the headspace of various plant species (Agelopoulos et al. 1999; Farag and Paré 2002; Verheggen et al. 2005) and does not provide information about prey presence on a stressed plant. This might explain why *(R)*-(+)-limonene did not provoke a behavioral effect on a gravid hoverfly female.

Whereas the tested monoterpenes elicited small EAG responses, the GLVs showed EAG responses that were three to four times higher for the six-carbon chain GLVs, and two to three times higher for the nine-carbon chain GLVs. These responses by *E. balteatus* differ from those by other aphid predators (Zhu et al. 1999). In addition, our results show that *(Z)*-3-hexenol increased the female's mobility, plant acceptance, and oviposition activity even in the absence of prey.

EβF, the common aphid alarm pheromone (Francis et al. 2005a), which acts as a kairomonal substance for several aphid predators (Francis et al. 2004, 2005b; Verheggen et al. 2007a), was detected by both male and female *E. balteatus* adults. In contrast to lacewings and lady beetles, *E. balteatus* showed a sex-specific response to EβF (Zhu et al. 1999; Verheggen et al. 2007a). This difference in antennal activity between sexes accentuates the importance of EβF in hoverfly foraging behavior, as females are looking for a suitable oviposition site. In contrast to the strong response to EβF, hoverflies showed no response to the two other tested sesquiterpenes, α-humulene and β-caryophyllene. Whereas β-caryophyllene induced antennal activity in both lady beetles and lacewings, α-humulene was not tested on these two aphidophagous predators (Zhu et al. 1999; Verheggen et al. 2007a). The lack of electrical response by *E. balteatus* to the two sesquiterpenes and the lower responses observed to the C9-GLV compared to the C6-GLV may also be caused by their lower volatility. Brockerhoff and Grant (1999) stated that EAG responses should be corrected by taking into account the volatility of the tested chemicals. However, EβF is as volatile as β-caryophyllene and α-humulene. EβF significantly increased hoverfly mobility, acceptance of the host plant, and the number of eggs laid (3.6 eggs/females). This aphid alarm pheromone is thus a key compound in prey-seeking behavior in aphidophagous hoverflies. Previous results have demonstrated a kairomonal role for *E. balteatus* larvae, which were attracted in a four-arm olfactometer (Francis et al. 2005b). In this study, we confirmed that female hoverflies are able to perceive this sesquiterpene and use it to select an oviposition site. Behavioral results obtained with an EβF-treated aphid-free plant and an aphid-infested plant were different. Therefore, the data suggest that predatory hoverfly oviposition site selection is influenced by a blend rather than a single chemical. This includes not only EβF but also secondary metabolites related to plant damage, such as GLVs.

Acknowledgments The authors are grateful to Dr Y. Brostaux (Department of Statistic and Computer Sciences, Gembloux Agricultural University) for his help in statistical analyses and to Adam Dellinger from Penn State University (USA) for the corrections he brought to the manuscript. Abstract It is known that human individuals show different levels of attractiveness to mosquitoes. In this study, we investigated the chemical basis for low attractiveness. We recorded behaviors of *Aedes aegypti* toward the hands of human volunteers and toward the volatile chemicals produced by their bodies. Some individuals, and their corresponding volatiles, elicited low upwind flight, relative attraction, and probing activity. Analyzing the components by gas chromatography coupled to electrophysiological recordings from the antennae of *Aedes aegypti*, enabled the location of 33 physiologically relevant compounds. The results indicated that higher levels of specific compounds may be responsible for decreased "attractiveness." In behavioral experiments, five of the compounds caused a significant reduction in upwind flight of *Aedes aegypti* to attractive human hands. Thus, unattractiveness of individuals may result from a repellent, or attractant "masking," mechanism.

Introduction

Mosquitoes (Diptera: Culicidae) have a sophisticated olfactory system that allows location of potential hosts and demonstrates interspecific preferences for certain vertebrate species. For example, *Anopheles* spp., which include vectors of malarial parasites, feed on higher vertebrates such as human beings and members of the bovidae; *Culex* spp., which include vectors of West Nile virus, are mostly ornithophilic while most *Aedes* spp., which include the yellow fever mosquito, *Aedes aegypti*, and some *Anopheles* spp. are highly anthropophilic (Takken 1991). These mosquitoes and other flies that bite vertebrates to obtain blood (sandflies, Diptera: Psychodidae and some blackfly species, Diptera: Simuliidae) also show intraspecific preferences for certain individuals (Acree et al. 1968; Hamilton and Ramsoondar 1994; Schofield and Sutcliffe 1996; Takken and Knols 1999; Dekker et al. 2001; Besansky et al. 2004; Jensen et al. 2004; Qiu et al. 2004). However, although this behavioral preference for certain individuals has been demonstrated, the basis for the phenomenon is unknown (Brouwer 1960; Khan and Maibach 1966; Mayer and James 1969; Burkot 1988; Schreck et al. 1990; Lindsay et al. 1993; Brady et al. 1997; Costantini et al. 1997; Qiu et al. 2004).

During host location, female mosquitoes use volatile chemicals released by their vertebrate hosts as long-range host location cues (Allan et al. 1987; Takken 1991; Takken and Knols 1999). Physical cues such as heat, moisture, and vision play a role during orientation and landing at close range (Khan et al. 1968; Eiras and Jepson 1994). The known olfactory stimuli from long-range orientation include CO_2, 1-octen-3-ol, acetone, and ammonia (Allan et al. 1987; Costantini et al. 1998; Takken and Knols 1999; Bernier et al. 2000, 2002; Bhasin et al. 2000, 2001; Jensen

et al. 2004). Different levels of attraction can be determined by volatile olfactory cues from breath and skin with its associated microorganisms (Allan et al. 1987; Steib et al. 2001; Bernier et al. 2002; Jensen et al. 2004). *Aedes aegypti*, *Anopheles stephensi*, *Anopheles gambiae*, and *Anopheles quadrimaculatus* show variation in attraction to hand odors from different individuals (Brouwer 1960; Khan and Maibach 1966; Mayer and James 1969; Schreck et al. 1990). Olfactometer studies have shown that human hands can be used as a "standard stimulus" typical of the whole body (Freyvogel 1961; Takken 1991; Eiras and Jepson 1994; Geier et al. 1996). Olfactometers have also shown that mosquitoes show positive behavioral responses to natural host volatiles that have been collected and then presented as an extract (Schreck et al. 1981; Takken 1991; Geier et al. 1996; Qiu et al. 2004). However, few studies have attempted to identify the chemicals within the extracts that are actually responsible for the attraction or lack of attraction of different individuals (Braks and Takken 1999; Braks et al. 2001; Healy et al. 2002; Qiu et al. 2004). One study tentatively identified 346 chemicals from human hand odors deposited onto glass beads (Bernier et al. 2000) that include members of diverse chemical groups: aldehydes, carboxylic acids, alcohols, aliphatics/aromatics, amides, amines, esters, halides, heterocyclics, ketones, sulfides, and thioesters. Of the 346 chemicals, 277 were suggested to be candidate attractants for *Aedes aegypti* (Bernier et al. 2000). Most investigations have focused on components of human odor that are described as attractants to mosquitoes, i.e., those that increase upwind flight activity in olfactometers or increase trap catches in field traps. These commonly include lactic acid, carbon dioxide (CO_2), ammonia, and acetone, with each showing varying abilities to elicit behavioral responses (Acree et al. 1968; Kline et al. 1990; Eiras and Jepson 1994; Geier et al. 1996; Bernier et al. 2003). It might be assumed that a lack of or reduction in such chemicals would contribute to low human attractiveness. It has been shown that adding lactic acid to the skin of formerly unattractive individuals increases their attractiveness (Steib et al. 2001) and that the removal of lactic acid from an attractive extract gives a loss of attraction (Geier et al. 1996). However, it is unlikely that compounds such as lactic acid and CO_2, which are produced ubiquitously by vertebrates as products of primary metabolism, are associated with differential attraction. It seems more likely that secondary volatile metabolites produced by the body or bacteria on the skin are involved. Three such human-specific compounds, 7-octenoic acid, (*E*) and (*Z*)-3-methyl-2-hexenoic acid, reduce catches of *Anopheles gambiae* at some concentrations in odor baited entry traps (Costantini et al. 2001).

An alternative basis for differential attractiveness is that some individuals produce additional compounds that interfere with their location by insects. This has been demonstrated in the attraction of the horn fly, *Haematobia irritans* (Diptera: Muscidae) to cattle (Steelman et al. 1993; Birkett et al. 2004; Jensen et al. 2004) where a volatile compound, 6-methyl-5-hepten-2-one, produced by unattractive cattle prevents fly attack. Furthermore, when this compound was applied in a slow-release sachet to cattle during a field study, fly-loads were significantly reduced (Birkett et al. 2004). Because many compounds, when applied at concentrations higher than they would occur naturally, can act as repellents (Pickett et al. 1998; Gikonyo et al. 2002, 2003), the mechanism for the reduction in fly-loads was suggested to be repellency or 'masking'.

In the present study, we examined the chemical basis of differential attractiveness of human subjects to *Aedes aegypti*. A newly developed volatile collection technique, along with coupled gas chromatography-electroantennography (GC-EAG), allowed the examination of complex extracts of human odors, at naturally occurring levels, and the identification of compounds that are physiologically relevant to the insects.

Methods and Materials

Insects A culture of *Aedes aegypti* was set up from the 'refm' strain obtained from the London School of Hygiene and Tropical Medicine. The culture was maintained at 27± 2°C, with a relative humidity of 55–60% and a L/D 12:12 hr photoperiod. Larvae were reared in trays and were fed daily with Tetramin® Tropical Fish Flakes. Adults were kept in plastic culture cages with a constant supply of 15% sucrose solution, and females were given access to sheep blood once a week via an artificial feeding system. For behavioral assays, female mosquitoes that had not been previously blood-fed were chosen at random from a population aged between 5 and 12 d. Mosquitoes were held in culture cages in the bioassay room (with access to 15% sucrose) for 24 hr and transferred to plastic pre-release chambers (without sucrose) 2 hr before use in the bioassay. Each replicate had 20–30 female mosquitoes.

Behavioral Assays Behavior of mosquitoes to human odors was assessed by using a Y-tube olfactometer as described by Geier and Boeckh (1999) in which adult insects (see above) could "choose" between a test sample or air alone. Two fluorescent light tubes (70 W; Luminux) were positioned overhead, approximately 1 m from the Y-tube, and the temperature and relative humidity were maintained at 27°C and 60%, respectively. Air was pushed through a glass bell jar (5 l) that contained distilled water (1 l) and an activated charcoal filter before being split between the arms

of the Y-tube (10 l min^{-1}). Two flowmeters controlled the airflow, to a mean speed of 0.13 m sec^{-1} in the arms and 0.11 m sec^{-1} in the stem of the olfactometer.

Three behaviors were recorded: (1) upwind flight activity (the proportion of mosquitoes that flew upwind beyond 30 cm in the stem of the Y-tube); (2) relative attraction (the proportion of mosquitoes in the arm of the Y-tube that contained the odor stimulus); (3) probing activity (the proportion of mosquitoes that probed their proboscis through the mesh in the treated arm of the Y-tube).

To test the effect of compounds that emanated from hands, 'test hands' were compared with a 'standard hand' (Y01) previously shown to be attractive, (i.e. causing approximately 70% of mosquitoes to fly upwind and with 80% relative attraction). Each test hand was placed in one side of the Y-tube with nothing in the other. This was repeated 10–12 times, and the average responses were calculated to determine levels of 'attractiveness'. Nine people were tested in this way. All were white European men and women, ranging from 21 to 60 years of age. The study was approved by the Bedfordshire and Hertfordshire Strategic Health Authority Local Research Ethics Committee, UK (Reference number: EC03652). Responses toward the 'standard hand' were shown to be consistent on each testing day by comparing the mean proportion for flight activity and relative attraction in response to the 'standard hand' and the control treatment using a χ^2 test for heterogeneity (Zar 1984).

To test the effect of compounds that emanated from whole bodies, air entrainment samples were applied to filter paper (10 µl) in one side of the Y-tube with a solvent control (redistilled diethyl ether on filter paper, 10 µl) in the other. CO_2 (0.1%) was added to the main air stream to activate mosquito flight (Dekker et al. 2005). This was not necessary for the hand experiments because hands themselves emit carbon dioxide (G. Lees, personal communication, University of Aberdeen).

For testing hands supplemented with other chemicals, the test compounds were applied to sterile filter paper contained in an external glass vessel, and air, controlled by flowmeters, was pumped (500 ml min^{-1}) from the glass vessel directly into the main air stream of the Y-tube, in front of the hand, via polytetrafluoroethylene tubing.

Individual chemical compounds identified from hands or extracts were tested by comparing control (clean air) vs control (clean air), the 'standard hand' vs control (clean air), and the 'standard hand' plus 5-decadic serial dilutions of a test compound ranging from 1×10^{-4} to 1×10^{-8} g in hexane (10 µl) vs 10 µl hexane control. The test compounds used were 6-methyl-5-hepten-2-one, octanal, nonanal, decanal, and geranylacetone. CO_2 was not added. Each odor stimulus was tested in a complete randomized block design, i.e. a control, a standard, and each dose of the same chemical was tested once within a block, and blocks were performed over several days, with 10 replicates for each.

Collection of Human-Derived Volatile Chemicals For 24 hr before the collection of volatiles, volunteers avoided spicy food, garlic, and alcohol, and used non-perfumed soap. Whole-body volatiles were collected by using a new system whereby volunteers were placed in individual aluminumized plastic bags (Lifesystems ™), with only their heads outside. Charcoal-filtered air was introduced into the top of the bag (flow rate, 2.2 l min^{-1}) and extracted from the bottom into two glass tubes that contained pre-conditioned 50 mg Porapak Q (Porapak tubes), while a positive pressure was maintained inside the bag. Air entrainments of individuals were run for 2 hr and were performed on the same day as the behavioral assays with hands. Moisture that had gathered in the Porapak tubes was removed by passing purified nitrogen through the tubes for 2 min after the entrainment. Porapak tubes were then eluted with freshly re-distilled diethyl ether (750 µl) to provide extracts.

Coupled Gas Chromatography-Electrophysiology GC-EAG was used to locate peaks within mixtures that could be detected by the antennae of mosquitoes. Test insects were unfed and mated 5- to 12-d-old, *Aedes aegypti* females, 'cooled' on ice for 30 sec before removing the head and the tips of both antennae. The indifferent electrode was inserted into the back of the head, and the distal ends of both antennae were inserted into the recording electrode. Recordings were made with Ag/AgCl electrodes inserted into glass pipettes filled with a saline solution (insect ringer—7.55 g NaCl, 0.64 g KCl, 0.22 g $CaCl_2$, 1.73 g $MgCl_2$, 0.86 g Na_2HCO_3, and 0.61 g Na_3PO_4 l^{-1} water). Electrodes were connected to an Autospike interface box and an AC/DC amplifier UN-06 (Syntech, The Netherlands). Preparations were held in a continuous, humidified, and charcoal-filtered air stream (1 l min^{-1}, Syntech Stimulus Controller CS-02, Syntech) that came from a glass tube outlet that was positioned 0.5 cm from the preparation. An HP 6890 gas chromatograph was used to separate the components of mixtures on a polydimethylsiloxane (HP1) column 30 m× 0.32 mm (film thickness, 0.52 µm). The oven temperature was maintained at 40°C for 2 min and then programmed at 5°C min^{-1} to 100°C and then at 10°C min^{-1} to 250°C. The carrier gas was hydrogen. Consistent antennal responses to individual components of the mixtures were determined by replicating the GC-EAG experiments (N=6–10), and EAG activity was confirmed by testing authentic chemicals obtained commercially.

Gas Chromatography and Coupled Gas Chromatography–Mass Spectrometry To identify compounds within air

entrainment extracts that elicited EAG responses, samples were injected into an HP 5890 GC fitted with a non-polar HP1 cross-linked polydimethylsiloxane capillary column (50 m, 0.32 mm ID, 0.52 μm film thickness), a cool on-column injector, and a deactivated HP1 pre-column (0.53 mm ID). The carrier gas was helium. The GC oven temperature was maintained at 30°C for 5 min and programmed at 5°C min^{-1} to 250°C. The GC was coupled to a VG Autospec double-focusing magnetic sector mass spectrometer (MS) and an integrated data system (Fisons Instruments, Manchester, UK). Ionization was by electron impact at 70 eV, 250°C (source temperature). All compounds of interest were tentatively identified by comparison of peaks on the GC with MS databases [NIST Standard Reference Database (Version 3.0.1.), 2002] and were confirmed by coinjection of authentic compounds on an HP1 and a DB-WAX column.

To analyze the air entrainment extracts, a Hewlett Packard (HP) 6890 gas chromatograph (GC) was used. This was fitted with a non-polar polydimethylsiloxane (HP1) cross-linked capillary column (50 m×0.32 mm ID, film thickness: 0.52 μm) and a polar DB-WAX column (30 m×0.32 mm ID, film thickness 0.82 μm) with hydrogen as the carrier gas. A cool on-column injector and a flame ionization detector (FID) were used. The GC oven temperature was held at 30°C for 1 min and programmed to increase at 5°C min^{-1} to 150°C, then 10°C min^{-1} to 240°C. To quantify the compounds within the air entrainment extracts, a multiple point external method was used.

Statistical Analyses For behavioral studies, pairwise comparisons were made between the 'standard hand' and the 'test hand', by using a generalized linear model (GLM) with binomial error and logit link (logistic regression)*r*. A logistic GLM was fitted (as above) to the data from extracts and standard hands plus chemicals (testing chemicals alongside a human hand). The mean proportions of mosquitoes that responded to all treatments were compared. Confidence intervals (95%) for each mean were calculated from the standard errors on the logit scale and $t_{0.05}$. These means, and 95% confidence intervals, were back-transformed to the proportion scale for presentation.

Volunteers were classified as 'attractive' or 'less attractive' based on significant behavioral differences in responses of mosquitoes to hands (see Fig. 1). Following analysis of the volunteers' extracts by GC, mean absolute amounts of each compound for the attractive and less attractive volunteer groups were compared by using a one-way analysis of variance (ANOVA). For each compound, the mean relative amount (percentage, p) was calculated (i.e., mean absolute amount divided by the mean total amount of all EAG-active compounds) and transformed by using the logit transformation [$\text{logit}(p)=\ln(p/(1-p))$]. Mean relative amounts were compared between the two groups by using a one-way ANOVA.

For the GC data from two groups of individuals, Group 1 (attractive to mosquitoes) and Group 2 (unattractive to mosquitoes), canonical variate analysis (CVA) was applied where $N=6$ for Group 1 and $N=4$ for Group 2. In this case, the method produces a one-dimensional representation of the data (because there are only two groups but many chemicals), which emphasizes group differences. Therefore, the new axis (canonical variate) is the linear combination of the original variates (chemicals), which maximizes the 'between-group' variability relative to the 'within-group' variability. Subsequent axes account for further variation not accounted for by previous canonical variates (CVs). For CVA, the loadings on the variates (chemicals) are scaled so that the average within-group variability in each canonical variate dimension is 1. Thus, the within-group variation is equally represented in each dimension. Loadings corresponding to roots less than 1 are for dimensions in the canonical variate space that exhibit more within-group variation than between-group variation.

Results

To test the responses of mosquitoes toward human odors directly from hands or whole body air-entrainment extracts, behavioral experiments were used to determine upwind flight activity, relative attraction, and probing activity.

Behavioral Assays—Hand Odors To ensure that valid comparisons of mosquito responses to hand odors from different individuals could be made on different days, each hand was compared to the standard hand of an 'attractive' individual on the day of testing. This showed that responses to the standard stimulus were consistent among testing days with the mean upwind flight activity for the standard stimulus being 71% (data not shown).

The responses of mosquitoes to odors from the hands of different individuals varied significantly (Fig. 1). For flight activity (Fig. 1a), test hands X09 ($P=0.001$), X07 ($P=0.012$), and X04 ($P=0.016$) induced greater proportions of *Aedes aegypti* mosquitoes to respond than did the standard hand. Hands X08 and X05 were not significantly different from the standard hand ($P=0.395$ and $P=0.935$, respectively), although they were different from clean air ($P=0.001$; data not shown). Significantly fewer mosquitoes performed upwind flight activity in response to four hands X06, Y04, Y05, and Y07 ($P<0.001$ for all volunteers) compared to the standard hand. However, all volunteers were also different from the control ($P=0.001$).

For relative attraction (Fig. 1b), hands X04 or X08 showed greater effects than did the standard hand ($P=0.002$

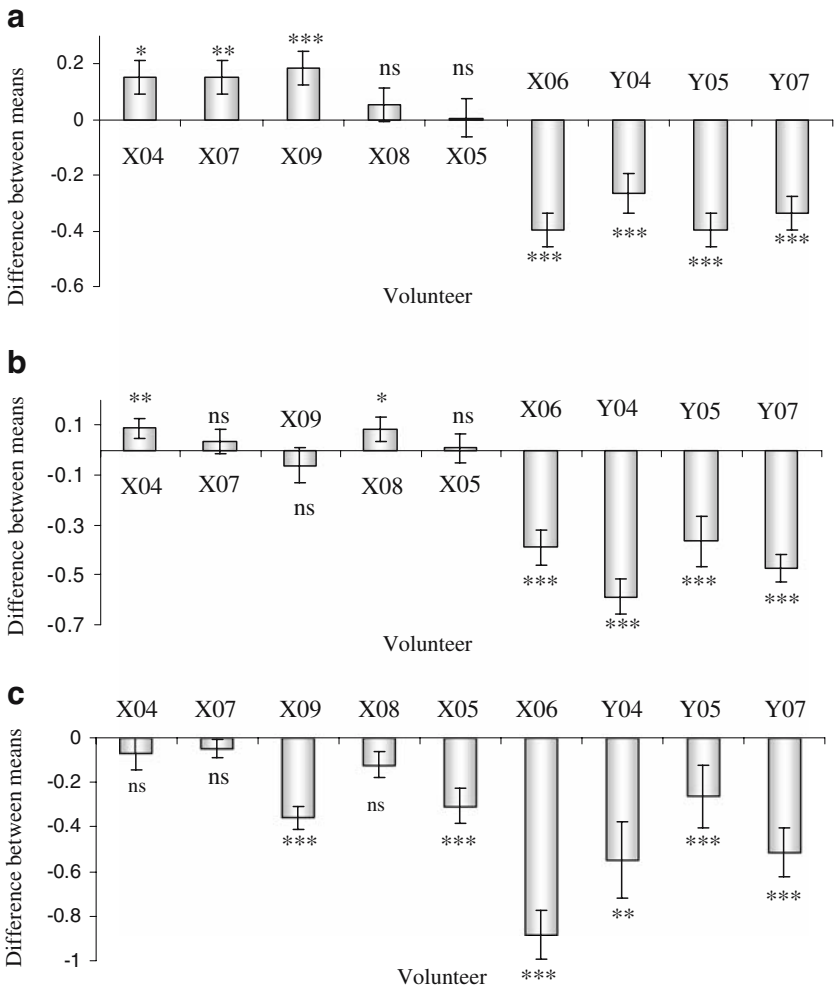

Fig. 1 Behavioral responses of *Aedes aegypti* female mosquitoes to nine test hands expressed as a difference from the standard hand. **a** Flight activity—the proportion of mosquitoes recorded upwind in the Y-tube; **b** relative attraction—the proportion of mosquitoes upwind recorded in the treated arm of the Y-tube; **c** probing activity—the proportion of mosquitoes upwind recorded probing in the treated arm of the Y-tube. Data are presented as differences between the response to the test hand and the response to the standard hand. Back transformed means+SED are shown. Asterisks indicate statistically significant differences determined by using a GLM (see text) (GLM, *$P<0.05$, **$P<0.01$, ***$P<0.001$; $n=10$–12 tests per volunteer; total mosquitoes per treatment, 287–485; total mosquitoes, 2,870–4,850)

and $P=0.019$, respectively), with the relative attraction of X07 and X09 being the same. However, relative attraction of hands X06, Y04, Y05, and Y07 was lower than that of the standard hand ($P<0.001$). These are the same four hands that induced low-flight activity.

For probing activity (Fig. 1c), hands X04 ($P=0.354$), X07 ($P=0.532$), and X08 ($P=0.082$) were not different form the standard, but all other hands showed lower responses to the standard stimulus (X09, $P<0.001$; X05, $P<0.001$; X06, $P=0.001$; Y04, $P=0.01$; Y05, $P=0.01$; Y07, $P<0.001$). Probing activity was not seen in response to the clean air control.

Behavioral Assays—Air Entrainment Extracts When air entrainment extracts were tested (Fig. 2a), the greatest flight activity was recorded for the extract from individual X07, followed by the extract from the standard (Y01), and extracts X09 and X04, all of which were greater than the clean air control ($P<0.001$ for all extracts; Fig. 2a). In good correlation with the hand experiments, extracts from individuals X06, Y04, Y05, and Y07 induced significantly less flight activity than the standard extract (Y01), and the response to these four extracts was not different from that of the clean air control ($P=0.54$, $P=0.71$, $P=0.69$, $P=0.226$, respectively; Fig. 2a). Extracts collected from the standard (Y01), X04, and X09 induced a significantly greater relative attraction than the control ($P<0.001$ for all extracts; Fig. 2b). However, again in correspondence with the hand experiments, relative attraction toward the extracts from X06, Y04, Y05, and Y07 was not significantly different from the solvent control ($P=0.562$, $P=0.296$, $P=0.889$, $P=0.767$, respectively; Fig. 2b). Probing activity did not occur in these experiments.

Electrophysiology, Gas Chromatography, and Gas Chromatography–Mass Spectrometry Four of the extracts shown in Fig. 2, i.e., those from the standard hand (Y01), the equally attractive test hand X04, and two much less attractive hands Y04 and Y05, were chosen for analysis by coupled GC-EAG. This revealed 33 peaks associated with EAG activity (an example is given in Fig. 3, which is labeled to show the eight EAG-active peaks found in

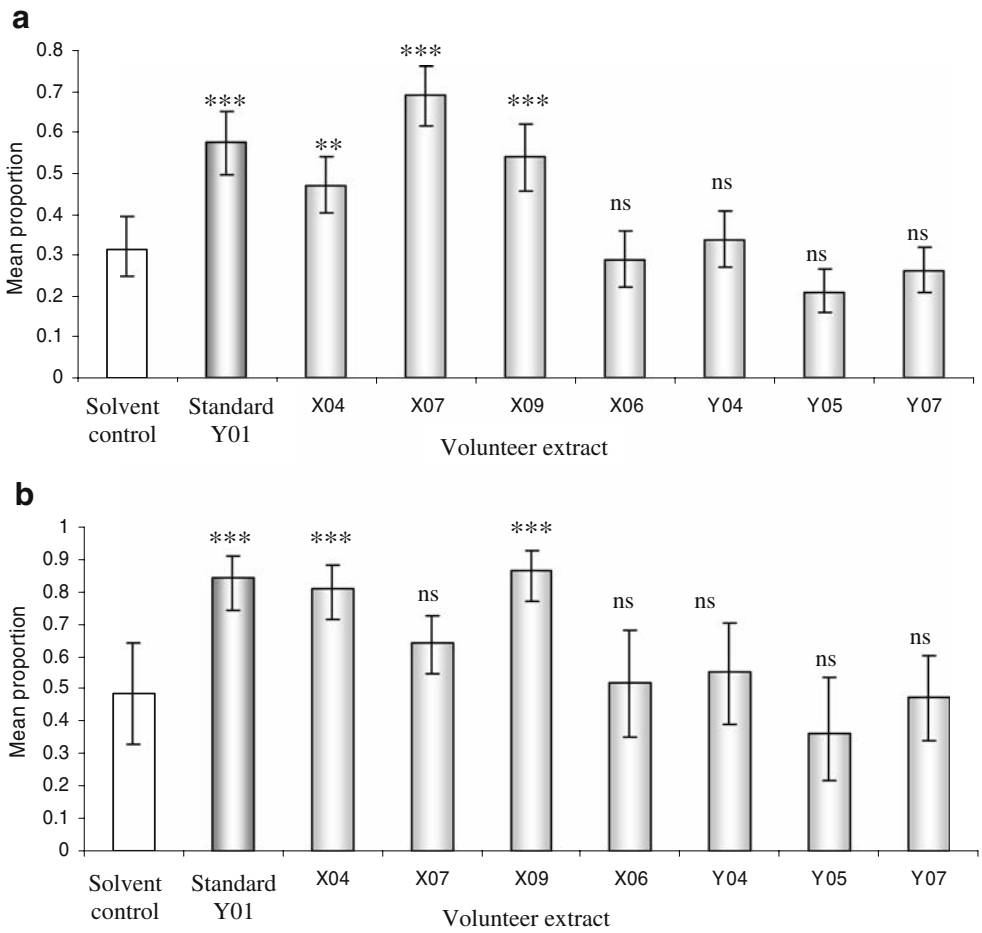

Fig. 2 Behavioral responses of *Aedes aegypti* female mosquitoes to air entrainment extracts (plus 0.1% CO_2) collected from seven people and the standard volunteer. **a** Flight activity—the proportion of mosquitoes recorded upwind in the Y-tube; **b** relative attraction—the proportion of mosquitoes upwind recorded in the treated arm of the Y-tube. Back-transformed means with 95% confidence intervals are shown. Asterisks indicate statistically significant differences from the control (solvent+CO_2) determined using a GLM (see text) (GLM, *P<0.05, **P<0.01, ***P<0.001; n=10–12 tests per extract; total mosquitoes per treatment, 151–232; total mosquitoes, 1449–2088)

greater amounts in the less-attractive group extracts). The compounds that gave rise to 23 of these peaks were tentatively identified by gas chromatography–mass spectrometry (GC-MS), and their identity was confirmed by peak enhancement on GC using two columns of different polarity by coinjection with authentic compounds (Table 1). The 23 peaks were thus identified and were examined by EAG using authentic samples, and the activity was confirmed. Ten EAG-active peaks, retention indices: 735, 792, 857, 829, 875, 907, 1030, 1130, 1345, and 2006 remain unidentified.

Thus, the coupled GC-EAG allowed location of physiologically relevant components within extracts. A comparison of mean absolute amounts of EAG-active compounds between the attractive and less-attractive subjects revealed a series of differences (Fig. 4a). Eight compounds (Fig. 3, Table 1) were found in significantly greater amounts (on average) in the less-attractive group compared with the attractive group, benzaldehyde, 6-methyl-5-hepten-2-one, octanal, unknown, nonanal, naphthalene, decanal, and geranylacetone [(*E*)-6,10-dimethyl-5,9-undecadien-2-one] (compound numbers: 2, 3, 4, 8, 10, 16, 17, 20, respectively in Fig. 4a; Table 1). There were no significant differences among the other compounds found in both the attractive and less-attractive groups. Mean relative amounts of 6-methyl-5-hepten-2-one, octanal, and decanal also differed, the less attractive being higher in each case (Fig. 4b). CVA, including the EAG-active compounds in Table 1, revealed statistically significant (P<0.05) discrimination of the attractive and less-attractive groups, based on the ratio of between- to within-group variability in the amounts of the 24 EAG-active chemicals (Fig. 4c).

Behavioral Assays–Human Odors Plus Compounds Five of the EAG compounds produced in greater quantities by less-attractive individuals (6-methyl-5-hepten-2-one, octanal, nonanal, decanal, and geranylacetone) were tested in behavioral trials. They were each tested in conjunction with the standard hand to see if they affected attractiveness. Upwind flight activity, relative attraction, and probing activity of *Aedes aegypti*, were recorded (Figs. 5, 6, and 7).

Although flight activity to the standard hand was shown to be significantly greater than to the clean air control, there was reduced flight activity to the hand plus 6-methyl-5-hepten-2-one (Fig. 5). This was significant for all five doses tested (P=0.039 for 1×10^{-4} g, P=0.04 for 1×10^{-5} g,

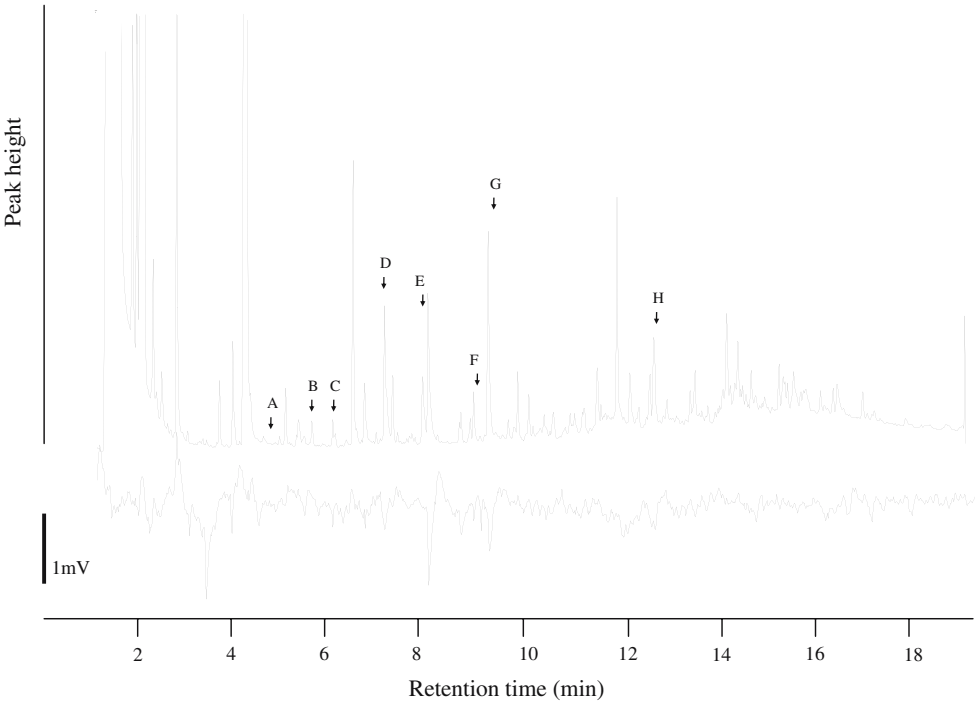

Fig. 3 Example of a coupled GC-EAG trace from *Aedes aegypti* showing antennal responses (lower trace) to a human standard, attractive air entrainment extract. The upper trace corresponds to the FID detector on the GC. Letters denote compounds with higher EAG activity in 'less attractive' individuals. **a** Benzaldehyde, **b** 6-methyl-5-hepten-2-one, **c** octanal, **d** unknown, **e** nonanal and linalool, **f** menthol and naphthalene, **g** decanal, **h** geranylacetone

P=0.019 for 1×10^{-6} g, and P<0.001 for 1×10^{-7} g, and 1×10^{-8} g). However, for all doses, flight activity was greater than to the clean air solvent control (P<0.001 for doses $\geq1\times10^{-6}$ g; P=0.004 and P=0.02 for 1×10^{-7} g and 1×10^{-8} g, respectively; Fig. 5). For octanal, all doses except 1×10^{-4} g gave reduced upwind flight activity (P<0.01), but again, there was still greater activity than to the clean air solvent control (P<0.01). Three doses of nonanal and decanal (1×10^{-6}, 1×10^{-5}, and 1×10^{-4} g) caused less flight activity (P<0.01), and the same treatments caused a greater amount of flight activity than the clean air solvent control (P<0.001 for all doses). For geranylacetone, flight activity was significantly less than to the standard hand alone (P< 0.001 for all doses), but in this case, only two, 1×10^{-5} and 1×10^{-4} g, induced greater upwind flight activity than the clean air solvent control (P<0.001).

When relative attraction of the mosquitoes was measured (Fig. 6), 6-methyl-5-hepten-2-one did not affect the attractiveness of the standard hand, but it did cause greater relative attraction compared with the clean air solvent control (P<0.001 for all concentrations). All octanal doses, except 1×10^{-4} g, gave less relative attraction than to the standard hand alone (P<0.01), and the 1×10^{-4} g gave greater relative attraction toward the treated arm than the clean air solvent control (P<0.001). For nonanal, relative attraction was lower than the standard arm alone in response to two doses (1×10^{-6} and 1×10^{-5} g; P=0.044 and P=0.013, respectively), and all doses induced greater relative attraction toward the treated arm than to the clean air control (P<0.001). Decanal at 1×10^{-6}, 1×10^{-5}, and 1×10^{-4} g gave a reduced relative attraction compared with the standard hand alone (P<0.001), and the 1×10^{-4} g dose reduced relative attraction to that of the clean air control (P=0.46). All geranylacetone doses caused a reduced relative attraction (P<0.001, except 1×10^{-8} g where P=0.02), but again, relative attraction was greater than the clean air solvent control (P<0.01 for all doses except 1×10^{-6} g where P=0.074).

Overall, probing activity differed among all odor stimuli (P<0.001; Fig. 7) and was reduced at the lower concentrations of 6-methyl-5-hepten-2-one, for doses 1×10^{-8} and 1×10^{-6} g (P=0.003 and P=0.022, respectively). Octanal, nonanal, and decanal had no effect on probing activity, and responses were not different from the standard hand alone (P=0.371, P=0.476, and P=0.077, respectively). Probing activity did differ between the standard hand and hand with four geranylacetone doses 1×10^{-8}, 1×10^{-7}, 1×10^{-6}, 1×10^{-5} g (P<0.001). Only one dose of geranylacetone, 1×10^{-4} g, did not reduce probing activity compared with the standard hand alone (P=0.33).

Taking results of the behavioral studies together (Figs. 5, 6, 7), it is clear that all five compounds significantly inhibited flight responses to a normally attractive hand at certain concentrations. 6-Methyl-5-hepten-2-one inhibited flight activation and probing activity but not relative attraction over a range of doses (1×10^{-8}–1×10^{-4} and 1×10^{-8}–1×10^{-6} g) and octanal reduced flight activation but not relative attraction or probing activity over a 1×10^{-8}–1×10^{-5} g range. Nonanal reduced both flight activity and relative attraction at 1×10^{-6}–1×10^{-5} g, but probing behavior was not significantly affected. Decanal reduced both flight activity and relative attraction over the range

Table 1 Names and Retention Indices for 24 EAG-Active Compounds with Loadings from the CVA

Compound No.	Retention Index	Compound Name	Latent Vector (Loadings)
1	776	Hexanal	0.00044
2[a]	932	Benzaldehyde	0.00133
3[a]	965	6-Methyl-5-hepten-2-one	−0.00427
4[a]	980	Octanal	0.00062
5	988	1,4-Dichlorobenzene	0.00126
6	1010	2-Ethylhexanol	0.00117
7	1022	Limonene	−0.0005
8[a]	1030	Unknown	0.00016
9	1057	Dihydromyrcenol	−0.00082
10[a]	1080	Nonanal	−0.00047
11	1083	Linalool	0.00047
12	1100	Undecane	0.0001
13	1135	(*E*)-2-Nonenal	0.00011
14	1151	Octanoic acid	0.00056
15	1160	Menthol	0.00097
16[a]	1160	Naphthalene	−0.00102
17[a]	1184	Decanal	−0.00245
18	1256	Indole	−0.00233
19	1384	Dodecanal	−0.00122
20[a]	1430	Geranylacetone	0.00042
21	1480	α-Isomethylionone	0.00037
22	1500	Pentadecane	−0.00067
23	1600	Hexadecane	−0.00024
24	1681	Heptadecene	0.00115

Latent vector is the complete set of loadings, i.e. the coefficients for the linear combination formed using the original set of variates (amounts of EAG-active compounds). The latent vector maximizes the ratio of between-group to within-group variation.
[a] Compounds found in greater amounts in extracts collected from less attractive individuals compared to attractive individuals.

1×10^{-6}–1×10^{-4} g but did not affect probing behavior. Geranylacetone gave reduced flight activity over all doses tested (1×10^{-8}–1×10^{-4} g) with relative attraction being reduced over the range 1×10^{-8}–1×10^{-4} g, and probing activity reduced over a range 1×10^{-8}–1×10^{-5} g. Indeed, geranylacetone could reduce flight activity toward the standard hand down to that found with clean air only at levels of 1×10^{-8}–1×10^{-7} g.

Discussion

In this study, we investigated the chemical basis of differences in the attraction of *Aedes aegypti* to individual human hosts. Previous studies had demonstrated that variation in attractiveness is mediated by volatile organic compounds that emanate from the skin, the actions of microorganisms, or the breath, but none has successfully identified any contributing compounds. The experiments in this study were designed to determine whether there are differences in particular compounds produced by less-attractive or attractive individuals. A new approach was developed to collect volatiles from human subjects, and for the first time, these volatile extracts were shown to elicit behavioral responses in mosquitoes that corresponded with responses initiated by the presence of human hands. Extracts from the four least attractive hands were no more attractive than an air control, suggesting that the volatiles alone, represented by the extracts, are responsible for the observed differences in behavioral responses of mosquitoes toward the hands.

Coupled GC-EAG was used to locate the volatile compounds within the extracts that are physiologically relevant to the insects, i.e. EAG-active. This identified 6-methyl-5-hepten-2-one, octanal, nonanal, decanal, and geranylacetone. Ten compounds remain unidentified, although only one, named as unknown with a Retention Index of 1030 (Table 1), could have been associated with unattractiveness. This was the only unidentified compound found in significantly greater amounts in the unattractive individuals. Care was taken to remove contamination of the extracts by controlling the washing regimes and the banning of the use of industrial or cosmetic chemicals by the individuals taking part in the trials. Despite this, some compounds including 1,4-dichlorobenzene, limonene, linalool, menthol, and 2-ethylhexanol were found, and these could be contaminants from cosmetics or food. However, limonene and naphthalene have been identified previously as human odor components (Sastry et al. 1980; Curran et al. 2005), and naphthalene has been previously identified in cattle odor (Birkett et al. 2004).

Some compounds identified in this study have been reported previously as human odor components. For example, studies of human odor samples (Schreck et al. 1981; Bernier et al. 2000; Qiu et al. 2004) have identified 346 compounds, 9 of which (octanoic acid, octanal, nonanal, decanal, benzaldehyde, pentadecane, hexadecane, 6-methyl-5-hepten-2-one, and indole) were EAG-active in our study. Hexanal, limonene, octanal, nonanal, octanoic acid, decanal, (*E*)-2-nonenal, geranylacetone, heptadecene, hexadecane, and naphthalene have also been identified previously from axillary sweat samples (Sastry et al. 1980; Zeng et al. 1991; Cork and Park 1996; Curran et al. 2005).

To test the hypothesis that the EAG-active compounds were potentially conferring low attractiveness, we tested the response of *Aedes aegypti* mosquitoes to the five compounds in a Y-tube olfactometer. All interfered significantly with the attractiveness of a normally attractive standard hand. Octanal, nonanal, and decanal reduced flight activity and relative attraction toward the standard hand at certain concentrations, and interestingly, these compounds, as well

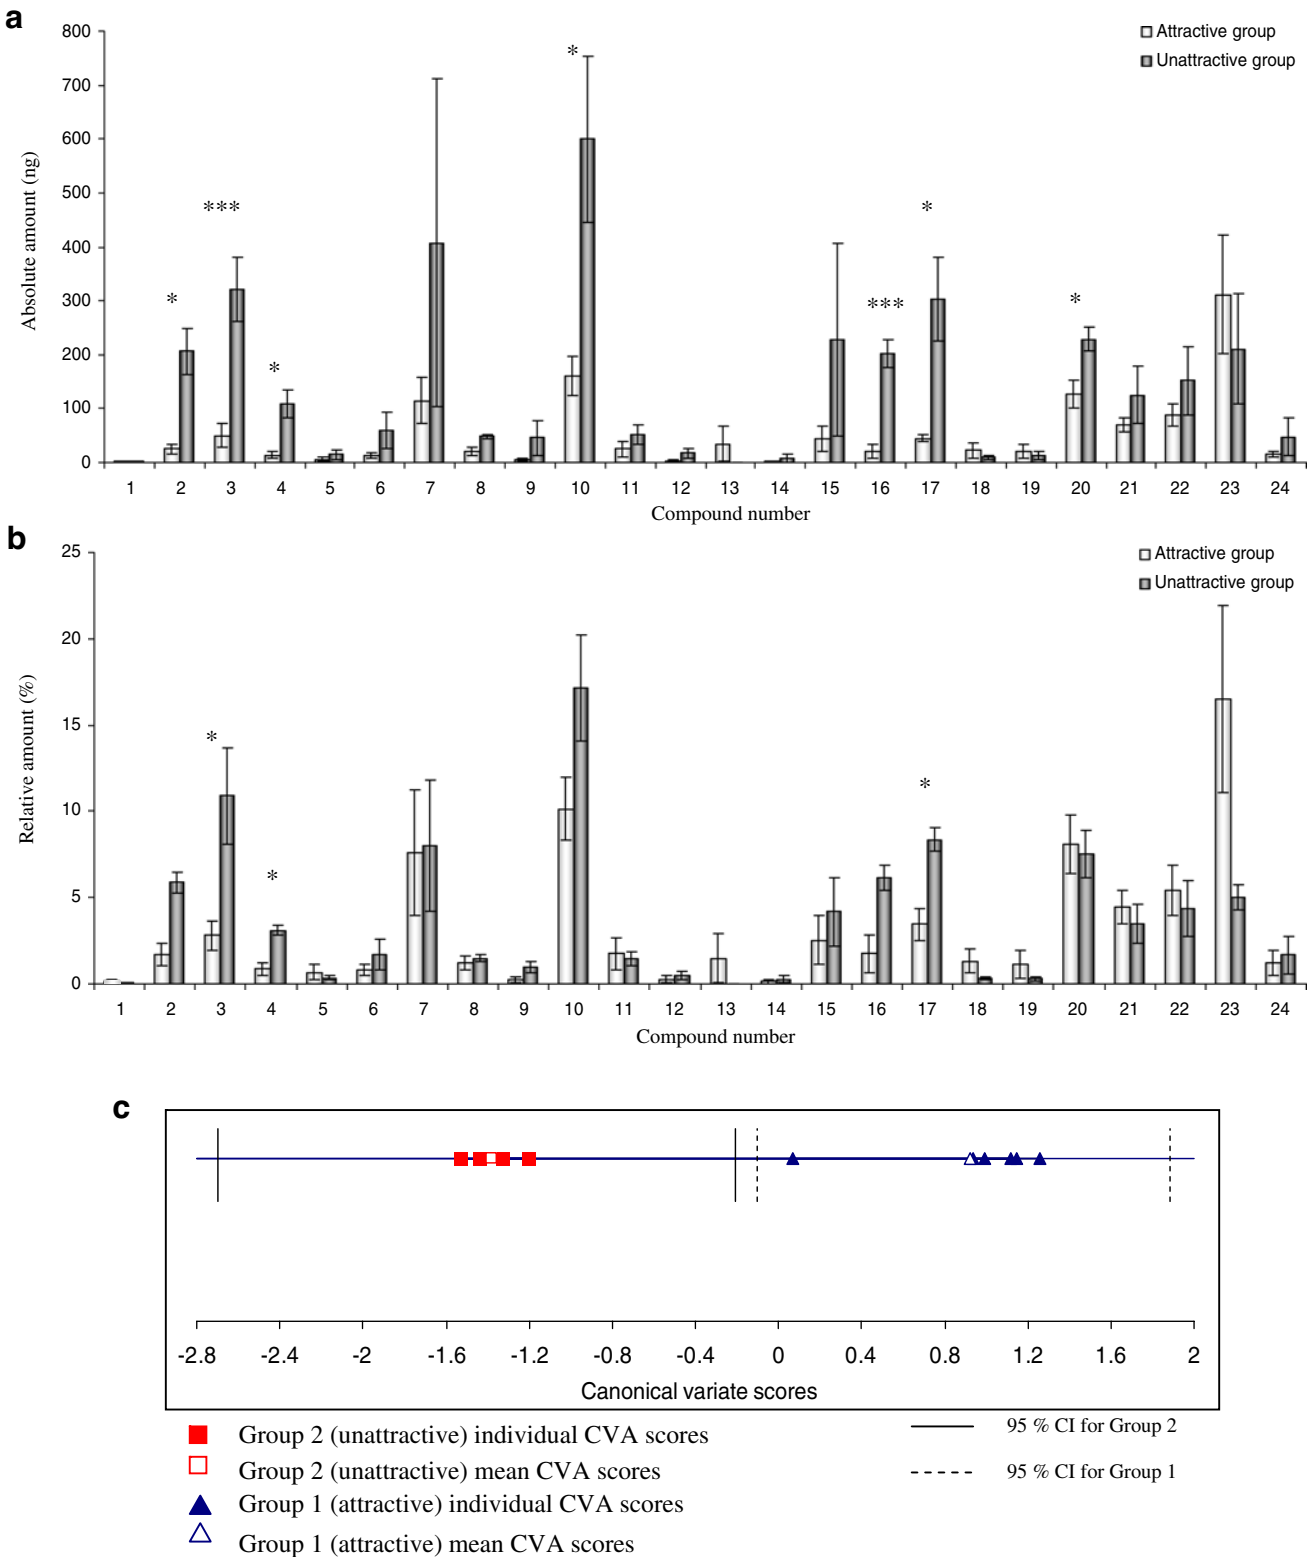

Fig. 4 Quantitative analysis of EAG-active compounds listed in Table 1. **a** Absolute amount (ng)+SE collected over 2 hr and **b** relative mean amounts of total compounds (%)+SE of EAG-active compounds collected from whole-body air entrainments of individuals within the 'attractive' group (N=6) and 'less attractive' group (N=4). Asterisks indicate statistically significant differences between the two means (ANOVA, *P<0.05; **P<0.01, ***P<0.001). **c** Plot of canonical variate scores based on the amounts of 24 EAG-active compounds within air entrainment extracts for all individuals

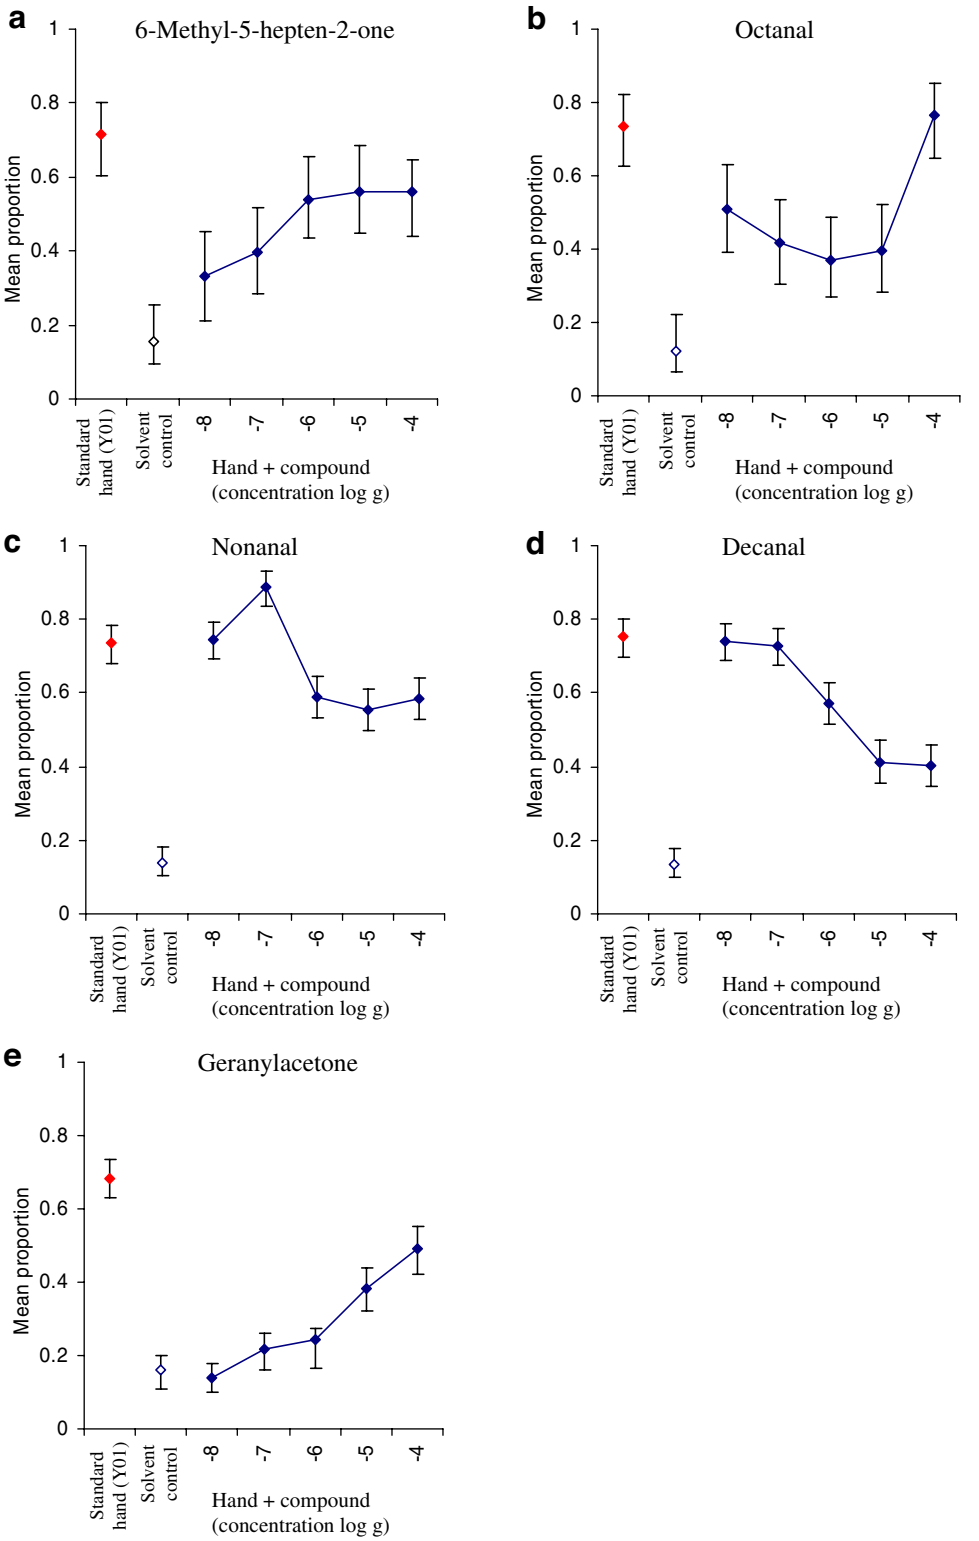

Fig. 5 Mean proportion of *Aedes aegypti* female mosquitoes showing upwind flight activity in response to the standard hand (in one side of the Y-tube with filter paper control in the other) and the hand plus differing concentrations of **a** 6-methyl-5-hepten-2-one, **b** octanal, **c** nonanal, **d** decanal, and **e** geranylacetone treatments (standard hand+chemical in one side of the Y-tube and filter paper plus solvent control in the other). Means with 95% confidence intervals (based on the binomial distribution) back-transformed from the logistic scale are shown (N=10 tests per concentration, total mosquitoes per compound, 200–227, and total number of mosquitoes, 1404–1589). Significant differences were determined using a GLM (see text)

as other aldehydes, have been suggested as a form of defense against ectoparasites in seabirds, and recently, octanal was demonstrated to be repellent to *Aedes aegypti* mosquitoes (Douglas et al. 2005). Similarly, giraffes may produce octanal and nonanal as bacteriostatic or fungistatic agents that may also repel ectoparasites (Wood and Weldon 2002).

One significant finding of our study is the reduction in flight activity and probing activity observed in response to 6-methyl-5-hepten-2-one at low concentrations, i.e., natu-

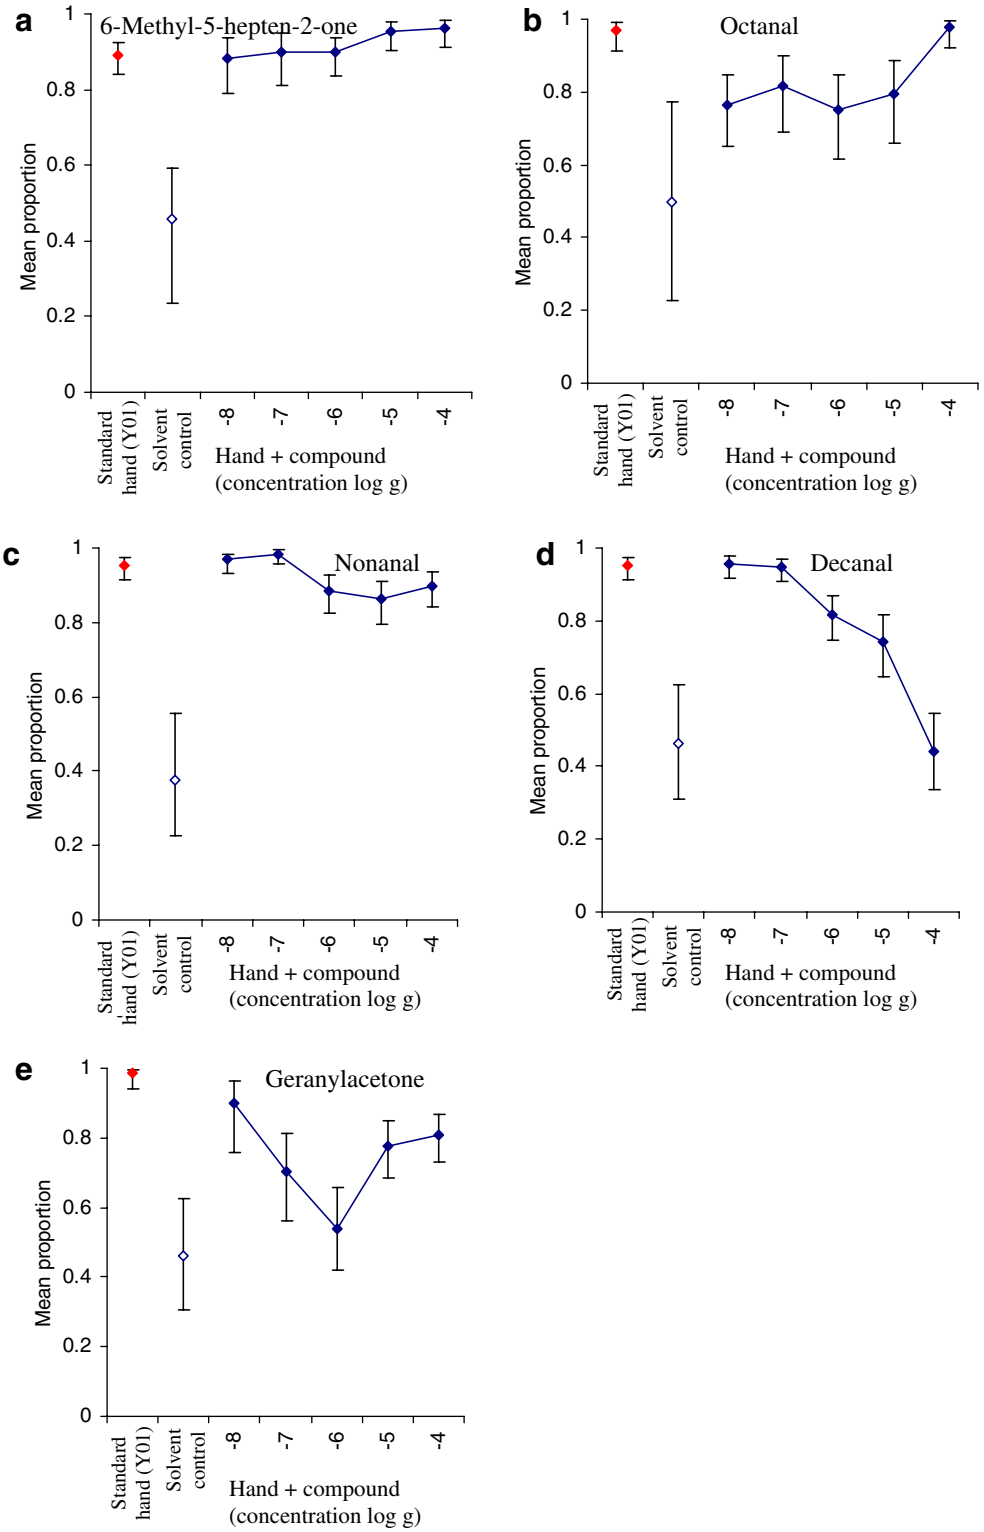

Fig. 6 Mean proportion of *Aedes aegypti* female mosquitoes showing relative attraction in response to the standard hand (in one side of the Y-tube with filter paper control in the other) and the hand plus differing concentrations of **a** 6-methyl-5-hepten-2-one, **b** octanal, **c** nonanal, **d** decanal, and **e** geranylacetone chemical treatments (standard hand + chemical in one side of the Y-tube and filter paper plus solvent control in the other). Means with 95% confidence intervals (based on the binomial distribution) back-transformed from the logistic scale are shown (N=10 tests per concentration of compound, total mosquitoes per compound, 200–227, and total number of mosquitoes, 1404–1589). Significant differences were determined using a GLM (see text)

rally occurring levels (Table 1). The doses used in the Y-tube behavior assay range from 1×10^{-8} g (10 ng) to 1×10^{-4} g (10,000 ng) applied to filter paper. The experiment lasted for 90 sec, and preliminary studies (Logan 2006—which used the same experimental procedure and equipment) have shown that the release rate of 6-methyl-5-hepten-2-one from the filter paper is 0.15 ng for the lowest concentration tested (1×10^{-8} g) and 1,500 ng for the highest (1×10^{-4} g) over the 90 sec testing period. As measured from GC analysis, 6-methyl-5-hepten-2-one was

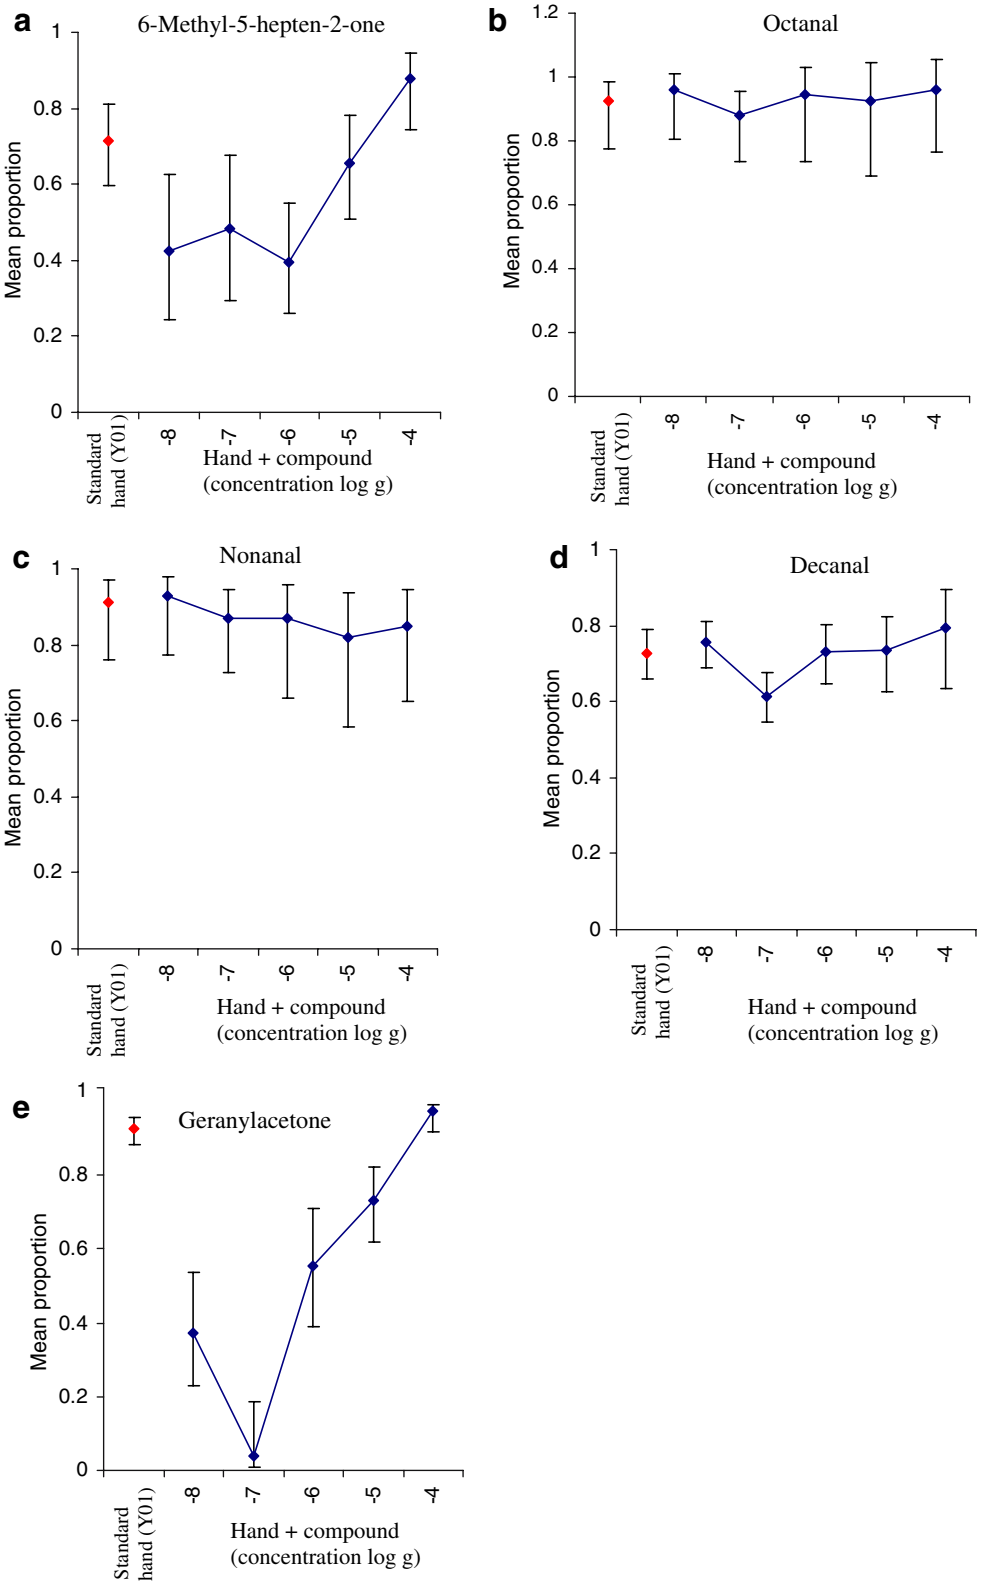

Fig. 7 Mean proportion of *Aedes aegypti* female mosquitoes showing probing activity in response to the standard hand (in one side of the Y-tube and filter paper control in the other) and the hand plus differing concentrations of **a** 6-methyl-5-hepten-2-one, **b** octanal, **c** nonanal, **d** decanal, and **e** geranylacetone chemical treatments (standard hand + chemical in one side of the Y-tube and filter paper plus solvent control in the other). Means with 95% confidence intervals (based on the binomial distribution) back-transformed from the logistic scale are shown (N=10 tests per concentration of compound, total mosquitoes per compound, 200–227, and total number of mosquitoes, 1404–1589). Significant differences were determined using a GLM (see text)

released from our volunteers at a rate of between 7 and 235 ng hr^{-1}, which is the equivalent of between 0.2 and 6 ng per 90 sec (i.e. the duration of the experiment). Therefore, the lower concentrations tested in this study are likely to represent naturally occurring levels. The effects of 6-methyl-5-hepten-2-one at these low levels indicate that the chemical has an effect on behavior at naturally occurring levels. This suggests that a small increase in this

chemical within the "normal" ratio of host odors could prevent mosquitoes from recognizing that an appropriate host is present. It is interesting that the few mosquitoes that did show flight activity were not then affected by the presence of 6-methyl-5-hepten-2-one during flight. This suggests that the compound affects behavioral responses to a human host only at the beginning and end of the mosquito's sequence of behaviors that lead to the successful location of a host. This may explain the reduced flight and probing activity observed to the human hands and extracts by less attractive individuals. However, it does not explain the differences observed in relative attraction and, therefore, is unlikely to play a role in discriminatory behavior between hosts. To our knowledge, this is the first time that 6-methyl-5-hepten-2-one has been shown to affect mosquito behavioral responses toward a normally attractive human host, and in this study, we have shown that inhibitory effects occur at lower rather than higher concentrations.

Bernier et al. (2002) suggested that 6-methyl-5-hepten-2-one plays a role in differential attraction and reported it to be present in lower quantities on the day that an individual was more attractive to mosquitoes. However, they also showed that 6-methyl-5-hepten-2-one was present in greater quantities on an attractive individual than an unattractive individual. Thus, a definitive role was not established. 6-Methyl-5-hepten-2-one has also been implicated in differential attraction of individual cattle to cattle flies, *Musca autumnalis* (de Geer) (Diptera: Muscidae) and *Haematobia irritans* (L.) (Diptera: Muscidae) (Birkett et al. 2004).

Compounds such as 6-methyl-5-hepten-2-one that are electrophysiologically and behaviorally active at low physiologically relevant levels are the most likely to be involved in a natural ecological system. At such levels, it is unknown whether they act as true repellents or have a "masking" effect that prevents attraction. The concept of "masking" is not fully defined, but could describe a process whereby insects no longer respond to their normal odor cues rather than actually being repelled. Interestingly, 6-methyl-5-hepten-2-one also affects phytophagous insect behavior toward host plants. For example, its production by wheat seedlings interferes with the location of wheat by *Rhopalosiphum padi* and *Sitodiplosis mosellana*, where it is thought to have repellent or "masking" properties (Bruce, 2005, personal communication; Quiroz et al. 1997).

Another important finding of our study is that geranylacetone, octanal, nonanal, and decanal had a significant effect on relative attraction and flight (at certain concentrations) of mosquitoes and, therefore, could be involved in orientation toward or away from a host. All doses of geranylacetone caused significantly less flight activity. Indeed, one dose reduced the response down to a level that was not significantly different from the solvent control. It also affected all three behaviors studied and was the most effective compound at reducing host location responses to a hand.

What remains unclear from our studies is whether the responses observed result from a direct repellent effect or another mechanism whereby the insects are failing to respond to normally attractive cues (i.e., "masking"). The Y-tube olfactometer used does not allow discrimination between the two possibilities, and this needs further study. Further trials are also required to determine whether these compounds could have an application in the field, for example, to develop a "push-pull" control strategy whereby the chemicals are used to prevent host location by "pushing" biting insects away from human hosts. At the same time, chemicals such as CO_2 and 1-octen-3-ol could be used as baits in traps to "pull" the insects away from hosts. The methodologies could also be applied to explore the interaction between human beings and other biting insects. This would include the malaria mosquito, *Anopheles gambiae* and the Scottish biting midge, *Culicoides impunctatus*. Although this study has shown that single human-derived compounds interfere with mosquito behavior, it is also important to understand whether mixtures and ratios play a role. We are currently doing field trials to test different mixtures and ratios against a broad range of hematophagous insects and other arthropods.

Acknowledgements J. G. Logan was supported by a BBSRC Studentship. We thank all the volunteers who participated in this study and Lifesystems™ for providing the foil bags. This study was approved by the Bedfordshire and Hertfordshire Strategic Health Authority Local Research Ethics Committee, UK (Reference number: EC03652), and informed consent was obtained from all volunteers. Rothamsted receives grant-aided support from the BBSRC. We also thank Professor Lin Field for her helpful comments on this manuscript.

Accumulation of Glucosinolates by the Cabbage Aphid *Brevicoryne brassicae* as a Defense Against Two Coccinellid Species

Corin Pratt · Tom W. Pope · Glen Powell · John T. Rossiter

Received: 5 July 2007 / Revised: 18 September 2007 / Accepted: 17 December 2007 / Published online: 13 February 2008

Abstract *Brassica nigra* plants, characterized by high levels of sinigrin, and artificial aphid diets to which sinigrin was selectively added were used to rear the crucifer specialist, *Brevicoryne brassicae*. Aphids were provided as a food source to two species of polyphagous ladybird, *Adalia bipunctata* and *Coccinella septempunctata*. First instar *A. bipunctata* were unable to survive when fed with *B. brassicae* reared on *B. nigra* or diets containing 0.2% sinigrin, but when fed with aphids reared on diets containing 0% sinigrin, survival rates were high. By contrast, first instar *C. septempunctata* were able to survive when fed with aphids reared on *B. nigra* or artificial diets containing up to 1% sinigrin. However, the presence of sinigrin in the aphid diet decreased larval growth and increased the time necessary for larvae to reach second instar for this species of ladybird. These results indicate that the presence of sinigrin in the diet of *B. brassicae* makes this aphid unsuitable as a food source for *A. bipunctata* but not for *C. septempunctata*, although for this ladybird species, there appear to be costs associated with feeding on aphids that contain this secondary metabolite.

Keywords *Adalia bipunctata* · *Coccinella septempunctata* · Glucosinolate · Chemical defense · Tritrophic interactions

Introduction

Secondary metabolites are important for plant survival in the environment, forming a chemical defense against pests and diseases (Wink 1988; Jander et al. 2001; Kliebenstein et al. 2005). Glucosinolates (anionic thioglucosides) are the main secondary metabolites accumulated by cruciferous plants (Brassicaceae). The plants also possess a myrosinase (β-thioglucoside glucohydrolase, EC 3.2.3.1; Bones and Rossiter 1996, 2006; Halkier and Gershenzon 2006). These two components are spatially segregated (Kelly et al. 1998; Koroleva et al. 2000) but are brought together upon attack by a pest or pathogen; glucosinolates are then hydrolyzed to biologically active products including nitriles, epithionitriles, thiocyanates, and isothiocyantes (Bones and Rossiter 1996, 2006; Halkier and Gershenzon 2006).

Despite this potent defense, crucifer specialists have evolved in several insect orders with counter adaptive biochemical mechanisms that allow feeding on plants that contain glucosinolates (Ratzka et al. 2002; Wittstock et al. 2004). The cabbage aphid *Brevicoryne brassicae* (L.) and the turnip aphid *Lipaphis pseudobrassicae* (=*erysimi*) (Kaltenbach) are not only able to feed on crucifers but have also developed a chemical defense system that exploits and mimics that of their host plants (Bridges et al. 2002; Kazana et al. 2007). These two aphid species are able to accumulate glucosinolates from their host plants and produce their own myrosinase that is compartmentalized into crystalline microbodies, thus avoiding internal glucosinolate hydrolysis under normal conditions. However, tissue damage as a result of attack by a predator results in production of hydrolysis products such as isothiocyanates (Francis et al. 2001; Kazana et al. 2007). Therefore, the aphid mimics the chemical defense system of its host plants and probably derives benefit in terms of protection from natural enemies. In addition, isothiocyanates also have been shown to synergize the response of *L. erysimi* to the aphid alarm pheromone, *E*-β-farnesene (Dawson et al. 1987) and may play a role in dispersing aphid colonies after attack.

Aphidophagous coccinellids have been used extensively in biological control programs for the control of aphid pests

(Obrycki and Kring 1998). Indeed, the seven-spot ladybird, *Coccinella septempunctata* (L.), is commonly found predating on *B. brassicae* (Acheampong and Stark 2004). By contrast, larval survival rates of the two-spot ladybird, *Adalia bipunctata* (L.), fed with *B. brassicae* reared on a range of crucifer host-plants were low (Francis et al. 2001). However, *A. bipunctata* larvae were able to develop when fed with peach-potato aphids, *Myzus persicae* (Sulzer), reared on the same species of crucifer. This result may reflect the fact that whereas *B. brassicae* accumulates glucosinolates from its host, *M. persicae* appears to excrete these compounds in the honeydew (Weber et al. 1986; Merritt 1996). In addition, *M. persicae* lacks myrosinase activity and, therefore, does not produce toxic hydrolysis products when attacked (Francis et al. 2001).

The use of a range of crucifer host plants on which *B. brassicae* were reared and fed to *A. bipunctata* larvae indicates that the myrosinase–glucosinolate system may be central to the aphids' defense against this natural enemy (Francis et al. 2001). In this study, an artificial aphid diet system was used to manipulate the levels of glucosinolate ingested by *B. brassicae.* The aphids were fed to *A. bipunctata* larvae to investigate the effects of glucosinolates on the next trophic level. This approach was extended to include *C. septempunctata* to determine what, if any, defense glucosinolate accumulation affords *B. brassicae* against this natural enemy.

Methods and Materials

Artificial Diets Parafilm© "M" (American Can Company, Greenwich, CT, USA) was stretched over circular curtain rings of 25 mm diameter. Three hundred microliters of an artificial aphid diet (see Diet B in Dadd 1967), to which 0.0, 0.2, 0.4, 0.6, 0.8, or 1.0% sinigrin had been added, was applied to the surface of the Parafilm. A second sheet of Parafilm was stretched over the ring to create a 'sachet' containing the diet. Excess Parafilm was removed, and diet rings were stored in a freezer until required.

Insects B. brassicae and *M. persicae* cultures were each reared on *Brassica nigra* (L.) Koch. Each plant was enclosed within a perforated bread bag and maintained at 18°C with a 16L/8D photoperiod.

B. brassicae were reared on artificial diet sachets by first transferring 5–10 adult wingless aphids to the underside of a diet ring. Diet rings were then placed into Petri dishes, which were covered with semi-transparent green discs to mimic leaf spectral reflectance. The adults were left for 72 hr before being removed. Aphid nymphs produced during this 72-hr period were transferred to fresh diet rings. Aphids used in experiments were undifferentiated nymphs (wing buds not visible), aged between 3–6 d. Aphids were reared on diet rings at 18°C with a 16L/8D photoperiod.

A. bipunctata and *C. septempunctata* cultures were each maintained at 20°C with a 16L/8D photoperiod. Adult ladybirds were kept, in groups of approximately 20, within ventilated sandwich boxes and were fed daily with an excess of pea aphids, *Acyrthosiphon pisum* (Harris), which were reared on tic bean (*Vicia faba* var. *minor* L.) seedlings. Ladybird eggs were collected by transferring three to four *C. septempunctata* or five to six *A. bipunctata* to ventilated 90 mm diameter Petri dishes and were provided with an excess of *A. pisum*. Adult ladybirds were removed after 24 hr, and any eggs laid were checked daily until they had hatched.

Effect of Sinigrin on Growth of B. brassicae Nymphs Adult wingless *B. brassicae* were transferred onto diet rings containing 0% sinigrin, as previously described, except that they were removed after 24 hr. Ten nymphs were selected at random and weighed before being returned to a fresh diet, also containing 0% sinigrin for 5 d. Similarly, 10 *B. brassicae* nymphs were selected, weighed, and then reared for 5 d on diet rings containing 1% sinigrin. All aphids were kept at 18°C with a 16L/8D photoperiod. After 5 d, the aphids reared on the 0 and 1% sinigrin diets were reweighed.

Growth and Survival of A. bipunctata and C. septempunctata Larvae Newly hatched *A. bipunctata* larvae were selected at random from various egg clutches and weighed (Mettler Toledo MX5, Switzerland) and isolated to separate glass tubes (internal diameter 18 mm, height 51 mm). Each larva was assigned a treatment and supplied with an excess of aphids (approximately 7 for *A. bipunctata* larvae and 10 for *C. septempunctata*). Ladybird larval weight and survival was recorded every 24 hr until the first molt was reached or until the larva died. After weighing, larvae were transferred to a clean tube, and fresh aphids were provided. Ten replicates of the experiment were carried out for each treatment. Experiments were conducted at 21°C, 16 hr light-phase/18°C, 8 hr dark-phase regime.

The following three experiments were completed with each ladybird species:

I. Larvae were fed mixed aged *B. brassicae* or *M. persicae* nymphs (aphids had been reared on *B. nigra*).
II. Larvae were fed 3- to 6-d-old *B. brassicae* nymphs reared on artificial diets containing either 0 or 1% sinigrin. An additional 'starved' treatment was included in this experiment to compare the effects of sinigrin with complete absence of food.

III. Larvae were fed 3- to 6-d-old *B. brassicae* nymphs reared on artificial diets containing 0, 0.2, 0.4, 0.6, 0.8, or 1% sinigrin.

Analysis Data were analyzed by using Student's *t* test and chi-square tests with Yates correction with the exception of the experiments investigating the effect of a range of sinigrin concentrations in the artificial aphid diet on ladybird growth, where an analysis of variance was completed using GenStat 8th Edition. Ladybird growth was analyzed by comparing larval weight after 24 hr. There was some variation in the weights of newly hatched ladybird larvae among different experiments, presumably because some batches may have hatched earlier than others, with more opportunity for egg-case consumption and sibling egg cannibalism (Omkar et al. 2007). However, initial larval weight did not differ significantly among treatments within each experiment (data not shown).

Results

Effect of Sinigrin on Growth of *B. brassicae*

Twenty *B. brassicae* nymphs were reared for 5 d on two artificial aphid diets that were identical with the exception that sinigrin was present at one of two levels, 0 and 1%, respectively (Table 1). Initial mean weights of *B. brassicae* nymphs (<24 hr old) born on either artificial diet did not differ significantly. Similarly, after 5 days continued feeding on these two artificial diets, mean nymph weights were not different.

Growth and Survival of *A. bipunctata* and *C. septempunctata* Larvae

Experiment I Weight gain and survival data of newly hatched *A. bipunctata* and *C. septempunctata* larvae fed with either *B. brassicae* or *M. persicae* nymphs reared on *B. nigra* were recorded (Table 2). The weight of *A. bipunctata* larvae fed with *M. persicae* nymphs was significantly higher (t=3.48, P=0.003) than that for larvae fed with *B. brassicae* nymphs after the first 24 hr of the experiment. Survival of *A. bipunctata* larvae was also affected by the aphid species provided as a food source, with 90% of *M. persicae*-fed ladybird larvae surviving to second instar, compared with 0% of larvae fed with *B. brassicae* nymphs. For *C. septempunctata*, the weight of larvae fed *M. persicae* nymphs was also higher (t=3.28, P=0.005) than for larvae fed *B. brassicae* nymphs. By contrast with survival data for *A. bipunctata*, an equal number, 90%, of *C. septempunctata* larvae survived to second instar when fed either *M. persicae* or *B. brassicae*. However, larvae fed *B. brassicae* nymphs took longer (t=3.16, P=0.006) than larvae fed *M. persicae* to reach this stage.

Table 1 Weight gain of *Brevicoryne brassicae* nymphs reared on artificial diets containing 0% or 1% sinigrin

	Sinigrin Content in Aphid Artificial Diet		Significance
	0%	1%	
Mean weight in mg (0 hr)	0.035± 0.002	0.034± 0.002	t=0.32, P=0.753
Mean weight in mg (120 hr)	0.122± 0.006	0.107± 0.006	t=1.74, P=0.100

Mean weights±SE, N=10

Experiment II Newly hatched *A. bipunctata* and *C. septempunctata* larvae were starved or fed with *B. brassicae* nymphs reared on artificial diets containing 0 or 1% sinigrin (Table 3). During the first 24 hr, whether *A. bipunctata* were starved or fed with *B. brassicae* nymphs reared on artificial diets containing 0 or 1% sinigrin significantly affected larval weights (F=16.59, P<0.001). Individual contrasts between means, using least significant difference (LSD) indicated that the mean weight of larvae (after 24 hr) fed *B. brassicae* reared on diet containing 0% sinigrin was significantly higher than for larvae that were starved or fed *B. brassicae* reared on the 1% sinigrin diet. Larvae that were starved or fed *B. brassicae* nymphs reared on diet containing 1% sinigrin had mean weights that did not differ significantly. Of the *A. bipunctata* larvae fed with *B. brassicae* nymphs reared on diet containing 0% sinigrin, 100% survived to second instar. By contrast, 0% of larvae that were starved or fed with *B. brassicae* reared on the 1% diet reached their first molt. Growth of *C. septempunctata* larvae during the first 24 hr of the experiment was also affected (F=36.08, P<0.001) by the food source provided. Analysis of differences between means, using least significant difference (LSD), indicates that, as for *A. bipunctata* larvae, weights after 24 hr for *C. septempunctata* larvae fed with *B. brassicae* reared on artificial diet containing 0% sinigrin were significantly higher than for larvae that were starved or fed *B. brassicae* reared on the 1% sinigrin diet. Weights of larvae fed *B. brassicae* nymphs reared on the 1% sinigrin diet were not significantly different from starved larvae. Although a greater number of *C. septempunctata* larvae fed with *B. brassicae* reared on the 0% sinigrin diet reached second instar compared with larvae fed with *B. brassicae* nymphs reared on the 1% sinigrin diet, this difference was not significant. In addition, *C. septempunctata* larvae took less time to reach second instar when fed with *B. brassicae* reared on the 0% sinigrin diet

Table 2 Survival, mean weight after 24 hr and time to second instar data for *Adalia bipunctata* or *Coccinella septempunctata* first instar larvae fed *Brevicoryne brassicae* or *Myzus persicae* reared on *Brassica nigra*

	Aphid Species		Significance
	Myzus persicae	*Brevicoryne brassicae*	
Adalia bipunctata			
% survival to second instar	90	0	χ^2=11.99, P<0.001
Mean weight after 24 hr (mg)	0.216±0.021	0.134±0.007	t=3.48, P=0.003
No. days to second instar	2.9±0.1	-	N/A
Coccinella septempunctata			
% survival to second instar	90	90	χ^2=0, P=NS
Mean weight after 24 hr (mg)	0.332±0.014	0.276±0.010	t=3.28, P=0.005
No. days to second instar	3.0±0.0	3.6±0.2	t=3.16, P=0.006

Mean weights±SE, N=10; *N/A* not applicable

compared to larvae fed *B. brassicae* reared on diet containing 1% sinigrin (t=6.52, P<0.001). Again, no larvae that were starved reached second instar.

Experiment III Weight gain and survival of *A. bipunctata* and *C. septempunctata* larvae fed with *B. brassicae* nymphs reared on artificial diets containing a range of sinigrin concentrations were recorded (Table 4). After 24 hr of feeding, growth of *A. bipunctata* larvae fed *B. brassicae* reared on artificial diets containing 0, 0.2, 0.4, 0.6, 0.8, or 1% sinigrin differed significantly (F=31.59, P<0.001). Individual contrasts between means, using LSD, indicates that the 24-hr weights of larvae fed *B. brassicae* nymphs reared on the 0% sinigrin diet were higher than for larvae fed *B. brassicae* reared on all other diets. Mean weight of larvae fed *B. brassicae* reared on diet containing 0.2% sinigrin was also higher than for larvae fed aphids reared on diets containing 0.4% sinigrin. However, larval weights did not differ significantly among the other treatments. Only larvae fed with *B. brassicae* reared on artificial diet containing 0% sinigrin reached second instar (90%). Sinigrin content of artificial diets used to rear *B. brassicae* nymphs, which were fed to *C. septempunctata* larvae, did not affect larval weights (F=1.05, P>0.05). This lack of overall significance suggests that individual contrasts between means are not appropriate. However, time to second instar was affected (F=5.20, P<0.001). Individual contrasts between means, using LSD, indicates that *C. septempunctata* larvae fed aphids reared on the 0% sinigrin diet reached second instar significantly faster than larvae fed aphids reared on other diets. However, survival was not affected, with similar numbers of larvae reaching second instar, regardless of the sinigrin content of the diet used to rear the aphids provided as a food source.

Discussion

Survival of *A. bipunctata* larvae fed with *B. brassicae* is known to be affected by the species of cruciferous plant on which the aphids were reared (Francis et al. 2001). This effect has been correlated with glucosinolate content of the host plant. In this study, we demonstrated through the use

Table 3 Survival, mean weight after 24 hr and time to second instar data for *Adalia bipunctata* or *Coccinella septempunctata* either starved or fed *Brevicoryne brassicae* reared on artificial diets containing 0 or 1% sinigrin

of artificial aphid diets how the presence of a single glucosinolate, sinigrin, affects survival of first instar *A. bipunctata*. By contrast, survival of larvae of a second polyphagous species of ladybird, *C. septempunctata*, was not compromised by the presence of sinigrin in the diet of *B. brassicae*. However, more subtle costs are apparent with extended development times in larvae fed *B. brassicae* reared on diets containing sinigrin compared with larvae fed with aphids reared on diets without sinigrin.

When aphids were reared on *B. nigra*, survival rates of first instar *A. bipunctata* larvae were 90% when fed with *M. persicae*, but 0% when fed with *B. brassicae*, confirming the earlier findings of Francis et al. (2001). The apparent suitability of the generalist *M. persicae* as a food source for *A. bipunctata* may reflect the fact that this species of aphid, although able to colonize crucifers, does not accumulate glucosinolates (Weber et al. 1986). Indeed, when *M. persicae* were fed to *A. bipunctata*, the species of cruciferous plant on which the aphids were reared did not significantly affect larval mortality (Francis et al. 2001). By contrast, the crucifer specialist, *B. brassicae*, not only accumulates glucosinolates in the hemolymph (Kazana et al. 2007) but also possesses, like its host plants, the ability to hydrolyze these secondary metabolites to biologically active products including isothiocyanates (MacGibbon and Allison 1968; Bridges et al. 2002). As these hydrolysis products are known to be toxic to both insects and fungi, it has been suggested that they may provide a direct defense against generalist natural enemies (Bridges et al. 2002; Bones and Rossiter 1996, 2006) as appears to be the case in this study for *A. bipunctata*. Air entrainments show that aphids reared on a glucosinolate-containing diet certainly release isothiocyanate when attacked by foraging ladybirds (Kazana et al. 2007).

Bridges et al. (2002) also suggested that as with specialist crucifer-feeding insects, natural enemies of these herbivores are probably adapted to toxic glucosinolate hydrolysis products. The polyphagous ladybird *C. septempunctata* is known to successfully predate upon *B. brassicae* (Blackman 1967), and results presented in this paper confirm that first instar *C. septempunctata* are able to develop successfully on both *M. persicae* and *B. brassicae*. However, *C. septempunctata* larvae performed better, in terms of weight after the first 24 hr of the experiment and time to second instar, when fed *M. persicae* as opposed to *B. brassicae*.

Results from Experiment I and the earlier work by Francis et al. (2001) suggest a possible direct defensive role for glucosinolates accumulated and hydrolyzed by *B. brassicae*. However, by providing *M. persicae* and *B. brassicae* as a food source, it is not possible to discriminate between aphid morphology, behavior, or chemical composition as possible explanations for the observed differences in ladybird performance (Omkar 2005). Therefore, subsequent experiments were completed where *A. bipunctata* and *C. septempunctata* larvae were fed with *B. brassicae* reared on artificial aphid diets to which a glucosinolate, sinigrin, was selectively added.

Results from these experiments confirm that the presence of sinigrin in the diet of *B. brassicae* results in this aphid becoming unsuitable as prey for *A. bipunctata* larvae. Indeed, whereas 100% of larvae tested were able to reach second instar when fed *B. brassicae* nymphs reared on a diet containing 0% sinigrin, no larvae were able to develop when fed nymphs reared on a 1% sinigrin diet. The presence of sinigrin in aphid diets had such a strong inhibitory effect on *A. bipunctata* that larval growth and survival were similar to those insects that were assigned to the starved treatment and completely deprived of aphid food. To confirm the suitability of *B. brassicae* reared on a diet containing 0% sinigrin for *A. bipunctata*, a small number of larvae were allowed to continue feeding on this group of aphids, and the predators then successfully completed their development (unpublished observations).

C. septempunctata larvae were able to predate upon *B. brassicae*, when fed aphids reared on diets containing either 0 or 1% sinigrin. However, the presence of the glucosinolate in the aphid diet appears to have consequences for the performance of this ladybird species. Larval weights were greater and time required to reach second instar shorter for *C. septempunctata* larvae supplied with *B. brassicae* reared on a 0% sinigrin diet compared with larvae fed aphids reared on a 1% sinigrin diet. However, there was no difference in survival of first instars fed with *B. brassicae* reared on diets containing either 0 or 1% sinigrin. By contrast with *A. bipunctata*, first instar *C. septempunctata* appear to have a mechanism that at least partially negates the effects of sinigrin or the toxic hydrolysis products produced by *B. brassicae* after tissue damage. It is, however, unclear from these data whether the mechanism involved is based on tolerance or detoxification. Interestingly, glutathione transferase levels in *A. bipunctata* increase after exposure to isothiocyanates (Francis et al. 1999).

A. bipunctata larvae did not reach second instar when fed *B. brassicae* nymphs reared on artificial diets containing 0.2, 0.4, 0.6, 0.8, or 1% sinigrin. Again, only when fed aphids reared on the 0% sinigrin diet were *A. bipunctata* larvae able to develop. The higher weight of larvae fed *B. brassicae* reared on a diet containing 0.2% sinigrin compared with larvae fed aphids reared on diet containing 0.4% sinigrin indicates that *A. bipunctata* can perhaps tolerate low levels of allyl isothiocyanate to some extent. However, given an estimated phloem sinigrin content of >0.4% in *B. nigra* (Merritt 1996), it is perhaps not surprising that *A. bipunctata* larvae were unable to survive when fed with *B. brassicae* reared on this host-plant.

Growth (after 24 hr) and survival of *C. septempunctata* larvae fed *B. brassicae* was not significantly affected by sinigrin content of the diet on which the aphids were reared. However, costs were apparent (in terms of extended development time) when larvae were fed *B. brassicae* reared on any of the diets containing sinigrin. There is some evidence that this cost increased with increasing concentration of sinigrin added to the artificial diet. Indeed, when diets containing 0, 0.2, and 0.4% sinigrin are considered, times to second instar were 3.7, 4.4, and 4.7 days, respectively. Interestingly, these trends appear to level out when larvae were fed *B. brassicae* reared on diets containing higher concentrations of sinigrin. Thus, the level of defense afforded to 3- to 6-d-old *B. brassica* nymphs through the accumulation of sinigrin appears to be a function, over a limited range, of the concentration of sinigrin present in the aphid's diet. The precise relationship between dietary sinigrin concentration and the level of this glucosinolate in aphid body tissues has not been investigated. It has been shown that wingless *B. brassicae* contain approximately 3.5 times higher levels of sinigrin when reared on 1% than on 0.1% (Kazana et al. 2007). Over the range of sinigrin concentrations tested, it is qualitative aspects of host-plant chemistry that determine the interaction between *B. brassicae* and *A. bipunctata*, whereas quantitative factors may be important in determining the interaction between this species of aphid and *C. septempunctata*.

By contrast with the results for the two species of ladybird, rearing *B. brassicae* on artificial diets that contain either 0 or 1% sinigrin had no effect on the weight gain of nymphs. Studies have previously demonstrated that sinigrin acts as a strong phagostimulant to *B. brassicae* (Wensler 1962; Nault and Styer 1972). However, the fact that aphids did not perform better when feeding on diet containing 1% sinigrin vs 0% sinigrin diet may reflect the artificial conditions encountered by aphids probing through Parafilm. Indeed, when probing plants, *B. brassicae* may be able to recognize host plants when the stylets make contact with mesophyll tissue, before the phloem is reached (Gabrys and Tjallingii 2002).

Results from this study indicate that accumulation of sinigrin and production of allyl isothiocyanate by *B. brassicae* appears to affect negatively the performance of *C. septempunctata* by slowing development. Use of crops with lower levels of glucosinolates may, therefore, enhance the performance of *C. septempunctata*, making this species perhaps more effective as a biological control agent for *B. brassicae*. However, crops with lower levels of glucosinolates may bring an increased risk from generalist herbivores (Raybould and Moyes 2001).

Experience-Induced Habituation and Preference Towards Non-Host Plant Odors in Ovipositing Females of a Moth

Hua Wang · Wen-Fei Guo · Peng-Jun Zhang · Zhi-Yi Wu · Shu-Sheng Liu

Received: 13 September 2007 / Revised: 14 November 2007 / Accepted: 11 January 2008 / Published online: 6 February 2008

Abstract In phytophagous insects, experience can increase positive responses towards non-host plant extracts or induce oviposition on non-host plants, but the underlying chemical and behavioral mechanisms are poorly understood. By using the diamondback moth, *Plutella xylostella*, its host plant Chinese cabbage, and a non-host plant *Chrysanthemum morifolium*, as a model system, we observed the experience-altered olfactory responses of ovipositing females towards volatiles of the non-host plant, volatiles of pure chemicals (*p*-cymene and α-terpinene) found in the non-host plant, and volatiles of host plants treated with these chemicals. We assessed the experience-altered oviposition preference towards host plants treated with *p*-cymene. Naive females showed aversion to the odors of the non-host plant, the pure chemicals, and the pure chemical-treated host plants. In contrast, experienced females either became attracted by these non-host odors or were no longer repelled by these odors. Similarly, naive females laid a significantly lower proportion of eggs on pure chemical-treated host plants than on untreated host plants, but experienced females laid a similar or higher proportion of eggs on pure chemical-treated host plants compared to untreated host plants. Chemical analysis indicated that application of the non-host pure chemicals on Chinese cabbage induced emissions of volatiles by this host plant. We conclude that induced preference for previously repellent compounds is a major mechanism that leads to behavioral changes of this moth towards non-host plants or their extracts.

Introduction

Studies of phytophagous insects have demonstrated a range of learned behavior that includes habituation, associative learning, food aversion learning, and induced preference (Papaj and Prokopy 1989; Schoonhoven et al. 2005). Experience-altered behavior has been observed in feeding (e.g., Jermy 1987; Cunningham et al. 1998a, 2004; del Campo et al. 2001; Held et al. 2001) and oviposition (e.g., Cunningham et al. 1998b; Rojas and Wyatt 1999). Earlier investigations on experience-altered host selection and oviposition behavior in adults were usually done with a range of host plants and generally showed that experience could enhance foraging efficiency in a changing host environment (Stanton 1984; Stephens 1993; Landolt and Molina 1996; Cunningham et al. 1998b). More recent investigations done with non-host plants or their extracts have shown that early adult experience could induce oviposition on non-host plants or a preference for host plants treated with non-host extracts (Liu et al. 2005; Liu and Liu 2006; Zhang et al. 2007). These recent findings have implications in both insect–plant evolution (Cunningham et al. 2001) and behavioral control of insect pests (Cunningham et al. 1999; Jallow et al. 2004) because oviposition on non-host plants is an essential step for host range expansion, and an induced preference for non-host plant-derived repellents may render these chemicals ineffective. However, the

chemical and behavioral mechanisms for this kind of experience-altered behavior towards non-host plants or their extracts are only superficially understood.

Odors emitted by a plant or its crude extract are a complex blend of individual volatile components, each with a potential effect on insect behavior (Schoonhoven et al. 2005). Host and non-host plants of a given insect may share common volatile compounds (Bengtsson et al. 2006). In some cases, it is possible that the odors of a non-host plant or its extract contain repellent as well as attractive compounds, and an experience-altered behavior may be due to a complex of chemical, neurophysiological, and behavioral causes. For example, preference for non-host plant odors by ovipositing females following experience may result from either an induced preference for the repellent compounds or a habituation to the repellents combined with an unchanged response to the attractive compounds. It has been suggested that these alternative explanations can be investigated by experiments that use individual pure chemicals found in non-host plants (Liu et al. 2005).

By using the diamondback moth *Plutella xylostella*, its host plant Chinese cabbage, and a non-host plant (*Chrysanthemum morifolium*) as a model system, we have shown that experience of the non-host plant extract results in the moths being more attracted to host plants treated with the non-host plant extracts and depositing a higher proportion of eggs on host plants treated with the extract than on untreated host plants (Liu et al. 2005). The same model system is used in this study. Here, we first identified two chemicals, α-terpinene and *p*-cymene, from the volatiles of *Chrysanthemum*. We next observed the olfactory responses of naive and experienced *P. xylostella* females to odors of the non-host plant, odors of the two chemicals, and odors of host plants treated with the two chemicals. Finally, we observed the oviposition preference of naive and experienced females towards chemical-treated host plants. These results demonstrate that induced preference for repellent chemicals is a major mechanism leading to behavioral changes towards non-host plants or their extracts.

Methods and Materials

Insects and Plants The *P. xylostella* culture was established from a field collection on a cabbage farm in a suburb of Hangzhou, China, in October 2004 and maintained on common cabbage, *Brassica oleracea* L. var. *capitata*, cultivar Jing-feng No. 1 in a temperature-controlled room at 26±1°C, 60–70% RH and 14L/10D photoperiod. The culture was replenished once a year with field-collected material.

A non-host plant of *P. xylostella*, *C. morifolium* cultivar Xiaoyangju, was used in this study. Plants of *C. morifolium* were first collected from Tongxiang, Zhejiang, China, and their shoots were transplanted in a potting mix (a mixture of peat moss, vermiculite, organic fertilizer, and perlite in a 10:10:10:1 ratio) in 1.5 l pots and grown in a greenhouse under ambient temperature and humidity and natural lighting. Plants of *C. morifolium* were used at the vegetative stage bearing about 20 leaves. The host plant, Chinese cabbage *Brassica campestris* L. ssp. *pekinensis*, cultivar Zaoshu No. 5, was used in the olfactory and oviposition tests. Chinese cabbage plants were cultivated in the above-mentioned potting mix in 1.5 l pots in greenhouses under ambient temperature and humidity and natural lighting to the five to six fully extended true-leaf stage when used in tests.

Collection and Analysis of Volatile Compounds of C. morifolium The volatile compounds of *C. morifolium* were collected by using solid-phase microextraction (SPME, Supelco, Shanghai, China) and analyzed with a gas chromatograph and mass spectrometer (GC-MS, Agilent HP6890N-HP5973, Agilent, Palo Alto, CA, USA).

The SPME holder had fiber covered with 100 μm polydimethylsiloxane. Before each session of extraction, the fiber was conditioned at 250°C for 30 min. For volatile extraction by SPME, the plant sample was enclosed in a glass container (16 cm diameter and 35 cm height). The SPME needle was injected through the septum of the sample container as well as the extended plunger to expose the fiber. Following equilibration between the fiber and the volatile sample for 30 min, the fiber was retracted into the needle. The SPME device was removed from the container and inserted directly into the GC for desorption and analysis. The port was operated in splitless mode. After 3 min, the split valve was opened, and the fiber was removed at the same time. This treatment and analysis were replicated twice.

Chemical constituents of the volatiles were identified following GC-MS analysis on an HP 6890N Series GC System connected to an HP 5973 Network Mass Selective Detector with an HP-5 column (30 m×0.32 mm i.d., 0.25 μm film thickness). The temperature program for GC was as follows: the initial temperature was maintained at 40°C, held for 2 min, heating up at 8°C/min to 120°C, and then at 1.5°C/min to 160°C. The carrier gas was helium (1 ml/min). The mass spectrum was repetitively scanned from 35 to 450 a.m.v. every 2 s. The MS was used in election impact ionization mode at 70 eV.

Chemical constituents of the volatile were identified by mass spectrum matching in the NIST98 library as well as by comparison of retention time and the fragmentation patterns of the mass spectra with those of authentic commercial samples.

Individual Pure Chemicals The pure chemicals, α-terpinene and *p*-cymene, were purchased from Sigma-Aldrich Chem-

icals, Poole, UK. Chemicals were dissolved in distilled water (containing 2% acetone) to make the test solutions. Solutions of α-terpinene or *p*-cymene were always applied at a concentration of 500 mg/l.

Analysis of Cabbage Plant Volatiles Headspace analysis was conducted to investigate volatile emission by cabbage plants that were untreated (control) or treated with a solution of pure chemicals. Cabbage plants were removed from the pots, and care was taken to ensure that roots were not damaged; then, the entire soil and root system was covered in aluminum foil. Preliminary tests showed that this treatment had little effect on plant growth and volatile collection. A volume of 10 ml solution of either α-terpinene or *p*-cymene was applied to each of the clean, undamaged cabbage plants. Plants that served as controls were sprayed with 10 ml of distilled water (containing 2% acetone). The plants were left to dry for 1 h before being placed into the collection vessels.

Volatiles were collected in a system modified from Turlings et al. (1998). Air was first pushed through a glass bottle with water to be humidified, a flow meter to measure and regulate the air flow, and a charcoal filter to purify the air. The moist and purified air then entered a glass cylinder (16 cm diameter and 35 cm height) at 400 ml·min^{-1}. To create a laminar flow, the air was forced through a glass frit at the top of the cylinder. Approximately 4 cm above the bottom, there was a 25 mm vertical female ground–glass connector for a collection trap. The trap was a glass tube (10 cm long, 5 mm diameter) that contained 30 mg of 80/100 mesh Super-Q (Altech, USA). The air passing over the plant was pulled through Super-Q adsorbent and vented out. The air-inlet, air-outlet, filter, and sampling vessel were connected with Teflon tubing. Each collection session lasted for 24 h. After each collection session, each trap was rinsed with 1 ml methylene dichloride, and the solution was concentrated to 100 μl by a stream of pure nitrogen. Volatile samples of control and chemical-treated cabbage plants were refrigerated at −4°C until they were analyzed. Each treatment was replicated twice.

Compounds were analyzed by using HP6890N GC equipped with an HP-5 column (30 m×0.32 mm i.d., 0.25 μm film thickness) and a flame ionization detector. A volume of 1 μl of sample was injected in splitless mode with nitrogen (1.6 ml/min) as the carrier gas. The column temperature was programmed to maintain at 40°C for 4 min and then increase at 8°C/min to 220°C. The temperature of the injector slit was 250°C.

Experience Treatment Test cohorts of *P. xylostella* were reared on common cabbage from egg to pupation in a temperature-controlled room at 26±1°C, 60–70% RH and 14L/10D photoperiod. Pupae were collected 2–3 days after pupation, taken out of their cocoons, and thoroughly washed in distilled water using the procedure described by Liu and Liu (2006). The pupae were placed in a clean, ventilated cage (45×45×45 cm) for adult emergence and mating. Adults were provided with 15% honey-water as food upon emergence but were not exposed to any plant odors (away from the rearing room) until either being used as untreated controls or being exposed to various experience treatments at 2–3 days post-emergence.

To investigate the effects of experience on the olfactory and oviposition preference of *P. xylostella* females, we treated the test insects by using the following procedures:

(1) Experience with non-host plant: For this treatment, a group of individuals from the test cohorts were moved manually (with a fine soft brush) at the late fourth instar from common cabbage to *C. morifolium* to force them to pupate on the non-host plants. The insects were left to emerge naturally on the plants. Adults were provided with 15% honey-water and enclosed with the non-host plants in a cage until being used in the olfactometer bioassay at 2–3 days post-emergence. A group of untreated adults reared from common cabbage were bioassayed as the "No experience" (naive) control for this experience treatment.

(2) Experience with pure chemicals: We used a clear, cylindrical, and ventilated plastic container (14.5 cm in height, with a top of 9 cm diameter and a base of 13 cm diameter) as the arena for experience treatments. The inner surface of the container was sprayed evenly with 1 ml of a chemical solution. A piece of filter paper (9 cm diameter) was placed at the bottom of the container, and 2 ml of a chemical solution was applied evenly onto the filter paper with a small pipette. The container with the treated filter paper was dried for 1 h, and then four females were introduced to experience the chemical for 10 min before they were used immediately in olfactory or oviposition preference tests. "No experience" control females were handled in the same manner except that the arena for experience was treated with distilled water (containing 2% acetone) only.

(3) Experience with chemical-treated host plants: Prior to each test, a cabbage plant was sprayed with 10 ml of a chemical solution and placed in a ventilated cage (45×45×45 cm) to air dry for 1 h. A group of untreated females was then transferred from the emergence cage onto the treated plant in the cage to experience the treated plant for 30 min before they were used immediately in olfactory or oviposition preference tests. A group of untreated females was taken from the emergence cage to be bioassayed as "No experience" control adults.

Basic Procedure for Testing Olfactory Preference We used a Y-tube olfactometer to observe the olfactory responses of

P. xylostella females (for details of the olfactometer, see Zhang et al. 2007). The two arms were connected to two separate glass containers holding the odor sources. The size of the glass containers varied from 6.5 cm diameter×8.5 cm height for holding a piece of filter paper to 16×35 cm height for holding a plant. A flow meter was connected to each arm of the olfactometer. A pump was used to draw air over a charcoal filter and then through the olfactometer at a rate of 400 ml·min^{-1}. As moths were most active at night, we conducted all observations in a dark room (lit with only a 15-W red light) at 26±1°C between 1900 and 2300 hours.

For each replicate of a given treatment, four females were released into the stem of the olfactometer and left in the olfactometer to respond for 15 min. When a moth walked up to the upwind end of an olfactometer arm, either within 4 cm to the blocking screen or into the corresponding moth-trapping bulb at the end of 15 min, it was recorded as making a choice for that odor. When a moth did not reach the end of either arm within 15 min, it was recorded as "no response". Each moth was used only once. After running five replicates, the connections of the odor sources to the olfactometer arms were exchanged to remove any asymmetrical bias in the set-up. The olfactometer tube and glass container were thoroughly washed with alcohol at the end of the observations for a given treatment and dried overnight in an oven at 200°C.

Olfactory Response to the Non-host Plant C. morifolium Females of *P. xylostella* were taken haphazardly from the "Experience with non-host plant" and the corresponding "No experience" control treatments and observed by using the Y-tube olfactometer procedure described above. One arm of the Y-tube olfactometer was connected to a glass container that held a fresh *C. morifolium* plant and the other arm to an empty glass container. For each of the two treatments, we conducted 20 replicates to bioassay a total of 80 females. The test plants were replaced by new ones of the corresponding categories after every five replicates.

Olfactory Response to Pure Chemicals For bioassays of females with prior experience of either α-terpinene or *p*-cymene, 2 ml solution of a chemical were applied evenly onto a piece of filter paper (9 cm diameter) with a pipette. The treated filter paper was air-dried for 1 h. Another piece of filter paper was treated similarly with 2 ml of distilled water (containing 2% acetone) as the control. The treated and control pieces of paper were placed separately into the two odor source containers of the Y-tube olfactometer. Four females of a given treatment were then observed in the olfactometer by using the procedure described above. For each experience treatment or its corresponding "No experience" control, we conducted 10 or 15 replicates to bioassay a total of 40 or 60 females, and fresh odor sources (i.e., fresh treated and control pieces of papers) were used for each replicate.

Olfactory Response to Cabbage Plants Sprayed with a Pure Chemical Prior to each bioassay, one cabbage plant was sprayed with 10 ml solution of either α-terpinene or *p*-cymene, and another cabbage plant was sprayed with 10 ml of distilled water (containing 2% acetone) as the control. The treated and control plants were air-dried for 2 h and then placed separately into the two odor-source containers of the Y-tube olfactometer. Four females of a given treatment were then observed in the olfactometer by using the procedure described above. For each experience treatment or its corresponding "No experience" control, we conducted 10 replicates to bioassay a total of 40 females. The test plants were replaced by new ones of the corresponding categories after every five replicates.

Oviposition Preference A dual-choice bioassay was used to determine whether the responses of ovipositing females would change following prior experiences of *p*-cymene. Cabbage plants were first sprayed with a solution of *p*-cymene (see above), while the control plants were sprayed with distilled water (containing 2% acetone), 10 ml solution per plant. Sprayed plants were air-dried for 2 h. One treated plant and one control plant were placed in diagonally opposite corners of a cage (55×55×55 cm), and the position of the plants adjusted so that the foliage of the two plants was approximately 20 cm apart at the closest point. Three *P. xylostella* females were then released into the center of each cage between 1900 and 2000 hours. After 12 h in darkness at 26±1°C, the moths were removed, and the eggs deposited on each of the two plants were counted.

We tested the oviposition preference of females of each of the following three experience treatments towards control and *p*-cymene-treated cabbage plants: no experience, experience of *p*-cymene-treated filter paper, and experience of *p*-cymene-treated cabbage. We conducted 11–13 replicates (each in a separate cage) for each of the treatments.

Statistical Analysis For the olfactometer bioassays, the number of females choosing each of the two odor arms in each of the experience or "No experience" treatments was compared with a replicated *G* test of goodness-of-fit with the null hypothesis of no preference, and for the observations on each odor source, a *G* test of a 2×2 table of independence was used to compare the relative proportions of responding and non-responding females between naive and experienced treatments. For the oviposition preference tests, a replicated goodness-of-fit *G* test was used to compare the numbers of eggs deposited on each pair of plants in a given plant treatment with the null hypothesis of no preference, and a *G*

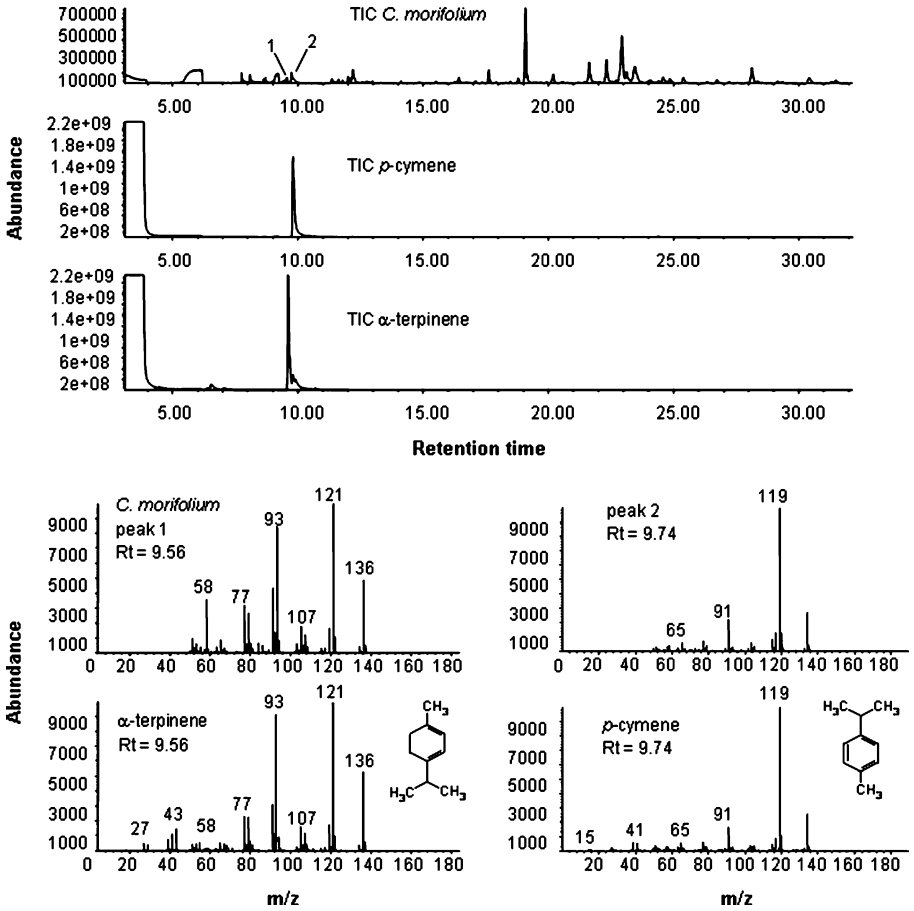

Fig. 1 GC-MS analysis of volatile compounds emitted from *C. morifolium* using authentic standards for comparison of retention times and mass spectra. Total ion current chromatogram of *C. morifolium* compared with that of two authentic standards. The mass spectra of peak 1 and peak 2, identified as α-terpinene and *p*-cymene, respectively, are shown together with that of the respective authentic standards

test of a 2×2 table of independence was used to compare the overall relative proportions of eggs laid on the control and treated host plants between females from any two experience treatments (Sokal and Rohlf 1995).

Results

Chemical Analysis of Plant Volatiles Identification of volatile compounds of *C. morifolium* (Fig. 1) was done by comparing GC-MS fragmentation patterns for the major peaks with authentic standards and NIST98 libraries. The mass spectra of peak 1 and peak 2 were identified as α-terpinene and *p*-cymene, respectively. The remaining peaks were not identified due to lack of authentic standards at the time.

Analysis of the volatiles released from control cabbage plants and cabbage plants sprayed with a solution of α-terpinene or *p*-cymene indicated that qualitative differences occurred in the volatiles collected following treatment with each of the two chemicals (Fig. 2). α-Terpinene- or *p*-cymene-treated cabbage plants emitted more volatiles in addition to the pure chemical applied to the plants compared to the volatile compounds from untreated plants.

Olfactory Response In the olfactometer choice tests with volatiles of "*C. morifolium* vs. air", a significantly lower proportion of females in the "No experience" (naive) control made their first choice towards the nonhost plant than air; in contrast, the proportions of females making their first choice towards *C. morifolium* or air did not differ significantly when the females had a prior experience of the nonhost plant (Table 1).

In the olfactometer choice tests with "α-terpinene vs. air", a significantly lower proportion of females in the naive

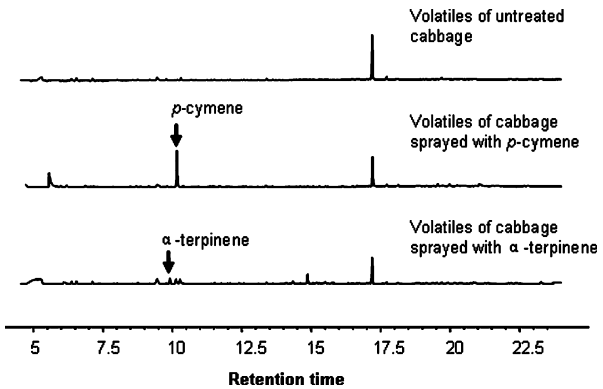

Fig. 2 GC-FID profiles of volatiles emitted from untreated cabbage plants compared with those of plants treated with *p*-cymene or α-terpinene solution

Table 1 Effect of prior experience of *C. morifolium* on choice responses of *P. xylostella* females to volatiles of "*C. morifolium* vs. air" in a Y-tube olfactometer

Experience of *C. morifolium* Plant	Number of Replicates[a]	Total Number of Choices to Volatiles		Mean % of Choices to Volatiles		Replicated *G* Test of Goodness-of-fit[b]	
		Air	*C. morifolium*	Air	*C. morifolium*	G_P	G_H
No	20	33	13	71.7	28.3	9.0*	26.0 NS
Yes	20	27	34	44.3	55.7	0.8 NS	27.6 NS

NS Non-significant
*$P<0.05$
[a] Four females per replicate, and non-responding females were excluded from the analysis.
[b] G_P *G*-pooled, $df=1$; G_H *G*-heterogeneity between replicates, $df=19$

control made their first choice towards α-terpinene; in contrast, a significantly higher proportion of females made their first choice towards α-terpinene when the females had a prior experience of the chemical (Table 2).

In the olfactometer choice tests that compared volatiles of "α-terpinene-treated cabbage vs. air", a significantly lower proportion of females in the naive control made their first choice towards α-terpinene-treated cabbage than air; in contrast, the proportions of females making their first choice towards α-terpinene-treated cabbage or air were similar when the females had a prior experience with α-terpinene-treated cabbage plants (Table 3).

In the olfactometer choice tests with "*p*-cymene vs. air", a significantly lower proportion of females in the naive control made their first choice towards *p*-cymene than air, whereas a significantly higher proportion of females made their first choice towards *p*-cymene than air when the females had a prior experience of the chemical (Table 4).

Similarly, for "*p*-cymene-treated cabbage vs. air", a significantly lower proportion of females in the naive control made their first choice towards *p*-cymene-treated cabbage than air; in contrast, a significantly higher proportion of females made their first choice towards *p*-cymene-treated cabbage than air when the females had a prior experience of *p*-cymene-treated cabbage plants (Table 5).

Prior experience reduced the relative proportion of non-responding females in all cases, although the reductions reached a significant level only in the treatments with two odor sources (Fig. 3).

Oviposition Preference In the choice tests that used *p*-cymene-treated and control cabbages, the numbers (mean± SE) of eggs laid per replicate (i.e., for three females) were 114.4±10.9, 85.0±12.5, and 79.3±14.2 for the naive females, females with prior experience of *p*-cymene, and females with prior experience of *p*-cymene-treated plants, respectively. These means did not differ significantly among the three groups of females (one-way analysis of variance, $F_{2,33}=2.74$, $P=0.079$). The naive females laid a significantly higher proportion of eggs (55.6%) on the control plants than on the *p*-cymene-treated plants (44.4%; $G_p=18.6$, $df=1$, $P<0.001$; $G_H=104.2$, $df=12$, $P<0.001$). In contrast, females with a prior experience of *p*-cymene deposited a significantly higher proportion of eggs (57.6%) on the *p*-cymene-treated plants than on the control plants (42.4%; $G_p=21.9$, $df=1$, $P<0.001$; $G_H=126.2$, $df=10$, $P<0.001$). However, the proportions of eggs laid on the *p*-cymene-treated and control plants (50.7% vs. 49.3%) did not differ significantly for females with prior experience of *p*-cymene-treated plants ($G_p=0.2$, $df=1$, $P=0.67$; $G_H=179.4$, $df=11$, $P<0.001$; Fig. 4). As indicated by the G_H

statistic, the variations among replicates were large in all three treatments.

Discussion

Odor compositions of host plants are taxon-specific, and the olfactory system of an insect has the capacity to distinguish these odors from others and use the plant chemical cues in host foraging (Schoonhoven et al. 2005). *C. morifolium* is a non-host plant of *P. xylostella* and produces many kinds of volatile compounds (Fig. 1). These volatile compounds can be obtained by various methods that involve extraction of the plant material. However, sampling air from around intact plants gives a more accurate picture of the volatile profile (Tholl et al. 2006). Our previous study showed that the extract of dried leaves of *C. morifolium* had a repellent effect on naive *P. xylostella* females, but experienced females were not repelled, and they were attracted instead by host plants treated with the non-host plant extract (Liu et al. 2005). In the present study, naive females of this insect showed an aversion to volatiles emitted from intact plants of *C. morifolium*, but females with a prior experience with the plant were not repelled by the plant volatiles (Table 1). In another study, *P. xylostella* females with a prior experience of pea, another non-host plant of the insect, showed preference for the non-host plant volatiles (Zhang et al. 2007). Thus, depending on the plant species, *P. xylostella* females can exhibit habituation or induced preference for volatiles emitted from non-host plants.

GC-MS analysis of volatile compound emitted from *C. morifolium* plants (by comparison with authentic standards) showed the presence of α-terpinene and *p*-cymene in the blend (Fig. 1). Naive females of *P. xylostella* showed aversion to both these volatiles at the concentration tested, but experienced females became attracted by them (Tables 2 and 4). Experience-altered responses towards volatiles of Chinese cabbage treated with each of the two compounds were similar to those towards the pure compounds, although the females with a prior experience of α-terpinene-treated plants only lost their aversion to the plant volatiles and did not become attracted by them (Tables 3 and 5). The somewhat different responses towards α-terpinene- and α-terpinene-treated plants were not surprising, as volatiles from α-terpinene-treated plants contained many more compounds in addition to α-terpinene (Fig. 2). The oviposition preference tests showed similar experience-altered behaviors to those revealed by the olfactory bio-assays. Naive females showed a preference for oviposition on untreated plants, whereas experienced females either showed a preference for oviposition on *p*-cymene-treated plants or were no longer repelled by the treated plants

(Fig. 4). The combined results of olfactory and oviposition bioassays demonstrate that experience-induced preference for previously repellent compounds is a major mechanism that leads to behavioral changes of ovipositing females towards non-host plants or their extracts and that increased acceptance of non-host plants or their extracts following experience does not have to involve initially attractive compounds (Liu et al. 2005). It is likely that similar behavioral changes towards repellents were involved in experience-induced preference for oviposition on substrates treated with neem-based products (Liu and Liu 2006).

Although experience-induced preference for repellents in ovipositing females of phytophagous insects has been demonstrated in only a few cases, it is likely a widespread phenomenon in view of the commonly observed evidence for habituation and induced preference to feeding deterrents in phytophagous larvae (Jermy 1987; Papaj and Prokopy 1989; Schoonhoven et al. 2005). In addition, experience-induced habituation and preference for repellents have been recorded in several saprophagous and blood-sucking dipterans (Jaenike 1982; McCall and Eaton 2001; Kaur et al. 2003). Experience-induced preference for repellents allows the insects to retain a degree of flexibility to more successfully deal with uncertainty in the environment, including ovipositing on poor host plants when highly suitable plants are not available (Stephens 1993). It may also play an important role in allowing insects to explore new host plants, a necessary precursor for the evolution of host range expansion (Janz et al. 2006; Zhang and Liu 2006; Zhang et al. 2007). For deployments of non-host plant-derived chemicals in behavioral manipulation of insect pests, effective strategies and techniques have to be developed to mitigate the decrease in responses to the repellents (Gould 1991; Akhtar and Isman 2003).

Charleston et al. (2006) found that cabbage plants treated with extract of the syringa tree *Melia azedarach* emitted large quantities of volatiles as well as some additional compounds that were not detected in either the syringa extract or the untreated plants, suggesting that the syringa extract induced the emission of cabbage volatiles. Such enhanced emission of volatiles caused by interactions between a plant and the extract of another plant was observed also in this study (Fig. 2). As the enhanced emission of volatiles by the treated plant may influence the

behavior of the herbivores as well as their natural enemies (Charleston et al. 2005, 2006), this kind of response has obvious implications in the deployment of non-host plant chemicals for behavioral manipulation of insect pests (Gould 1991; Isman 2006; Liu et al. 2006).

Structure–Activity Relationships of Phenylpropanoids as Antifeedants for the Pine Weevil *Hylobius abietis*

B. Bohman · G. Nordlander · H. Nordenhem · K. Sunnerheim · A.-K. Borg-Karlson · C. R. Unelius

Received: 23 July 2007 / Revised: 19 December 2007 / Accepted: 16 January 2008 / Published online: 29 February 2008

Abstract Ethyl cinnamate has been isolated from the bark of *Pinus contorta* in the search for antifeedants for the pine weevil, *Hylobius abietis*. Based on this lead compound, a number of structurally related compounds were synthesized and tested. The usability of the Topliss scheme, a flow diagram previously used in numerous structure–activity relationship (SAR) studies, was evaluated in an attempt to find the most potent antifeedants. The scheme was initially followed stepwise; subsequently, all compounds found in the scheme were compared. In total, 51 phenylpropanoids were tested and analyzed for SARs by using arguments from the field of medicinal chemistry (rational drug design). Individual Hansch parameters based on hydrophobicity, steric, and electronic properties were examined. The effects of position and numbers of substituents on the aromatic ring, the effects of conjugation in the molecules, and the effects of the properties of the parent alcohol part of the esters were also evaluated. It proved difficult to find strong SARs derived from single physicochemical descriptors, but our study led to numerous new, potent, phenylpropanoid antifeedants for the pine weevil. Among the most potent were methyl 3-phenylpropanoates monosubstituted with chloro, fluoro, or methyl groups and the 3,4-dichlorinated methyl 3-phenylpropanoate.

Introduction

The pine weevil *Hylobius abietis* (L.) is a severe pest in areas of Europe where clear-cutting of conifer forests with subsequent replanting is practiced (Långström and Day 2004) because newly planted seedlings are frequently killed by the feeding of adult weevils on the stem bark (Day et al. 2004). There is a strong demand in Sweden and other European countries for new methods that prevent this pest from damaging forest plantations without the use of pesticides (Långström and Day 2004). Pine weevils walking on the ground locate the seedlings by responding to both olfactory and visual stimuli (Björklund et al. 2005).

Previously, it has been shown that lodgepole pine, *Pinus contorta* Douglas ex Loudon, is not as severely attacked as Scots pine, *P. sylvestris* L. (Bratt et al. 2001). This observation led to the hypothesis that the bark of *P. contorta* contains secondary metabolites that act as natural antifeedants against *H. abietis*. This was confirmed in laboratory bioassays where bark extracts from *P. contorta* deterred feeding more than bark extracts from *P. sylvestris*. Bioassay-guided fractionation of *P. contorta* bark led to the

isolation and identification of two compounds, ethyl cinnamate and ethyl 2,3-dibromo-3-phenylpropanoate, which possessed antifeedant activity (Bratt et al. 2001). Ethyl cinnamate and structurally related esters are more potent antifeedants than the corresponding carboxylic acids (Sunnerheim et al. 2007). The results of an investigation of benzoate derivatives as antifeedants for *H. abietis* indicated that even small changes in the structure of a derivative might induce dramatic effects on the antifeedant activity (Unelius et al. 2006). Therefore, it is important to understand the relation between the substitution pattern of the aromatic ring and also the antifeedant effect in phenylpropanoids.

When looking for new bioactive compounds, it might not be feasible to test a large number of structures to find the most potent one. Under these circumstances, it is beneficial to test compounds for activity as they are synthesized and to use the results to select the next analog to be tested. These ideas are applied in the Topliss approach (Topliss 1972), which we used as a tool in search for the phenylpropanoid with the highest antifeedant effect. A Topliss scheme is a flow diagram designed such that the optimal substituent can be found expediently (Topliss 1977), and it gives recommendations on how to proceed after each compound has been tested. The substituents in the Topliss scheme have been chosen based on physico-chemical properties in combination with ease of synthesis. The test approach drawn up by Topliss is a modified and simplified quantitative SAR (QSAR) method developed from the Hansch method for structure–activity correlations. In the Hansch method, mathematical functions are used to correlate biological activity to chemical structure. For instance, the biological activities of a number of substituted aromatic compounds on bacteria, insects, and mammals have been examined and correlated to the properties of the substituents (Hansch and Fujita 1963). Depending on the structural configurations of the receptor active sites, different factors may affect efficiency. In this study, the relationships between individual Hansch parameters and potency of antifeedants against the pine weevil are presented.

To further explore the effects of structural changes in the aromatic rings of compounds such as phenylpropanoids, the number of substituents and the substitution pattern on the ring can be examined and evaluated in relation to activity, i.e., antifeedant efficacy. Certain positions are expected to be beneficial for a strong interaction to a target receptor. In addition to monosubstituted analogs, compounds with two or three substituents can also be tested and evaluated. As biological activity is potentially dependent upon the electronic properties of the entire molecule, it is important to investigate whether acrylates or propanoates are the superior antifeedants. The choice of parent alcohol for the ester is also likely to be important (Unelius et al. 2006).

The overall goal of the present study was to find new effective antifeedants related to ethyl cinnamate that could be used for conifer seedling protection. Throughout this process, we wanted to evaluate the Topliss approach for finding more potent antifeedants by using a low number of syntheses and biological tests. Individual Hansch parameters were also evaluated, as were the number, pattern, and properties of substituents on the aromatic ring. Furthermore, a number of 3-phenylpropanoates and 3-phenylacrylates were compared in search of a potential effect of conjugation. In addition, methyl, ethyl, propyl, and butyl esters of selected 3-phenylpropanoic and 3-phenylacrylic acids were included to determine the importance of the parent alcohol part of the esters. Finally, we compared the results from structural alterations on the antifeedant activity of the phenylpropanoids with the results from a similar previous study on benzoic acid derivatives (Unelius et al. 2006) in search for similarities and differences in selectivity.

Methods and Materials

Collection and maintenance of weevils Both sexes of *H. abietis* were collected during spring migration at a saw mill in southern Sweden where they landed in large numbers. After collection, weevils were stored in darkness at 10°C and provided with fresh branches of Scots pine, *Pinus sylvestris*, as food. These storage conditions interrupted the reproductive development so that females did not begin ovipositing until about a week after they had been transferred to the experimental conditions, i.e., a light regime of L18/D6 at 22°C. This transfer was made about 10 d before the insects were used in the following bioassay.

Laboratory bioassay Compounds were tested for their antifeedant effect on *H. abietis* by means of a two-choice laboratory bioassay (Bratt et al. 2001; Legrand et al. 2004; Borg-Karlson et al. 2006; Unelius et al. 2006). For each test, 40 pine weevils (20 females+20 males) were starved for 24 hr before the test period. Each weevil was placed in a Petri dish (142 mm diameter) and provided with a Scots pine twig (prepared as described below) placed on a moistened filter paper. One day before the test, the twigs were wrapped in aluminum foil, and two holes (diameter 5 mm; 25 mm apart) were punched in the foil with sharp-edged metal rings. After the removal of the aluminum foil inside the rings, one of the two areas was treated with 100 μl of a 50- or 5-mM methyl acetate solution of the compound to be tested, and the other was treated with the same amount of pure solvent as control. When the solvent had evaporated on the following day, the metal rings were removed and the bioassay started. After 24 hr, the proportion of treated bark and control area of each test

twig that had been consumed was recorded. There was generally no significant difference in response between the sexes, and the data presented have been pooled.

The effects of the various treatments are described by two alternative antifeedant indices (AFI) (Blaney et al. 1984) with the general formula: $100\times(C-T)/(C+T)$. The two variants are: (1) antifeedant index, area (AFIa) where C represents the mean area of the control surfaces consumed and T represents the mean area of the treated surfaces consumed and (2) antifeedant index, number (AFIn) where C represents the number of the control surfaces with feeding scars and T represents the number of the treated surfaces with feeding scars.

Thus, AFIa is a measure that captures the reduction in feeding, whereas AFIn is a measure of the frequency of complete inhibition of the initiation of feeding. The two indices were fairly well correlated, but AFIa tended to be higher than AFIn because the antifeedant substances generally affected both the initiation of feeding and the amount of bark consumed if feeding commenced. For both indices, positive values (up to a maximum of 100) reflect an antifeedant effect, whereas negative ones (down to a minimum of −100) indicate a stimulant effect.

Test chemicals The origins of the compounds tested are given in Tables 1, 2, and 3. Final purities ranged from 96% to 99%. When necessary, compounds were purified by preparative chromatography (Baeckström et al. 1987) or flash chromatography on silica gel (Merck 60, 0.040–0.063 mm, Darmstadt, Germany). The tested esters were synthesized by methods A–F (see "Synthesis" below), purchased from Sigma-Aldrich Sweden AB, Sweden or obtained from previous work by H. Erdtman and T. Norin at KTH Chemistry, Organic Chemistry, Stockholm. All cinnamic acid derivatives had the (*E*)-configuration.

Synthesis Commercial phenylpropanoic and phenylacrylic acids were either esterified by using methods A or B or the esters were formed according to methods C–F.

Method A: Acid-catalyzed esterification from corresponding commercial phenylpropanoic or -phenylacrylic acids. A typical procedure is given for the synthesis of methyl 3-(4-methylphenyl)acrylate: 3-(4-methylphenyl)acrylic acid (1.2 mmol) was dissolved in methanol (11 ml). Concentrated sulfuric acid (three drops) was added. The mixture was refluxed for 4 hr, concentrated with a rotary evaporator, diluted with water, and extracted with ethyl ether. The ether phase was washed with Na_2CO_3 (aq), dried over $MgSO_4$, and evaporated to give white crystals (1.15 mmol, 93%).

Method B: Preparation of esters by reaction of the carboxylic acid with dicyclohexylcarbodiimide (DCC), 4-methylaminopyridin (DMAP), and methanol in CH_2Cl_2. A typical example is the synthesis of methyl-3-(4-(dimethylamino)phenyl)acrylate: 3-(4-(dimethylamino)phenyl) acrylic acid (3.15 mmol) and DCC (3.67 mmol) were dissolved in methanol (35 ml). A solution of DMAP (1.23 mmol) in CH_2Cl_2 (5 ml) was added, and the reaction mixture was refluxed for 2 hr, concentrated with a rotary evaporator, dissolved in CH_2Cl_2, filtered, washed with water, and dried over $MgSO_4$. Evaporation of the solvent and purification by silica gel chromatography yielded the product (2.44 mmol, 77%) as yellow crystals.

Method C: Preparation of propanoates by catalytic hydrogenation of acrylate analogs (Vogel 1989). A typical example is the formation of methyl 3-(4-(dimethylamino)phenyl)propanoate: Methyl 3-(4-(dimethylamino)phenyl)acrylate (1.32 mmol) was dissolved in methanol (30 ml). To the solution, 39 mg Pd/C (10%) were added, and the reaction mixture was set under an atmosphere of hydrogen. When the reaction was completed after 45 min, the catalyst was filtered off, and the solvent evaporated. Methyl 3-(4-(dimethylamino) phenyl)propanoate was obtained (0.83 mmol, 63%) as slightly yellow crystals.

Method D: Preparation of propanoates by *O*-alkylation of hydroxyl-substituted analogs (Legrand et al. 2004): Isopropyl 3-(4-methoxyphenyl)propanoate was obtained by reacting isopropyl 3-(4-hydroxyphenyl)propanoate with methyl iodide and potassium carbonate in acetone. Methyl 3-(4-butoxyphenyl)propanoate was obtained by reacting methyl 3-(4-hydroxyphenyl)propanoate with potassium hydroxide and butyl iodide. Methyl 3-(3,4-dimethoxyphenyl)propanoate was obtained by reacting methyl 3-(3,4-dihydroxyphenyl)propanoate with sodium hydride and methyl iodide in THF according to the standard procedure (Vogel 1989).

Method E: Preparation of 3-phenylacrylates by Knoevenagel reaction (Harwood et al. 1998) followed by acid-catalyzed esterification. A typical example is the synthesis of methyl 3-(4-ethylphenyl)acrylate: Malonic acid (10.4 mmol) was dissolved in pyridine (3 ml) with heating. 4-Ethylbenzaldehyde (10.2 mmol) and a catalytic amount of piperidine (10 drops) were added while stirring. The reaction mixture was refluxed until the production of carbon dioxide

Table 1 Structures of mono-substituted phenylpropanoids and physical properties - Hansch parameter values for substituents on the aromatic rings (Hansch et al. 1973; Topliss 1972; Swain and Lupton 1968)

[a] prepared from the corresponding carboxylic acids by refluxing in the alcohol with H_2SO_4 as a catalyst: Method A

[b] prepared by catalytic hydrogenation of acrylates: Method C.

[c] obtained from previous work by H. Erdtman and T. Norin at the Dep. of Organic Chemistry, KTH, Stockholm.

abated. HCl (aq, 2 M, 10 ml) was added, and the precipitate formed was filtered off by suction and washed with HCl (aq, 2 M, 10 ml), water (10 ml), and hexane (10 ml) and dried *in vacuo* to yield methyl 3-(4-ethylphenyl)acrylic acid (7.8 mmol, 76%). The carboxylic acid was esterified according to method A.

Method F: Methyl 3-(4-acetyloxyphenyl)propanoate was prepared from methyl 3-(4-hydroxyphenyl) propanoate according to the standard procedure (Vogel 1989).

All reactions were monitored by thin layer chromatography. The spectroscopic data of the products were analyzed and compared with literature data.

Spectroscopy H NMR (400 or 250 MHz) and C NMR (100 or 63 MHz) spectra were recorded on Varian 400, Bruker 400, or Bruker 250 instruments using the solvent signals, $CDCl_3$ or CD_3OD, as internal standards.

The Topliss scheme The first substance in the Topliss scheme possesses an unsubstituted aromatic ring (or a phenylic compound with one or more substituents not being changed over the time of the study) (Topliss 1972). In the modified Topliss scheme used, we started with methyl 3-phenylpropanoate (Fig. 1). The analogs were tested at 50 mM concentration in methyl acetate with the solvent as control treatment. As the AFI values for many substances were close to 100 at 50 mM, new tests were conducted at 5 mM concentration. The Topliss scheme was used continuously in the dynamic experimental plan, i.e., after the synthesis of each compound and after the evaluation of the test results from bioassays, the scheme was consulted for the choice of compound next to be synthesized and tested. Finally, analogs from all positions of the scheme were synthesized and tested to critically evaluate the method.

Hansch parameters The Hansch equation (Eq. 1) contains a number of parameters that reflect different properties of substituents on aromatic rings (Hansch and Deutsch 1966), such as hydrophobicity (π), electronic effects (σ, F, and R) and steric factors (molar refractivity [MR] and molecular weight [MW]). The relation between steric parameters can be found in the Lorentz–Lorentz equation (Eq. 2). One expression for the relationship between electronic effects is also shown (Eq. 3).

$$\mathrm{Log}(1/C) = k_1(\log\pi)^2 + k_2\log\pi + k_3\sigma + k_4\mathrm{MR} + k_5 \quad (1)$$

$$\mathrm{MR} = \mathrm{MW}\left(n^2-1\right)/d\left(n^2+2\right)\left[\mathrm{cm}^3/\mathrm{mol}\right] \quad (2)$$

$$R = \sigma - k_6F \quad (3)$$

C is the concentration required for biological activity, k_1–k_6 are the system-dependent constants, n is the refraction index, and d is the density.

In this study, the hydrophobic parameter used was π, derived from log P values (Hansch et al. 1973). Three

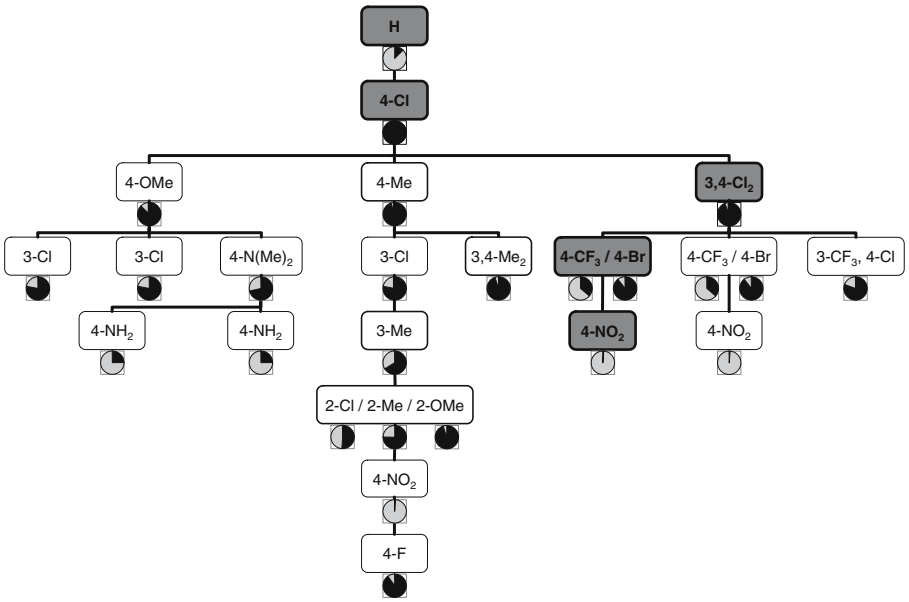

Fig. 1 The complete modified Topliss scheme used in this study. Substituents on the aromatic ring are shown for each analog. From each "parent" compound (from the top of the scheme) the choice of the next analog is shown, depending on the result of the previous test. If the potency increased for the latest tested compound, the next compound to be tested is the one to the right in the next lower level of the scheme, i.e., first, the unsubstituted compound and the 4-chloro-substituted compound is tested, and if the latter compound is more active, the 3,4-dichloro analog is tested next. If the activity is equally high, the analog straight below is tested, i.e., if the 4-Cl analog is equally active as the 4-H, the 4-Me analog is tested next. If the activity is lower, the analog below to the left is tested, i.e., if the 4-Cl analog is less active than the unsubstituted compound, the 4-OMe analog is tested next. Our results directed us to conduct the test series indicated by *shaded, bold boxes*. The results (AFIn) are shown in circle diagrams below each analog (*filled black circle* AFIn=100, *empty gray circle* AFIn=0; all tests carried out at 50 mM)

different electronic parameters were applied: σ, F, and R. The widely used σ parameter has the disadvantage that the resonance effect contributes for metasubstituted aromatic rings (σ values for orthosubstituted compounds have not been included), whereas for parasubstituted systems, the field factors affect the values of σ (Swain and Lupton 1968). For the parameters F and R, the field effects (F) and resonance effects (R) are separated. The steric parameters used to measure the "bulk" of the molecules were molecular weight (MW) and molar refractivity (MR). MR differs from MW in having an electronic contribution, as it is directly proportional to polarizability (Eq. 2; Hansch et al. 1973). The values of all parameters used in this study are available in the literature (Hansch and Deutsch 1966; Swain and Lupton 1968 and Hansch et al 1973).

Results

Evaluation of the Topliss method for finding potent methyl 3-phenylpropanoate antifeedants To determine fully the usability of this approach, the scheme was initially followed step by step (as was intended in Topliss' method); but in a second phase of the study, all compounds found in all branches of the scheme were obtained and compared.

The investigation started with methyl 3-phenylpropanoate (entry 1, Table 1). The first analog to be tested was the more hydrophobic and electron-withdrawing 4-chloro compound (entry 2, Table 1), which was more active than the unsubstituted compound. The next analog to be tested according to the scheme was the 3,4-dichloro compound (entry 5, Table 1), which was even more hydrophobic, and the ring was more electron-poor. This analog showed similar or slightly lower activity. The 4-CF_3 analog (entry 6, Table 1), which did not have a metasubstituent and was less lipophilic than 3,4-Cl but more lipophilic than 4-Cl, was tested next and was less active than the previous one. The 4-Br analog (entry 8, Table 1), an alternative to 4-CF_3, also showed low activity. Finally, the analog with the less lipophilic but more electron-withdrawing 4-NO_2 substituent, can be found in the bottom of scheme 1. Ethyl 3-(4-nitrophenyl)propanoate (entry 20, Table 1) was tested instead of methyl 3-(4-nitrophenyl)propanoate but the results can be compared with the results from ethyl 3-phenylpropanoate (entry 48, Table 3), and it is obvious that nitro analogs have relatively low activities (Fig. 2a and Table 1).

To find out if the Topliss method generated the optimal antifeedant, we decided to investigate all three branches in parallel.

Following the right branch of the Topliss scheme, all compounds except methyl 3(4-chloro-3-trifluoromethyl-phenyl)propanoate (entry 41, Table 2) were tested, as the scheme was followed systematically. This compound was less active than the analogs substituted with 4-Cl (entry 2,

Table 1), 3,4-Cl (entry 5, Table 1), and 4-Br (entry 8, Table 1) but more active than the 4-CF_3 (entry 6, Table 1) and 4-NO_2 (entry 20, Table 1) analogs (Fig. 2a).

In the center branch, the 4-methyl (entry 15, Table 1) and 3,4-dimethyl analogs (entry 40, Table 2) were tested next. Further down this branch, steric factors were examined by testing the 2- and 3-substituted analogs, i.e., the 3-chloro (entry 4, Table 1) and the 2-chloro (entry 3, Table 1), 2-methyl (entry 13, Table 1) and 2-methoxy (entry 11, Table 1) analogs. These compounds generally had lower activity than the 4-substituted analogs but the electronic factors did not seem to greatly affect the activity. The 4-F analog (entry 9, Table 1) has similar values of the Hansch parameters but showed higher potency than the parent unsubstituted methyl 3-phenylpropanoate (Fig. 2b).

For the left branch of the scheme, the choices after the electron-donating 4-methoxy analog (entry 10, Table 1) were other more electron-donating compounds: the 4-N$(Me)_2$ (entry 22, Table 1) and the 4-NH_2 (entry 21, Table 1) analogs. The dimethylamino compound had similar potency compared with the 4-methoxy compound, whereas the amino compound was much less potent (Fig. 2c). As a hypothesis, the polarity of the amino group is the cause of the low antifeedant activity.

To be able to better compare the most potent antifeedants, which all had AFI values close to 100, additional tests were carried out at 5 mM concentration. The results from these tests showed a stronger decrease in activity at the lower concentration for the methoxy analogs than for the analogs with chloro, bromo, fluoro, and methyl substituents (Fig. 3).

As potent antifeedants were found in all branches of the Topliss scheme and not preferentially among the analogs obtained when the proposed route was followed, the Topliss approach was abandoned. Consequently, we continued our survey of the SARs of phenylpropanoids by using other methods.

Effect of the position of substituents on the aromatic ring To see whether substituents on the aromatic ring should be situated in the ortho, meta, or para position for optimal activity, tests were performed for all monosubstituted isomers of the methyl (entries 13–15, Table 1), chloro (entries 2–4, Table 1), and methoxy (entries 10–12, Table 1) analogs (Fig. 3a). For the methyl-substituted compounds, the difference in position did not greatly affect the potency, neither on AFIn nor AFIa. For the monochlorinated compounds, there was a larger difference in activity in the order para>meta>ortho. For the methoxy analogs, the metasubstituted and parasubstituted compounds showed similar potency in all tests, whereas it is interesting to note that the activity of the orthosubstituted analog was almost nil at 5 mM (Fig. 3a).

Effects of unsaturation and conjugation To understand the importance of conjugation to the carbonyl group in the phenylpropanoids, several substituted methyl 3-phenylpropanoates were compared with their corresponding 3-phenylacrylates (Fig. 4). Most of the pairs of conjugated (3-phenylacrylates) and nonconjugated compounds (3-phenylpropanoates) had similar activities (Fig. 4). However, when we compared the activities of the analogs with the most electron-withdrawing and electron-donating groups, we found a trend. The activities of the compounds with electron-withdrawing groups (4-CF_3 and 4-NO_2) (entries 6–7, 20, 25, Table 1) were favored by conjugation, whereas the activity of compounds with electron-donating substituents (4-N$(CH_3)_2$ and 4-NH_2) (entries 21–24, Table 1) decreased for the conjugated analogs (Fig. 4b).

Comparison of disubstituted and trisubstituted compounds We also investigated whether it was possible to improve the activity by adding more substituents to the aromatic ring and by optimizing the substitution pattern. Consequently, several compounds with two or three substituents were tested (Fig. 3b). Different substitution patterns were compared for dimethoxy- and trimethoxy-substituted (entries 33–35, 38, Table 2) methyl 3-phenylpropanoates. For the dimethoxy-substituted compounds, there was a strong effect favoring 2,3- and 3,5-substitution over 3,4- and 3,4,5-substitution. The 2,3- and 3,5-disubstituted methoxy analogs were slightly less active compared with the monosubstituted methoxy analogs (Fig. 3b). For disubstituted methyl analogs (entries 39–40, Table 2), the 2,4-analog was slightly more potent than the 3,4-analog, but the difference was minor. The disubstituted methyl compounds were approximately as potent as the monosubstituted analogs (Fig. 3c). Furthermore, methyl 3-(4-ethylphenyl)acrylate (entry 17, Table 1) was tested to establish whether the larger and more hydrophobic ethyl group alone could enhance the activity, but this compound was less active than the ones previously tested.

The 3,4-dichlorinated analog (entry 5, Table 1) was tested and compared with the monohalogenated analogs. It showed similar potency as the 3-chloro, (entry 4, Table 1) but slightly less potency than the 4-chloro compound (entry 2, Table 1).

A series of dimethoxy-substituted 3-phenylacrylates (entries 29–32, Table 2) were also tested for the influence of substitution pattern on activity. The order of reactivity between combinations of substituents was 2,3>2,4≫3,5>3,4 (Fig. 4a). These results corresponded well with the results from the dimethoxyphenylpropanoates above.

Activity of phenylpropanoates with mixed substituents - Three analogs with mixed substituents were added to the

test series. These were the 3-bromo-4-methoxy (entry 36, Table 2), 4-chloro-3-trifluoromethyl (entry 41, Table 2), and 4-hydroxy-3-methoxy analogs (entry 37, Table 2). The first compound was less active than the corresponding mono-substituted analogs ((3-Br, 4-OCH_3) vs. 4-Br and 4-OCH_3). The (3-CF_3, 4-Cl) analog was less potent than 4-Cl but more potent than 4-CF_3, and the (3-OCH_3, 4-OH) analog was a more active antifeedant than 4-OH (Fig. 5a). Although not all possible variations were tested, the conclusion from our test series was that no beneficial effects could be found by mixing different substituents on the aromatic ring.

Effect of the parent alcohol part of the esters on antifeedant activity of phenylpropanoids The methyl (entry 10, Table 1) and isopropyl (entry 49, Table 3) esters of 3-(4-methoxyphenyl)propanoate and five alkyl cinnamates (ethyl-, *n*-propyl-, isopropyl-, *n*-butyl-, and 2-butylcinnamate) (entries 43–47, Table 3) were compared to elucidate the effect of the parent alcohol of the esters. All compounds were tested at 50 mM concentration. Isopropyl cinnamate was the most potent of the cinnamates (Fig. 5b) while methyl 3-(4-methoxyphenyl)propanoate was more potent than the corresponding isopropyl ester analog (Fig. 5c). The butyl esters were much less active in all tests, and therefore, no esters derived from higher alcohols were tested.

Furthermore, the methyl and ethyl esters of 3-phenylpropanoic acid, (entry 1, Table 1, vs. entry 48, Table 3), 3-(4-methylphenyl)propanoic acid (entry 15, Table 1, vs. entry 50, Table 3) and 3-(4-chlorophenyl)propanoic acid (entry 2, Table 1, vs. entry 51, Table 3) were compared. Apparently, no major difference in activity between methyl and ethyl esters were detectable except for the unsubstituted 3-phenylpropanoate where the methyl ester was considerably less active compared to the ethyl ester (Fig. 5c).

Influences by Hansch parameters By comparing Hansch parameters in relation to antifeedant activity for a series of substituted methyl 3-phenylpropanoates, the effect of each parameter was analyzed. The aim was to find the importance of each parameter and thus the properties of the substituents that affect antifeedant activity. In total, 29 methyl 3-phenylpropanoates and 11 3-phenylacrylates were compared.

The Hansch parameters that were examined for correlations to antifeedant activity were σ, π, F, R, MR, and MW (Tables 1, 2, and 3). For the electronic parameter σ and the field effect (F), there was no apparent correlation to antifeedant potency. A similar result was found after analyses of the steric parameters (MR and MW), i.e., small and light molecules as well as bulky and heavy compounds showed good antifeedant activity. For the lipophilicity parameter (π), there was a correlation with antifeedant potency. If π was negative ($\pi<-0.1$), the activity was, on average, lower (Fig. 6a). The resonance factor R also showed a correlation to AFI: No compound with good antifeedant potency had $R<-0.5$ (Fig. 6b). For 3-phenylacrylates, the results were similar.

Comparison with benzoate antifeedants In a previous study, we measured the AFI of a large number of benzoates (Unelius et al. 2006). Methoxy-substituted benzoates showed high antifeedant activity. Therefore, the following analogous phenylpropanoids were tested in addition to the compounds already discussed: Methyl 3-(4-butoxyphenyl) propanoate, (entry 26, Table 1), methyl 3-(4-hydroxyphenyl) propanoate (entry 27, Table 1), methyl 3-(4-acetyloxyphenyl)propanoate (entry 28, Table 1), and methyl 3-(4-hydroxy-3-methoxyphenyl)propanoate (entry 37, Table 2). In agreement with the results from the benzoate study, the methoxy analogs (for example, 3-(4-methoxyphenyl)prop-

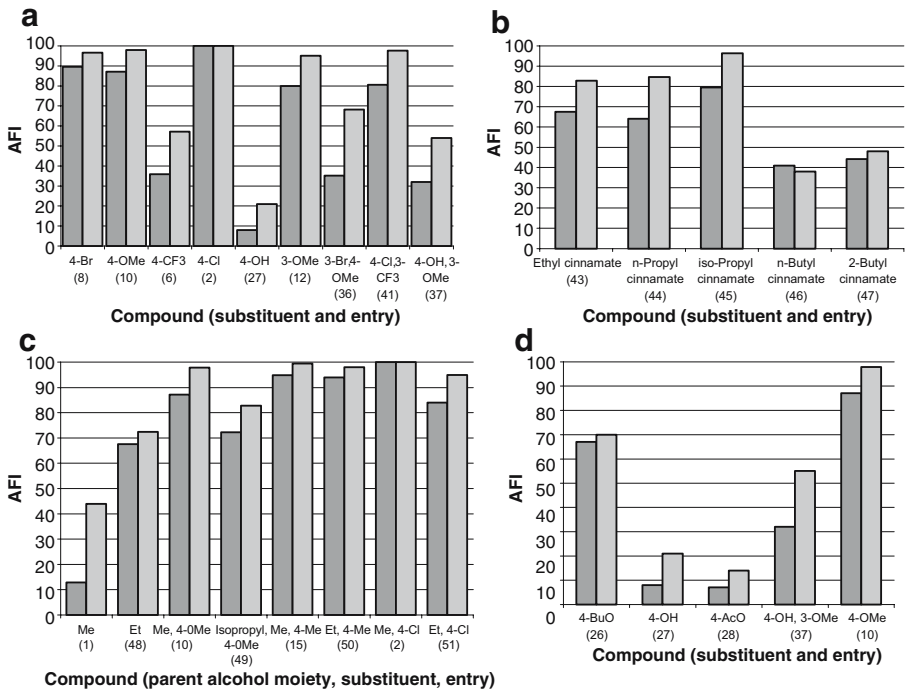

Fig. 5 AFI for 3-phenylpropanoids (at 50 mM concentration). AFIn is represented by *dark columns* and AFIa by *light columns*. Substituent (s) and entry number (in *parentheses*) are given beneath the *x*-axis: **a** methyl 3-phenylpropanoates with mono and mixed substituents; **b** cinnamates with different parent alcohol moieties; **c** 3-phenylpropanoates with different parent alcohol moieties; **d** derivatives of methyl 3-(4-hydroxyphenyl)propanoate

anoate; entry 10, Table 1) were most effective (Fig. 5d), but, in contradiction to the results from the benzoate study, the tested methyl- or halogen-substituted phenylpropanoids had similar or even higher antifeedant activity than the methoxy analogs.

Discussion

When initially applying the Topliss approach in our search for potent antifeedants, the most active compounds happened to appear early in the scheme, so the use of the remaining scheme became redundant. Normal rational design was used, therefore, during the reminder of this SAR study. Nevertheless, the Topliss approach may be a useful tool in other projects within the field of chemical ecology where an effective semiochemical is to be found in a limited time and at low costs.

To correlate the structures of the phenylpropanoids to their antifeedant activity for *H. abietis* was difficult. Apart from the result that highly polar substituents were unfavorable for activity, it was difficult to discriminate any particular factors that affected the antifeedant activity. The position of substituents on the aromatic ring does not appear to be critical for the antifeedant activity–a number of 2-, 3-, and 4-substituted analogs had similar potency. The most potent compounds tested were methyl 3-phenylpropanoates mono-substituted with chloro, fluoro, or methyl groups, and the 3,4-dichlorinated methyl 3-phenylpropanoate.

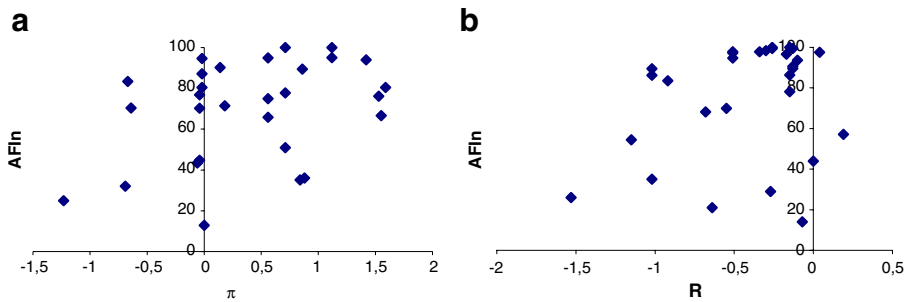

Fig. 6 AFIn for methyl 3-phenylpropanoates (at 50 mM concentration) vs. values of various Hansch parameters: **a** AFIn vs. the hydrophobicity parameter π; **b** AFIn vs. the steric parameter *R*

In a comparison of 3-phenylpropanoates and acrylates, the lower flexibility caused by the double bond in the acrylates may be an important factor that affects interactions with a receptor. Nevertheless, we focused on the electronic effects in our analyses of conjugated vs. nonconjugated analogs. In compounds with electron-withdrawing substituents on the aromatic ring, the antifeedant effect increased with conjugation, and for compounds with electron-donating substituents, the effect decreased for the conjugated analogs. Electron richness in the aromatic ring of the phenylpropanoids may be important for high activity. Alternatively, or additionally, the carbonyl moiety should be deprived of electron density. Eriksson (2006) studied the antifeedant activity of 3-phenylpropenals and 3-phenylpropanals against *H. abietis* and concluded that conjugation does not seem to be critical for activity.

In the comparison between monosubstituted and disubstituted compounds, the disubstituted methyl analogs were slightly less potent than the monosubstituted. The decreased potency cannot be correlated to a negative effect of the increased bulkiness of the compounds as this effect was not seen for the chloro analogs. The magnitude of difference observed (more than tenfold difference) between the disubstituted and trisubstituted methoxy analogs is intriguing. The 3,4- and 3,4,5-substituted saturated compounds were much less active than the 2,3- and 3,5-substituted, which is in agreement with the results from saturated analogs of cinnamic aldehyde (Eriksson 2006). When we compared the antifeedant effect of conjugated acrylate analogs (3,4-OCH_3, 2,4-OCH_3, 2,3-OCH_3, and 3,5-OCH_3), the results differed considerably. In this case, the 2,3- and 2,4-analogs were more potent than the 3,4- and 3,5-analogs, which is contradictory to the results for the corresponding phenylpropenals (Eriksson 2006). Our results indicate that there was an effect by conjugation.

For the compounds with mixed substituents, the (3-Br, 4-OCH_3) analog was less potent than the monosubstituted compounds, which implies that the increased bulk lowered activity. In contrast, the (3-CF_3, 4-Cl) compound was more potent than its monosubstituted analogs.

When esters with different alcohol parts were compared, methyl, ethyl, and isopropyl esters showed potency within the same range, whereas the butyl esters tested showed lower potency. One explanation could be that the bulkiness of the butyl analogs caused the lower antifeedant activity.

The investigation of the relation of the various Hansch parameters to antifeedant activity revealed a correlation to π and R, respectively. For π, a negative value ($\pi<-0.1$) gave a lower AFI. All eight compounds with a more negative F had AFIa<60 at 50 mM concentration. This result was expected as too highly hydrophilic compounds have not been very active in previous investigations of antifeedants for *H. abietis* (Unelius et al. 2006; Sunnerheim et al. 2007). A similar relationship was found for R where compounds having $R<-0.5$ showed low AFIn and AFIa values, i.e., a relatively high resonance potential seems to be necessary. The steric parameters, MR and MW, showed no correlation to antifeedant activity. When the steric factors for each position (ortho, meta, para) on the aromatic ring were correlated to the AFIs, no general trend was found, but the number of compounds tested was limited (10 para, 3 meta and 3 orthomonosubstituted compounds). These results may be indicative of a multireceptor response that causes the antifeedant effect, since small as well as bulky, and light as well as heavy compounds all showed similar antifeedant potency. This multireceptor hypothesis is supported by the fact that most other parameters also did not correlate to AFI.

In the relatively few studies available on the responses of other organisms to phenylpropanoids, there are both similarities and dissimilarities with our results for *H. abietis*. That esters of phenylpropanoids are more active than the corresponding alcohols and acids was shown both in the present study and in studies of derivatives of cinnamic acid as bird repellents (Jacubas et al. 1992; Watkins et al. 1999). An example of a compound with diverging effects between organisms is ethyl 3-(4-nitrophenyl)acrylate, which showed no antifeedant activity against *H. abietis* although it has previously been found to be an oviposition deterrent for the onion fly *Delia antique* (Meigen) (Cowles et al. 1990). Another related compound, cinnamaldehyde, has been proved to act as an antifeedant for grain storage insects (Huang and Ho 1998). A comparison of the phenylpropanoid vs. the benzoate antifeedants of *H. abietis* (Unelius et al. 2006) reveals a number of similarities: Carboxylic acids are generally less effective antifeedants than the corresponding esters, which also is in agreement with the results from the study on *H. abietis* by Eriksson (2006). Furthermore, the length of the alkyl chain in the parent alcohol moiety of the esters should be short, and methoxy-substituted aromatics are more potent than hydroxy-substituted in both classes of substances. On the other hand, the prerequisites of the substitution pattern for good antifeedant activity seem to differ between benzoates and phenylpropanoids. For example, the best benzoate is the 2,4-dimethoxy analog, whereas the corresponding 2,4-dimethoxy-phenylpropanoids have rather low activity, and the most effective propanoids, the halogen- or methyl-substituted compounds, have very low AFIs as benzoate analogs.

Among the 51 compounds tested in this study, a large number of potent antifeedants were found. A majority of the compounds tested was more effective than the lead compound, ethyl cinnamate, which has been identified in the inner bark of *Pinus contorta* (Bratt et al. 2001). The most potent compounds were methyl 3-phenylpropanoates monosubstituted with chloro, fluoro, or methyl groups on the aromatic

ring, and the 3,4-dichlorinated methyl 3-phenylpropanoate. These compounds are good candidates for further studies in the laboratory and in the field. A pool of over 20 highly active phenylpropanoid compounds provides many possibilities to develop mixtures of compounds that could potentially be even more effective than the single compounds tested so far. Field assays that evaluate chemical and physical properties, such as volatility and stability to resist water and UV radiation, are required to establish the effectiveness of these compounds for conifer seedling protection under field conditions.

Our findings are probably a consequence of effects from the stimuli of several taste and odor receptors processed by the insect brain. Earlier investigations (Wibe et al. 1996, 1997, 1998) have described the response of numerous receptors in the antennae of *H. abietis*, of which some are highly specific and some more generally tuned to olfactory stimuli, within groups of monoterpenes and aromatic compounds. Thus, it is likely that several receptor types are activated during feeding and that each type is tuned to molecules with different structural properties. The results from a study of structural analogs of naphthoquionones as feedants/antifeedants for the larvae of the Mexican bean beetle, *Epilachna varivestis*, are as intriguing as ours. A complex interplay of electronic, steric, electrochemical, and positional requirements was found that affected the feeding response (Weissenberg et al. 1997).

The ecological background to why feeding of *H. abietis* is affected by derivatives of phenylpropanoates is still largely unknown. Although it is possible that ethyl cinnamate is partly responsible for the fact that *H. abietis* feeds less on the bark of *P. contorta* than of *P. sylvestris* (Bratt et al. 2001), this is at least not specifically a substance used by *P. contorta* for defense against this insect, as the tree and the insect species have their natural distributions in different parts of the world. However, phenylpropanoates may be of more general importance in plant–insect interactions than presently acknowledged, as indicated by the frequently strong antifeedant responses in the pine weevil.

Acknowledgments We thank The Swedish Research Council for Environment, Agricultural Sciences and Spatial Planning, The Swedish *Hylobius* Research Program, and The University of Kalmar for supporting this study. Henning Henschel, Abtin Daghigi, Meral Sari, Veronica Siljehav, Konstantin Dubrovinski, Tonja Freisolt, and Magnus Besev were helpful in the syntheses of the test compounds and Claes Hellqvist in processing the bioassay data.

Responses of *Helicoverpa armigera* to Tomato Plants Previously Infected by ToMV or Damaged by *H. armigera*

Li Lin · Tse-Chi Shen · Yi-Hua Chen · Shaw-Yhi Hwang

Received: 21 August 2007 / Revised: 17 January 2008 / Accepted: 23 January 2008 / Published online: 20 February 2008

Abstract We report the comparative inducing effects of a phytopathogen and a herbivorous arthropod on the performance of an herbivore. Tomato, *Lycopersicon esculentum* Mill., was used as the test plant, and tomato mosaic virus (ToMV) and corn earworm, *Helicoverpa armigera* Hübner, were used as the phytopathogen and herbivore, respectively. There were decreases in the efficiency of conversion of ingested food and efficiency of conversion of digested food when *H. armigera* was reared on tomato plants that had been previously inoculated with ToMV. However, virus inoculation did not affect feeding or oviposition preferences by *H. armigera*. In contrast, approximate digestibility, total consumption, relative growth rate, and relative consumption rate were lower for fourth-instar *H. armigera* that fed on plants previously damaged by the same herbivore. Feeding and oviposition were both deterred for *H. armigera* that fed on previously damaged plants. The duration of development of *H. armigera* was also prolonged under this treatment. Infection by ToMV and feeding damage by *H. armigera* increased the host plant's peroxidase and polyphenol oxidase activity, respectively, suggesting that the performance of *H. armigera* may be affected by the induced phytochemistry of the host plant. Overall, this study indicated that, in general, insect damage has a stronger effect than ToMV infection on plant chemistry and, subsequently, on the performance of *H. armigera*.

Keywords Corn earworm · *Helicoverpa armigera* · Induced plant chemistry · Peroxidase · Plant–phytopathogen–herbivore interaction · Polyphenol oxidase · Tomato mosaic virus (ToMV)

Introduction

Almost every plant species is used as a food source by a variety of phytopathogens and herbivores, and these exploiters seldom exist in isolation from each other. When considering their abundance and biodiversity (Hawksworth 1991), it is obvious that the concurrent or sequential occurrence of phytopathogens and herbivores on a host plant is common, and that interactions between phytopathogens and herbivores can be expected. Thus, plants often deal with diverse enemies (Moran 1998; Genoud and Metraux 1999; Maleck and Dietrich 1999; Paul et al. 2000; Kruess 2002; Rostás and Hilker 2002, 2003). Owing to their sedentary life traits, plants have evolved specific ways to cope with their multiple enemies. They synthesize a broad range of constitutive and induced phytochemicals that may directly affect the inducers themselves or indirectly affect subsequent intruding herbivores or phytopathogens (Moran 1998; Rostás et al. 2002; Wittstock and Gershenzon 2002; Johnson et al. 2003).

Interactions among diverse plant enemies can be direct or indirect, mutualistic, detrimental or neutral, and these effects may be exerted by induced plant chemistry (Hatcher et al. 1995; Moran 1998; Rostás and Hilker 2002, 2003; Johnson et al. 2003; Stout et al. 2006). Both phytopathogens and herbivores are biotic stress factors that induce changes in the plant metabolism, such as changes in patterns of nutrient allocation and induction of defense-related phytochemistry (Ayres 1992; Baldwin and Preston 1999; Hammerschmidt 1999; Rostás and Hilker 2002; Stout et al. 2006). Thus, phytopathogens and herbivores interact indirectly by influencing the suitability of their shared host plant.

Several studies have indicated that cross-resistance between herbivores and phytopathogens occurs, e.g., prior attacks by phytopathogenic fungi increase resistance against subsequent attacks by herbivores (Karban et al.

1987; Hatcher et al. 1994, 1995; Hatcher 1995; Siemens and Mitchell-Olds 1996; Kruess 2002; Rostás and Hilker 2002; Rostás et al. 2003; Stout et al. 2006), and previous herbivore-damaged plants become less suitable for fungi (Karban et al. 1987; Hatcher et al. 1994; Hatcher and Paul 2000; Rostás et al. 2003). Most studies of plant–phytopathogen–herbivore interactions, however, have been focused on the effects of phytopathogenic fungi (Moran 1998; Kruess 2002; Rostás and Hilker 2002; Rostás et al. 2002, 2003; Johnson et al. 2003), and relatively little is known about the effects of phytopathogenic viruses on plants and on lepidopteran insects (Stout et al. 1999; Mayer et al. 2002; McKenzie et al. 2002). In addition to the plant–phytopathogen–herbivore interactions, many studies have also revealed a plant–herbivore–herbivore interaction (Karban and Myers 1989; Stout and Duffey 1996; Karban and Baldwin 1997; Denno et al. 2000). Different herbivores of a host plant may be separated spatially or temporally, but they may interact with each other through mediation of the host plant. Most plant–herbivore–herbivore research has been concerned with the effect of plant-induced responses on herbivores (Karban and Baldwin 1997; Felton and Eichenseer 1999; Underwood 1999; Bezemer and van Dam 2005). However, diverse effects have been found for plant-mediated interaction, and this may be because of complicating interactions among the defense-related signalling pathways and the resulting induction of plant secondary compounds (Stout et al. 2006).

Corn earworm, *Helicoverpa armigera* (Hübner), has a worldwide distribution and is a highly polyphagous agricultural pest. The host plant spectrum of *H. armigera* includes important agricultural crops such as tomato, cotton, maize, chickpea, sorghum, cereals, and soybean (Fitt 1989; Cunningham et al. 1999; Gupta et al. 2003; Diongue et al. 2004). Feeding on foliage or fruiting structures by insatiable larvae usually leads to substantial economic losses (Reed and Pawar 1982). Tomato mosaic virus (ToMV) causes mosaic disease of tomato and other important crop plants (Green et al. 1987; Breman 1989; Duarte et al. 2001). The ToMV-infected tomato plants display light and dark green mottled areas of the leaves, and fruits may be reduced in size and number with irregular ripening (Green et al. 1987). In tomato plantations, both *H. armigera* and ToMV may occur simultaneously. We investigated the interactions among tomato, ToMV, and corn earworm (*H. armigera*). Specifically, this study focused primarily on plant-mediated indirect interactions between ToMV and *H. armigera*, and on the indirect interactions between insect-induced responses and *H. armigera* performance. In addition, we assessed changes in plant chemistry because of induction by herbivore damage or virus infection that might be relevant to the performance of *H. armigera*.

Methods and Materials

Plants Tomato plants (*L. esculentum* Mill. cv Tainan-Yasu No. 6) were grown from seeds in a greenhouse (27–30°C). Supplemental light was provided 16 hr/d in addition to natural daylight. Before sowing, seeds were soaked first in 5% bleach for 30 min and rinsed with distilled water three times to eliminate contamination. Seeds were potted in standard potting soil, watered daily, and fertilized once a week with commercial synthetic 25–5–20 (N–P–K) fertilizer (1/1,000 Hyponex®4). Plants were transplanted to 17.8 cm diameter pots when they had three fully expanded leaves (20 to 28 d after sowing).

H. armigera and ToMV H. armigera were obtained as eggs from the Taiwan Agricultural Chemicals and Toxic Substances Research Institute, Council of Agriculture. Larvae were reared on an artificial diet in a growth chamber (27°C, 12L/12D photoperiod). ToMV was obtained from the laboratory of Dr. F. J. Jan (Department of Plant Pathology, National Chung Hsing University, Taiwan). As the standard method, ToMV was suspended in 10 mM sodium phosphate (pH 7.0) and inoculated onto the true leaf of *Chenopodium quinoa*. For the experimental inoculation treatments, the virus suspension was obtained by grinding the infected *C. quinoa* leaves with a sodium phosphate buffer. To prevent loss of viral activity, all treatments were conducted in a cold room (4°C), and the virus suspension was used within 8 hr after suspension.

Plant-mediated interactions between ToMV and H. armigera To evaluate the effects of systemic infection by ToMV on the resistance of tomato foliage to *H. armigera*, four-leaf tomato plants were assigned in equal numbers to two treatment groups (approximately 60 plants per treatment). Plants in the first group were subjected to a localized infection by ToMV, and those in the second group were the control group. Inoculations were confined to the terminal leaflet of the third leaf. Leaflets were sprayed first with corundum powder; then, they were inoculated by gently rubbing the upper surfaces of the leaflet with a pestle saturated with a virus suspension (in phosphate buffer, pH 7.0). Plants in the control group received the same inoculation treatment, except that a phosphate buffer was used instead of the virus suspension. Three days after the inoculation, leaflets of the fourth leaf (not the treated leaf) were used to evaluate the effects, to assess the chemical changes caused, and to determine the suitability of the treatment for *H. armigera*. Chemical analyses and the bioassays used to assess the suitability of the inoculation treatment for *H. armigera* are described below.

A larval feeding preference bioassay utilized newly molted, fourth-instar *H. armigera*. One leaflet from the fourth leaf was collected from both treated and control tomato plants. Areas of these leaflets were measured first with a portable area meter (Li-3000A, Li-Cor, Lincoln, NE, USA). The leaf petiole of each leaflet was inserted into a water pik to maintain leaf turgor, and leaflets from both treatments were placed in a Petri dish (140×15 mm). Seven 4th instars were placed in the center of each Petri dish and allowed to randomly select and feed on foliage for 6 hr. After they had fed, larvae were removed and the leaf areas of both leaflets were measured again. Feeding percentage was calculated as: Feeding preference (%)=[(leaf area consumed, either treated or control leaflet)/(leaf area consumed of treated leaflet+leaf area consumed of control leaflet)]×100%. Six replicates were performed.

We also evaluated the effect of foliage quality of treated plants on the oviposition choice of adult *H. armigera*. Pupae were separated by sex, and 3 d after eclosion, 10 moths (five of each sex) were placed into a glass cylinder (90 mm long×55 mm diameter) for mating. One day after mating, these 10 moths were transferred to a nylon mesh cage (60×60×60 cm), and two plants, one representing treatment (virus infection) and the other control, were provided for the moths to deposit eggs. Seventy-two hours later, plants were removed from cages, eggs were counted, and the oviposition preference was calculated as: Oviposition preference (%)=[(egg number from either treated or control leaflet)/(egg number from treated leaflet+egg number from control leaflet)]×100%. Six replicates were performed.

Short-term feeding trials were conducted to evaluate the effect of foliage quality on growth rate, food consumption rates, and food processing efficiencies of fourth instars of *H. armigera*. Three days after the inoculation, leaflets of the fourth leaf (untreated leaf) were used. Fifty newly hatched larvae were grown on artificial diet in a Percival growth chamber (12L/12D photoperiod) at a constant 27°C until molting to fourth instars. Each assay consisted of a newly molted and weighed larva placed into a rearing cup (250 ml) that contained a leaf from a plant that had received one of the two different treatments (N=15 replicates per plant treatment). Leaves (above the fourth leaf) were changed every 1–2 d or as necessary during the bioassay. Upon molting to fifth instar, larvae were frozen, oven-dried at 50°C for 1 wk, and reweighed. Nutritional indices were calculated to evaluate insect growth, consumption, and food utilization efficiency (Haynes and Millar 1998; Schoonhoven et al. 1998). These indices were calculated from standard formulas for approximate digestibility (AD), efficiency of conversion of digested food (ECD), and efficiency of conversion of ingested food (ECI) as described by Waldbauer (1968) and Haynes and Millar (1998). The initial rather than the average weights of the larvae were used to calculate the relative growth rate (RGR) and relative consumption rate (RCR) (Farrar et al. 1989). Analysis of covariance (ANCOVA) has been suggested to be more appropriate than the use of ratio variables for the analysis of nutritional indices (Raubenheimer and Simpson 1992, 2003; Raubenheimer 1995; Packard and Boardman 1999; Thompson et al. 2005). Therefore, we performed an ANCOVA (PROC GLM; SAS Institute 1999) on the absolute growth rate (AGR) (weight gained per day) and absolute consumption rate (ACR) (food consumed per day) by using initial weights as covariates. We reported the results from both the standard (ratio) and ANCOVA approaches for a reason: any errors introduced by variation in initial larval weights are inconsequential when the range of initial weights is small, as was the case in this study. Initial dry weights of the test insects were estimated based on a wet-to-dry weight conversion factor determined from five newly molted fourth instars. Similarly, initial dry weights of leaves fed to insects were estimated by dry weight conversion using foliage collected from each plant group at the time of the bioassay. Means and standard errors were calculated for duration, RGR, AGR, RCR, ACR, total consumption (TC), AD, ECD, and ECI for insects fed on foliage from differently treated plants. During the bioassay, additional leaf material from the test plants was collected to measure their chemical content.

Plant-mediated interactions between insect damage and H. armigera To evaluate the effects of systemic induction by *H. armigera* feeding on resistance of tomato foliage to *H. armigera*, four-leaf tomato plants (28-d-old) were assigned in equal numbers to the two treatment groups (approximately 60 plants per treatment). Plants in the first group were subjected to localized feeding by *H. armigera*, and those in the second were the control group. Feeding was confined to the third leaf. One newly molted fourth-instar larva was restricted by a mesh bag and fed on the third leaf. Twenty-four hours after feeding (about half of the leaf area was removed), each larva was removed from the plant. Plants in the control group received the same bag treatment except no larva was used. Three days after feeding, the leaflets of the fourth leaf (untreated leaf) were used to evaluate the effects of the treatment on the suitability of the leaf in preference and feeding trials for *H. armigera* and to assess any chemical changes caused by the treatments. The bioassays used to assess the suitability of leaflets for *H. armigera* (preference and feeding trials) and leaf sampling were similar to those used previously (see "Plant-mediated interactions between ToMV and *H. armigera*").

Chemical analyses Concurrent with the feeding bioassay, foliar samples were collected for chemical analysis. Systemic leaves (i.e., not the virus- or insect-treated leaves, but the fourth leaf and leaves growing above the fourth leaf) from treated tomato plants (six plants), and similarly aged leaves from control plants (six plants) were harvested (0, 3, 7, 14, and 21 d after treatment). Leaves were sampled from different plants (not previously sampled) at the various sampling time intervals to insure independence of sampling. The fourth leaf was used for measuring the total protein concentration and the activities of polyphenol oxidase and peroxidase. The fifth and above leaves were flash frozen in liquid nitrogen, freeze-dried, ground, and stored in a freezer for water and nonstructural carbohydrate analyses at a later date.

Spectrophotometric assays of the activities of polyphenol oxidase and peroxidase were performed with an extract of the fourth leaf (Moran 1998; Stout et al. 1999). Leaf extract was prepared with a tissue grinder (Drill Press Stand Model 212; Dermel, Racine, WI, USA) to homogenize the whole leaf in pH 7 phosphate buffer containing 7% (*w*/*v*) polyvinylpolypyrrolidone. A volume (1.5 ml) of homogenate was removed and placed into a 1.7-ml centrifuge tube. Then, 100 µl of a 10% solution of Triton X-100 were added by mixing with the homogenate. This homogenate was centrifuged at 6,000×*g* for 15 min. The resulting supernatant was used for enzyme activity determination. Total protein was assessed with bovine serum albumin as the standard (Bradford 1976). Polyphenol oxidase and peroxidase activity were measured as in Stout et al. (1999) for the rate of formation of melanin-like material from the phenolic substrates. For polyphenol oxidase assays, 10 to 100 µl of enzyme extract were added to 500 µl of 10 mM catechol in pH 8 potassium phosphate buffer (0.1 M), and the change in absorbance of the mixture at 470 nm was recorded for 30 sec. The method for measuring peroxidase activity was similar, but the substrate for peroxidase activities consisted of 5 mM guaiacol with 0.02 mM H_2O_2 added as a cofactor. Polyphenol oxidase and peroxidase activities were reported as ΔOD_{470} min^{-1}mg fresh $weight^{-1}$ (Ryan et al. 1982).

Foliar water and total nonstructural carbohydrate contents were also quantified for each foliar sample. Differences between wet and dry weights of leaf samples were used to determine water contents. An enzymatic method was used to measure the total nonstructural carbohydrates (TNC) of each sample. Extracts of TNC (starch plus soluble carbohydrates/sugars) were incubated with amyloglucosidase to completely hydrolyze starch before assaying for reducing sugars (Madsen 1997; Liao 2003).

Statistical analyses For all bioassays, means and standard errors (SE) were calculated for the insect performance parameters (feeding and oviposition preference, growth rate, consumption rate, and food utilization efficiencies) and plant chemistry. The Student's *t* test (PROC TTEST; SAS Institute 1999) was used to compare insect performance among virus-inoculated, previously damaged (by insects), and control host plants.

Results

Plant-mediated interactions between ToMV and H. armigera Infection of tomato plants by ToMV had no effect on larval feeding and adult oviposition preference (Fig. 1). Larvae consumed almost equal amounts of foliage from both the virus-infected and the control leaves. Adult moths laid slightly more eggs on the control plants (58%) than on the virus-infected plants (42%), but this difference was not significant.

Performance (duration, growth rates, and consumption rates) of fourth-instar *H. armigera* was similar between the virus-infected and the control plants (Table 1). Analysis of covariance (rate variables) and analysis of variance (ratio variables) gave identical results for growth (AGR, RGR) and consumption (ACR, RCR) parameters (Table 1). However, larvae that fed on virus-infected plants had significantly reduced food conversion efficiencies (ECD and ECI).

Plant-mediated interactions between insect damage and H. armigera Previous feeding on tomato plants by *H. armigera* resulted in a dramatic change in preference of the fed-upon plants to subsequent feeding by *H. armigera*. Fourth-instar larvae consumed more than nine times the amount of foliage of control plants than they did of treated plants (Fig. 1). Female moths laid significantly more eggs on control plants than they did on treated plants (Fig. 1).

Performance (duration, growth rates, and consumption rates) of the fourth instars varied substantially between treated and control plants (Table 1). Analysis of covariance (rate variables) and analysis of variance (ratio variables) also gave similar results for growth (AGR, RGR) and consumption (ACR, RCR) parameters (Table 1). In contrast to the virus-infected study, growth rates (RGR) and consumption rates (RCR) varied significantly between control and treatment plants. Both growth rates (RGR) and consumption rates (RCR) were higher for insects fed on foliage of the control tomatoes (Table 1). Larval duration (DUR), however, was longer for insects that fed on insect-damaged plants. In addition, *H. armigera* larvae had higher digestibility (AD) on control than on treated host plants. The efficiencies of conversion of ingested and digested food (ECD and ECI), however, were not significantly

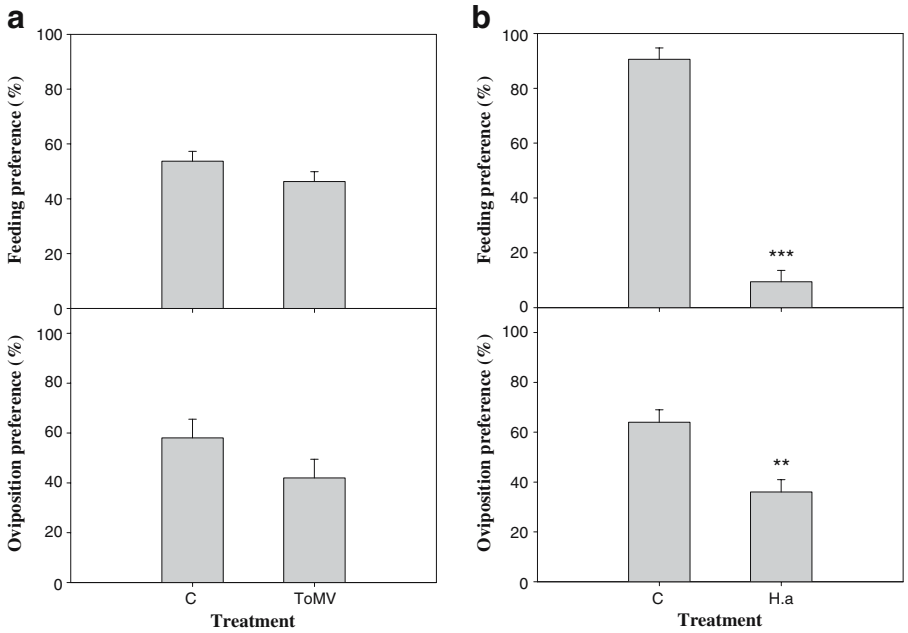

Fig. 1 Larval feeding and adult oviposition preferences (mean±SE, N=6 per treatment) of *H. armigera* in differently treated tomato leaves. **a** Foliage of tomato was inoculated with ToMV. **b** Foliage of tomato was fed on previously by *H. armigera*. *C* control, *ToMV* leaf of tomato plants that were inoculated previously with ToMV, *H. a* leaf of tomato plants that were fed on previously by *H. armigera* larvae. *Asterisks* denote significant differences (**P<0.01, ***P<0.001; Student's t test for independent samples)

different between control and treated plants. In summary, when fed on the previously fed-upon foliage, *H. armigera* larvae consumed less foliage (reduced RCR), had lower digestibility (reduced AD), and grew more slowly (reduced RGR and increased DUR).

Foliage chemistry Based on the bioassays, biochemical analyses were conducted to assess the relationship between the effect of the treatments on pest resistance and the expression of specific enzyme activities or compounds that are probably resistance mechanisms. Peroxidase activity increased slightly with leaf age in all experiments. Peroxidase activity, however, was significantly induced in tomato plants inoculated with ToMV in the systemic leaves by the seventh day after infection (Fig. 2a), and was 30% higher than in control plants. In contrast, peroxidase activity was not significantly different between the previously fed-upon plants and the controls (Fig. 2b).

Polyphenol oxidase activity also increased with leaf age of tomatoes, but the activity was not significantly different between the control and virus-infected plants (Fig. 2a). In contrast, in the insect-feeding treatment (Fig. 2b), polyphenol oxidase activity was significantly higher (30%) than in control plants on the third day after the feeding treatment.

Our results also indicated that foliar water and total protein contents were similar between the treatments and their controls (Fig. 3). Foliar water contents remained between 85% and 90% throughout the experiments. In

addition, the foliar total nonstructural carbohydrate contents were similar between the virus-infected and control treatments during the experiments (Fig. 3). However, in the insect-damage treatment, the total nonstructural carbohydrate content decreased significantly on the third day after the feeding treatment (Fig. 3).

Discussion

We showed that herbivory and viral infections have varied effects on performance and food processing efficiencies of *H. armigera*. Herbivory and virus infection may also affect host plant biochemistry, and changes in host oxidase activity because of induction might affect subsequent performance of *H. armigera*.

Previous investigations have indicated that plant-mediated interactions may occur between phytopathogens and herbivores or between various herbivorous species (Moran 1998; Stout et al. 1999; Thaler et al. 1999; Kruess 2002; Mayer et al. 2002; Rostás and Hilker 2002; Rostás et al. 2002; Johnson et al. 2003). Many studies were focused on the effect of prior attacks by phytopathogens on herbivores or vice versa (Karban et al. 1987; Hatcher et al. 1994, 1995; Siemens and Mitchell-Olds 1996; Hatcher and Paul 2000; Kruess 2002; Rostás and Hilker 2002; Stout et al. 2006), or on plant–herbivore–herbivore interaction (Karban and Myers 1989; Stout and Duffey 1996; Karban and Baldwin 1997; Denno et al. 2000). Among the plant–phytopathogen–herbivore interaction studies, most were focused on the cross-effects between fungal infection and insects (Hatcher 1995; Stout et al. 1999, 2006; Rostás and Hilker 2002; Rostás et al. 2003), and only a few looked at the cross-effects between virus infection and lepidopteran insects.

In our study, we compared concurrently the relative inducing effects of phytopathogenic virus and feeding by an arthropod herbivore on herbivore performance. The larvae of *H. armigera* prefer to feed on undamaged foliage rather than on herbivore-attacked foliage, and the adults also exhibit a decreased preference for leaflets of herbivore-damaged plants. Previous studies have indicated that after a prior attack by herbivores, plants can be induced to increase their polyphenol oxidase activity, which decreases the nutrient value of the foliage and reduces the feeding preference of the insects (Felton et al. 1992; Stout and Duffey 1996; Bostock et al. 2001). Our results show that *H. armigera* prefers to feed or oviposit on the control (undamaged) foliage, which also contains the lower polyphenol oxidase activity. In contrast to the herbivore-induced results, no difference was found in the preference behavior of *H. armigera* between control (undamaged) foliage and virus-infected foliage. Although some workers have suggested that adult beetles will avoid feeding and will avoid ovipositing on fungus-infested leaves (Kruess 2002; Rostás and Hilker 2002; Rostás et al. 2002), conflicting results have also been reported (Moran 1998). The cause for these varied results is unclear. Recent literature that deals with herbivore and pathogen effects has indicated that the effects of induced resistance are often not specific to any particular attacker, and the signal transduction pathways involved in induction after attack by herbivores or pathogens may overlap (Paul et al. 2000). Hypothetically, the resistance response induced by one attacker might be effective against a range of other potential attackers. However, in our system, the induced resistances

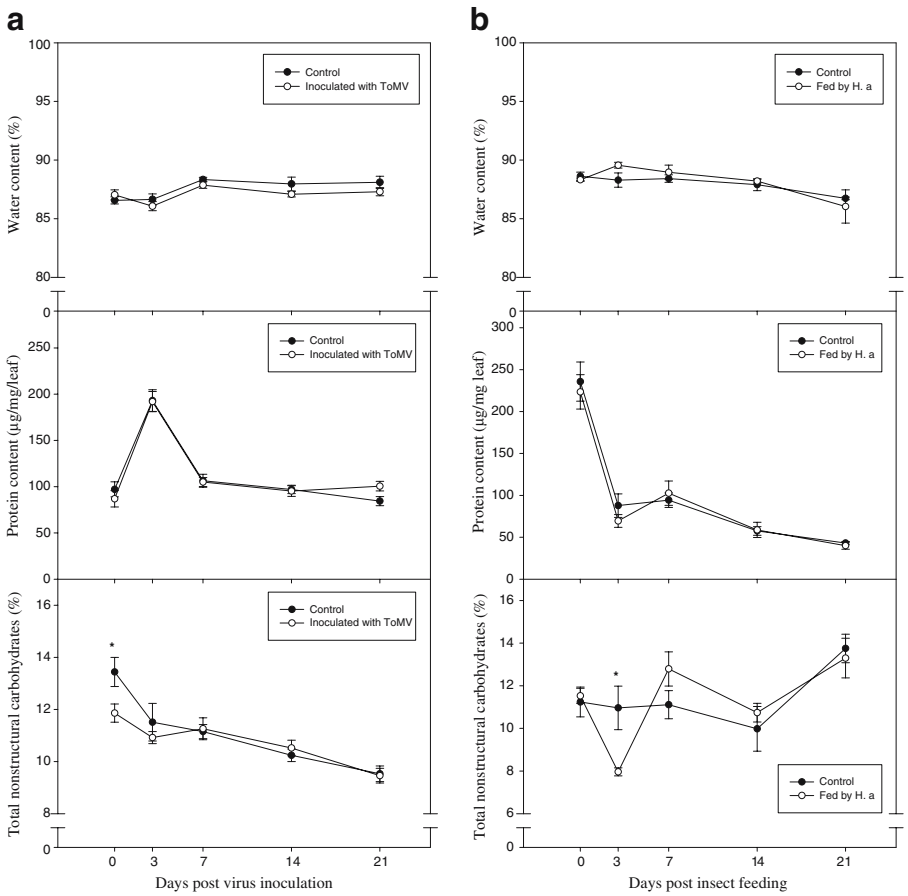

Fig. 3 Response of foliar water, protein, and total nonstructural carbohydrates (mean±SE, N=6 plants per treatment) to ToMV/*H. armigera* infestation. **a** Foliar water, protein, and total nonstructural carbohydrates contents in tomato inoculated with ToMV over time. **b** Foliar water, protein, and total nonstructural carbohydrates contents in tomato previously fed on by *H. armigera* over time. *Asterisks* denote significant differences (*P<0.05; Student's t test for independent samples)

show some degree of specificity, and resistance induced by a phytopathogenic virus may not be effective against a herbivore. In addition, studies of the role of cross-talk in tripartite interactions that involve jasmonic acid (JA) and salicylic acid (SA) pathways have demonstrated that a potential negative effect may occur between these induction-related pathways. This may lead to a reduction in resistance to the second attacker relative to plants not subject to initial attack (Stout et al. 2006).

In the short-term feeding trials, fourth-instar *H. armigera* performed differently between treatments and controls. Fourth instars grew more slowly and consumed less food on herbivore-damaged foliage than on control (undamaged) foliage. Stout and Duffey (1996) also indicated that beet armyworm, *Spodoptera exigua*, larvae grew slower and consumed less leaf tissue from corn earworm (*Helicoverpa zea*)-damaged plants than from control plants. This may be because of the decrease in the nutritional value of herbivore-damaged foliage. As previously mentioned, after having been damaged by insect feeding, plants increase their polyphenol oxidase activity and reduce their foliar carbohydrate concentrations. This increase in oxidase activity and decrease in carbohydrate content might decrease the nutritive value and thus reduce performance of subsequent feeding insects (Felton et al. 1989, 1992; Stout and Duffey 1996; Simpson and Raubenheimer 2001; Bostock et al. 2001; Lee et al. 2002). Similarly, our results of food utilization efficiencies show that larvae fed on herbivore-induced foliage have significantly lower absorption efficiency (AD). However, food conversion efficiency was not different. On the other hand, larval growth and consumption rates were not significantly different between virus-induced and control (undamaged) foliage. We found that larvae fed on virus-infected foliage had slightly lower food processing efficiencies (ECD and ECI) than those on control foliage, but the consumption and growth rates were not different. Other studies as well as ours have revealed an increase in peroxidase (POD) after insect or artificial damage in cucumber, corn, tomato, and other plants (Miller and Kelley 1989; Svalheim and Robertsen 1990; Dowd and Norton 1995; Bi et al. 1997; Moran 1998; Stout et al. 1998). Some studies have indicated that peroxidase induction is concurrent with the induction of systemic acquired resistance (SAR) against subsequent infection by the phytopathogenic fungus *Colletotrichum orbiculare* (Hammerschmidt et al. 1976; Moran 1998) or other phytopathogens. However, this increased peroxidase activity may also play a role in a plant's defense against insects, although the specific function of this enzyme in defense is unclear. We found that the elevated level of peroxidase activity in tomato after virus inoculation

may have a slight effect on an insect's food processing efficiencies, and this may be because of the toxicity of oxidized metabolites or free radicals (Duffey and Felton 1991).

In summary, this study compared the relative inducing effects of a phytopathogenic virus and herbivores on plants and on their subsequent herbivory. The result indicated that damage by insects had a stronger effect on plant chemistry and on performance of *H. armigera* than did virus infection. In addition, phytochemical analysis indicated that ToMV infection and damage by *H. armigera* can increase a host plant's level of peroxidase and polyphenol oxidase activity, respectively. In addition, *H. armigera* feeding can also reduce a host plant's carbohydrate concentration shortly after damage. A synthesis of these effects suggests that the increase in the level of polyphenol oxidase activity and the decrease in carbohydrate concentration may have some negative effects on the behavior and growth performance of *H. armigera*. Finally, although the literature concerning herbivores and pathogens has frequently shown that the effects of induced resistance are often not specific to any particular attacker (Paul et al. 2000), we found that the induced resistance did show a certain degree of specificity and that the resistance induced by a phytopathogen may not have a strong effect against subsequent herbivore attack.

Acknowledgments We thank Mr. R. Haesevoets and two anonymous reviewers for their comments on the manuscript.

Effect of a Rugulosin-producing Endophyte in *Picea glauca* on *Choristoneura fumiferana*

J. David Miller · Mark W. Sumarah · Gregory W. Adams

Received: 13 October 2007 / Accepted: 4 December 2007 / Published online: 12 February 2008

Abstract Disease-free second instar *Choristoneura fumiferana* (eastern spruce budworm) were placed on trees infected with a rugulosin-producing needle endophyte in two experiments. They were allowed to grow to sixth instar when survivors were collected. First, by using 3-yr old trees, a comparison was made of budworm growth on infected and uninfected trees. A second experiment used 4-yr old trees to study the effect of rugulosin content in the needle on growth. This permitted an examination of a dose response in relation to growth, and allowed us to eliminate the potential for differences in environment or foliar chemistry affecting the results. At sixth instar, budworms feeding on infected trees that contained rugulosin were smaller than those on uninfected trees. At needle concentrations above the dietary low observed effect level of rugulosin for *C. fumerana* >0.5 μg g^{-1}, a dose response was seen. For the first time, this demonstrates an inverse effect in outdoor nursery experiments between budworm weight and rugulosin concentration.

Introduction

Toxic metabolites produced by endophytic fungi (*Epichloë* and *Neotyphodium* species) in fescue grasses greatly reduce the populations of associated herbivorous insects. This has a beneficial effect on plant fitness. These fungi produce various alkaloids that affect herbivore growth (insects, mammals; Clay and Schardl 2002), and they are found in plant tissues in the 1–30 μg g^{-1} range for positive samples (Rottinghaus et al. 1991; Spiering et al. 2005). There is some evidence for translocation of the toxins, as well as for a possible role of plant enzymes in changing their structures (Spiering et al. 2005). There is also one report that the presence of the endophyte directly affects the growth of a nematode that damages one grass species, regardless of the toxins (Panaccione et al. 2006).

Conifer needles are also infected by systemic fungal endophytes. Carroll and Carroll (1978) first proposed that these may play a role in limiting insect herbivory among other interactions (Carroll 1988; Ganley et al. 2004). We have been studying their role in *Picea glauca* (white spruce) in limiting conifer needle herbivory by *Choristoneura fumiferana* and some other insect species. *C. fumerana* is a major cyclical pest of spruce and fir trees, especially in the northeast US and Canada (Royama et al. 2005). Over the past two decades, we have collected foliar endophytes of conifers from the Acadian forest and studied them for their ability to produce compounds toxic to *C. fumerana* larvae (Findlay et al. 2003a,b; Sumarah, Punaiani, Blackwell, and Miller—unpublished).

Successful experimental inoculation of *P. glauca* seedlings with the needle endophyte 5WS22E1 (DAOM 229536, CBS 120377), which produces rugulosin, has been demonstrated in previous studies conducted in growth

chambers and under nursery conditions (Miller et al. 2002; Sumarah et al. 2005, 2008). Based on DNA sequence information, this fungus is a species of *Phialocephala* (unpublished data), related to strains previously reported as endophytic in Norway spruce (Grunig et al. 2002). Grown under nursery conditions, needle samples from 2-yr old infected trees contained 0.15 to 24.8 μg g^{-1} rugulosin with a geometric mean concentration of 1 μg g^{-1} (Sumarah et al. 2005). Young trees have a uniform distribution of toxin, so the variation in concentration is largely among individuals. As the trees age, there is interbranch variation in rugulosin concentration. Once inoculated as seedlings, trees in a test site maintained similar needle rugulosin concentrations 5 yr post inoculation (Sumarah et al. 2008).

In growth chamber studies, occurrence of the fungus and its toxin in needles reduced the growth rate of *C. fumerana*. The effect level was between 0.5 and 8 μg g^{-1} needle dry weight (0.7 and 10 μg g^{-1} adjusted for recovery). This approximated a best estimate of the effect level in diet based on the extent data (Miller et al. 2002). *In vitro*, rugulosin reduced body weight and/or affected instar development in *C. fumerana* (Calhoun et al. 1992; Sumarah et al. 2008), *Lambdina fiscellaria* and *Zeiraphera canadensis* (Sumarah et al. 2008) at dietary concentrations in the 10–50 μM range. The purpose of this experiment was to determine whether similar concentrations of rugulosin in needles reduced the growth of *C. fumerana* in nursery-grown trees.

Methods and Materials

Nursery Experiments Tests were conducted at the J.D. Irving, Limited Sussex Tree Nursery in New Brunswick, Canada (45°43′N, 65°31′W; elevation 21.30 m). In two successive years, several hundred seedlings grown as container stock in multipot 67 seedling containers were inoculated with the rugulosin-producing endophyte 5WS22E1 (DAOM 229536; CBS 120377). A description of the *P. glauca* populations, planting and inoculation methods used in these experiments is given in Sumarah et al. (2005). All trees were labeled with nine digit codes, and all measurements done with the samples blinded.

Three-year old Seedlings The first group was sown on June 6, 2003, and inoculated on August 1, 2003. After 4 mo in the greenhouse, they were tested for endophyte colonization by enzyme-linked immunosorbent assay (ELISA) (Sumarah et al. 2005) and segregated. Along with 5WS22E1-free seedlings from the same crop, the endophyte-positive group was maintained under commercial conditions. After 1 yr, all seedlings were transplanted into plastic pots and held at the nursery site for 1 more year post inoculation.

Four-year old Seedlings The second group was from a test sown on February 1, 2002 and inoculated on April 28, 2002. These had been tested for endophyte infection after 4 mo growth by ELISA. The seedlings were transferred to pots after 1 yr and held as above.

Experiment 1 with Younger Trees This comprised 100 trees, 50 of which were infected with the endophyte and a similar control group. On May 25, 2006, five second instars were placed on a first-year lateral branch on shoots with buds on each tree by using a fine artist's brush (nylon #5). The buds were swelling when the larvae were applied. Insects were obtained as second instars from Insect Production Services, Natural Resources Canada, Canadian Forest Service (Sault Ste. Marie, ON) and stored at 5°C. The whole tree (the experimental unit) was covered with a mesh screen bag (polyester drapery shear material) prepared after Parsons et al. (2005) for both endophyte-positive and negative trees.

Experiment 2 with Older Trees Two budworms were placed as above on each of three or four first-year branches on shoots with buds on each of 48 four-year old trees. Each branch (the experimental unit) was then covered with a mesh bag (Fig. 1). This experiment permitted a factorial

Fig. 1 Photograph of 4-yr old trees showing mesh coverings on individual branches

analysis of inter-tree (differences in needle chemistry due to shade history, needle class, etc.) and inter-branch variation in rugulosin concentration (Sumarah et al. 2008).

The use of too many insects would have defoliated the trees regardless of the presence of the toxin in most if not all treatments. The number of budworm on the two sizes of trees in the present study was determined by using data from Parsons et al. (2005). They showed that the lowest detectable damage on balsam fir of early instar sawfly larvae occurred at a density of 50 larvae/m^2 branch.

Temperature recorders (Hobo Dataloggers, Onset Computer Corporation, Pocasset, MA, USA) were placed in the holding area. The development of the insects was visually monitored until the budworms reached sixth instar. At termination, all insects that could be found were collected and frozen individually. These were weighed on a Mettler PJ360 analytical balance (± 0.02 mg). Previous studies demonstrated that the frozen wet weight was correlated with the freeze-dried weight (N=134 animals, Pearson correlation R=0.841, Bonferroni-adjusted P<0.001). Head capsule widths were determined by using a stereo microscope at ×40 with ocular and stage micrometers. After collecting the budworm, the trees were sprayed with insecticide to ensure that no larvae survived to escape.

On June 26, 2006, both experiments were terminated and five to six lateral branches were removed from the 3-yr old trees and frozen. The branches where budworms were collected from the 4-yr old trees were removed and frozen individually. Needles were removed from all branches individually, freeze-dried, and used to determine infection by ELISA and rugulosin after Sumarah et al. (2005, 2008). The method limit of detection (LOD) for cell mass was 60 ng g^{-1}, and the limit of quantification (LOQ), i.e., a positive, was 120 ng g^{-1} dry weight of needle. The LOD and LOQ for rugulosin were both 150 ng g^{-1} (Sumarah et al. 2005).

Analyses of variance (ANOVA) with the Tukey–Kramer test were performed on the weights and head capsule widths of the insects from the 3-yr old trees with NCSS 2004 software (Kaysville, UT). An equal variance t test was also done on the weights with the same software.

On the 4-yr old trees, insects were stratified into those collected from needles with toxin concentrations approximating the needle no observed effect level (>0.5 µg g^{-1}; Miller et al. 2002). As noted by the same authors, this is similar to that estimated from the low observed effect of rugulosin for *C. fumerana* concentrations in synthetic diet based on the extant data (10 µM; Calhoun et al. 1992; Sumarah et al. 2008 found the value to be 25 µM). This takes into consideration several factors that necessarily must be estimated. This includes the mean ratio of dry weight/wet weight for needles, reported summer water content of spruce needles (Gary 1971), and hydrated insoluble content of needles (Reina et al. 2001; Zwiazek 1991). The artificial spruce budworm diet used has a water activity (a_w) of ~0.99, i.e., is essentially aqueous.

For statistical purposes, values negative by ELISA and below the analytical detection limit were entered at half the detection limit for rugulosin (as is normal for exposure characterization). Needles that were negative for rugulosin but positive by ELISA were entered at the detection limit because there was positive evidence for the presence of the fungus in the needle. Routine statistical tests as well as the paired t-tests, Wilcoxon signed rank test, and ANOVA were performed on the data from the 4-yr old trees by using SYSTAT v 10.2 (San Jose, CA, USA).

Results

The mean temperature was 18.4±2.2°C starting at 15–17°C and rising to 23°C in the last few days. Virtually all the insects recovered were sixth instar.

Three-year old Trees ELISA analysis of the control group revealed that five of the endophyte negative trees were positive at 36 mo, i.e., were false negatives when previously tested. These were excluded from the analysis. The geometric mean toxin concentration corrected for recovery in the endophyte positive group was 0.85 µg g^{-1}. The number of budworms recovered per tree was 3.3 for the infected (161 total) and 3.5 for the uninfected trees (152 total). ANOVA indicated that the weights of treated and control budworms were significantly different (P=0.018; df=1; F ratio 5.64). The distribution of insect weights between endophyte-infected and uninfected 3-yr old trees is shown in Fig. 2. Mean weight of the controls at termination

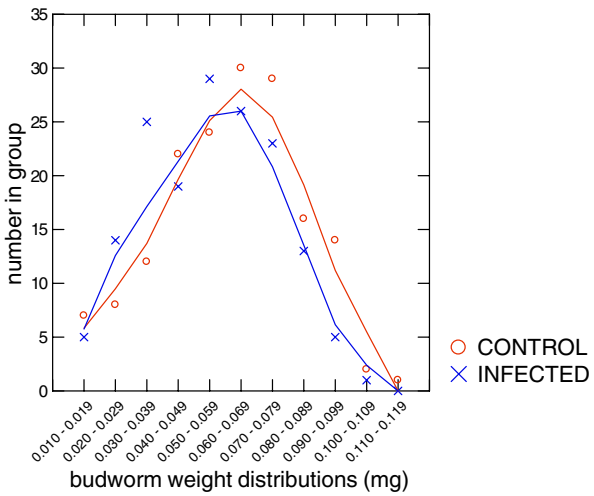

Fig. 2 Distribution of insect weights between endophyte-infected and uninfected 3-yr old trees; the weights between the two groups were significantly different by ANOVA, P=0.018)

was 0.061±0.02 mg and 0.055±0.02 mg for those collected on the infected trees. This difference was statistically different (P=0.009, equal-variance t test). Mean head capsule widths for the budworm on the control and infected trees were 1.89±0.21 mm and 1.90±0.18 mm, respectively. These were not different by ANOVA (P=0.646; df=1, F ratio 0.21).

Four-year old Trees The geometric mean rugulosin concentration corrected for recovery was 0.8 μg g^{-1} in all samples and the mean of the positives ≥0.5 μg g^{-1} was 1.3 μg g^{-1}. By ANOVA, there was no significant interaction between tree and insect weight, or tree and rugulosin concentration. The mean weight of the 166 insects recovered from the 4-yr old trees was 0.072± 0.02 mg. Considering the branches above 0.5 μg g^{-1}, there was an inverse relationship between rugulosin concentration and budworm weight (Pearson correlation −0.288; Bonferroni-adjusted P=0.023). Head capsule widths averaged 1.95±0.15 mg.

An average of 1.4 budworms were recovered from the original two placed on each branch. When the branches were stratified into quartiles of rugulosin concentration (40 each), the frequency of branches with two survivors was higher in the three quartiles with lower rugulosin concentrations compared to that with the highest concentration (ca. 1.6 versus 1.3; Wilcoxon signed rank test, P=0.025).

Disregarding a few trees where budworms were collected from only one branch, the trees fell into one of three distributions. A large percentage (38%) comprised the situation where all branches were above the threshold of rugulosin toxicity, and 16% where all were below the threshold. In neither case, would there be intra-tree variation in rugulosin concentration to study. The remainder, comprising the majority, had individual branches above and below the threshold. Typical data from trees with multiple branches analyzed are shown in Table 1. All three branches analyzed on tree 1034 had concentrations far in excess of the toxic threshold. Only one budworm per branch was recovered, and the animal from the branch with the lowest concentration had the highest weight, higher than the mean noted above. One branch from tree 1360 was far above the threshold. In this case, the weight of the insect collected was at the mean. Two insects were collected from the two remaining branches with a mean weight at the average. A similar pattern can be seen in tree 2022.

Discussion

In growth chamber studies, the occurrence of fungus and its toxin in needles reduced *C. fumerana* growth. These experiments were done by using detached needles from 4-mo old seedlings with an established method to screen for

Table 1 Budworm weights on different branches from 4-yr old trees and rugulosin concentration

[a] Below dietary concentration of threshold for toxicity of rugulosin *in vitro.*

variation in foliar resistance (Miller et al. 2002). The present experiments were conducted by placing budworm on trees that grow outdoors.

We have examined two aspects of the effect of rugulosin in needles on *C. fumerana* growth under outdoor nursery conditions. The first was a comparison of the impact on budworm growth on infected trees and uninfected trees. The second was to use a group of older trees such that needles from the infected tree served as a control. This strategy is typically used in toxicology to eliminate possible confounding variables that arise from intra-individual variance. The intention here was to look for evidence of a dose response to rugulosin. These might be anticipated to result from potential changes in needle chemistry because of variables that include needle age, shade, and the fungus itself. Shading (Lhotakova et al. 2007) and needle age as well as soil conditions are known to affect foliar composition, and these in turn can affect budworm growth (Carisey and Bauce 1997; Clancy et al. 2004; Nealis and Nault 2005). The trees used in the present studies represented a diverse genetic population used for reforestation in eastern Canada and Maine.

Although an attempt was made to terminate the experiments so that there was a distribution of instars, virtually all were sixth instar. This is probably because of higher temperatures in the final 24 hr of the experiments compared to the previous week. Mean head capsule widths were ~1.94 mm. This value is at the upper end of those found in nature. McGugan (1954) reported that the mean head capsule widths from a natural epidemic in northwestern Ontario were 1.63 mm for males and 1.79 mm for females. Field collections from New Brunswick were reported to be 1.66 mm without sex being specified (Anon. 1981, Data Fact Sheet, Determination of spruce budworm larval stage; CANUSA Spruce Budworm Program). This difference may relate to the fact that the animals used in this experiment were parasite- and disease-free versus the natural situation (see the following).

The distribution of animal weights collected on infected needles at termination was different from the respective controls (Fig. 2). There was also a statistically significant difference in budworm weights between the two groups. As in the growth chamber, the presence of the fungus and its toxin reduced *C. fumerana* growth. Similar experiments on infected and uninfected grass endophytes have resulted in similar findings and effects on development (e.g., Hardy et al. 1985).

The second aspect of the present experiments was the use of older trees from which the effect on budworm growth on multiple branches from the same infected tree could be observed. This was possible because variation in rugulosin concentration was observed among individual branches within a single tree. As was found previously, rugulosin concentrations were typically above those that affect the growth of *C. fumerana* in needles and *in vitro* (Miller et al. 2002; Sumarah et al. 2008) and *Lambdina fiscellaria* and *Zeiraphera canadensis in vitro* (Sumarah 2008). In this component of the study, two effects were seen. First, a comparison of those branches with concentrations above the threshold of rugulosin toxicity demonstrated there was an inverse relationship between budworm weight and rugulosin concentration (-0.288; $P=0.023$). A further support of the reliability of this conclusion comes from the fact that on the branches with the highest rugulosin concentrations, survival was significantly lower than on branches compared to those with lower concentrations. In addition, there was a small but significantly increased weight in the survivor population found on branches in the quartile of branches with the highest rugulosin concentration. It is known that when *C. fumerana* are under nutrient limitations, they will resort to cannibalism, which provides a plausible explanation of the latter observation. Nonetheless, there was evidence of a rugulosin dose response where single animals were recovered (e.g., tree 1034B).

In synthetic diet (Calhoun et al. 1992; Sumarah et al. 2008), the presence of ca. 10- to 25-μM rugulosin resulted in the reduction in *C. fumerana* growth rate (ranging to 50 μM for some other herbivorous insect species). In needles, the minimum lowest observed effect level of >0.5 μg g^{-1} appears close to this value (Miller et al. 2002; see above). Using the weight of evidence rule in toxicology, the effects seen in this study are largely explained by the toxin, and are consistent with other endophyte interactions that have been studied.

In a monograph on *C. fumerana* population dynamics in New Brunswick, Royama (1984) discusses the cyclical nature of epidemics to date. He postulated an unknown factor to modulate upward the observed population changes in relation to his model. The central characteristic of the unknown factor was that it increased the response of the insect populations to known factors such as predation and disease. As the primary effect of rugulosin *in vitro* and in the plant is to slow the growth rate, the insects would be exposed to these environmental and biotic factors for longer durations. We have also postulated that this effect might put cohorts of the insects out of reproductive synchrony.

Another hypothesis is that the presence of the toxins would result in immune modulation, which is a feature of mammalian exposure. Moth immunology remains incompletely understood but shares some features of the mammalian system with more primitive features. In both experiments, the insects were uniformly larger than expected from field data (McGugan 1954; Anon 1981), i.e., at the top of the normal range for sixth instar. As noted, these animals were disease-free and reared on trees grown under optimal conditions. When budworm populations are

expanding, the percentage of insects infested with parasitoids rises (e.g., Shepherd 1959; Quayle et al., 2003). In addition, there is a prevalence of pathogenic *Bacillus* species on budworm collected on balsam fir in New Brunswick (Strongman et al. 1997). Adventitious occurrence of the facultative fungal pathogen *Aspergillus fumigatus* is common in trees infested with *C. fumerana* (Miller et al. 1985; Sumarah et al. 2008). Had the tests been done in the wild and thereby including other mortality factors, fitness on rugulosin-containing branches might have been lower.

In summary, we have shown that the presence of a foliar endophyte of conifers and its toxin, rugulosin, in trees grown under production conditions resulted in reduced growth of *C. fumerana* in a dose-dependent manner. In addition, these experiments show that the effect is primarily explained by rugulosin. Further experiments are needed to examine the implications for growth and development under field conditions.

Acknowledgments We thank Arthur deWolfe, Hartmut Kunze, and Janet Steeves (Sussex Tree Nursery); John Dedes (Insect Production Services, Canadian Forestry Services); and Greg Slack, Aaron Wilson, and Julian Walcott (Carleton University). Prof. Arthur Schaafsma, University of Guelph and two unidentified reviewers provided many useful comments on the manuscript. Altitudinal Variation of Phenolic Contents in Flowering Heads of *Arnica montana* cv. ARBO: a 3-Year Comparison

Renate Spitaler · Andrea Winkler · Isabella Lins · Sema Yanar · Hermann Stuppner · Christian Zidorn

Received: 19 July 2007 / Revised: 9 November 2007 / Accepted: 16 November 2007 / Published online: 8 February 2008

Abstract In continuation of our studies of altitudinal effects on secondary metabolite profile of flowering heads from taxa of the Asteraceae, we investigated phenolic contents and radical scavenging potential from cultivated plants of *Arnica montana* cv. ARBO during the growing seasons 2003, 2004, and 2005. By conducting experiments on potted plants, we excluded that differences in phenolic contents from plants grown at different altitudes were related primarily to differences in soil composition at these sites. To assess altitudinal and interseasonal variation, plants of *A. montana* cultivar ARBO were grown in nine experimental plots at altitudes between 590 and 2,230 m at Mount Patscherkofel near Innsbruck, Austria. In all growing seasons and regardless of the soil the plants were grown in, the proportion of flavonoids with vicinal-free hydroxy groups in ring B to flavonoids lacking this feature, and the total amount of caffeic acid derivatives, significantly increased with elevation. These increases of antioxidant phenolics corresponded to an increase of the radical scavenging potential of extracts from plants grown at different altitudes. The results are discussed in regard to previous studies that suggest that enhanced UV-B radiation and decreased temperatures trigger augmented biosynthesis of UV-absorbing and antioxidant phenolics in higher plants.

Introduction

Previous studies on altitudinal variation of phenolic compounds in different wild and cultivated taxa from the Asteraceae suggested that factors related to altitude of the growing site are causing significant shifts in the quantity of secondary metabolites in flowering heads (Zidorn and Stuppner 2001; Zidorn et al. 2005; Spitaler et al. 2006). Such effects were first observed in wild Asteraceae populations that grow in natural habitats, e.g., in populations from *Leontodon helveticus* Mérat emend. Widder growing in the Eastern Alps (Zidorn and Stuppner 2001). Subsequent studies confirmed that altitudinal effects also occur in populations from neophytic taxa in newly acquired distribution areas (Zidorn et al. 2005). Genetic differences as the only source of altitudinal variation were ruled out by cultivation experiments with *Arnica montana* L. cv. ARBO (Spitaler et al. 2006) in the Tyrolean Alps.

A multitude of environmental factors change with altitude of the growing site. These include precipitation, mean temperature, soil, wind speed, low and high temperature extremes, duration of snow cover, length of vegetation period, and intensity of radiation under clear sky conditions. Enhanced UV-B radiation and lower temperatures at high altitudes have been intensely discussed as having an impact on plant secondary metabolism (Körner 1999; Bilger et al. 2007). The increase of irradiance, especially UV-B radiation, is well documented for the Alps and the Innsbruck area, in particular (Blumthaler et al. 1997). Irradiance under clear sky conditions increases by 8% for total irradiance, 9% for UV-A radiation, and 18% for

erythemal effective radiation (mainly UV-B) per 1,000 m of altitude.

As a protective response against damage from excessive UV-B radiation, plants enhance the biosynthesis of UV-B-absorbing and antioxidant phenolic compounds (Markham et al. 1998b; Körner 1999). The induction of enzymes involved in flavonoid biosynthesis with experimentally supplemented UV radiation is well known (Wellmann 1975; Jaakola and Määttä-Riihinen 2004). The role of phenolics in protecting plants from peak UV-B exposure is not limited to UV-B screening (Markham et al. 1998b), and observed changes in ratios among different types of flavonoids (*ortho*-dihydroxylated vs others) indicate that the enhanced radical scavenging potentials of *ortho*-dihydroxylated flavonoids like luteolin and quercetin are also contributing to UV-B protective activity (Markham et al. 1998a; Spitaler et al. 2006).

Field experiments to assess the actual impact of the altitude of the growing site on plant secondary metabolism have been performed only for a limited number of species. The present study aimed to clarify three questions. These questions are based on an *Arnica* field trial (Spitaler et al. 2006): (1) Do (random) natural climate fluctuations cause the observed variation; (2) are altitudinal variations due to differences in soil characteristics; and (3) do differences in profiles of phenolics correlate with antioxidant capacity?

Methods and Materials

Plant Material Plantlets from *A. montana* cultivar ARBO were purchased from Saatzucht Steinach GmbH (Steinach/Germany) in May 2002 and planted at Mount Patscherkofel as described previously (Spitaler et al. 2006). Experimental plots were located at the following altitudes above mean sea level: site 1, 590 m; site 2, 870 m; site 3, 1,020 m; site 4, 1,260 m; site 5, 1,430 m; site 6, 1,620 m; site 7, 1,890 m; site 8, 1,960 m; site 9, 2,230 m. In 2004, a second batch of plantlets was planted in black plastic pots (23.5 cm diameter; depth 18.5 cm) filled with a mixture (1/1, *v*/*v*) of peat and sand. These pots were transferred to the experimental sites during the summer of 2004 and dug into the surrounding soil. To exclude ontogenetic differences, only flowering heads with at least two rows of flowering ray florets were collected (Douglas et al. 2004). Terminal flowering heads of each stem were collected separately from lateral capitula. Only terminal flowering heads were analyzed (Spitaler et al. 2006). Flowering heads were collected in batches of 12, air-dried, and afterwards kept at −20°C until analysis. For each site and harvest year, three batches of flowering heads were collected and analyzed separately. Flowering heads were pooled in batches of 12 to minimize the effects of chance factors due to variations among individual plants, without the necessity of an unreasonably high number of high-performance liquid chromatography (HPLC) analyses. Three batches per altitude and season (and soil treatment) were analyzed to gain some idea about variation among the populations during each season at each altitude.

Plants for phytochemical analyses were collected on the following dates (numbers in brackets refer to the nine experimental sites from 1, lowest altitude, to 9, highest altitude): 2003 growing season: see Spitaler et al. (2006); 2004 growing season: 07.06. (1); 17.06. (2, 3); 30.06. (4, 5, 6); 08.07. (6, 7); 21.07. (4, 6, 7); and 04.08. (7, 8); 2005 growing season natural soil: 31.05. (1); 06.06. (2); 10.06. (1); 22.06. (4, 5, 6); 30.06. (4, 5, 6, 7); 09.07. (7, 8); 14.07, (7, 8); 21.07. (8); 04.08. (9); and 12.08. (9); and 2005 growing season potted plants: 30.05. (2); 31.05. (1); 10.06. (3); 17.06. (2, 3): 22.06. (3, 4, 5, 6); 30.06. (4, 5); 09.07. (7, 8); 14.07. (8); 21.07. (7, 8); 28.07. (9); 04.08. (7, 9); and 12.08. (9).

Extract Preparation Each batch of 12 air-dried flowering heads was ground, and phenolics were analyzed by HPLC/DAD as described previously (Spitaler et al. 2006). In detail, after adding 2.50 mg of the internal standard compound cynarin as a stock solution in MeOH, $(CH_3)_2CO$, and H_2O (3/1/1, *v*/*v*/*v*), ground flowering heads (500.0 mg) were sonicated twice for 30 min with a mixture of MeOH, $(CH_3)_2CO$, and H_2O (3/1/1, *v*/*v*/*v*), and once for 30 min with a mixture of MeOH and H_2O (1/1, *v*/*v*; total extraction volume 25 ml for each cycle). Extracts were filtered, the remaining plant material rinsed with 20 ml of a mixture of MeOH, $(CH_3)_2CO$, and H_2O (3/1/1, *v*/*v*/*v*), and the combined extracts were filled up to 100.0 ml with a mixture of MeOH, $(CH_3)_2CO$, and H_2O (3/1/1, *v*/*v*/*v*); 10.0 ml of this solution was brought to dryness *in vacuo* and redissolved in 2.00 ml of a mixture of MeOH, $(CH_3)_2CO$, and H_2O (3/1/1, *v*/*v*/*v*). After filtration, this solution was used for HPLC analysis. Comparative investigations that used different extraction media and longer times of sonication and a larger number of sonication cycles proved that the chosen procedure led to an exhaustive extraction. All quantitative analyses were run in triplicate. The extraction procedure for the 1,1-diphenyl-2-picrylhydrazyl (DPPH) assays was identical to the one described above, with the exception that no cynarin (a potent radical scavenger itself) was added before the first step of extraction.

HPLC Analyses HPLC analyses of phenolics were performed as described previously (Spitaler et al. 2006). In detail, HP-1090 and HP-1100 ChemStations equipped with DAD detectors were employed, and the following parameters were applied: column, Phenomenex Synergi Hydro-

Rp 80A 150×4.6 mm (4 μm material); guard column, Phenomenex Security Guard C18 (ODS, Octadecyl) 4.0 mm×3.0 mm; mobile phase A, H_2O/HCOOH/CH_3COOH (99/0.9/0.1, *v*/*v*/*v*); phase B, MeCN/MeOH/HCOOH/CH_3COOH (89/10/0.9/0.1, *v*/*v*/*v*/*v*); flow rate, 1.00 ml/min; injection volume 10 μl; detection wavelength 350 nm; oven temperature, ambient; linear gradient, 0 min 5% B, 5 min 15% B, 20 min 16% B, 35 min 18% B, 45 min 19% B, 55 min 27.5% B, 60 min 65% B, 65 min 98% B, 70 min stop; post time, 12 min. The amounts of phenolics were estimated by comparing the peak areas obtained for the particular flavonoids **F1**–**F6** and caffeic acid derivatives **P1**–**P9** with the peak area obtained for the internal standard cynarin (**CYN**).

Compound Identification Phenolics were grouped into flavonoids (**F**) and caffeic acid derivatives (phenolic acids, **P**) based on their characteristic UV spectra (**F**: a broad maximum at 350 nm, **P**: a maximum at 330 nm with a shoulder at 295 nm). Peaks assignable to flavonoids (**F1**–**F6**) and phenolic acids (**P1**–**P9**) were numbered consecutively with increasing HPLC retention times. Peak characterization and compound identification was performed as previously described (Spitaler et al. 2006). Peak identities are assigned in Table 1.

DPPH Assays DPPH assays were performed in 96-well-plates by using a Hidex Chameleon plate reader in the absorption mode at 515 nm. DPPH was purchased from Sigma-Aldrich, Steinheim, Germany. Ascorbic acid, which was used as a reference compound, was purchased from Merck, Darmstadt, Germany. The final concentration of DPPH in the test mixture was set to 40.0 mg/l. *Arnica* extracts were tested in final concentrations of 1.00, 0.50, 0.25, 0.125, and 0.0625 mg/ml. The reference compound ascorbic acid (Merck, Darmstadt, Germany) was measured in final concentrations of 20.0, 10.0, 6.00, 2.00, and 1.00 μg/ml. Each concentration was applied six times on one plate, and for each extracts, three plates were prepared. After the solutions were mixed, plates were shaken slightly and kept in the dark for 30 min. Then, plates were measured three times at 515 nm.

IC_{50} values for each replicate of the extracts and ascorbic acid solutions were calculated by using the following formula: $IC_{50}=[(50-LP)/(HP-LP)\times(HC-LC)]+LC$. LP = low percentage, i.e., highest percent inhibition less than 50%; HP = high percentage, i.e., lowest percent inhibition greater than 50%; HC = high concentration, i.e., concentration of test substance (or extract) at the high percentage, LC = low concentration, i.e., concentration of test substance (or extract) at the low percentage. To get standardized results

[a] These sites yielded in the harvest year at hand only one charge of flowering heads for analysis and therefore SDs between charges could not be calculated.
[b] Due to adverse weather conditions, this site yielded no flowering heads in the 2004 growing season.
[c] Plants of site 3 in the natural soil had all died until 2005.

for the radical scavenging activity of the extracts, which can be compared to results from other studies, inhibitory concentrations were expressed as ascorbic acid equivalents per gram dried plant material by using the following formula: AAE (mg/g)=1,000×IC_{50AA}/IC_{50AMO}. AAE: ascorbic acid equivalents, IC_{50AA}: 50% inhibitory concentration of ascorbic acid (AA), $IC50_{AMO}$: 50% inhibitory concentration of *A. montana* (AMO) flowering heads.

Data Analysis Pearson correlation coefficients and linear regression equations were calculated by using the MINITAB 13.31 software package (State College, PA, USA).

Results

Variation of Phenolics in Relation to Altitude Analogous to a previous investigation, six flavonoids **F1-F6** and nine phenolic acids **P1-P9** were quantified by HPLC: quercetin 3-*O*-β-D-glucoside **F1**, patuletin 3-*O*-β-D-glucoside **F2**, kaempferol 3-*O*-β-D-glucoside **F3**, kaempferol 3-*O*-β-D-glucuronide **F4**, 6-methoxykaempferol 3-*O*-β-D-glucoside **F5**, hispidulin **F6**, chlorogenic acid **P1**, 3,5-dicaffeoylquinic acid **P4**, 1-methoxyoxaloyl-3,5-dicaffeoylquinic acid **P5**, 4,5-dicaffeoylquinic acid **P6**, and unknown hydroxycinnamate esters **P2**, **P3**, **P7**, **P8**, and **P9** (Spitaler et al. 2006 and Table 1). In Table 1, Pearson correlation coefficients for individual compounds and for the sums of compound groups (flavonoids and caffeic acid derivatives, and the ratio of *ortho*-dihydroxy vs other flavonoids) are summarized.

Quantification data for the total flavonoid contents are summarized in Table 2. Total flavonoid content showed no significant positive correlation with altitude of the growing site in any growing season (Table 1). Neither did most of the individual compounds show statistically significant correlation with altitude. In contrast, the ratio of flavonoids with a 3′,4′-dihydroxylation pattern in ring B to flavonoids lacking this feature [(**F1**+**F2**)/(**F3**+**F4**+**F5**+**F6**)] showed highly significant increases with altitude (ranging from r=0.484, P=0.017 to r=0.738, P<0.001). This correlation was stable over all growing seasons, including potted plants and plants grown in the natural soil. When all results for the quotient of *Q*/*K* from all growing seasons and soil treatments were combined (which might be a bit problematic from a purely statistical point of view), the Pearson correlation coefficient was r=0.528 (P< 0.001; Fig. 1).

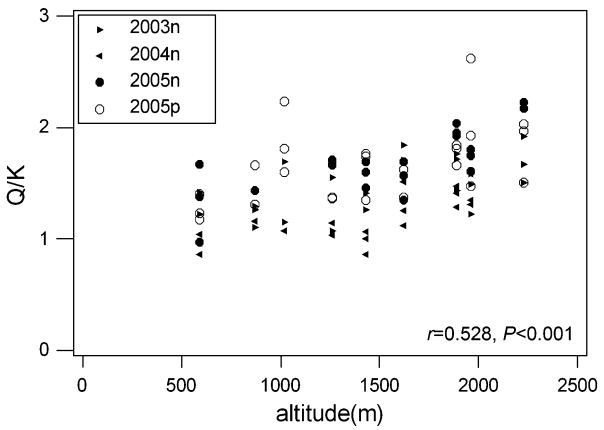

Fig. 1 Correlation of the altitude of the growing site and the quotient of *ortho*-dihydroxy-substituted flavonoids to other flavonoids {*Q*/*K*= [(F1+F2)/(F3+F4+F5+F6)]} in flowering heads of *A. montana* harvested in different years. Each symbol represents one analyzed batch. Plants grown in natural soil (n) and potted plants (p), respectively. Correlation coefficients and corresponding *P* values for each season are displayed in Table 1

Quantification of total caffeic acid derivatives (Table 3) revealed that they were positively correlated with altitude of the growing site in all investigated seasons, although the coefficients and their corresponding P values varied between $r=0.381$, $P=0.107$, and $r=0.696$, $P<0.001$ (Table 1).

The correlation of the quotient of the total caffeic acid derivatives to total flavonoids ($\sum_{P1-P9}/\sum_{F1-F6}$)positively correlated with altitude ($r=0.351$, $P=0.001$ for all investigated samples). However, it is hard to judge whether this result implies a significant shift in biosynthetic pathways or whether it is merely a mathematical artefact resulting from the fact that one variable (caffeic acid derivative contents) varies with altitude, whereas the second (total flavonoid contents) does not.

Variation of Antioxidant Activity in Relation to Altitude The radical scavenging activity of extracts obtained from flowering heads harvested at different altitudes was assessed for samples harvested in 2004 and 2005, but not for the 2003 harvest because the DPPH assaying system for crude plant extracts had not yet been established in our lab when the HPLC analyses of the 2003 samples were performed.

Results of the DPPH assays expressed as ascorbic acid equivalents (in mg) per gram dried plant material are summarized in Table 4. The corresponding Pearson correlation coefficients of altitude of the growing site and the DPPH radical scavenging potential were $r=0.606$ ($P=0.006$) for 2004, $r=0.395$ ($P=0.069$) for 2005 for plants in natural soil (n) and $r=0.752$ ($P<0.001$) for 2005 for potted plants (p). These coefficients were calculated from the mean values obtained for each batch, not from mean values for each site. The latter procedure would have resulted in even higher correlation coefficients [$r=0.787$, $P=0.020$ (2004), $r=0.491$, $P=0.217$ (2005n), $r=0.928$, $P<0.001$ (2005p)], although due to smaller sample sizes, there are also higher P-values.

Table 4 Overview of the radical scavenging activity (given as equivalents of ascorbic acid in mg per g dry plant material) of extracts from flowering heads of *A. montana* cv. ARBO grown in different altitudes and harvested in different growing seasons.[a,b]

[a] These sites yielded in the harvest year at hand only one charge of flowering heads for analysis and therefore SDs between charges could not be calculated.
[b] Due to adverse weather conditions, this site yielded no flowering heads in the 2004 growing season.
[c] Plants of site 3 in the natural soil had all died until 2005.

Discussion

The data confirm that climatic factors related to altitude of the growing site have profound and reproducible effects on the quantitative composition of profiles of certain secondary metabolites in flowering heads of genetically homogenous plants of *A. montana*. The results also confirm that changes in the quantity of phenolic compounds in flowering heads have an impact on the radical scavenging activity of extracts derived from these heads. Moreover, we demonstrated that altitudinal effects on the quantity and relative composition of phenolics are not caused primarily by changes in soil composition at the growing sites.

The most pronounced effect and the one least varying within the years of observation was the ratio of 3′,4′-dihydroxylated flavonoids to flavonoids without that substitution pattern (quercetin vs kaempferol derivatives). The data revealed that the DPPH radical scavenging potential of flowering heads from plants grown at higher altitudes was significantly higher than that of lowland plants. This result was not surprising as caffeic acid derivatives, whose amounts were also positively correlated with altitude, are potent radical scavengers (Rice-Evans et al. 1996). However, the result is nonetheless noteworthy as other compounds, which are present in plant extracts but which are not detected by the employed HPLC system (such as ascorbic acid), are also contributing to the overall antioxidant potential of the extracts. Moreover, the positive correlation of the ratio of quercetin derivatives to kaempferol derivatives to the altitude of the growing site is also a factor that contributes to the enhanced radical scavenging activity of flowering heads from higher altitudes because quercetin derivatives are three to four times more potent scavengers than kaempferol derivatives (Rice-Evans et al. 1996).

The results provide further proof for the assumption that factors related to altitude indeed have an effect on plant secondary metabolism. However, the data are not conclusive as to which factors are decisive in causing these changes. In addition to the enhanced UV-B radiation at higher altitudes, which was assumed to be the main factor responsible for these differences in previous studies (Spitaler et al. 2006; Alonso-Amelot et al. 2007), the decreased temperature at higher altitudes might play a more important role than previously assumed. Bilger et al. (2007) demonstrated that decreased temperatures during the growth period trigger increased biosynthesis rates of phenolics in a variety of plant species even in the absence of UV-B radiation. Phenolic compounds play a vital role in the hydrogen peroxide scavenging system of plants, which besides phenolics comprises peroxidase, ascorbic acid, and glutathione (Takahama and Oniki 1997). This system functions less efficiently at low temperatures, and more phenolics have to be produced to prevent damage to plants grown at lower temperatures (Bilger et al. 2007). Even if the later harvest dates of the plants grown at higher altitudes are taken into account, the mean temperature during the growing and flowering phase of the high altitude plants was significantly lower than that of the lowland plants. Thus, it may be assumed that not only the increase of UV-B at higher altitude sites but also the lower temperatures at these sites are contributing to the observed altitudinal variations of phenolics.

As reported previously (Spitaler et al. 2006), factors other than temperature and UV-B radiation, which usually change with altitude in mountain ranges of Central Europe and which also might have an impact on plant secondary metabolism, are nearly unaffected by altitude in the Tyrolean Central Alps due to their continental climate. These other factors are, therefore, to be excluded as potential factors that contribute to the altitudinal variation observed in the secondary metabolite profiles of *A. montana* cv. ARBO in the Tyrolean Alps.

Salivary Amylase Induction by Tannin-Enriched Diets as a Possible Countermeasure Against Tannins

G. da Costa · E. Lamy · F. Capela e Silva · J. Andersen · E. Sales Baptista · A. V. Coelho

Received: 24 July 2007/ Revised: 26 November 2007/ Accepted: 28 November 2007 / /Published online: 6 February 2008

Abstract Tannins are characterized by protein-binding affinity. They have astringent/bitter properties that act as deterrents, affecting diet selection. Two groups of salivary proteins, proline-rich proteins and histatins, are effective precipitators of tannin, decreasing levels of available tannins. The possibility of other salivary proteins having a co-adjuvant role on host defense mechanisms against tannins is unknown. In this work, we characterized and compared the protein profile of mice whole saliva from animals fed on three experimental diets: tannin-free diet, diet with the incorporation of 5% hydrolyzable tannins (tannic acid), or diet with 5% condensed tannins (*quebracho).* Protein analysis was performed by one-dimensional gel electrophoresis combined with Matrix-Assisted Laser Desorption Ionization-Time of Flight mass spectrometry to allow the dynamic study of interactions between diet and saliva. Since abundant salivary proteins obscure the purification and identification of medium and low expressed salivary proteins, we used centrifugation to obtain saliva samples free from proteins that precipitate after tannin binding. Data from Peptide Mass Fingerprinting allowed us to identify ten different proteins, some of them showing more than one isoform. Tannin-enriched diets were observed to change the salivary protein profile. One isoform of α-amylase was overexpressed with both types of tannins. Aldehyde reductase was only identified in saliva of the quebracho group. Additionally, a hypertrophy of parotid salivary gland acini was observed by histology, along with a decrease in body mass in the first 4 days of the experimental period.

Keywords Salivary proteins · Amylase · SDS-PAGE · Mass spectrometry · Defense mechanisms against tannins · Taste

Introduction

Tannins are plant secondary metabolites (PSMs) with an enormous structural diversity and are found worldwide in many families of higher plants. One of the characteristic properties of these natural high-molecular-mass polyphenols is their high capacity to bind proteins, forming

complexes that tend to precipitate (Haslam 1998). In the mouth, the precipitates are perceived via mechanoreceptors as rough, puckering, or drying oral sensations characteristic of astringency (Breslin et al. 1993; Prinz and Lucas 2000). The astringent properties, together with the frequently associated bitter taste (Lesschaeve and Noble 2005), may result in the avoidance of some plants or plant parts by herbivores. Taste perception is generally considered to be an adaptive response in assessing nutritional value and/or coping with toxicity in potential foods (Le Magnen 1986). Animals with a relatively high occurrence of bitter and potentially toxic compounds in their diet (e.g., browsing herbivores) are believed to have developed a high bitter-taste threshold and tolerance (Glendinning 1994). The cause for this tolerance can be rooted in physiological postingestive adaptative mechanisms, namely, modifications of saliva composition or flow rate, which can contribute to mitigate the negative biological effects of PSMs.

Saliva contains a complex mixture of proteins with different biological roles in digestion, host defense, and lubrication (Humphrey and Williamson 2001). Its composition is diverse among animal species and changes with circadian rhythm (Hardt et al. 2005a) and diet (Katsukawa and Ninomiya 1999; Neyraud et al. 2006), among other factors. As the secretion of salivary fluid and proteins is controlled by autonomic nerves (Proctor and Carpenter 2007), saliva plasticity represents a rapid mechanism that allows animals to adapt to random dietary changes, thus conferring an important advantage. Rats and mice that consumed tannin-rich diets showed both parotid gland hypertrophy and increased synthesis and accumulation of salivary proline-rich proteins (PRPs; Mehansho et al. 1983, 1985, 1987; Jansman et al. 1994). These molecular and cellular effects produced by high-tannin diets, both on the salivary gland tissue and on the saliva of mice and rats, are indistinguishable from those produced by recurrent stimulation with the beta-adrenergic agonist isoproterenol (Ann et al. 1987, 1997). Recently, Gho et al. (2007) observed the induction of a group of salivary polypeptides (designated by isoproterenol-induced polypeptides) both by tannins and isoproterenol. Mice salivary PRP induction was suggested as acting as a countermeasure against tannins through the formation of tannin–protein complexes that remain insoluble in the conditions found in the digestive compartments (Hagerman et al. 1998; Lu and Bennick 1998). Apart from these protein species, little is known about possible changes in other salivary proteins that are induced by tannins, namely proteins that do not form insoluble complexes with these PSMs. Besides PRPs, isoproterenol also induces changes in the expression levels of salivary proteins, such as cystatins (Shaw and Yu 2000) and amylase (Gallacher and Petersen 1983), among others. Therefore, the possibility of changes in relative amounts of other proteins cannot be excluded. The characterization of such modifications may be useful for better understanding mammalian physiological countermeasures. Rodents have been traditionally used as an animal model for studies of the anatomy of the salivary glands and physiology, and several proteins have been reported as constituents of their saliva: PRPs (Lin and Ann 1991), namely the parotid salivary protein, (Madsen and Hjorth 1985) and amylase (Hagenbüchle et al. 1980). However, to our knowledge, a systematic characterization of rodent saliva proteome has not been reported. The most complete rodent salivary protein profile reported to date is a two-dimensional map of rat parotid saliva, in which the identification of detected proteins was inferred from determined molecular masses in the gel (Williams et al. 1999).

Peptide mass fingerprinting (PMF) that uses matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectra is a current strategy for the identification of proteins expressed in certain physiological conditions, allowing comparisons of different treatments. Here, our first objective was to identify salivary proteins from mice whole saliva by using MALDI-TOF mass spectrometry after separation by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and subsequently to evaluate if ingestion of tannins induced changes in the expression of these proteins. We tested the influence of hydrolyzable (tannic acid) and condensed (*quebracho*) tannins on saliva samples from which insoluble tannin–protein complexes had been removed before the analysis, to better assess proteins expressed in lower concentrations. Light microscopy was also used to study morphological changes in parotid glands.

Methods and Materials

Animals Thirty-one inbred male Balb/c mice, 4-week-old, were obtained from the licensed bioterium of Instituto Gulbenkian de Ciência (Oeiras, Portugal). The animals were housed in mice cages, type IV (Techniplast; (10 to 11 mice per cage), according to European Union (EU) recommendations and revision of Appendix A of European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (ETS No. 123) and maintained on a 12:12 h, light/dark cycle at a constant temperature of 22°C with ad libitum access to water and to a standard diet with 21.86% crude protein (dry basis) in the form of pellets (RM3A-P; Dietex International, UK). Animals were individually marked and submitted to a 7-day acclimation period to minimize stress associated with transportation. This period was followed by a 7-day pretrial period to allow adaptation to the ground diet used during the feeding trials. The standard pellet diet was ground daily

with a blender to obtain a meal with visibly homogeneous fine-sized particles. Before the feeding-trial period, animals were individually weighed and allocated to three experimental groups, each group having no significant differences in body mass (24.5±3 g).

All procedures involving the animals were approved by the scientific committee, supervised by a Federation of European Laboratory Animal Science Associations (FELASA)-trained scientist and conforming to the regulations of the Portuguese law (*Portaria 1005/92*), following European Union Laboratory Animal Experimentation Regulations.

Feeding Trials Immediately after the pretrial period, we started the 10-day experimental period, the first day of which we consider day 1. The control group (n=10) received a tannin-free diet, the same standard ground diet as in the pretrial period. The tannic acid group (TA; n=10) and the quebracho group (Q; n=11) received the standard ground diet plus tannic acid (Merck Ref 1.00773.100; hydrolyzable tannin) or quebracho extract (Tupafin-Ato, SilvaChimica SRL; 72%±1.5 of condensed tannins), respectively, added to obtain a mixture with 5 g tannin/100 g wet weight of the standard diet. Food and water were provided ad libitum, and the diets were prepared daily with a blender, as described for the pretrial period. Body mass changes during the first 8 days were determined daily.

Saliva and Salivary Gland Collection and Sample Preparation On day 11, individual mice whole saliva was collected. The mice remained in the cages, with food and water available, until the time of collection. Saliva production was induced with an intraperitoneal injection of pilocarpine (Sigma; 5 mg kg^{-1} body weight), dissolved in 1 ml 9% (*m*/*v*) sodium chloride, and prepared immediately before use, as described by Muenzer et al. (1979). Saliva was individually collected by aspiration from all the mice, directly from their mouths with a micropipette. Saliva samples were frozen immediately in liquid nitrogen and stored at −80°C until required. Before protein quantification, samples were centrifuged at 16,000×*g* for 5 min at 4°C to remove particulate matter and salivary proteins that could be precipitated. Only the soluble fraction was used for further analyses. All animals were injected intraperitoneally with anesthetic (xylazine hydrochloride combined with ketamine hydrochloride) and euthanized with an overdose. Both parotid salivary glands were dissected, washed briefly with phosphate buffer 0.1 M, pH 7.4, and fixed in 10% neutral buffered formalin, to carry out further routine histological procedures.

Protein Quantification and Gel Electrophoresis Total protein concentration was determined by the bicinchoninic acid (BCA) protein assay method (Pierce) by using a microplate reader (SpectroMAX 340, Molecular Devices, Union City, CA, USA). One-dimension SDS-PAGE was run with 20 μg of saliva total protein after reduction with dithiothreitol (USB) and alkylation with iodoacetamide (Sigma). Denatured protein samples were loaded on bis-tris polyacrilamide 4–12% gradient precast gels (100×100×1 mm; Nupage Invitrogen) with MES SDS (Nupage Invitrogen) used as a running buffer. Molecular mass markers (BioRad, Ref 161-0317) were run simultaneously with the samples in each gel to calibrate molecular masses of the protein sample bands. Protein bands were stained with colloidal Coomassie blue (Neuhoff et al. 1988) and with Comassie blue R-250 following Beeley et al (1991). Digital images of the gels were acquired with a densitometer with internal calibration (Molecular Dynamics, Amersham Biosciences Europe GmbH, Freiburg, Germany), and gels were subjected to linescan analysis by using Imagequant Software 5.0 (Amersham Biosciences Europe GmbH, Freiburg, Germany). Sensitivity 9.0 and kernel 4.0 were the software parameters used to assign the detected significant bands in the protein profiles obtained. Only bands present in at least 50% of individuals were considered.

Protein Identification Protein bands were excised from all gels and the polypeptides subjected to digestion with a sequence grade modified trypsin (Promega) according to Pandey et al. (2000). Sample peptides were assayed for peptide mass fingerprinting in a Voyager-DE STR (Applied Biosystems, Foster City, CA, USA) MALDI-TOF mass spectrometer. Peptide co-crystallization was achieved by applying 0.5 μl of the peptide digest on the MALDI plate and adding an equal volume of recrystallized matrix α-cyano-4-hydroxycinnamic acid 10 mg/ml prepared in acetonitrile 70% (*v*/*v*) with 0,1% trifluoroacetic acid (*v*/*v*). The mixture was allowed to air dry (dried droplet method). Average spectra were obtained in the mass range between 800 and 4,000 Da, using three spectra acquired with 500 laser shots in the positive-ion reflectron mode. Spectra were processed and analyzed by the Data Explorer (version 4.0, Applied Biosystems, Foster City, CA, USA). Monoisotopic peptide masses were used to search for protein identification with Mascot software (Matrix Science, UK; Perkins et al. 1999). Searches were performed in the National Center for Biotechnology Information nonredundant protein-sequence database. A minimum mass accuracy of 100 ppm, one missed cleavage in peptide masses, and carbamidomethylation of Cys and oxidation of Met as fixed and variable amino acid modifications, respectively, were considered. Criteria used to accept the identification were significant homology scores achieved in Mascot, significant sequence-coverage values, and similarity between the protein molecular mass calculated from the gel and for the identified protein (Roxo-Rosa et al. 2006).

Table 1 Mean body masses in grams of mice fed with different diets through the first 8 days of the experiment (mean±SD)

Same lowercase letters indicate no differences among the values of the columns in the same line (Tukey–Hsu test; $P<0.05$). Same uppercase letters indicate no differences among the values of the lines in the same column (Tukey–Hsu test; $P<0.05$).

Histology To confirm that the doses of tannins used were enough to induce significant changes in glandular morphology, salivary glands were observed through light microscopy with a Nikon Eclipse 600 microscope (Kanagawa, Japan). After embedding the fixed parotid glands in paraffin wax, using routine procedures, a series of sections of 5 mm thick were cut with a microtome, and the slides were stained with hematoxylin and eosin. Three animals from each group were used, and for each animal, ten pictures from random parotid areas were collected with a Nikon DN100 camera (Kanagawa, Japan) at ×200 magnification. For each animal, the area and perimeter of 150 parotid acini were randomly chosen and measured by using SigmaScan Pro5.0 software (SPSS, Chicago, IL, USA).

Statistical Analysis Body mass data were tested for normality and homocedasticity by Kolmogorov–Smirnov and Levene tests, respectively. Body mass was analyzed according to a general linear model procedure with two fixed factors and one nested factor:

$$Y_{ijkl} = \mu + T_i + W_k + T(A)_{i(j)} + T \times W_k + \varepsilon_{ijkl}$$

where Y_{ijkl} are the observed values for body mass, μ is the observed mean value, T_i is the fixed effect of treatment, W_k is the fixed effect of weighing day, $T(A)_{i(j)}$ is the nested effect, and ε_{ijkl} is the random error or residual effect.

Means significantly different were submitted to post hoc comparisons of means (Tukey–Hsu test) and regarded as significantly different when $P<0.05$.

All statistical analysis procedures were performed by NCSS 2001 software package (Kaysville, UT, USA).

Results

Body Mass Animals were weighed daily to search for changes in body masses that reflect physiological adaptation of the animals to tannin diets, including the induction of PRPs (Mehansho et al. 1983; Skopec et al. 2004). We observed that tannic acid and quebracho groups lost weight during the first 3–4 days, respectively, after which they recovered, whereas the control group increased in body mass in the first 2 days and remained nearly stable after that. Statistically significant differences were observed on days 3 and 4, with the animals from the tannin groups presenting lower mean body masses than animals from control group (Table 1). Despite the increases in body masses after day 4, for animals from either tannic acid or quebracho groups, that increase was less pronounced in the tannic acid group, with animals remaining with lower body masses until the end of the trial.

Histology A dramatic increase in the acinar area and the perimeter of the parotid salivary gland was observed in the animals that received tannin-enriched diets over a period of 10 days (Fig. 1). Levels of 5 g of hydrolyzable or condensed tannin per 100 g wet weight in the diet seem to produce a hypertrophy of the secretor tissue (Table 2).

Saliva Protein Concentration Total protein saliva concentration, after the 10 days of the feeding trial, was significantly higher in the control group than in the quebracho and in tannic acid groups (Table 3).

Saliva Protein Profile We characterized the saliva profile of the control group by using the Imagequant 5.0 software to assign significative bands in the profiles obtained. These results are in agreement with visual observation of the gel pattern. Despite slight interindividual variations in whole saliva composition, 21 protein bands (from a to u) were present consistently in all animal saliva protein profiles ($n=10$). Fig. 2a shows a typical 1-DE pattern of the control group saliva and also an overlay of the ten linescans resulting from the analysis of the control group saliva protein profiles. The molecular masses of the proteins were calculated by gel analysis software, after superimposing the linescan of the molecular mass markers on each sample linescan.

With regard to the control group, interindividual protein profile variability was assessed for the TA ($n=10$) and

Q (n=11) groups. Only slight variation was found among the animals on the tannin-fed diets. By comparing the saliva protein profile of the control group with the TA group, we identified one additional band (band β, Fig. 2b) around molecular mass 51 kDa that was not visible in the control saliva protein profile. The saliva protein profile of the Q group, when compared with the control saliva protein profile, presented two additional bands (Fig. 2c). There was an intense protein band presented in the saliva protein profile of the TA group around 51 kDa (band β), and an additional band (band γ) of reduced intensity and molecular mass around 20 kDa.

Protein Identification Identification of all protein bands excised from the control group can be seen in Table 4. The only band whose identification was not possible was band *p*, probably due to the presence of a low amount of protein. From the 21 protein bands excised, we identified ten different polypeptides. The other ten bands were assigned to four of the already identified polypeptides: four additional bands to salivary amylase 1, one to carbonic anhydrase VI, four to parotid secretory protein (PSP), and one to androgen-binding protein. This was attributed to the existence of post-translational modifications and/or protein fragments. Band *u* was assigned to a mixture of β and γ subunits of the androgen-binding protein.

The two protein bands that were detected additionally in the saliva profile of the animals submitted to a tannin-enriched diet (β and γ) were also used for protein identification following the PMF approach. As seen in Table 4, these two bands were identified as amylase 1 and aldehyde reductase, respectively. Aldehyde reductase was observed only in the Q group.

Discussion

Tannins act as feeding deterrents, due both to their aversive chemosensory properties (such as bitter taste and astringency) and the negative postingestive effects they exert (Glendinning 1994). A reduction in body mass in the first days of tannin administration has been reported previously (Mehansho et al. 1983, 1985; Jansman et al. 1994; Shimada et al. 2004, 2006). In mice and rats, this effect is reversed after 2–3 days, when a hypertrophy of parotid glands occurs, coincident with a dramatic increase in salivary PRPs production (Mehansho et al. 1983). In the present work, tannin-fed mice decreased in body mass in the first days (Table 1). This effect ceased after 3–4 days. Despite the body mass recovery of tannin-fed mice, animals from the tannic acid group remained with lower body masses until the end of the trial, which suggests a greater capacity to adapt to quebracho tannin. The parotid hypertrophy usually associated with tannin consumption was also observed in this experiment. This effect in parotid glands is associated with the expression of a number of isoproterenol-induced salivary proline-rich polypeptides (Lopez-Solis and Kemmerling 2005; Gho et al. 2007), which seems to be related to β1 adrenergic activity (Gonzalez et al 2000). We

thus found those changes relevant, demonstrating that the tannin levels used were enough to induce an effect at glandular level.

This study helps explain changes in whole saliva protein composition that occur when mice consume tannin-enriched diets. Most studies suggest a defense response associated with the induction of salivary proteins (mainly PRPs) that precipitate PSMs, preventing them from exerting negative effects (Bennick 2002). We predicted that tannin consumption would also influence other salivary proteins. To ensure that the minor expressed-salivary proteins would not be masked by overexpression of the tannin-binding proteins, we removed the insoluble fraction that is expected to contain the tannin–protein complexes. We assumed that this was achieved since total protein concentration from the tannin-fed groups was lower compared with the control group. The lack of observation of pink bands in the Coomassie stained gels (according to Beeley et al. 1991) supports the idea that we efficiently removed the majority of PRPs.

Although a great number of salivary protein studies have been performed on mice, a global perspective that relates whole saliva protein profile to protein identification is presently unknown. Williams et al. (1999) provide a 2-DE protein profile, referring to the presence of PRPs, amylase, acidic epididymal glycoprotein, deoxyribonuclease, parotid secretory protein, and common salivary protein, although a protein identification was not performed but rather inferred from the position of protein spots. Our results showed the presence of ten different salivary proteins, some showing more than one isoform. This situation is documented in human saliva (Hirtz et al. 2005b), where a simultaneous low diversity in terms of variety of accessions and a high complexity in terms of number of protein bands identified in the same accession are reported. This degree of redundancy displayed by extensive salivary protein polymorphisms seems to be important in saliva plasticity. Moreover, the presence of several families of structurally and functionally closely related molecules indicates that these proteins have been subjected to evolutionary pressures that may reflect selection for improved function (Oppenheim at al. 2007).

The identified proteins have been described previously in saliva: acidic chitinase, mucin apoprotein, amylase 1, carbonic anhydrase VI, apolipoprotein A-I, parotid secretory protein, immunoglobulin heavy chain, submandibular gland 15 kDa protein, androgen-binding protein, and glandular kallikrein (Table 4). The first seven have multiple functions in saliva and are involved in the formation of enamel pellicle, have hydrolytic activity, and act as a first line of defense against microorganisms (Yao et al. 2003; Huang 2004; Vitorino et al. 2004; Hardt et al. 2005b). The submandibular gland 15 kDa protein is known as a gross cystic disease fluid protein that was initially described in humans as a protein secreted by the T47D human breast cancer cell line. This protein is produced in many exocrine glands such as sweat, salivary and lachrymal; however, its function remains unknown (Myal et al. 1998). Androgen-binding protein

secreted by mice submandibular salivary glands has been hypothesized as having a major role in mate selection. This member of the secretoglobins family is secreted into saliva in two different dimer forms: an α subunit disulfide bridged to either a β or a γ subunit (Karn and Laukaitis 2003). However, cellular site(s) of synthesis, mode of function, and evolution patterns of this biologically important protein are otherwise unknown (Dlouhy et al. 1987). Glandular kallikrein, mainly secreted by submandibular glands, is a peptidase that belongs to the serine proteases family, which brings about maturation of growth factors and polypeptide hormones, by conversion of inactive precursors to biologically active peptides (Kim et al. 1991). Parasympatic stimulation that causes an increase in saliva flow will promote low outputs of this protein without degranulation of acinar or granular tubules cells (Shori and Asking 2001).

The control group electrophoresis gel pattern presents five different bands identified as salivary amylase 1, between masses 48 and 66 kDa—one intense band at a lower molecular mass (band *g*), and four weak or medium intense bands at higher molecular mass values. Different bands may correspond to different isoforms. Glycosylation and deamidation of amylase 1 have been described (Bank et al. 1991; Hirtz et al. 2005a). Glycosylation could be an explanation for the higher molecular mass of the amylase bands observed in the gel, compared to the amylase native form. Knowing that glycosylated asparagine residues almost always occur in the sequence Asn-X Ser/Thr, two potential *N*-glycosylation sites for mice α-amylase are 412–414 and 461–463 (peptide residue numbered taking into account that the 15 amino acid peptide signal is lost during the secretion process). These two sites were also referred for human α-amylase (Bank et al. 1991; Hirtz et al. 2005a). The peptide that contains the first site is detected for all our amylase bands, so a glycosylation should not occur in that position. On the other hand, *N*-glycosylation can occur in the second potential site, since the peptide that contains it systematically fails to be detected in mass spectra. Although some (Bank et al., 1991) have considered that *N*-glycosylation is more prone to occur in the first potential site, Hirtz et al. (2005a) found results similar to ours for human α-amylase. The lack of the specific detection of glycoproteins does not allow the confirmation of this hypothesis since the absence of peptide 458–466 can also be explained based on experimental limitations. Bank et al. (1991) proposed that amylase-deaminated isoforms correspond to the lower molecular-mass bands observed in the saliva SDS-PAGE profile. By using the software Findmod (http://www.expasy.ch/tools/findmod/), it is possible to assign two peaks in the salivary amylase mass spectra of band *g* as deaminated peptides, both in the control group and in the Q and AT groups. These post-translational modifications can occur at one of two residues of peptide 46–76 and at one of three residues of peptide 414–436. These modified peptides were also observed for band β, present only in the animal groups that were submitted to the tannin-enriched diet. The deamination of these residues does not seem to be characteristic of any of the amylase isoforms observed.

Although salivary proteins can bind tannins as a mode of defensive action, other physiological mechanisms, including enzymatic or immune responses, can not be excluded. The only effect common to both types of tannins in the salivary profile of proteins was an increase in amylase. The overexpression of amylase 1 induced in both groups (band *β*, Fig. 2) overlaps the medium molecular mass and less intense band of this protein in the control group (band *f*, Fig. 2). This suggests that only the medium molecular mass isoform of amylase 1 is overexpressed in the tannin-rich diet fed groups or that a new amylase isoform is induced in these groups. Furthermore, protein band *g* (Fig. 2), the most intense band in the control group, identified as amylase 1, did not show any significant expression level change with tannin treatment. Several differences can be observed between the tryptic peptide mass spectra of band *β* and of band *g*. We could not assign these peaks to described modifications of salivary amylase 1, but it suggests that a different isoenzyme of salivary amylase 1 is being expressed in the Q and AT groups.

The increase in salivary α-amylase levels may be a consequence of tannin stimulation of sympathetic pathways. Isoproterenol and tannins lead to similar changes in salivary glands, and it has been suggested that these changes are due to stimulation of the β1 adrenergic receptors (Waters et al. 1998). Beta adrenergic agonists are capable of stimulating salivary α-amylase release (Gallacher and Petersen 1983). There is a recurrent pattern across studies that shows that salivary α-amylase levels increase in response to physical and psychological stress (Chatterton et al. 1996; for a comprehensive review see Granger et al. 2007). As a result, salivary α-amylase has been used as a surrogate marker of the autonomic/sympathetic nervous system component of stress in humans. Other oral stimulators that influence texture and flavor perception have also been observed to increase α-amylase expression. Amylase increased with taste stimulation in rabbits (Gjorstrup, 1980) and humans (Neyraud et al. 2006), and a strong correlation between α-amylase and texture perception was observed by Engelen et al. (2007).

We suggest that, despite the primary biological function of salivary α-amylase being the digestion of polysaccharides, the increase of its expression is not a direct consequence of dietary carbohydrates but a result of adrenergic stimulation. Indirectly, this increase can also represent a co-adjuvant for the inhibition of tannin biological activity. Tannins are potent inhibitors of salivary amylase 1 (Kandra et al. 2004; McDougall et al. 2005), although affinity of α-amylase for tannins is not as high as PRPs affinity (De Freitas and Mateus 2001). Tannins have been described as responsible for an enlarged pancreas (Ahmed et al. 1991; Mahmood and Smithard. 1993), stimulation and secretion of an increased amount of amylase, which, to some extent, may counteract the inhibition of this enzyme during gut digestion. Although α-amylase in saliva and the pancreas are produced by independent sources, we believe that a similar function could be involved, and amylase content may increase when animals are fed with tannins, thus counteracting the inhibition of this enzyme in the mouth.

Salivary amylase is stored in large dense-core secretory granules that undergo stimulated secretion in response to extracellular stimulation. (Gorr et al. 2005). The α-amylase

increase observed in the present study could result from the exocytosis of acinar secretory mature granules, as usually occurs in the first hours after isoproterenol administration (Henriksson 1982). Moreover, chronic stimulation with isoproterenol is reported to decrease (Madsen and Hjorth 1985; Ann et al. 1987) or maintain (Bedi 1993) amylase levels. To the best of our knowledge, this is the first reference of overexpression of salivary amylase 1 after the ingestion of polyphenols and, surprisingly, not all the amylase isoforms changed with tannins but only one. Band ß could be an induction of a newly produced isoform, or could represent an overexpression of one of the previously visible isoforms.

Another detected difference was the expression of protein band γ (n=8) in the quebracho tannin-fed diet group. This protein was identified as aldehyde reductase. Aldehyde reductase belongs to the aldo-keto reductases (AKR) superfamily. They are carbonyl-reducing enzymes, along with the short-chain dehydrogenases/reductases, and are responsible for the reduction of aldehydes, ketones, and quinones to their corresponding hydroxyl derivatives (Hoffmann and Maser 2007). Although salivary levels of enzymes that belong to the human aldo-keto reductase superfamily were found to be high in humans subjected to a continuous intake of coffee, which has a high content of polyphenols (Sladeck 2003), we interpret this result with caution. First, this enzyme, although ubiquitous (present in plants, fungi, insects, fish, bacteria), has been found mainly in the intracellular media and in tissues. In mice, it is found in several tissues, such as the liver (Ahmed et al. 1978), lung (Nakayama et al. 1986), and ovary (Iwata et al. 1990). A search in the University of California at Los Angeles Human Salivary Proteome Project database (http://www.hspp.ucla.edu) found only two salivary proteins from the AKR family 1 in saliva (Aldose reductase-like and *Trans*-1,2-dihydrobenzene-1,2-diol dehydrogenase). Secondly, quebracho used in this study is a plant extract that contains only 72% tannins. The presence of carbonyl-group-bearing substances, such as small phenolics, other PSMs, or even quinones, resulting from oxidation during the extraction process, is not to be overlooked. The presence of aldehyde reductase could be a consequence of chemical species other than tannin.

We conclude that amylase up-regulation is an unspecific adaptation of saliva to dietary tannins that could be a consequence of the stimulation of sympathetic pathways and of amylase inhibition. Indirectly, and through these mechanisms, tannin adverse effects could be reduced, probably due to preferential involvement of one amylase isoform more prone for this activity. Despite the similarities of results obtained for tannic acid and quebracho, we think that further studies with other forms of tannins would help to clarify whether a specific protein defense response exists for the type of tannin.

Comparison of Electrophoretic Protein Profiles from Sheep and Goat Parotid Saliva

Elsa Lamy · Gonçalo da Costa · Fernando Capela e Silva · José Potes · Ana Varela Coelho · Elvira Sales Baptista

Received: 30 October 2007 / Revised: 22 January 2008 / Accepted: 23 January 2008 / Published online: 21 February 2008

Abstract Saliva provides a medium for short-term adaptation to changes in diet composition, namely, the presence of plant secondary metabolites. Salivary proteins have biological functions that have particular influence on oral homeostasis, taste, and digestive function. Some salivary proteins, such as proline-rich proteins, are present in browsers but absent in grazers. Despite the significance of salivary proteins, their expression patterns in many herbivores are unknown. We investigated the sodium dodecyl sulfate-polyacrylamide gel electrophoresis profile of parotid salivary proteins from two domesticated species, one a grazer, the sheep, *Ovis aries*, and the other a mixed feeder, the goat, *Capra hircus*, both fed on the same conventional diet. With 12.5% polyacrylamide linear gels, we observed uniform patterns of salivary proteins within the two species. In the goat profile, 21 major bands were observed, and 19 in the sheep profile. Each band was subjected to peptide mass fingerprinting for purposes of identification, allowing for 16 successful protein identifications. Marked differences were observed between the species in the region of 25–35 kDa molecular weights: one band was present in significantly different intensities; three bands were present only in goats; and one band was present only in sheep. This is the first report of a comparison of the protein salivary composition of sheep and goats and suggests that future research should be conducted to reveal a physiological function for salivary proteins related to the differences in feeding behavior of these species.

Introduction

Salivary function is closely related to oral health and digestion. Humphrey and Williamson (2001) organized the functions of saliva into five major categories: (1) lubrication

and protection, (2) buffering action and clearance, (3) maintenance of tooth integrity, (4) antibacterial activity, and (5) taste and digestion. Saliva modulates taste perception through the transportation of taste substances and the protection of taste receptors, as well as through the chemical interaction of salivary constituents with taste substances. Salivary flow rate and composition are influenced by the quality of taste stimuli (Spielman 1990), drugs and physiological factors (Aps and Martens 2005), and, at the same time, salivary flow rate and composition affect taste perception (Matsuo 2000). Some salivary proteins are involved in feeding behavior, namely von Ebner's gland salivary protein (Kock et al. 1994), salivary cystatins (Katsukawa et al. 2002), and salivary kallikreins (Yamada et al. 2006). Levels of tannin-binding salivary proteins (TBSPs) in animal saliva are associated with tannin levels in the diet (Mehansho et al. 1983, 1987, 1992; Austin et al. 1989; Hagerman and Robbins 1993; Fickel et al. 1998; Makkar and Becker 1998; Clauss et al. 2003a, b). A recent review by Shimada (2006) stresses the importance of gathering basic information on salivary proteins as a way of understanding the relationships between feeding niches and saliva composition.

Sheep and goats are both generalist herbivores. They have similar body sizes and frequently graze together in major farming systems (Bartolome et al. 1998; El Aich and Waterhouse 1999). Although they are competing species that co-exist in the same niche and have access to the same forage items, they often show different feeding behavior, selecting and ingesting diets that overlap to variable degrees (Ngwa et al. 2000; Pande et al. 2002). In the context of the three feeding types proposed by Hofmann (1989), sheep are considered grazers, whereas goats are viewed as intermediate feeders, capable of dealing with large amounts of browse in their diets. There are several possible explanations for these differences in feeding behavior. According to the detoxification limitation hypothesis (Freeland and Janzen 1974, recently reviewed by Marsh et al. 2006), goats could have a greater ability to eliminate plant secondary metabolites (PSMs), when compared to sheep. A second explanation is based on one of the deductive generalizations of Hofmann's morphophysiological hypothesis, which suggests that goats may have large salivary glands that produce large amounts of fluid, which helps to digest browse and provides a medium of defense against PSMs.

To our knowledge, salivary protein expression patterns have not been reported from sheep and goats, and only a limited number have been identified for these two species. Austin et al. (1989) used electrophoretic approaches to search for TBSPs in the whole saliva of sheep, cattle, and deer but did not characterize the entire protein profile in the saliva. The aim of the present study was to gain a better understanding of the parotid saliva protein composition of the domestic sheep, *Ovis aries*, and of the goat, *Capra hircus*. To this end, we used one-dimensional sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) for protein separation and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) for protein identification by peptide mass fingerprinting (PMF).

Methods and Materials

Animals To obtain saliva samples, we used adult females that had been reared in separate sheep and goat flocks and had grazed on Mediterranean rangeland. Collections were made during six different periods, over the course of 1 yr. In each period, five Merino sheep, *O. aries*, and five Serpentina goats, *C. hircus*, were used and kept in the same location in separated crates for 15 d preceding the saliva collection. During this period, all animals were fed with vetch-oat hay, *Vicia sativa*×*Avena sativa*, and had water and food available *ad libitum*. The objective of the pre-trial period was to keep sheep and goats in similar conditions so as to minimize diet effects when comparing them. Before each saliva collection period, polyethylene urinary cat stylet catheters (1.0 or 1.3×130 mm) were introduced into one of the parotid ducts of each animal, which had previously been anaesthetized intravenously with Xylazine/Ketamine (0.1/5.0 mg/kg). To facilitate the positioning of the catheter, an intravenous 14G cannula was previously inserted into the masseter muscle from the inside to the outside. The catheters were then introduced into the parotid papilla, from the exterior to the interior of the mouth (Fickel et al. 1998), by using guide wires. The free end of the catheter, which protruded 1 cm, was fixed to the cheek skin by transfixation knots. To avoid any possible effect of the anesthetics on the saliva composition (Edwards and Titchen 2003; Edwards et al. 2003), sample collection was initiated 1 d after surgery. In the morning and before food distribution, samples were collected during each of the following 3 d. At least 2 ml of parotid saliva were collected from each animal by aspiration with a syringe.

Saliva Collection and Preparation for Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis Each saliva sample was collected into capped polypropylene sample tubes. All samples were frozen immediately in liquid nitrogen and stored at −70°C. Prior to protein quantification, samples were centrifuged at 16,000×*g* for 5 min at 4°C to remove particulate matter. Protein concentration of the parotid saliva was determined by the bicinchoninic acid (BCA) method (Pierce, Rockford, IL, USA), in which bovine serum albumin (BSA) is used as the standard. For

the analysis, 10 μl of either BSA (0–2.0 mg/ml) or saliva were mixed with 200 μl of the BCA reagent and incubated for 30 min at 37°C. Absorbance was measured at 565 nm by using a microtiter plate reader (SpectroMAX 340, Molecular Devices, Union City, CA, USA). Before SDS-PAGE separation, salivary proteins were concentrated with a 5-kDa cut-off ultra-filtration microfuge tube (Millipore, Eschborn, Germany; Ref: UFV5BCC00).

Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis Individual samples of parotid saliva from sheep and goats were run simultaneously in each gel for comparison. Proteins were separated with 12.5% SDS-PAGE (200× 200×1 mm) in a Protean II xi slab gel apparatus (BioRad, CA, USA). Saliva samples with 70 μg of protein were mixed with 4× concentrated SDS sample buffer (0.125 M Tris–HCl pH 6.8, 2% SDS, 5% 2-mercaptoethanol, 20% glycerol with traces of bromophenol blue). The mixture was heated at 90°C for 5 min and immediately cooled on ice until gel application. Electrophoresis was carried out by using a running buffer [0.025 M Tris, 0.192 M glycine, 1% (*w*/*v*) SDS] at pH 8.3, with 100 V constant current. After the sample entered the separation gel, the voltage was changed to 250 V. Molecular mass protein standards (from 15 to 200 kDa; PageRuler Protein Ladder, SM0661, Fermentas, Ontario, CA, USA) were also included in each gel for reference.

Gel Staining and Densitometry Gels were fixed and stained overnight in a solution of 0.1% Coomassie brilliant blue R-250 in 50% (*v*/*v*) methanol and 10% (*v*/*v*) acetic acid and destained with several changes of 10% (*v*/*v*) acetic acid, following the protocol of Beeley et al. (1991) for proline-rich proteins. Digital images of the gels were obtained by using a densitometer (Molecular Dynamics, Amersham Biosciences Europe GmbH, Freiburg, Germany), and the gels were subjected to linescan analysis by using ImageQuant 5.0 software with parameter sensitivity 9.0 and kernel 4.0 (Amersham Biosciences Europe GmbH) to assign the significant bands in the protein profiles.

Protein Identification For protein identification, the PMF approach was used. Stained bands were excised, washed, reduced with dithiothreitol, alkylated with iodoacetamide, and dried in a speedvac. Gel pieces were rehydrated with digestion buffer (50 mM NH_4HCO_3) containing trypsin (Promega, Madison, WI, USA) and incubated overnight at 37°C. The buffered peptides were acidified with formic acid, desalted, and concentrated with C8 microcolumns (POROS R2, Applied Biosystems, Foster City, CA, USA). The peptides were eluted with matrix solution that contained 10 mg/ml α-cyano-4-hydroxycinnamic acid dissolved in 70% (*v*/*v*) acetonitrile/0.1% (*v*/*v*) trifluoroacetic acid. The mixture was allowed to air-dry (dried droplet method). Mass spectra were obtained with a Voyager-DE STR (Applied Biosystems) MALDI-TOF mass spectrometer in the positive ion reflectron mode. External calibration was made by using a mixture of standard peptides (Pepmix 1, LaserBiolabs, Sophia-Antipolis, France). Spectra were processed and analyzed with MoverZ software (Genomic Solutions Bioinformatics, Ann Arbor, MI, USA). Peakerazor software (GPMAW, General Protein/Mass Analysis for Windows, Lighthouse Data, Odense, Denmark; http://www.gpmaw.com) was used to remove contaminant *m*/*z* peaks and for internal calibration. Monoisotopic peptide masses were used to search for protein identification by using Mascot software (Matrix Science, London, UK; http://www.matrixscience.com). Database searches were performed against MSDB (a non-identical protein sequence database maintained by the Proteomics Department at the Hammersmith Campus of Imperial College, London; http://csc-fserve.hh.med.ic.ac.uk/msdb.html) and SwissProt. The following criteria were used to perform the search: (1) mass accuracy of 50–100 ppm; (2) one missed cleavage in peptide masses; and (3) carbamidomethylation of Cys and oxidation of Met as fixed and variable amino acid modifications, respectively. Criteria used for protein identification in the Mascot software were (1) significant homology scores achieved in Mascot; (2) significant sequence coverage values; and (3) similarity between the protein molecular mass calculated from the gel and for the identified protein.

Results

Salivary Protein Profile Salivary protein concentrations in both animals ranged from 30 to 2,000 μg/ml. Twenty-one and 19 protein bands (Fig. 1) were reproducibly displayed in goat and sheep parotid saliva protein profiles, respectively. There was a similar pattern to the parotid saliva profiles for the two species, except for the 25 to 35 kDa molecular mass range. In this range, the parotid saliva electrophoretic profile from sheep had two visible bands (o and s, corresponding to approximately 32 and 26 kDa, respectively), whereas the profile from goat had four bands (p, q, r, and s, corresponding to approximately 30, 28, 27, and 26 kDa, respectively). Band o, which was an intense band in the sheep profile, was not present in goat saliva. Bands p, q, and r, observed in goats, were absent from sheep. Moreover, the protein band s, common to both species, was more intense in sheep. The parotid salivary protein profiles from individual goats (N=4) and sheep (N=5; Fig. 2) revealed patterns that were similar among individuals of each species but different between the species.

Salivary Protein Identification Mass spectra from a total of 21 and 19 peptide digests of well-resolved bands from

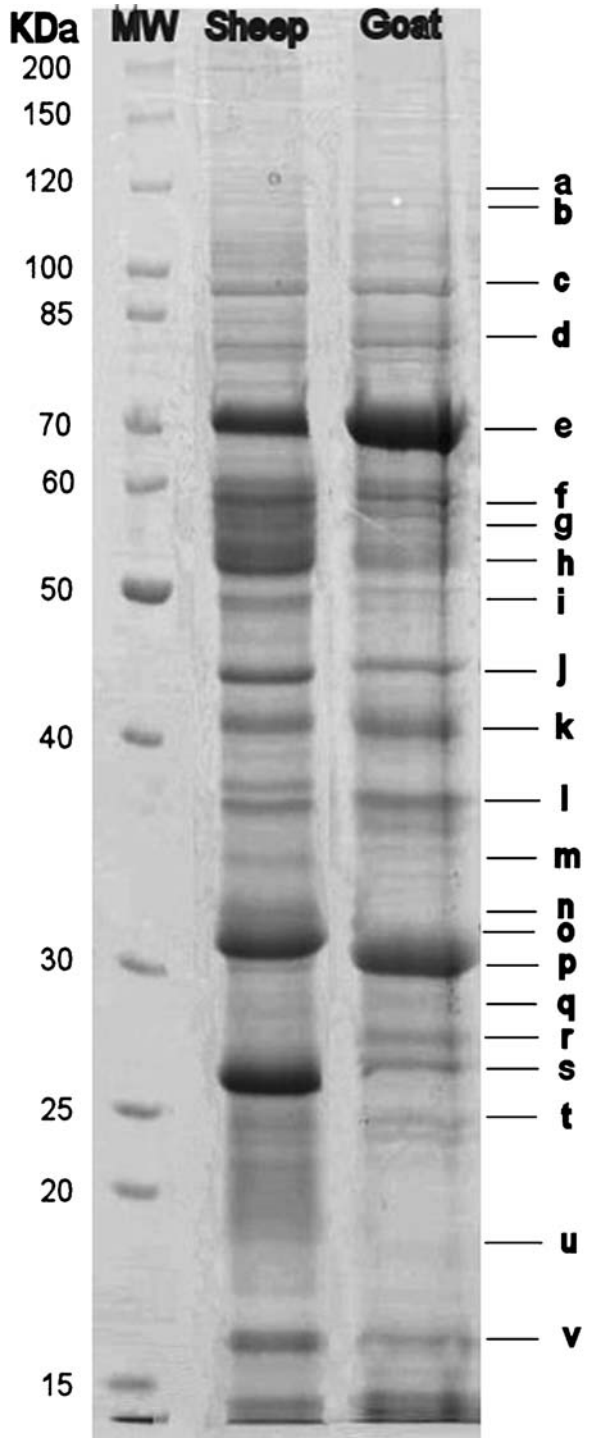

Fig. 1 Typical profiles of sheep and goat parotid salivary proteins in a 12.5% linear gel. Each lane represents the profile from an individual saliva sample. Molecular markers (*MW*) are represented on the *left side* of the figure. The protein bands are identified by letters *a* to *v*

goats and sheep, respectively, were analyzed. The MSDB database was searched by using a taxonomic restriction for "other mammals," and 16 different proteins were identified (Table 1). In most instances, the same proteins were identified in both species. However, the identification of the bands h, n, o, q, r, u, and v were not possible due perhaps to a low amount of protein in some bands or to the existence of several different proteins in the same band or even to a lack of homologous proteins in the searched protein sequence databases. Peptide map comparison for goat and sheep band f shows the presence of some peaks that correspond to the catalase predicted tryptic peptide masses; however, more peaks with relevant intensities were observed. This suggests that catalase is also present in goat f band, probably mixed with other unidentified proteins. Similar results were obtained when peptide maps for band s were compared between goat and sheep. Apolipoprotein A-I was likely present in sheep band s, but the band may also contain other unidentified proteins. This interpretation was supported both by the higher intensity of this band in sheep when compared with the corresponding one from goat and by the presence of mass peaks not observed in goat band s peptide map.

Discussion

Electrophoretic profiles of salivary proteins have been reported for several species, such as rats (Ekström et al. 1996; Williams et al. 1999a), ferrets (Williams et al. 1999b), and cats (Marshall et al. 1993), but the bulk of the studies on salivary profiles have been performed on humans (Ghafouri et al. 2003; Vitorino et al. 2004; Wilmarth et al. 2004; Hardt et al. 2005; Hirtz et al. 2005; Hu et al. 2005; Guo et al. 2006; Walz et al. 2006). According to our knowledge, this is the first study in which the SDS-PAGE electrophoretic profiles of parotid salivary proteins from sheep and goats have been characterized, with MALDI-TOF MS used to identify the more representative proteins.

The proteins identified in the present study (Table 1) can be sorted into three main functional categories. The largest group includes salivary proteins that exhibit immune response or oral protection functions: complement C3 precursor, gelsolin precursor, serotransferrin precursor, catalase, immunoglobulin, annexin A1, cathepsin H precursor, and glutathione S-transferase P. Among these, catalase and glutathione S-transferase P have a more specific role in detoxification. They are associated with feeding behavior because their presence has been associated with plant consumption (Felton and Duffey 1991; Rodman and Miller 1992; Sreerama et al. 1995; Lampe et al. 2000). Annexin A1 has also been related to taste perception (Neyraud et al. 2006).

A second functional category includes proteins involved in protein biosynthesis: elongation factor 2, heat shock protein HSP 90-beta, and protein disulfide-isomerase A3

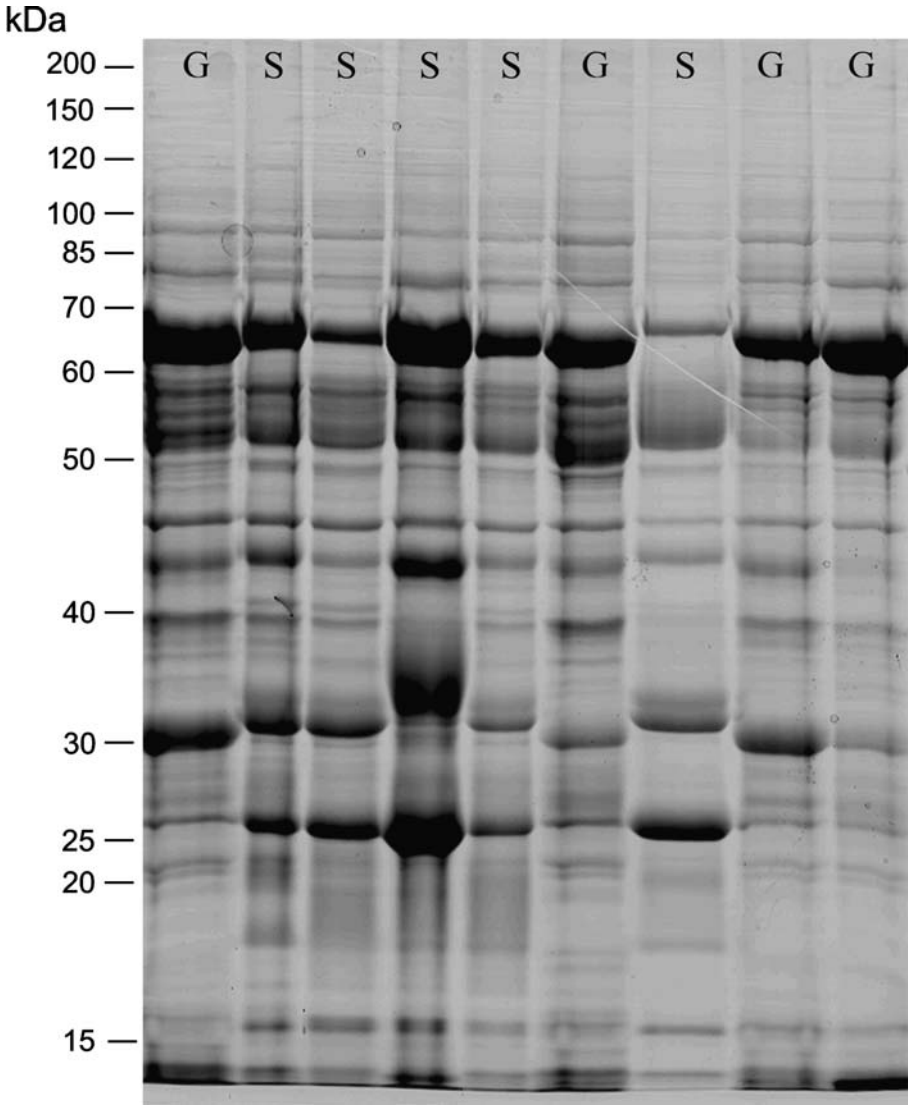

Fig. 2 SDS-PAGE of goat and sheep parotid salivary proteins. Samples were obtained from four different goat (*G*) and five different sheep (*S*) under the same dietary conditions. Similarities among individuals from the same species and differences between species are evident

precursor. The third functional category includes typical serum proteins that, among other functions, are concerned with transport: serotransferrin precursor, serum albumin precursor, and apolipoprotein A-I precursor. The functions of actin and deoxyribonuclease 1 in saliva are not well understood. Some authors have considered deoxyribonuclease 1 as a digestive enzyme (Takeshita et al. 2000), despite others having previously suggested that deoxyribonuclease 1 activity in human parotid saliva is insufficient to fulfill any digestive function (Yaegaki et al. 1982). The presence in saliva of cytoplasmatic proteins, such as actin, may be a consequence of the apocrine-like type of secretion reported for ruminant parotid glands (Stolte and Ito 1996).

Carbonic anhydrase VI is the only protein that has been previously reported from sheep parotid glands, and this is the only sheep salivary protein sequence deposited in databases (Fernley et al. 1988a, b). Carbonic anhydrase VI has a role in electrolytic equilibrium and in the buffer properties of saliva (Kimoto et al. 2006). Its presence in saliva has also been associated with the development of adequate taste function (Henkin et al. 1999).

Our results suggest a strong similarity between the electrophoretic profiles of sheep and goat salivary proteins. From the 16 proteins identified, only one, band p, is not common to both species (Table 1). The similarity likely reflects the phylogenetic proximity of the two species and the consumption of an equal diet during the study. Not surprisingly, we found more pronounced differences when we compared our results with the salivary protein composition of carnivores (Marshall et al. 1993; Williams et al. 1999b) and omnivores (Beeley et al. 1991; Williams et al. 1999a; Hardt et al. 2005). In the dietary habits ranging from carnivores through omnivores to those animals that are exclusively herbivores, plant allelochemical levels increase progressively. It has been suggested (McArthur et al. 1995) that during the evolution from meat to plant eater, selective

pressure encouraged salivary proteins with defense functions against anti-nutritive and/or toxic substances present in plants. Saliva is one of the behavioral and physiological mechanisms that mammals have evolved for coping with hazards related to feeding. For herbivores, this can mean having to deal with toxic and anti-nutritive substances, whereas for omnivores, the major risk faced is that of foodborne illness. The tradeoff between costs/nutritional benefits could be reflected in the salivary profiles of different trophic groups, with differences in the proportion of proteins. In humans and rodents, the proportion of serum proteins, relative to total salivary proteins, is lower than the proportion observed in the present study for sheep and goats. Saliva with a composition similar to serum can be more useful for ruminants than for humans or rodents. The lack of digestive enzymes in ruminant saliva has been widely reported and probably reflects digestive characteristics, such as the low levels of starch in the diet and the

importance of ruminal fermentation of structural carbohydrates. An adequate digestion is achieved by the rhythms of salivary secretion and by a more marked role of saliva in providing and maintaining a buffered environment for ruminal fermentation, contributing to half of the bicarbonate entering the rumen (Owens et al. 1998). The digestive differences between ruminants and omnivores, such as humans and rodents referred to above, can also explain why the latter possess other salivary proteins, which we have not found in sheep and goats.

Despite the similarities, the differences found between sheep and goats parotid salivary protein profiles are also meaningful. From the bands common to both profiles, differences in intensity were observed only for band s, identified as apolipoprotein A-I, which was more intense in the sheep profile. The large number of peaks in the peptide map for band s suggests additional unidentified proteins of similar mass in the same gel band. A more pronounced difference was observed in the region of 25–35 kDa. Band p, which was only observed in the goat profile, contained cathepsin H. This protein is involved in the degradation of proteins in lysosomes, and no role in digestion has been attributed to it. As previously discussed, the presence of this cytoplasmic protein in saliva may result from the apocrine-like type of secretion characteristic of ruminants (Stolte and Ito 1996). In addition to the cathepsin peaks, a large number of other peaks were present in the peptide map, suggesting the presence of unidentified proteins in this intense gel band as well. It is possible that cathepsin is also present in sheep parotid saliva in low concentrations, which were insufficient to allow a band observation in Coomassie stained gels. For band o, which was only observed in the sheep profile, and bands q and r, only observed in the goat profile, we were unable to obtain identification.

Some authors (Austin et al. 1989; Fickel et al. 1998) refer to the presence of salivary PRPs in browser ruminant species and to their absence in sheep saliva. As sheep are grazers and goats are intermediate feeders, one possibility is that goats could have salivary PRPs. Human basic PRPs, which are the group of PRPs with a higher affinity for tannins, have molecular masses between 14 and 45 kDa (Bedi and Bedi 1995), which correspond to mass values of the unidentified bands. We tested the presence of PRPs by staining the gels with Coomassie brilliant blue R-250, following the protocol of Beeley et al. (1991), but were unable to observe the characteristic pink bands. The absence of salivary PRPs in sheep and goat parotid saliva may reflect the low tannin diet consumed by the two species during the experiment. Further studies with the incorporation of high levels of tannins into the diet may be useful in assessing the induction of this particular group of salivary proteins.

This study provides a first step to the full characterization of the goat and sheep parotid saliva protein profile, and it provides useful information that can be used to study further the immediate oral adaptation to the diet. Based on the differences between the species, even when fed under a similar feeding situation, we suspect that salivary protein composition can play an important role in feeding choices. The complexity of parotid saliva is evident from the great number of protein bands, the lack of identification of some of them, and the large number of tryptic peptides obtained for each one. This highlights the importance of the use of more powerful separation techniques. Moreover, we think that more dynamic information can be obtained by studying these two species subjected to different diets. We intend to use two-dimensional electrophoresis coupled to MS and MS/MS to study potential changes in the parotid saliva proteome caused by the consumption of tannin-enriched diets.

Abstract With a combination of dichloromethane extraction and analysis by gas chromatography–mass spectrometry (GC-MS), we found 39 compounds (corresponding to 38 GC peaks) in the anogenital gland secretion (AGS) of captive adult giant pandas, *Ailuropoda melanoleuca*, during the non-mating season. In addition to indole, squalene, and some of the straight-chain fatty acids that had been characterized previously from the AGS of giant pandas, we identified several new compounds such as decenal, two isomers of decadienal, phenylacetic acid, 5-methylhydantoin, hydroquinone, phenylpropanoic acid, and erucic acid. Quantitative comparison of the relative abundances of the 20 main GC peaks revealed that 5-methylhydantoin, indole, and erucic acid are putative female pheromones, whereas squalene and hydroquinone are putative male pheromones. In addition to the presence of a few individual-specific compounds, the relative abundances of most of the 21 constituents varied more among individuals than within individuals. This suggests that individual identity might be coded in both digital and analog form. The chemical composition of different AGS samples from the same pandas consistently displayed a minimum cluster distance, much smaller than that between samples from different individuals in a hierarchical linkage cluster (average linkage) dendrogram. Our results indicate that the AGS might contain an "odor fingerprint." Although putative sex pheromones such as squalene and erucic acid should be assessed further by bioassay, our study suggests that synthetic chemosignals might be useful in modulating the behavior and physiology of giant pandas.

Introduction

Pheromones play crucial roles in modulating sexual and social behavior in mammals (Brown and MacDonald 1985). However, compared with our knowledge of pheromonal compounds of insects, mammalian chemical signals have seldom been characterized structurally, partially owing to their complex composition. Nonetheless, a large amount of information has been amassed about pheromonal functions of whole odorant secretion/excretion in mammals (Brown and MacDonald 1985; Novotny et al. 1999). For a comprehensive understanding of mammalian chemical communication, it is necessary to combine bioassay and

chemical analysis to identify the pheromonal components involved (Singer et al. 1997; Novotny et al. 1999). Fortunately, a systematic approach to screening for pheromonal compounds from numerous scent sources by gas chromatography (GC) has been established in mice, whereby odorant components that vary with biological characters can be considered as pheromone candidates for further verification by bioassay (Singer et al. 1997; Novotny et al. 1999). By using this approach, we have recently characterized some new pheromone components from the preputial glands of the house mouse, *Mus musculus*, and Brandt's vole, *Lasiopodomys brandtii*, and from the flank glands of the golden hamster, *Mesocricetus auratus* (Zhang et al. 2007a, b; J.X. Zhang, unpublished data). These new pheromone components include high boiling compounds such as hexadecanol, hexadecyl acetate, farnesyl acetate, tetradecanoic acid, and hexadecanoic acid (Zhang et al. 2007a, b; J.X. Zhang, unpublished data). The discovery of these higher boiling compounds has extended the spectrum and concept of mammalian pheromones.

The giant panda, *Ailuropoda melanoleuca*, is an endangered species that inhabits fragmented mountainous areas of Sichuan, Shaanxi, and Gansu provinces in China. Poor in eyesight and hearing ability, pandas mainly use their anogenital gland secretions (AGS) and urine to communicate with each other and mediate their social interactions (Schaller et al. 1985; Swaisgood et al. 1999; Liu et al. 2002). Behavioral tests with giant pandas have revealed that the AGS carries a wealth of information about sex and individuality (Swaisgood et al. 2000; White et al. 2002, 2003; Liu et al. 2005; Tian et al. 2007). Male and female pandas show different behavioral responses to AGS samples from conspecific donors of the same and opposite sex. The chemosensory response in the panda differs between the sexes and is age-dependent (Swaisgood et al. 2000; White et al. 2002, 2003; Liu et al. 2005; Tian et al. 2007). Chemical analysis of the AGS should provide further information about pheromone-based behavioral discrimination in the panda. So far, however, sex-and age-dependent pheromonal components have not been identified due largely to the distractive presence of numerous inactive alkanes (e.g., Yuan et al. 2004; Liu et al. 2006) and to inadequacies in the analytical system, which is often capable of detecting only a small portion in the repertoire of odorant compounds (Hagey and MacDonald 2003).

In the current study, we improved our analytical system and used the relative abundances of the principal GC peaks (Sun and Müller-Schwarze 1998a, b) to compare qualitatively and quantitatively male and female AGS samples and to search for components that differ between the sexes in giant pandas during the non-mating season. With the relative standard deviation (RSD) and hierarchical cluster analysis of the relative abundances of the main GC peaks, we compared AGS samples among individuals. This method has been successfully used in similar studies in several *Mustela* species, the house mouse, the Brandt's vole, and the golden hamster (Zhang et al. 2003, 2005, 2007a, b; J.X. Zhang, unpublished data).

Methods and Materials

Subjects Sixteen adult giant pandas (M/F = 1:1, age >5yr) housed at the Bifengxia Panda Base ($N = 10$) and Wolong Breeding Center ($N = 6$), China Conservation and Research Center for the Giant Panda, Wolong, China were used as AGS donors. Six subjects were kept in traditional enclosures and ten in semi-natural enclosures (Table 1). Each traditional enclosure contained a night pen (5.8 × 2.3m) and an outdoor yard (5.8 × 13m) with grass, some climbing apparatuses, and a small pond as a water source. Each outdoor yard adjoined two others via a cement wall in which there was a small wire mesh fence door (1 × 10m). Each semi-natural enclosure contained a night pen (4 × 3m)

and an outdoor yard (25 × 60m) that stretched along a 35 to 40° mountain slope with pine trees, shrubs, herbs, some bamboo, *Fargesia robusta*, and a small pond as a water source. Concrete walls separated these adjoining outdoor yards as well. Each subject could hear and see neighboring animals over the walls in certain areas of the yards. All subjects were provided with a daily routine of food consisting of steamed buns (five to six times per day), as well as apples and carrots (three to four times per day). Bamboo was available *ad libitum*. Additional details of housing, management, and diet are available elsewhere (Liu et al. 1998, 2003).

Scent Sample Collection and Extraction Scent samples were collected in 2006 during the non-mating season. The pandas used in our study were docile after several years in captivity, and hence, it was easy for us to collect their scent marks without any anesthesia. On 23 and 27 December 2006, we collected AGS samples with clean and sterilized cotton swabs (Chengdu Medical Inc., Chengdu, Sichuan, China) by rubbing each swab directly on the surfaces of panda anogenital glands while the subjects were induced with an apple or a carrot to sit by a zookeeper. All swabs used were previously treated with alcohol (99%) overnight and air-dried before use for sample collection. The swabs were only handled with gloved, not bare, hands. Odor samples of some pandas were collected twice (one collection on each of the two collection dates). We sealed all samples individually in clean glass vials with lids lined with Teflon and immediately stored them at −20°C in Bifengxia and Wolong, respectively, for 1wk. Later, the samples were packed on ice and air-shipped to the laboratory in Beijing (about 2-hr flight) and stored at −20°C for less than 1wk until they were extracted for analysis by GC–mass spectrometry (GC-MS).

We used dichloromethane (purity >99.5%, Beijing Fine Chemical Company, Ltd., Beijing, China) to extract the compounds from the AGS samples. To do so, we used a clean pair of scissors to cut away the outer 1mm layer of cotton that contained the AGS secretion and then put the resulting cotton pieces into a vial containing dichloromethane. The cotton was extracted in a volume of dichloromethane that reflected an extract concentration of approximately 1mg/10μl solvent. After 12hr, we removed the cotton pieces and stored the remaining solution at −20°C for less than 2d until they were analyzed by GC-MS. We wore PE disposable plastic gloves (Shanghai Dudeli Plastic Inc., Shanghai) when we handled the materials and never touched the swabs, cotton pieces, or instruments with bare hands.

GC-MS Analysis Analytical GC-MS was performed on an Agilent Technologies Network 6890N GC system coupled with 5973 Mass Selective Detector with the NIST/EPA/NIH Mass Spectral Library (2002 version; Agilent Technologies 2002). Chemstation Software (Windows 2000) was used for data acquisition and processing. The GC was equipped with a 30m HP5-MS glass capillary column (0.25mm i.d. × 0.25-μm film thickness). Helium was used as the carrier gas at the flow rate of 1.0ml/min. The temperature of the injector was set at 280°C. The oven temperature was programmed as follows: 100°C as the initial temperature, which was increased by 5°C/min up to 260°C and held for 10min. Finally, the temperature was increased to 280°C and held for 10min for a post-run cleaning of the column. Unknowns were identified by matching their retention times and mass spectra with authentic analogs after separation with the non-polar column (HP5-MS) and confirmed in some cases by using a polar column (DB-WAX, 30m long, 0.25mm i.d. × 0.25-μm film thickness) for separation and matching of retention times and mass spectra with standards. For the analysis with the polar column, GC injector temperature was set at 270°C; the oven temperature was initially set at 100°C, then increased by 5°C/min to 250°C and held for 20min at the flow rate of 1.0ml/min. Electron impact ionization was used at 70eV. Transfer line temperature was 280°C. Scanning mass ranged from 30 to 450amu. One microliter of sample was injected in the splitless mode.

Tentative identifications were made by matching the mass spectra of the GC peaks with those in the MS library (Agilent Technologies 2002). Thirteen (corresponding to 13 GC peaks) of the 39 tentatively identified compounds were verified by matching retention times and mass spectra with those of the authentic standards of *E*2-decenal (peak 1), 5-methylhydantoin (peak 2), hydroquinone (latter portion of peak 4), indole (peak 5), *E*2,*E*4-decadienal (peak 6), phenylpropanoic acid (peak 7), tetradecanoic acid (peak 13), hexadecanoic acid (peak 16), heptadecanoic acid (20), *Z*9-octadecenoic acid (peak 22), octadecanoic acid (peak 23), erucic acid (peak 31), and squalene (peak 38; Table 2). Although the chromatographic and spectral data for *Z*9-octadecenoic acid matched that of the authentic standard, we did not analyze this compound by dimethyldisulfide derivatization to unambiguously establish the position of the double bond. Thus, we take the more conservative approach and designate it as "an octadecenoic acid."

Phenylpropanoic acid (97%), tetradecanoic acid (99.5%), hexadecanoic acid (98%), heptadecanoic acid (95%), octadecanoic acid (97%), *Z*9-octadecenoic acid (97%), *E*-2-decenal (95%), *E*2,*E*4-decadienal (95%), indole (99%), and hydroquinone (99%) were purchased from ACROS Organics, Geel, Belgium. 5-Methylhydantoin (97%) and squalene (98%) were purchased from Sigma-Aldrich Inc., St. Louis, MO, USA. Erucic acid (96.5%) was purchased from Tokyo Kasei Kogyo Co. LTD., Tokyo, Japan.

Table 2 GC-MS data and identified compounds in anogenital gland secretion of giant pandas, *A. melanoleuca*

[a] Compounds verified with authentic standards; other components were identified by comparison with spectra listed in the NIST (Agilent Technologies 2002) mass spectral library and analogous data.
[b] Italicized ions indicate the molecular ion

We converted the peak area of a particular compound into a percentage of the summed peak areas from the 20 main GC peaks (peaks 1–7, 11–14, 16, 20, 22, 23, 26–28, 31, 35, and 38) as a measure of the relative abundance of the relevant compound. If a given GC peak was too small to display the diagnostic MS ions of the corresponding compound, its area was taken as zero.

Statistical Analysis To test the hypothesis that there was sexual dimorphism in the relative abundances of the 20 main GC peaks in the crude extract of the AGS, we first examined the distribution of the raw data by the Kolmogorov–Smirnov test in SPSS for Windows (SPSS Inc. 1999). Then, we used either parametric tests (if the data were normally distributed) or non-parametric tests (if the data were not normally distributed) to analyze the relative abundances of the compounds. We used an independent two-tailed *t* test to analyze for sexual differences in the relative abundances of the compounds represented by peaks 13, 16, 22, 23, 26–28, and 38 (which had normally distributed raw data) and the Mann–Whitney *U* test for the remainder of the 20 main GC peaks (which did not have

normally distributed raw data). All statistical analyses were conducted by using SPSS for Windows (version 10.0; SPSS Inc. 1999). The critical values were set at $\alpha = 0.1$ (used commonly in similar studies, e.g., Gassett et al. 1996) except the intra-individual comparisons where α was set at 0.05.

Hierarchical cluster analysis is a statistical method for finding relatively homogenous clusters of cases based on measured characteristics. We used this analysis (average linkage) with Pearson's correlation coefficients to test the similarity of inter- and intra-individual AGS constituents (based on the 20 main GC peaks in the samples; Zhang et al. 2005).

To determine the variability of the AGS composition between individuals, RSD was used and calculated with the formula:

$$\mathrm{RSD} = (\mathrm{SD}/\mathrm{mean}) \times 100$$

where mean and SD are the average of each volatile peak-area percentage for all same-sex individuals and their standard deviation, respectively (Zhang et al. 2003).

Results

Anogenital Gland Secretion Constituents We tentatively identified 39 compounds from eight male and eight female giant pandas (Fig. 1). Chromatographic and spectral data were used to make these preliminary identifications (Table 2). By matching GC retention times and MS spectra with those of authentic standards, we identified peaks 1, 2 (latter portion of peak 2), 4, 5, 6, 7, 13, 16, 20, 22 (see note in "Methods and Materials"), 23, 31, and 38. The identities of these compounds were verified by a second analysis of the extracts and standards with the DB-WAX polar column.

Compounds in GC peak 2 were not completely resolved when analyzed under our conditions on the HP5-MS capillary column, but the peak included phenylacetic acid [as implied by *m/z* 136 (40 = relative intensity) and *m/z* 91 (100)] and 5-methylhydantoin (5-methyl-2,4-imidazolidinedione) [as indicated by *m/z* 114(94), *m/z* 43(58), and *m/z* 42(100)] (Table 2). GC peak 3 with similar MS data to *E*2, *E*4-decadienal (peak 6) might imply another decadienal (Table 2). Some peaks (e.g., peak 15, 17, 18, and 21) eluted earlier than hexadecanoic acid (peak 16), heptadecanoic acid (peak 20), or octadecanoic acid (peak 23), but showed similar MS data. They may be branched isomers of the corresponding acids. However, their identities were not verified by analysis with authentic standards (Table 2).

GC peaks 9, 10, and 12 were likely alkanes (Table 2). GC peaks 8, 15, 17–19, 21, 24, 25, 29, 30, 32–34, and 36 were tentatively identified as fatty acids and were seldom present in all samples. GC peak 37 might be cholestatriene. These trace GC peaks were excluded from the quantitative analysis (Fig. 1, Table 2).

Sex Differences Quantitative analyses revealed that the relative amount of the compound in peak 38 (squalene) was significantly higher in males and three compounds (peaks 2, 5, and 31) were higher in females (Table 3). Other compounds did not show differences between the sexes. GC peak 2 was only detected in one (Qiangqiang) of the eight males. Mass spectral data indicated that this peak from Qiangqiang only contained phenylacetic acid. However, in five of the eight female subjects, GC peak 2 was composed of 17.82 ± 27.37% ($N = 5$) phenylacetic acid and 82.18 ± 27.37% ($N = 5$) 5-methylhydantoin, which were estimated by each GC area percentage in peak 2 calculated after manually splitting GC peak 2. The latter was more abundant than the former ($t = 2.629$, $df = 4$, $P = 0.058$, paired t test). In other words, 5-methylhydantoin in GC peak 2 was not only female-specific in quality, but it was also more characteristic of chemical signals of females in quantity than phenylacetic acid. Further analysis indicated that phenylacetic acid showed no difference between the sexes (0.133 ± 0.236 vs. 0.022 ± 0.063 for females and males, respectively, both $N = 8$, $Z = 1.532$, $P = 0.125$). GC peak 4 (hydroquinone) was detected in two males (Didi and Longfei) and peak 5 (indole) in three females (Caocao, Zhuyun, and Zizhu). These compounds seem to be sex-specific in the AGS of the panda.

Intra-individual Similarity and Inter-individual Dissimilarity For males, cluster analysis showed that AGS composition in the samples remained relatively constant within individuals (i.e., Qiangqiang, Longsheng, Didi, and Longfei, cluster distance <1; Fig. 2). For females, two scent samples of Zizhu also showed a cluster distance less than one, but Caocao did not exhibit such a similarity in the dendrogram. Instead, the components of her AGS were closer to those of Ximei or Youyou (both females). This indicated that individual female AGS composition might fluctuate to a certain degree. However, further examination of each peak revealed that peaks 2 and 7 were present only in the extract from Caocao, whereas peaks 1 and 3 were present only in extracts from Ximei and Youyou. As a result, these compounds may be the keys for distinguishing Caocao from the other two whose individual attributes were not reflected as expected by the average linkage dendrogram. Likewise, the hierarchical cluster analysis failed to separate males from females despite the presence of sexual differences in several key compounds. In addition, peak 2 was present only in five females (Caocao, Meiqing, Zhuyun, Lesheng, and Zizhu) and peak 1 only in three other females (Yeye, Ximei, and Youyou).

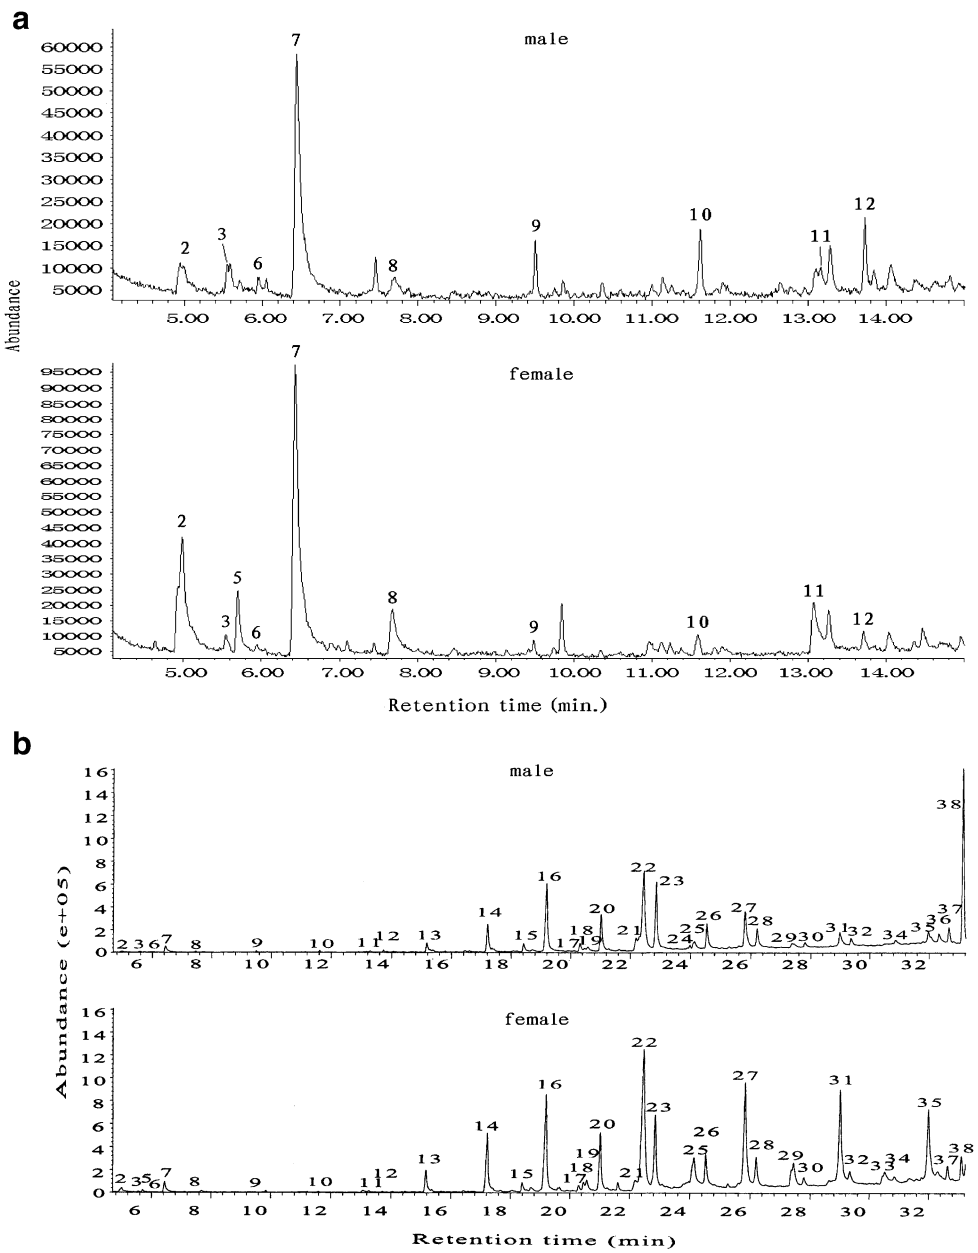

Fig. 1 Representative gas chromatogram of separation of the crude extract of the anogenital gland secretion of male (*top panels* of **a** and **b**, Qiangqiang) and female (*bottom panels* of **a** and **b**, Caocao) giant pandas, *A. melanoleuca*, on a 30-m HP5-MS capillary column. **a** Gas chromatogram (enlarged view) representing 4 to 15 min of retention time; **b** Gas chromatogram (normal view) representing 6–32 min of retention time. The numbers that label the GC peaks correspond to peak numbers in Table 2. Compounds 1 and 4 were undetectable in these two samples

Furthermore, the relative abundances of most compounds in inter-individual scent mark samples of either males or females exhibited much higher RSDs than those of samples drawn five times from the same individual (Ximei; Table 4). This further suggested that many AGS constituents may differ quantitatively among individuals.

Discussion

Our data show that many of the detectable 39 compounds (corresponding to 38 numbered GC peaks) from the AGS of giant pandas are straight-chain fatty acids. This, and the identification of squalene, in general, agrees with the previous findings of Yuan et al. (2004) and Liu et al. (2006), but shows a marked difference from the work of Hagey and MacDonald (2003) who found 111 volatiles smaller than indole. Moreover, we add several new compounds to the AGS of giant pandas that include decenal, decadienal, phenylacetic acid, 5-methylhydantoin, hydroquinone, phenylpropanoic acid, and erucic acid. The divergence in AGS compounds among studies might be explained by differences in the analytical systems, the concentration of samples analyzed, the season during which samples were collected, or the duration of sample storage. We analyzed our samples by injecting aliquots and concentrations that would not overload the column or cause overlap in retention times of the extract constituents. We

[a] Independent t test was used to analyze compounds 13, 16, 22, 23, 26–28, 38; Mann–Whitney U test was used to analyze the rest of the compounds. The level of significance for each test was set at α=0.1.
[b] Compounds identified using authentic standards
[c] Figures in the parentheses refer to the numbers of individuals for which the compound was detectable.

might have detected more compounds in our extracts by analyzing higher sample concentrations. Nonetheless, the 111 compounds reported by Hagey and MacDonald (2003) included compounds detected from both urine and vaginal secretions in addition to the AGS.

To further screen for pheromone candidates from the identified compounds, we conducted a quantitative analysis

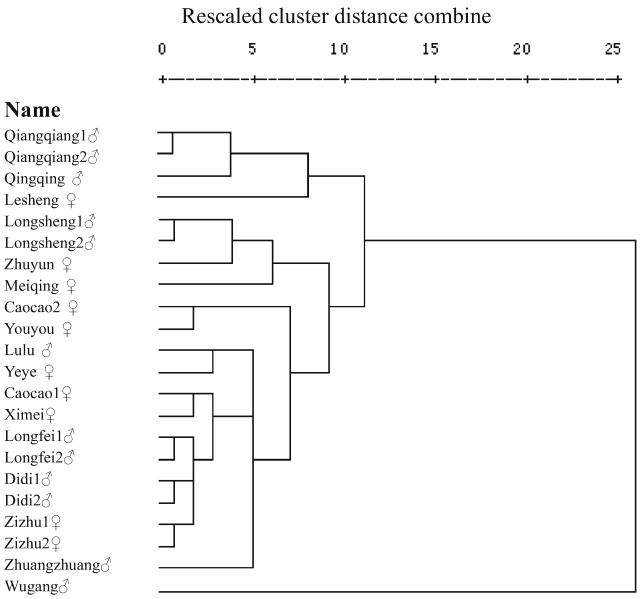

Fig. 2 Hierarchical linkage cluster (average linkage) dendrogram of the anogenital gland secretion of giant pandas, *A. melanoleuca*. The *numbers after the panda names* indicate the date [23 (=1) or 27 (=2) December 2006] on which AGS samples were collected. If no number is present, the sample was collected on 23 December 2006

to determine which compounds covary in relative abundance with sex or individual. For this analysis, all alkanes, which are pheromonally inactive, and high molecular weight fatty acids (present in trace amounts) were excluded (Singer et al. 1997; Novotny et al. 1999; Zhang et al. 2003, 2005, 2007a, b). We selected GC peaks for quantitative analysis by checking each GC profile of all samples; the GC profile in Fig. 1 is representative, but not inclusive of all data from all samples.

Some of the compounds that we detected (e.g., decenal and decadienal) might be products of oxidative degradation of fatty acids in the AGS, either while the secretion was associated with the animal or during our collection, storage, or extraction of the sample. In comparison, comparative analyses of fresh and 1-mo frozen extracts of flank gland samples from golden hamsters in our laboratory revealed no appreciable differences in chemical content (J.X. Zhang, unpublished data). Nonetheless, the relative roles of stable or degradative components in the semiochemical system of giant pandas bears further study. Compounds derived from decompositional processes may have ecological value in giant panda communication.

Our results suggest that the panda AGS contains a wealth of information that codes for sexes and individuality, which is consistent with previous behavioral tests (Swaisgood et al. 1999, 2000; White et al. 2002, 2003, 2004; Liu et al. 2005; Tian et al. 2007). The information concerning sex and individuality might be coded by the components in analog (quantitative differences of common compounds) and/or digital (unique compounds) forms proposed by Sun

Table 4 Variation in relative abundance of AGS constituents from male and female giant pandas, *A. melanoleuca*

GC Peak	RSD[a] of Inter-individuals		Intra-individuals (five replicates of Ximei's AGS sample, ♀)	
	Male (N=8)	Female (N=8)	RSD	Mean±SD

t values[b]	3.662	3.789		
P values	0.002	0.001		

[a] RSD refers to relative standard deviation, which was calculated using the formula RSD = (SD/mean)×100, where mean and SD are the average of each compound peak area (in percentage) and their standard deviation, respectively

[b] An independent t test was used to compare RSDs from the same compounds between the male group and replicated data from Ximei and between the female group and replicated data from Ximei. The level of significance was set at α=0.05

and Müller-Schwarze (1998a, b) for the beaver and exemplified further by three *Mustela* species (Zhang et al. 2003, 2005). Other studies have documented that the odorant compounds that covary in quality or quantity with biological characters can be considered putative pheromones (Singer et al. 1997; Novotny et al. 1999). Based on qualitative and quantitative differences in the AGS extracts from the giant panda, we hypothesize that indole (female-specific), 5-methylhydydantoin, and erucic acid are potential female pheromones, whereas hydroquinone (male-specific) and squalene are potential male pheromones. This concurs with previous results in the elevation of the squalene level with sexual maturation in the panda (Liu et al. 2006). Squalene also has been shown to be active in tamarin, *Saguinus fuscicollis* (Epple et al. 1979) and male Canadian red-sided garter snakes, *Thamnophis sirtalis* (Mason et al. 1989). Indole and long-chain fatty acids pheromones are found in a variety of vertebrates including male ferret, *Mustela furo* (Clapperton et al. 1988), leopard geckos, *Eublapharis macularius* (Mason and Gutzke 1990), and golden hamsters (J.X. Zhang, unpublished data). Some straight-chain fatty acids and various isomers of decadienal are common components of insect pheromone blends (El-Sayed 2005). Such convergent uses of the same compounds in different species show that these compounds may possess some typical chemical properties of pheromones, one of which appears to be their volatility, which allows them to convey airborne cues over a distance.

Hierarchical cluster analysis and RSD of the relative abundances of 20 of the GC peaks in combination with individually unique compounds suggest that individual information may be borne in the giant panda by both the kind and degree of the scent constituents. Such coding patterns for individual identity have been found in three *Mustela* species (Zhang et al. 2003, 2005). In ferrets, for instance, Clapperton et al. (1988) identified inter-individual variation in the combination of five compounds in anal gland secretions. In female ferrets, the intra-individual similarity of urinary volatiles is not always elucidated by hierarchical cluster analysis; instead, dramatic fluctuations of a few compounds reveal an inter-individual dissimilarity (Zhang et al. 2005). Significant differences in RSD within and between individuals have also been used successfully to show the possibility of coding for information about individuality with the anal gland secretion in the Siberian weasel and steppe polecat and preputial gland secretion in the house mouse and Brandt's vole (Zhang et al. 2003, 2007a, b). The preputial glands in mice and voles seldom contain compounds that are unique to a specific individual or sex despite their sexual dimorphism in quantity, whereas the anal glands of carnivores always have noticeable individual-specific compounds (Zhang et al. 2003, 2007a, b). For

example, no two individuals share an identical compound composition in the urine of the lion, *Panthera leo* (Andersen and Vulpius 1999). In the giant panda, a fingerprint-like individual scent composition might be an alternative for the "genetic fingerprint," which provides a new powerful tool in the accurate census of wild giant pandas (Zhan et al. 2006). Preliminary comparisons of the data suggest that there is likely no correlation between the similarity of the AGS composition and genetic distance in the panda. For example, although Qingqing (♂), Longfei (♂), Longsheng (♂), Meiqing (♀), Zhuyun (♀), and Ximei (♀) all are sired by Dadi (♂), and Dadi (♂) and Didi (♂) are sired by Panpan (♂; Xie and Gipps 2005), their AGS compositions failed to reflect such genetic relationships. To conduct a thorough analysis of the extent of the role of genetic distance on AGS composition, one would need to include a chemical analysis of the AGS composition from all parents and exclude experimentally the effects of non-genetic factors, such as microbial community, housing condition, reproductive status, and food (Gosden and Ware 1976; Ferkin et al. 1997; Zhang et al. 2003).

In summary, according to the established methods used to screen for pheromones from numerous scent compounds detected by GC-MS, we propose several putative sex pheromones for the giant panda, especially male-produced squalene and female-produced erucic acid, which were present in all pandas in this study. Our results also show an individual "odor fingerprint" from the AGS of the giant panda. Verification of their pheromonal activity via bioassays and application of synthetic chemosignals to conserve this species will be subjects of our future studies.

Acknowledgments We are grateful to Dr. Steven J Seybold and the anonymous reviewers who gave us many helpful suggestions and comments. This work was supported by grants from NSFC (Nos. 30470233 and 30670268); International Cooperative Giant Panda Projects of State Forestry Administration, China (nos. WH0306 and WH0309) and International Partnership Project of Innovative Research, Chinese Academy of Science (CXTDS2005-4).

A Male-produced Aggregation Pheromone Blend Consisting of Alkanediols, Terpenoids, and an Aromatic Alcohol from the Cerambycid Beetle *Megacyllene caryae*

Emerson S. Lacey · Jardel A. Moreira · Jocelyn G. Millar · Lawrence M. Hanks

Received: 19 July 2007 / Revised: 20 November 2007 / Accepted: 27 December 2007 / Published online: 6 February 2008

Abstract Bioassays conducted with a Y-tube olfactometer provided evidence that both sexes of the cerambycid beetle *Megacyllene caryae* (Gahan) were attracted to odor produced by males. Odor collected from male *M. caryae* contained eight male-specific compounds: a 10:1 blend of (2*S*,3*R*)- and (2*R*,3*S*)-2,3-hexanediols (representing 3.2±1.3% of the total male-specific compounds), (*S*)-(−)-limonene (3.1±1.7%), 2-phenylethanol (8.0±2.4%), (−)-α-terpineol (10.0±2.8%), nerol (2.1±1.5%), neral (63.3±7.3%), and geranial (8.8±2.4%). Initial field bioassays determined that none of these compounds was attractive as a single component. Further field trials that used a subtractive bioassay strategy determined that both sexes were attracted to the complete blend of synthetic components, but the elimination of any one component resulted in a decline in trap captures. Blends that were missing (2*S*,3*R*)-2,3-hexanediol, (2*R*,3*S*)-2,3-hexanediol, or citral (a 1:1 mixture of neral and geranial) attracted no more beetles than did controls. A pheromone blend of this complexity, composed of alkanediols, terpenoids, and aromatic alcohols, is unprecedented for cerambycid species.

Introduction

Male-produced aggregation pheromones have been identified for nine species in four tribes of the cerambycid beetle subfamily Cerambycinae (Lacey et al. 2004, 2007b; Hanks et al. 2007). In another three species, male-produced pheromones attract only females (reviewed by Lacey et al. 2004). The pheromones of all these species are comprised of one to three compounds that share a similar structural motif, consisting of molecules that are 6, 8, or 10 carbons in length, with hydroxyl or carbonyl groups at C_2 and C_3 (reviewed by Lacey et al. 2004, 2007b). There are two exceptions to this trend: the male-produced aggregation pheromone of the cerambycine *Phymatodes lecontei* Linsley, (*R*)-2-methylbutan-1-ol (Hanks et al. 2007), and a component of the sex pheromone of *Hylotrupes bajulus* (L.), 1-butanol (Reddy et al. 2005). Volatile pheromones of species in the subfamily Cerambycinae apparently are produced by glands in the prothorax and secreted through pores lying within depressions in the cuticle (Ray et al. 2006; Hanks et al. 2007; Lacey et al. 2007b). Pheromone release by males of several species has been associated with a characteristic body posture, termed the "pushup stance" (Lacey et al. 2004, 2007a, b): Males fully extend their front legs, elevating the head and thorax, and remain motionless for extended periods.

The cerambycine species *Megacyllene caryae* (Gahan) is endemic to North America. The larvae develop in woody tissues of stressed, moribund, and dead trees of a variety of

hardwood species (Linsley 1964). Adults are active in early spring, and collection records from the area of our study, east-central Illinois, range from March 29 to June 7 (Illinois Natural History Survey, Champaign, IL). The adult beetles reportedly feed on flowers of trees in the genus *Crataegus* (Rosaceae; Dusham 1921), but dissections of field-collected adults of both sexes revealed that their guts contained pollen from trees in the genus *Quercus* (Fagaceae; unpublished data). In the laboratory, beetles can live for more than 30 d if provided sugar water (Lacey, personal observation). Adults are active from ~11:00 to 18:00 hours. Both sexes aggregate on larval hosts in numbers that may exceed 40 individuals. They mate soon after emergence, and females begin ovipositing immediately. Generation time is usually 1 yr.

M. caryae exhibits several characteristics that have been associated with production of volatile pheromones in other cerambycine species. For example, adults aggregate on larval hosts (Lacey, personal observation), males have sex-specific gland pores on their prothoraces (Ray et al. 2006), and males on larval hosts commonly assume the pushup stance (Lacey, personal observation). We report here the identification and testing of sex-specific volatile pheromone components produced by adult male *M. caryae*.

Methods and Materials

Source of Insects Adult *M. caryae* used in olfactometer bioassays and for pheromone collections were reared from logs of honey locust, *Gleditsia triacanthos* L. (Fabaceae), that were naturally colonized by beetles from April to May 2003 on the campus of University of Illinois at Urbana–Champaign (UIUC). Periodically, logs were moved to a 3×2×1-m rearing cage of window screen in a laboratory room (ambient conditions: fluorescent lighting, ~12:12 L/D, 20°C, 50% relative humidity) during January and March 2004. Most adults emerged within 14 d of moving logs into the laboratory. Freshly emerged adults were caged individually in 0.1-m^3 cylindrical cages of aluminum window screen with plastic Petri dishes at top and bottom, under ambient laboratory conditions. They were provided 10% sucrose solution dispensed from 8-ml vials plugged with cotton dental rolls (Patterson Dental Supply, South Edina, MN). Adults used in experiments appeared healthy and active.

Testing for Attractant Pheromones Bioassays for attractants produced by adult *M. caryae* were carried out with a horizontal glass Y-tube olfactometer (6 cm diameter, main tube 26 cm long, arm length 22 cm, 70° angle between arms). Bioassays were conducted outdoors in partial shade because beetles either were sedentary or appeared agitated when placed in the olfactometer under laboratory conditions. We conducted bioassays between 11:00 and 16:00 hours for 4 d in April 2004 (skies clear, air temperatures 17–24°C). A 2-l plastic chamber containing a cylinder of aluminum screen as a perch was attached to each arm of the Y-tube. One chamber contained six male beetles and the other six females. Ambient air was pulled through the olfactometer with a vacuum cleaner connected to a variable power supply (air speed ~1.0 m sec^{-1}). For each trial, a beetle was released at the base of the Y-tube and allowed 10 min to respond to an odor source by crossing a line 18 cm down one arm. Beetles that did not respond within 10 min were recorded as "no response." Chambers were alternated between arms of the Y-tube every three trials to control for positional bias. Chambers and the olfactometer were washed and rinsed with acetone each day. We bioassayed 20 individuals of each sex and compared numbers of beetles responding to treatments with a χ^2 goodness-of-fit test corrected for continuity (Sokal and Rohlf 1995).

Identification of Potential Pheromone Components Volatile compounds were collected from adult *M. caryae* by placing five females and males in separate glass vacuum traps (~0.3 l, custom manufactured by the glass shop, School of Chemistry, UIUC) that were lined with an aluminum screen to provide perches. A glass tube (6 cm×4 mm inner diameter [i.d.]) containing 100 mg of 80/100 mesh SuperQ® (Alltech Associates, Deerfield, IL) held between plugs of silanized glass wool was attached to one nipple of each chamber with an 8-cm-long section of Teflon® tubing, and charcoal-purified air was pulled through the apparatus with a water aspirator (0.7 l min^{-1}). Males and females were aerated simultaneously on a laboratory windowsill from 11:00 to 16:00 hours in April and May 2004. We selected this period because it was the only time during the day that males displayed the pushup stance. Collectors were eluted with three 0.5-ml aliquots of CH_2Cl_2 and the resulting extracts analyzed at the University of California Riverside on a Hewlett-Packard® (HP) 5973 mass selective detector interfaced to an HP 6890 gas chromatograph, fitted with a DB5-MS column (30 m×0.25 mm i.d., 0.25 μm film thickness; J&W Scientific, Folsom, CA), temperature-programmed from 40 (held for 1 min) to 250°C at 10°C min^{-1}. Injector temperature was 250°C, and injections were made in the splitless mode. Absolute configuration of the insect-produced compounds was determined by analysis of the extract on a Cyclodex-B gas chromatography (GC) column (30 m×0.25 mm i.d., 0.25 μm film thickness, J&W Scientific) with the GC programmed from 50 (held for 1 min) to 200°C at 5°C min^{-1}; injector and detector temperatures were 100 and 200°C, respectively. Identifications of peaks were confirmed by coinjections of extracts with authentic standards.

Synthesis of Pheromone Components The stereoisomers of 2-hydroxy-3-hexanone and 2,3-hexanediol (see "Results") were synthesized as described below and shown in Fig. 1. Racemic 2-hydroxy-3-hexanone and racemic (2*R**,3*S**)- and (2*R**,3*R**)-2,3-hexanediols were available from previous studies (Lacey et al. 2004, 2007b; Hanks et al. 2007). All other compounds were obtained from Sigma-Aldrich (St Louis, MO), including (*S*)-(−)-limonene (96%), 2-phenylethanol (99%), (−)-alpha-terpineol (90%), nerol (≥90%), and citral (95%; see "Results"). Because neral and geranial (see "Results") were not readily available as pure isomers, citral (a 1:1 mixture of neral and geranial; Sigma-Aldrich) was used in the bioassays.

Tetrahydrofuran was distilled from sodium/benzophenone ketyl under argon. ^{1}H- and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded with a Varian INOVA-400 (400 and 100.5 MHz, respectively) spectrometer as $CDCl_3$ solutions. Chemical shifts were expressed in parts per million relative to $CDCl_3$ (7.26 and 77.23 ppm for ^{1}H- and ^{13}C-NMR, respectively). Mass spectra were obtained with an HP 5890 GC interfaced to an HP 5970 mass selective detector, in electron impact mode (70 eV), with helium as the carrier gas. The GC was equipped with a DB5-MS column (25 m×0.20 mm i.d.×0.33 μm film; J&W Scientific). Solutions were dried over anhydrous Na_2SO_4 and concentrated under partial vacuum by rotary evaporation unless otherwise stated. Crude products were purified by flash or vacuum flash chromatography with silica gel (230–400 mesh, EM Science, Gibbstown, NJ). Reactions with air- or water-sensitive reagents were carried out in oven-dried glassware under argon. GC with a chiral stationary phase column was performed with an HP 5890 GC fitted with a Cyclodex B column (30 m×0.25 mm i.d.× 0.25 μm, J&W Scientific), programmed from 50 (held for 1 min) to 200°C at 5°C min^{-1}, with the injector at 100°C and helium as carrier gas (20 psi).

Ethyl (S)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate [(S)-2] 3,4-Dihydro-2H-pyran (53.4 g, 635 mmol) was added dropwise to a stirred solution of ethyl (*S*)-(−)-lactate (*S*)-1 (50.0 g, 423 mmol; Aldrich Chem., Milwaukee, WI)

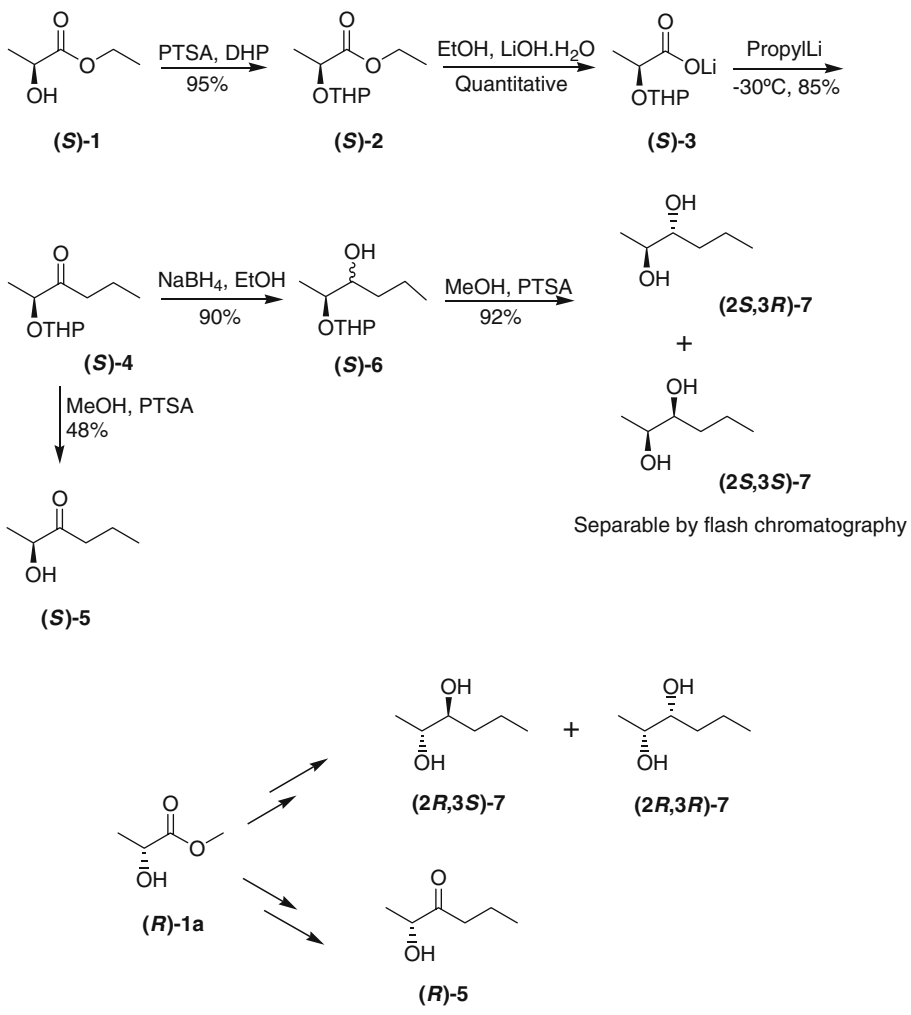

Fig. 1 Syntheses of all four 2,3-hexanediol stereoisomers and the two 2-hydroxy-3-hexanone enantiomers from ethyl (*S*)-lactate and methyl (*R*)-lactate

and 100 mg *p*-toluenesulfonic acid in 120 ml CH_2Cl_2 at 0°C under argon. The mixture was warmed to room temperature and stirred until all the starting material had been consumed (~5 hr). The mixture was then diluted with diethyl ether (60 ml) and washed with saturated aqueous $NaHCO_3$ and brine, dried, and concentrated. The crude product was Kugelrohr distilled (64–68°C, 0.25 mmHg), yielding 81.4 g of protected alcohol (*S*)-2 (95%) as a mixture of diastereoisomers (2:1—measured by GC). ^{1}H-NMR (major stereoisomer): δ 1.26 (t, *J*=7.2 Hz, 3H), 1.44 (d, *J*=7.0 Hz, 3H), 1.48–1.90 (m, 6H), 3.47–3.55 (m, 1H), 3.80–3.88 (m, 1H), 4.11–4.25 (m, 3H, two quadruplets overlapped with signals of other stereoisomer), 4.66–4.72 (m, 1H, dd overlapped with signals of other stereoisomer). ^{1}H-NMR (minor stereoisomer): δ 1.27 (t, *J*=7.2 Hz, 3H), 1.38 (d, *J*=6.8 Hz, 3H), 1.48–1.90 (m, 6H), 3.40–3.47 (m, 1H), 3.88–3.95 (m, 1H), 4.11–4.25 (m, 2H - quadruplet overlapped with signals of other stereoisomer), 4.40 (q, *J*= 7.0 Hz, 1H), 4.66–4.72 (m, 1H, dd overlapped with signals of other stereoisomer); mass spectrometry (MS; *m/z*: relative intensity): 144 (1), 130 (3), 129 (4), 101 (19), 85 (100), 73 (11), 67 (12), 57 (16), 55 (17), 45 (25), 43 (24).

Methyl (R)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate [(R)-2a] In the same manner as described above, methyl (*R*)-(+)-lactate (*R*)-1a (20.0 g, 192 mmol; Aldrich Chem., 96% enantiomeric excess [ee]) was converted to a mixture (2:1—measured by GC) of methyl (*R*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate diastereoisomers (*R*)-2a (34.24 g) in 95% yield after Kugelrohr distillation (62–66°C,1.3 mmHg). ^{1}H-NMR (major stereoisomer): δ 1.44 (d, *J*=7.0 Hz, 3H), 1.46–1.90 (m, 6H), 3.40–3.54 (m, 1H), 3.72 (s, 3H), 3.76–3.93 (m, 1H), 4.41 (d, *J*=7.0 Hz, 1H), 4.65–4.71 (m, 1H) (some signals overlapped with signals of the other stereoisomer). ^{1}H-NMR (minor stereoisomer): δ 1.38 (d, *J*=6.8 Hz, 3H), 1.46–1.90 (m, 6H), 3.40–3.54 (m, 1H), 3.72 (s, 3H), 3.76–3.93 (m, 1H), 4.19 (d, *J*=6.8 Hz, 1H), 4.65 – 4.71 (m, 1H) (some signals overlapped with signals of the other stereoisomer); MS (relative intensity) *m/z*: 130 (2), 129 (6), 116 (2), 101 (28), 85 (100), 73 (7), 67 (15), 57 (20), 55 (26), 45 (25), 43 (30).

Lithium (S)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate [(S)-3] Ethyl (*S*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate (*S*)-2 (80.00 g, 396 mmol) was added to a stirred suspension of $LiOH.H_2O$ (16.60 g, 396 mmol) in ethanol (200 ml) under argon at 0°C. The reaction was stirred for 30 min at 0°C, warmed to room temperature, and stirred for 3 hr. The mixture was concentrated under vacuum, and hexane (50 ml) was added to the concentrate, followed by concentration under vacuum to remove traces of ethanol and water as azeotropes. This procedure was repeated four times, and the residue was pumped under vacuum (0.1 mmHg) for 10 hr. ^{1}H-NMR showed that ethanol was still present in the salt, and so the crude lithium salt was suspended in benzene, the benzene distilled off at atmospheric pressure, and the residue again pumped under vacuum for 10 hr, affording lithium (*S*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate (*S*)-3 as a light yellow solid in quantitative (99.7%) yield. ^{1}H-NMR (major stereoisomer): δ 1.39 (d, *J*=6.8 Hz, 3H), 1.42–1.92 (m, 6H), 3.40–3.55 (m, 1H), 3.82–3.92 (m, 1H), 4.18 (q, *J*=6.8 Hz, 1H), 4.70 (t, *J* 3.5 Hz, 1H). ^{1}H NMR (minor stereoisomer): δ 1.34 (d, *J*=6.8 Hz, 3H), 1.42–1.92 (m, 6H), 3.40–3.55 (m, 1H), 4.00–4.05 (m, 1H), 4.12 (q, *J*=7.0 Hz, 1H), 4.54 (dd, *J*=2.3 and 7.0 Hz, 1H). Some NMR signals from the two diastereomers overlapped.

Lithium (R)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate [(R)-3] Methyl (*R*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate (*R*)-2a (34.20 g, 182 mmol) was converted to lithium (*R*)-2-(2-tetrahydropyranyloxy)-propanoate (*R*)-3 (32.70 g) as described above, in quantitative yield. ^{1}H-NMR and mass spectra matched those of the corresponding (*S*)-enantiomer mixture.

(S)-2-[(Tetrahydro-2H-pyran-2-yl)oxy]-3-hexanone [(S)-4] Lithium wire (1% sodium content; 1.39 g, 200 mmol, previously rinsed with hexane) was cut into small pieces directly into a three-necked flask charged with anhydrous diethyl ether (85 ml) under argon. A few drops of a 1-bromopropane (12.3 g, 100 mmol) solution in 15 ml ether were added, and the mixture was stirred at ambient temperature until the reaction started. The mixture was then cooled to −20°C, and the remaining solution of bromopropane was added dropwise over 1.5 hr. When the addition was complete, the mixture was allowed to warm to room temperature and stirred for an additional hour before use.

The resulting propyllithium solution (~1.0 M in ethyl ether, 80 ml) was added dropwise to a suspension of lithium (*S*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate (*S*)-3 (9.63 g, 53.5 mmol) in Et_2O (100 ml) under argon at −30°C. The reaction was allowed to warm to room temperature, stirred overnight, poured into crushed ice, and extracted with Et_2O (3×100 ml). The combined organic layers were washed with saturated aqueous NH_4Cl and brine, dried, and concentrated. The residue was purified by vacuum flash chromatography on silica gel (hexane: EtOAc, 9:1) affording (*S*)-2-[(tetrahydro-2H-pyran-2-yl) oxy]-3-hexanone (*S*)-4 (9.14 g, 85%). ^{1}H-NMR (major isomer): δ 0.90 (t, *J*=7.4 Hz, 3H), 1.34 (d, *J*=7.0 Hz, 3H), 1.45–1.95 (m, 8H), 2.40 (dt, *J*=7.2 and 17.3 Hz, 1H), 2.50 (dt, *J*=7.3 and 17.3 Hz, 1H), 3.40–3.53 (m, 1H), 2.77–3.90 (m, 1H), 4.27 (q, *J*=7.0 Hz, 1H), 4.54 (dd, *J*=3.1 and 4.5 Hz, 1H). Some NMR signals overlapped with the

signals from the minor stereoisomer. MS (major stereoisomer): 156 (1), 129 (3), 101 (1), 99 (1), 85 (100), 71 (9), 67 (13), 57 (14), 55 (9), 43 (30), 41 (22). ^{1}H-NMR (minor isomer): δ 0.91 (t, *J*=7.4 Hz, 3H), 1.25 (d, *J*=6.8 Hz, 3H), 1.45–1.95 (m, 8H), 2.56 (dt, *J*=7.2 and 17.8 Hz, 1H), 2.62 (dt, *J*=7.4 and 17.9 Hz, 1H), 3.40–3.53 (m, 1H), 2.77–3.90 (m, 1H), 4.07 (q, *J*=6.8 Hz, 1H), 4.60 (dd, *J*=2.8 and 5.3 Hz, 1H). MS (minor stereoisomer): 156 (1), 129 (3), 101 (1), 99 (1), 85 (100), 71 (7), 67 (12), 57 (15), 55 (10), 43 (32), 41 (22).

(R)-2-[(Tetrahydro-2H-pyran-2-yl)oxy]-3-hexanone [(R)-4] Lithium (*R*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-propanoate (*R*)-3 (10.52 g, 58.4 mmol) and *n*-propyllithium (0.73 M in ethyl ether, 120 ml) were reacted as described above, giving (*R*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-3-hexanone (*R*)-4 (7.51g, 64%). NMR and mass spectra were in accord with those of the (*S*)-2-diastereomers.

(S)-2-Hydroxy-3-hexanone [(S)-5] Pyridinium-*p*-toluene sulfonate (100 mg) was added to a stirred solution of (*S*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-3-hexanone (*S*)-4 (9.1 g, 45.5 mmol) in methanol (100 ml) at 0°C under argon. The reaction was allowed to warm to ambient temperature and stirred overnight. The methanol was removed by fractional distillation under reduced pressure. Water was added to the residue, and the mixture was extracted with Et_2O (4× 30 ml). The organic phase was washed with saturated $NaHCO_3$ and brine and dried, and the solvent was removed by distillation through a Vigreux column. The residue was purified by vacuum flash chromatography (silica gel, eluting with pentane/Et_2O 9:1), removing the solvent by distillation through a Vigreux column, followed by Kugelrohr distillation (34°C, 1.60 mmHg), giving 2.53 g (48%) of (*S*)-2-hydroxy-3-hexanone (*S*)-5. The moderate yield was primarily a result of losses during purification because of the volatility of the compound, rather than to any problem with the chemistry. ^{1}H-NMR: δ 0.92 (t, *J*=7.4Hz, 3H), 1.36 (d, *J*=7.2 Hz, 3H), 1.58–1.72 (m, 2H), 2.39 (dt, *J*=17.0 and 7.3 Hz, 1H), 2.48 (dt, *J*=17.0 and 7.2 Hz, 1H), 3.57 (d, *J*= 4.5 Hz, 1H), 4.22 (dq, *J*=4.5 and 7.2 Hz, 1H). ^{13}C-NMR: δ 13.96, 17.29, 20.03, 39.60, 72.80, 212.80. MS: 116 (M^+, 1), 87 (1), 83 (1), 74 (12), 73 (36), 72 (19), 71 (64), 55 (59), 45 (87), 43 (100), 41 (19).

(R)-2-Hydroxy-3-hexanone [(R)-5] (*R*)-2-Hydroxy-3-hexanone was obtained in 49.6% yield (2.10 g) from (*R*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-3-hexanone (*R*)-4 after purification. NMR and mass spectra were identical to those of (*S*)-2-hydroxy-3-hexanone.

(S)-2-[(Tetrahydro-2H-pyran-2-yl)oxy]-3-hexanol [(S)-6] A solution of (*S*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-3-hexanone (*S*)-4 (10.00 g, 49.9 mmol) in ethanol (25 ml) was added dropwise to a stirred suspension of $NaBH_4$ (1.89 g, 50 mmol) in 25 ml ethanol at 0°C, and the mixture was stirred overnight. The mixture was concentrated, 100 ml brine added to the residue, and the product was extracted with ethyl acetate (5×50 ml). The combined organic phases were dried and concentrated. Purification by vacuum flash chromatography (hexane/EtOAc—9:1) afforded 9.08 g (90%) of product (*S*)-6. MS (*m/z*, rel. intensity): 158 (2), 157 (2), 129 (2), 101 (10), 85 (100), 67 (12), 57 (23), 56 (12), 55 (22), 45 (20), 43 (28), 41 (29). Because there were four stereoisomers in the product mixture, ^{1}H- and ^{13}C-NMR spectra were complex and not useful.

(R)-2-[(Tetrahydro-2H-pyran-2-yl)oxy]-3-hexanol [(R)-6] Compound (*R*)-6 was obtained in similar fashion with a 93% yield from (*R*)-2-[(tetrahydro-2H-pyran-2-yl) oxy]-3-hexanone (*R*)-4. Mass and NMR spectra were in accord with the (*S*)-6 mixture.

(2S,3S)-2,3-Hexanediol ((2S,3S)-7) and (2S,3R)-2,3-hexanediol [(2S,3R)-7] A solution of (*S*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-3-hexanol (*S*)-6 (9.05 g, 45 mmol) and 100 mg *p*-toluenesulfonic acid in methanol (50 ml) was stirred overnight. After concentration, the residue was diluted with ethyl acetate (100 ml) and washed with saturated aqueous $NaHCO_3$ and brine, dried, and concentrated. Purification by vacuum flash chromatography (hexane/EtOAc—4:1) followed by Kugelrohr distillation (90–98°C, 4.5 mmHg) gave a mixture of (2*S*,3*S*)-2,3-hexanediol (2*S*,3*S*)-7 and (2*S*,3*R*)-2,3-hexanediol (2*S*,3*R*)-7 (48:52, respectively). The diastereoisomeric diols (6.18 g) were separated by flash chromatography in 2-g batches (hexane/acetone—5:1; column 32 cm long×5 cm diameter) followed by recrystallization at 4°C (50 ml hexane/g of diol) affording 2.55 g of pure (2*S*,3*S*)-2,3-hexanediol (diastereomeric excess [de]>98%) and 2.89 g of (2*S*,3*R*)-2,3-hexanediol (de>96%). (2*S*,3*R*)-7: ^{1}H-NMR: δ 0.96 (t, *J*=6.8 Hz, 3H), 1.15 (d, *J*=6.4 Hz, 3H), 1.30–1.46 (m, 3H), 1.46–1.60 (m, 1H), 1.99 (br s, 2H), 3.62–3.67 (m, 1H), 3.76–3.84 (m, 1H). ^{13}C NMR: δ 14.29, 16.84, 19.39, 34.13, 70.67, 74.86. MS: 103 (1), 85 (1), 75 (10), 73 (61), 72 (34), 57 (18), 55 (100), 45 (36), 43 (35), 41 (11). (2*S*,3*S*)-7: ^{1}H NMR: δ 0.94 (t, *J*=7.2 Hz, 3H), 1.19 (d, *J*=6.4 Hz, 3H),1.34–1.58 (m, 4H), 2.43 (br s, 2H), 3.31–3.37 (m, 1H), 3.59 quint, *J*=6.2 Hz, 1H). ^{13}C NMR: δ 14.26, 18.96, 19.70, 35.69, 71.13, 76.16. (2R,3S)-2,3-Hexanediol ((2R,3S)-7) and (2R,3R)-2,3hexanediol [(2R,3R)-7] In analogous fashion, a mixture of (2*R*,3*S*)-2,3-hexanediol (2*R*,3*S*)-7 and (2*R*,3*R*)-2,3-hexanediol (2*R*,3*R*)-7 (51:49, respectively) was obtained

in 92% yield from (*R*)-2-[(tetrahydro-2H-pyran-2-yl)oxy]-3-hexanol (*R*)-6. After purification, 2.51 g of (2*R*,3*S*)-2,3-hexanediol (de>97%) and 2.41 g (2*R*,3*R*)-2,3-hexanediol (de>98%) were obtained. NMR and mass spectra matched those of the (2*S*,3*R*)- and (2*S*,3*S*)-enantiomers, respectively.

Field Bioassays of Synthetic Pheromone Aeration extracts from male *M. caryae* contained eight male-specific compounds (see "Results"). Initially, we predicted that the hexanediols would have the greatest activity, based on pheromones that have been identified for closely related beetle species (see "Introduction"). Therefore, field bioassays of the individual components (including citral in place of neral and geranial) were first conducted before mixtures of compounds were tested. Bioassays were conducted at Allerton Park (Piatt, IL), a 600-ha mixed hardwood forest that harbors a population of *M. caryae*, between 22 and 31 May 2004 (skies clear, air temperatures ~19–28°C, average wind speed 8–20 kph). Sticky card traps ("mouse glue trap" cards, 12.6×22 cm, baited, Victor® Pest Control Products, Lititz, PA) were stapled to 1.5-m-tall wooden stakes, with the middle of the card ~1 m above the ground. Traps were positioned 10 m apart in a straight line approximately perpendicular to the prevailing wind direction. Traps were baited with a cotton dental wick that was loaded with 5 mg of the compound in 0.1 ml of methylene chloride and attached to the middle of the card. There were seven treatments that were randomly assigned to traps, as follows: racemic (2*R**,3*S**)-2,3-hexanediol, (*S*)-(−)-limonene, 2-phenylethanol, (−)-α-terpineol, nerol, citral, and a solvent control. Release rates of these lures were unknown, but similar lures loaded with 2,3-hexanediols remained attractive to *N. a. acuminatus* for at least 18 hr (Lacey et al. 2004). The study was replicated five times. For each replication, traps were set up at 11:00 hours, captured beetles were removed from traps the following morning, and the numbers and sex of beetles responding to treatments were recorded.

The 2004 bioassay was conducted late in the activity period for *M. caryae*, when populations were declining, and trap catches were low (see "Results"). Therefore, the bioassay was repeated on 8–20 May 2005 at the same site (skies clear, air temperatures ~16–27°C, wind speed 8–20 kph). By that time, we had discovered that adult beetles could extract themselves from sticky cards (Lacey et al. 2007b) and, therefore, adopted cross-vane flight-intercept panel traps (black, 1.2×0.30 m, Intercept™, model PT, APTIV, Portland, OR) that had proven efficient in capturing other species of cerambycid beetles (Lacey et al. 2007b). Traps were positioned as described above, and test chemicals were applied neat to cotton dental wicks (except [2*R**,3*S**]-2,3-hexanediols, which were dissolved in 0.025 ml of hexanes) in uncapped 1-dram vials that were hung in the open central slot of each trap (Lacey et al. 2007b). The study was replicated five times as described above. Too few beetles were captured in both the 2004 and 2005 studies to warrant statistical analysis (see "Results").

Field bioassays of blends of synthetic compounds were conducted in an abandoned plantation of mixed tree species ~1 km south of the campus of the UIUC in April to May 2006 (skies clear, air temperatures ~19–28°C, wind speed ~8–20 kph). A subtractive scheme was used to compare activity of the complete blend with seven treatments that each lacked a different component, as well as a solvent control. We used the same panel traps and lures as described above. The lures were baited with pheromone components, each diluted in 0.025 ml hexane, in ratios that approximated the mean relative abundances in extracts from aerations of males (see "Results") with two exceptions: (1) The relative proportions of hexanediols were increased because other cerambycine species had responded to relatively high quantities of similar compounds (see Lacey et al. 2004, 2007b) and (2) the total proportion of citral was decreased to compromise between the high proportion of geranial and lower proportion of neral that are produced by males (see "Results"). Lure quantities were: (2*S*,3*R*)-2,3-hexanediol (2.5 mg), (2*R*,3*S*)-2,3-hexanediol (0.5 mg), (*S*)-(−)-limonene (1.5 mg), 2-phenylethanol (5 mg), (−)-α-terpineol (5 mg), nerol (2 mg), citral (12 mg), and the control (0.175 ml hexane). Traps were positioned 8 m apart in transects approximately perpendicular to the direction of the prevailing wind. On each date, traps were baited at 10:00 hours, and beetles were collected at ~18:00 hours. Traps were cleaned with glass cleaner (Windex®, S. C. Johnson & Sons, Racine, WI) and lures replaced each day. The bioassay was replicated 14 times. Overall differences between treatments in numbers of beetles captured were tested by one-way analysis of variance (ANOVA), and differences between pairs of treatment means were subsequently tested with the least significant difference test (Analytical Software 2000). Three replicates that captured fewer than four beetles were excluded from the data analysis.

Results

Testing for Attractant Pheromones In olfactometer bioassays, 100% of female and 90% of male *M. caryae* responded by walking upwind. Of the 20 females that were tested, 19 were attracted to odor emitted by males and only one responded to odor of females. Males showed a similar response, with 16 responding to odor of males and only two responding to odor from females ($\chi^2_{1,\ 18}=21.8$, $P<0.001$).

Identification of Potential Pheromone Components GC-MS analysis of volatiles produced by male *M. caryae* revealed seven peaks that were absent in analogous samples of females. The first compound to elute (Fig. 2) was tentatively identified as 2,3-hexanediol, with a mass spectral base peak at *m/z* 55 (100) and characteristic mass fragments at *m/z* 75 (10), 73 (61), 72 (34), 45 (36), and 43 (35). The identification was confirmed by matching the mass spectrum and the retention time with those of an authentic standard of (2*R**,3*S**)-2,3-hexanediol; this diastereomer is completely resolved from the (2*R**,3*R**)-2,3-diastereomer on a DB5-MS column (Lacey et al. 2004). The enantiomeric composition of the insect-produced compound was determined to be a ~10:1 mix of (2*S*,3*R*)- and (2*R*,3*S*)-2,3-hexanediols by analysis on the Cyclodex-B column, with baseline resolution of the enantiomers. These diols represented 3.2±1.3% (*N*=7 aeration extracts) of the total male-specific compounds. The remaining compounds, in order of elution (Fig. 2), were (*S*)-(−)-limonene (3.1±1.7%), 2-phenylethanol (8.0±2.4%), (−)-α-terpineol (10.0±2.8%), nerol (2.1±1.5%), neral (63.3±7.3%), and geranial (8.8±2.4%). These compounds were tentatively identified by mass spectral fragmentation patterns, and the identifications were confirmed by retention time and mass spectral matches with authentic standards. The absolute configurations of those compounds that were chiral were determined by analyses and coinjections with appropriate standards on the Cyclodex-B GC column. Relative abundances of compounds varied between samples, with neral, 2-phenylethanol, (−)-α-terpineol, and geranial always being most abundant, whereas the hexanediols, (*S*)-limonene, and nerol were not detectable in some samples. We have found that beetles of other cerambycine species also produce pheromone sporadically under the conditions of aeration in closed chambers (unpublished data).

Syntheses of Pheromone Components Chiral 2,3-hexanediols were synthesized by modification and extension of the strategy developed by Hall et al. (2006) to produce chiral 2-hydroxy-3-decanones (Fig. 1). Thus, the alcohol function

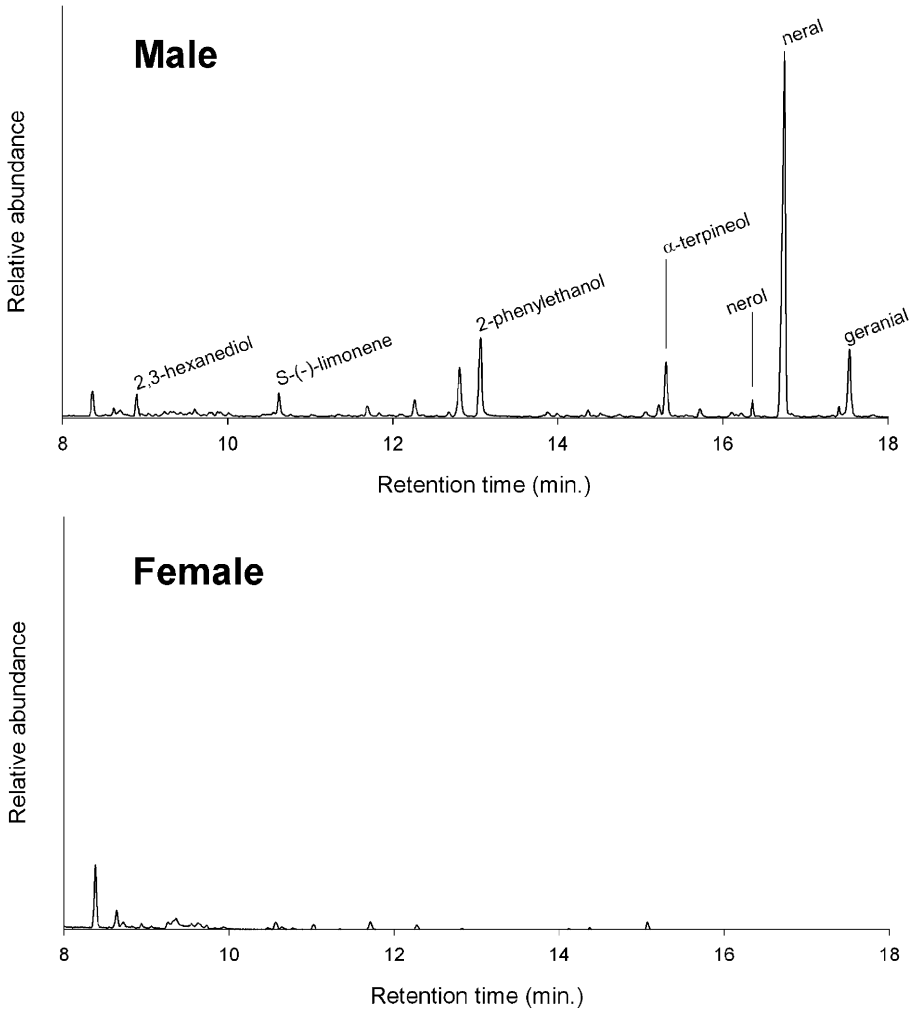

Fig. 2 Representative total ion chromatograms of extracts of headspace volatiles produced by male (*top*) and female (*bottom*) *Megacyllene caryae*

of ethyl (*S*)-(−)-lactate (*S*)-1 was protected as the tetrahydropyranyl (THP) ether (*S*)-2, followed by hydrolysis of the ester group to give the lithium salt of the carboxylic acid (*S*)-3 in quantitative yield. Alkylation of the salt with propyllithium in ether then yielded the THP-protected 2-hydroxy-3-hexanone (*S*)-4. (2*S*,3*R*)- and (2*S*,3*S*)-2,3-hexanediols were produced by reduction of THP-protected 2-hydroxy-3-hexanone (*S*)-4 with sodium borohydride in ethanol, giving the monoprotected diols mixture (*S*)-6. Acid-catalyzed removal of the THP group gave a diastereoisomeric mixture of (2*S*,3*R*)-2,3-hexanediol [(2*S*,3*R*)-7) and (2*S*,3*S*)-2,3-hexanediol ((2*S*,3*S*)-7]. The diastereomers were separated by flash chromatography on silica gel followed by recrystallization from hexanes, giving the two diols in high purity (>96% de). Analogous results were obtained for the syntheses of (2*R*,3*R*)-2,3-hexanediol [(2*R*,3*R*)-7) and (2*R*,3*S*)-2,3-hexanediol ((2*R*,3*S*)-7] starting from THP-protected hydroxyketone (*R*)-4.

Alternatively, removal of the THP group from compound 4 with acid catalysis in methanol gave (*R*)- and (*S*)-2-hydroxy-3-hexanones, (*R*)- and (*S*)-5, both of which are known pheromone components for cerambycid beetles (see Hanks et al. 2007). GC analysis on a Cyclodex-B column confirmed that no isomerization or racemization (see Lacey et al. 2007b) had occurred during the synthesis.

Field Bioassays of Synthetic Pheromone In field bioassays that tested the activity of individual compounds, sticky traps captured a total of two *M. caryae* in 2004, and panel traps captured a total of five in 2005. We concluded from this experiment that probably neither the 2,3-hexanediols nor any of the other compounds in the volatile blend produced by males were attractive to adult *M. caryae* as single components.

In bioassays that tested blends of components in 2006, traps captured 147 adult *M. caryae* (76 females and 71 males; sex ratio not significantly different from 1:1, $\chi^2_{1,\ 147}=0.17$, $P>0.05$). Treatments differed significantly in numbers of *M. caryae* that were captured (Fig. 3; sexes combined, overall ANOVA $F_{10,\ 147}=9.56$, $P<0.001$). The greatest numbers of beetles were captured in traps baited with the complete blend of pheromone components, whereas trap catches were reduced by ~50% in treatments that were missing (*S*)-(−)-limonene, 2-phenylethanol, (−)-α-terpineol, or nerol and reduced to levels not significantly different from controls in treatments missing (2*S*,3*R*)-2,3-hexanediol, (2*R*,3*S*)-2,3-hexanediol, or citral (Fig. 3).

Discussion

Attraction of both sexes of *M. caryae* to odor produced by live males in olfactometer bioassays provided the first evidence that males produce an aggregation pheromone. That this was an aggregation pheromone and not a sex pheromone was confirmed during field bioassays with synthetic pheromone, in which similar numbers of males and females were attracted to baited traps.

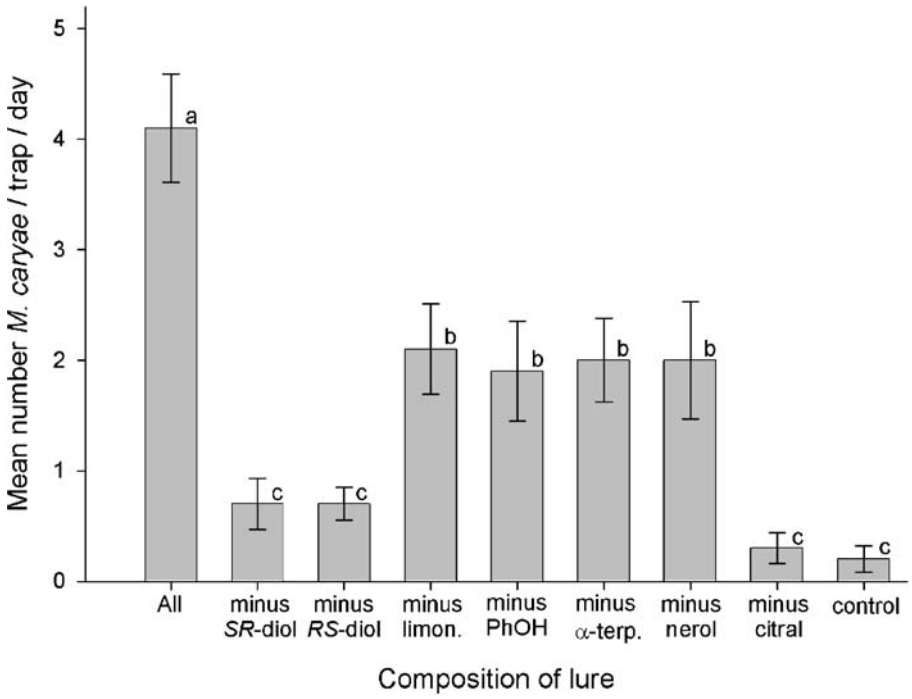

Fig. 3 Relationship between mean (±SEM) number of adult *Megacyllene caryae* caught in cross-vane panel traps (sexes combined) and composition of the lure. Treatments included the complete blend of synthetic components (All), and the complete blend minus (2*S*,3*R*)-2,3-hexanediol, (2*R*,3*S*)-2,3-hexanediol, (*S*)-(−)-limonene, 2-phenylethanol (*phoh*), (−)-α-terpineol, nerol, and citral (a 1:1 blend of neral and geranial), and a solvent control. *Means with different letters* are significantly different (LSD tests; $P<0.05$)

Although (2*S*,3*R*)- and (2*R*,3*S*)-2,3-hexanediol constituted only about 3 and 0.3%, respectively, of the total blend of volatile compounds produced by males, absence of either in synthetic blends resulted in a significant loss of activity. This finding indicated that adult *M. caryae* are sensitive to both components, unlike other clytine species that produce blends of enantiomers but respond strongly to the dominant component alone (see Hanks et al. 2007). Among the remaining components, one or both isomers of citral (neral or geranial) were equally as important to attraction as were the 2,3-hexanediols. Whereas the remaining components ([*S*]-[−]-limonene, 2-phenylethanol, [−]-α-terpineol, and nerol) increased attraction significantly, they were not necessary for attraction because beetles showed a partial response to blends lacking these compounds. The increased response of adult *M. caryae* to the complete blend of synthetic compounds confirmed that all of these compounds have a role in the natural pheromone blend.

The structure of the hexanediols produced by male *M. caryae* is consistent with the diol/hydroxyketone structural motif of pheromones reported for another 12 species in the subfamily Cerambycinae (see "Introduction"). To our knowledge, this motif is unique to cerambycine beetles. Whereas exceptions to the motif have been identified from two cerambycine species (see "Introduction"), the complex blend of compounds produced by male *M. caryae*, in addition to the components that are consistent with the structural motif, is unprecedented among cerambycines that have been studied to date.

All of the terpenoids and 2-phenylethanol produced by male *M. caryae* have been identified as pheromones of species in a broad range of insect and arachnid orders, serving a variety of behavioral functions (see Mayer and McLaughlin 1991). These compounds are also common in essential oils of plants (Budavari 1996), suggesting that beetles might acquire them from their host plants. However, it seems more likely that beetles produce the compounds *de novo* because adult male *M. caryae* from which volatile compounds were collected had been reared in the laboratory and so had not been exposed to host plants of adults.

Previous research suggests that the compounds produced by male *M. caryae* may have semiochemical functions in other species of cerambycids. For example, in electroantennograph studies of potential host plant volatiles, antennae of both sexes of *Xylotrechus pyrrhoderus* Bates and *Arhopalus tristis* (F.) responded to citral and α-terpineol, respectively (Iwabuchi et al. 1985; Suckling et al. 2001). Both α-terpineol and limonene were repellent to adult *Semanotus japonicus* Lacordaire in choice bioassays (Yatagai et al. 2002). Male *Xylotrechus quadripes* Chevrolat produce 2-phenylethanol, although it does not appear to be a pheromone component (Hall et al. 2006). A similar compound, 1-phenylethanol, is produced from metasternal glands of a congener of *M. caryae*, *M. robiniae*, and has been suggested to serve in defense against natural enemies (Wheeler et al. 1988). The fact that the terpenoids of *M. caryae* are produced by only one sex suggests that they are unlikely to have a defensive function.

The preparation of (2*S*,3*R*)- and (2*S*,3*S*)-2,3-hexanediols (and their enantiomers) in high diastereomeric and enantiomeric purity took advantage of the fact that during nonselective syntheses of mixtures of all four diol stereoisomers by the reduction of 2,3-hexanedione (Hanks et al. 2007), we observed that the diastereomeric 2,3-hexanediols were readily separable in gram quantities by flash chromatography. Thus, we reasoned that nonselective reduction of the ketone function of a chiral, THP-protected 2-hydroxy-3-hexanone precursor, in which the configuration at the carbon bearing the protected alcohol was fixed and known, should produce a mixture of the two diastereomers, each in high enantiomeric purity. Reduction of THP-protected (*S*)-2-hydroxy-3-hexanone (*S*)-4 gave an approximately 1:1 ratio of the two expected alcohol products. Removal of the THP-protecting group and separation of the resulting diol diastereomers by flash chromatography gave the (2*S*,3*R*)- and (2*S*,3*S*)-stereoisomers in quantities of several grams. Analogous reaction of the THP-protected (*R*)-2-hydroxy-3-hexanone (*R*)-4 gave the other two stereoisomers. Thus, this synthetic strategy provided ready access to all four 2,3-hexanediols in high stereoisomeric purity from readily available lactate ester synthons. In contrast, our previous syntheses of 2,3-hexanediol stereoisomers using the Sharpless asymmetric dihydroxylation protocols (Kolb et al. 1994) had produced diols with only 80–90% ee (Lacey et al. 2004). The synthetic strategy described above also has advantages in comparison to previously published syntheses of the 2,3-hexanediol stereoisomers, in which each stereoisomer was synthesized individually from a different chiral precursor (Schröder et al. 1994). It should also be noted that exactly the same strategy can be applied to the syntheses of the homologous 2,3-octanediols and 2,3-decanediols, compounds that also may be pheromone components of cerambycid beetles (e.g., Hall et al. 2006). This straightforward method of producing multigram quantities of all four stereoisomers of 2,3-alkanediols of any desired chain length should prove beneficial in the unraveling of pheromone blends for other cerambycid species.

A Simple, Convenient, and Efficient Preparative GC System that Uses a Short Megabore Capillary Column as a Trap

Satoshi Nojima · Charles S. Apperson · Coby Schal

Received: 11 October 2007 / Revised: 16 January 2008 / Accepted: 18 January 2008 / Published online: 23 February 2008

Abstract A simple, convenient, and highly efficient preparative GC system has been developed that uses short sections of megabore capillary columns as sample collection (sorbent) traps. The performance of this system with various types of capillary column traps and under various collection conditions was systematically investigated with model compounds, including C4 to C20 normal alkanes, esters, and alcohols. The thickness and polarity of the sorptive stationary phase and the temperature of the collection trap affected trap performance. Each group of compounds was efficiently trapped above a critical Kovat's index, and the type of trap (deactivated, methyl polysiloxane, polyethylene glycol), film thickness, and whether or not the trap was cooled significantly shifted this threshold index. Above this critical index, recovery efficiencies of traps with methyl polysiloxane films were 80–100% for a wide range of injected sample mass. For example, a DB-1 collection trap with a film thickness of 1.5 μm methyl polysiloxane operated at ambient temperature trapped >84% of the mass of injected compounds of all three chemical classes with Kovat's index >1,100 (determined on a nonpolar column) with injected sample mass ranging from 10 to 1,000 ng of each compound. This preparative GC system is technically and economically feasible for most researchers. Furthermore, it is suitable for the preparation of NMR samples of volatile and semivolatile compounds, especially with sample sizes ranging from several nanograms to several micrograms.

Introduction

The identification of semiochemicals is an essential step for understanding chemically mediated behavioral and ecological interactions. Numerous substances have been identified, and the databases of these compounds have grown exponentially in recent years. Nonetheless, identification of semiochemicals, some of which occur in trace amounts, remains an arduous but indispensable prelude for the ensuing basic and applied research.

The isolation and purification of active compounds are key steps in a bioassay-guided identification process, and preparative GC is a powerful purification technique for volatile and semivolatile compounds (Heath and Dueben 1998). However, there are several technical and practical constraints associated with preparative GC: (1) the necessity to condense volatile compounds by cooling the collection trap with a refrigerant, commonly dry ice, dry ice/acetone, or liquid nitrogen (Heath and Dueben 1998), a rather inconvenient process that makes rapid exchanges of traps cumbersome and time-consuming; (2) low, unsatisfactory recovery efficiency of volatile compounds; and (3) expense and difficulty of setting up a commercial instrument or of fabrication of a custom-built system.

Capillary collection traps, or open tubular traps (OTT), have been used to enrich and concentrate volatile organic compounds from the headspace of various samples for GC/

GC-MS analyses of environmental and food samples (Baltussen et al. 2002; Pillonel et al. 2002; Kloskowski et al. 2007). This technique was first developed by Grob and Habich (1985), and later, Blomberg and Roeraade (1987) applied it to volatile collection from preparative GC with the advantage of high recovery efficiencies of volatiles without cryogenic trapping. They suggested that this preparative GC technique could be an attractive approach for many applications. However, in the last two decades, there has been limited practical application of their innovation (Shimoda et al. 1993, 1996).

The parameters involved in sample collection for both instrumental analyses and preparative GC by using OTT appear to be the same. Although many parameters that influence the trapping efficiency of OTT for sample enrichment have been studied (Grob and Habich 1985; Burger and Munro 1986, 1987; Blomberg and Roeraade 1987; Cao and Hewitt 1992; Zhirong et al. 1999; Pettersson et al. 2004), most previous methodological studies were done with custom-made super thick film OTT along with custom-made sample collection and desorption devices and custom-modified instruments mainly for gaseous and solvent-like highly volatile compounds such as environmental pollutants. For example, Blomberg and Roeraade (1987) used custom-made 200 cm, 80 μm silicon film collection traps for preparative GC for compounds ranging from solvent-like to C12 hydrocarbon. In practical applications, however, it is convenient and cost-effective to use commercially available materials with standardized parameters that should yield more consistent results. Moreover, there has not been extensive and systematic evaluation of OTT performance for preparative GC collection especially for volatile and semivolatile semiochemicals.

Nojima et al. (2004) previously reported on a manual preparative GC system, which is relatively simple and inexpensive and achieves high recovery efficiency by using cryogenic trapping with a short section of a deactivated megabore capillary tube. This system has facilitated the efficient purification of semiochemicals for NMR analysis even at the submicrogram scale and has been used for structure elucidation of a few micrograms of a thermally and chemically unstable female sex pheromone of the German cockroach (Nojima et al. 2005). Nevertheless, this preparative system requires some familiarity with instrumentation, a refrigerant for cryogenic trapping, and a major drawback is that it is not suitable for sequential fractionation of multiple compounds within a single GC run.

In this study, we report a further improvement of this preparative GC approach that consists of a simple modification of a regular GC system coupled to an OTT sample collection by utilizing only commercially available materials and systematic evaluation of the system by using a wide range of model compounds.

Methods and Materials

Chemicals Straight chain methyl esters (C4–C16), hydrocarbons (C7–C20), and alcohols (C4–C16) were obtained from Supelco (Bellefonte, PA, USA) or Aldrich (Milwaukee, WI, USA).

Preparative GC

Modification of the GC An HP5890 gas chromatograph was converted to a preparative GC. Schematic diagrams of the preparative GC configuration and outlet port assembly are shown in Fig. 1. A split–splitless (S/SL) injection port assembly equipped with heat sink, heater cartridge, and sensor was used for the preparative GC outlet port and installed adjacent to the FID port. The heater and sensor were connected to the control ports assigned to detector B so that the temperature of the preparative GC outlet port could be controlled and monitored as "detector B."

The S/SL injection port was modified to an outlet port for the preparative GC as follows (Fig. 1a–c). The septum well on the weldment nut, which is welded to 1/16″ tubing

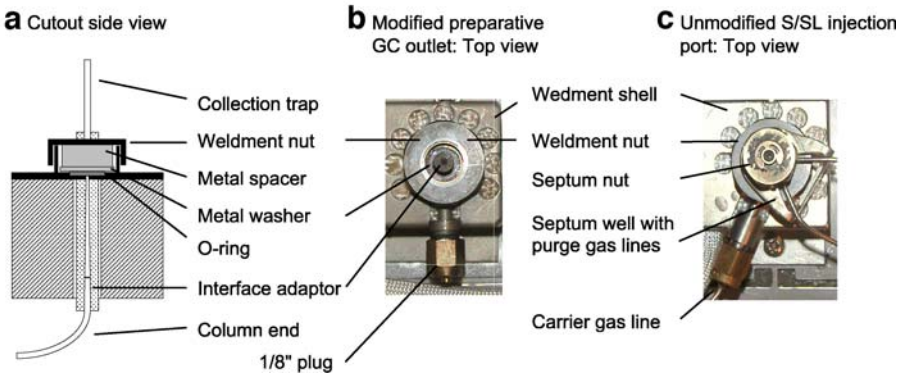

Fig. 1 **a–c** Schematic diagrams of the preparative GC configuration and outlet port assembly

for the purge gas and retained on the weldment nut by a retainer ring, was removed from the injection port. The metal spacer, used for supporting the weldment nut against the septum well, was kept and utilized for fixing an interface adaptor between the column end and collection traps. The carrier gas line welded to the shell weldment was sealed with a 1/8″ stainless steal plug (Swagelok®) (Fig. 1b).

Installation of a megabore capillary column The distal column end was cut with a column cutter, and finger lipids and other contaminants were removed by wiping with methanol-wetted tissue paper. The column end was inserted into the preparative GC outlet port so that its end protruded several centimeters above the port. A direct injection glass liner (1 mm Uniliner® for 0.32/0.53 mm ID, columns, 1.0 mm ID, 6.3 mm OD×78.5 mm; Restek, Bellefonte, PA, USA) was used as an interface adaptor between the column end and collection trap (Fig. 1a and b). The column was pushed into the longer tapered seat of the liner to make a securely tight seal. Then, the glass liner–column assembly was retracted into the outlet port. An O-ring for inlet glass liners for Agilent GCs (6.3–6.5 mm ID), a flat stainless steel washer (6.7 mm ID, 17.2 mm OD), and the metal spacer that was taken from the septum well were put on the liner in this order (Fig. 1a). Then, the weldment nut was put on the glass liner, finger-tightened, and then tightened with a wrench while holding the glass liner with clean forceps. It was important to avoid rotating the glass liner while tightening the weldment nut to prevent twisting and stressing the connection between the glass liner and the column. Any tension at this connection may result in an unexpected detachment of the column under frequent temperature/pressure fluctuations and vibrations from the oven fan. The end of the column was not fixed to the modified S/SL outlet port with a column nut and ferrule to provide some free rotation for the column.

Collection traps Sections (40 cm) of various types of megabore (0.53 mm ID) capillary columns were used as collection traps: (a) collection traps without stationary phase whose inner surface was deactivated (Agilent Technologies, Santa Clara, CA, USA); (b) nonpolar collection traps on which a methyl polysiloxane film was bonded at a film thickness of 0.5, 1.5, or 5.0 μm (DB-1, Agilent Technologies); and (c) a polar collection trap on which polyethylene glycol film was bonded at a film thicknesses of 1.5 μm (Stabilwax®, Restek, Bellefonte, PA, USA). The collection traps were rinsed twice with 100 μl of methylene chloride and dried at room temperature overnight. Both ends of the collection traps were cut and cleaned with methanol on tissue paper. For reuse, the traps were reconditioned by rinsing with solvent, and the trap was carefully examined for a square and even end for a secure connection to the interface adaptor.

Preparative GC conditions A nonpolar EC-5 megabore capillary column (1.0 μm film thickness, 0.53 mm ID× 30 m, Alltech Associates, Deerfield, IL, USA) was used as a separation column, and a 2-m deactivated column (0.53 mm ID, no stationary phase; Alltech Associates) was connected to the front of the separation column with a press fit connector (Alltech Associates). Helium was used as the carrier gas at a head pressure of 27.6 kPa and a flow rate of 5.5 ml min^{-1}. The oven temperature was set at 45°C for 2 min, increased at 15°C min^{-1} to 250°C, and held for 5 min. The injector and collection port temperatures were held at 270°C and 250°C, respectively. The septum purge flow rate was set at 3 ml min^{-1} with a total flow rate of 22 ml min^{-1} in the split injection mode (split ratio of 1:5), whereas the total flow rate was set at 50 ml min^{-1} in the splitless injection mode with the purge valve off for 1 min. Retention times of model compounds were established before preparative GC work by FID under the same analytical conditions. The Kovat's retention indices (Heath and Dueben 1998) of model compounds were estimated by retention times of straight chain hydrocarbons.

Sample Collection and Compound Recovery from Traps

Sample collection For collection with cryogenic trapping, a detachable and well-insulated sheath equipped with a reservoir for a refrigerant was used to cool the collection traps (Fig. 2a; see detail in Nojima et al. 2004). The reservoir cup was filled with dry ice, and a collection trap was inserted into the sheath for equilibration. To collect compounds, the trap–sheath assembly was connected to the interface adaptor in the outlet port by gently pushing the trap end into the tapered seat of the adaptor just before a sample collection window. A gentle connection gave a secure seal that resulted in high recovery efficiencies and facilitated easy, smooth, and quick exchanges of collection traps for multiple collections. A tighter connection may cause breakage of the tip of the collection trap during trap exchanges, resulting in poor recovery when column fragments were in the glass liner. We found that a syringe cleaning wire (0.17 mm OD; Hamilton, Reno, NV, USA) worked well to remove column fragments from the adaptor. During the collection, the lower end of the cooling sheath was kept in contact with the interface adaptor so that a gradual cooling zone was generated along the collection trap for better recovery efficiencies (Brownlee and Silverstein 1968). At the end of a sample collection window, the collection trap was withdrawn together with the sheath; the trap was pulled out from the sheath and set up on a lab

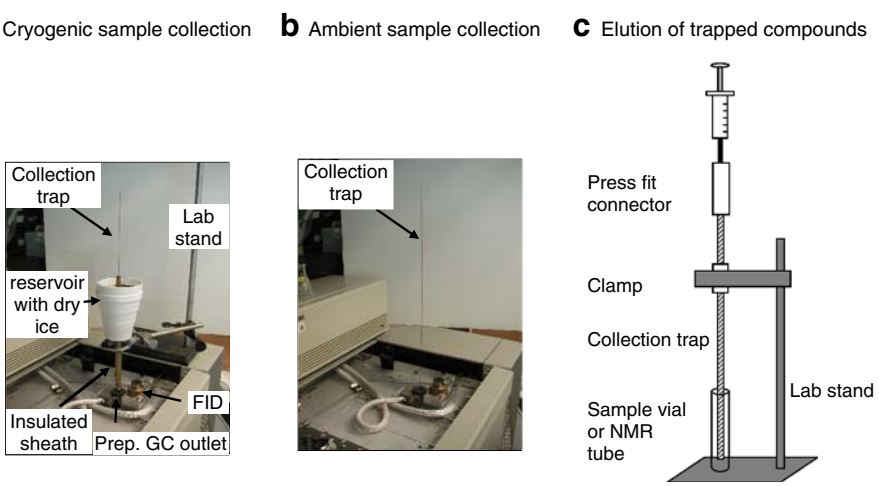

Fig. 2 Sample collections under cryogenic (**a**) and ambient (**b**) conditions, and sample elution from the trap (**c**)

stand for the extraction step. For a long collection, a lab stand and a clamp were used to hold the sheath (Fig. 2a).

For sample collection at ambient temperature, a clean collection trap was connected to the interface adaptor as described above. The connection between the trap and the adaptor was secure enough to hold the 40-cm collection trap without any other support (Fig. 2b).

Elution of compounds from the traps The collection trap was set up vertically on a lab stand as shown in Fig. 2c. A press fit connector was attached to the upper end of the trap, and the other end was put into a sample vial. Then, a GC syringe was used to introduce solvent containing an internal standard into the press fit connector. In a preliminary experiment, compounds trapped on various types of collection traps were fully extracted with 40 μl of hexane, methylene chloride, or ether; 10 μl methylene chloride was found to be sufficient to extract trapped compounds for qualitative analyses.

Analytical GC conditions Sample analysis was conducted on an HP5890 GC equipped with a nonpolar EC-5 capillary column (0.25 μm film thickness, 0.25 mm ID×30 m; Alltech Associates). Helium was used as the carrier gas at a head pressure of 115 kPa (flow rate, 1.5 ml min^{-1}). Oven temperature was set at 50°C for 2 min, increased at 15°C min^{-1} to 250°C, and held for 5 min. The injector and detector temperatures were set at 270°C. Septum purge flow rate was set at 3 ml min^{-1} with a total flow rate of 14 ml min^{-1} in the split injection mode (split ratio of 1:10), whereas a total flow rate was set at 50 ml min^{-1} in the splitless injection mode with the purge valve off for 1 min.

Experiment 1: qualitative comparison of various types of collection traps under ambient and cryogenic conditions The trapping capabilities of deactivated capillary tubes (0 μm film), DB-1 capillary tubes with a film thickness of 1.5 μm, and Stabilwax® capillaries with a film thickness of 1.5 μm were compared. A mixture of model compounds that included straight chain methyl esters (C4–C16), hydrocarbons (C7–C20), and alcohols (C4–C16) in methylene chloride at a concentration of 300 ng μl^{-1} each was used for this experiment. One microliter of the mixture was injected into the preparative GC in split mode (split ratio of 1:5) so that the C4 ester, methyl butanoate, separated from the solvent peak that obscured it in the splitless injection mode. The collection window was 2 to 18.5 min, so that all compounds from a single injection were collected in the same collection trap (Fig. 3). The collections were made both under cryogenic and ambient conditions. Trapped compounds were eluted with 10 μl methylene chloride, and 2 μl of each extract were analyzed in split mode at a split ratio 1:5. Two replicates were made for each trapping condition.

Experiment 2: qualitative comparison of various film thicknesses of DB-1 collection traps under ambient and cryogenic conditions. The same collections were made using DB-1 capillary traps with film thicknesses of 0.5, 1.5, and 5.0 μm. Trapped compounds were recovered and analyzed as described above.

Experiment 3: quantitative comparison of the trapping efficiencies of various film thicknesses of DB-1 collection traps at ambient temperature. Mixtures of model compounds at concentrations of 10, 100, and 1,000 ng μl^{-1} of each compound in hexane were used for this experiment. For deactivated collection traps (0 μm film), a mixture of C13–C16 methyl esters, C16–C19 hydrocarbons, and C13–C16 alcohols was used, whereas for DB-1 collection traps (which exhibited better trapping capabilities in preliminary studies), a mixture of C8–C11 methyl esters, C11–C14 hydrocarbons, and C8–C11 alcohols was used. One microliter of each mixture was injected into the preparative GC in

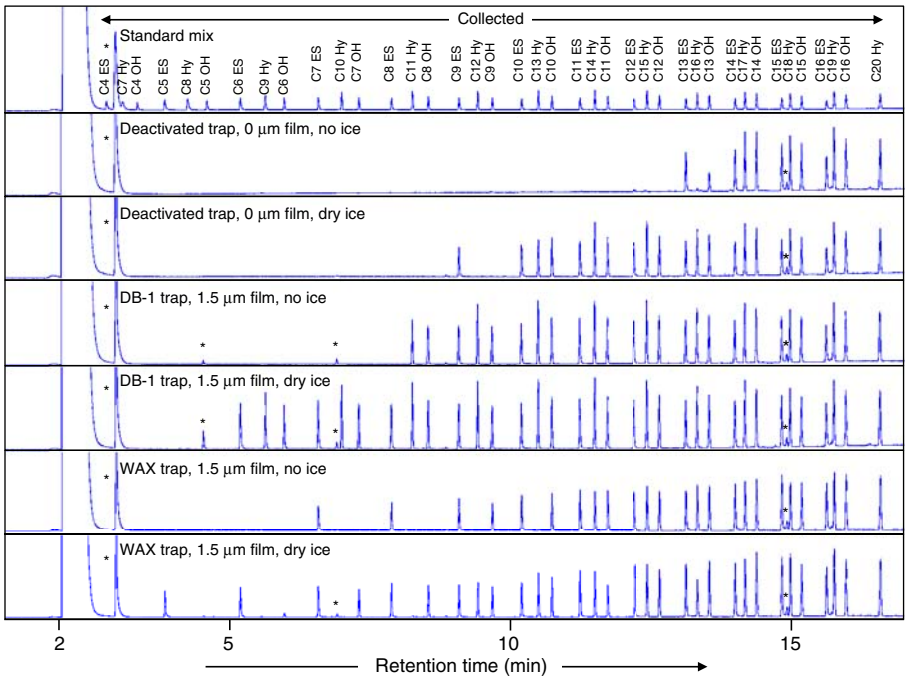

Fig. 3 A comparison of trapping of model compounds by three types of collection traps under ambient and cryogenic conditions. One microliter of a mixture of straight chain methyl esters (C4–C16), hydrocarbons (C7–C20), and alcohols (C4–C16) at a concentration of 300 ng μl^{-1} per compound was injected into the preparative GC in split mode, and all compounds were collected in a single collection trap between 2 and 18.5 min of each run. Collections were made with both dry ice and at ambient temperature. Trapped compounds were eluted with methylene chloride, and the extracts were analyzed by GC-FID. *Asterisks* indicate impurities that likely originated from the instrument, the solvent, and not from the traps (see text)

splitless mode, and all compounds in the mixture were collected in the same collection trap during each run. The collection windows were 13–18 min for deactivated collection traps and 8–13.5 min for DB-1 collection traps. All collections were made at ambient temperature. Trapped compounds were eluted with 20 µl hexane, then 10 µl hexane containing 500 ng pentacosane internal standard, and then an additional 20 µl hexane. Extracts were combined, and 1 µl of each sample was subjected to quantitative (FID) GC analysis in splitless mode. Five replicates were made for each trap condition.

Experiment 4: qualitative analysis of distribution of trapped compounds in the collection traps. We used the same mixtures of compounds at a concentration of 1,000 ng μl^{-1} each compound, and the same conditions described above for deactivated and DB-1 collection traps. After the collections, each 40 cm collection trap was cut into 10 cm sections, and each was eluted with 20 µl hexane, then 10 µl hexane containing 500 ng pentacosane internal standard, and then an additional 20 µl hexane. One microliter of each extract was analyzed by GC-FID in splitless mode. Two replicates were made for each collection trap.

Experiment 5: a practical collection trial. A mixture of C4–C12 methyl esters, C7–C15 hydrocarbons, and C4–C12 alcohols in methylene chloride, at a concentration of 300 ng μl^{-1} each compound, was used for this experiment. One microliter of this mixture was injected into the preparative GC in splitless mode, and compounds were collected in groups of similar retention index (a C_n methyl ester, $C_{(n+3)}$ hydrocarbon and C_n alcohol; Fig. 7), except for the last three groups that were collected together in the same DB-1 trap with 1.5 µm film thickness. Each collection window for a group was about 1 min except for the last three groups. Trapped compounds were eluted with 20 µl hexane, and 1 µl of each extract was injected into a GC-FID in split mode at a split ratio 1:16.

Results and Discussion

Experiment 1: Qualitative Comparison of Various Types of Collection Traps under Ambient and Cryogenic Conditions

Trapping of model compounds in megabore collection traps varied with trap type and whether or not we used cryogenic conditions (Fig. 3). Cooling the collection traps with dry ice greatly increased the trapping capabilities of various types of collection traps. At ambient temperature, a deactivated megabore column (0 µm film) failed to trap all three compound types at or below a retention index of about 1600 (on an EC-5 column), but with cryogenic trapping the same trap was effective down to 1300. Addition of a nonpolar stationary phase (DB-1, 1.5 µm film thickness) extended the range of compounds trapped down to 1100 without cooling and to 900 with dry ice. Although a polar megabore collection trap (Stabilwax®, 1.5 µm film thickness) was less effective at trapping hydrocarbons than the DB-1 trap, the WAX trap effectively trapped the C7 ester (retention index 1000) at ambient temperature and down to a C5 ester (retention index 800) with dry ice (Fig. 3). Thus,

the presence of a stationary phase greatly improved the trapping capabilities of collection traps, and cryogenic conditions (with or without stationary phase) extended the range of compounds trapped to a lower retention index. As in gas chromatography, it appears that both the affinity of compounds to the film and their volatility play important roles in the effectiveness of WAX collection traps. Although the WAX trap was more effective for esters, DB-1 traps are more suitable for practical use because this nonpolar stationary phase effectively traps highly volatile compounds and is less selective of the three chemical classes we tested. Moreover, bonded DB-1 columns tolerate both high temperatures and repeated solvent extractions.

It is important to note that even without cooling the collection trap, the addition of a stationary phase to the megabore traps vastly improved their trapping effectiveness of early eluting compounds, which practically covers a wide range of volatile–semivolatile semiochemicals. The stationary phase alleviates the need to use a refrigerant, which has been a rather inconvenient process that makes rapid exchanges of traps cumbersome and time-consuming.

Contamination is often a serious issue in preparative GC, especially when collecting minute amounts of sample. Several minor contaminants (asterisks in Fig. 3; see also experiment 2; Fig. 4) likely originated from the instrument or extraction solvents and not from traps because the contaminants became negligible after repeated sample processing (see Figs. 6 and 7).

Experiment 2: Qualitative Comparison of Various Film Thicknesses of DB-1 Collection Traps under Ambient and Cryogenic Conditions

We compared the trapping effectiveness of various film thicknesses of DB-1 collection traps. Under ambient trap conditions, a collection trap with a film thickness of 5.0 μm consistently trapped compounds of retention index 1000 and above, whereas 1.5 and 0.5 μm films trapped above 1100 and 1200, respectively (Fig. 4). All three film thicknesses trapped smaller hydrocarbons and alcohols, but not esters. The addition of cryogenic conditions extended the range of compounds trapped by 2C units to retention indices of 800 for 5.0 μm, 900 for 1.5 μm, and 1000 for 0.5 μm films. Thus, traps with thicker films were more effective than traps with thinner films. However, the addition of more stationary phase to traps already containing the same phase yielded only moderate benefits compared to the initial addition of a sorptive phase to traps without film or the choice of polar or nonpolar phase. Nevertheless, with dry ice cooling, the effectiveness of DB-1 collection traps with a film thickness of 5.0 μm extended to solvent-like compounds, C5 ester, C8 hydrocarbon, and C5 alcohol. Based on these results, we expect that thicker films on WAX collection traps will also extend the trapping effectiveness of polar compounds that elute earlier than C4 alcohol.

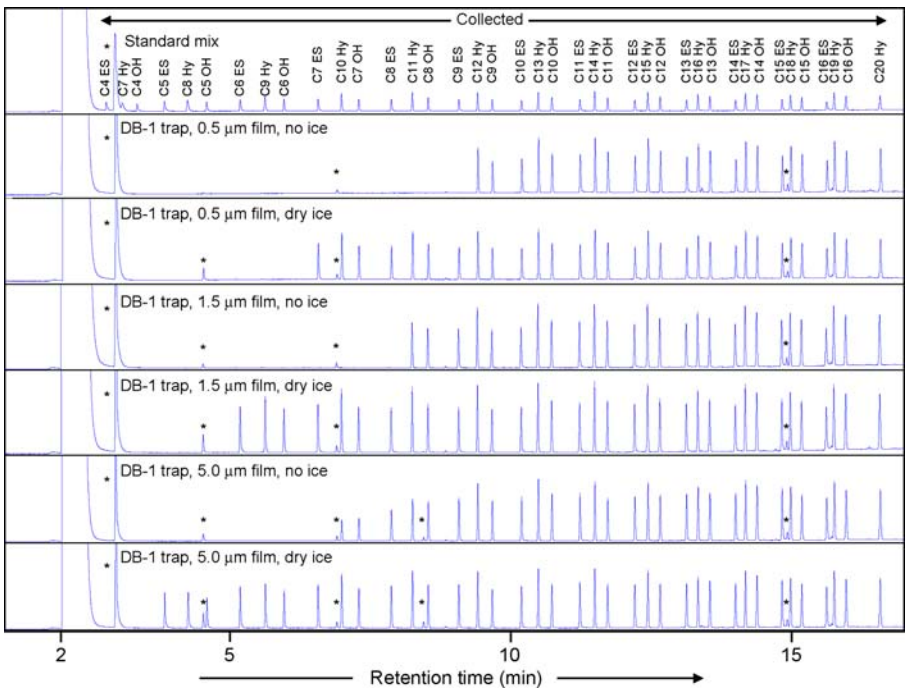

Fig. 4 A comparison of trapping of model compounds on DB-1 traps with various film thicknesses. The same mixture as in Fig. 3 was used for this experiment. The mixture was injected into the preparative GC in split mode, and all compounds were collected in a single collection trap between 2 and 18.5 min of each run. Collections were made with both dry ice and at ambient temperature. Trapped compounds were eluted with methylene chloride, and the extracts were analyzed by GC-FID. *Asterisks* indicate impurities that likely originated from the instrument, the solvent, and not from the traps

Experiment 3: Quantitative Comparison of the Trapping Efficiencies of Various Film Thicknesses of DB-1 Collection Traps at Ambient Temperature

The recovery efficacy of deactivated traps (0 μm film) varied with chemical class and sample loading (Fig. 5a). With injections of 1000 ng per compound, these traps efficiently collected >92% of all three chemical classes tested at and above the retention index of 1600. However, early eluting compounds exhibited a clear dose–response with poor trapping at low sample loadings. For alcohols, this pattern extended for all compounds in the mixture, from C13 to C16 ($P<0.05$, ANOVA). There are two main explanations for this observation. First, irreversible adsorption of alcohols to the inner surface of the deactivated trap might occur, and it would be more significant at lower sample loading sizes. Second, at high sample loading, the early eluting trapped compounds may form a stationary phase on the deactivated column, thus retarding the loss of other compounds.

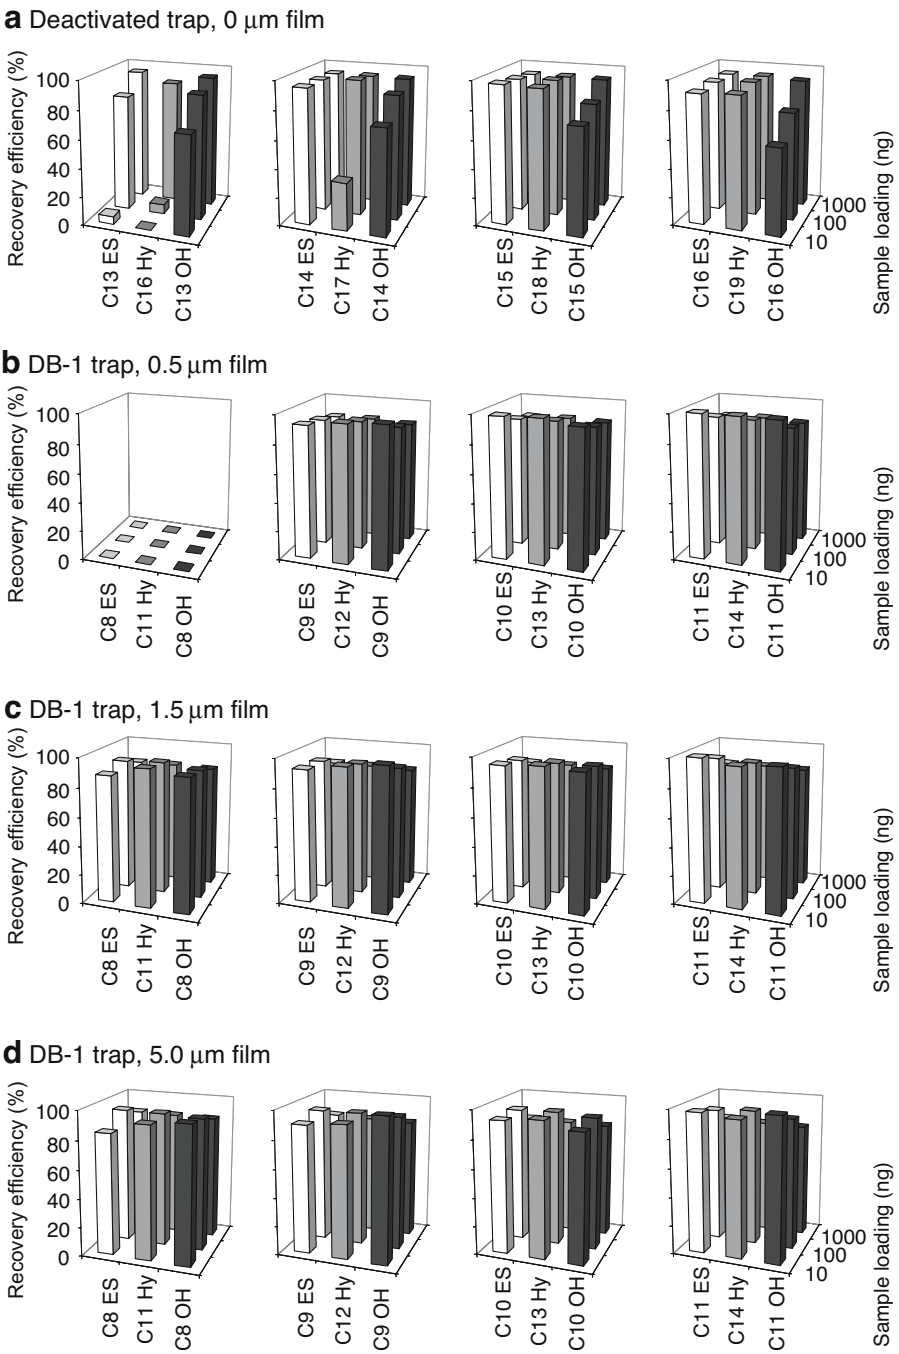

Fig. 5 a–d Trapping and recovery efficiencies of DB-1 traps with various film thicknesses and at different sample loadings conducted at room temperature. A mixture of straight chain methyl esters (C13–C16), hydrocarbons (C16–C19), and alcohols (C13–C16) was used with deactivated traps (0 μm film), and another mixture of methyl esters (C8–C11), hydrocarbons (C11–C14), and alcohols (C8–C11) was used with DB-1 traps. Preparative collections were made at sample loadings of 10, 100, and 1,000 ng of each compound. All compounds were collected in a single collection trap between 13.5 and 18.0 min for deactivated traps and between 8.0 and 13.5 min for DB-1 traps. Trapped compounds were eluted with hexane, and the extracts were analyzed by GC-FID

The recovery efficacies of DB-1 traps with a 0.5-μm film showed a distinct threshold retention index at about 1,200, below which almost none of the compounds were trapped (Fig. 5b). Adding more stationary phase (1.5 or 5.0 μm) greatly improved trapping efficiency to >80% for all tested compounds down to a retention index of 1100, and at all sample loadings (Fig. 5c,d). It is interesting to note that the DB-1 traps with a 1.5-μm film showed much better trap capability for C8 ester in this experiment in which the collection window was 8–13.5 min than in the qualitative experiment (#1) in which the collection window was 2–18.5 min (Fig. 4). It is probably because of the shorter collection window of this experiment than the earlier experiments (see the results and discussion of experiment 5). The threshold retention indices for the traps with 1.5 or 5.0 μm films could not be quantified but should be lower than 1000–1100 based on the results of qualitative experiments (Fig. 4). There was an overall inverse relationship between recovery efficiency of all DB-1 traps and the amount of sample injected ($P<0.05$, ANOVA). This is opposite to what was expected based on the classical Brownlee and Silverstein (1968) method in which recovery efficiencies decreased with decreasing amounts of injected sample. Nevertheless, the efficiency of trapping was 90–100% for almost all small samples, and even with injections of 1,000 ng per compound the trapping efficiency was >80%, generally considered satisfactory.

The connection between the column end and the collection trap is critical for achieving satisfactory recovery of eluting compounds in this preparative GC technique. An uneven cut on the column and trap ends can introduce reactive surfaces and a loose connection, both of which will diminish trapping efficiency. In our quantitative experiments, the recovery efficiencies were overall satisfactory through a wide range of sample loading sizes and different chemical classes, indicating that the interface adaptor system that used a direct injection glass liner between the column end and the traps was secure.

In preparative GC, it is thought that a gradual temperature gradient along the collection trap is necessary to achieve high recovery (Brownlee and Silverstein 1968) because a mist could be formed as the eluting compounds in the gas phase are rapidly cooled as they exit the hot GC, and the mist could then be propelled out through the trap by the relatively high linear velocity of capillary GC. In this experiment, the collection traps were kept at ambient temperature with no insulation before and during collections. This configuration probably resulted in a short gradual cooling zone along the trap in which compounds were quickly cooled from 250°C at the preparative GC outlet to about 25°C within the trap. However, the recovery efficacies were overall satisfactory. In principle, the trap collection at ambient temperature may be similar to the Grob splitless injection procedure whereby compounds are vaporized in the injection port and then condensed (solvent or thermally refocused) onto the head of the column to achieve narrow bands and sharp signals (Grob and Grob 1969). Nevertheless, as shown in experiments 1 and 2, a gradual cooling zone along the trap by a well-insulated sheath in combination with cryotrapping with dry ice significantly improved the efficiency of trapping.

Experiment 4: Qualitative Analysis of Distribution of Trapped Compounds in the Collection Traps

Under ambient collection conditions, in the deactivated collection trap (0 μm film), all injected compounds were condensed in the first 10 cm section of the trap (Fig. 6a). With the addition of a nonpolar stationary phase, not only the range of trapped compounds extended to a retention index of 1100 (again, better than in experiment 1 because a shorter collection window was used), but the condensed compounds were distributed farther up the trap, depending on the film thickness (Fig. 6b–d); more volatile compounds were trapped in sections farther from the GC outlet. Thus, threshold compounds that were trapped in the lowest 10 cm on a 5.0-μm stationary phase (e.g., retention index of approximately 1200) were trapped in the 10- to 20-cm zone on a 1.5-μm phase, and in the 10- to 30-cm zone on 0.5 μm DB-1 film thickness (Fig. 6b–d). Likewise, more volatile compounds, for example, with a retention index of 1100, were trapped in the 10- to 20-cm section on a 5.0-μm stationary phase, in the 20- to 40-cm zone on a 1.5-μm phase, and were not trapped at all on a DB-1 megabore trap with only 0.5 μm film thickness. This finding undoubtedly relates to greater interaction with the thicker stationary film, as also evidenced by later retention times on thicker films under otherwise identical GC analytical conditions. Therefore, for compounds with a retention index >1200, even a 10-cm section of megabore trap would yield satisfactory results in preparative GC. We have used 10 cm DB-1 traps with 1.5 μm film thickness to study the behavior of model compounds (data not shown). In practice, however, a longer trap is easier to handle and is more amenable to cryogenic trapping of solvent-like compounds. It is worth mentioning that when a mixture at a concentration of 1,000 ng per compound was injected, a narrow 10 mm band approximately 5 mm from the GC outlet became opaque as compounds condensed at the base of the traps.

Experiment 5: A Practical Collection Trial

Practical preparative GC generally targets single peaks for bioassay or analytical procedures that require pure compound (microchemical, spectrometric). The collection window is, therefore, much narrower than the 5–16.5 min used

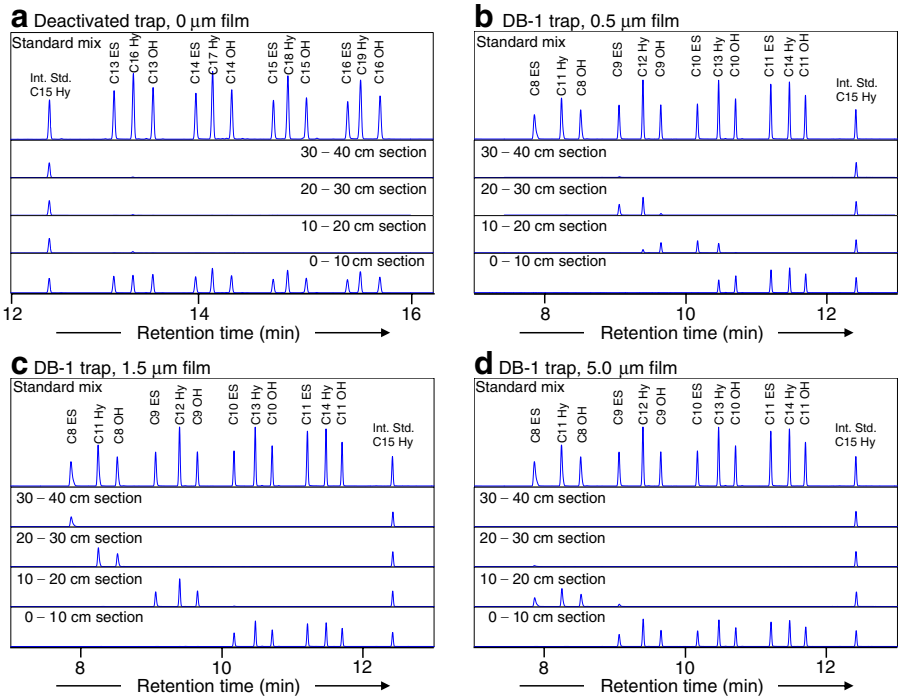

Fig. 6 a–d Qualitative analysis of the distribution of condensed compounds along the collection traps. A mixture of straight chain methyl esters (C13–C16), hydrocarbons (C16–C19), and alcohols (C13–C16) was used with deactivated traps (0 µm film), and another mixture of methyl esters (C8–C11), hydrocarbons (C11–C14), and alcohols (C8–C11) was used with DB-1 traps at a concentration of 1,000 ng μl^{-1} of each. One microliter of the mixture was injected into the preparative GC in splitless mode, and all compounds were collected in the same collection trap at each run at ambient temperature. After the collection, the 40-cm collection traps were cut into 10 cm sections and each section was extracted with hexane and subjected to GC-FID analysis

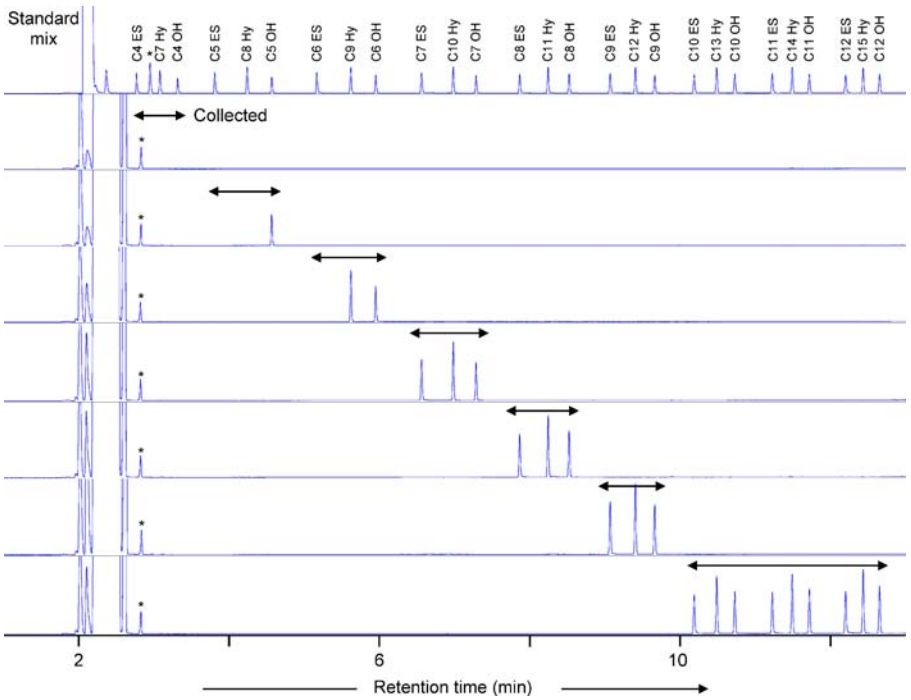

Fig. 7 A practical fractionation trial using DB-1 traps with 1.5 µm film at ambient temperature. A mixture of methyl esters (C4–C12), hydrocarbons (C7–C15), and alcohols (C4–C12) at a concentration of 300 ng μl^{-1} of each compound was used for this experiment. One microliter of the mixture was injected into the preparative GC in splitless mode, and compounds were collected in groups based on similar retention index, such that each group consisted of a methyl ester (C_n), hydrocarbon (C_{n+3}), and alcohol (C_n). The last three groups (retention index 1300 to 1500) were trapped together in the same trap. Each collection window for the groups was about 1 min except for the last three groups. Trapped compounds were eluted with hexane, and the extracts were analyzed by GC-FID. *Asterisks* indicate impurities that likely originated from the solvent and not from the traps

in the previous experiments. To verify the performance of our system with a more practical collection window, we conducted sequential fractionations of single injections by using 40 cm DB-1 megabore collection traps with 1.5 μm film. Compounds were fractionated in groups, each comprising a methyl ester (C_n), hydrocarbon (C_{n+3}), and alcohol (C_n) (Fig. 7). All collection windows for each fraction were about 1 min, except the last fraction, which was approximately 3 min. The results showed that each group was perfectly fractionated with ease and without any cross contamination (Fig. 7). The shorter collection times revealed even greater efficacy of this preparative GC approach. All three compounds around retention index 1000 were now entirely trapped, whereas this threshold was at retention index 1100 with long collection windows (see Figs. 3 and 4). Also, more volatile compounds, such as C5 alcohol, which could not be trapped even under cryogenic conditions (Figs. 3, 4), were now trapped at ambient conditions with a short collection window. It thus appears that highly volatile compounds condense in the stationary phase of the trap, but if the trap remains coupled to the GC outlet, a combination of the high velocity of the carrier gas and gradual heating of the trap might chromatograph the trapped compounds and discharge them out of the trap. In practice, on a long megabore column, the peak width near the base of early eluting compounds (i.e., collection window) is only one to several seconds, and we expect that our preparative GC system will perform even more efficiently under these conditions.

General Discussion and Conclusions

There are several technical and practical constraints associated with preparative GC, as pointed out earlier. Major advantages of our system are: (1) a wide range of volatile compounds can be effectively trapped without cooling the collection traps; (2) the collection traps can be rapidly and easily exchanged for trapping multiple but discrete GC peaks with 80–100% recovery; (3) the modification of a regular GC system into this preparative system can be achieved easily and inexpensively by using commercially available materials; and (4) commercially available capillary columns with a wide range of stationary phases, widths, and film thicknesses facilitate optimization of traps to the target compounds and to the analytical column to minimize pressure drop as compounds enter the trap. Indeed, this system could be used in a hybrid mode with longer traps with thicker film and cryotrapping for early eluting compounds and short traps with thinner film operated at ambient conditions for less volatile compounds.

A minor disadvantage of this system is that compounds are collected based on their retention times, which are determined by FID in a prior injection. Although this disadvantage is rather negligible because switching between the FID and preparative GC outlets is easy and takes only minutes, a variable or fixed splitter could be introduced at the end of the column to alleviate this problem.

In conjunction with a large-volume injection system coupled to a megabore capillary column, this preparative GC system can be used practically like a preparative HPLC system for samples up to microgram amounts. Furthermore, our preparative GC system is suitable for a simple two-step preparation of NMR samples of volatile and semivolatile compounds: a compound of interest can be optimally trapped on a short section of the megabore column and eluted directly into an NMR tube with minimal NMR solvent, resulting in high recovery of a clean sample with minimal background noise.

Olfactory Responses of Neotropical Short-Tailed Singing Mice, *Scotinomys teguina*, to Odors of the Mid-Ventral Sebaceous Gland: Discrimination of Conspecifics, Gender, and Female Reproductive Condition

Received: 3 May 2007 / Revised: 11 November 2007 / Accepted: 3 January 2008 / Published online: 7 February 2008

Abstract We examined the olfactory communication of the Neotropical short-tailed singing mouse, *Scotinomys teguina*, by investigating whether *S. teguina* responded to odors produced by the mid-ventral sebaceous gland of conspecifics. Females spent significantly more time investigating male odor than an odorless stimulus or a female odor. Males spent significantly more time investigating female odor than an odorless stimulus, but not that of a male odor. This latter result does not seem to be explained by differences in age or sexual experience of test subjects, but may be influenced by reproductive condition of the female odor donor. Male *S. teguina* spent significantly more time (1) investigating and (2) in total proximity to odors of estrous than non-estrous females. Males spent more time (1) investigating and (2) in total proximity to odors of males than non-estrous females. Finally, given the choice between odor of males vs proestrous females, males showed no preference. Thus, the mid-ventral gland in *S. teguina* seems to convey information about conspecifics, sex, and female reproductive condition. Male odor, compared with proestrous female odor, is equally interesting to males, suggesting that the gland also plays an important role in male–male communication. Sexual dimorphism in the size of the gland and in the amount of secretion produced by the gland may be related to either male–male competition or female choice.

Introduction

In animal communication, information is obtained through several sensory channels, and the olfactory channel is a commonly used channel by the majority of mammalian species (Johnston 1983; Duvall et al. 1986). In many species of rodents, the sense of smell is an important source of information about their conspecifics and their environments (Blaustein 1981; Johnston 1983, 2003; Kleiman and Eisenberg 1983; Halpin 1980, 1986; Brown and MacDonald 1985). In fact, odor cues play an important role in sexual selection. Small mammals such as rodents that lack sexual dimorphism in size may be sexually dimorphic in terms of odor, thus evolving alternative traits for sexual selection (Kleiman 1977; Blaustein 1981).

The literature on rodents is replete with evidence of sex-specific effects of olfactory signals in species such as house mice, voles, and hamsters. Reproductive behavior and physiology in both sexes could be affected easily by the odor cues from conspecifics (Koyama 2004). Many rodents can distinguish odors from conspecifics, heterospecifics (Stoddart 1986; Hurst et al. 1994), and the opposite sex (Hurst 1990c; Sawrey and Dewsbury 1994; Ferkin and Johnston 1995; Solomon et al. 1999), in addition to recognizing sexual receptivity (Bakker et al. 1996; Xiao et al. 2004), age (Solomon and Rumbaugh 1997; Drickamer

and Brown 1998; Ferkin 1999), social status (White et al. 1986; Hurst 1990a,b,c), kin (Mateo 2003), and sexual experience (Taylor et al. 1983). Rodents have also been shown to detect parasite infection by odors, an ability that can affect mate choice (Kavaliers and Colwell 1995; Kavaliers et al. 2004; Zala et al. 2004).

Mammalian skin glands frequently are the sources of odoriferous secretions involved in scent-communication (Müller-Schwarze 1983). In rodents, mid-ventral sebaceous glands are commonly found in association with the hair follicles on the surface of the skin (Quay and Tomich 1963; Müller-Schwarze 1983; Brown 1985; Flood 1985), and their development and activity depend on androgenic steroids from testes, ovaries, or the adrenal cortex (Brown 1985; Flood 1985). The product (sebum) secreted by the sebaceous gland varies in composition, but usually is oily and rich in lipids with antimicrobial properties (Flood 1985). Secretion rates of sebaceous glands are usually slow, and the sebum reaches the skin surface from body movement, rubbing of the skin, grooming, and contractions of the arrector muscles of the hair (Flood 1985).

Beyond contributing to an individual's odor and maintaining quality of the pelage, the role of the secretion produced by sebaceous glands is not completely clear in many species (Flood 1985), and it is likely to have multiple functions (Müller-Schwarze 1983). Secretions from the mid-ventral sebaceous gland may be involved in reproduction by signaling sexual identity and reproductive condition. Chemical constituents of urine, vaginal products, and scent gland secretions can all change with the estrous cycle as a means of advertisement of female readiness to mate (Johnston 1983). Studies that test male responsiveness to female odors in different reproductive conditions have shown that males of many species are more attracted to odors of females in behavioral estrus than to those in non-estrus (Johnston 1983; Bakker et al. 1996; Portillo and Paredes 2004).

Animal communication in Neotropical rodents is an area that is almost completely unexplored. *Scotinomys teguina* (Family Cricetidae) is a rodent from the highland mountains of southeast Mexico and Central America that shows an interesting system of vocal communication (Hooper and Carleton 1976). As expected in rodent species, communication by *S. teguina* seems to also involve chemical components. However, chemical communication in *S. teguina* has never been examined systematically. *S. teguina* has a mid-ventral sebaceous gland beneath a small patch of dusky-white fur, from which it is suspected that the noticeable musky odor (characteristic of the genus) is produced (Hooper and Carleton 1976). The mid-ventral sebaceous gland is sexually dimorphic. It is larger and more visible in males, and is probably associated with sexual maturity (Hooper and Carleton 1976). Although a promiscuous mating system has been demonstrated only in *Scotinomys xerampelinus*, the closest related species (Blondel 2006), the social and mating system of *S. teguina* is unknown. However, pair bonding and male parental care have been suggested because females are tolerant of male's presence at the nest during a few days after the birth of pups (Hooper and Carleton 1976).

In this study, we focused on olfactory signals produced by the sebaceous gland of *S. teguina*. The objective was to determine whether *S. teguina* responds to the olfactory cues produced by the mid-ventral sebaceous gland of conspecifics. We hypothesized that this rodent communicates chemically by using the odor cues produced by its mid-ventral gland, and that those cues may provide information about conspecifics, sex, and female reproductive state. In experiment 1, we gave both males and females a choice between an opposite sex odor and an odorless stimulus. In experiment 2, males and females had a choice between male and female odors, but we did not control for the reproductive condition of target females. In experiment 3, we explored the effects of female reproductive condition by examining whether *S. teguina* males discriminate (a) between mid-ventral sebaceous gland odor from estrous and non-estrous females, (b) between the odors of a male and a female in non-estrus, or (c) between the odors of a male and a female in vaginal proestrus (behavioral estrus).

Methods and Materials

Animals and Rearing Conditions The animals used in this study came from a laboratory colony of *S. teguina* at the Department of Zoology, University of Florida at Gainesville. The laboratory colony was started with 22 wild animals caught in 2003 from Monteverde, Costa Rica. In 2005, the colony was composed of 19 males and 22 females and in 2006 of 15 males and 19 females. Eight males and 16 females used in 2005 were also present in the 2006 colony. Ages of the females ranged between 2 and 23 mo (in 2005) and 11 and 35 mo (in 2006). The ages of males ranged between 4 and 21 mo (in 2005) and 11 and 32 mo (in 2006). The mice were kept in a climate-controlled environment with a constant temperature of 21±2°C and on a 12:12-hr light:dark cycle, with lights turning on at 8:00 EST. All animals were housed in glass terrariums (26×51×35 cm), with sterile bedding (Harlan Teklad lab grade "sani chips," Madison, WI, USA) lining the bottom, sterile moss for humidity, a running wheel for exercise, and a "log" for shelter (half of an 18 cm long PVC tube cut transversally). All animals were housed individually in their cages with the exception of breeding pairs (in 2005 and 2006) and same litter sibling pairs (only five pairs in 2005). Food (a mixture of dry cat chow, nuts, and seeds) and water

were provided *ad libitum*. Furthermore, because they are insectivorous, each mouse received mealworms three times a wk.

Test Subjects We used 17 males and 18 females as test subjects for experiments 1 and 2, and 15 males for experiment 3. All test subjects were sexually mature [sexual maturity in females is between 28 and 39 d; in males puberty is reached at approximately 6–8 wk (Hooper and Carleton 1976)]. Nine (experiments 1 and 2) and six (experiment 3) test subjects were sexually experienced, and the rest were nonsexually experienced. Sexually experienced individuals were those that had previously been breeding animals and had shared a cage with an individual of the opposite sex. Nonsexually experienced individuals were virgin animals that had never been in a cage with another opposite sex individual. Each test subject was used only once in each experimental session, and there was a 2- to 4-d interval between experiments. The order of experimental sessions was random for each test subject.

Odor Collection In all experiments, we collected the odor stimulus immediately before testing. We collected the odor stimulus by gently rubbing a cotton swab (Q tip) against the mid-ventral sebaceous gland for 20 sec (10 sec for each cotton tip). We then placed the swab inside a Petri dish. The Petri dish was constructed of two separate plastic dishes fitted together with a screw in the middle. The plastic dishes had 3 mm perforations scattered over the upper surface, allowing odors to be detected from outside the dish. In experiment 1, the odorless stimulus consisted of a cotton swab with distilled water inside the Petri dish. We prevented odor contamination by changing surgical gloves and rinsing hands with 70% ethanol after manipulating each mouse. All equipment was washed between trials with hot water and soap, and then rinsed with 70% ethanol and allowed to dry to prevent contamination or residual odors.

As a consequence of a relatively small number of animals in the colony, our choices for test subjects and odor donor animals were constrained. Animals used as test subjects were also used as odor donors in different trials. However, we used the odor of each animal only once in each experiment, and there was an interval of 2 d before any odor donor was used as a test subject. The odor of a test subject was never used as an odor stimulus during its own test. We selected the odor donors randomly, but made sure that the odor donor was not closely related and was unfamiliar to the test subject. Thus, pairs of animals sharing a cage (e.g., breeding pairs or same litter siblings), familiar with each other, were never paired as test subject-odor donor in a given trial. In this study, we did not test the response to odors from familiar and unfamiliar conspecifics. In addition, subjects and donors varied in age and sexual experience because of the small number of available animals.

Assessment of Female Reproductive Condition Fernández-V (2006) described the estrous cycle in *S. teguina* and developed the protocol for the vaginal cytological assay used in these experiments. In brief, *S. teguina* shows an estrous cycle similar to the one described for laboratory rats and house mice. The cycle lasts about 4 to 5 d and consists of proestrus (PRO), estrus (ES), metestrus (ME), and diestrus (DI) stages. Before the behavioral experiments and over a 20-d period, we determined the estrous cycle and its phases for each female by daily vaginal cytological assays. Although we assayed each female on the day of the test, the estrous stage was not only determined by the smear obtained on the test day, but also was confirmed by information from earlier cycles. Lastly, it is important to emphasize that in accordance with Nelson (2000), we classified proestrus as the vaginal phase that coincides with behavioral estrus. Thus, odor donors revealing a vaginal smear in proestrus were considered to be in behavioral estrus and physically prepared to mate.

We compared odors from non-estrous and proestrous females. We considered a female to be in a non-estrous condition when she presented in the vaginal smear a phase in transition of ES–ME, metestrus (ME), or transition ME–DI. We determined that a female was in proestrus when the vaginal smear indicated a transition DI–PRO phase or vaginal proestrus (behavioral estrus). During this phase, the vaginal smear contained large numbers of nucleated epithelial cells outnumbering and completely dominating the number of cornified epithelial cells.

Behavioral Assays At the beginning of each experimental trial, we moved the subject animal to the experimental room (away from the colony room) and allowed it to acclimate for 20 min. During experimentation, room lights were off, and a red light was turned on. Experiments 1, 2, and 3 shared the design of the preference test. In all tests, the experimental arena was a rectangular glass terrarium (26×51×35 cm) with the bottom covered with 1.5 cm of clean bedding.

Each trial started with a 4-min acclimation period of the test subject inside a vertical PVC tube set in the middle of the arena (terrarium) half-way between two different odor stimuli placed at each end of the terrarium. For each trial, we randomly selected the left or right position for each odor stimulus in the arena. After the acclimation period, we removed the tube and recorded the amount of time the test subject spent sniffing and investigating the odor stimulus (Petri dish) during a 5-min test. We defined "sniffing and investigating" whenever the test subject had its nose directly over the odor stimulus (Petri dish) and was drawing

in air (nostrils wiggling). Sniffing and investigating was our measure of discrimination in experiments 1, 2, and 3. In addition, only in experiment 3, we also recorded the time each male spent in proximity to, but not sniffing, the odor stimulus. We defined proximity as the time spent sitting near (within 2 cm of the Petri dish) or on top of the Petri dish containing an odor stimulus. We used these data to calculate a second measure of discrimination: "total proximity" (calculated as time spent sniffing and investigating the Petri dish plus time spent sitting in proximity). Because of inconclusive results obtained in session 2.2, we recorded time in proximity only in experiment 3 to obtain additional behavioral data that could be potentially useful for the interpretation of male odor responses.

The rationale behind this experimental design was that if one odor is detected as different from the other odor presented during the test, then the test subject is likely to spend more time investigating one odor compared to the other. A significant difference in time spent investigating demonstrates odor discrimination and possible preference. A nonsignificant difference demonstrates that there is no preference, but cannot be taken as evidence that the subject cannot detect a difference between the odors. It is possible that an animal that spent an equal amount of time with each stimulus was able to detect the difference between stimuli, but simply was not motivated to spend more time with one or the other (Rothblat and Kromer 1991; Englemann et al. 1995; Tang-Martinez 2001).

Experiment 1: Discrimination of Heterosexual Conspecific Odor This experiment attempted to establish whether *S. teguina* can distinguish between an odorless stimulus and an odor stimulus collected from the mid-ventral sebaceous gland of an opposite sex conspecific. We divided this experiment into two sessions. Session 1.1 consisted of a female as the test subject (N=11), distilled water as an odorless source, and odor of a male collected from the mid-ventral sebaceous gland as the conspecific odor stimulus. Session 1.2 consisted of a male as the test subject (N=10), distilled water as an odorless source, and odor of a female collected from the mid-ventral sebaceous gland as the conspecific odor stimulus. We predicted that if males or females distinguish an odor from an opposite sex individual, they should spend more time sniffing and investigating the odor sample than the water sample.

Experiment 2: Discrimination between Male and Female Odor The aim of this experiment was to determine whether females and males distinguish mid-ventral sebaceous gland odors collected from the same vs opposite sex conspecifics. We divided experiment 2 into two sessions. In session 2.1, a female was the test subject (N=9), whereas in session 2.2 a male was the test subject (N=11). In both sessions, we presented the test subject with two odor stimuli from the mid-ventral sebaceous gland, one collected from a male and the other from a female. In this experiment, we selected female odor donors at random, and we did not control for the stage of the estrous cycle of the females. A difference in time spent sniffing and investigating one odor stimulus vs the other will demonstrate the ability of the experimental subject to discriminate male vs female odors and possibly also show a preference for a particular sex odor.

Experiment 3.1: Male Discrimination of Female Reproductive Condition The goal of this experiment was to determine whether males discriminate between mid-ventral gland odors of a non-estrous female vs a proestrous female. The experiment consisted of exposing a male test subject to the two female odors collected from the mid-ventral sebaceous glandular area. Our prediction was that the male would prefer the odor of a proestrous female to that of a non-estrous one.

Experiment 3.2: Male Discrimination of Male Odor vs Non-estrous Female Odor The aim of experiment 3.2 was to determine whether males spent more time with, and in proximity to, male vs female mid-ventral gland odors, when the female is in a non-estrous stage of the cycle. We presented the male subject with two odor stimuli, one taken from a male and the other taken from a female in non-estrus. Given the results obtained in experiment 2.2., we predicted that the male will prefer male over female odor, if the female odor donor was in a non-estrous phase.

Experiment 3.3: Male Discrimination of Male Odor vs Vaginal Proestrus Female Odor The objective of this experiment was to determine whether males investigated and spent more time with, and in proximity to, an odor stimulus collected from a male or from a female in vaginal proestrus (behavioral estrus). Thus, the design was exactly the same as that of Experiment 3.2, except that the female odor stimulus was collected from a female in proestrus. Our prediction was that males would prefer this female odor compared to the male odor.

Data Analyses Paired-sample tests were used to examine significant differences in time spent sniffing and investigating and time in total proximity to the two stimuli. In all comparisons, the critical level of α was set at 0.05 (significant) or 0.001 (highly significant). In experiment 1, a one-tailed test was employed because the obvious prediction is that the test subject will be more attracted to the odor of a conspecific than to an odorless stimulus. In experiment 2, we used a two-tailed test because it was difficult to make unequivocal, clear-cut predictions. In experiment 3.1, we used a one-tailed test because the *a*

priori prediction is that the test subject will be more attracted to the odor of a proestrous female over a non-estrous female. In experiments 3.2 and 3.3, we used two-tailed tests because unequivocal predictions were not possible. Time spent sniffing and investigating and time in total proximity to each odor stimulus are presented as mean seconds (sec)±standard error (SE). In all cases, we assessed normality of the data by using the Shapiro and Wilk method (JMP, SAS Institute Inc. 1989–1997). To determine differences in the response to each odor stimulus, we used a paired *t*-test when data were normally distributed and Wilcoxon matched-pairs signed-ranks test (*W*) when data were not normally distributed (JMP, SAS Institute Inc. 1989–1997 and InStat, GraphPad Software Inc. 1998). We used three-factor analysis of variance (ANOVA) to determine whether potentially confounding variables such as sexual experience or age had an effect on the results obtained in experiments 2.2 and 3.3. The factors analyzed were odor stimuli (male and female odor) × sexual experience (sexual and nonsexual) × age (young <18 mo and old ≥18 mo; JMP, SAS Institute Inc. 1989–1997).

Results

Experiment 1 Discrimination of Heterosexual Conspecific Odor In experiment 1, both females and males spent significantly more time investigating the conspecific odor when compared with the odorless stimulus. Specifically, female *S. teguina* spent more time investigating the odor stimulus obtained from the sebaceous gland of a male than the odorless source (distilled water; t=4.23, df=10, P< 0.001; Fig. 1). Males also spent more time investigating the odor stimulus from a female than the odorless source (t= 2.17, df=9, P=0.028; Fig. 1).

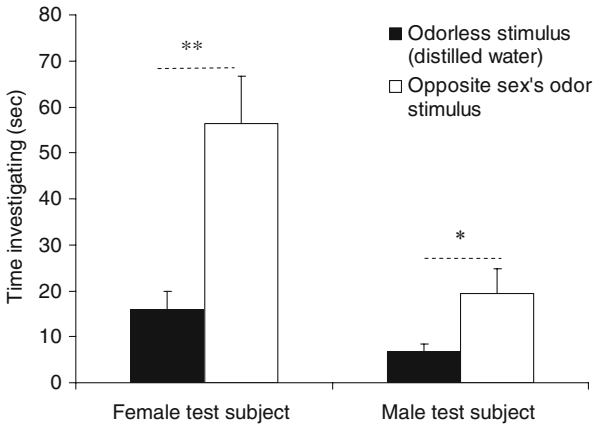

Fig. 1 Time (sec; mean±SE) spent by *S. teguina* test subjects sniffing and investigating an odorless stimulus (distilled water) vs an odor stimulus collected from an opposite sex individual. Female test subjects in session 1.1 (N=11) and male test subjects in session 1.2 (N=10). Significant differences between odor pairs, *P<0.05, **P< 0.001

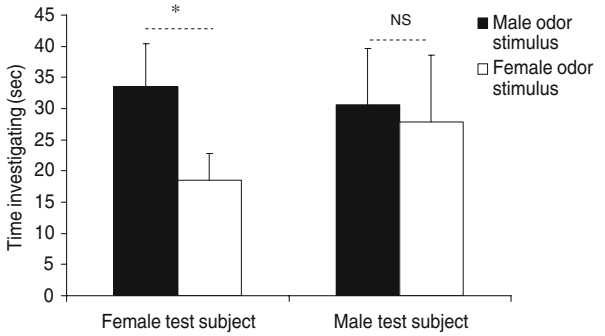

Fig. 2 Time (sec; mean±SE) spent by *S. teguina* test subjects sniffing and investigating the odor stimulus of a female vs the odor stimulus of a male. Female test subjects in session 2.1 (N=9) and male test subjects in session 2.2 (N=11). Significant differences between odor pairs, *P< 0.05. Nonsignificant difference (NS) between odor pairs, P>0.05

Experiment 2 Discrimination between Male and Female Odor The results for sexual discrimination by odors in experiment 2 demonstrated a different pattern in females when compared with males. Females sniffed or investigated male odors more than the same sex odors (t=3.26, df=8, P= 0.011; Fig. 2). However, males spent relatively the same amount of time investigating the gland odor of females and males (W=−7, P=0.765; Fig. 2). This unexpected result was not related to the sexual experience or age of the male subjects. A three-factor ANOVA performed on log-transformed data demonstrated that there were no significant effects of odor stimuli, sexual experience, or age on the time *S. teguina* spent sniffing and investigating the odor sources ($F_{1,16}$<2.43, P>0.139). Interactions between factor pairs were also not significant. The outcome in experiment 2.2 may have resulted from the fact that the reproductive state of female odor donors was uncontrolled; this led us to design experiment 3.

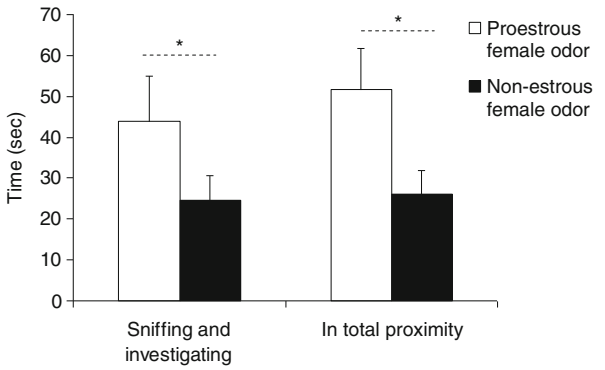

Fig. 3 Time (sec; mean±SE) spent by *S. teguina* male test subjects (N=10) sniffing and investigating, and in total proximity to the odor of a proestrous female vs the odor of a non-estrous female. Significant differences between odor pairs, *P<0.05

Experiment 3.1 Male discrimination of Female Reproductive Condition In experiment 3.1, *S. teguina* males spent more time sniffing and investigating the odor stimulus from a female in proestrus (behavioral estrus) than from a female in non-estrus (W=39.0, P=0.024; Fig. 3). We found the same odor preference pattern for time in total proximity (time spent investigating plus time in proximity to the Petri dish). Specifically, males spent more time in total proximity to the proestrous female odor stimulus compared to the non-estrous female odor stimulus (W=45.0, P=0.01; Fig. 3).

Experiment 3.2 Male Discrimination of Male odor vs Non-estrous Female Odor In experiment 3.2, the time spent by the male sniffing and investigating the male odor was different from the time spent sniffing and investigating the non-estrous female odor (W=−45.0, P=0.004) (Fig. 4). When one considers the time the male subject spent in total proximity, males spent more time in total proximity to the male odor compared to the non-estrous female odor (t=2.88, df=9, P=0.018; Fig. 4).

Experiment 3.3 Male Discrimination of Male Odor vs Vaginal Proestrous Female Odor Contrary to our prediction, results obtained in experiment 3.3 showed no male preference for any odor stimulus. Neither male odor nor proestrous female odor stimulated more sniffing or investigation (t=0.55, df=11, P=0.592; Fig. 5). The difference in the time the male subjects spent in total proximity to the two stimuli was also not significant (t=1.28, df=11, P=0.227; Fig. 5). Finally, there were no significant effects of odor stimuli, sexual experience, or age on the time male *S. teguina* spent sniffing and investigating the odor sources (three-factor ANOVA; $F_{1,18}$<2.73, P>0.116). Interactions between factor pairs were not significant either.

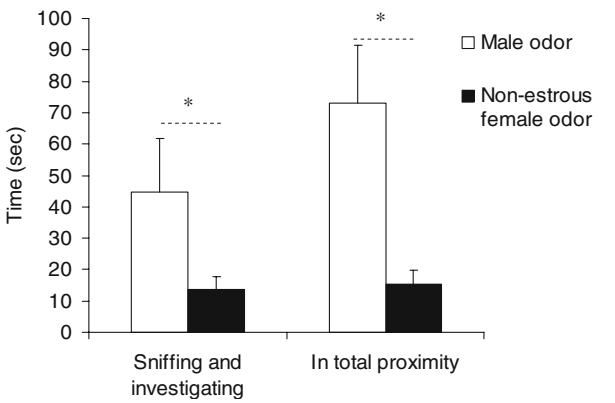

Fig. 4 Time (sec; mean±SE) spent by *S. teguina* male test subjects (N=10) sniffing and investigating, and in total proximity to the odor of a male vs the odor of a non-estrous female. Significant differences between odor pairs, *P<0.05

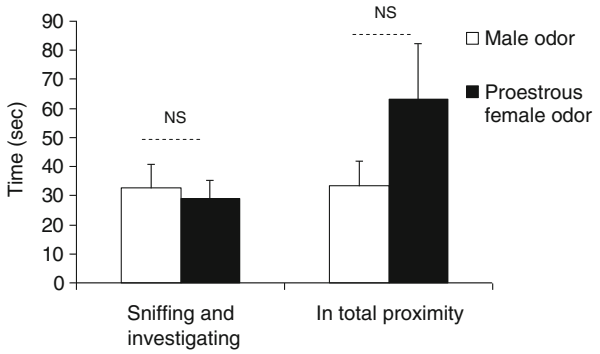

Fig. 5 Time (sec; mean±SE) spent by *S. teguina* male test subjects (N=12) sniffing and investigating, and in total proximity to the odor of a male vs. the odor of a proestrous female. Nonsignificant difference (NS) between odor pairs, P>0.05

Discussion

We found that there is chemical communication in *S. teguina* mediated by the odor produced by the mid-ventral sebaceous gland. Both male and female *S. teguina* distinguished between opposite sex conspecific odor and distilled water. In rodents, heterosexual conspecific identification mediated by olfactory cues is important during social encounters. During dyadic interactions, *S. teguina*, as is the case in many species of rodents (e.g., Gavish et al. 1983; Johnston 1985), engage in mutual nasal, oral, and anal sniffing, followed by genital and mid-ventral gland investigation (Hooper and Carleton 1976; personal observation). These typical behaviors may provide information about individual differences (Halpin 1980, 1986; Johnston and Jernigan 1994; Mateo 2006), which may be essential in identifying mates and enhancing mating success (Newman and Halpin 1988; Tang-Martínez et al. 1993). Individual identification through olfactory cues in *S. teguina* remains to be demonstrated in future studies.

Generally, sexual discrimination through odor cues is indicated by preference for the odor from those individuals that are of the opposite sex (Johnston 1983; Brown 1985; Ferkin and Johnston 1995). Female *S. teguina* showed a significant preference for male sebaceous gland odors compared to female odors. Therefore, *S. teguina* females can discriminate gender through mid-ventral gland odors. Female preference for male odor has also been demonstrated in other species of rodents (e.g., in Sawrey and Dewsbury 1994; Ferkin and Johnston 1995; Petrulis et al. 1999; Solomon et al. 1999; Zenuto et al. 2004). In montane voles (*Microtus montanus*), the female attraction to male bedding is related to the species' reproductive physiology because exposure to scent from territorial males promotes ovulation in the female (Sawrey and Dewsbury 1994). However, in *S. teguina*, male secretions from the mid-ventral sebaceous gland do not induce ovulation in females likely because *S. teguina* is a spontaneous ovulator

(Fernández-V 2006). Possibly, *S. teguina* male odor is a sexual attractant to females. Such a function would explain the strong preference for male sebaceous gland odors demonstrated by female *S. teguina.*

Male *S. teguina* were able to distinguish a female's reproductive state from chemical cues produced by the female's mid-ventral sebaceous gland. Specifically, males spent significantly more time sniffing/investigating and in total proximity to odors of estrous females than non-estrous females (Fig. 3). Therefore, the mid-ventral sebaceous gland seems to provide information to males about female sexual receptivity. Based on studies of other species (Johnston 1983; Bakker et al. 1996; Portillo and Paredes 2004), these results are not surprising because for males, the ability to distinguish proestrous from non-estrous females and their preference for proestrous odors are likely to be highly adaptive and may enhance a male's reproductive success. Likewise, advertisement of estrous condition by females is likely to attract males, thereby also increasing female reproductive success.

The lack of preference in male *S. teguina* for female odors, when compared with male odors (experiment 2.2) suggested that males, in contrast to females, may not be able to discriminate gender through mid-ventral gland odors. However in experiment 3.2, *S. teguina* males preferred to spend significantly more time sniffing and investigating and in total proximity to the odor samples collected from male glands compared to those collected from non-estrous female glands (Fig. 4). Thus, it appears that if a female is nonreproductive, males might be more interested in investigating another male's odor. These results suggest that males can distinguish gender identity through ventral gland odors, but they are more attracted to male than non-estrous female odors. Finally, given the choice between male odor and proestrous female odor, males again as in experiment 2.2, showed no preference for female vs male stimuli (Fig. 5).

It is intriguing that when males were asked to choose between male odors and female odors (either non-estrous or proestrous), the male subjects either showed no preference or preferred the male odors. These results raise the question of why male odor is so interesting to other males. There are two hypotheses that could explain these results.

First, it is possible that *S. teguina* males were unable to distinguish male odors from proestrous female odors because of hormonal abnormalities in the males. It has been shown that manipulation of circulating levels of testosterone and differences in sexual motivation, affect odor preferences in males (Bakker et al. 1996; Portillo and Paredes 2004; Xiao et al. 2004). In our study, we did not test the hormonal levels of each male subject, nor, for that matter, of male odor donors. However, these animals had never experienced any treatment related to hormonal studies such as hormone injection or castration. Unless rearing *S. teguina* in captivity has an effect on hormonal levels and behavior in males, as has been reported in a few other rodent species (Gottreich et al. 2000; Künzl et al. 2003), it is likely that the males in our study were hormonally and motivationally normal. Consequently, we do not consider that this is a plausible explanation for the pattern observed.

The second and most likely explanation of the observed pattern is that *S. teguina* males did not discriminate behaviorally between odors from males and from proestrous females because *the chemical signal produced by the gland in males is important in male–male communication*. The results from experiment 3.1 demonstrated that the female mid-ventral gland provided chemical cues that allowed males to discriminate female reproductive condition. However, if those chemical signals are also important for male–male communication (possibly in agonistic contexts), it might be expected that males would show more interest in these male odor cues than in those of non-estrous females. Consequently the odors of females in proestrus and the odors of males may be equally important for males.

In Nearctic cricetines (e.g., *Neotoma, Peromyscus, Rattus*), mid-ventral glands commonly are more developed in males than in females (Quay and Tomich 1963), and male odor is believed to contain more compounds than female odor (Blaustein 1981; Brown 1985). In female *S. teguina*, the gland is smaller, less visible, and lacks the heavy staining of the pelage observed in males (Hooper and Carleton 1976). Possibly, the secretion is also less copious and the odor less strong or chemically complex than in males. Sexual differences in the secretion and size of the mid-ventral gland may be related to sexual selection, through either female choice or male–male competition. This could explain the sexual dimorphism of the mid-ventral sebaceous gland and the different sexual responses to odors in *S. teguina*.

During male–male competition, dominant male rodents might produce different cues, or different amounts of the same cue, when compared with subordinate male rodents, and females could choose on the basis of the signal emitted (Johnston 1983; Brown 1985; White et al. 1986). Dominant males of many species have a larger scent gland than subordinates, and their odor may potentially indicate their dominance (Brown 1985). Although the social system in *S. teguina* is not well known, aggression and dominance interactions in male adults after male–male encounters have been reported for both *S. teguina* and *S. xerampelinus* (Hooper and Carleton 1976). We also observed agonistic interactions between *S. teguina* males during experiments with dyadic interactions (unpublished data).

Finally, males in territorial species such as montane voles, *Microtus montanus*, and tuco-tucos, *Ctenomys talarum*,

also have failed to show a preference for female odor when compared with male odor (Sawrey and Dewsbury 1994; Zenuto et al. 2004). Presumably, in these species, males are interested in male odor for attainment and maintenance of a breeding territory and in female odor for reproduction (Sawrey and Dewsbury 1994; Zenuto et al. 2004). Likewise in *S. teguina*, male and proestrous female odors seem to be equally interesting. However, it is not known whether *S. teguina* actively defends a territory. In contrast to both territorial montane voles and tuco-tucos (Jannett 1981; Zenuto et al. 2004), *S. teguina* does not deposit scent on substrates by using their mid-ventral gland. During experiments designed to stimulate scent marking in *S. teguina*, we did not observe scent deposition on the substrate with their mid-ventral gland (Fernández-V 2006). In contrast, the only circumstances in which we have observed *S. teguina* individuals use the mid-ventral sebaceous gland have been during self-grooming sessions (spreading the secretion over their own fur) or during allo-grooming bouts (spreading the secretion over a conspecific's fur; unpublished data). These behaviors may suggest that in *S. teguina*, the gland is used to mark individuals (e.g., females) rather than a territory. Such a lack of territoriality would be in agreement with the absence of male intrasexual exclusive space use found in *S. xerampelinus* (Blondel 2006).

In summary, this study demonstrates that chemical communication is important in *S. teguina* and that the mid-ventral sebaceous gland mediates discrimination of heterosexual conspecifics, sex, and female reproductive condition. However, the social organization and mating system in *S. teguina* need to be studied further in order to fully understand how the communication system evolved and how it currently works.

A Sterol-Like Odorant in the Urine of Mozambique Tilapia Males Likely Signals Social Dominance to Females

Abstract Many species of freshwater fish with relatively simple mating strategies release hormonally derived sex pheromones in urine. However, it is not known whether species with more complex reproductive strategies use specialized urinary chemical signals. We addressed this by using the Mozambique tilapia (*Oreochromis mossambicus* Peters 1852), a lek-breeding species in which males establish dominance hierarchies and visiting females mate preferentially with territorial/dominant males. We measured urination frequency of territorial males in social isolation and in the presence of females that were either ready to spawn or had finished spawning. In groups of fish, we monitored the volume of urine stored in subordinate and dominant males to determine if urine volume and olfactory potency (by recording electro-olfactograms, EOG, in females) are related to the male's social rank. Dominant, territorial males stored more urine than subordinates and released it in short pulses, the frequency of which increased in the presence of females ready to spawn but not in the presence of post-spawn females. Urine from subordinate and dominant males was fractionated by liquid chromatography and fractions tested for olfactory potency by using the EOG, with the most potent fraction analyzed by mass spectrometry (MS). The olfactory system of females was sensitive to a urinary compound that was more abundant in the urine of dominant males than in that of subordinates. MS analysis suggested the compound is a sulfated amino-sterol-like compound with a formula of $C_{29}H_{40}N_2O_{10}S$. Therefore, we suggest that dominant/territorial tilapia males dramatically increase urination frequency in the presence of females ready to spawn and that the urinary odorant acts as a pheromonal signal of dominance, thereby influencing female spawning.

Introduction

Although sex pheromones are known to mediate reproduction in fish, detailed information on chemical identities, physiological origin, control of release, and function is available only from a small number of species with relatively simple reproductive strategies (Stacey and Sorensen 2006). Among these, the goldfish (*Carassius auratus*) is the best studied. It has a scramble-competition polygynous mating system, representative of many other cyprinids; females

release steroids and prostaglandins via the gills and/or the urine, which act as hormonal pheromones that affect the reproductive physiology and behavior of males. Sexually receptive females control the release of urinary prostaglandin pheromones while exhibiting simple behaviors. This is thought to represent a specialization of pheromone release related to marking spawning habitat, so as to lure males (Appelt and Sorensen 2007). Cichlids, in contrast, employ a range of relatively complex mating systems (Barlow 1991). Typical among the mouth-brooding cichlids is polygynandry, wherein males defend a spawning territory that is visited by females and where males display conspicuous courtship behaviors (Barlow 1991; Nelissen 1991). The possibility of chemical communication in these reproductive interactions, however, has been little studied in this group.

The Mozambique tilapia (*Oreochromis mossambicus* Peters 1852) is a maternal mouth-brooding cichlid that spawns repeatedly throughout the year, with the females having a regular ovulatory cycle of 15–20 days (Coward and Bromage 2000). Males aggregate in breeding arenas or leks, where territorial males adopt a characteristic black coloration and defend small territories centered on the nests (pits) that they dig in the sand (Bruton and Boltt 1975). Females visit the leks when ready to spawn but then collect and brood the fertilized eggs and subsequent fry away from the leks (Fryer and Iles 1972). In captivity, male tilapia form a stable linear hierarchy (Oliveira and Almada 1996, 1998b), with the largest alpha males receiving the majority of spawning females (Oliveira and Almada 1996). Previous studies have found that the olfactory system of females is highly sensitive to substances released to the water by territorial males and to male body fluids, with urine being of special importance (Frade et al. 2002). This suggests the possibility of male urinary pheromones being involved in tilapia reproduction and, if males control their release, for chemical communication in this species.

In the present study, we tested whether male tilapia send chemical signals to females and whether this ability depends on male social status. Three experiments were conducted. First, we assessed urination frequency of males, with and without pre-ovulatory (ready to spawn) and post-ovulatory (post-spawn) females, to determine whether they may use urinary pheromone(s) to communicate. Second, we formed groups of fish and monitored the volume of urine stored in subordinate and dominant males to determine if urine volume and urine olfactory potency on females are related to male social rank. Finally, to characterize the urinary odorants, samples of urine collected from subordinate and dominant males were fractionated by liquid chromatography, the resulting fractions were tested for olfactory potency on females, and the most potent fraction was analyzed by mass spectrometry.

Methods and Materials

Experimental Animals

Before the experiments, groups of fish (one male and three or four females) were housed for several weeks in re-circulating aquaria. The aquaria (93×60×55 cm) contained 200 l dechlorinated tap water at 27°C and sand substrate. The photoperiod was 12 L:12 D, and the fish were fed twice a day with commercial cichlid food (Nutrafin basix®; Rolf C. Hagen, Inc., Montreal, Canada). Spawning occurred in all fish groups, but the eggs were removed to stimulate the initiation of a new ovulatory cycle. Each female was observed over at least two ovulatory cycles before use in behavioral experiments to ensure the predictability of ovulation. "Pre-ovulatory" females were used in experiments on the day before or on the day predicted for their next ovulation; their ovulation cycle ranged from 9 to 16 days (mean ± SD; 15.0±3.1 days; N=7). "Post-ovulatory" females were used 1–3 days after their last ovulation.

Visualization of Urine and Quantifying Patterns of Urination Behavior

To determine whether males use urine to communicate during reproductive behavior, the urination frequency of a male was assessed in social isolation and while a female was present. In each replicate, a male was taken from its family tank and isolated in a glass tank (79×35×45 cm, 50 l, 27°C, aerated), with a sand substratum, for 24 h before the experiment. The male was lightly anesthetized by immersion in iced water for 2–3 min and injected in the dorsal musculature with 100 µl patent blue violet (100 mg ml^{-1} in 0.9% NaCl; Sigma-Aldrich), a dye that is released mainly through the urine and allows monitoring of the frequency of urine release (Appelt and Sorensen 1999, 2007; Barata et al. 2007). The fish was then placed back into its tank, and after the first urine pulse, urination was measured and fish behavior was recorded on video for 45 min (social isolation). Then, a pre- or post-ovulatory female (taken from a different family tank) was introduced to the tank and urine release and behavior recorded for another 45 min. Frequency and duration of each urine pulse was recorded by the observer with a hand-held computer (Psion Organizer LZ64) programmed for timing the start and end of each urine pulse. The procedure was replicated with seven males (mean ± SD, standard length = 156.3±18.6 mm, and body weight = 119.5±18.6 g) and seven pre-ovulatory females (length = 147.0±20.9 mm; weight = 100.1±41.8 g), and with another group of seven males (length = 155.0±26.2 mm; weight = 120.7±48.2 g) and seven post-ovulatory females (length = 146.1±18.5 mm; weight = 96.6±45.9 g). After each replicate, the males were returned to their

original family tanks, but the females were deeply anesthetized (500 mg l^{-1} 3-aminobenzoic acid ethyl ester, MS222, Sigma-Aldrich), and then a sharp blow to the head was applied to assure death before assessing their ovarian condition. The ovaries of each female were weighed and the gonadosomatic index (GSI = gonads mass/body mass × 100) calculated. A random sample of ten eggs was also weighed, and their diameters measured under a binocular microscope.

Male behavior was classified as not displaying (hovering or active swimming when the female was present), courting (including nest digging), or aggressive. Female behavior was classified as not displaying, receptive (following the male during its courtship displays), or submissive. These behaviors are described in detail by Baerends and Baerends van Roon (1950) and by Oliveira (1995). Total duration of all behaviors was quantified by using The Observer Video-Pro 4.0 software (Noldus Information Technology, Wageningen, The Netherlands).

Quantifying Urine Stored in Subordinate and Dominant Males

To determine if urine volume stored in the bladder is related to male social behavior and to obtain urine for testing olfactory potency and mass spectrometry analysis, males in social groups were monitored daily. Two groups (A and B) of 12 males and ten females (previously kept in family tanks as described above) were sequentially housed for 15 days in a plastic tank (128×110×50 cm) containing dechlorinated tap water (approximately 600 l) at 25–27°C; the photoperiod was 12 h, and feeding was once a day. The males were tagged with colored plastic labels (T-Bar extra small anchor—FF-94, Floy Tag Inc., Seattle, WA, USA) attached to the muscle near the dorsal fin and their behavior observed each morning, midday, and afternoon over 10 days (30 observations per male). Systematic behavioral observations started on the four day after formation of each fish group. The frequency of submissive (escape from an aggressive opponent, submission displays during agonistic interactions, or absence of dark coloration without social interaction) and dominant behaviors (aggressive displays, nest-digging, courtship displays towards females, or dark coloration without social interaction) was recorded over 5 min for each male. Although the tank had no sand, some males exhibited nest-digging behavior by nipping the bottom, as they normally do with a sand substratum. At the end of each afternoon's observations, each male was slightly anesthetized (50 mg l^{-1} MS222), and urine was taken by gently squeezing the area immediately above and anterior to the genital papilla. Squeezing of this abdominal area caused erection of the genital papilla, and a jet of urine was collected. Urine volume was measured by weighing, and the urine was stored at −20°C until use (see below). The fish were allowed to recover and placed back in the tank.

The standard length and weight of each fish were measured at the start of each replicate (mean ± SD; group A: male length = 137.8±5.6 mm, male weight = 81.6± 11.3 g, female length = 103.7±9.6 mm, female weight = 39.9±9.1 g; group B: male length = 144.4±6.3 mm, male weight = 86.4±10.0 g, female length = 111.2±10.4 mm, female weight = 46.6±10.2 g) and at the end to calculate their daily growth. The GSI of males of different social rank was compared between six dominant males (three from each group) and six subordinates (two from fish group A and four from group B) following the procedure described above for females. Samples of urine obtained from these males were assessed for olfactory potency on females, fractionated by liquid chromatography, and the resulting fractions assessed for olfactory potency and analyzed by mass spectrometry (see below). Samples of urine collected daily from all males in the two replicates were also assessed for olfactory potency to determine whether there is a relationship between males' social rank and the olfactory potency of their urine (see below).

Liquid Chromatography Coupled with Mass Spectrometry To determine which odorants are found in the urine of dominant and subordinate males, solid-phase extraction (SPE) of urine samples was carried out followed by fractionation and analysis by liquid chromatography–mass spectrometry (LC–MS). Urine samples from the same male were pooled for analysis. Urine (2 ml) was passed through a C18 cartridge (Sep-Pak®, Waters, Milford, MA, USA) and eluted with methanol (2 ml). Half of the eluent was kept at −20°C until used for assessment of olfactory potency on females by recording the electro-olfactogram (EOG; see below), while the other half was fractionated by LC–MS. Distilled water (2 ml) was subjected to the same procedure to generate a control eluent.

For LC–MS, the unconjugated bile acid chenodeoxycholic acid (CDCA; Steraloids Inc, Newport, RI, USA) was added (1 μg) to each of the sep-pack eluates (internal standard) to standardize retention times and injection volumes between samples of male urine. Eluates were dried under a stream of nitrogen, reconstituted in 110 μl methanol/water (60/40, *v*/*v*) and transferred to autosampler glass vials for LC–MS. The LC column (Nova-Pak reversed-phase C18, 4 μm, Waters Chromatography Division, Milford, MA, USA) was coupled to a mass spectrometer with electrospray ionization (ESI; LCQ Classic, Thermo Electron Corporation, Waltham, MA, USA). The mobile phase was isocratic at 15% methanol for 4 min, increased linearly from 15% to 100% methanol from 4 to 91 min, and allowed to run at 100% methanol for 5 min before ramping back to 15% methanol for the next sample.

The flow was 1 ml min^{-1}. After passing through the column, the sample was routed to a splitter—10% to the mass spectrometer and 90% collected into 30 3-min fractions for 90 min by using an autosampler (FC203, Gilson Inc., Madison, WI, USA). The 12 samples were run in succession, alternating between subordinate and dominant males. The fractions from each male were kept at −20°C until assessment of olfactory potency on females (see below).

Mass spectra were acquired with an ion trap mass spectrometer equipped with an ESI source and analyzed with Xcalibur software (Thermo Electron Corporation). The ion trap was operated in the negative ion mode with a spray voltage of 5 kV. A stream of 99% pure nitrogen at 60 psi was used as the sheath gas. Data were collected continuously in the range *m*/*z* 200–950. The relative peak areas (normalized to the area of the internal standard, CDCA) in the LC fractions that had significant olfactory potency were determined with Xcalibur software. Positive-ion MS was performed on olfactory-active fractions to determine whether any other compound could be present that was not detectable in the negative-ion mode. MS–MS at various energies was performed in the negative-ion mode in an attempt to ascertain more structural information about compounds in active fractions.

To deduce the chemical formula of compounds in active fraction(s), negative-ion high-resolution electrospray ionization was performed with a QSTAR1 MS (Applied Biosystems, Foster City, CA, USA) equipped with a hybrid quadrupole/time-of-flight detector. The most likely formulae were deduced by making several conservative assumptions about structure: (1) the presence of between 0 and 40 carbon atoms (high numbers were used so as to be conservative), (2) the presence of between 0 and 90 hydrogen atoms, (3) an even number of (or no) nitrogen atoms with a maximum of 12 nitrogens, (4) at least one sulfur and four oxygen atoms (consistent with the presence of at least one sulfate group as observed with MS/MS) with a maximum of three sulfur and 12 oxygen atoms, and (5) a mass accuracy within 15 ppm (a conservative measure, as a properly calibrated instrument should measure within 10 ppm). We identified all potential molecular formulae that fit this description and then systematically eliminated remaining formulae when the measured isotopic distribution pattern (i.e., the entire spectra, including the parent ion and all of its isotopes) did not match a structure's theoretical isotopic distribution pattern (for details on this procedure, see Sorensen et al. 2005 and Hoye et al. 2007).

Olfactory Sensitivity of Females to Male Urine Whole urine, urine extracts obtained by SPE, and LC fractions were tested for olfactory potency on females. The EOG was recorded as previously described (Frade et al. 2002). Briefly, male tilapia were anesthetized in water containing 100 mg l^{-1} MS222 and immobilized with gallamine triethiodide (3 mg kg^{-1} in 0.9% saline). The fish were placed in a padded Perspex® V-clamp, and their gills irrigated with aerated water containing MS222 (50 mg l^{-1}). The olfactory rosette was exposed by removing the ring of cartilage surrounding the nostril and continually irrigated with dechlorinated, charcoal-filtered tap water (6 ml min^{-1}). Stimulus-containing water was introduced into this flow via a three-way solenoid valve. At least 1 min was allowed to elapse between successive stimuli. The DC voltage was recorded by two glass micropipettes filled with 0.9% NaCl in 4% agar, one being placed close to the olfactory epithelium, and the other placed lightly on the skin of the head. The signal was amplified ($\times 10^3$) and recorded on a PC running Axoscope software (version 1.1, Axon Instruments, Inc., Foster City, CA, USA). The peak amplitude of the EOG to a given stimulus was blank-subtracted and normalized to the response to 10^{-5} M L-serine (standard).

Stimuli were made up on the day of recording by using the same dechlorinated, charcoal-filtered tap water used to irrigate the fish's nostril. Urine collected each day from males in the social groups was tested at a dilution of $1{:}10^4$ in water (*v*/*v*) on the same female, with six females (mean ± SD; length = 114.0±4.7 mm; weight = 47.6±6.1 g) used to assess the olfactory potency of all urine samples. Untreated urine from six subordinate and six dominant males and the corresponding urine SPE eluents were tested on each of the three females at a dilution of $1{:}10^4$ (*v*/*v*). Using another group of females, the SPE urine eluent and corresponding LC fractions of one male of each social rank were tested on the same female; the stimuli from each male were tested on three females. Therefore, 18 females (mean ± SD; length = 123.1±18.1 mm; weight = 62.0±33.4 g) were used to assess the olfactory potency of these male-derived stimuli at a dilution of $1{:}10^4$ (*v*/*v*; an equivalent dilution of the untreated sample urine). As a control, methanol was tested at 0.015% to 0.1% in water (the range of methanol concentration in urine extracts and LC fractions).

Statistical Analysis Frequency and duration of urine pulses from males and behavioral data of both sexes were compared between social contexts or between female reproductive conditions (social isolation, pre- or post-ovulatory female) by either the Student's *t* tests (paired samples) or one-way analysis of variance (ANOVA). The non-parametric Kendall's correlation was used to evaluate (within each of the two social groups of fish) the relationship between the mean urine volume per day and male size or mean dominance index per day (calculated as the ratio of the summed frequency of all dominant behaviors and the summed frequency of all dominant and submissive behaviors). The daily growth rate (length and

weight) within each fish group was tested for difference from zero with the Student's *t* test; the relationship between growth rate and the mean dominance index per day was evaluated by the Kendall's correlation. Univariate regression was used to evaluate the relationship between the mean EOG amplitudes evoked by daily urine samples of each male and fish group (fixed factor), mean urine volume per day, dominance index per day, and two-way interactions between the continuous covariates and the fixed factor. The Student's *t* test for independent samples was used to compare the relative area of LC peaks in fractions that had significant olfactory potency between subordinate and dominant males. Normalized EOG amplitudes (mean from three females for each stimulus) evoked by crude urine, SPE eluents, and LC fractions from subordinate and dominant males were compared by one-way repeated measures ANOVA with male type as between-group variable and stimulus type as within-subject variable. Statistical analyses were carried out with SPSS® 14.0 for Windows software (SPSS Inc., 1989–2005), and in all cases, statistical significance was set at $P<0.05$. All data are shown as mean ± SEM.

Ethical Statement Our research has followed the European Convention for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes (European Treaty Series No. 123), the ASAB/ABS Guidelines for the Use of Animals in Research (published in Animal Behavior, 2003, 65:249–255), and the Guidelines for the Use of Fishes in Research by the American Fisheries Society (http://www.fisheries.org/afs/publicpolicy/guidelines2004.pdf).

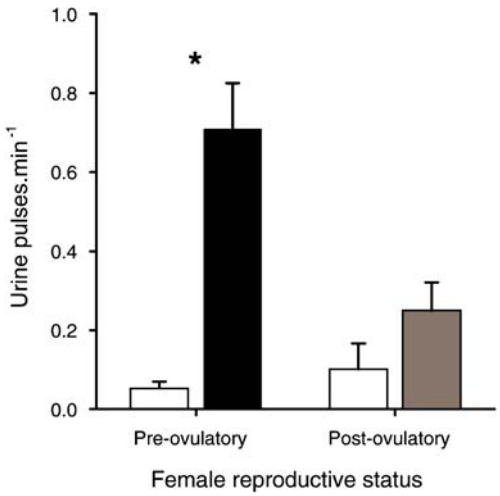

Fig. 1 Urination of male tilapia in isolation and in the presence of a female. Urination frequency (mean ± SEM) with a pre-ovulatory female (*black bar*, $N=7$) was significantly higher than in isolation (*open bar*, $N=7$; *asterisk* Student's *t* test for paired samples, $t_6=5.46$, $P<0.005$). With a post-ovulatory female (*gray bar*, $N=7$), the frequency of urination was not different from that when in social isolation (*open bar*, $N=7$; $t_6=1.77$, $P=0.127$)

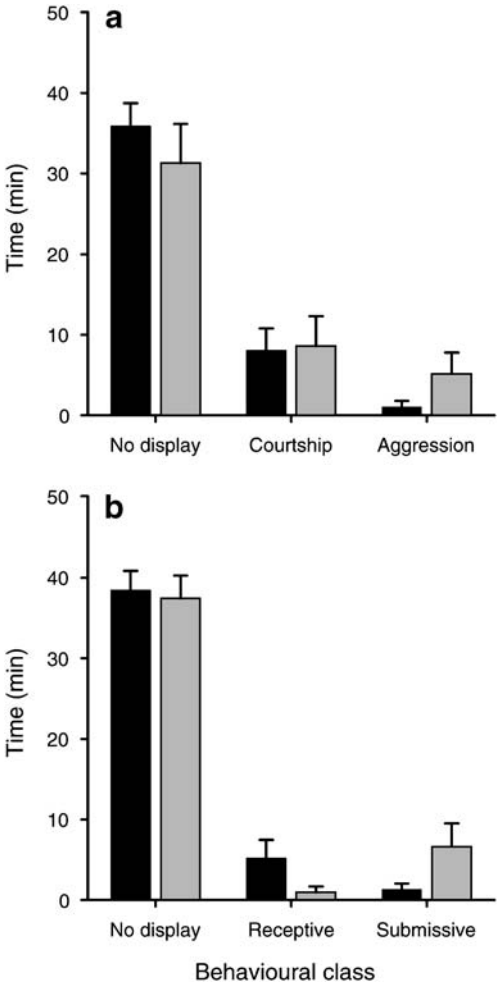

Fig. 2 Behavior of male and female tilapia. **a** Males in the presence of pre-ovulatory females (*black bars*, $N=7$) or post-ovulatory females (*gray bars*, $N=7$) did not differ (Student's *t* tests for independent samples, $df=12$, $P>0.05$) in the time (mean ± SEM) spent in different behavioral classes. **b** Pre-ovulatory females (*black bars*, $N=7$) and post-ovulatory females (*gray bars*, $N=7$) did not differ in the time spent in different behavioral classes in the presence of a male (Student's *t* tests for independent samples, $df=12$, $P>0.05$)

Results

Male Urination Frequency and Behavior In isolation, male tilapia urinated at low frequency (about once every 10 min) and expelled urine in short-duration pulses (about 1 s). When together with a pre-ovulatory female, males significantly increased their urination frequency; this did not happen with a post-ovulatory female (Fig. 1). No obvious changes in the release of feces or intestinal fluids were seen. The duration of urinary pulses was not different among the three social contexts (isolation, 1.43±0.27 s, $N=44$; with pre-ovulatory female, 1.26±0.14 s, $N=225$; with post-ovulatory female, 1.31±0.12 s, $N=78$; one-way ANOVA, $F_{2,344}=0.16$, $P=0.856$).

Male behavior was not different in the presence of pre- or post-ovulatory females. Males were never indifferent to

the presence of a female and spent most of the time swimming in her vicinity (no display), sometimes displaying obvious courtship behaviors and, more rarely, aggressive behaviors (Fig. 2a). Pre- and post-ovulatory females did not differ in their behavior either. The females spent most of the time swimming in the vicinity of the male and sometimes exhibiting receptive or submissive behaviors, depending on the male's behavior (Fig. 2b). The pattern of urine release varied among males; higher urination frequency was not necessarily associated with specific behaviors of either the male or the female. For example, a male might urinate at high frequency during clear courtship displays or while he was swimming in the vicinity of a pre-ovulatory female without displaying obvious courtship (Fig. 3, example 1). Also, a male would sometimes urinate with high frequency in the presence of a pre-ovulatory female without displaying obvious courtship (Fig. 3, example 2). Finally, in the presence of a post-ovulatory female, the male would sometimes exhibit clear courtship behaviors without urinating at high frequency (Fig. 3, example 3).

Analysis of females' ovarian states confirmed that they were in different reproductive condition. The GSI of pre-ovulatory females (4.4±1.7%) was higher than that of post-ovulatory females (1.4±0.4%; Mann–Whitney U, z=3.1, N_1=N_2=, P<0.005). The average egg weight was also higher in pre-ovulatory females (2.48±1.40 mg) than in post-ovulatory females (0.17±0.06 mg; z=3.1, P<0.005). This was due to larger egg sizes between 1.6 to 2.5 mm (54.3±24.4% of the eggs) in pre-ovulatory females, whereas in the post-ovulatory females, the eggs did not exceed 1.0 mm in diameter.

Social Hierarchies, Urine Volume, and Olfactory Potency of Urine In two groups of fish, males maintained a stable social hierarchy over 10 days of observation. In each group, three males were dominant (mean dominance index per day higher than 0.5), occupying a fixed territorial position in the tank, showing dark coloration and frequently displaying courtship or aggression. Among the other males of lower social rank, two in each group adopted intermittently dominant and submissive behaviors (mean dominance index per day between 0.2 and 0.4), whereas the remaining seven males in each group were clearly subordinate (mean dominance index per day lower than 0.2) and rarely or never exhibited territorial/dominant behaviors (e.g., dark coloration, courtship, or aggressive displays). Although the urine volume collected daily from each male varied, males of higher social rank consistently produced more urine than males of a lower social rank; within each group, the mean urine volume collected per male was positively correlated to the male's social rank (Fig. 4a) rather than its size either at the start (group A: length, T=0.28, P=0.206; weight, T=0.25, P=0.265; group B: length, T=0.38, P=0.084; weight, T=0.12, P=0.583) or at the end of observations (group A: length, T=0.15, P=0.486; weight, T=0.20, P=0.369; group B: length, T=0.37, P=0.107; weight, T=0.24, P=0.075). In both groups, males had a small daily growth that was not correlated with social rank (Table 1).

Univariate regression analysis used to evaluate the relationship between the mean olfactory potency of urine and fish group (fixed factor), mean urine volume per day, and mean dominance index per day provided a significant explanatory regression model (R^2_{adj}=0.61, $F_{7,16}$=7.01, P=0.001). The variation in the mean olfactory potency of male

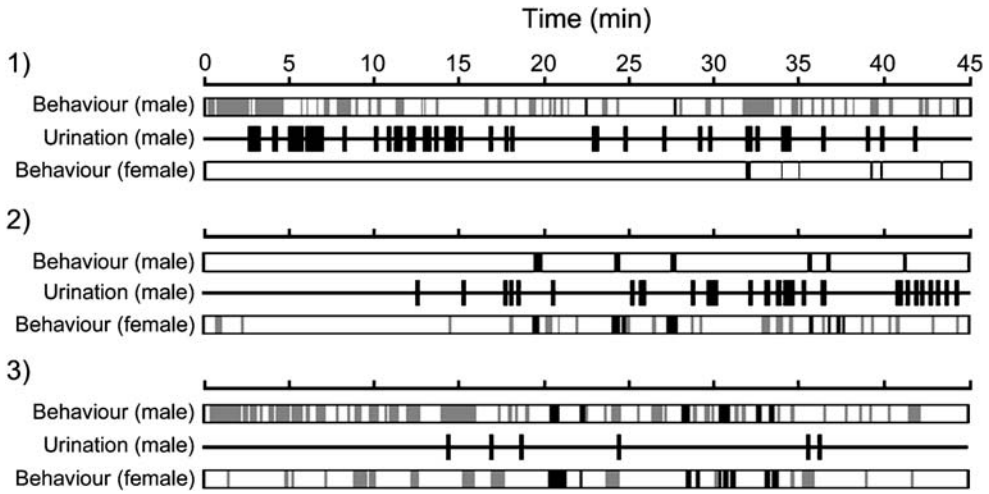

Fig. 3 Examples of male behavior, release of urine, and female behavior. Each example (*1* to *3*) shows the male's behavior (*top horizontal bar*: *white* no display, *gray* courtship displays, *black* aggressive displays), the male's urination (urine pulses of about 1 s are indicated by *vertical black bars* below the behavior of each male) and the female's behavior (*low horizontal bar*: *white* no display, *gray* receptive, *black* submissive). In examples 1 and 2, both males were in the presence of a pre-ovulatory female, and in three, the male was in the presence of a post-ovulatory female

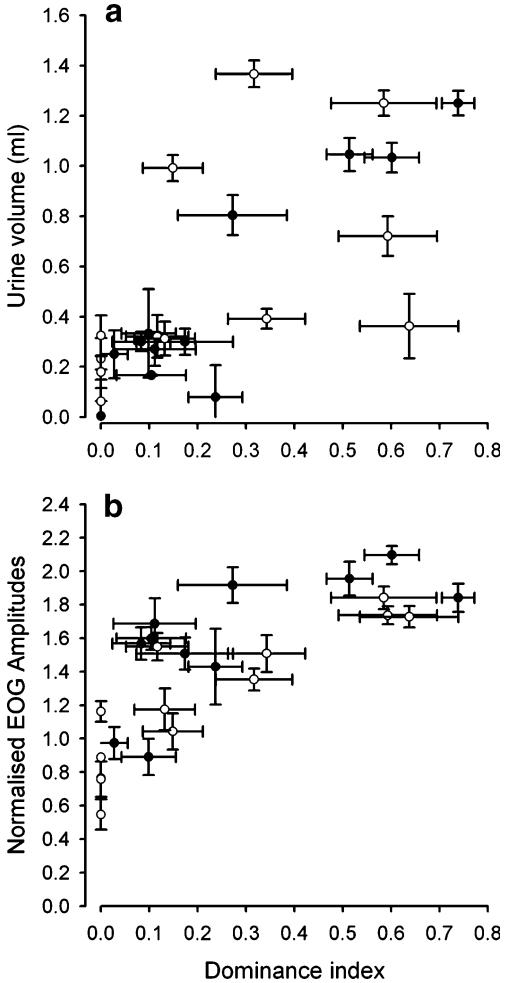

Fig. 4 Urine volume, urine olfactory potency, and dominance index of donor male tilapia in groups. Male's dominance index was calculated as the ratio of the summed frequency of dominant behaviors and the summed frequency of dominant and submissive behaviors (see "Materials and Methods"). **a** Scatter plot of mean dominance index per day (±SEM, N=10 d) and mean urine volume per day (±SEM, N=10 days) from each male in fish group A (N=12; *filled circles*) or B (N=12; *open circles*). In both groups, the urine volume was positively correlated (Kendall's correlation) to the male's dominance index (group A, T=0.60, P<0.001; group B, T=0.51, P< 0.05). **b** Relationship between dominance index (mean per day ± SEM, N=10 d) of males in fish group A (*open circles*, N=12) and B (*filled circles*, N=12), and normalized EOG amplitudes evoked by corresponding male urine (diluted 1:10,000) collected each day (mean ± SEM, number of urine samples varied between one and ten)

urine was explained by variation in the mean dominance index per day ($F_{1,18}$=4.67, P=0.044) and not by differences between the two male groups ($F_{1,18}$=1.65, P=0.215), variation in the mean urine volume collected per day ($F_{1,18}$=0.480, P=0.497), or by the interaction between the fish group and male behavior or urine volume ($F_{1,18}$= 0.502, P=0.488). The mean EOG amplitudes elicited by male urine increased with the mean dominance index per day (Fig. 4b).

Odorants in the Urine of Dominant and Subordinate Males Urine and C18 SPE eluents of urine from six dominant males evoked higher amplitude EOG responses than those of six subordinate males; matching samples of urine and SPE eluent from either group of males were not significantly different (Fig. 5). These dominant and subordinate males differed in the mean dominance index per day and mean urine volume per day; however, they did not differ in length, weight, daily growth, or GSI (Table 2).

EOG responses to liquid chromatography (LC) fractions of SPE eluent showed that fraction 15 (eluted from the LC column between 42 and 45 min) of both dominant and subordinate males evoked the largest EOG amplitudes in females, followed by fraction 16 (eluted between 45 and 48 min; Fig. 6a). The two fractions from dominant males evoked higher EOG amplitudes than the same two fractions from subordinate males (fraction 15: $F_{1,10}$=8.04, P<0.05; fraction 16: $F_{1,10}$=12.98, P<0.01; Fig. 6b). For both dominant and subordinate males, no significant difference was found between the olfactory potency of the original SPE eluent and LC fraction 15 (Student's t tests for paired samples: dominant males, t_5=0.07, P=0.946; subordinate males, t_5=2.30, P=0.07), suggesting that fraction 15 contained most of the olfactory potency found in the total SPE eluent. Control SPE eluent and methanol alone at 0.015% to 0.1% in water did not evoke EOG amplitudes higher than the water blank (data not shown).

Chromatograms of urine SPE eluent of subordinate and dominant males both had about 25 detectable peaks (Fig. 7a and b). The average retention time (RT) for CDCA (internal standard) was 68.37±0.078 min (mean ± SD). Fraction 15 corresponded to an apparent single peak (RT=43.96± 0.45 min; range from start to finish of peaks in all 12 samples = 42.5–46.5 min), which, for some samples, tailed into fraction 16. The relative area of this peak (normalized to the area of the internal standard) was higher in dominant males (11.69±1.14) than in subordinate males (6.12±0.74; Student's t test, t_{10}=4.08, P<0.005). The MS of fraction 15 was composed of two negative ions at 609.0 and 511.4 m/z for both dominant and subordinate males (Fig. 7c) with the same retention time (data not shown) strongly suggesting that they were from a single compound. The difference of m/z 98 between the two ions suggests the loss of H_2SO_4, seen for all sulfated steroids tested by Fine (2006). MS/MS on m/z 609.0 yielded a dominant negative ion of m/z 511.4, demonstrating that the two ions are from a single compound, and MS/MS on m/z 511.4 yielded a dominant ion of m/z 493.3 (loss of 18), suggesting at least one hydroxyl group in the molecule (Fig. 7d). Positive-ion MS of the peak in fraction 15 yielded three ions: m/z 535.2 $\left[M - H_2SO_4^+Na\right]$, m/z 1,047.3 [2M-2 $(H_2SO_4)^+Na$], and m/z 1,070.4 [2M-2$(H_2SO_4)^+2Na$]), consistent with fraction 15, containing a single compound. High-resolution MS analysis of the compound in fraction 15

Table 1 Daily growth (mean ± SEM, N=12) of tilapia males in two groups of fish and its correlation with dominance index

	Males in group A		Males in group B	
	Length (mm/day)	Weight (g/day)	Length (mm/day)	Weight (g/day)
Daily growth,[a] Kendall's correlation	0.41±0.04 T=0.01 P=0.666	0.33±0.07 T=0.05 P=0.836	0.22±0.04 T=0.03 P=0.881	0.27±0.05 T=0.16 P=0.472

[a] Daily growth in length and weight was significantly different from zero (Student's t test, P<0.05).

yielded ions at m/z 609.2303 and 511.2768. Although 34 potential formulae met the required criteria, only $C_{29}H_{40}N_2O_{10}S$ could explain the observed isotopic ratios that were measured (see "Materials and Methods").

Discussion

Territorial/dominant tilapia males seem to signal females by using a urinary odorant that may allow females to discriminate dominant from subordinate males. This is supported by three lines of evidence. First, territorial males urinate at higher frequency in the presence of females ready to spawn (pre-ovulatory) than they do in the presence of sexually inactive females (post-ovulatory) or in social isolation. Given that the duration of urine pulses did not change among the different social contexts, then a greater volume of urine must also be released when the male is in the presence of a spawning female. Second, a putative sulfated aminosterol-like compound with high olfactory potency is found in larger amounts in the urine of territorial/dominant males than in that of non-territorial/subordinate males. This is consistent with previous work that showed that males release sulfated steroid-like odorants in the urine (Frade et al. 2002). Third, subordinate males store less urine in the bladder than do males of higher social rank, agreeing with a previous study (Barata et al. 2007). Taken together, these results suggest that territorial/dominant males advertise social status by increasing the release of a potent urinary odorant in the presence of a spawning female; subordinate males are less capable of stimulating a female because they produce lesser quantities of the (putative sulfated aminosterol-like) odorant and are also less capable of increasing urination frequency because they store less urine.

The mixed-sex groups of fish were formed with males that previously had been kept separated from each other, all being territorial in their original tanks with four or five females, and where reproduction occurred regularly. However, when these males were placed together, a clear dominance hierarchy emerged. The dominant males were effective in defending a fixed territorial position and displayed courtship to approaching females, whereas males of lower social rank seldom or never adopted the black coloration typical of a territorial male and did not court females. This is in agreement with previous behavioral studies that showed that mating success is highly skewed toward dominant males in established groups of captive Mozambique tilapia (Oliveira and Almada 1996, 1998a). Our study also showed that dominant males store more urine than males of lower social rank, and urine of dominant males was of higher olfactory potency and related to a higher concentration of a sulfated aminosterol odorant. Therefore, we suggest that both the urine volume stored in the bladder and concentration of the sulfated aminosterol odorant reflect social dominance rather than reproductive capability (i.e., presence of mature testes).

The olfactory potency of the C18 (methanol) eluent of male urine was not significantly different from that of crude urine (Fig. 5). This indicates that the most active/important odorant(s) found in male urine are relatively non-polar (compared to substances that would have passed through

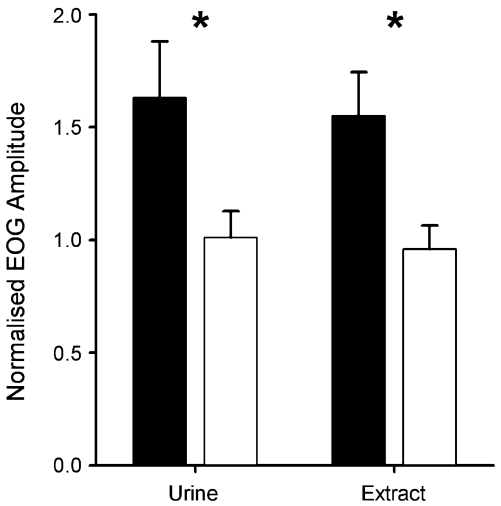

Fig. 5 Olfactory potency of male tilapia urine and extracts of urine on females. EOG amplitudes (mean ± SEM) evoked by urine and solid-phase extracts of urine (diluted 1:10,000) from subordinate (*open bars*; N=6) and dominant (*filled bars*; N=6) males. The urine and extracts of urine from dominant males elicited higher EOG amplitudes than those from subordinate males (*asterisk* between groups, $F_{1,10}$= 6.12, P<0.05); within each male type, no significant differences were found between the EOG responses elicited by the urine and the extract of urine (within subjects, $F_{1,10}$=0.58, P=0.46)

Table 2 Comparison of dominance index, urine volume, and size of dominant and subordinate tilapia males (mean ± SEM, N=6 per group)

	Dominant[a]	Subordinate[a]	t_{10} and P values
Dominance index	0.61±0.03	0.07±0.03	13.63, P<0.001
Urine volume per day (ml)	0.94±0.35	0.34±0.30	2.99, P<0.05
Length (mm)	143.5±2.8	139.7±1.7	1.17, P=0.268
Weight (g)	89.8±5.8	78.7±1.7	1.84, P=0.095
Growth in length (mm/day)	0.31±0.18	0.29±0.17	0.25, P=0.811
Growth in weight (g/day)	0.27±0.08	0.14±0.08	1.22, P=0.251
GSI (%)	1.03±0.09	0.95±0.07	0.69, P=0.505

[a] Males that were urine donors for assessment (in females) of the olfactory potency of urine, urine C18-extracts, and liquid chromatography fractions of the urine extracts

the C18 adsorbent in the aqueous urine). Furthermore, because the olfactory potency of the only EOG-active LC fraction (no. 15) was not significantly different from that of the urine extract and it contained only a single compound (as indicated by mass spectrometric analysis), it seems likely that the olfactory potency of urine extract is largely due to a single odorant (of m/z 609). Mass spectrometric analyses indicated that the odorant is a sulfated steroid derivative with a molecular weight of 610 Da. High-resolution negative-ion mass spectral data pointed to a molecular formula of $C_{29}H_{40}N_2O_{10}S$; the presence of two nitrogens in the molecule indicates that this is a sulfated aminosterol-like compound. However, further structural studies (e.g., nuclear magnetic resonance spectroscopy)

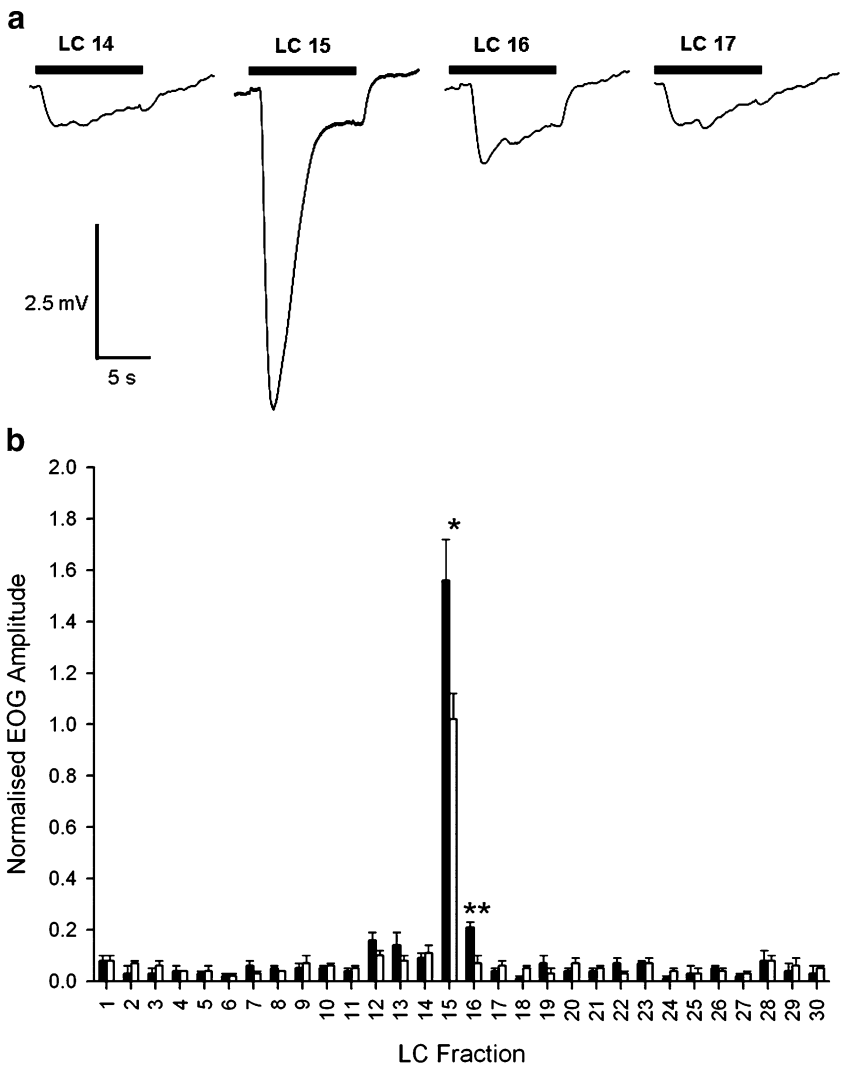

Fig. 6 Olfactory responses of female tilapia to liquid chromatography (LC) fractions of C18 solid-phase extraction eluents of male urine. **a** Typical electro-olfactograms (EOGs) recorded in response to stimuli (*black horizontal bars*) of LC fractions 14 to 17 (elution from the LC column between 40 and 51 min; each fraction corresponds to 3 min elution) diluted 1:10,000 in water. b Normalized EOG amplitudes (mean ± SEM) elicited by LC fractions (1 to 30 collected every 3 min) of extracts of urine (diluted 1:10,000) from subordinate (*open bars*; N=6) and dominant males (*filled bars*; N=6). LC fractions 15 (elution between 42 and 45 min), and 16 (elution between 45 and 48 min) from dominant males elicited higher EOG amplitudes than those from subordinate males (*P< 0.05; ** P<0.01)

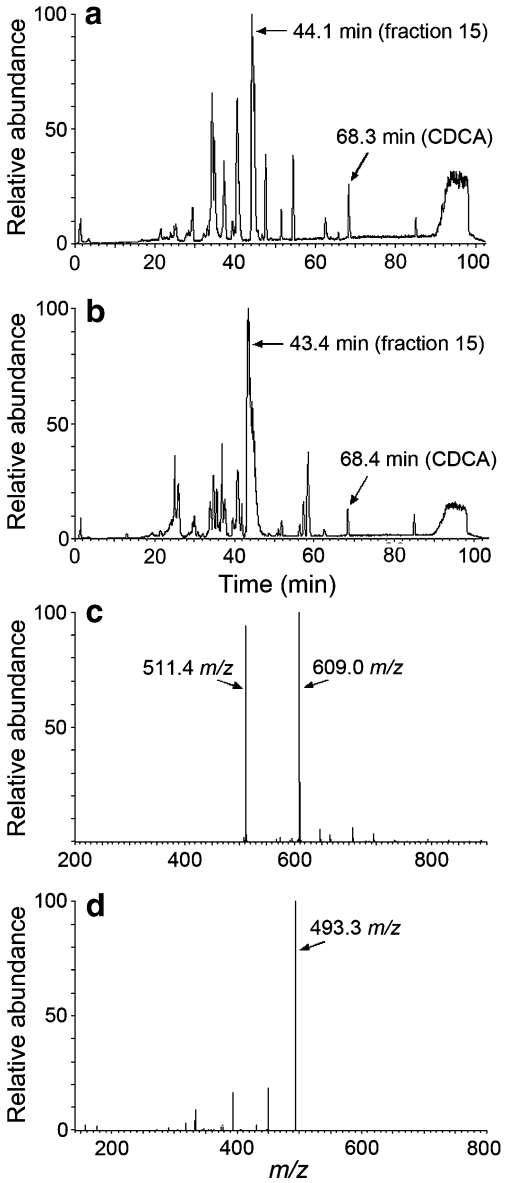

Fig. 7 Representative liquid chromatography–mass spectrometry chromatograms of male tilapia urine extracts. Subordinate male (**a**) and a dominant male (**b**). In both chromatograms, the olfactory active peak of fraction 15 (42–45 min) is indicated by the arrow and corresponding retention time; chenodeoxycholic acid (CDCA; 1 μg) was added as internal standard. **c** Mass spectrum of the peak centered at 43.4 min in (**b**). Both ions are from a single compound; the smaller shows the loss of a sulfate from the larger. The spectrum for the peak at 44.1 min in (**a**) is identical (data not shown). **d** Mass spectrometry/mass spectrometry of 511.4 *m*/*z* in **c**. The dominant ion (*m*/*z* 493.3) shows the loss of H_2O

are required for complete identification and structure assignment. Interestingly, novel sulfated aminosterols have been identified as important constituents of the migratory pheromone of the sea lamprey *Petromyzon marinus* (Sorensen et al. 2005; Hoye et al. 2007). If further studies show that the putative urinary pheromone of male tilapia is an aminosterol, it would be the second instance that such a class of compound has been shown to act as an odorant and, possibly, as pheromones in vertebrates.

The finding of a single odorant in the urine extract, the chemical identity of which does not resemble any known reproductive steroids, is intriguing. In male tilapia, the concentration of urinary steroids is modulated by social context; testosterone (T), 11-ketotestosterone (11KT), 17,20β-dihydroxy-4-pregnen-3-one (17,20β-P), and 17,20α-dihydroxy-4-pregnen-3-one (17,20α-P) are positively correlated to dominance (Oliveira et al. 1996). However, none of these steroids evokes significant EOG responses even at concentrations as high as 10^{-6} M (Frade et al. 2002), and the current study confirmed that the female olfactory system is insensitive to male urinary sex-steroids. This contrasts with the idea that pheromones are generally mixtures of compounds (Wyatt 2003) and that, in teleosts, reproductive pheromones are mixtures of sex hormones (and their metabolites) in which the ratio of components varies between species and gender and, within a sex, varies with reproductive status (Stacey and Sorensen 2006). However, we have not investigated thoroughly all possible urinary odorants. The methanol eluent from our C18 purification procedure should contain relatively low polarity compounds; more polar compounds should have passed through the column with the water of the urine. Therefore, it is possible that we missed a fraction of urinary odorants for females because we did not test the olfactory potency of the aqueous eluent.

Tilapia females have high olfactory sensitivity to male-conditioned water and to bile and intestinal fluids of males (Frade et al. 2002), suggesting that the urinary odorant found in this study may be detected as part of a mixture of odorants and that females may use the ratio, rather than the absolute amount, to discriminate between dominant and subordinate males. Possibly, dominant males but not subordinates change this ratio by increasing their urination rate in the presence of a female ready to spawn; subordinate males not only produce less of the urinary odorant but are apparently unable to store as much urine in the bladder. Subordinate males would thus be less capable of changing their profile of odorants when in the presence of a female ready to spawn. Although longer urine retention by dominant males would, at least partly, explain the higher concentration of the aminosterol odorant in their urine than in that of subordinate males, our results suggest that production of urinary odorants is higher in dominant than in subordinate males. Further research is required to determine the site of production of urinary odorants, especially the aminosterol-like compound.

Female reproductive condition affects the urination frequency of territorial males; males showed the same intensity of courtship behaviors with pre- or post-ovulatory females but urinated much more in the presence of pre-

ovulatory females. The behavior of the two groups of females was not different (perhaps due to stress because of handling before their introduction in the male's tank), suggesting that the increase in urine release by males was triggered by odors from pre-ovulatory females as previously suggested (Miranda et al. 2005). In contrast to males, females release urine in shorter pulses and at higher frequency, and this is, apparently, unaffected by the presence of a territorial male (Almeida et al. 2005). Our study appears to be the first to link the release of a urinary aminosterol-like odorant directly with both the social status of a male fish and its reproductive opportunity, which may be perceived through female odors (including urinary odorants).

Chemical signaling through urinary pheromones has been previously shown in female goldfish, which increase their release of urine containing the post-ovulatory hormonal pheromone, prostaglandin $F_{2\alpha}$ and, thereby, mark spawning sites and attract males (Appelt and Sorensen 2007). The goldfish scramble-competition mating system, floating spawning substrate, and prostaglandin pheromones in female urine are representative of many species of cyprinids (Stacey and Sorensen 2006). In other fish groups, different suites of hormonal products in the urine are used as pheromones (Colombo et al. 1980; Liley 1982; Katsel et al. 1992; Vermeirssen and Scott 2001; Stacey and Sorensen 2006) in what appears to be insipient specialization for chemical communication between the sexes. This varies taxonomically but may also be related to different life histories or reproductive strategies. In contrast, in tilapia, chemical signaling seems to be more complex occurring both between males (Barata et al. 2007) and reciprocally between males and females.

In summary, dominant/territorial tilapia males release urine in pulses of short duration, the frequency of which increases dramatically in the presence of females ready to spawn, but which does not increase in the presence of post-spawn females. Male urine is a vehicle of a putative sulfated aminosterol that is an important urinary odorant detected by the female's olfactory system. Both the concentration of this odorant and the urine volume in the bladder are higher in dominant than in subordinate males, implying that males of low social rank are less capable of stimulating females ready to spawn. We suggest that the putative aminosterol in male urine may act as a pheromonal signal of dominance and influence female spawning.

Metasternal Gland Volatiles and Sexual Communication in the Triatomine Bug, *Rhodnius prolixus*

Gina B. Pontes · Björn Bohman · C. Rikard Unelius · Marcelo G. Lorenzo

Received: 15 June 2007 / Revised: 26 November 2007 / Accepted: 9 January 2008 / Published online: 4 March 2008

Abstract Twelve compounds produced by the metasternal glands (MGs) of the triatomine bug *Rhodnius prolixus* were identified by solid phase microextraction (SPME) combined with coupled gas chromatography-mass spectrometry (GC-MS) using achiral and chiral columns. All substances were ketones or alcohols, and the same compound profile was found in the secretions produced by either sex. The most abundant compounds were 2-methyl-3-buten-2-ol, (2*S*)-pentanol, (3*E*)-2-methyl-3-penten-2-ol, and (2*R*/2*S*)-4-methyl-3-penten-2-ol. Emission of these compounds was detected more frequently from females than males, and females released them more frequently during the early hours of the scotophase, the period when sexual activity in this species is at its peak. These compounds were also detected in the headspace above mating pairs. Finally, the occlusion of the MG orifices of male or female bugs with paraffin resulted in a significant decrease in copulation frequency compared to sham-operated insects. Together, these data suggest that the MG secretions of *R. prolixus* may be involved in sexual communication.

Introduction

Rhodnius prolixus Stål 1859 (Heteroptera: Reduviidae) is the main vector of Chagas disease in northern South America and in parts of Central America (Schofield 1994). This species is well adapted to live in rural houses and is considered to be of major epidemiological importance (Monteiro et al. 2003). Approximately 16–18 million people in Latin America are infected with the Chagas disease parasite, *Trypanosoma cruzi*, and another 120 million are at risk (WHO 2005).

Baldwin et al. (1971) reported that copulating pairs of *R. prolixus* emit a pheromone that is attractive to males. This phenomenon has also been observed for another vector of Chagas disease, the bug *Triatoma infestans* (Manrique and Lazzari 1995). Relatively little is known about the mechanisms of long- or short-distance orientation that mediate sexual encounters between adults of species in the subfamily Triatominae, although Baldwin et al. (1971) suggested that feeding triggers the development of sexual attraction in *R. prolixus* and that unfed males of this species do not respond to the apparent odor emitted by mating pairs.

R. prolixus adults have a pair of metasternal glands (MGs) that open to the ventral metathorax (Brindley 1930). Their function and the chemical identity of any secretions are unknown. Another set of glands of this insect, the Brindley's glands, which secrete isobutyric acid as the most abundant compound, are likely associated with alarm and defense functions (Ward 1981; Cruz López et al. 1995; Rojas et al. 2002; Manrique et al. 2006). It has been suggested that compounds produced by Brindley's glands are involved in the sexual chemical communication of triatomines (Cruz López et al. 2001; Rojas et al. 2002; Guerenstein and Guerin 2004).

In a recent study, Manrique et al. (2006) suggested that the secretions of the MGs of *T. infestans* are involved both in sexual and alarm communication, and that the secretions of Brindley's glands are restricted to alarm and defensive roles. These authors identified several highly volatile ketones and alcohols produced by the MGs and showed that the contents of these glands are emitted by adults of this species during copulation.

Our primary objective in this study was to identify volatile secretions produced by the MGs of *R. prolixus*. We further tested whether the MG compounds are emitted at different phases of the light/dark cycle by virgin males and females and examined if mating pairs of this species emit these substances. Finally, we tested whether the compounds emitted from these glands influence copulation.

Methods and Materials

Insects Insects were reared at 26±2°C and 60±10% r.h. Groups of fifth instars were sorted by sex and placed in separate flasks to keep them unmated until use in experiments. All insects used were kept under the 12:12 L:D photoperiod for at least 3 d before any experiment. Virgin insects were used for all experiments, and their nutritional status was varied according to the experiment performed. For odor-identification studies, unfed insects were dissected at d 20 after ecdysis. For the detection of emission of MG compounds, insects were fed at d 10, and used 20 d after ecdysis. For the remaining two experiments (i.e., detection of emission of MG odors during mating and evaluation of the effect of gland occlusion on mating success), insects were used at d 20 after being fed at d 10. All assays were performed at 26±2°C and 60±10% r.h.

Identification of Compounds Produced by Metasternal Glands Samples of 12 glands were obtained from six insects and stored in 2-ml vials sealed with Teflon®/silicone-lined caps. Control samples were prepared with pieces of tissue and cuticle from hind leg coxae. Female and male tissue was stored at −8°C for not more than 10 d before analysis. No change of the chemical profile was observed after storage when compared with freshly prepared samples.

Gland samples were sonicated (Thornton T14, Inpec Eletrônica, Brazil, 40 kHz) for 5 min and then heated at 50°C for 30 min. A solid phase microextraction (SPME) fiber (2 cm, DVB/CAR/PDMS-50/30 μm, Supelco, Bellefonte, PA, USA) was exposed in the headspace of the samples (in vials) for 10 min at 50°C immediately before analysis by gas chromatography-mass spectrometry (GC-MS). GC-MS analysis was performed by using coupled Shimadzu 17A-5050A machines. Desorption time in the splitless injection port of the GC was 1 min. Helium at 30 cm s^{-1} was used as carrier gas. Transfer line and GC injector temperatures were 250 and 230°C, respectively. Analyses were performed by using a SupelcoWax-10 column (30 m×0.25 mm i.d.×0.25 μm film; Supelco), with an oven program of 40°C for 5 min, 3°C min^{-1} to 120°C, then 15°C min^{-1} to 200°C.

Tentative identification of volatile compounds was based on the comparison of retention indices (Kováts 1965) and mass spectra with data from the literature and spectral library (NIST-02). All tentative identifications were confirmed by peak enhancement in co-injections with authentic synthetic samples (Birkett et al. 2004). A typical procedure for co-injection/peak enhancement is given for 2-pentanol: A gland sample was prepared and analyzed as described. After a chromatogram was obtained, the gland sample was treated again according to the same protocol (i.e., sonicated, heated, and sampled by SPME). In parallel, a sample of synthetic standard was prepared: 1 μl of the compound was absorbed on a small piece of filter paper (1×1 cm) in a 10-ml open vial. The vial was heated at 50°C for 3 min and cooled to ambient temperature for 1 min. The same SPME fiber was exposed to the standard sample for 2 sec, and the odors were desorbed from the fiber into the GC injector. The results of both injections were compared and the identity of the compound confirmed when three criteria were fulfilled. First, the peak from the MG compound and the synthetic compound overlapped fully. Second, the peak area increased in the second injection. Third, no difference between the mass spectral profiles was observed after a scan-by-scan analysis.

The stereochemistry of chiral compounds was determined by GC with flame-ionization detection (FID; Shimadzu 17A) and GC-MS analysis. Gland samples were heated at 50°C for 30 min, and the SPME fiber was exposed in the headspace for a given time depending on the relative abundance of a compound. The method used for analysis was the same as for the GC-MS analysis, except the carrier gas velocity was 31 cm sec^{-1}, the injector and detector temperatures were both 225°C, and a CYCLOSILB column (30 m×0.25 mm i.d.×0.25 μm film, J & W Scientific) at either 80°C, for 4-methyl-3-penten-2-ol, or 30°C, for the other compounds, was used. Because a number of peaks overlapped with this column and conditions, chiral GC-MS analysis was carried out by using a GammaDex 225 column (30 m×0.25 mm i.d.×0.25 μm film) at 30°C. The retention times of compounds were compared with synthetic standards, and co-injection (peak enhancement) was carried out to confirm the identities of the enantiomers of all compounds. The configuration of 2-methyl-3-penten-2-ol was confirmed by co-injection with the synthetic (*E*)-isomer, derived from *trans*-methyl crotonate (for synthesis details, see below).

Emission of MG Compounds by Virgin Adults Groups of three virgin adults of the same sex were separated 7 d after ecdysis and transferred into 10-ml vials covered with gauze with a piece of filter paper inside as a substrate for the bugs. These vials were enclosed separately in 150-ml closed plastic containers so as to isolate each group of bugs. We worked with groups of insects to increase both the likelihood of emission and the amount of MG odors (preliminary assays with individual insects failed probably because of low levels of compounds). Each treatment included three groups of three insects. The different series of assays monitored odor emission by: (1) unfed females during the dark phase; (2) unfed females during the light phase; (3) females fed at d 9 after ecdysis, during the dark phase; (4) females fed at d 9 after ecdysis, during the light phase; (5) unfed males during the dark phase; (6) unfed males during the light phase; (7) males fed at d 9 after ecdysis, during the dark phase; and (8) males fed at d 9 after ecdysis, during the light phase. Odor sampling with a SPME fiber was carried out for 1 hr for each treatment. Volatile compounds on the fiber were desorbed immediately after sampling the headspace. This procedure was repeated every second day over a period of 12 d with all groups, i.e., giving a total of six samples per group of three insects and 18 samples for each of the eight treatments. Control samples were obtained by SPME analyses of vials containing a piece of filter paper.

The data from studies of emission of MG compounds by *R. prolixus* adults were analyzed both for individual substances and for pooled samples. This allowed the comparison of emission activity between series (treatments). Every time a MG odor was detected over the samples, this was recorded as a "detection event".

Emission of MG Compounds During Copulation One *R. prolixus* female and one male were gently transferred onto a piece of filter paper inside a 10-ml vial, so as to avoid disturbance and the consequent emission of Brindley's glands' products (Manrique et al. 2006). The vial was closed with a Teflon®/silicone-lined cap. After copulation had begun, volatiles present in the headspace were sampled for 60 min with a SPME fiber. Volatile compounds were analyzed immediately after sampling the headspace. Twenty assays were performed. Each pair of insects was used only once and then discarded.

Odors Emitted by MGs and Possible Effect on Mating in R. prolixus A pair of bugs was gently introduced into a Petri dish (10×2 cm) lined with a piece of filter paper and covered with glass to prevent escape. Whether the pair copulated or not was observed for 60 min; if the pair did not commence copulation within this time, it was considered that no copulation occurred. To evaluate the relevance of MG odors for the success of copulation, the proportion of mating pairs under different treatments was compared: (1) pairs in which males had the MG orifices occluded with paraffin (N=20), (2) pairs in which females had the MG orifices occluded with paraffin (N=20), and (3) pairs in which both males and females had the MG orifices occluded with paraffin (N=20). To test whether this treatment affected the behavior of the insects, two series of control assays were performed: (4) a group in which sham males had paraffin applied on a different area of the cuticle without covering the MG orifices (N=20), and (5) a group in which sham females had paraffin applied on a different area of the cuticle without covering the MG orifices (N=20). An additional control series (6) evaluated the mating frequency in intact pairs (N=20). All experiments were performed at 26±2°C and 60±10% r.h. The behavior of insects was studied during the first half of the dark phase of their activity cycle.

Chemicals 2-Butanone, 2-pentanone, (2*R*)-2-butanol, (2*S*)-2-butanol, 2-methyl-3-buten-2-ol, 3-pentanol, 2-pentanol, 4-methyl-2-pentanol, 3-hexanol, and 2-methyl-1-butanol were purchased from Sigma-Aldrich (Brazil). (2*S*)-3-Methyl-2-butanol, (2*S*)-2-pentanol, and (2*S*)-4-methyl-2-pentanol were purchased from Lancaster Synthesis (UK). (3*E*)-2-Methyl-3-penten-2-ol was synthesized from methyl crotonate according to Stavinoha et al. (1981), and 4-methyl-3-penten-2-ol was synthesized according to Johnson and Rickborn (1970).

(3E)-2-Methyl-3-penten-2-ol Methyl crotonate (0.96 g, 9.6 mmol) was added dropwise at <−10°C under nitrogen to an ether solution of 1.6 M methyllithium (20-ml, 32 mmol) over 30 min. The mixture was stirred for an additional 3 hr at 0°C before Baeckströms reagent (celite/Na_2SO_4, 1:1 *w*/*w*) was added. The mixture was filtered and concentrated *in vacuo*, giving (3*E*)-2-methyl-3-penten-2-ol as a colorless liquid (0.57 g, 60%). ^{1}HNMR: δ: 5.63 (m, 2H), 1.68 (d, 4.5 Hz, 3H), and 1.30 (s, 6H). ^{13}CNMR: δ: 139.37, 122.16, 70.89, 29.97, and 17.87 ppm.

4-Methyl-3-penten-2-ol Sodium borohydride (0.19 g, 5.0 mmol) was dissolved in ethanol (50%, 10-ml). 4-Methyl-3-penten-2-one (mesityl oxide, 1.0 g, 10.0 mmol) was added dropwise, while stirring at 0°C. The reaction mixture was stirred at ambient temperature overnight. K_2CO_3 was added until the solution was saturated, after which the product was extracted with diethyl ether (2× 20-ml). The ether phase was washed with brine (20-ml) and dried over $MgSO_4$. Evaporation of the solvent gave 4-methyl-3-penten-2-ol as a colorless liquid (0.88 g, 87%). ^{1}HNMR: δ: 5.20 (d, 8.6 Hz, 1H), 4.55 (dq, 8.4, 6.3 Hz, 1H), 1.71 (s, 3H), 1.68 (s, 3H), and 1.22 (d, 6.3 Hz, 3H).

^{13}CNMR: δ: 134.43, 129.57, 65.03, 25.87, 23.84, and 18.23 ppm.

A mixture enriched in (2*S*)-4-methyl-3-penten-2-ol was obtained from the racemate by a lipase-catalyzed reaction (Amano PS immobilized on diatomite, Sigma-Aldrich, Sweden; Brenna et al. 1998). Racemic 4-methyl-3-penten-2-ol (20 mg, 0.20 mmol) and vinyl acetate (100 mg, 0.86 mmol) were dissolved in dichloromethane (1-ml). Amano PS-DI (20 mg) was added to the mixture, which was left for 5 hr, with occasional shaking. Chiral GC-MS analysis showed a product enriched in the *S*-enantiomer. The assignment of the stereochemistry was based on the well-known stereochemical preference of the Amano-PS lipase (Kazlauskas et al. 1991). A mixture enriched in (3*S*)-hexanol was obtained according to the same protocol.

For all synthesized compounds, ^{1}H-NMR and ^{13}C-NMR spectra of $CDCl_3$ solutions were recorded at 500 and 125 MHz by using a Varian Unity spectrometer. Chemical shifts were expressed in ppm in relation to tetramethylsilane. The starting materials were obtained from commercial suppliers and used without further purification. NMR data corresponded well with literature data (Ando et al. 1982; Gau et al. 1999).

Statistical Analyses The results, expressed as the numbers of mating pairs per group of bugs, with or without their glands occluded, were analyzed by means of a Chi-square test followed by multiple comparisons using the Bonferroni correction. Therefore, only comparisons having $P<0.003$ were considered to show a significant difference.

Results

Identification of Compounds Produced by MGs Our results showed that the MGs of *R. prolixus* are the sources of a complex mixture of volatile substances. Twelve ketones and alcohols were identified in the MGs of *R. prolixus*, with the most abundant compound being 2-methyl-3-buten-2-ol, followed by 2-pentanol, (3*E*)-2-methyl-3-penten-2-ol, and 4-methyl-3-penten-2-ol (Table 1). The same substances were detected in the MGs of both sexes. The chiral alcohols 2-butanol, 2-pentanol, 4-methyl-2-pentanol, and 3-hexanol were found as *S*-enantiomers only, while 4-methyl-3-penten-2-ol (mesityl alcohol) was found as a mixture of the two enantiomers (Table 1). Because 3-methyl-2-butanol and 2-methyl-1-butanol were present at very low concentrations and/or co-eluted with other major compounds on both of the columns used, the chiral analysis was not unequivocal.

Emission of MG Compounds by Virgin Adults MG compounds were consistently detected in the headspace of adult bugs (Fig. 1, Table 2). Detection events (i.e., each time any MG compound was detected) were recorded more frequently in both females and males during the scotophase than the

[a] Retention time (SupelcoWax-10 column)
[b] Retention indices calculated according to Kováts (1965)
[c] Relative amount (mean and SD) from eight female samples
[d] Relative amount (mean and SD) from eight male samples
[e] Relative amount (mean and standard deviation) from all 16 samples
[f] Average amount ≤0.5% of total amount of compounds in sample
[g] Three (one ♂ and two ♀) out of 16 samples contained 10.5–13.1%, and the remaining 13 samples 0.0–3.4%

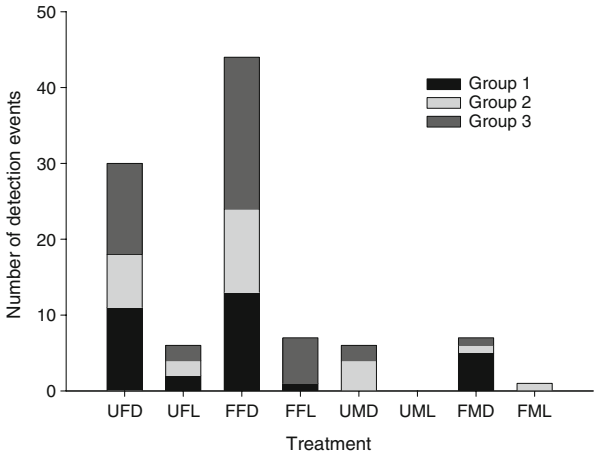

Fig. 1 Number of detection events of various *R. prolixus* metasternal gland compounds in different groups (each of three individuals) of fed/unfed males and females during the light and dark phases. *UFD* Unfed females during dark phase, *UFL* unfed females during light phase, *FFD* fed females during dark phase, *FFL* fed females during light phase, *UMD* unfed males during dark phase, *UML* unfed males during light phase, *FMD* fed males during dark phase, *FML* fed males during light phase

photophase (Fig. 1, Table 2). In general, more detection events were recorded from females than males under all experimental conditions (Fig. 1, Table 2). There was no apparent difference between unfed and fed insects.

Nine out of the 12 compounds found in the MGs were detected in the headspace over females over all the different treatments (Table 2), whereas only three of them were found in the headspace over males (Table 2). 2-Methyl-3-buten-2-ol was the most frequently detected compound in these analyses (Table 2).

Emission of MG Compounds During Copulation In 19 out of 20 assays with pairs, a successful copulation resulted. The average duration of copulation was 49.7±3.6 min. At least one of the compounds identified in the MGs was detected during 70% of the copulations. The most abundant compound produced by the MGs (2-methyl-3-buten-2-ol) was detected in 40% of the copulations. The compound most frequently found during copulation (in 60% of the samples) was 2-methyl-1-butanol. 2-Pentanone was detected in 10% of the assays.

Relevance of the Odors Emitted by MGs for the Success of Mating The percentage of copulation of untreated control pairs was 95% (Fig. 2, N=20). This was not significantly different from the percentages of copulation observed in sham-operated male and female treatments (Fig. 2). However, occlusion of female MG orifices or male MG orifices resulted in significant (P<0.003) decreases in copulation frequencies (30%, N=20 and 15%, N=20, respectively). Occlusion of both male and female orifices also resulted in a significant (P<0.003) decrease (relative to the controls) of mating percentage (15%, N=20).

Discussion

The results show that the metasternal glands of *R. prolixus* are a rich source of volatile compounds. GC-MS analysis

Table 2 The detection of *Rhodnius prolixus* metasternal gland compounds in various treatments, related to sex, feeding status, and time of day

Compound	UFD	UFL	FFD	FFL	UMD	UML	FMD	FML
2-Butanone	1	0	3	0	0	0	0	0
2-Pentanone	2	0	2	0	0	0	0	0
(2*S*)-Butanol	3	1	8	1	0	0	0	0
2-Methyl-3-buten-2-ol	7	2	11	3	4	0	6	1
3-Methyl-2-butanol	5	0	4	0	0	0	0	0
3-Pentanol	0	0	0	0	0	0	0	0
(2*S*)-Pentanol	4	1	5	1	1	0	0	0
