To determine the configuration of the sugar moiety, the isolated compound was refluxed with 6 N HCl (5 ml) at 100°C for 2 h (Li et al., 2009b). The mixture was extracted with $CHCl_3$ to remove the aglycone, then the aqueous layer was neutralized with Na_2CO_3, filtered, and dried under vacuum. A portion of the aqueous residue was dissolved in H_2O for sugar analysis by thin layer chromatography (TLC) (Macherey-Nagel, SilG/UV254, 0.20 mm) with n-BuOH: HOAc:H_2O (6:1:2) as the solvent. TLC sample spots were detected by spraying aniline hydrogen phthalate reagent (100 ml n-butanol saturated by H_2O, 0.96 g aniline and 1.66 g phthalic acid) and heating. The absolute configuration of glucose was determined by chiral GC-FID analysis using an Agilent GC and a 0.25 mm×25 mm Hydrodexb-6-TBDM chiral capillary column (Macherey-Nagel, Germany). *β*-D-glucose (Sigma) was used as an authentic GC standard. A portion of the aqueous layer residue also was resuspended in 1 ml dichloromethane followed by the addition of 50 μl trifluoroacetic anhydride. The mixture was allowed to react at room temperature for 16 h and dried under a stream of nitrogen at room temperature. The sugar derivative was separated on the GC using the following temperature program: inlet temperature at 240°C; hydrogen carrier gas and a 1/20 split using nitrogen as the makeup gas; column temperatures starting at 120°C, ramping to 220°C at 50°C min^{-1} and maintenance for 12 min.

Microarray Total RNA was extracted from *Arabidopsis* seedlings grown on agar plates for 6 d with or without 4-MU supplementation using the RNeasy plant mini kit (Qiagen, Valencia, CA, USA). cDNA was prepared using Superscript II reverse transcriptase (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. Three biological replicates were collected for each sample. An *Arabidopsis* 26 K cDNA array (Qiagen, Valencia, CA, USA) was hybridized with Cy5- and Cy3-labelled probe pairs from the 4-MU treated and untreated samples. Probe labeling, hybridization, and washing were conducted using a CyScribe Post-Labeling kit according to the manufacture's instruction (Amersham Biosciences, Pittsburgh, PA, USA). Hybridized slides were scanned on a GenePix 4000B scanner (Axon Instruments Inc., Union City, CA, USA). The intensity (I) of each spot at λ_{546nm} and λ_{647nm} was transformed into a I_{546}:I_{647}ratio with Array-Pro Analyzer 4.0 (Media Cybernetics Inc., Bethesda, MD, USA). Microarray data initially were imported into BASE 1.2.16. The data then were filtered, normalized, and analyzed with Gene-Spring 6.1 (Silicon Genetics, Redwood City, CA, USA) as previously described (Zhao et al., 2009), and imported into MapMan for category analysis.

Real Time RT-PCR mRNA from the microarray experiment was converted to cDNA with SuperScript III First-Strand Synthesis SuperMix (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. Quantitative real time PCR analysis (qRT-PCR) was carried out using a Platinum SYBR Green qPCR SuperMix-UDG kit (Invitrogen, Carlsbad, CA, USA) on an ABI PRISM StepOnePlus Real-Time PCR System (Applied Biosystems) as previously described (Gao et al., 2009; Li et al., 2011). The *Arabidopsis*

Ef-1α gene was chosen as an endogenous reference gene. Primer sequences for qRT-PCR were designed using Oligo Perfect Primer Design software provided by Invitrogen (http://tools.invitrogen.com/) (Table 2). For each pair of primers, gel electrophoresis and melting curve analyses were performed to ensure that only a single PCR amplicon of the expected length and melting temperature was generated. Each sample was assayed in triplicate, and data were analyzed using Step-One v2.0 (Applied Biosystems). The level of each mRNA was calculated using the mean threshold cycle (Ct) value and normalized to that of the reference gene *Ef-1α*. All results are shown as means of at least three biological replicates with corresponding standard deviations (SD).

Glucosyltransferase Activity Assay To generate constructs for GST-UGT expression, the full length open reading frames (ORFs) of *UGT73B4* and *UGT75B2* were amplified by PCR using primers 73B4-PET-F and 73B4-PET-R for *UGT73B4* and primers 75B2-PET-F and 75B2-PET-R for *UGT75B2* (Table 2), and cloned into the pET102/D/TOPO vector using the directional TOPO cloning system (Invitrogen, Carlsbad, CA, USA). All constructs were confirmed by DNA sequencing. The recombinant plasmids were transformed into *Escherichia coli* BL21 Star (DE3) cells (Invitrogen, Carlsbad, CA, USA), and the protein was purified as a GST fusion according to the manufacturer's instructions (Qiagen, Valencia, CA, USA). Each glucosyltransferase activity assay mix (2 ml) contained 100 μg of recombinant protein, 50 mM Tris-HCl, pH 7.0, 10 mM β-mercaptoethanol, 10 mM UDP-glucose, and 1 mM 4-MU as substrate. The reaction mix was incubated at 28°C for 1 h, stopped with the addition of 200 μM trichloroacetic acid, and subjected to reverse-phase HPLC analysis as described above. Absorbance at λ_{320} was used to monitor chromatogram profiles, and the identity of peaks (compounds) was confirmed by comparing retention times and photo-diode array profiles with authentic standards.

Statistical Analysis All experiments were conducted in triplicate and mean data (±SD) analyzed with ANOVA for significance (LSD at $P<0.05$) using SAS 9.0 (SAS Institute, Inc. Cary, NC, USA), unless otherwise indicated. For microarray analysis, log ratios of intensity after

background correction were scaled to have similar distribution across and consistency among arrays. The ANOVA model "log $(y_{ijkgr})=\mu+A_i+D_j+T_k+G_g+AG_{ig}+DG_{jg}+TG_{kg}+\varepsilon_{ijkr}$" was employed to detect differentially expressed genes using the normalized data, where log (y_{ijkgr}) represents the background-corrected and normalized natural logarithm of the intensity of the r^{th} replicate of gene g on array i, with dye j, and treatment/condition k; μ represents the average natural logarithm of gene intensity over all the genes, arrays and dyes; A, D, T, and G represent the array, dye, treatment and main gene effect, respectively; and ε_{ijkr} represents normal distribution with mean zero (Li et al., 2009a).

Results

Identification of 4-MU as a Root Growth Effector A set of 128 natural compounds was screened for their impact on *Arabidopsis* seed germination, primary root growth, root architecture, and seedling establishment. Out of this screening, seven coumarins and five phenolic acids delayed *Arabidopsis* seed germination and inhibited root growth. One coumarin and two ginsenosides inhibited root growth alone, and one phenolic acid and one flavonoid inhibited seed germination alone (Supplementary Table 1). Of all compounds tested, 4-MU affected all three parameters, including root architecture. Since 4-MU was the only compound to affect root architecture, it became the focus of the remainder of this study

Seed germination was inhibited by a range of 4-MU treatments. Germination rates were 90% and 75% with 125 μM and 250 μM 4-MU, respectively. Seeds were unable to germinate when the concentration of 4-MU was increased to 500 μM (data not shown). Primary root growth was inhibited in 6-d-old seedlings grown on medium supplemented with 125 μM or 250 μM 4-MU (Fig. 1a,b,c). Primary root length was reduced by 25% and 75%, respectively, compared to untreated control seedlings over a 22 d time period (Fig. 2a), but growth of cotyledons, hypocotyls and rosette leaves was not affected at these concentrations (Figs. 1a,b, c and 2b). Accompanying the negative effect on primary root growth, the development of root hairs on primary roots also was affected by 4-MU. Approximately 20% of root hairs on primary roots were bulbous at 125 μM 4-MU (Fig. 1h), while very few root hairs were fully emerged at 250 μM 4-MU (Fig. 1i). After exposure to 125 μM 4-MU, lateral roots began to form as buds by day 14, and abundant lateral roots had formed by 22 days, even though primary root growth was hindered (Fig. 2c). Since accumulation of coumarins can be detected in plant tissues under UV light (Chong et al., 2002; Kai et al., 2008), the 6-d-old *Arabidopsis* seedlings grown on media supplemented with 4-MU were compared with untreated roots under UV light. Consistent with the

Accumulation and Glucosylation of 4-MU in Arabidopsis Roots To confirm the presence of 4-MU in *Arabidopsis* roots, we analyzed the phytochemical composition of roots of 6-d-old seedlings by HPLC-UV/MS. In MeOH extracts from roots exposed to 125 µM 4-MU, 4-MU and a large additional peak were detected at *Rt* 36.5 min and *Rt* 23.0 min, respectively. Neither of these peaks was detected in the roots of untreated seedlings (Fig. 3a). Comparison of the ^{1}H NMR spectrum of the new reaction product with that of 4-MU (Supplementary Data Figs. 2 and 3) showed no significant chemical shifts in the aromatic proton signals, but an additional set of sugar moiety signals appeared at δ 4.95 (1H, *d*, J=7.6 Hz), 3.82 (1H, *d*, J=11.8 Hz), 3.62 (1H, *dd*, J=5.6, 11.8 Hz), and 3.32-3.45 (3H, m) (Table 1). Combinational ^{1}H-^{1}H COSY and HMBC NMR spectra (Supplementary Data Figs. 4 and 5) were used to elucidate the structure. The sugar moiety was identified as glucose on the basis of an acid hydrolysis reaction, which gave a reaction product with the same R_f on a TLC plate as an authentic glucose standard compound (data not shown). The coupling constant $J_{H1', H2'}$ (7.6 Hz) of the new enzyme reaction product, followed by chiral GC analysis, indicated an absolute configuration of β-D-glucose. The new reaction product was defined as $C_{16}H_{18}O_8$ [4-MU-β-D-glucopyranoside (4-MU-Glc)] based on its HRESIMS ($[M+Na]^+$, *m/z* 361.0906, calc. 361.0899) (Fig. 3b). This indicates that 4-MU is partially transformed into 4-MU-Glc by glucosylation after uptake in *Arabidopsis* roots.

To gain additional insight into how *Arabidopsis* plants react to 4-MU by glucosylation after seed germination, we conducted a microarray analysis of 6-d-old seedlings grown on medium containing 125 µm 4-MU (Supplementary Data Tables 2 and 3). A total of 316 genes showed statistically significant up-regulation, while 243 showed statistically significant down-regulation. Genes determined to be up-regulated or down-regulated ≥ 2-fold in the treated relative to the untreated sample were catalogued and placed into twelve categories based on gene function according to *Arabidopsis* Gene Ontology (Supplementary Data Fig. 6). Although differences between treated and untreated samples were noted for individual genes, the number of up-regulated and down-regulated genes were similar in the categories of response to stress (51 vs. 48), response to

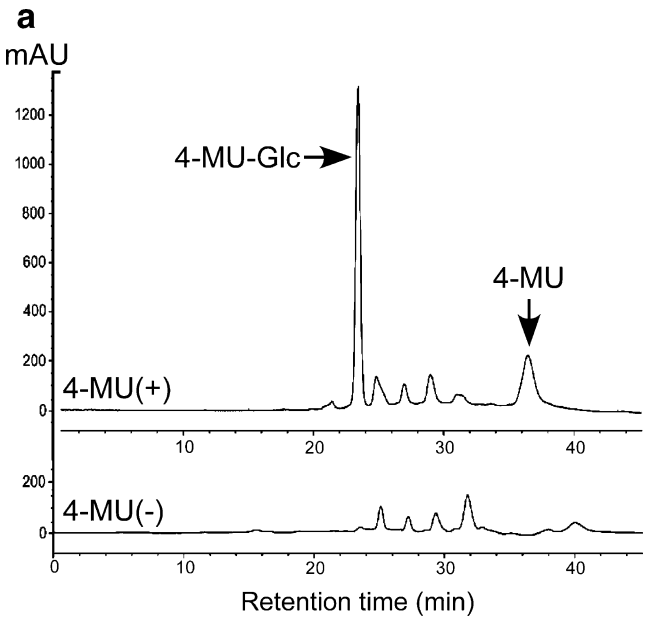

Fig. 3 Glucosylation of 4-MU in *Arabidopsis* roots. **a** HPLC-UV profiles (λ_{325}) of 80% methanol extracts from roots of 6-d-old seedlings treated with (upper panel) or without (bottom panel) 125 μM 4-MU. A new product was identified as 4-MU-*β*-D-glucoside (4-MU-Glc) in the 4-MU treated root extracts. **b** Schematic of the UGT-catalyzed biotransformation of 4-MU to 4-MU-Glc in *Arabidopsis* roots

abiotic and biotic stresses (49 vs. 44), and transportation (32 vs. 25), respectively. It was notable that most of the genes with altered expression did not have known functions (99 vs. 145, respectively). Four genes encoding uridine diphosphate (UDP) glycosyltransferases (UGTs) were up-regulated more than two-fold in the 4-MU treated seedlings, these included *UGT73B4*, *UGT73C1*, *UGT75B2*, and *GAUT2* (At2g46480). Consistent with the microarray data, qRT-PCR analysis revealed significant up-regulation of these four *UGT* genes in roots of 6-d-old seedlings exposed to 125 μm 4-MU (Fig. 4). Since UGT73B4, UGT73C1, and UGT75B2 are active on hydroxycoumarins, scopoletin, and esculetin (Lim et al., 2003), we tested whether 4-MU could be glucosylated by these UGTs using purified recombinant UGT73B4 and UGT75B2 enzymes. Reverse-phase HPLC

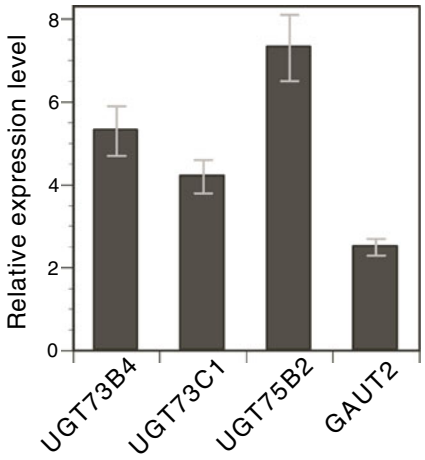

Fig. 4 Induction of glycosyltransferase genes by 4-MU in *Arabidopsis* roots. Quantitative RT-PCR analysis was used to analyze expression of genes encoding glycosyltransferases in the roots of 6-day-old seedlings treated with 125 μM 4-MU relative to levels from untreated seedlings. *Ef-1α* was used as a reference gene

and the identification of compounds in the post-reaction mixture showed a product with a retention time (22.1 min) and a photo-diode array profile identical to the authentic standard 4-MU-Glc in the reaction with UGT73B4, indicating that 4-MU is a substrate of this UGT (Fig. 5). UGT75B2 enzyme activity was not detected with 4-MU (data not shown).

Involvement of Auxin Efflux in 4-MU-Induced Lateral Root Formation Auxin plays a key role in controlling lateral root

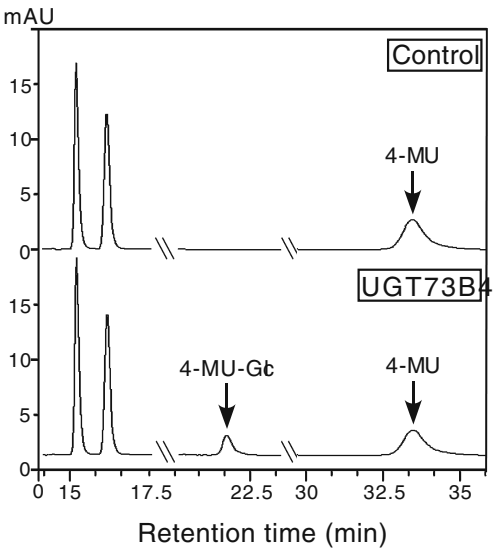

Fig. 5 HPLC-UV profiles of the reaction products of UGT73B4 recombinant protein incubated with 4-MU. Reaction products of GST protein (Control) or GST-UGT73B4 fusion (UGT73B4) were subjected to HPLC analysis and the products were detected at λ_{320}, (RT, 22.1 min) and confirmed by NMR, showing that UGT73B4 catalyzes the conversion of 4-MU to a 4-MU-Glc

formation (Fukaki and Tasaka, 2009). To test whether lateral root formation induced by 4-MU treatment was accompanied by an alteration in auxin signaling, we performed qRT-PCR analysis on genes involved in either auxin signal transduction, flux, or biosynthesis using total RNA extracted from 4-MU-treated roots of 14-d-old seedlings when lateral root branching has been initiated and *DR5::GUS* was actively expressed (Supplementary Data Fig. 1). For auxin flux facilitator genes, we chose *PIN2* and *PIN3* in preference to the other five *PIN* genes, which have additional or other functions. For example, *PIN1* is involved in vascular development, phyllotaxis, vein formation, embryogenesis, and lateral organ development (Petrásek and Friml 2009). *PIN2* and *PIN3* were up-regulated by 4-MU, whereas the expression of an auxin receptor *TIR1*, a rate-limiting for the auxin biosynthetic gene *YUCCA1* (Zhao et al., 2001), and an auxin-responsive GH3 family member At2g14960 (Mishra et al., 2009) was unchanged relative to untreated seedlings (Fig. 6a). Additionally, the transcript level of *IAA14/SLR1*, one of the most important auxin responsive AUX/IAA genes involved in lateral root initiation (Fukaki et al., 2002; Fukaki and Tasaka, 2009), was elevated by 4-MU. This analysis suggested that 4-MU affected auxin redistribution rather than biosynthesis. To eliminate the possibility that 4-MU treatment affects endogenous auxin biosynthesis, β-glucuronidase (GUS) activity under the control of the synthetic auxin-responsive promoter *DR5* (DR5::GUS) was determined in roots of 14-d-old seedlings grown on medium supplemented with 125 μM 4-MU. MUG activity (as measured by a fluorometric assay) in *DR5::GUS*—transformed *Arabidopsis* lines grown in the presence of 4-MU showed no difference compared to lines without 4-MU treatment (Fig. 6b), indicating that 4-MU had no effect on the regulation of auxin biosynthetic genes.

Alteration of Actin Filament Organization by 4-MU Treatment The actin cytoskeleton is important for root growth and is also thought to play a role in the polarization of auxin fluxes (Dhonukshe et al., 2008; Nick et al., 2009). We, therefore, examined the organization of the actin cytoskeleton system in roots in response to 4-MU. *Arabidopsis* plants were transformed with the actin-binding domain (ABD)-GFP protein fusion construct, which specifically binds filamentous (F)-actin (Motes et al., 2005) and allows visualization of the F-actin cytoskeleton. ABD-GFP florescence strongly accumulated in the root caps of untreated 6-d-old seedlings (Fig. 7b), whereas GFP fluorescence was observed in the meristematic tissues of seedlings treated with 125 μM 4-MU (Fig. 7e). Alteration of the root F-actin organization in plants treated with 125 μM 4-MU was accompanied by an abnormal root tip phenotype in which root caps appeared to be physically detached with irregularly shaped cells (Fig. 7d,f).

Discussion

We have characterized the response of the *Arabidopsis* root system to treatment with 4-MU. In the presence of this compound, seed germination was inhibited, primary root growth and root hairs were reduced, and lateral root emergence was stimulated, while cotyledons and seedling rosette leaves were unaffected (at least up to 22 days of evaluation). At high concentrations (500 μM), germination

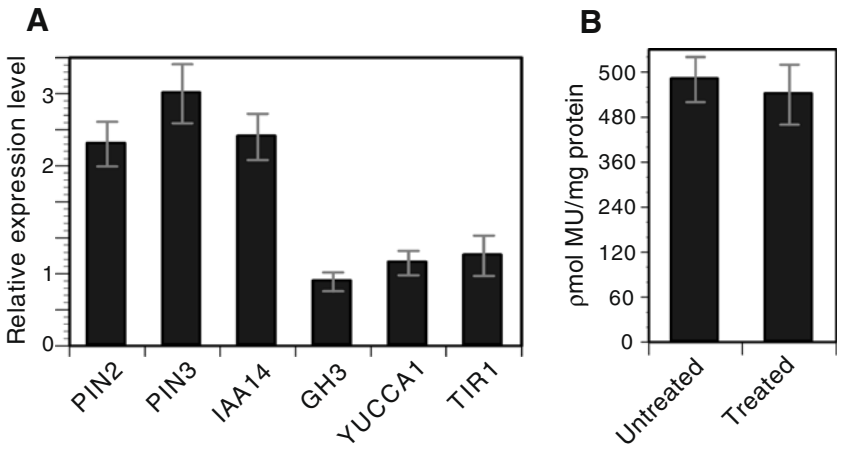

Fig. 6 (A) Transcript abundance of auxin biosynthesis, efflux, signalling, and responsive genes after 4-MU treatment. Expression was tested for the auxin efflux facilitators *PIN2* and *PIN3*, the auxin-responsive genes *IAA14* and *GH3* (At2g14960), the major auxin biosynthetic gene *YUCCA1* and the auxin receptor *TIR1*. Real time PCR was used to examine transcript levels of the six genes are relative to that in untreated *Arabidopsis* seedlings. *Ef-1α* was used as a reference gene. (B) Auxin biosynthesis as detected by GUS activity levels in *DR5::GUS* transgenic seedlings untreated or treated 125 μM 4-MU. Values are the means ± SD of triplicate samples

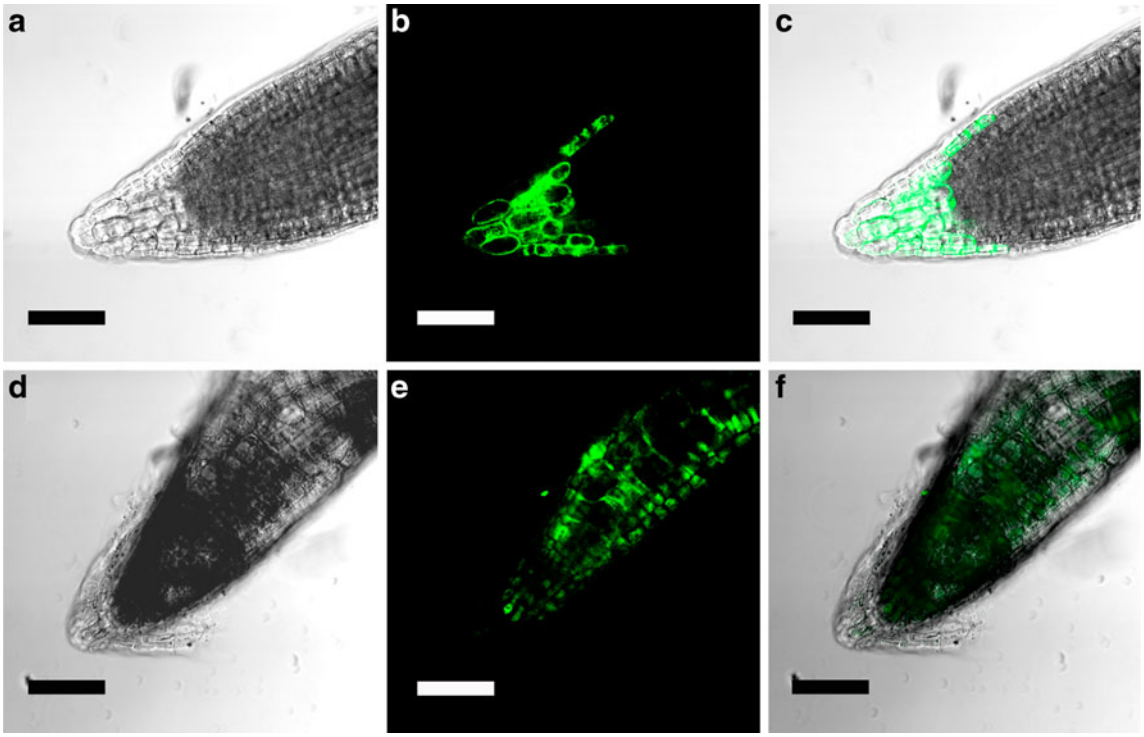

Fig. 7 Alteration of actin cytoskeleton organization in *Arabidopsis* root tips in response to 4-MU. Primary root tips of 6-d-old *35S::ABD-GFP* transformed seedlings were examined by fluorescence microscopy. (**a**, **b** and **c**) A root tip in the absence of 4-MU. (**d**, **e** and **f**) A root tip treated with 125 μM 4-MU. Brightfield (**a** and **d**), GFP channel (**b** and **e**), and merged (**c** and **f**) images are shown. Scale bar, 100 μm

was completely inhibited. Transcripts of three UGTs (UGT73B4, UGT73C1, UGT75B2) also were up-regulated after treatment with 4-MU, and a recombinant UGT73B4 enzyme could catalyze the glucosylation of 4-MU *in vitro* into the same end product (4-MU-Glc) that was accumulated with 4-MU *in vivo* in roots of the treated plants.

Plants have evolved complex pathways for responding to chemicals and toxins, such as glutathione sulphotransferase (GST)-catalyzed conjugation of glutathione and UGT-catalyzed glucosylation of diverse acceptors (Edwards et al., 2000; Gandia-Herrero et al., 2008). Glucosylation alters the properties of acceptor chemicals, such as their bioactivity, stability, hydrophilicity, and subcellular localization (Bowles et al., 2005). UGTs are involved in the synthesis and modification of glucoconjugates via transfer of sugars to a wide range of acceptor molecules that include plant secondary metabolites, phytotoxins, and xenobiotics (Bowles et al., 2005). UGT73B4 and several other UGTs have been shown to glucosylate coumarins, scopoletin, and esculetin, the flavonoid quercetin and 2,4,6-trinitrotoluene (TNT) (Lim et al., 2003; Gandia-Herrero et al., 2008). Hence, UGT-catalyzed glucosylation of 4-MU may represent a mechanism to inactivate this compound in *Arabidopsis* roots.

Auxin and its polar transport and redistribution are key factors controlling lateral root initiation, formation, and development (Nibau et al., 2008; Fukaki and Tasaka, 2009; Peret et al., 2009; Vanneste and Friml, 2009). Lateral root emergence was correlated with changes in auxin responsive gene expression in *Arabidopsis* challenged with 4-MU. Genes that encode the auxin efflux facilitators PIN2 and PIN3 were strongly up-regulated by 4-MU, and expression of the auxin receptor TIR1 or the key auxin biosynthetic enzyme YUCCA1 was unchanged in the presence of 4-MU. The F-actin fibrils in the primary root also were disrupted, and the root cap was detached under 4-MU exposure. These observations suggest that 4-MU induces lateral root emergence and root branching through auxin redistribution rather than auxin biosynthesis and does so in concert with (and as a consequence of) the inhibition of primary root growth.

Small compounds with impacts on cellular activity are useful, potent chemical tools for defining protein function (Walsh and Chang, 2006) and have provided insight into regulatory mechanisms, e.g., toyocamycin inhibition of auxin signaling (Hayashi et al., 2009). Our identification and characterization of 4-MU as a positive regulator of *Arabidopsis* root branching as a consequence of primary root inhibition is a starting point for continued chemical

genetics investigations aimed at identifying the cellular target of 4-MU. At this point, we also anticipate that 4-MU will prove to be a useful chemical tool for studying root biology and development in crop plants, particularly the *Brassicas* which are genetically close to *Arabidopsis*.

Although cover crops provide added value to commercial crops in agronomic systems, many species used as coverage are toxic due to the high concentrations of phytochemicals. Velvetbean (*Mucuna pruriens*. DC. var. utilis) is an example of an efficient cover crop with several highly active natural products. It has been grown widely in tropical areas as a soil-improving crop, a cover crop to control weeds, green manure, and a forage plant (Anaya, 1999). Many secondary compounds are produced by velvetbean, but the major one is the non-protein amino acid, L-3,4-dihydroxyphenylalanine (L-DOPA), which represents from 0.5 to approximately 1.5% of the fresh weight of leaves (Fujii et al., 1991) and from 6 to 9% of the seeds (Rehr et al., 1973). L-DOPA is released from the roots of velvetbean (Furubayashi et al., 2005), and the soil concentration can reach 50 mg l^{-1} in the vicinity of the roots (Nishihara et al., 2005). This concentration is sufficient to affect the growth of neighboring plants due to both reduced seed germination and suppression of root growth (Fujii, 1999).

The allelopathic action of L-DOPA has been attributed to its ability to reduce the growth of several plant species, including weed species such as wild mustard (*Sinapis arvensis*), creeping thistle (*Cirsium arvense*), field poppy (*Papaver rhoeas*), henbit (*Lamium amplexicaule*), and crop species such as wheat (*Triticum vulgare*), barley (*Hordeum vulgare*), pumpkin (*Cucurbita moschata*), lettuce (*Lactuca sativa*), cucumber (*Cucumis sativus*), and cabbage (*Brassica oleraceae*) (Nishihara et al., 2004; Topal and Kocaçalişkan, 2006). In previous work (Soares et al., 2007) we observed that the reduction of soybean (*Glycine max*) root growth by L-DOPA is associated with increases in the enzyme activities of the phenylpropanoid pathway, such as phenylalanine ammonia-lyase (PAL) and peroxidase (POD), and increases in phenolic compounds and lignin content. Based on these findings, we hypothesized that one mode of action of L-DOPA may be related to its effects on the phenylpropanoid pathway, which triggers excessive production of lignin and a reduction in soybean root growth.

Hachinohe and Matsumoto (2007a) hypothesized that the phytotoxicity of L-DOPA might be due to reactive oxygen species (ROS) formed during its oxidation to melanin. Using suspension-cultured carrot (*Daucus carota*) cells, they observed that exogenous L-DOPA was metabolized to melanin, and ROS species generated by this process caused oxidative damage followed by growth reduction. It is known that melanin biosynthesis from L-DOPA requires the action of the polyphenol oxidase (PPO) and POD enzymes (Albrecht and Kohlenbach, 1990; Nishihara et al., 2004) in an oxidative process that can generate ROS, such as H_2O_2, $^1O_2$, $O_2^{\bullet -}$, and $OH^{\bullet}$ (Riley, 1997). The oxidative damage induced by ROS includes chlorophyll degradation, structural and functional changes of proteins, DNA fragmentation, ion leakage, lipid peroxidation, and cell death (Moller et al., 2007). However, there also is evidence that L-DOPA can act as an antioxidant agent (Spencer et al., 1996). Randhir et al. (2006) suggested that L-DOPA is an effective direct quencher of free radicals and a potential modulator of the antioxidant enzyme response. Also, Gülçin (2007) proposed that L-DOPA has an antioxidant property similar to synthetic antioxidants, such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), α-tocopherol and Trolox.

In view of this apparent contradiction concerning the oxidative or antioxidative property of L-DOPA, the purpose of this study was to investigate further the mode of action of L-DOPA in soybean roots by evaluating its effects on several parameters related to the oxidative stress condition. The production of $O_2^{\bullet -}$ and H_2O_2 and the level of lipid peroxidation as well as the activities of some enzymes of the antioxidant defense systems, including PPO, POD, superoxide dismutase (SOD), and catalase (CAT) were measured. The production of melanin from L-DOPA also was evaluated.

Methods and Materials

General Procedures Soybean (*Glycine max* L. Merr. cv. BRS-184) seeds were surface-sterilized with 2% sodium hypochlorite for 5 min, rinsed extensively with deionized water, and dark-germinated (at 25°C) on two sheets of moistened filter paper. Twenty-five 3-d-old seedlings of uniform size were supported by an adjustable acrylic plate and dipped into a glass container (10×16 cm) filled with 200 ml of half-strength Hoagland's solution (pH 6.0), with or without 0.1 to 1.0 mM L-DOPA. All nutrient solutions were buffered with 17 mM potassium phosphate buffer. The containers were kept in a growth chamber (at 25°C, with a 12:12 hr L:D photoperiod and a photon flux density of 280 μmol m^{-2} s^{-1}) for 24 hr. L-DOPA was purchased from Sigma-Aldrich (St Louis, MO, USA), and all other reagents used were of the purest grade available.

Quantification of Melanin Fresh roots (50 mg) were incubated with 1 ml of 1 N NaOH at 100°C. After 1 hr, the absorbance was recorded at 470 nm. Melanin content was calculated by using a standard curve prepared with known concentrations of melanin (Abdel-Naser et al., 2003). The results are expressed as μg melanin g^{-1} fresh weight.

Enzyme Assays PPO activity was estimated according to the method of Oktay et al. (1995). Fresh roots (0.5 g) were ground in a mortar with 0.01 g of polyvinylpolypyrrolidone (PVPP) and 5 ml of 0.05 M phosphate buffer (pH 7.0). The

extract was centrifuged (2,200×*g*, 5 min, 4°C), and the supernatant was used to determine the activity of PPO. The reaction mixture contained 3.6 ml of 0.05 M phosphate buffer (pH 6.0), 0.1 ml of 0.1 M catechol, and 1 ml of enzyme extract. The mixture was vortexed for 15 sec, followed by incubation at 30°C for 30 min; after transfer to an ice bath, 0.2 ml of 1.4% perchloric acid were added, and the mixture was vortexed. After 10 min, the absorbance of the solution was followed for 5 min at 395 nm. One unit of PPO activity was defined as an increase in the A_{395} by 0.001 min^{-1} ml^{-1}. The enzyme activity is defined as unit g^{-1} fresh weight.

SOD activity was assayed by using the photochemical nitroblue tetrazolium (NBT) method (Giannopolitis and Ries, 1977). Fresh roots (0.5 g) were ground in a mortar with 0.01 g of PVPP and 2 ml of 50 mM potassium phosphate buffer (pH 7.8) containing 1.0 mM EDTA. After centrifugation (2,200×*g*, 20 min, 4°C), the supernatant was used for the determination of the enzyme activity. The reaction mixture (1.5 ml) contained 75 μM NBT, 4 μM riboflavin, 13 μM methionine, 50 mM phosphate buffer (pH 7.8) containing 1.0 mM EDTA, and 20 μl of enzyme extract. To exclude eventual interference on SOD activity, parallel controls with L-DOPA or melanin added in the reaction mixture without enzyme preparation were undertaken under the same experimental conditions. The reaction was initiated by placing the reaction-mixture tubes under 15-W fluorescent lamps (56 μmol m^{-2} s^{-1}) for 10 min. The reaction was stopped by keeping the tubes in the dark for 10 min. The photoreduction of NBT (formation of purple formazan) was measured at 560 nm. One unit of SOD enzyme activity was defined as the amount of enzyme required to produce a 50% inhibition of the reduction of NBT. SOD activity is expressed as unit g^{-1} fresh weight.

For the POD assay, fresh roots (0.5 g) were ground in a mortar with 0.01 g of PVPP and 5 ml of 67 mM phosphate buffer (pH 7.0). The extract was centrifuged (2,200×*g*, 5 min, 4°C), and the supernatant was used to determine the activity of POD. The enzyme activity was determined according to the method of Cakmak and Horst (1991), with modifications. The reaction mixture (3 ml) contained 25 mM sodium phosphate buffer (pH 6.8), 2.58 mM guaiacol, and 10 mM H_2O_2. The reaction was initiated by the addition of the enzyme extract. The oxidation of guaiacol was followed for 5 min at 470 nm, and the enzyme activity was calculated from the extinction coefficient (25.5 mM^{-1} cm^{-1}). POD activity is expressed as μmol tetraguaiacol min^{-1} g^{-1} fresh weight.

For the CAT assay, fresh roots (1.0 g) were ground in a mortar with 0.01 g of PVPP and 1 ml of 0.1 M potassium phosphate buffer (pH 7.0). The extract was centrifuged (2,200×*g*, 10 min, 4°C), and the supernatant was used to determine the activity of CAT. The enzyme activity was determined according to method of Tománkóva et al. (2006). The reaction mixture (0.5 ml) contained 60 mM H_2O_2 in 60 mM sodium phosphate buffer (pH 7.4). The reaction was initiated by the addition of 0.1 ml of enzyme extract. The mixture was incubated for 4 min at 37°C, and the reaction was stopped by the addition of 0.5 ml of 32.4 mM ammonium molybdate. The yellow complex of molybdate and H_2O_2 was measured at 405 nm, and the enzyme activity was calculated from the extinction coefficient (0.0655 mM^{-1} cm^{-1}). CAT activity is expressed as μmol H_2O_2 consumed min^{-1} g^{-1} fresh weight.

Reactive Oxygen Species (ROS) Content Superoxide anion $\left(O_2^{\bullet -}\right)$ was determined colorimetrically, according to the method of Wu and von Tiedemann (2002). Roots (0.5 g) were homogenized with 2.7 ml of 50 mM phosphate buffer (pH 7.8). The homogenate (900 μl) was incubated with 100 μl of hydroxylamine (15 min, 30°C), and then 350 μl of the mixture were mixed with 350 μl of 17 mM sulfanilamide (in 30% acetic acid) and 350 μl of 7 mM naphthalene. Absorbance was measured at 540 nm. Results are expressed as μmol $O_2^{\bullet -}$ g^{-1} fresh weight.

The H_2O_2 content was determined colorimetrically, according to the method of Hsu and Kao (2007), with modifications. Roots (2 g) were homogenized in 3 ml of 50 mM phosphate buffer (pH 6.8). The homogenate was centrifuged (2,200×*g*, 20 min), and then 3 ml of the extracted solution were mixed with 1 ml of 0.1% titanium chloride in 20% (v/v) H_2SO_4. The mixture was centrifuged at 2,200×*g* for 15 min. Absorbance of the supernatant was measured at 410 nm by using the reaction mixture without the tissue extract as a blank. The H_2O_2 content was calculated from the extinction coefficient (0.25 mM^{-1} cm^{-1}). Results are expressed as μmol H_2O_2 g^{-1} fresh weight.

Lipid Peroxidation After 24 hr of incubation, seedlings were removed, and the roots were detached for the determination of the level of lipid peroxidation in terms of malondialdehyde (MDA). Fresh roots (0.25 g) were extracted with 2.5 ml of 67 mM phosphate buffer (pH 7.0). The extract was centrifuged (10,000×*g*, 15 min, 4°C), and the supernatant was used to determine the content of MDA (Doblinski et al., 2003). An aliquot of 0.5 ml of the supernatant was added to 4 ml of 0.5% of thiobarbituric acid (prepared in 20% of trichloroacetic acid). The mixture was heated in boiling water for 10 min and then quickly cooled in an ice-bath; samples were then centrifuged (3,500×*g*, 5 min). Absorbance of the supernatant was recorded at 532 nm, and this value was subtracted from the nonspecific absorbance (at 600 nm) value. The quantity of MDA was calculated from the extinction coefficient (155 mM^{-1} cm^{-1}). The level of lipid peroxidation is expressed as nmol MDA g^{-1} fresh weight.

Statistical Analysis The experimental design was completely randomized, and each plot was represented by one glass container with 25 seedlings. The data are expressed as the mean of three independent experiments ± SE. Data were analyzed with Mintab® package (Version 15, Minitab Inc., USA), and tested for normality (Kolmogorovy Smirnov-test) and homogeneity of variances (Levene's test) followed by one-way ANOVA. The differences between the parameters were evaluated by means of the Dunnett's multiple comparison test, and P values ≤0.05 were considered as statistically significant.

Results

Melanin Production from L-DOPA To verify whether melanin was formed from L-DOPA, soybean seedlings were grown in a nutrient solution with this allelochemical (0.1 to 1.0 mM). The L-DOPA increased the PPO activities by approximately 30%, regardless of its concentration, when compared with the control (Fig. 1a). In addition, Fig. 1b reveals that the roots exposed to L-DOPA produced a significant amount of melanin. After treatment with 0.1 to 1.0 mM L-DOPA, the melanin content reached from 0.44 to 1.23 μg g^{-1} fresh weight, respectively.

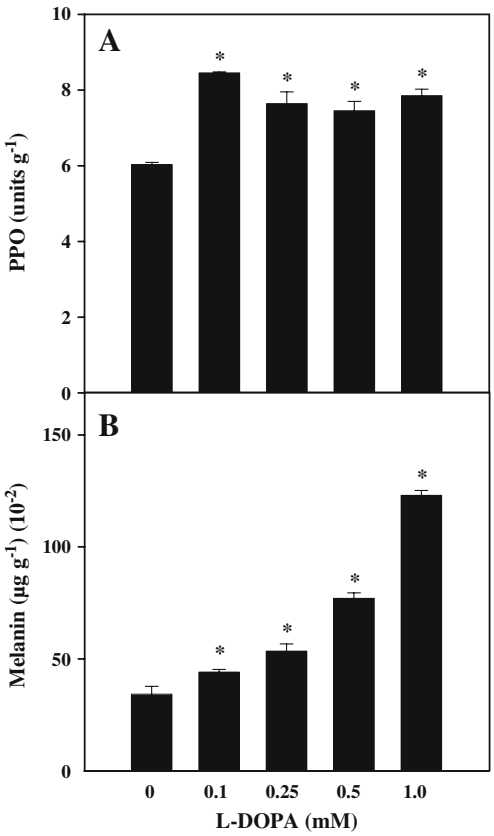

Fig. 1 The effects of different concentrations of L-DOPA on the activity of polyphenol oxidase (PPO) and the melanin contents in soybean roots. *Values (N=3±SE) differ statistically (Dunnett's multiple comparison test) from the control (P≤0.05)

Figure 2 shows the typical effects of 0.1 to 1.0 mM L-DOPA on soybean roots. There are noticeable differences in the roots: in particular, the elongation of the primary root of the treated seedlings was inhibited by the allelochemical. Furthermore, the roots became black, thicker, and less flexible.

Effects of L-DOPA on Antioxidant Enzymes The antioxidant enzymes activities in the roots of seedlings treated with L-DOPA were significantly different from those of controls (Fig. 3). The data revealed that 0.1 to 1.0 mM L-DOPA increased the SOD activities from 35% to 190%, in comparison with the control (Fig. 3a). POD activities also were significantly increased by approximately 43%, regardless of the L-DOPA concentration, when compared to the control (Fig. 3b). In contrast, CAT activities were reduced by approximately 40% after the exposure of 0.1 to 1.0 mM L-DOPA, when compared to the control (Fig. 3c).

Effects of L-DOPA on ROS and Lipid Peroxidation The exposure of soybean seedlings from 0.1 to 1.0 mM L-DOPA significantly reduced the $O_2^{\bullet-}$ contents from 63% to 37% (Fig. 4a) and the H_2O_2 contents from 66% to 80% (Fig. 4b), respectively, in comparison with the control. Lastly, the data revealed that the levels of lipid peroxidation decreased from 46% (at 0.1 mM L-DOPA) to 66% (at 1.0 mM L-DOPA), with respect to the control (Fig. 4c).

Discussion

Overall, our results reveal that L-DOPA increased PPO activity and melanin production at all of the concentrations

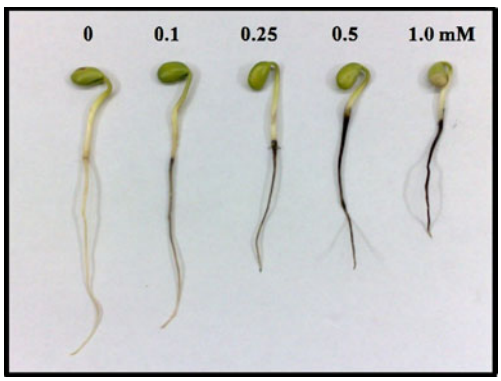

Fig. 2 A comparison of root coloration in non-treated (0 mM) and 0.1 to 1.0 mM L-DOPA-treated soybean seedlings

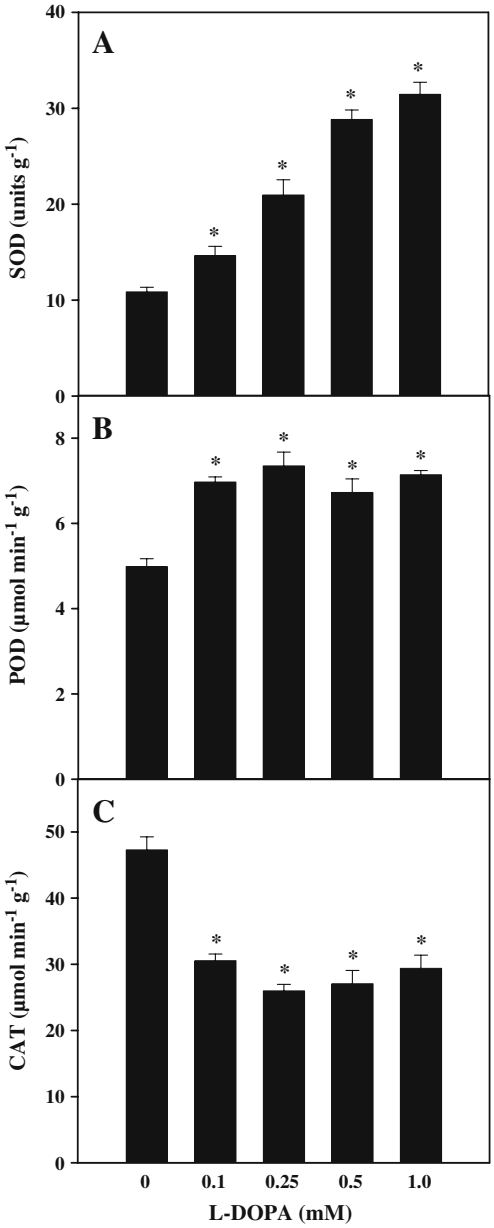

Fig. 3 The effects of different concentrations of L-DOPA on the activities of superoxide dismutase (SOD), peroxidase (POD), and catalase (CAT) in soybean roots. *Values (N=3±SE) differ statistically (Dunnett's multiple comparison test) from the control ($P \leq 0.05$)

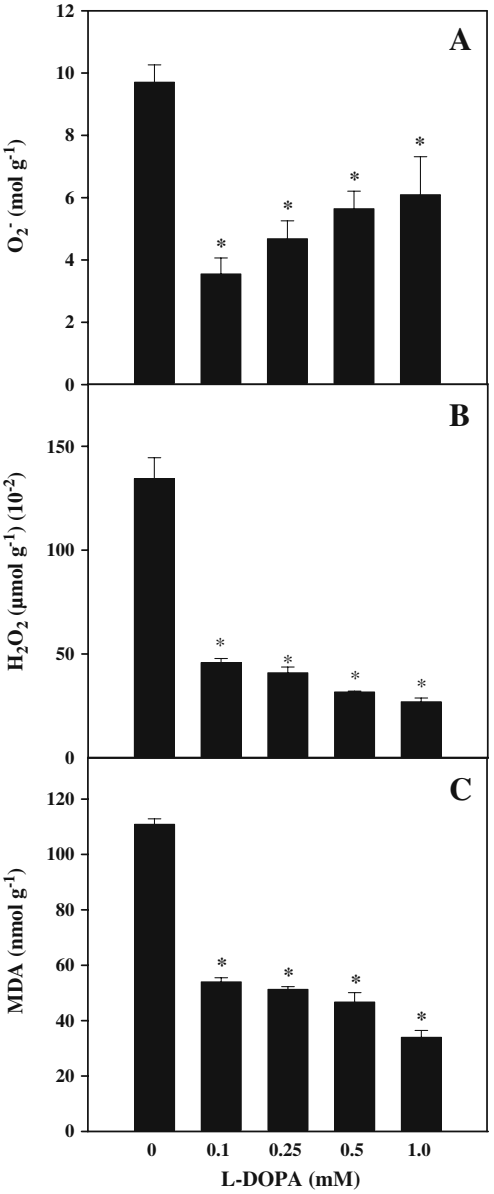

Fig. 4 The effects of different concentrations of L-DOPA on the contents of superoxide anion $\left(O_2^{\bullet -}\right)$ and hydrogen peroxide (H_2O_2) and the levels of lipid peroxidation in soybean roots. *Values (N=3± SE) differ statistically (Dunnett's multiple comparison test) from the control ($P \leq 0.05$)

tested (Fig. 1). The activities of both SOD and POD increased and were accompanied by a decrease in the $O_2^{\bullet -}$ and H_2O_2 contents; these results also were associated with a significant reduction in the levels of lipid peroxidation (Figs. 3 and 4). The only exception, with regards to the tested oxidative factors in the roots, was CAT activity, which was substantially lower after L-DOPA treatments (Fig. 3c).

Reduction of root growth by L-DOPA has been reported in several plant species and it has been considered as an allelopathic effect of this phenolic non-protein amino acid (Hachinohe et al., 2004; Nishihara et al., 2004; Topal and Kocaçalişkan, 2006; Hachinohe and Matsumoto, 2007b; Soares et al., 2007). After absorption, L-DOPA can be metabolized to melanin by enzymatic reactions (Pattison et al., 2002). Both PPO and POD are active enzymes in the production of pigments in damaged plant tissues (Albrecht and Kohlenbach, 1990). PPO is a copper protein that uses molecular oxygen to catalyze the oxidation of monophenols to *o*-diphenols and further to *o*-quinones (Muñoz-Muñoz et al., 2010); POD mediates the oxidation of L-DOPA to form dopaquinone and melanin (Nishihara et al., 2004). By

evaluating the response of seed germination of different plant species to the allelochemical, L-DOPA, Nishihara et al. (2004) confirmed a relationship between the changes of color on filter paper and the inhibition of radical growth. They verified that the radicle became shorter and turned black or light brown in L-DOPA-treated seedlings, when compared to controls. Using carrot (*Daucus carota* L.), Hachinohe and Matsumoto (2007a) have shown that the reduction of cell growth and melanin accumulation is dependent on the L-DOPA concentration. Our results showed that the significant increase in the PPO (Fig. 1a) and POD (Fig. 3b) activities was associated with an expressive browning of the roots (Fig. 2), thus, providing evidence for the active synthesis of melanin from the oxidation of L-DOPA (Fig. 1b).

Hachinohe and Matsumoto (2007b) reported that the amount of melanin accumulated in lettuce roots correlated with the growth inhibitory activity of L-DOPA. We have not found, however, a good correlation between the increased melanin concentration in soybean roots and the degree of root growth inhibition (r^2=0.64, P=0.104, regression analysis; data not shown). This finding indicates that melanin is not the only cytotoxic substance responsible to inhibitory effects on soybean roots.

It has been suggested that L-DOPA generates ROS ($O_2^{\bullet-}$, H_2O_2, and $OH^{\bullet}$) or semiquinone radicals and quinones during the production of melanin (Pattison et al., 2002). In general, ROS and quinones can interact with cellular components, triggering stresses in plants, damaging membranes, blocking nutrient uptake, and hindering the root growth (Gill and Tuteja, 2010). In this context, Hachinohe and Matsumoto (2007b) evaluated whether the phytotoxicity of L-DOPA was due to the ROS formed during its oxidation to melanin. Those authors reported that ascorbic acid and α-tocopherol reduced the observed oxidative damage, alleviating the suppression of lettuce root growth that was caused by L-DOPA and preventing the accumulation of melanin. However, they did not quantify the ROS species that were formed during the oxidation of L-DOPA *in vivo*, even though ROS generation has been verified *in vitro* by electron spin resonance (Kruk et al., 1999). Our results contradict those described by Hachinohe and Matsumoto (2007b) since the levels of ROS species ($O_2^{\bullet-}$, H_2O_2) decreased in soybean roots treated with L-DOPA, when compared to controls (Fig. 4). A possible explanation for this might be that different plant species operate different mechanisms to protect cells from L-DOPA effects, as suggested by Nishihara et al. (2004). In agreement, Hachinohe et al. (2004) demonstrated significant differences in sensitivity to L-DOPA among many plant species, including barnyardgrass (*Echinochloa crus-galli*) and lettuce, tolerant and susceptible species, respectively. In this regard, the levels of melanin and thiobarbituric acid reactive substances (TBARS) increased remarkably in L-DOPA-treated lettuce roots, but not in barnyardgrass (Hachinohe and Matsumoto, 2005). Thus, we presume that the phytotoxicity of L-DOPA in soybean roots is not due to oxidative stress caused by ROS generated from the melanin synthesis pathway.

Several studies have reported an antioxidant activity of L-DOPA. For example, a direct role as a scavenger of free radicals and as a modulator of cellular antioxidant enzymes has been postulated (Randhir et al., 2006). Gülçin (2007) investigated the antioxidant properties of L-DOPA by using butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), α-tocopherol, and Trolox as references. In that study, it was reported that L-DOPA inhibited 68% of the lipid peroxidation, whereas BHA, BHT, α-tocopherol, and Trolox inhibited 74, 71, 55, and 20% of the linoleic acid peroxidation, respectively. Interestingly, some studies have also suggested an antioxidant role for melanin in animals (Wang et al., 2006; Tu et al., 2009). Using *in vitro* bioassays, Tada et al. (2010) verified that melanin potentially interacted with $O_2^{\bullet-}$ and $^1O_2$, thus, scavenging these free radicals. However, this possible antioxidant role of melanin in plants deserves more studies.

The SOD, POD, and CAT enzymes are well-known scavengers of ROS. SOD acts as the first line of defense against ROS, dismutating $O_2^{\bullet-}$ to H_2O_2. POD and CAT also are indispensable for this defense mechanism because, subsequent to the action of SOD, both enzymes detoxify H_2O_2 to H_2O (Apel and Hirt, 2004). In the current study, SOD and POD activities were significantly increased following L-DOPA exposures (Fig. 3a and b), and these increases were associated with decreases in the levels of $O_2^{\bullet-}$ and H_2O_2 (Fig. 4a and b). The observation that these ROS species were reduced was corroborated by the decrease in the levels of lipid peroxidation (Fig. 4c).

Another important fact is that the content of H_2O_2 is reduced during the synthesis of lignin at the cell wall. Soares et al. (2007) have observed a significant increase in the cell wall-bound POD activity involved in the lignification of soybean roots treated with the phenolic amino acid L-DOPA. In fact, lignification requires oxidative coupling and is dependent on H_2O_2. In the present study, because the POD activities increased (Fig. 3b), the decline in H_2O_2 that was observed after the L-DOPA treatments (Fig. 4b) is also in agreement with the reduced activities of CAT (Fig. 3c). This may be explained by the fact that H_2O_2 is decomposed by POD during the lignin synthesis, as suggested by Soares et al. (2007). Furthermore, these results are also consistent with previous research, because other phenolic allelochemicals, such as *p*-coumaric and caffeic acids have been shown to increase POD activity associated to the decrease in H_2O_2 levels (Zanardo et al., 2009; Bubna et al., 2011). It is possible, therefore, that the reduction in CAT activity

(Fig. 3c) is due to low levels of H_2O_2 in soybean roots treated with L-DOPA.

This combination of findings provides some support for the premise that there is a coordinated and precise balance between SOD, POD, and CAT activities that suppress the ROS levels. In general, when one of these enzymes is reduced, others are upregulated (Apel and Hirt, 2004). From all these observations, we suggest that the antioxidant enzymatic system is directly involved in the reduction of ROS levels. In addition, the possible antioxidant properties of L-DOPA or melanin cannot be ruled out, since the production of ROS did not increase, but rather decreased below the control in the presence of L-DOPA (Fig. 4a and b).

The striking fact revealed in the current study is that, at least for soybean, the phytotoxicity of L-DOPA seems not due simply to ROS species generated during its oxidation to melanin, as hypothesized by Hachinohe and Matsumoto (2007b). Moreover, we found additional experimental support for our previous hypothesis that an excessive production of lignin and premature lignification of the cell walls is an important mode of action of L-DOPA in soybean (Soares et al., 2007).

More recently, Golisz et al. (2011) used DNA microarrays to analyze the gene expression profiles of *Arabidopsis thaliana* exposed to L-DOPA. The authors verified the expression of 179 genes and suggested that the response of plants to L-DOPA can affect genes involved in amino acid metabolism, oxidative stress, melanin synthesis, lipoperoxides, phenolic compounds, and lignification. Regarding the latter, a future study investigating the gene expression profiles of soybean roots exposed to L-DOPA would be interesting. This approach may lead to a better understanding of the mode of action of L-DOPA in plants, and an allelopathic role in an agroecological system, especially with regard to reducing the use of synthetic herbicides.

(Cardé and Willis, 2008), odors from different plumes are not homogeneously mixed when plumes come into contact. This may facilitate discrimination of relevant filaments from background semiochemicals. The size and shape of the odor source, as well as air turbulence, are major factors that determine the structure of the plume (Murlis et al., 1992, 2000; Riffell et al., 2008). In addition, the odor concentration in the plume decreases with downwind distance (Baker and Haynes, 1989; Murlis et al., 2000) but, due to the filamentous structure, some odor packages may remain relatively undiluted far away from the source (Murlis and Jones, 1981; Cardé and Willis, 2008).

In this study, we conducted a series of field trapping experiments in which the responses of the spruce bark beetle, *Ips typographus* (Coleoptera, Curculionidae, Scolytinae), and the Egyptian cotton leaf worm, *Spodoptera littoralis* (Lepidoptera, Noctuidae), to separation of different odor sources were compared. Concurrently, plume structure and overlap were measured. The structure of an odor plume may be measured in detail using equipment that is highly sensitive, with a high sampling rate (Murlis and Jones, 1981; Riffell et al., 2008), or by using inexpensive smoke or soap-bubble generators, which more easily visualize plumes (David et al., 1983). Several studies have investigated odor plume structure, and the mechanisms by which insects navigate in plumes (reviewed in e.g., Cardé and Willis, 2008). However, the manner in which plumes from different sources interact (overlap) physically, and how different insects discriminate between them, are less known. Plume discrimination studies have focused mainly on the responses of male moths to female sex pheromone and pheromone antagonists. These studies show great plume discrimination ability by moths. Spacing between components, by as little as a few millimeters, can influence pheromone attraction, and simultaneous perception of an antagonist is required to suppress pheromone source location (Witzgall and Priesner, 1991; Rumbo et al., 1993; Valeur and Löfstedt, 1996; Fadamiro et al., 1999). Less is known about the responses of non-lepidopteran insects to overlapping odor plumes, although two studies on *Dendroctonus* bark beetles demonstrated synergistic pheromone component interactions over source spacing distances of several meters (Byers, 1987; Sullivan and Mori, 2009).

Male and female *I. typographus* are attracted to the male-produced aggregation pheromone, a mixture of (4*S*)-*cis*-verbenol (cV) and 2-methyl-3-buten-2-ol (MB), which is released when a suitable host tree is located. Both components are necessary for attraction (Schlyter et al., 1987a). Pheromone attraction is modulated by anti-attractive, non-host volatiles (NHV) from angiosperm plants (Zhang and Schlyter, 2004). A strong, synergistic effect of inhibition is obtained by a combination of green leaf volatile (GLV) alcohols, C_8-alcohols, *trans*-conophthorin, and verbenone (Zhang and Schlyter, 2003). 1,8-Cineole, a monoterpene abundant in attacked spruce, also suppresses pheromone attraction (Andersson et al., 2010).

The female sex pheromone of *S. littoralis* consists of (*Z,E*)-9,11-tetradecadienyl acetate (Z9E11-14Ac; major component) and (*Z,E*)-9,12-tetradecadienyl acetate (Z9E12-14Ac; minor component), (Kehat et al., 1976). The monoene, (*Z*)-9-tetradecenyl acetate (Z9-14:Ac), is found in low amounts in the pheromone gland (Nesbitt et al., 1973), but inhibits attraction to pheromone at high doses (Campion et al., 1980).

In this paper, we report how trap catches of *I. typographus* and *S. littoralis* to their respective pheromones are affected by spacing between pheromone components, as well as by spacing between the pheromone and behavioral inhibitors. As the beetle colonizes both standing and fallen trees, spatial separation was performed both vertically and horizontally. Apart from using point sources, we also studied the effect of an artificially created non-host odor background, corresponding to a larger scale "habitat odor" concept (Zhang and Schlyter, 2003; Jactel et al., 2011), on bark beetle trap catches. Our hypotheses were: (*a*) At the scale of the trapping devices used in our system, overlap of two plumes will depend on the distance between the sources; (*b*) Spacing of odor sources will modulate the behavioral responses of the two species over similar distances; (*c*) The scale of responses to spaced attractant sources and spaced attractant and anti-attractant sources is the same; (*d*) A more homogeneous background of anti-attractant will give a stronger reduction of attraction than will discrete sources. Our experiments were designed to mimic natural or semi-natural situations, and revealed not only differences between species, but also provided information that may be used to develop efficient ways to use semiochemicals for disruption of host and/or mate finding in the two pest insects.

Methods and Materials

Odor Plume Measurements and Visualizations Odor plume concentrations were measured under semi-field conditions (at SLU campus, Alnarp, Sweden) with a photo ionization detector (PID; ppbRAE + model PGM7240, equipped with a 10.6 eV lamp, RAE systems Inc. San Jose, CA, USA). The detector measures concentrations to the low ppb range. Three open PE #733 vials (20 mm diam. opening, Kartell, Italy), filled with 5 ml hexane, were used as odor sources, as the dispensers in the trapping experiments released too low concentrations of volatiles to be detected. Dispensers were placed under an inverted 250 ml grey plastic cup (as in the *Ips* experiments, described below), positioned 90 cm above ground, a similar height as in our *Ips* experiments.

The PID inlet was 90 cm above ground, and plume concentration data were collected at 1 Hz, over 2 min, at various distances downwind. The detector was kept stationary during a replicate, irrespective of changes in wind direction. The wind speed was <0.5 m/s.

For longer distances, plume width, as well as vertical and horizontal overlap of plumes, were visualized and estimated using soap bubble generators (Gazillion bubble machine, item # 32417, Funrise Inc., China) hung on Lindgren traps, positioned like the dispensers in the vertical and horizontal trapping experiments with *Ips* (see below). The experiment was performed on a lawn, with ca 50 m to the nearest tree, at SLU, Alnarp. Measurements were taken on 3 d (i.e., replicates), and average wind speeds recorded for 30 sec intervals. Because of variable wind speed and wind direction, two or three estimates of plume width and overlap were recorded: typical, maximum, and/or minimum. Accuracy of plume estimates was aided by equally spaced marked poles in the ground at various distances downwind from the trap. Estimates were taken when bubbles exited the generators in the same direction as the wind flow. Video recordings confirmed visual estimates.

Spacing Experiments with Ips, General Design Field trapping experiments with *I. typographus* were conducted 3 May–3 June 2008 at Sporrakulla (56° 16′34″ N, 14° 15′20″ E) and Parismåla (56° 34′50″ N, 15° 28′56″ E), both in south Sweden. Treatment positions were initially randomized, and changed after each replicate, so that each treatment appeared in each location at least once (i.e., temporal Latin square design). Beetle collection and dispenser rotation were carried out when ≥100 beetles were caught by all traps collectively. A replicate lasted from one to a few hours, depending on flight activity. Dispensers were put under an inverted 250 ml grey plastic cup. Traps were separated by at least 15 m. Table 1 lists chemicals, dispensers, and release rates used in all *I. typographus* and *S. littoralis* experiments.

Spacing Between Pheromone Components of Ips MB and cV were added to separate dispensers and used in the vertical and horizontal pheromone source spacing experiments. Lindgren multiple-funnel traps, extended to 19-funnel size (height ca 160 cm, diam. 19 cm), were used to study the effect of vertical separation of the two components at 16, 32, 48, 80, and 112 cm (Supplementary Material, Fig. S1-A). The cV and MB dispensers were spaced at equal distances in opposite directions from the central funnel. For each spacing distance, two traps were used: one with cV moved upwards and MB downwards, and another with the opposite pattern. Controls were, blank, only MB, only cV, and both components at 0 cm spacing.

In the horizontal experiment, Lindgren traps (5-funnel size) were connected to lightweight wind vanes (designed and manufactured by company Fa: J. Lantz, Smedstorp, Sweden) placed on tripods. Wind vanes were used to minimize variation in trap catch and to ensure a constant distance between plumes, despite changes in wind direction (Supplementary Material, Video 1). An aluminum rod, on which dispensers were hung, was fixed horizontally at the central funnel, at a right angle compared to the wind vane (and thus to wind direction). In treatments with the components separated by 16, 32, 48, and 80 cm, dispensers for cVand MB were positioned at opposite directions, away from the center of the trap. The positions (i.e., right or left arm) were switched between replicates to control for directional effects. Controls were, MB, cV, and both components at 0 cm separation.

Spacing Between Pheromone Components of Spodoptera The effect of horizontal pheromone component spacing on *S. littoralis* males was studied in a cotton field, 25 km north of the city of Assiut, middle Egypt in 2009 (27° 10′58″N, 31° 10′58″ E). Z9E11-14Ac and Z9E12-14Ac were tested at three doses (5:0.05, 50:0.5, and 500:5 μg, respectively; Table 1), and spaced 2, 3, 4, 8, and 16 cm apart. Half of the traps (Economic green funnel trap, Oecos, Hertfordshire, UK; height 22 cm, diam. 13 cm) that contained both components had the major component in the center and the minor moved outwards, and the other half of the traps *vice versa*. Dispensers outside the trap were shaded from sunlight (Supplementary Material, Fig. S1-B). Z9E11-14Ac or Z9E12-14Ac alone, 0 cm spacing of both components, and a blank trap were controls. Traps were placed in the cotton canopy with an inter-trap distance of 10 m. Two separate experiments were run. Experiment 1 was performed from July 25 to August 12, and Experiment 2, in which the natural population was boosted with 450 laboratory-reared pupae, was run 6–24 September. Catches were checked, and treatments rotated (= one replicate) two trap positions every second day. For practical reasons, wind-oriented traps could not be used for *Spodoptera*.

Spacing Between Pheromone and Anti-attractant of Ips In two (vertical and horizontal source spacing) experiments, the commercial IT ECOLURE Tubus aggregation pheromone dispenser (Fytofarm Ltd., Bratislava, Slovakia) was used in combination with an anti-attractive NHV cocktail (*trans*-conophthorin, 3-octanol, 1-octen-3-ol, 1-hexanol, 1,8-cineole, and verbenone Zhang and Schlyter 2004; Andersson et al. 2010; individual compounds in separate dispensers; Table 1). In the vertical experiment, the same experimental design, traps, and spacing distances as in the analogous pheromone component spacing experiment were used. A blank trap, a trap with 0 cm between pheromone and NHV sources, and a pheromone-only trap were controls. The design of the horizontal experiment was

[g] Release rate for 1 g flakes/day

similar to the horizontal pheromone component experiment, and the same traps were used. The difference was that the attractant was always placed in the center of the trap to ensure that attracted beetles were caught. Control traps were as in the vertical pheromone/NHV test.

Spacing Between Pheromone and Anti-attractant of Spodoptera The effect of separating the reported (Campion et al., 1980) pheromone antagonist, Z9-14Ac, from the pheromone (Z9E11-14Ac: Z9E12-14Ac; 500:5 μg), was studied in an experimental field, ca 4.5 km north-east of Assiut, Egypt, 11–29 September 2009, using a similar experimental design as in the pheromone component separation experiment. The pheromone source was placed in the center of the trap and the antagonist placed outwards, 2, 3, 4, 8, and 16 cm away from it. Three doses of Z9-14Ac were tested (2.5, 25, and 250 μg). A blank trap, a pheromone-only trap, and 0 cm distance between pheromone and antagonist sources were controls.

Pheromone Attraction of Ips in a Background of Anti-attractant The effect of an artificial NHV "background" on catches of beetles in pipe traps (Zhang and Schlyter, 2003) baited with aggregation pheromone (IT-ECOLURE) was tested during 27–30 April and 30–31 May 2009, in Skillingaryd (57° 28′39″ N, 14° 7′58″ E), south Sweden. We used a randomized block design with 8–10 blocks. Treatment positions were maintained throughout the experiment. NHV background was created by placing semi-commercial *I. typographus* repellent IT-REP (Fytofarm Ltd; 1-hexanol, *trans*-conophthorin, 3-octanol, 1-octen-3-ol, and verbenone as active chemicals) dispensers at eight positions (at ca. 1.2 m height) in a ring around a central pheromone trap (Supplementary Material, Fig. S1-C). Three separate experiments were performed, using a ring of NHV dispensers at radii of 1, 2, and 3 m, respectively, around the pheromone trap. Two NHV doses were tested: 1 (low) or 3 (high) dispensers per position.

In an additional experiment, a more uniform NHV background was created by using NHV-containing flakes (Hercon Environmental, Emigsville, PA, USA). Flakes baited with verbenone (Gillette et al., 2009) or 1-hexanol plus *trans*-conophthorin, were used in combination (50:50 weight: weight ratio). A total of 40 g (ca 6000 flakes) were distributed on the ground around the pheromone trap, covering an area with a 2 m radius. The release of active

compounds from this amount corresponded to the release of eight IT-REP dispensers, as calculated from weight-loss experiments and odor collections in the laboratory. Hence, 8 IT-REP dispensers at 1 m distance were a positive control. A control test in which the IT-REP dispenser was placed in the trap with the pheromone confirmed the activity of the semi-commercial repellent.

Data Analysis Regressions were used to analyze how plume width and overlap changed with downwind distance.

In the vertical spacing experiments with *Ips*, we found no difference between catches regardless of which dispenser was positioned above or below the other. Therefore, we pooled catches from these treatments by calculating the average catch per replicate in each trap pair. Similarly, there was no difference between the two horizontal pheromone component spacing experiments (i.e., 25 July–12 August, and 6–24 September, respectively) with *Spodoptera,* and these data were also pooled, doubling the number of replicates.

As trap catches consist of count data that usually do not fulfill all assumptions for testing by General Linear Models, absolute catches were analyzed by Generalized Linear Models (*GzLM*), using the Poisson distribution as model (Hoffmann, 2004). However, in the bark beetle spacing experiments, goodness of fit analyses and likelihood ratio tests demonstrated over-dispersion (i.e., variances greater than the means), and that the negative binomial distribution with log link (SPSS 16.0) was better suited as model. In all tests, Pearson χ^2 was used to obtain variance estimates and significance levels. The *Sidak* test was used in pair-wise comparisons.

Traditionally, data from field tests similar to ours have been analyzed by *ANOVA*, typically after some transformation to achieve normality and homoscedasticity (e.g., Zhang and Schlyter, 2003; Reeve and Strom, 2004). For comparison with our *GzLMs*, we also analyzed our data with factorial *ANOVA* on, untransformed catches in the *Spodoptera* tests, catch proportions (p) within replicates for the NHV background experiments with *Ips*, and arcsin $p^{0.5}$ transformed catches for the *Ips* odor spacing experiments. *GzLMs* and *ANOVAs* always gave numerically similar *P*-values and did not differ in terms of acceptance or rejection of tested null hypotheses. Thus, for data sets in which we tested both, we only report the *GzLM* statistics. Pair-wise comparisons were done with *t-tests* or, alternatively, *Mann–Whitney U tests* in case of unequal variances. *Ips* sex ratios were analyzed with 95% binomial confidence intervals (CI) (Newcombe, 1998). All tests were performed using SPSS 16.0 at α=0.05.

Hedges' g standardized unbiased effect sizes (Hedges and Olkin, 1985) were calculated for data from all field-trapping experiments. The effect size is a unit-less measure of a treatment effect, obtained by dividing the difference between the means of the control and treatment with the pooled standard deviation for those means (Nakagawa and Cuthill, 2007). The effect size measure facilitates comparisons between different studies or insect systems. For *I. typographus*, effect sizes were calculated from catch proportions, rather than raw numbers caught, as replicates differed widely in absolute catch. An effect size above 0.8 is often regarded as a large effect (Nakagawa and Cuthill, 2007).

Results

Odor Plume Measurements and Visualizations Photo ionization detector (PID) measurements taken downwind of hexane dispensers (similar to those in the *Ips* experiments) showed responses up to a distance of 2 m (Fig. 1a). Maximum concentration per odor burst (Fig. 1b) and the frequency of detected bursts (Fig. 1a) decreased with downwind distance from source. The response of the PID to background odors was zero ppb.

The pattern of bubbles produced by the soap bubble generator attached to a Lindgren trap showed that odor plume width increased linearly during downwind displacement (Fig. 2a). In general, wind speed and direction were highly variable, which sometimes made it difficult to obtain accurate estimates. The 'minimum' estimates were observed typically during gusts of higher than average wind speed. Average wind speed (during 30 sec) ranged from 0.3 to 7.3 m.sec^{-1}, with an overall mean of 3.1 m.sec^{-1}. Occasionally, at low wind speed, soap bubbles went straight up, and on other occasions reached ground a few meters downwind, indicating variation in vertical air movement, although gravity may have been responsible for the soap bubble descent.

Attaching a second bubble generator to the trap showed that the downwind distance at which the plumes started to overlap increased linearly with vertical or horizontal distance between generators (Fig. 2b, c). In general, plume overlap started farther downwind with increasing wind speed, but we also observed large variation during periods of relatively unchanged wind speed, especially with larger source spacing (Supplementary Material, Video 2 and 3). For the 'typical' measurement, the horizontal and vertical spacing showed similar patterns of plume overlap.

Spacing Between Pheromone Components of Ips Separating the cV and MB reduced trap catch, with the effect being distance dependent (Fig. 3a, b). The response to spacing was similar in the vertical and horizontal tests (i.e., no interaction between spacing distance and direction; $\chi^2_4 = 1.8$, $P>0.05$). Having the pheromone components spaced 16 cm apart resulted in as many beetles caught as

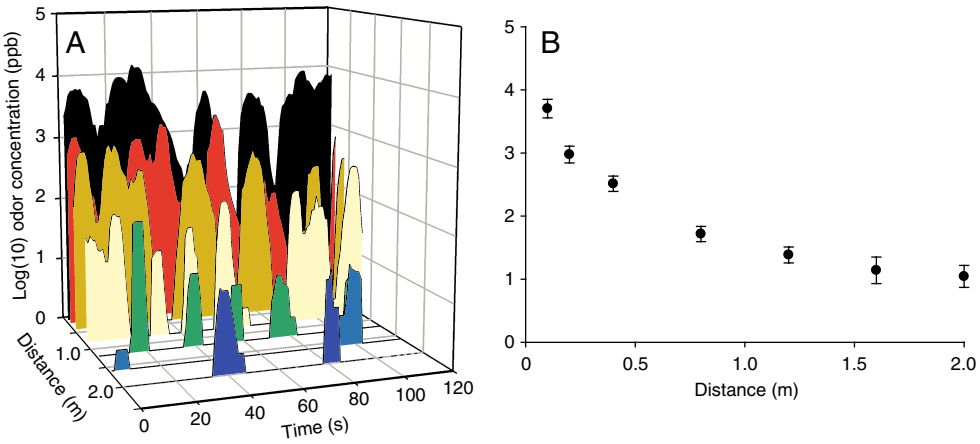

Fig. 1 Plume characteristics with respect to downwind distance from an odor source, as measured by a photo ionization detector (*PID*). **a** Raw PID data over a 2 min replicate, illustrating spatial and temporal changes in odor concentration. Fewer bursts and lower concentrations were detected further downwind. The position of the detector during a replicate was kept constant. **b** Mean maximum concentration per odor burst (N=3). *Error bars* show SEM. Note: the drop in concentration with downwind distance may be amplified by the low sampling rate (1 Hz) of the detector, as compared to previous studies (Murlis and Jones, 1981; Murlis et al., 2000; Justus et al., 2002)

when the components were together (*Hedges' g* effect size close to zero). In the vertical test, 112 cm spacing caught more beetles (*GzLM*: $\chi^2_3 = 52.6$, $P<0.001$, followed by the *Sidak post-hoc* test) than the negative controls (blank, cV, or MB alone). None of the pheromone components alone caught more beetles than the blank. In the horizontal test, 80 cm between pheromone components caught more beetles ($P<0.05$) than cV alone, and almost more than MB alone ($P=0.074$) (*GzLM*: $\chi^2_2 = 16.9$, $P<0.001$, followed by the *Sidak* test). Thus, in both experiments, a large spacing of pheromone components did not fully shut down bark beetle trap catch.

In the horizontal test, the percentage of males (27–43%) caught increased with spacing distance (0–48 cm), as analyzed by 95% binomial CI. However, at 80 cm spacing, the percentage of males caught was only 35%. The percentage of males caught did not differ between treatments in the vertical test.

Spacing Between Pheromone Components of Spodoptera We found a general pattern of increased spacing between components resulting in reduced male *S. littoralis* trap capture. However, whether the major compound was positioned in the center of the trap (Fig. 3c) or moved outwards (Fig. 3d) had an effect on trap capture ($\chi^2_1 = 41.8$, $P<0.001$, $g=0.42$). This effect was dependent on spacing distance (interaction between position of major compound and spacing distance, *GzLM*: $\chi^2_4 = 34.2$, $P<0.001$). More males were caught when the major compound was positioned in the center (mean catch ± SD: 1.4±1.3) as compared to when the minor compound was positioned there (0.9±1.0). At the 16 cm-spacing distance (Fig. 3c–d), the effect of position was especially strong, as shown by a g-value of 1.69. Data were subsequently analyzed separately, with respect to the position of the major compound, to test for the effect of spacing. *GzLM* demonstrated effects of both spacing distance and pheromone dose on male trap catch, irrespective of the position of the major compound (Fig. 3c–d). A strong effect ($g<-1.0$) of spacing was observed already at 2 cm between compounds. Higher doses caught more moths, especially when the compounds were positioned close together. The 0 cm spacing attracted more males than all other treatments ($P<0.001$).

Compared to treatments with the major component in the center, traps with the major component alone caught more moths than the two components spaced 4–8 cm (*GzLM* followed by the *Sidak* test: $P<0.001$). Catch to the major component alone was not different from that to the 2 cm and 16 cm spacing distances (Fig. 3c). Traps with the minor component alone caught more males than those with both components spaced 8 cm ($P<0.05$). Compared to the treatments with the minor component in the center, traps with the major component alone caught more males than those with both components spaced 3–16 cm ($P<0.01$–$P<0.001$; Fig. 3d). Catches to the 16 cm spacing were, in this case, not different from the minor component alone.

Spacing Between Pheromone and Anti-attractant of Ips Spacing distance between the pheromone and the NHV blend had a strong effect on beetle trap catch (Fig. 4a, b). In the vertical experiment, the catch in the 112 cm spacing treatment was still lower ($t_{30}=3.46$, $P<0.01$) than that in the pheromone control and, along with the large effect size ($g=-1.2$), this indicated that the inhibitory effect of NHV reached beyond a separation of 112 cm. In the horizontal test, however, the 80 cm spacing caught similar numbers of

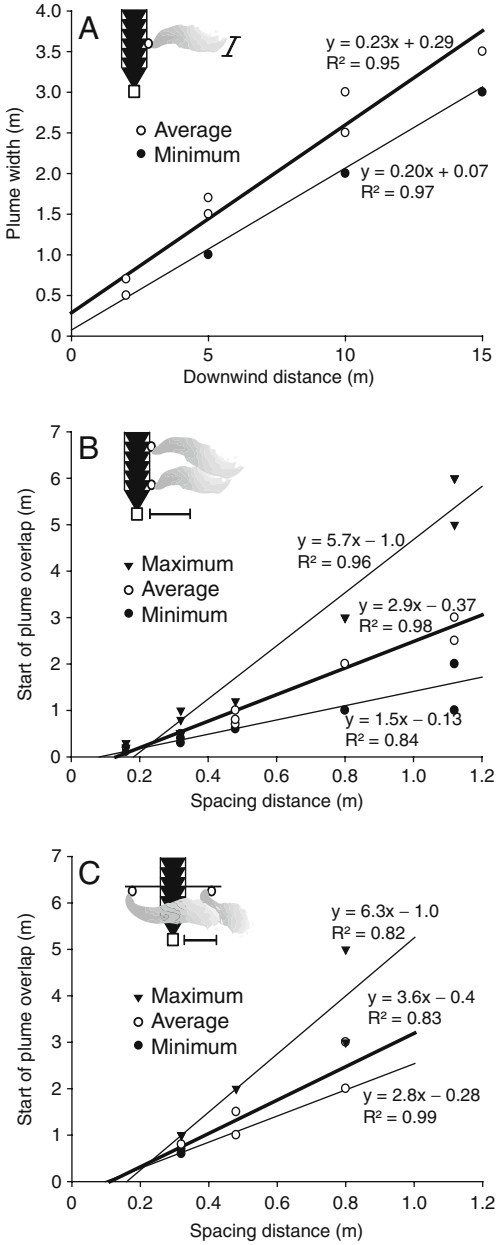

Fig. 2 **a** Relationship between plume width and downwind distance from a single bubble generator. Effect of, **b** vertical, or **c** horizontal spacing between two bubble generators on the downwind distance at which plume overlap started. N=3

beetles as the pheromone control (t_{26}=0.38, P>0.05). Otherwise, the response to increased spacing was similar between the vertical and horizontal tests, as shown by the absence of an interaction between spacing distance and direction ($\chi^2_4 = 1.6$, P>0.05). In both experiments, NHV at 0 cm spacing from the pheromone resulted in greatly reduced trap catch (g=−2.6 and g=−2.1 for vertical and horizontal test, respectively), but the catch was larger than that in blank traps (vertical: z=−4.30, P<0.001; horizontal: z=−4.81, P<0.001).

In the vertical test, the percentage of captured males was reduced by the presence of NHV, compared to pheromone alone (27–32% males in NHV treated traps, 35% in the pheromone alone trap). A similar, but non-significant, tendency was found in the horizontal test (24–31% in NHV traps, 34% in the pheromone alone trap). Spacing distance, as such, had no effect on the percentage of males captured.

Spacing Between Pheromone and Anti-attractant of Spodoptera The anti-attractant, Z9-14Ac, modulated trap catch differently, depending on dose (Fig. 4c). Only at the high dose (250 μg) was it antagonistic when positioned at the same point (g=−1.7) as the pheromone (*GzLM* followed by the *Sidak* post hoc test: P<0.05). In fact, the lowest dose (2.5 μg) elicited increased male catch (P<0.05, g=1.6), whereas the medium dose (25 μg) had no influence. Furthermore, *GzLM* demonstrated that the effect of spacing distance between pheromone and antagonist was dose-dependent, as shown by the interaction between dose and distance (Fig. 4c). Analyzing the doses separately, showed an effect of anti-attractant spacing at the low ($\chi^2_5 = 12.0$, P<0.05) and high ($\chi^2_5 = 23.4$, P<0.001) doses, with increased spacing reducing and increasing trap catch, respectively. Spacing distance at the intermediate dose did not affect trap catch ($\chi^2_5 = 3.2$, P>0.05).

Pheromone Attraction of Ips in a Background of Anti-attractant A control experiment verified the strong effect of the IT-REP dispensers, as one dispenser positioned inside the pheromone trap caught, on average, 6.5% of the beetles within a replicate, compared to the pheromone alone control, which caught 93.5% (g=−14.8 based on catch proportions within replicates; N=6). Pheromone trap catch was reduced by a background of NHV, released from IT-REP dispensers at eight positions around the trap. Factorial *ANOVA* showed an interaction between treatment and distance between NHV and pheromone (Fig. 5a). Thus, separation distances were further analyzed, separately, using one-way *ANOVAs*. Dispensers, both at 1 m and 2 m from the trap, reduced pheromone attraction (1 m distance: $F_{2,\ 21}$=36.8, P<0.001, g<−3.0; 2 m distance: $F_{2,\ 27}$=16.0, P<0.001, g<−1.7; Fig. 5a); there was no difference between the low and high NHV dose. At the 3 m distance, we found no difference between treatments ($F_{2,\ 21}$=2.2, P> 0.05), although a tendency for reduced-catch effects of NHV was apparent, as shown by the relatively large effect size (g≈−0.8).

The more uniform NHV background, created by ca 6000 flakes, also caused reduced pheromone trap catch (Fig. 5b). The number of beetles caught by traps surrounded by flakes was lower than that caught by the pheromone control, but not different from that caught by the negative

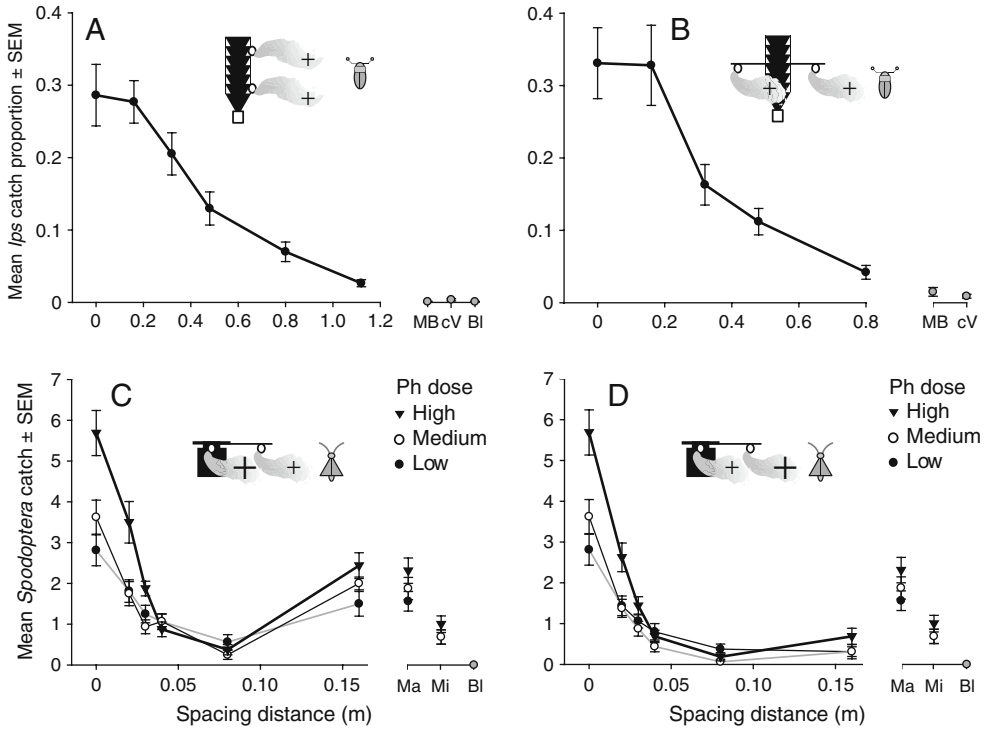

Fig. 3 Trap catches of *Ips typographus* with **a** vertical, and **b** horizontal spacing between pheromone components, *cis*-verbenol (cV) and 2-methyl-3-buten-2-ol (MB). Trap catch was affected by spacing distance (*GzLM*: $\chi^2_5 = 95.8$, $P<0.001$ for vertical and horizontal tests collectively, $N=14$). **c** Trap catches of male *Spodoptera littoralis* with horizontal spacing of pheromone components, with the major component at the center of the trap ($N=16$). Three doses (Low, Medium, High; 5, 50, 500 μg, respectively), based on major component, were tested. *GzLM* indicated that dose ($\chi^2_2 = 10.5$, $P<0.01$) and spacing distance ($\chi^2_5 = 228.9$, $P<0.001$) had effects on catch. **d** Trap catches of male *S. littoralis* with horizontal spacing of pheromone components, with the minor component at the center of the trap ($N=16$). Three doses, as in (**c**), were tested. Dose ($\chi^2_2 = 10.0$, $P<0.01$) and spacing distance ($\chi^2_5 = 289.2$, $P<0.001$) had effects on catch. Right panel in graphs shows response to control treatments. Controls are the same in (**c**) and (**d**). *Ma* major component Z9E11-14Ac; *Mi* minor component Z9E12-14Ac; *Bl* blank

control (IT-REP, low dose, 1 m distance). The anti-attractive effect was similar to the effect of the IT-REP dispensers positioned 2 m (low dose) from the trap ($g \approx -1.7$ for both treatments). The flakes appeared to have a greater suppression of trap catch during the first day in the field, when 22% of the beetles were caught by this treatment (c.f., during the second day, the catch was 32%). However, this tendency was not significant, as shown by the absence of a statistical interaction between treatment and capture day (*ANOVA*: $F_{2,\ 54}=2.1$, $P>0.05$); therefore, data for the 2 days were analyzed together.

Effect Size Comparison Spacing of odor sources had strong effects on both species, but similar effects were obtained at very different spacing distances (Fig. 6a). This comparison highlights the superior sensitivity to small-scale spacing of the moth and the potential long-distance effect of NHV on the beetle. For the moth, the effect of the low dose of antagonist was lost when it was separated only 0.02 m from the pheromone. However, for the beetle, strong effects of eight NHV point sources and of ca 6000 NHV flakes were found at meter-scale spacing (Fig. 6b).

Discussion

Beetle vs. Moth The distances at which odor source spacing affected responses differed greatly between the beetle and the moth, falsifying hypothesis *b*. In both the pheromone component and pheromone/anti-attractant spacing experiments, effects on catches of male moths were apparent at spacing distances of a few centimeters (ca 0.01–0.1 m), whereas for beetles, similar effects on catches were apparent at spacing distances approximately one order of magnitude larger (ca 0.1–1 m). The lack of wind vanes on the moth traps means that maximum separation between plumes only occurred at two wind directions, suggesting that the modulation by spacing for the moth could occur at an even smaller scale than indicated by the results.

At a 16 cm spacing, bubbles from the two generators mixed almost immediately, and produced only one discernible plume, but, even so, catches of moths were affected at even smaller spacing distances. Possibly, the smaller moth trap (height: 22 cm, diam.: 13 cm; compared to Lindgren trap, height: >1 m, diam.: 19 cm) was less affected by turbulence, which affects plume structure and flight

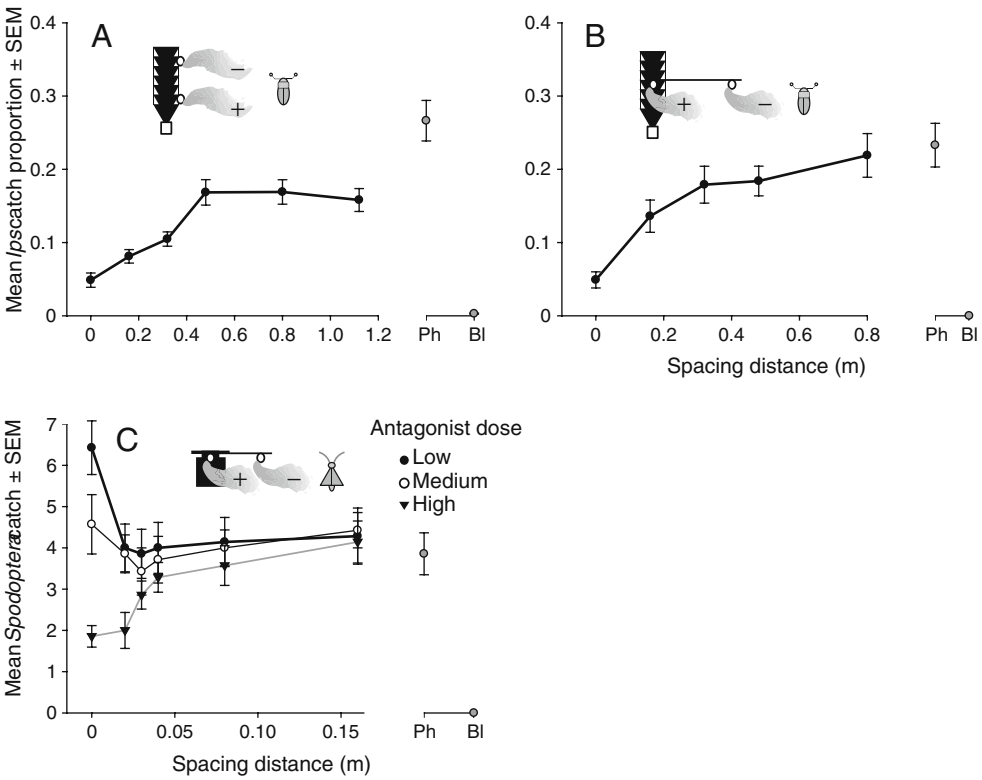

Fig. 4 Trap catches of *Ips typographus* with **a** vertical (N=16), and **b** horizontal (N=14) spacing between pheromone (*cis*-verbenol + 2-methyl-3-buten-2-ol) and anti-attractant (non-host volatile blend) sources. Trap catches were affected by spacing distance (*GzLM*: $\chi^2_5 = 29.8$, $P<0.001$ for vertical and horizontal tests collectively). C) Trap catches of male *Spodoptera littoralis* with horizontal spacing between sex pheromone and three doses (Low, Medium, High; 2.5, 25, 250 µg, respectively) of a pheromone antagonist (N=7). The response to spacing depended on dose, as shown by an interaction between spacing distance and dose ($\chi^2_{10} = 23.7$, $P<0.01$). Right panel in graphs shows response to control treatments. *Ph* pheromone; *Bl* blank

behavior (Willis et al., 1991; Mafra-Neto and Cardé, 1994). Alternatively, mixing of the small scale eddies did not occur, despite the apparent overlap of plumes. It was not possible to measure overlap of plumes from the moth trap, but it appears unlikely that different trap designs would explain the different scales of odor separation that influenced trap catches in the respective species. Possibly, visual cues from the vertical beetle trap, resembling a tree trunk, may have enhanced beetle attraction, especially in the vertical pheromone component spacing test. However, it is difficult to imagine that it could account for the long-distance, anti-attractive effect of NHV. Odor plumes differ between fields and forests (Murlis et al., 2000). However, as the beetle tests were carried out in open areas, it is unlikely that physical environment had a significant influence on plume structure in the different tests.

Plume overlap depended on distance between sources, confirming hypothesis *a*. At 0.5–1 m source spacing, plume

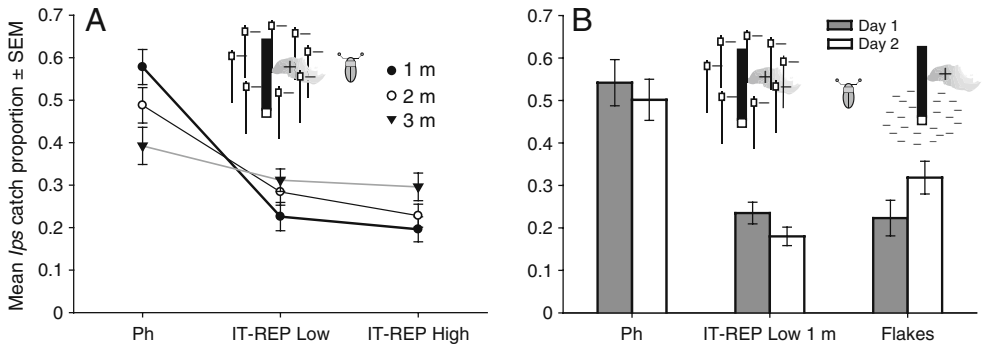

Fig. 5 **a** The effect of surrounding a pheromone trap with eight anti-attractant point sources [IT-REP non-host volatile (*NHV*) dispensers; two doses, low and high, at 1, 2, or 3 m distance from the pheromone] on *Ips typographus* trap catch (N=8–10). *Ph* pheromone control trap. The distribution of beetles among the three treatments was dependent on distance between pheromone and NHV, as shown by the interaction between treatment and distance (factorial *ANOVA*: $F_{4,\ 69}=4.98$, $P<0.001$). **b** The effect of NHV treatment on *I. typographus* trap catch (N=10). Flakes=ca 6000 NHV-treated flakes. *ANOVA* demonstrated a difference among treatments ($F_{2,\ 27}=18.5$, $P<0.001$). Catch in traps surrounded by flakes was lower than that in the pheromone control ($P<0.001$), and not different from that of the IT REP (low dose, dispensers 1 m from trap) negative control ($P>0.05$). Note: as the experiments (1, 2, 3 m distance, and flakes) differed greatly in the total number of beetles caught, we analyzed the effect of NHV only on relative catch

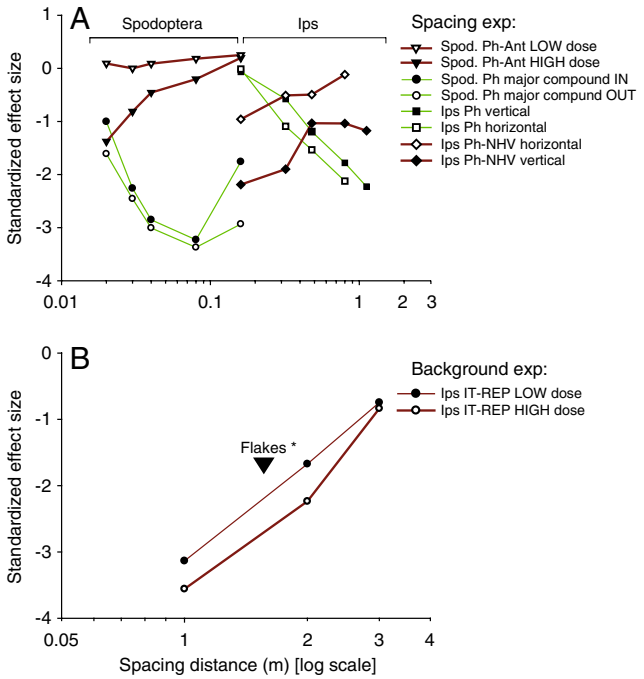

Fig. 6 **a** Effect sizes for the various spacing distances in the *Ips typographus* and *Spodoptera littoralis* spacing experiments (*Hedges'* unbiased *g*). The effect size provides a measure of a biological treatment effect, by scaling the difference between the treatment and control means, with the pooled standard deviation for those means. Effect sizes further from zero than 0.8 are regarded as strong effects. In all experiments, the pheromone bait alone (zero distance between components) was the control. The 0 cm spacing distance in experiments involving anti-attractants is omitted for clarity. **b** Effect sizes in the *Ips* anti-attractant background experiments using IT-REP dispensers at eight positions, or flakes around the trap. * Flakes were evenly distributed on the ground 0–2 m from the trap. Thus, this treatment is "not to scale" on the x-axis. *Ph* pheromone; *Ant* antagonist (*Z*)-9-tetradecenyl acetate; *NHV* non-host volatiles

overlap typically started ca 1–3 m from the trap, suggesting that beetles discern filaments from the two plumes several meters downwind. As indicated by our PID measurements, at 1–2 m from the source, the frequency and concentration of bursts were much lower than when closer to the source, suggesting that filament discrimination in the two insects is performed under different olfactory conditions. However, changes in wind direction may have lowered the frequency of filament encounters by the stationary PID more strongly further downwind. The measured drop in concentration over decimeter-scale downwind distances was sharper than previously found in a wind tunnel (Justus et al., 2002). It is possible that the lower sampling rate of our detector is a reason for this difference. In the field, however, plumes have not been measured at such small downwind distances previously (Murlis and Jones, 1981; Murlis et al., 2000).

The different scale of source spacing distances that affected trap catches in the two species may reflect the actual difference in size of the natural odor sources to which they orient. A male moth orients to a single calling female, whereas bark beetles often orient to large patches, with hundreds of calling individuals. This likely has resulted in different selection pressures on the olfactory system of the two insects (as discussed by Murlis et al., 1992). The male moth pheromone processing system has been selected for locating mates. In contrast, in bark beetles, aggregation pheromone may be used to locate multiple resources, including food, mates, and oviposition sites; therefore, a wider range of selection pressures and tradeoffs may have come to bear on the bark beetle olfactory system. The pheromone processing subsystem in moths, in general, appears more specialized than that of bark beetles. In moths, olfactory receptor neurons (ORNs) for pheromone components and antagonists typically are housed within a special type of sensillum (*trichodea*), different from the sensilla that detect plant odors (Ljungberg et al., 1993). In contrast, *I. typographus* harbors at least one sensillum that contains a pheromone ORN, detecting cV, in addition to an ORN for the plant compound 1,8-cineole (Andersson et al., 2010). In the antennal lobe (AL), axons of moth pheromone ORNs project to glomeruli in an enlarged, and male specific, macroglomerular complex (MGC) (Galizia and Rössler, 2010). Although the ALs of bark beetles are not as well-studied, preliminary observations indicate no apparent MGC in *I. typographus* (Andersson M.N., unpublished).

Mechanisms Variability (difference between maximum and minimum estimates) in plume overlap increased with distance between bubble sources; even for the larger spacings, plumes occasionally overlapped close to the trap. Only when plumes overlap can an insect detect filaments from two plumes coincidently. Therefore, it is possible that insects entered (or avoided, depending on experiment) a trap predominantly when overlap at close range to the sources occurred. We speculate that variation in trap catches may partly reflect variation in the duration of plume overlap close to the trap. Coincident detection of pheromone components improves temporal spiking pattern resolution of projection neurons in moths (Christensen and Hildebrand, 1997), which seems consistent with the behavioral effects of separation between odor components (Fadamiro et al., 1999). The lack of bark beetle response to small-scale spacing may imply that coincidence detection is of less importance for bark beetles.

Pheromone Component Spacing For *S. littoralis*, the major component alone, and the 16 cm spacing between pheromone components (major component in center), captured more males than the 8 cm spacing between components. Possibly, when component sources are separated by 16 cm,

a moth may perceive the two signals as distinct and, therefore, will orient toward the most attractive one. In contrast, at 8 cm the moth may perceive only a single low-quality signal and, therefore, will arrest its movement toward the source. Similar results have been found previously (Linn and Gaston, 1981; Lux et al., 1994). In contrast, the beetle appeared unaffected by 16 cm spacing between pheromone components; some beetles were captured even when the components were separated by >0.5 m. In the western pine beetle, *Dendroctonus brevicomis*, attraction to pheromone was observed when components were separated by as much as 4 m (Byers, 1987).

Pheromone/Anti-attractant Spacing For both the beetle and the moth, the effects on trap catches in response to spacing of pheromone and anti-attractant occurred at separation distances similar to those in response to spacing of pheromone components, thus confirming hypothesis *c*. The bark beetle vertical test indicated that NHV probably influences pheromone attraction over long distances, as the 112 cm spacing distance between pheromone and NHV attracted fewer individuals than the pheromone control. However, no such effect was found in the horizontal test. The fact that soap bubbles sometimes went straight up suggests that convective air movements from the ground in the clearings (possibly pronounced inside the sun-heated black Lindgren trap in the vertical test) may have resulted in mixing of plumes more frequently in the vertical than in the horizontal tests.

The ability of *S. littoralis* to distinguish small separation distances between pheromone and antagonist is similar to that found for other moths (Witzgall and Priesner, 1991; Liu and Haynes, 1992; Fadamiro et al., 1999). Interestingly, Z9-14Ac (our "antagonist") reduced trap capture only at the highest dose, with the lowest dose actually resulting in increased trap capture. As this compound is found in low amounts in the pheromone gland (Nesbitt et al., 1973), this suggests that Z9-14Ac could be a minor component of the sex pheromone, with high doses distorting the natural blend ratio and producing an antagonistic effect. A similar result was found for an antagonist of the moth *Cydia pomonella* (Coracini et al., 2003).

Applications Forest pest insect infestations typically occur less frequently in diverse habitats (Jactel and Brockerhoff, 2007). This may be due, in part, to the presence of non-host volatiles that impede host location (Jactel et al., 2011; Schiebe et al., 2011), as suggested by the "semiochemical diversity hypothesis" (Zhang and Schlyter, 2003). Our two NHV background experiments indicate that attraction to pheromone by bark beetles was reduced by NHV within 2–3 m of the pheromone source. These results are largely consistent with the previously determined "active inhibitory range" (AIR) of NHV, and support our semiochemical diversity hypothesis (Zhang and Schlyter, 2003). It is striking that the NHV background reduced catches of beetles to such a large extent, especially as the pheromone dose used was high, comparable to that from a mass-attacked tree (Schlyter et al., 1987b). However, trap catch was not shut down completely, suggesting that NHV may be more effective for reducing the risk of trees being attacked (Jakuš et al., 2003), rather than counteracting mass-attacks. Indeed, successful attempts to protect standing trees using NHV dispensers attached to every second tree showed an effect over ca 2 m, comparable to the typical distance between trees (Jakuš et al., 2003). In yet another study, groups of 10 standing trees were protected with 20 NHV dispensers, with beetle attacks diverted to trees >15 m away (Schiebe et al., 2011).

Approximately 6000 NHV flakes gave equivalent reduction in trap catch as did the 8 IT-REP dispensers. Thus, the (presumed) more uniform 'cloud' of NHV from the large number of flakes did not 'mask' the pheromone any better than the 8 point sources, thus falsifying hypothesis *d*. Flakes releasing the anti-attractant verbenone protect pine trees from attack by *Dendroctonus* bark beetles (Gillette et al., 2009), but whether they can be used successfully in forest protection against *I. typographus* needs further investigation.

For *S. littoralis*, the effect of separating pheromone components was stronger than expected; the major component alone was more attractive than several treatments with both components spatially separated. This could have implications for pheromone mating disruption. In most, but not all, cases of mating disruption, more complete pheromone blends have provided greater disruption (Minks and Cardé, 1988). This is expected if the dominating mechanism is competition with calling females (Miller et al., 2006). However, if moths orient to spatially separated pheromone components and arrest once plumes no longer overlap, disruption may be increased (Byers, 1987). However, as a note of caution, separate dispensers may be less feasible for large-scale use.

In summary, a comparative approach that uses different insect taxa may allow a more general understanding of insect olfactory-mediated behaviors to be developed. Our results suggest that, at least for the beetle, orientation to attractive sources may be hampered in semiochemically diverse habitats. Additionally, the moth was more sensitive than the beetle to spacing distances between odor sources. However, the source spacing distances that affected trap catches were similar in the two tests (i.e., pheromone source spacing, and pheromone/anti-attractant spacing) for both species. The two NHV background experiments on *I. typographus*, in addition to three other differently designed studies (Jakuš et al., 2003; Zhang and Schlyter, 2003;

Schiebe et al., 2011), indicate that NHV could be used in forest protection to reduce the risk of bark beetle attacks.

Acknowledgements We thank Drs. T. Dekker and P. Witzgall for constructive criticism on the manuscript. We are also grateful to C. Schiebe for field assistance, Dr. R. Unelius (Linnaeus University, Kalmar) and C. Schiebe for providing flakes, Saber A. Ali for field assistance in Egypt, and Dr. M. Bengtsson for dispenser preparation. We also acknowledge Drs. G. Mustafa (Ayyub Agriculture Research Institute, Pakistan) and M. Ahmad (Nuclear Institute for Agriculture and Biology, Pakistan) for collaboration during a pilot field test. The study was funded by FORMAS project #230-2005-1778 "Semiochemical diversity and insect dynamics", the Linnaeus program "Insect chemical ecology, ethology, and evolution (ICE^3)", and by the Department of Plant Protection Biology, SLU, Alnarp. M. B. was funded by Higher Education Commission (HEC) of Pakistan, and M. M. S. was funded (grant 348-2006-66489) by SIDA-Swedish Research Links via The Swedish Research Council (VR).

ketones (Raspotnig et al., 2005; Jones et al., 2009). Hitherto known secretions of the Palpatores include acyclic ketones, alcohols, and aldehydes, present in some sclerosomatid Eupnoi (Blum and Edgar, 1971; Meinwald et al., 1971; Jones et al., 1976, 1977; Ekpa et al., 1985), and naphthoquinones reported from one species of phalangiid Eupnoi (Wiemer et al., 1978). Only one study is available on scent gland secretions of the Dyspnoi, demonstrating the presence of naphthoquinones, methoxy-naphthoquinones, and anthraquinones in the scent glands of a nemastomatid species (Raspotnig et al., 2010). However, with respect to the number of species investigated, secretions of the mostly tropical Laniatores appear to be best studied. Laniatorean secretions are chemically distinct from the secretions of cyphophthalmids and palpatoreans, and specific patterns of phenols and benzoquinones have been demonstrated from a growing number of species since the 1950s (e.g., Estable et al., 1955; Eisner et al., 1971, 1977, 2004; Roach et al., 1980; Hara et al., 2005; review by Gnaspini and Hara, 2007; Shear et al., 2010a,b; Pomini et al., 2010; Föttinger et al., 2010). Essentially, nearly all published studies deal with representatives of groups of more-derivative Laniatores. Thus, the current knowledge on laniatorean secretions is strongly biased in favor of the Grassatores. The chemistry of scent gland secretions in the Insidiatores – a second, more basal laniatorean group – is almost unknown, but is crucial for a consistent picture of opilionid scent gland chemistry. Only one example of insidiatorean chemistry has been published so far (Ekpa et al., 1984), revealing a series of completely aberrant components from an American travunioid species, *Sclerobunus robustus*. These compounds include terpenes, such as bornyl esters, camphene, and limonene, and two alkaloids, namely N,N-dimethyl-ß-phenylethylamine and the tobacco alkaloid nicotine.

One important and well recognized taxon within the Insidiatores is the Cladonychiidae (superfamily Travunioidea), including about 15 species in 5 extant genera (a 6th genus was described from Baltic amber by Ubick and Dunlop in 2005). While genera *Cryptomaster*, *Erebomaster*, *Speleomaster*, and *Theromaster* are restricted to the northern United States, an exclusively European clade is represented by eight species of *Holoscotolemon*, occurring from Western Europe to Romania and southwards to Serbia and Montenegro. As a first contribution to scent gland research in European Insidiatores, we here report on the scent gland chemistry of four species of *Holoscotolemon*, covering a representative part of European Cladonychiidae.

Methods and Materials

Collection of Species Specimens of *Holoscotolemon jaqueti* (Corti, 1905), *H. lessiniense* Martens, 1978, *H. oreophilum* Martens, 1978, and *H. unicolor* Roewer, 1915, were collected by hand under stones and litter, and from samples of leaf litter by means of a soil sifter. While *H. jaqueti* is a species with a disjunct South-East European and Carpathian distribution (Hungary, Slovakia, Romania, Ukraine, Bosnia and Hercegovina, Serbia), *H. unicolor* is restricted to the Eastern Alps (Austria, Slovenia, North Eastern Italy), and both *H. lessiniense* and *H. oreophilum* are local endemics of the southwestern Alps (Italy). *Holoscotolemon oreophilum* can be found in a small area in the Sea Alps/Alpes Maritimes and Ligurian Alps in Italy, and *H. lessiniense* inhabits the Monti Lessini close to the Lake Garda in the Southern Alps. The investigated material was collected in Serbia (*H. jaqueti*), Italy (*H. oreophilum, H. lessiniense*), and Austria (*H. unicolor*) (Table 1). For determination of the *Holoscotolemon* species, we used descriptions of Martens (1978). The material is stored in the collections of Ch. Komposch (Graz), G. Raspotnig (Graz), and I. Karaman (Novi Sad).

Extraction and Analysis of Secretions Scent gland secretion was obtained by whole body extraction of individuals in 150 µl of hexane or ethyl acetate for about 30 min as previously described and standardized for other opilionids (Raspotnig et al., 2005, 2010). In total, 21 extracts were prepared, mostly extracts of single individuals (adults), but in some cases also pooled extracts (juveniles), as summarized in Table 1. Aliquots of extracts (2 µl) were subject to gas chromatographic - mass spectrometric (GC-MS) analysis, using a Trace GC2000 coupled to a Voyager MS, both from Thermo (Vienna, Austria). The GC was equipped with a ZB-5MS fused silica capillary column (30 m×0.25 mm i.d., 0.25 µm film thickness, Phenomenex, Germany). Injection was splitless with helium (at 1.5 ml/min) as carrier gas. The column temperature was programmed from 50°C (held for 1 min) to 200°C at 10°C/min, and then to 300°C at 15°C/min. The ion source of the MS and the transfer line were kept at 170°C and 310°C, respectively. Electron impact (EI) spectra were recorded at 70 eV.

Reference Compounds Authentic nicotine (mixture of (*R*)- and (*S*)-nicotine) for comparison of GC-MS data was purchased from Sigma (Vienna, Austria). As a reference for authentic anabaseine, we used anabasine (from Sigma, Vienna, Austria), which also contained a small amount of anabaseine (about 1%).

Quantification of Secretion Components Determination of absolute amounts of nicotine in secretions are based on the integration of peak areas in the chromatograms, and comparisons to a calibration curve established for authentic nicotine.

Table 1 Collection of *Holoscotolemon*-species and preparation of extracts

Species	Location (co-ordinates, altitude)	Date	Extracts no.[a](Individuals)
H. jaqueti	Serbia: Ovčar-Kablar Gorge, above Ovčar Banja (43°53′N, 20°11′E, 375 m)	20 Mai 2009	1754 (1 juv), 1755 (1♀), M430 (1 juv)
H. oreophilum	Italy: Alpi Marittime, Coli de Tende S Limonette (44°09′ N, 7°32′ E, 1,475 m)	29 July 2010	2447 (1 ♂), 2448 (1 ♀)
H. lessiniense	Italy: Mt. Lessini, Monte Pasubio (45°46′ N, 11°07′ E, 760 m)	17 July 2009	M353 (1♀), M354 (1♀), M355 (1♀), M356 (1♀)
	Italy: Mt. Lessini, NNE Verona, S Velo Veronese (45°35′N, 11°04′ E, 920 m)	31 July 2010	2449 (1 ♀)
H. unicolor	Austria: Carinthia, Villach, Eichholzgraben (46°38′ N, 13°50′ E, 590 m)	5 April 2010	1935 (1♀), 1936 (1♂)
	Austria: Styria, Graz, Maria Trost (47° 06′ N, 15° 29′ E, 445 m)	20 April 2010	1973 (1 juv), 1983 (3 juv)

	Austria: Styria, Aibl (46° 41′ N, 15° 13′ E, 400 m)	27 June 2010	2127 (1 juv)
	Austria: Carinthia, Soboth, road between Krumbach and Rothwein (46°81′ N, 15°07′ E, 1,000 m)	23 June 2010	2243 (1♀), 2244 (1♂), 2245 (1♀)

[a] Refers to intern labelling of extracts

Scanning Electron Microscopy For scanning electron microscopy (SEM), specimens were fixed in Bouin, washed, dehydrated, air-dried, and mounted on aluminum stubs prior to sputter coating with gold (AGAR sputter coater, Gröpl, Tulln, Austria). Micrographs (SEM) were taken with a Philips XL30 ESEM (Philips/FEI, Vienna, Austria) at high vacuum mode and 20 kV accelerating voltage.

Results

Chemical Identification of Extract Components GC-MS analyses of extracts of adult *Holoscotolemon jaqueti*, *H. oreophilum*, and *H. lessiniense* revealed two major (components A and E), and three minor compounds (components B, C, and D) (Fig. 1). All components were identified as pyridine alkaloids as outlined in the following and as summarized in Table 2.

Major Components Component A showed an EI-mass spectrum consistent with that of nicotine [3-(1-methyl-2-pyrrolidinyl)-pyridine], exhibiting a molecular ion (M^+) at a mass charge/ratio (*m/z*) of 162, loss of a hydrogen atom (*m/z* 161), and a base ion at *m/z* 84. The base ion corresponded to loss of the pyridyl moiety ($M^+ - 78$). Further fragments were observed at *m/z* 133 ($M^+ - 29$) and *m/z* 119 ($M^+ - 43$), both of which are reported as characteristic of nicotine, and correspond to losses of C_2H_5- and C_3H_7-radicals from the molecular ion by different processes of rearrangement (Duffield et al., 1965). As a reference for comparison of GC retention, we used a racemic mixture of nicotine (nicotine has an asymmetric carbon atom in position 2 of the pyrrolidine-ring). The specific enantiomers, however, were not separable due to the chromatographic conditions used, and both enantiomers eluted as a single peak at RT= 10.54 min, exactly matching the retention time of component A. Thus, we did not determine the chirality of nicotine from *Holoscotolemon* spp. So far, only the (*S*)-enantiomer is known to occur in nature.

The EI-mass spectrum of the second major component (E) had a molecular ion at *m/z* 160, again exhibiting loss of hydrogen (base ion at *m/z* 159), and losses of 15 (leading to the ion at *m/z* 145), 29 (*m/z* 131), and 56 (*m/z* 104) mass units. The spectrum appeared to be similar, but not fully consistent, with reported spectra of anabaseine (a nicotine-related tobacco nicotinoid) from the literature (e.g., Wheeler et al., 1981). However, a comparison of mass spectral fragmentation and retention times to an authentic sample of anabaseine [3,4,5,6-tetrahydro-2,3′-bipyridine] showed full correspondence.

Minor Components On the basis of mass spectral fragmentation patterns of components B and C, two further nicotinic alkaloids were indicated, both showing mass spectra similar to that of nicotine: Component B appeared

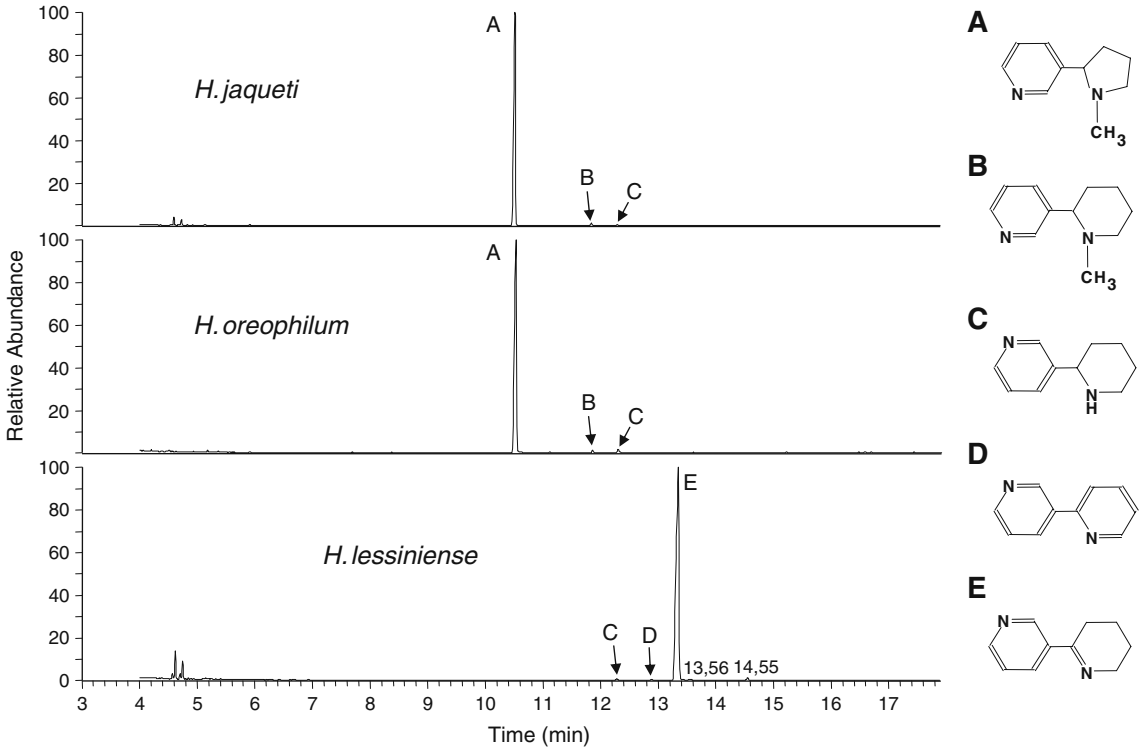

Fig. 1 Chemical profiles of scent gland secretions in three species of *Holoscotolemon*. Compound A [nicotine], compound B [3-(1-methyl-2-piperidinyl)-pyridine], compound C [anabasine], compound D [2,3′-bipyridyl], compound E [anabaseine]. *Compounds at RT=13.56 min and RT=14.55 min were found inconsistently in extracts of *Holoscotolemon lessiniense*, and possibly represent isomeric, not fully characterized pyridines with a molecular weight of *M*=174

to be a higher homolog to nicotine with M^+ at *m/z* 176 and a base ion at *m/z* 98, suggesting a piperidine-structure instead of the pyrrolidine-ring. The compound was tentatively identified as 3-(1-methyl-2-piperidinyl)-pyridine by mass spectral comparisons to literature, and to spectra from the NIST-library. The mass spectral fragmentation of component C differed from that of nicotine mainly in the presence of prominent twin ions at *m/z* 105 and *m/z* 106, being characteristic of anabasine [= 3-(2-piperidinyl)-pyridine]. The compound was identified by comparisons of spectra and retention times with an authentic sample of anabasine. Only the mass spectrum of component D was clearly different from all other spectra, although again showing an intense molecular ion at *m/z* 156 (base ion) along with loss of hydrogen (*m/z* 155). The isotopic M+1-ion (about 12% relative intensity) still indicated the presence of 10 carbon and 2 nitrogen atoms, suggesting a molecular formula of $C_{10}H_8N_2$, and thus corresponding to the fully aromatic homolog of anabasine and anabaseine, 2,3′-bipyridyl [2-(3-pyridinyl) pyridine].

Table 2 Gas chromatographic and mass spectral data to components from extracts of *Holoscotolemon lessiniense*, *H. oreophilum*, and *H. jaqueti*

Peak	Retention time (min)	EI-fragmentation (*m/z*)	Identified as
A	10.54	162 (M^+, 49), 161 (46), 133 (79), 119 (24), 118 (16), 92 (23), 84 (100), 65 (21), 51 (22), 42 (61)	nicotine = (S)-3-(1-methyl-2-pyrrolidinyl)-pyridine
B	11.85	176 (M^+, 12), 175 (7), 147 (7), 133 (9), 119 (24), 98 (100), 42 (28)	3-(1-methyl-2-piperidinyl)-pyridine[a]
C	12.29	162 (M^+, 26), 161 (23), 133 (45), 119 (45), 106 (49), 105 (60), 92 (19), 84 (100), 80 (22), 78 (20), 57 (29), 51 (28), 41 (38)	anabasine = 3-(2-piperidinyl)-pyridine
D	12.89	157 (12), 156 (M^+, 100), 155 (71), 130 (20), 128 (12), 104 (7), 79 (13), 78 (22), 51 (13)	2,3′-bipyridinyl = 2-(3-pyridinyl)-pyridine[a]
E	13.35	161 (12), 160 (M^+, 97), 159 (100), 145 (46), 132 (14), 131 (79), 118 (8), 105 (44), 104 (76), 78 (27), 77 (29), 51 (36), 41 (29)	anabaseine = 3,4,4,6-tetrahydro-2,3′-bipyridine

[a] Tentatively identified on the basis of mass spectral data

Subsequent mass spectral comparisons confirmed a mass spectral fragmentation pattern indistinguishable from spectra of authentic 2,3′-bipyridyl from literature and from the NIST-library.

Extract Profiles Two different extract patterns were clearly distinguished: (1) Nicotine-rich and (2) anabaseine-rich extracts. The extracts of *Holoscotolemon oreophilum* and *H. jaqueti* were dominated by compound A (nicotine: >97% of the secretion, based on calculation of peak areas, see also Table 2 and Fig. 1). Components B (3-(1-methyl-2-piperidinyl)-pyridine) and C (anabasine) were found constantly as accompanying minor or trace components (each about 1% of the secretion). In *H. lessiniense,* anabaseine (compound E) was the major compound in the extracts (>95%, see Table 2 and Fig. 1), accompanied by trace amounts of anabasine and 2,3′-bipyridyl (each about 1–3% of the secretion). In two out of five extracts, two trace components were also found at RT=13.56 min and 14.55 min (each about 1% of the secretion), both showing a pyridine-like pattern and a molecular weight of 174, but both remain unidentified.

It is noteworthy that some individuals did not show any components. In particular, extracts of three specimens (all collected at one locality in Serbia, see Table 1) of *H. jaqueti* were investigated, and two of these (one female, one juvenile) consistently showed the nicotine-rich composition mentioned above. In the extract of the remaining specimen (a juvenile), no components could be detected. For *H. lessiniense*, we analyzed extracts of five individuals (all female), which were from two different collections (see Table 1): Three extracts (two of collection no. 1, one of collection no. 2) exhibited the anabaseine-rich scent gland profile described above. No components could be extracted from two other specimens (from collection no. 1). For the largest species of the genus, *H. oreophilum*, only two individuals (one male, one female) were available to us, both of which discharged large amounts of nicotine. Absolute amounts of secretions were determined for *H. oreophilum,* and were calculated to be about 15 μg nicotine per individual (11.8 μg measured for one specimen, 16 μg for the other specimen).

Thus, only for *H. oreophilum* (nicotine-rich), could male and female extracts be compared, showing no differences. For *H. jaqueti* (nicotine-rich) and *H. lessiniense* (anabaseine-rich), only females and juveniles (subadult females) were available; between subadults and adults, no differences were recognized.

Holoscotolemon unicolor Contrasting the results obtained from *H. jaqueti*, *H. oreophilum*, and *H. lessiniense*, no components were detected in any of the nine extracts from adults of *H. unicolor.* This was surprising since these specimens were from several different collection sites in Austria and were collected at different times of the year (see Table 1). Scent glands in *H. unicolor*, as well as openings (ozopores) appeared to be as well developed as in the other *Holoscotolemon* species (Fig. 2). However, in one extract of an early-instar juvenile, traces of three nitrogen-containing compounds were detected (not shown), whereas extracts of 11 other juveniles did not show any compounds. The trace components in the single juvenile extract were tentatively identified as dimethyl-isoalkylpyrazines by mass spectral comparisons to literature, and to spectra from the NIST-library (compound 1: a dimethyl-isobutylpyrazine, M^+ at *m/z* 164; compounds 2 and 3: isomeric dimethyl-isopentylpyrazines, M^+ at *m/z* 178).

Discussion

Origin of Extract Components We assume that the compounds found in the whole body extracts of *Holoscotolemon* herein investigated are from the scent glands of these species. This view is based on several facts, and on corroborating evidence from previous studies. First, scent glands are the only glandular structures capable of producing such amounts of secretions; they are large and well developed in all species of the genus *Holoscotolemon*. Corroborative evidence for the scent gland origin of extract components comes from extraction-attempts of individuals with obviously depleted gland reservoirs. We assume that we may have examined many “empty” specimens, as indicated by the lack of any compound in the gas chromatograms of extracts. From previous investigations, we know that depletion of gland reservoirs can be a rapid process, mainly depending on external irritation stimuli. Refill of glandular reservoirs is slow; according to Holmberg (1970), this process takes a few days in phalangiids. We do not know anything about the refilling capability in species of *Holoscotolemon*. In our study, the relation of specimens with well-filled gland reservoirs to specimens with depleted reservoirs was about 1:1 for *H. jaqueti* and *H. lessiniense.* Glandular depletion may be explained by irritating stimuli in the course of collection and transport. Absolute amounts of secretion, as shown for nicotine in extracts of *H. oreophilum,* were calculated to be about 15 μg per individual. Such amounts correspond to a volume of 15 nl of nicotine (which is a liquid with a density of 1.01 g/ml at room temperature), and hence to two hypothetical spherical “droplets” of about 130 μm in diameter. Moreover, droplets of that size would be consistent with the expected dimension and filling capacity of glandular reservoirs in *Holoscotolemon*, at least if glandular dimensions in other opilionids of comparable

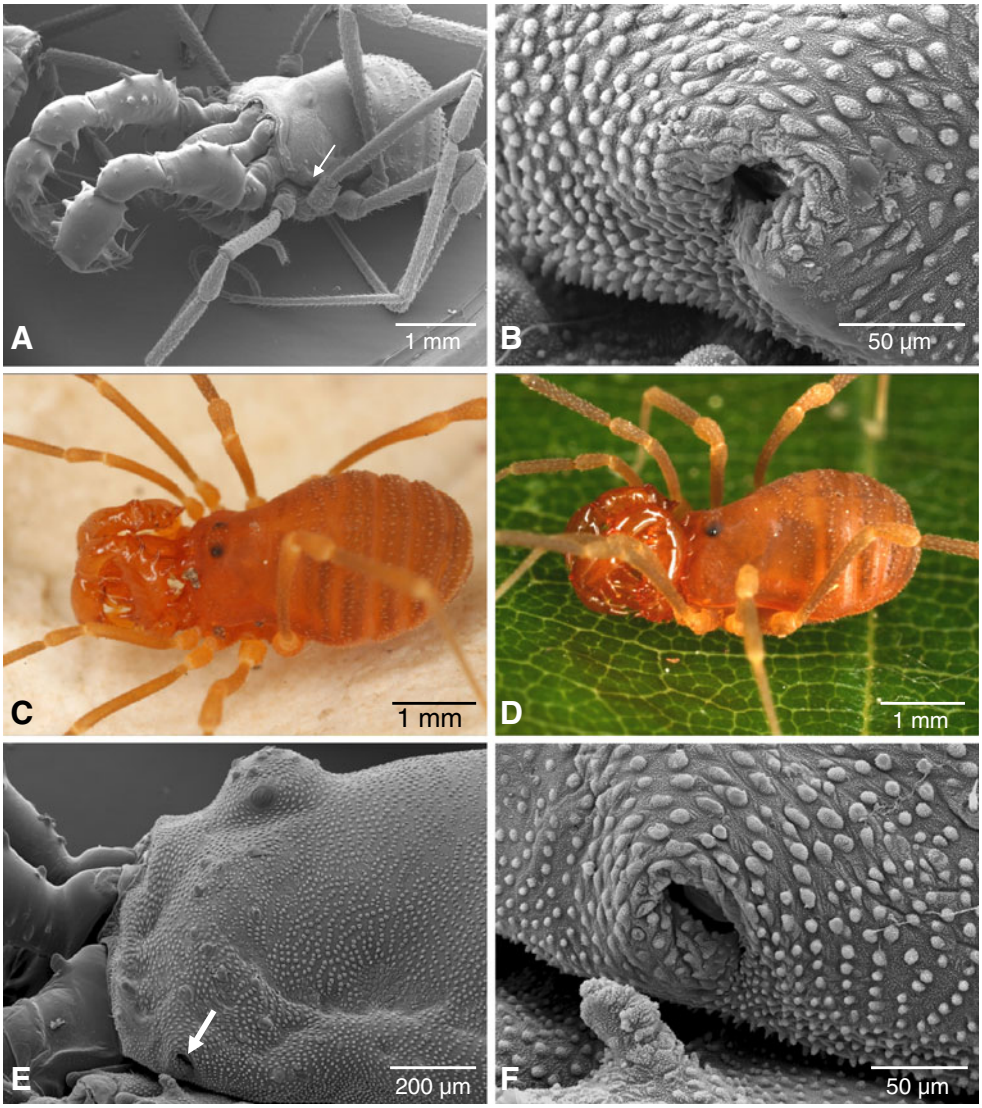

Fig. 2 Position and morphology of ozopores in species of genus *Holoscotolemon*. Arrows point to ozopores that are located near dorsally to coxae II. **a** *Holoscotolemon unicolor,* and **b** detail of ozopore. **c** *Holoscotolemon oreophilum*; **d** *Holoscotolemon lessiniense*; **e** and **f** details of left ozopore in *Holoscotolemon jaqueti*

size are considered (e.g., Juberthie, 1976; Schaider and Raspotnig, 2009).

In general, the whole body extraction-method is widely used and commonly accepted for the assessment of exocrine products in small arthropods that are too tiny to sample or dab their secretions directly from the gland orifices. The method has been standardized for investigations of exocrine glandular products in oribatid and astigmatid mites over many years (Sakata and Norton, 2001; Raspotnig et al., 2001, 2008), and also has been used to assess scent gland exudates of opilionids of different groups (Raspotnig et al., 2005, 2010; Jones et al., 2009; Shear et al. 2010a,b). For instance, in sironids (Cyphophthalmi) direct sampling of secretions from ozopores leads to the same chemical results as working with hexane whole body extracts (Raspotnig et al., 2005).

Nicotine and Anabaseine In general, tobacco alkaloids are unusual components in arthropod exocrine secretions. Nicotine is known only from *Sclerobunus robustus* (a travunioid laniatorean) (www.pherobase.com). Anabaseine, on the other hand, is new for scent gland secretions of Opiliones. However, this compound is a nicotine-derived alkaloid. Nicotine is a defensive neurotoxin of some plants, and anabaseine is a neurotoxin from nemertine worms that use it for paralyzing prey and possibly for deterring predators (Kem, 1971; Kem et al., 1971, 1976). Regarding arthropods, anabaseine-rich secretions appear to be rare. One example, however, is the poison glands of certain myrmicine ants (Wheeler et al., 1981; Leclercq et al., 2001; Co et al., 2003), where anabaseine also may act as a part of the trail pheromone (Attygalle et al., 1998). In certain hymenopterans, anabaseine is found as a by-product in anabasine-rich secretions (Co et al., 2003; Cruz-Lopez et al., 2006). Anabaseine is remarkable for exhibiting striking neurotoxic effects by interacting with nicotinic receptors, and a synthetic anabaseine-derivative has proved to be a

promising test agent to study and cure cognitive function loss associated with several human diseases (Kem et al., 1997, 2006). To our knowledge, *H. lessiniense* is the only arthropod species producing an exocrine secretion almost exclusively based on anabaseine. It is further interesting to note that *H. lessiniense* (anabaseine-rich) and *H. oreophilum* (nicotine-rich), both occurring in the Italian Southern Alps and separated by an air-line distance of just 300 km, use differently composed secretions; this might indicate more specific communicative functions of scent gland secretions in cladonychiid harvestmen, in addition to assumingly defensive roles.

Pyridines and Alkyl-pyrazines Three minor components in the *Holoscotolemon*-secretions were classified as pyridines, chemically close to nicotine and anabaseine. These compounds may represent by-products of the biosynthetic pathways to nicotine and anabaseine, but the possibility of their artificial formation from major compounds in the hot injector of the gas chromatograph cannot be excluded. In fact, small amounts of 2,3′-bipyridyl also could be detected when analyzing an authentic sample of anabasine, calling the scent gland origin of 2,3′-bipyridyl into question. On the other hand, 2,3′-bipyridyl is known to represent a second neurotoxic component in nemertine worms, in addition to anabaseine (Kem et al., 1976), and also occurs in exocrine glands of certain *Aphaenogaster* and *Messor* ants (Attygalle et al., 1998; Co et al., 2003). The alkyl-pyrazines detected in the extract of one single juvenile of *H. unicolor* also are widespread exocrine compounds in several species of ants and wasps (Cavill and Houghton, 1974; Borg-Karlson and Tengö, 1980; Wheeler et al., 1982; Tecle et al., 1987; Brophy, 1989; Jones et al., 1998; Morgan et al., 1999). In some cases, alkyl pyrazines seem to accompany alkaloids of the anabasine-type as minor components in exocrine secretions of some hymenopterans (e.g., Cruz-Lopez et al., 2006). However, our preliminary chemical data for *H. unicolor,* deviating from the chemistry of the other three *Holoscotolemon* species, need further clarification, and we hope to unravel this question in the near future.

Chemosystematics in Genus Holoscotolemon Our study provides an analysis of the scent-gland chemistry of all four Alpine and Carpathian *Holoscotolemon* species. In this context as well as from a zoogeographical and evolutionary point of view, questions concerning the presently inhabited areas of these species are of interest, particularly with respect to the hypothetical regions where they outlasted the last ice-age (Würm). *Holoscotolemon unicolor* is endemic to the Eastern Alps and, following Holdhaus (1954), Thaler (1966, 1976), and Komposch (2009), is a re-wanderer of long distance, which probably survived the last ice age in "massifs de refuge" of the South-Eastern Alps. *Holoscotolemon oreophilum* and *H. lessiniense* are local endemics of the Southern Alps, and should have survived the Würm ice-age in "massifs de refuge" in the areas of their present distribution in the Sea Alps (*H. oreophilum*) and Monti Lessini (*H. lessiniense*), respectively. Martens (1978) found no close relationship between *H. lessiniense* and *H. unicolor*, and believed the former species is closer to *H. oreophilum*. Therefore, it is surprising that the available chemical information points toward a high similarity between the most western (*H. oreophilum*) and the most eastern species (*H. jaqueti*). Thus, tentatively, nicotine may represent a plesiomorphic compound in *Holoscotolemon* (and possibly also in Travunioidea, see below) while *H. lessiniense*, occurring in an area in between, shows a clearly distinct although related chemistry (i.e., anabaseine-rich), possibly representing the derivative status.

Scent Gland Chemistry in Insidiatores The major part of laniatorean scent gland research has been performed on grassatorean Laniatores, and this strong bias may have contributed to the picture of a typical, rather homogenous, phenolic and benzoquinone-rich "laniatorean chemistry". Phenol- and benzoquinone-rich secretions have been identified from representatives of all grassatorean families hitherto investigated, such as many Gonyleptidae (see Gnaspini and Hara, 2007 and references therein; Hara et al., 2005; Machado and Pomini, 2008; Föttinger et al., 2010), Cosmetidae and Manaosbiidae (Eisner et al., 1971, 1977; Roach et al., 1980), Stygnommatidae (Duffield et al., 1981), Stygnopsidae (Pomini et al., 2010; Shear et al., 2010b), and Phalangodidae (Shear et al., 2010a). Even though components other than phenols and benzoquinones (i.e., some accompanying acyclic compounds and alkyl-dihydro-pyrans) have been found in certain Gonyleptidae (Hara et al., 2005; Rocha et al., 2011), nitrogen-containing compounds or even tobacco alkaloids do not seem to occur in the scent glands of the Grassatores. On the other hand, there is growing evidence that insidiatorean secretions – or at least those of superfamily Travunioidea – are based on a completely different chemistry that relies on nitrogen-containing compounds as major secretory constituents. This idea is corroborated by the pioneering study of Ekpa et al. (1984) who found two nitrogen-containing compounds (ß-dimethyl-phenylethylamine and nicotine) in the scent gland secretion of *Sclerobunus robustus*, a travunioid species from both another continent (America) and a second travunioid family (Travuniidae; Kury 2000 onwards). For grouping of "Northern Hemisphere Triaenonychoidea" such as *Sclerobunus* with Travunioidea see Giribet and Kury (2007). Preliminary chemical results from representatives of travuniids in Europe (unpublished) also indicate consistently that tobacco alkaloids constitute major secretory components in species of *Travunia* and *Abasola* (for possible synonymies see Kury

and Mendes 2007) as well as in the so-far systematically unplaced but travunioid *Trojanella* (Karaman, 2005). In this respect, nitrogen-containing compounds: (1) may be widespread or even common in the Travunioidea; and, (2) according to the basal phylogenetic position of Travunioidea within Laniatores, these compounds also may represent the ancestral scent gland equipment of laniatoreans.

Opilionid scent gland secretions generally seem to be a promising pool of group- or even species-specific chemical characters, representing an independent set of data of phylogenetic value, in addition to characters from traditional morphology and molecular genetics. The importance of scent gland chemistry for studies of opilionid phylogeny has been emphasized previously (Roach et al., 1980; Duffield et al., 1981), and more recent papers have added to this topic (Raspotnig et al., 2005, 2010; Jones et al., 2009). So far, an evolutionary line may be traced from the naphthoquinone- and acyclic ketone-rich secretions of the Cyphophthalmi to the similarly structured secretions in eupnoid and dyspnoid Palpatores (see introduction), but any evolutionary link to the chemically distinct secretions of Laniatores is still missing. Additionally, within the Laniatores, the "chemical gap" between the alkaloid-rich secretions of the Travunioidea on the one hand and the generally phenol- and benzoquinone-rich chemistry in the Grassatores on the other hand is not yet well explained. In this regard, information on the unknown scent gland chemistry of the "true" Triaenonychoidea (sensu Kury, 2000 onwards) would be important, as this mainly Southern Hemisphere-distributed group of Insidiatores (see Pinto-da-Rocha and Giribet, 2007) may represent the missing link in the chemosystematic puzzle of harvestmen.

fish on large outdoor racks. The export of dried stockfish from Norway exceeds 70 million € each year, and the majority of this export is dried Atlantic cod (*Gadus morhua*; Linnaeus, 1758), produced in the Lofoten archipelago. In a typical year, the Norwegian stockfish industry experiences revenue losses of 5–10% resulting from damage to fish from blowfly activity, with local quality downgrading and discarding of fish possibly amplifying losses to 30–40% (values given by the Norwegian Stockfish Association). Stockfish production is confined to a 3–4 month period in the early spring. The only insect species that causes damage to stockfish production is the saprophagous *C. vicina* (Aak et al., 2010b). Despite more than 1,000 years of commercial stockfish production (Sturlason, 1226), few efficient methods for control of this pest are available. Chemical treatment of fish, protective nets, and indoor drying are considered undesirable, because of human health concerns, operational difficulties, and excessive cost.

Mass trapping as a potential control method for *C. vicina* in stockfish production was explored in an earlier investigation, in which dimethyl trisulphide, which attracts *C. vicina* (Stensmyr et al., 2002), was applied to yellow sticky traps and funnel traps (Aak et al., 2010b). In that study, the sticky traps were efficient at catching blowflies during the early phase of stockfish production (February until late April), whereas the funnel traps increased in efficiency toward the end of production (April until the summer). The funnel traps showed high *C. vicina* specificity, and more than 90% of the blowflies caught were female. Overall, in that preliminary study, we estimated that some 5–30% of the flies causing damage were caught, indicating that mass trapping has the potential to reduce blowfly damage in stockfish production.

In the present study, we conducted a 4-year mass-trapping experiment for control of blowflies in stockfish production areas in Lofoten, Norway. Yellow sticky traps were used specifically during the production phase, whereas target-specific funnel traps, with odor bait, were used over the entire season. Damage to stockfish in treatment vs. control areas was used as an indicator of success. Blowfly population monitoring with white sticky traps also was carried out in the mass-trapping areas, so as to establish a connection between blowfly activity and damage, as well as to evaluate the long-term effects of trapping on local blowfly populations.

Methods and Materials

Study Area The Lofoten archipelago is located immediately north of the Arctic Circle and reaches approximately 200 km southwest into the Gulf Stream in the Norwegian Sea. The climate is oceanic, and the islands contain a mix of middle boreal, north boreal, and alpine habitats. Normal temperature (Vestvågøy, 1961–1990) for January is -0.4°C, April 2.3°C, July 12.0°C, and October 5.8°C (Norwegian Meteorological Institute—data base—www.met.no). The mass-trapping experiment was carried out at Gimsøy (68°21′N, 14°05′E), Henningsvær (68°09′N, 14°12′E), Ballstad (68°05′N, 13°33′E), Sund (68°01′N, 13°13′E), and Sørvågen (67°53′N, 13°01′E), located in the central and outer part of the archipelago (Fig. 1).

Experimental Design Five pairs of similar stockfish production areas were selected in cooperation with the Norwegian Stockfish Association (Fig. 1). The experiment was carried out at the main locations for stockfish production in Lofoten. The production sites in each pair were located geographically close to each other, with one site being used for mass trapping and the other as a control. The maximum and minimum distance between pairs of control and treatment was 9 and 1.5 km, respectively. The first year of mass trapping was 2006, and the experiment was continued for 4 consecutive years. Trapping began in the 9th week of each year, which corresponded to the start of drying. Traps were emptied every 4th week: until October (eight trapping periods) in 2006, and until November (nine trapping periods) in the subsequent 3 years. No trapping took place from December–February.

After drying, each stockfish was inspected by professional quality controllers, and the percent-damaged stockfish in the treatment and control areas calculated. Damage levels are influenced by time of hanging and sun exposure (Aak et al., 2010b). To avoid confounding effects of these two elements, an additional test was conducted in the final year. Three hundred fish from each treatment and control area were selected to ensure that drying had begun in the same week, in the control-treatment pairs, and that all fish had received approximately the same level of sun exposure. The 3,000 fish from the 10 sites were inspected by one professional quality controller to avoid subjective differences in evaluation. The origin of each batch was unknown to the quality controller.

The mass-trapping effort in each of the treatment areas was balanced according to the production size (Table 1), but always incorporated at least 10 odor-emitting funnel traps and 30 yellow sticky traps at each site. The number of traps was constant across all years of experimentation.

Yellow Sticky Traps Yellow plastic sticky boards (Komadur ES, highly shock resistant PVC, 330 mm×1,000 mm×2 mm; Vink Plast Kolbotn, Norway) were coated with 85 g Tanglefoot insect trap coating (The Tanglefoot Company, MI, USA). The traps were evenly distributed on sun-exposed sides of drying racks. Flies caught in the traps

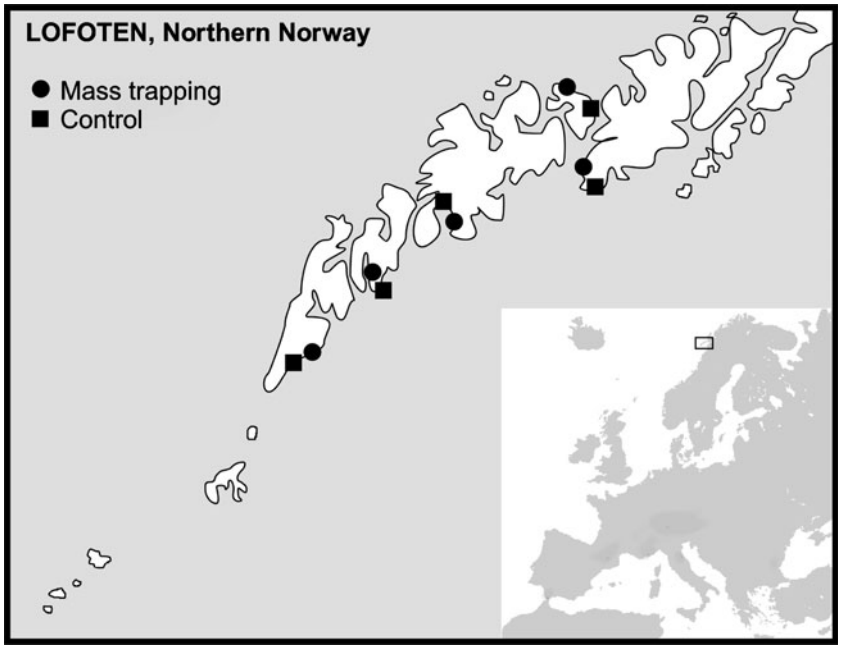

Fig. 1 Location of the 10 stockfish production sites included in the mass-trapping experiment in Lofoten, Norway. Circles represent mass-trapping areas, and squares represent control areas. From north to south the pairs represent stockfish production at Gimsøy, Henningsvær, Ballstad, Sund, and Sørvågen

were identified as *Calliphora* spp. in the field and counted every 4th week, from the start of the drying period until trap stickiness was reduced to such an extent that no additional flies were caught (after 16 week of trapping). To avoid large catches of non-target species, the traps were not replaced or reactivated.

Odor-Emitting Funnel Traps Advantage funnel traps (J.F. Oakes, USA), modified with mesh to reduce the opening of the entry funnel, were used with synthetic lures. The dimethyl trisulphide lure (25%, in ethanol) was replaced in 2007 by a three-component lure (25%, in ethanol), consisting of equal amounts of dimethyl trisulphide (Aldrich Chemical Co, MO, USA, 98% purity), *o*-cresol (Fluka Co, MO, USA, 99% purity), and mercapto-ethanol (Fluka Co, MO, USA, 99.5% purity). The three-component lure was developed by the authors during the mass-trapping work, and was used because it yielded higher catches of blowflies than did dimethyl trisulphide alone (Aak et al., 2010a). One milliliter of lure was placed inside the traps in a 2 ml polystyrene microtube. Traps were evenly distributed in the production area, but always hung at the border of drying racks, and were emptied every 4th week and reactivated with bait. Captured flies were frozen and transported back to the laboratory for counting and identification.

Population Monitoring To monitor blowfly populations in the production areas, we used a small number of white sticky traps made from bucket lids (*Ø*=27 cm) that were coated with 20 g Tanglefoot. These lids were used because they were cheap and practical for field application, and white is as efficient as yellow for catching *Calliphora* spp in Lofoten (Aak, 2010). At each of the 5 sites, 10 traps

Table 1 Location, production volume, trap numbers, and economic effects of blowfly damage at the production sites included in the mass-trapping experiment performed in Lofoten, Norway

Location:	A Gimsøy 68°21′N, 14°05′E	B Henningsvær 68°09′N, 14°12′E	C Ballstad 68°05′N, 13°33′E	D Sund 68°01′N, 13°13′E	E Sørvågen 67°53′N, 13°01′E
Production (tons of dried fish):	70–80	25–30	40–50	80–120	40–60
Number of monitoring traps :	10	10	10	10	10
Number of yellow sticky traps:	40	30	40	50	30
Number of funnel traps:	15	10	14	18	10
Yearly trapping cost:	1,150 €	1,000 €	1,120 €	1,250 €	1,000 €
Average yearly loss:	25,000 €	7,500 €	12,500€	50,000 €	65,000 €

The production size and annual loss are based on numbers reported by the producers, whereas the cost of trapping is based on trap prices and the cost of preparing, mounting, and maintaining traps

were mounted vertically, 1.5 m above ground, on sun-exposed, south-facing, sides of drying racks. The monitoring traps were replaced at the end of each 4-wk trapping period. Continuous monitoring in control areas was not performed. Instead, a point measurement was obtained in these areas (10 traps at each control site, mounted in sun-exposed areas) during the 3 rd trapping period, when fly activity was expected to be maximal (Aak et al., 2010b). Because of administrative and practical difficulties, this point measurement was obtained only in the 4th year of the experiment. The numbers of flies in the treatment-control pairs were compared, and female *C. vicina* were dissected for evaluation of egg developmental state, according to three ordinal categories: 1) white-to-translucent follicles delineating a circular structure with no developed eggs; 2) medium developed, circular-to-ellipsoid eggs with yolk; and 3) fully developed elongate eggs.

Statistical Methods For comparisons between two groups, we used *t*-tests or paired *t*-tests, and for multiple comparisons we used ANOVA. In cases in which tests for normality failed, and it was not possible to normalize data through transformation, we used Wilcoxon Signed-Rank tests. Ordinal logistic regression was used in tests with the categorized data on egg development. In the pair-wise comparison of damage levels to fish, two points had to be removed from the data set, because production was lacking in the control area. One additional measurement was excluded because of extremely late hanging dates resulting in almost 100% damage; this site also was removed from correlation analyses, together with one datum point from 2008, in which the producer failed to kill larvae in the storage room, resulting in release of an unknown, but very high, number of flies at the stockfish production site.

Results

Blowfly Trapping Approximately 306,000 *C. vicina* were caught during the study. Of these, 10.6% were caught with the monitoring traps, 21.1% with yellow sticky traps, and 68.3% with odor-emitting funnel traps. The monitoring traps caught similar numbers of males and females, while the funnel traps caught five times more females than males. The sex ratio was not investigated in the yellow sticky traps.

The white sticky traps used for population monitoring of *C. vicina* showed two distinct activity peaks in all 4 years (Fig. 2). One small peak appeared during production, whereas the second, and most numerous, peak appeared 1 month after production. The catch in the monitoring traps showed seasonal trends similar to the yellow sticky traps during the production period, but diverged from the funnel traps after the production period with a more abrupt drop in fly density following the trapping period in June/August (Fig. 3a, b). There was also a large discrepancy between monitoring traps and odor-emitting traps in May/June when the fish was removed from the drying areas. At this time, odor-emitting traps maintained a high catch while monitoring traps showed a drop. The difference in total catch per production site, between yellow sticky traps and funnel traps, varied according to trapping period (Fig. 3a). The funnel traps had lower catches in the first (*t-test*; t=2.38, N=5, P=0.044) and second (*t-test*; t=6.23, N=5, P<0.001) trapping periods, compared to the yellow sticky traps. The total catch was similar for both trap types in the third period, whereas funnel traps caught more flies than yellow sticky traps in the fourth period (*t-test*; t=8.32, N=5, P<0.001), and continued to catch flies until November, when trapping was terminated.

Effect of Trapping Pair-wise comparisons between treatment and control plots showed that damage caused by blowflies was lower in the mass trapping areas (*Wilcoxon Signed-Rank*; T=27.0, N=17 pairs, P=0.046). The average relative damage reduction varied from 8–31% across experimental years (Table 2). In the final year, when care was taken to ensure similar times of hanging and sun exposure levels, a damage reduction of 63% was found (*Wilcoxon Signed-Rank*; T=7.5, N=5 pairs, P=0.031; Fig. 4).

The total number of flies caught in the monitoring traps each year did not change over the study (Fig. 2; *ANOVA*; $F=0.75_{3,16}$, P=0.54). Comparing control and treatment sites in the third trapping period in 2009, no differences with respect to total number of flies (*paired t-test*; t=0.351, N=5 pairs, P=0.743), number of males (paired *t*-test; t=0.375, N=5 pairs, P=0.727), or number of females (*paired t-test*; t=0.226, N=5 pairs, P=0.832) were observed. However, flies in the control areas had more developed eggs than flies in mass trapping areas (*Ordinal logistic regression*; *Chi-sq*=23.2, *df*=1, P<0.001), with average category scores of 2.6±0.07 (N=98) and 2.2±0.05 (N=95), respectively. There was also a significant difference between the five localities (*Chi-sq*=12.5, *df*=4, P=0.014) but, because there was no significant interaction between treatment and location, the effect from trapping on egg development was present at all sites.

Damage and Blowfly Activity The size of the large summer cohort of *C. vicina* adults (average of the 5th and 6th trapping periods; the two trapping periods following the stockfish production, Fig. 2) was positively correlated with blowfly damage during the production period (r^2=0.58, N=18, P<0.001).

To investigate the correlation between blowfly activity during production and damage to stockfish, we performed linear regressions with the number of blowflies caught in the monitoring traps in each of the first four trapping periods

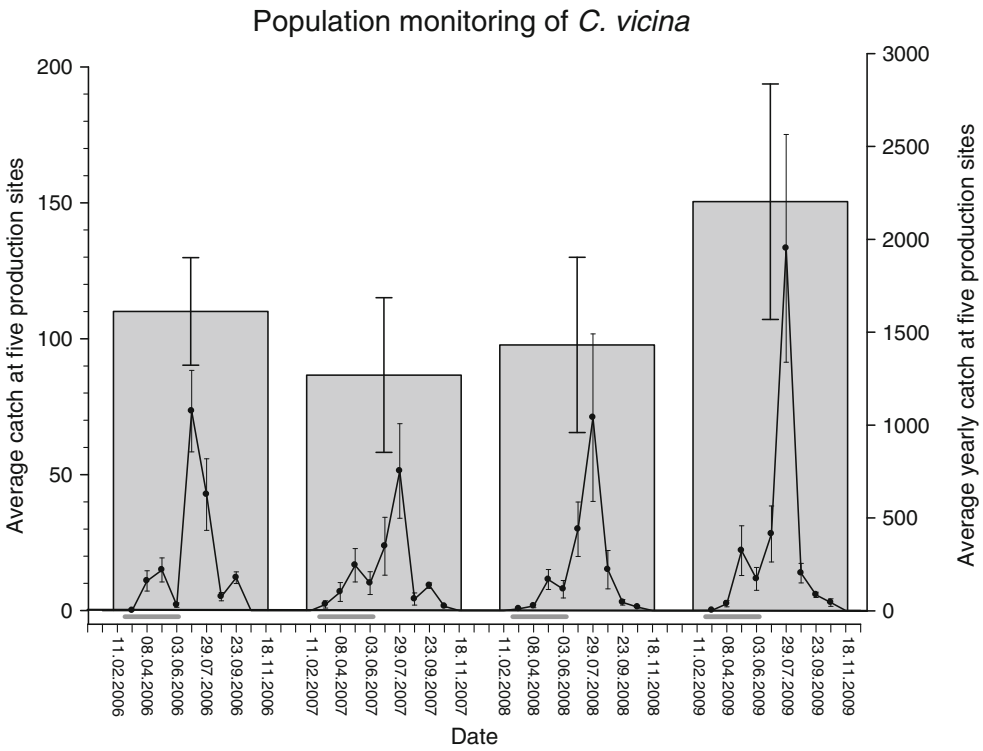

Fig. 2 Adult *Calliphora vicina* caught in white monitoring traps during the 4 years of mass trapping (2006–2009). The grey bars represent the average (± SE) yearly catch at the five production sites (*right y-axis*), and the line represents the average (± SE) catch at the five production sites in each trapping period (*left y-axis*). The stockfish production period is indicated by the thick grey line

(February to June in Fig. 2) as the predictor variable, and the percent damage the same year as the response variable. In the first trapping period, fly activity was low and damage to fish was independent of fly density (r^2=0.01, N=19, P=0.734). In the second period, fly numbers influenced damage slightly (r^2=0.20, N=19, P=0.058), whereas, in the third period, increasing fly activity strongly influenced damage (r^2=0.66, N=19, P<0.001). The connection between the number of flies and damage was weak in the fourth trapping period (r^2= 0.16, N=19, P=0.087), when the number of flies in the monitoring traps decreased.

Discussion

Control programs that target sheep-striking blowflies by using natural odor sources or synthetic lures have shown promise with regard to damage reduction and blowfly population suppression (Anderson et al., 1990; Smith and Wall, 1998; Broughan and Wall, 2006; Urech et al., 2009). Entry traps, or sticky surfaces that combine olfactory and visual stimuli, commonly are used to trap blowflies (Broce et al., 1977; Jiron, 1984; Anderson et al., 1990; Green and Warnes, 1992; Wall et al., 1992; Wall and Smith, 1996; Hall et al., 2003). Synthetic lures also have been developed for screwworm flies (Mackley and Brown, 1984; Horton et al., 1999; Morris, 2005; Urech et al., 2009). In this study, we demonstrated that mass trapping of *C. vicina* blowflies is an economically viable control method in stockfish production.

Our mass-trapping study demonstrated a reduction in damage of stockfish by *C. vicina* of 8–31% per year. The pairs of control and mass trapping sites were kept as similar as possible but, after adjusting for drying time and sun exposure, both of which contribute to damage (Sømme and Gjessing, 1963; Aak et al., 2010b), an even larger reduction (63%) in damage was obtained. This figure more likely reflects the potential impact of mass trapping *C. vicina* in this production system. One might expect that reduction in damage to stockfish should lead to reduced local population densities over time. However, this was not observed. Even when we achieved significant levels of damage reduction, relative to the control, we did not observe any changes in fly numbers over the duration of the trial (i.e., from the first to the last year). The blowfly population density, as measured by catches in the monitoring traps, was determined mainly by flies appearing after production, and these numbers correlated with damage to stockfish 2 months prior. Because the variation in mean damage (3.5–11.2%) among years was much larger than the mean difference in damage (0.6–3.0%) between control and treatment sites, any long-term population suppression effects would have been masked by the large among-year variation. As constant population monitoring was not performed in the control areas, a difference in fly density in mass trapping areas, relative to control areas, could not be investigated.

Fish only are susceptible to fly oviposition during the first 4–6 weeks of drying (Sømme and Gjessing, 1963; Aak et al., 2010b). As the connection between fly activity and damage increases from the second to third trapping periods,

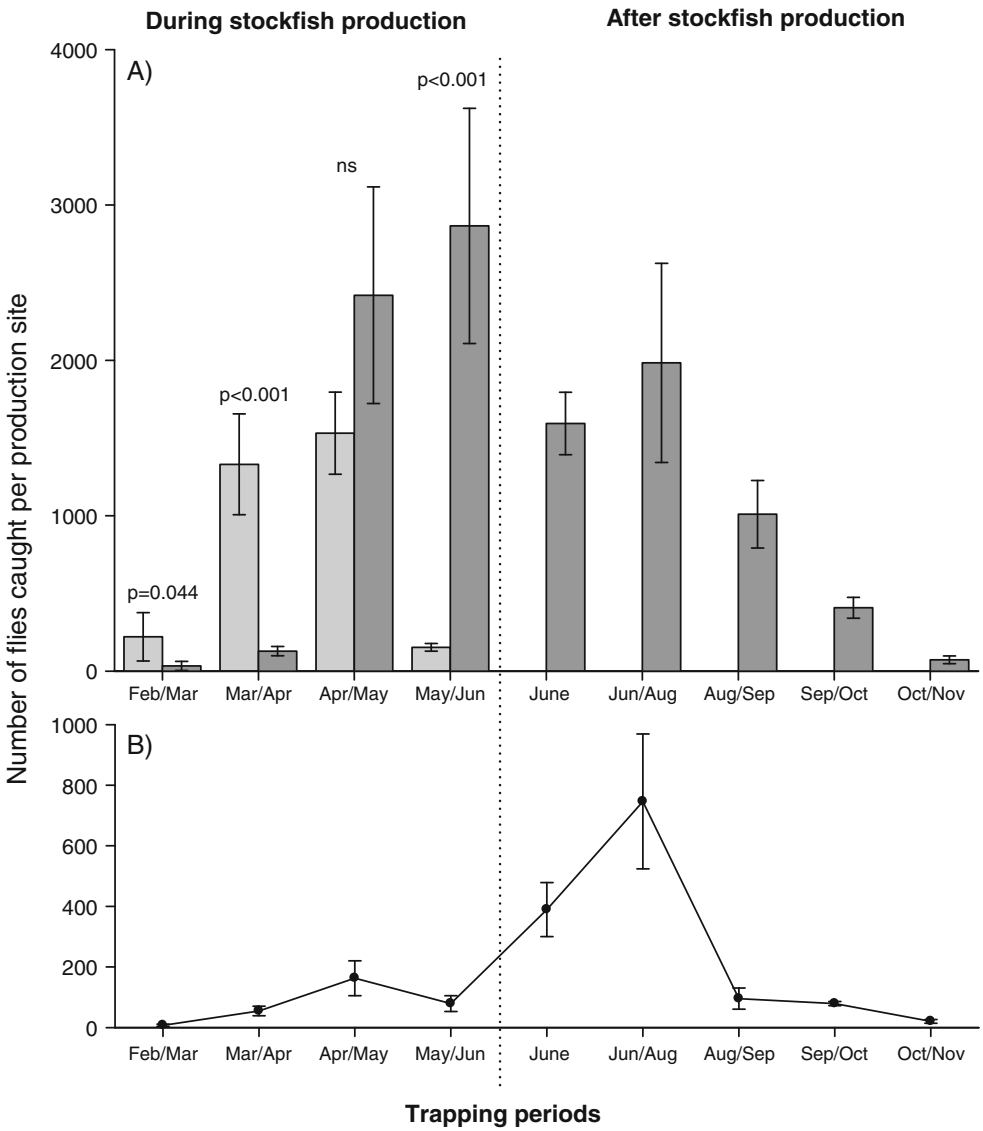

Fig. 3 Average catch (± SE) of *Calliphora vicina* per trapping period at five production sites, from 2006–2009. The dotted vertical line indicates the end of stockfish production. **a** Yellow sticky traps (*light grey bars*) and funnel traps (*dark grey bars*) baited with a synthetic lure consisting of dimethyl trisulphide, *o*-cresol and mercaptoethanol. Significant differences between the trap types in a trapping period are indicated by corresponding *P*-values. **b** White monitoring traps

it is likely that most of the infestation actually occurred in the transition between these periods. At this time, blowfly activity is high, and the fish is not yet dry enough to preclude larval infestation. Most egg-laying blowflies present at this time are likely to belong to a cohort with a univoltine lifecycle, originating from larvae that developed on stockfish in the previous production year (Aak et al., 2011). Blowflies also may breed in natural resources to produce autumn offspring, which spend the winter as larvae and pupae (Aak et al., 2011). The appearance of a second cohort of adults, emerging to co-exist with the parental generation in early spring, may mask a reduction of fly

Table 2 Percent damage to stockfish per year caused by *Calliphora vicina* in the mass-trapping experiment

	Control area	Mass trapping area	Range	Damage reduction
2006	7.6±2.7	7.0±2.3	4.0–13.6	8%
2007	7.1±2.5	5.8±2.2	0.3–11.7	18%
2008	3.5±1.6	2.4±0.9	0.0–7.5	31%
2009	11.2±3.2	8.2±3.2	1.1–17.0	27%

Data were obtained from five pairs of mass-trapping and control sites

The relative damage reduction was calculated from the average difference between the two treatments each year

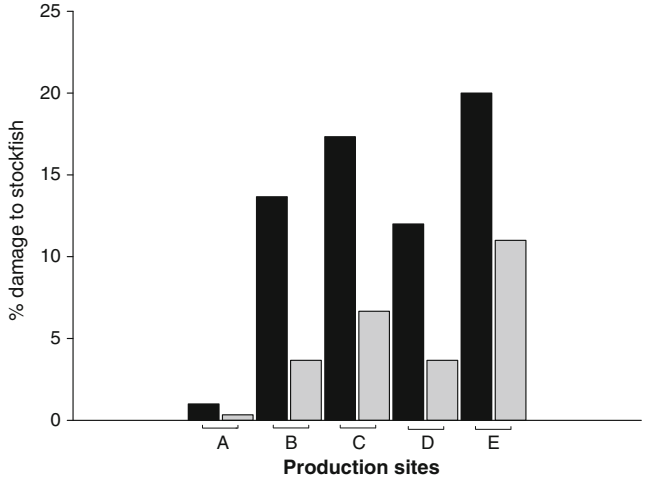

Fig. 4 Percent damage to 3,000 stockfish from five pairs (**a**–**e**) of control (*black bars*) and mass-trapping sites (*grey bars*) in 2009. Fish were selected to ensure that drying had begun in the same week for each control-treatment pair and that all fish received approximately the same sun exposure

numbers, and could also explain our inability to detect differences in blowfly numbers or sex ratios between the control and treatment areas.

The funnel traps were effective from the third trapping period, and caught flies throughout summer to remove egg-laying females from the population. These traps also maintained a higher catch in late summer and autumn, as compared to the more passive monitoring traps. This indicates a selective removal of reproductive females and may contribute to a reduction in the number of over-wintering flies capable of causing damage the following spring. It is possible that the measured reduction in egg developmental state in the mass trapping areas, as compared to the control areas, could be explained by this year-long selective trapping. However, if a mix of cohorts were to occur in the third trapping period, selective trapping of the elder cohort during production also would result in decreases in egg developmental status of the females in the mass trapping areas, relative to the control.

Even though the overall catch was largest in the female-specific funnel traps, the sticky traps caught most flies during the early drying periods, when flies were likely to commence oviposition on the drying fish. Because of this, and the large number of flies caught, the relative contribution of the sticky traps probably was important for the damage reduction observed in this experiment. Thus, such traps should be included in future mass-trapping programs. In a preliminary study, yellow sticky traps were baited with dimethyl trisulphide to increase blowfly catch (Aak et al., 2010b). However, addition of the lure did not appear to change the early efficiency of these traps compared to the lack of lure used in the present study. Most likely, low volatility of the lure at low ambient temperatures, or odor competition from fresh fish, rendered the lure ineffective during the first trapping periods.

Attracting relatively high numbers of adult females, extensive trapping prior to damage, and a pest species with a predominantly univoltine lifecycle, are important factors that contribute to the success of mass trapping programs. These factors were present in our study system, and a successful reduction in blowfly damage in stockfish production was achieved. El-Sayed et al. (2006) reviewed mass trapping as an insect control method, and defined some additional important elements contributing to success: 1) high levels of attraction, capable of competing with natural odor sources; 2) efficient traps at proper densities; 3) isolated insect populations with low immigration rates; and 4) appropriate biology of the pest species; specialized species being considered more advantageous. In our mass-trapping program, we (at least partially) avoided competition with natural odors by trapping flies before stockfish production. The traps also caught flies during production, indicating an ability of traps to compete with fish drying on the racks. We did not investigate the effect of trap density as such, but our high catches of females indicate that the density we used was relatively efficient at removing large numbers of relevant (i.e., adult females) individuals. *Calliphora vicina* can be regarded as a generalist saprophage, having larval development in substrates ranging from garbage to living animals (Ferrar, 1987; Rognes, 1991). Nevertheless, natural larval breeding sites are scarce, and *C. vicina* has a strong, specialist-like response to cues from decaying protein resources (Stensmyr et al., 2002; Angioy et al., 2004; Aak et al., 2010a). No information exists regarding the degree of population isolation, or of immigration/emigration rates at the stockfish production sites, but as these specialists are considered strong flyers, their range of activity may be large.

Mass trapping of *C. vicina* is effective and its use may help to increase profitability for stockfish producers. The yearly trapping costs at the five production sites ranged from 1,000–1,250 €, which is relatively small compared to the estimated loss inflicted by the flies, which is in the range of 7,500–65,000 €. The Norwegian Stockfish Association has set the acceptable level of damage to 3%, which we only achieved in some production areas and, as an average over all mass trapping sites, only in 2008. This control method could be augmented by other non-chemical methods, such as regular collecting and killing of blowfly larvae leaving the fish. Moreover, its efficacy could be enhanced by optimizing the number and relative amounts of the two trap types. Wind tunnel attraction of blowflies to the three-component blend, used in the present study, was 64%, while attraction to authentic dead fish odor was 88% (Aak et al., 2010a). Thus, identification of more behaviorally active compounds or adjustments of blend ratios could further enhance trapping efficacy.

Acknowledgements This study was financed by the Fishery and Aquaculture Industry Research Fund, the Norwegian Stockfish Association (Tørrfiskforum), the Norwegian Institute of Public Health and the Research Council of Norway. We would like to thank the stockfish producers Bjarne Notø, Ragnar Riksheim, Helge Haug, Johannes Langås, Ole E. Olsen, Ståle Olsen, Johan B. Larsen, and Øyvind Arntzen for participating in the project. We also thank Professor Eline B. Hågvar and Dr. Dag Hjerman for valuable comments on the manuscript

ambrosia beetles in the tribe Xyleborini, there is extensive inbreeding and haplodiploid sex determination (Rabaglia, 2002). Males of *X. glabratus* are haploid and flightless, and mate with sibling or parental females (consanguineous polygyny) within the brood galleries. Diploid females emerge from their natal trees and engage in brief dispersal flights to locate and colonize new hosts.

Although not considered a pest in Asia, females of *X. glabratus* are primary colonizers of hosts in the U.S., capable of attacking healthy unstressed trees. During gallery excavation, females introduce spores of several symbiotic fungi (Harrington et al., 2010), including the pathogenic *Raffaelea lauricola* T.C. Harr., Fraedrich & Aghayeva (Harrington et al., 2008), carried in mycangial pouches located at the base of the mandibles (Fraedrich et al., 2008). The resultant fungal growth (ambrosia) provides food for larvae and adults within the gallery, but the fungus also invades the host vascular system. Similar to the situation with oak wilt (Jacobi and MacDonald, 1980), it is thought that laurel trees infected with *R. lauricola* respond by forming walls within the xylem vessels (parenchymal tyloses) and by secreting gums and resins that block water transport. This results in systemic wilt and ultimately tree death, which can occur in as little as 6 weeks (Mayfield et al., 2008).

Primary host trees in the southeastern U.S. are native *Persea* species, including redbay [*Persea borbonia* (L.) Spreng.], swampbay [*P. palustris* (Raf.) Sarg.], and silkbay (*P. humilis* Nash), but avocado (*P. americana* Mill.) also has been confirmed as a susceptible host (Mayfield et al., 2008). Additional U.S. hosts include sassafras [*Sassafras albidum* (Nuttall) Nees], camphor tree [*Cinnamomum camphora* (L.) J. Presl], spicebush [*Lindera benzoin* (L.) Blume], pondberry [*Lindera melissifolia* (Walter) Blume], and pondspice [*Litsea aestivalis* (L.) Fernald] (Fraedrich et al., 2008), but other woody lauraceous species still need to be evaluated. In Florida, the widespread distribution of hosts, particularly redbay and swampbay, has facilitated a rapid southward spread of the pest complex since its initial detection in the state in 2005. This has been exacerbated by human transport of infested material, particularly firewood (FDACS-DPI, 2010). In February 2011, laurel wilt and breeding populations of *X. glabratus* were detected in swampbay trees in Miami-Dade County (FDACS, 2011), approximately 14.5 km north of commercial avocado groves.

Avocado production in Florida is worth $14 million annually (USDA-NASS, 2011), and replacement costs of commercial and backyard avocado trees in south Florida have been estimated at $429 million (Evans and Crane, 2008). California produces 60% of the U.S. market, with annual production worth $415 million (USDA-NASS, 2011). Mexico is the largest producer worldwide, with 'Hass' production for the 2010–2011 market year forecast to reach 1.24 million metric tons (USDA-FAS, 2010), of which one third is exported, valued at $645 million (UN, 2010). Due to the serious economic threat posed by *X. glabratus*, there is a critical need for effective attractants to detect, monitor, and control the spread of this invasive pest. This is particularly important for early detection at ports of entry in southern California, Mexico, and avocado production areas in South America. Preliminary research has provided no evidence of an aggregation pheromone and no strong attraction to its fungal symbiont, to its frass, or to ethanol (a standard attractant for ambrosia beetles), suggesting that host tree volatiles are the primary semiochemicals utilized by dispersing females (Hanula et al., 2008). Additional studies have identified manuka oil and phoebe oil [essential oil extracts from *Leptospermum scoparium* Forst. & Forst. (Myrtaceae) and *Phoebe porosa* Mez. (Lauraceae), respectively] as attractive baits for field monitoring of *X. glabratus* in South Carolina (Hanula and Sullivan, 2008). Based on comparisons of volatile chemicals emitted from chipped redbay wood, manuka oil, and phoebe oil, Hanula and Sullivan (2008) hypothesized that two sesquiterpenes, α-copaene and calamenene, were likely the primary host attractants.

We evaluated the response of female *X. glabratus* to volatile chemicals released from commercially available manuka and phoebe oil lures, from freshly-cut logs (bolts) of avocado (cultivars representative of the three horticultural races), and from freshly-cut bolts of lychee (*Litchi chinensis* Sonn., Sapindacaeae), a presumed non-host recently found to contain large quantities of α-copaene (Niogret et al., 2011). Studies included two field tests conducted in natural stands of swampbay with known infestations of *X. glabratus,* and several laboratory bioassays to assess attraction and boring behaviors in newly-emerged female *X. glabratus*. In addition, volatile collections and gas chromatography-mass spectroscopy (GC-MS) were performed to quantify the sesquiterpene content of the substrates used in field and laboratory tests. These studies were designed to address three principal questions: (1) Does *X. glabratus* show a preference among the three races of avocado; (2) Are essential oil lures competitive with host avocado wood for capture of *X. glabratus*; and (3) Does α-copaene content account for the patterns of attraction observed with female *X. glabratus*?

Methods and Materials

Field Tests Field trapping experiments were conducted in north-central Florida (Alachua County) at the Lochloosa Wildlife Conservation Area (St. John's River Water Management District). This area consisted of mesic forest

composed of an overstory of slash pine, *Pinus elliottii* Englem., with a mixed middlestory that included numerous swampbay trees exhibiting advanced stages of laurel wilt. Presence of *X. glabratus* and symptomatic *Persea* trees had been observed at this area since 2007 (A. E. Mayfield, personal communication). GPS coordinates for the four corners of the study site were as follows: N29.47416, W82.14974; N29.47354, W82.15018; N29.47673, W82.15099; and N29.47707, W82.15013. Test I was conducted from 7 October to 2 December 2009 and evaluated attraction of *X. glabratus* to six treatments: a commercial manuka oil lure (release rate 50 mg oil/d; Synergy Semiochemicals, Burnaby, BC, Canada), wood bolts from three avocado cultivars ['Simmonds', West Indian race, *P. americana* var. *americana* Mill.; 'Brooks Late', Guatemalan race, *P. americana* var. *guatemalensis* Williams; and 'Seedless Mexican', Mexican race, *P. americana* var. *drymifolia* (Schlect. and Cham.)], bolts from lychee (cultivar unknown), and an unbaited control. Test II was conducted from 5 November to 29 December 2009 (adjacent to test I) and contained a commercial phoebe oil lure (50 mg oil/d; Synergy Semiochemicals) in addition to the six treatments used in test I.

Wood bolts were obtained from the USDA-ARS germplasm collection at the Subtropical Horticulture Research Station (SHRS), Miami, FL, USA 1 day prior to test deployment. At time of collection, the ends of the bolts were coated with wax to prevent desiccation, and then both ends re-cut when used as bait at the start of each test. Trap design consisted of two bolts (5 cm diam. × 15 cm length) wired together and hung vertically with two white sticky panels (23×28 cm, Sentry wing trap bottoms; Great Lakes IPM, Vestaburg, MI, USA) stapled back-to-back to the bottom of the bolts. Paired sticky panels were secured further with several binder clips around the edges. The essential oil lures were deployed in four-unit Lindgren funnel traps (BioQuip, Rancho Dominguez, CA, USA), with a single lure tied to the side of the trap, suspended midway between the second and third funnel. The collection cups were filled with 300 ml of an aqueous solution of 10% propylene glycol (Low-Tox antifreeze; Prestone, Danbury, CT, USA) to retain and preserve captured insects.

Field tests followed a randomized complete block design, with five replicate blocks arranged in a rectangular grid. Each block consisted of a row of traps hung ~2 m high in non-host trees, with a minimum of 10 m spacing between adjacent traps in a row, and with 50 m spacing between rows. Both tests were 8 wk in duration and checked every 2 wk. At each sampling date, the retention solutions and sticky panels were collected, a thin layer (~1 cm) was sawed from the bottom of each bolt (to "renew" release of wood volatiles), the solutions/sticky panels were replaced, and the trap positions were rotated sequentially within each row to minimize positional effects on beetle capture.

All sample collections were sorted in the laboratory at the Subtropical Horticulture Research Station (SHRS), and species of bark and ambrosia beetles were counted, photographed, and stored in 70% ethanol. Specimens removed from sticky panels were soaked overnight in histological clearing agent (Histo-clear II; National Diagnostics, Altanta, GA, USA) prior to storage in alcohol. Beetle identifications were confirmed at the Florida Department of Agriculture and Consumer Services, Division of Plant Industry (FDACS-DPI, Gainesville, FL, USA), and voucher specimens were deposited at both SHRS and FDACS-DPI.

Laboratory Bioassays Behavioral bioassays were conducted from March to April 2010 at the University of Florida (Department of Entomology and Nematology, Gainesville, FL, USA) by using the same germplasm accessions used in field tests. Choice tests were performed primarily to assess relative attraction of substrates; no-choice tests were performed to document boring behaviors of host-seeking females presented with individual substrates. Both bioassays were designed to document behavioral responses over time. Experimental insects were female *X. glabratus* (≤3 days post-emergence) reared from field-collected logs of *P. borbonia* maintained in the laboratory under a 0:24 hr (L:D) photoperiod at 25±2°C (Brar et al. unpublished). Test baits were wood bolts (5 cm diam. × 15 cm length) cut 24 hr prior to testing, with the cut surfaces left uncoated. This allowed for partial wound healing and prevented a sticky surface at the cut site that could potentially immobilize beetles.

Two-choice tests were performed in arenas consisting of rectangular plastic bins (122 cm length, 61 cm width, 16 cm height) with tight-fitting lids containing screen inserts. The full length of the bin floor was lined with paper to provide a rough surface upon which the beetles could walk. Single bolts of lychee and avocado ('Simmonds' cultivar) were placed at opposite ends of the bin, and 20 female *X. glabratus* were introduced at the center and immediately covered with an inverted glass funnel (6 cm diam.). After 10 min acclimation, the beetles were released by gently removing the funnel, and the test was initiated. The number of beetles on each bolt was recorded at 1, 2, 4, 8, 24, and 48 hr. At 48 hr, the number of beetles that had bored completely into the bolts and the location of the bore site were also recorded. Two-choice tests were replicated five times (run concurrently) by using separate arenas, baits, and beetles, and the position of the bolts was alternated between replications.

Arenas for three-choice tests consisted of the rectangular bins described above, but only the center of the bin floor was lined with a paper disk (60 cm diam.). Single bolts of

the three avocado cultivars were placed in random order around the edge of the paper, and 25 female *X. glabratus* were introduced at the center and allowed to acclimate prior to testing (as above). The number of beetles that had bored completely into each of the bolts and the location of the bore sites were recorded after 24 hr. The experiment was replicated five times (run concurrently) by using separate arenas, bolts, and beetles.

No-choice tests were performed in cylindrical plastic arenas (4.4 l buckets) with screened lids. Each bucket was lined with a paper disk (15 cm diam.) and set up to contain one bolt and 10 female *X. glabratus*. Bolt treatments consisted of lychee, the three cultivars of avocado, and live oak, *Quercus virginiana* (Fagaceae), as a non-host control (Fraedrich et al., 2008; Mayfield et al., 2008). For this bioassay, a beetle was scored positive for boring (considered fully committed to the boring behavior) at the point when full insertion of the pronotum (approximately half the body length, 1 mm) was observed. The number of beetles boring and their location on the bolt were recorded at 2, 4, 6, 8, 24, and 48 hr. No-choice tests were replicated five times for each of the five bolt treatments, by using separate arenas, new bolts, and new beetles for each replicate.

Chemical Collection and Analysis Samples for chemical analysis were prepared by manually rasping the outer layers from freshly-cut branches (5.0±0.5 cm diam.) of lychee, avocado, and live oak, by using methods reported previously (Niogret et al., 2011). Branches of lychee and avocado were collected from the same germplasm accessions used in field tests. Samples consisted of the outer bark and cambial tissue (the lateral meristem including the vascular cambium and cork cambium layers that carry the secondary metabolites). Volatile chemicals were collected from rasped wood (6-g samples, 3 replicates per tree) and from essential oil lures (phoebe and manuka, aged 1 wk in the field, 3 replicates per lure) by using Super Q traps (Analytical Research Systems, Gainesville, FL, USA) according to published methods (Heath and Manukian, 1992; Heath et al., 1993). Samples were spread in a cylindrical glass chamber (4.5 cm diam. × 25 cm length for rasped wood samples; 10 cm diam. × 38 cm length for essential oil lures), purified air was introduced into the chamber (1 l/min), and headspace volatiles were collected for 15 min. Super Q traps were cleaned by soxhlet extraction with methylene chloride for 24 hr and dried in a fume hood prior to each use. Volatile chemicals were eluted from the Super Q adsorbent with 200 µl of high purity methylene chloride (99.5% pure; ACROS, Morris Plains, NJ, USA). An aliquot of C_{16} standard (5 µg) was added to each sample for quantitative analysis. All chemical sampling was performed within 2 hr of collecting the branch material.

Chemical extracts were analyzed by using a gas-chromatograph (ThermoQuest Trace GC 2000, Austin, TX, USA). The column was fused silica, 25 m long, 0.25 mm i.d., DB-5MS phase (J&W Scientific, Agilent Technologies, Santa Clara, CA, USA), programmed from 50 to 130°C at 15.0°C/min, then from 130 to 220°C at 10.0°C/min, and then held at 220°C for 4 min. The column used in the gas chromatograph interface to the mass spectrometer (Agilent Technologies 5975B) was 25 m long, 0.25 mm i.d., DB-5MS phase (J&W Scientific, Agilent Technologies), programmed at 40°C for 2 min, then from 40 to 130°C at 10.0°C/min, then from 130 to 220°C at 20.0°C/min, and then held at 220°C for 4 min. Chemicals were identified by using the NIST mass spectral program version 2.0 d and the NIST/EPA/NIH mass spectral library (NIST05) when Reverse Matches and Matches were >950 and >900‰, respectively. For each sesquiterpene, the Kovats Retention Index (RI) was compared with the RI calculated from synthetic chemicals when commercially available [RI=1358, 1391, 1442, 1477 for α-cubebene (Bedoukian Research Inc., Danbury CT, USA), α-copaene (Fluka Analytical, Stenheim, Germany), β-caryophyllene (Sigma Chemical Co., St. Louis, MO, USA), and α-humulene (Sigma), respectively] or with previously published data [δ-elemene (Singh et al., 2007), β-elemene (Hosni et al., 2008; Karlsson et al., 2009), alloaromadendrene (Tokushima et al., 2010), cadinene (Singh et al., 2007; Ibrahim et al., 2010), and calamenene (Ibrahim et al., 2010)].

Statistical Analysis Results from the field tests and three-choice bioassays were analyzed by analysis of variance (ANOVA) with Proc GLM (SAS Institute, 2001) followed by least significant difference test (LSD) for mean separation ($P<0.05$). The Box-Cox procedure, which is a power transformation that regresses log-transformed standard deviations ($y+1$) against log-transformed means ($x+1$), was used to determine the type of transformation necessary to stabilize the variance prior to analysis (Box et al., 1978). Paired *t*-tests were used to analyze results from the two-choice bioassays, and regression analysis was used to document patterns in boring behaviors observed in the no-choice bioassays (Systat Software, 2006a). For each sesquiterpene, the captures of *X. glabratus* in field test II were compared to the quantity of chemical per substrate by using Pearson product moment correlation (Systat Software, 2006b). Unless otherwise noted, results are presented as mean ± s.d.; probability was considered significant at a critical level of $\alpha=0.05$.

Results

Field Tests Population levels were low at the study site, and the combined trapping results from both field tests

totaled ~600 ambrosia beetles. *Xyleborus glabratus* was the dominant species, comprising 75.4 and 86.2% of the captures in tests I and II, respectively. Non-target captures included 12 species representing four tribes of ambrosia beetles. Data on the diversity of ambrosia beetles captured with lychee, avocado, and essential oil lures are presented elsewhere (Kendra et al., 2011).

In field test I (Fig. 1a), there were differences in capture of female *X. glabratus* among the six treatments

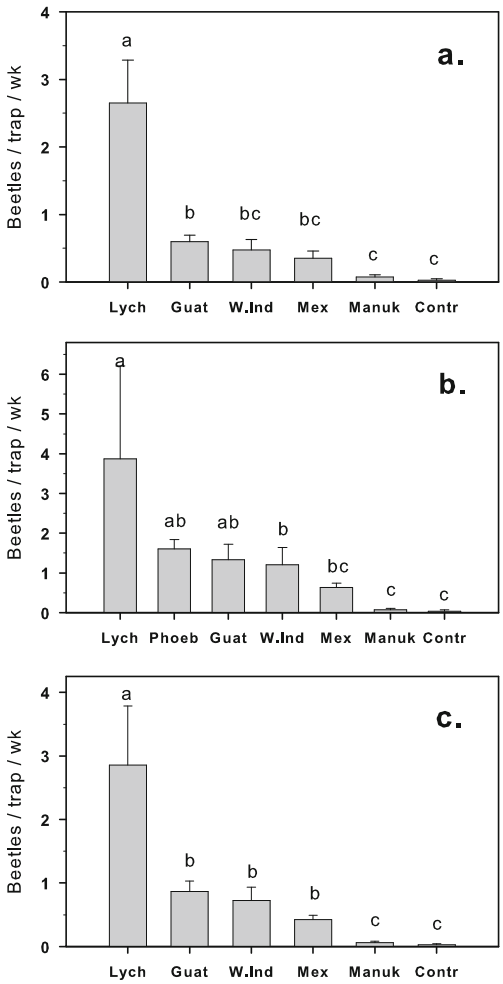

Fig. 1 Mean (±s.e.) captures of female *Xyleborus glabratus* in 8-wk field tests conducted in north-central Florida. (**a**) Test I (N=5) evaluated captures with a manuka oil lure (Manuk); with wood bolts of lychee, *Litchi chinensis* (Lych); and with wood bolts of three cultivars of avocado, *Persea americana*: 'Brooks Late', Guatemalan race (Guat); 'Simmonds', West Indian race (W. Ind); and 'Seedless Mexican', Mexican race (Mex). (**b**) Test II (N=5) evaluated the same treatments as Test I, but also included a phoebe oil lure (Phoeb). (**c**) Combined analysis of the in-common treatments from tests I and II (N=10; There were no interactions between test and treatment for beetle captures, nor an effect caused by test). Commercial lures were deployed in 4-unit Lindgren funnel traps; wood bolts were deployed with sticky traps. Both tests included a control (Contr) treatment that consisted of an unbaited sticky trap. Bars topped with the same letter are not significantly different (LSD mean separation on square root [x+0.5]-transformed data, nontranformed means presented, P<0.05)

(F=16.67; df=5, 29; P<0.001). Traps baited with lychee bolts caught significantly more beetles than any other treatment. Captures with avocado bolts were intermediate, and there were no differences observed among the three cultivars evaluated. Manuka-oil-baited traps captured the fewest beetles, but captures were not significantly different from traps baited with the Mexican or West Indian avocado cultivars. Manuka lure-baited traps captured *X. glabratus* during the first 2 wk only; no beetles were captured with manuka lure-baited traps from wk 3 to 8, despite capture of beetles with all other treatments.

Mean captures of *X. glabratus* were slightly higher during the second field test (Fig. 1b), and there were differences in captures among the seven treatments (F=6.51; df=6, 34; P<0.001). Overall, the hierarchy of captures was similar to that observed with test I. Lychee bolts captured the greatest number of beetles, although not significantly different from captures with the phoebe lure or the Guatemalan avocado. The phoebe lure was also competitive with bolts from all three avocado cultivars. All beetle captures with manuka lure-baited traps occurred within the first 2 wk of the test.

Two-way ANOVA indicated there were no interactions between test and treatment for captures of *X. glabratus* (F=0.58; df=5, P=0.714), nor was there an effect caused by test (F=0.81; df=1, P=0.373). Therefore, data from the two field tests were combined, generating 10 replicate blocks of the six in-common treatments. With the increase in number of observations, there were differences in captures among treatments (F=18.26; df=5, 59; P<0.001) and improved separation of means (Fig. 1c). Captures with lychee bolts were significantly greater than captures with avocado bolts, and captures with avocado were significantly greater than captures with manuka lure, which was comparable to the unbaited control treatment.

Laboratory Bioassays In two-choice tests with bolts of lychee and avocado (Fig. 2), more *X. glabratus* were attracted to lychee at the initial 1-hr and 2-hr observations (t=−2.49, df=8, P=0.038; and t=−2.41, df=8, P=0.043, respectively). By 4 hr, there were equal numbers of beetles on both choices (t=−0.30, df=8, P=0.770). By 8 hr, many of the beetles had left the lychee, but the numbers on avocado remained unchanged. By the end of the 48-hr test, the pattern had reversed and there were more *X. glabratus* on avocado (t=3.236, df=8, P=0.012). With both lychee and avocado, the majority of *X. glabratus* were actively boring into the bolts for all observations taken at or beyond 8 hr. At 48 hr, there were more beetles boring on avocado than on lychee (t=2.467, df=8, P=0.039). A higher percentage of boring occurred on the cut ends of the bolts as compared to the bark surfaces (91.3 and 80.0% for avocado and lychee, respectively).

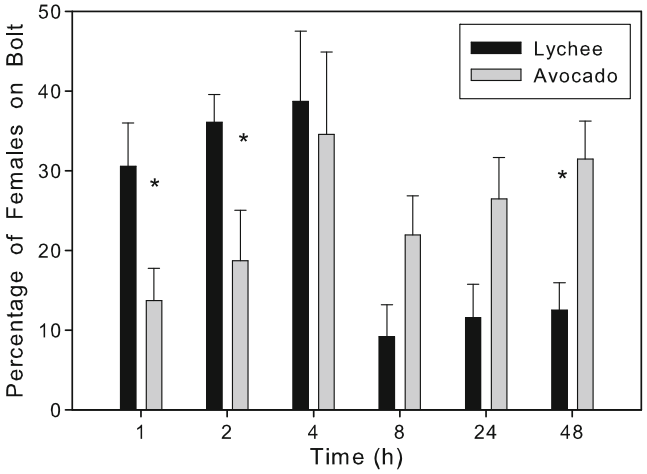

Fig. 2 Mean (±s.e.) percentage of female *Xyleborus glabratus* on wood bolts of lychee, *Litchi chinensis*, or avocado, *Persea americana* cv. 'Simmonds', West Indian race, presented in a 48-hr two-choice bioassay. With both choices, the majority of beetles were boring into the bolts at readings ≥8 hr. Asterisk indicates that mean responses to lychee and avocado are significantly different (*t*-test, $P<0.05$)

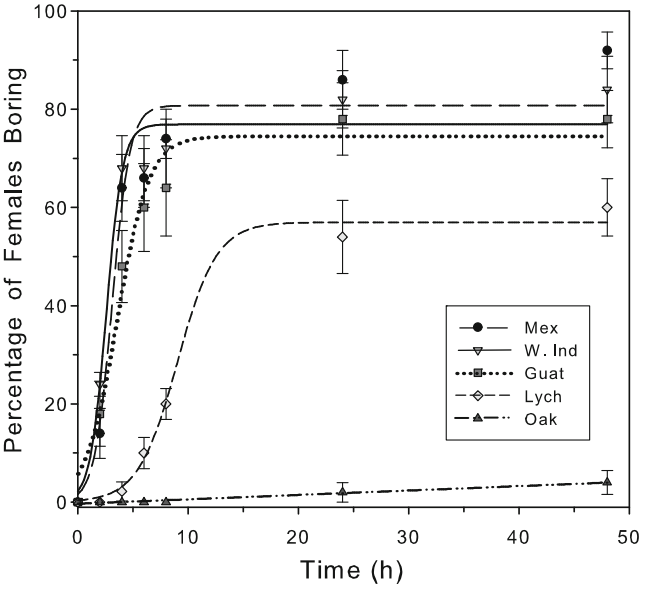

Fig. 3 Mean (±s.e.) percentage of female *Xyleborus glabratus* boring into wood bolts presented in a 48-hr no-choice bioassay. Treatments consisted of three cultivars of avocado, *Persea americana*: 'Brooks Late', Guatemalan race (Guat), 'Simmonds', West Indian race (W. Ind), and 'Seedless Mexican', Mexican race (Mex); lychee, *Litchi chinensis* (Lych); and Live oak, *Quercus virginiana* (L. Oak). Rate of boring was best fit by sigmoidal regression models (see text)

In three-choice tests among the avocado cultivars, the percentage of *X. glabratus* boring into each cultivar after 24 hr was as follows: 31.2 (±16.5)% West Indian; 28.6 (±20.3)% Guatemalan; and 40.2 (±7.0)% Mexican. There was not a significant difference among choices ($F=0.755$; $df=2, 14$; $P=0.491$). The percentage of boring on cut ends of avocado bolts (all cultivars combined) was 64.5%.

The composite results of no-choice bioassays with different bolt treatments are presented in Fig. 3. Regression analysis with sigmoidal models best described the relationships between the time after presentation of avocado or lychee bolts and the percentage of female *X. glabratus* engaged in boring behaviors [Mexican: $y = 80.75/\left(1+e^{-[(x-3.13)/0.80]}\right)$, $R^2=0.951$; West Indian: $y = 76.92/\left(1+e^{-[(x-2.53)/0.76]}\right)$, $R^2=0.971$; Guatemalan: $y = 74.47/\left(1+e^{-[(x-3.56)/1.44]}\right)$, $R^2=0.973$; and lychee: $y = 56.99/\left(1+e^{-[(x-9.04)/1.78]}\right)$, $R^2=0.995$]. Boring was initiated quickly with the avocado cultivars, with the maximum percentage reached by ~8 hr. With lychee bolts, females spent more time walking on the wood substrate before choosing a site and committing to boring. This resulted in a delay (relative to avocado) in boring response with the maximum percentage not reached until ~15 hr. At the conclusion of the test, the mean percentage of boring was as follows: 80.75 (±5.16)% Mexican; 76.92 (±3.42)% West Indian; 74.47 (±3.84)% Guatemalan; and 56.99 (±1.65)% lychee. Few beetles responded to the bolts of live oak (4.0±1.09%), and the responses observed were likely to be thigmotactic rather than olfactory or gustatory-guided behaviors related to host selection. Response of *X. glabratus* to live oak was best fit by linear regression ($y=-0.326+0.09x$, $r^2=0.976$). At 48 hr, there were differences in boring among the five bolt treatments ($F=32.863$, $df=4, 24$; $P<0.001$). There was no difference in percentage of boring among the three avocado cultivars. Percentage of boring in avocado was greater than in lychee, and boring in live oak was significantly less than in all other treatments. The percentage of boring on cut ends (all bolt treatments combined) was 71.9%.

Chemical Analysis A total of 29 volatile chemicals (detected at quantities ≥0.5 μg) were isolated and identified by Super Q collections and GC-MS analysis. Of these, there were nine sesquiterpenes found in common (Table 1). Sesquiterpene content varied both qualitatively and quantitatively among the samples (Fig. 4), but only three chemicals were positively correlated with captures of *X. glabratus* in field test II. These included α-copaene (*Pearson coeff.*=0.427, $P=0.010$; Fig. 4, peak 3), β-caryophyllene (*Pearson coeff.*=0.395, $P=0.019$; Fig. 4, peak 5), and α-humulene (*Pearson coeff.* = 0.514, $P=0.002$; Fig. 4, peak 6). Volatiles from lychee wood (Fig. 4a) contained large amounts of all three chemicals correlated with beetle captures, but also contained a large peak (identification unknown; RI=1504, quantity=9.21±2.10 μg) not detected in other samples. Wood from the West Indian avocado (Fig. 4c) was lower in α-copaene compared to the other two cultivars. Wood from live oak (Fig. 4e) was low in both α-copaene and α-humulene, but had moderate levels of β-caryophyllene. Calamenene was not correlated with beetle

Table 1 Quantity of volatile sesquiterpenes emitted from wood bolts of lychee, *Litchi chinensis*, three cultivars of avocado, *Persea americana*, and from commercial lures of phoebe oil and manuka oil

Chemical	RI[a]	Lychee	Avocado Cultivars			Live Oak	Essential Oil Lures

[d] Identification based on comparison with RI from synthetic chemicals (see text)

[e] Co-eluted with ylangene

captures and was a major component only in the manuka lure sample (Fig. 4g, peak 9).

Discussion

The current detection and monitoring system for *X. glabratus* in the United States is the Lindgren funnel trap baited with manuka oil lures (Lindgren, 1983; CISEH, 2010). Results from our field tests indicated that manuka lures were not competitive with the volatiles released from host avocado wood. In the original studies conducted by Hanula and Sullivan (2008), neat manuka oil dispensed from glass vials was as attractive to *X. glabratus* as wood bolts from redbay. The commercial lure evaluated in our tests released ~50 mg/d of manuka oil (total oil loss determined gravimetrically, per manufacturer specifications). This may not be adequate for extended capture of *X. glabratus*, since no beetles were caught with manuka lures after 2 wk in either test. Two additional field tests conducted in 2010 (Kendra et al. unpublished) confirmed a maximum field life of 2–3 wk for this lure in Florida. Further work is needed to determine the effective loading dosage of manuka oil as well as the release rates of individual attractive components (i.e., α-copaene, calamenene), as has been quantified for other insect lures (Heath et al., 2007). Published chemical analyses of manuka oil have shown a high degree of variability among extracts from trees of different geographic regions in New Zealand (Porter and Wilkins, 1998), which may also contribute to variability in attraction of *X. glabratus.*

Commercial phoebe oil lures were competitive with host avocado wood for capture of *X. glabratus*, and were effective throughout the entire 8-wk test. Unfortunately, the source of phoebe oil, the Brazilian walnut tree, is a limited resource in the Amazon rain forest and may not be available for future use. Another drawback of both manuka and phoebe lures was their non-specificity for *X. glabratus*. Ambrosia beetles are a large, diverse faunal group in tropical and subtropical regions (e.g., >500 recognized *Xyleborus* spp. from the neotropics, Africa, and Asia; Rabaglia, 2002), and numerous non-target species were captured in traps baited with essential oil lures in north Florida (Kendra et al., 2011). Once healthy swampbay trees were attacked by *X. glabratus*, the stressed trees were susceptible to further attack by an array of secondary colonizers (primarily species from within the tribe Xyleborini). These secondary species were attracted to the same host-based volatiles as *X. glabratus*, contributing to high non-target captures in field traps (14, 25, and 85% non-target captures at three field sites in Alachua and Marion Counties, FL). A similar diversity of ambrosia beetles (~15 species) has been observed to attack stressed avocado trees in south Florida (Peña et al. unpublished), and manuka-baited Lindgren traps deployed in avocado groves (Miami-Dade County, FL, USA) captured high numbers of

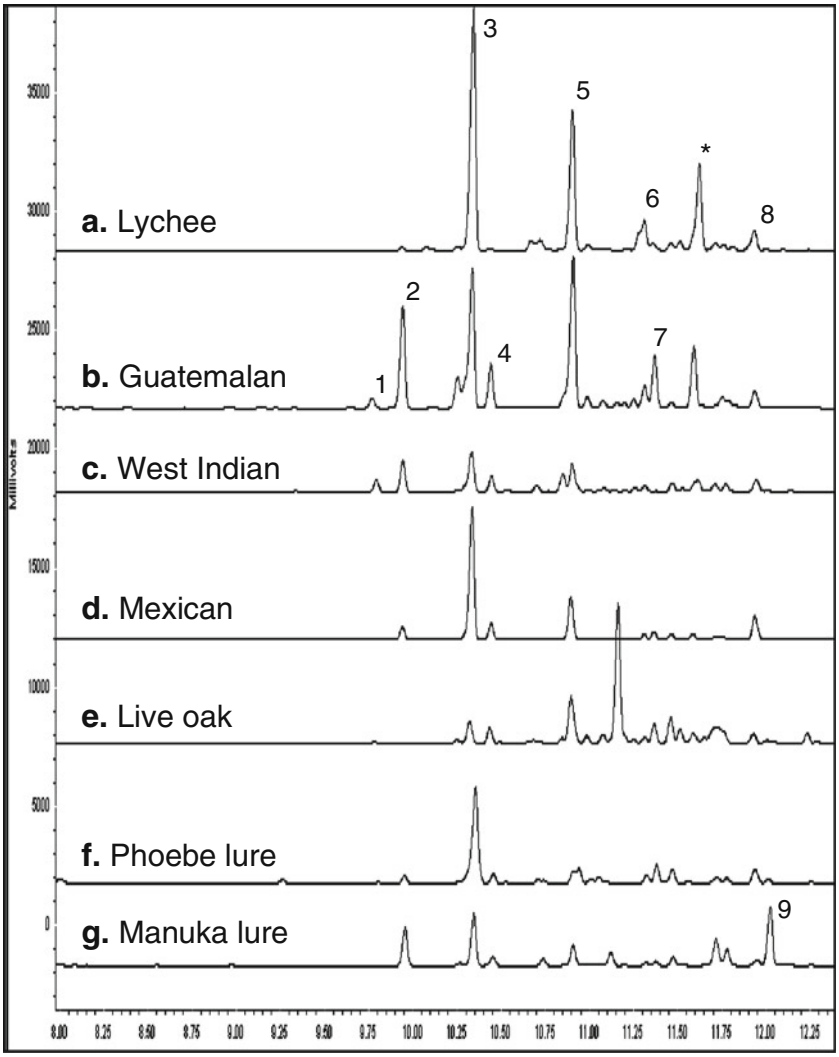

Fig. 4 Representative GC-MS analyses of sesquiterpenes obtained by Super Q collections from wood of (**a**) lychee, *Litchi chinensis*, from wood of three cultivars of avocado, *Persea americana*: (**b**) 'Brooks Late', Guatemalan race, (**c**) 'Simmonds', West Indian race, and (**d**) 'Seedless Mexican', Mexican race; from wood of (**e**) live oak, *Quercus virginiana*, and from commercial lures of (**f**) phoebe oil and (**g**) manuka oil. Peak identifications are as follows: 1) δ-elemene, 2) α-cubebene, 3) α-copaene, 4) β-elemene, 5) β-caryophyllene, 6) α-humulene 7) alloaromadendrene, 8) cadinene, 9) calamenene, and * unidentified chemical (RI=1504)

Ambrosiodmus obliquus (LeConte) and *Hypothenemus* spp. (Kendra et al., 2011).

Two trap types were used in our field tests evaluating captures of *X. glabratus* with attractive substrates: funnel traps with the formulated lures of manuka and phoebe oil; and sticky traps with the wood bolts of avocado and lychee. In an initial field test conducted in Marion County, FL, USA (Kendra et al., 2011), few ambrosia beetles were captured with funnel traps baited with wood bolts. At the recommendation of A. E. Mayfield (USDA-Forest Service, Asheville, NC, USA), we changed our trap design to a sticky panel for evaluation of host wood in the current tests. However, in our experiments, funnel traps were used for deployment of commercial lures rather than sticky panel traps because our goal was to evaluate the efficacy of the current monitoring tool for detection of *X. glabratus.*

Our study provided no evidence that female *X. glabratus* show a preference among the horticultural races of avocado. There were no differences in attraction to bolts from the three cultivars presented in field tests nor in the three-choice bioassays, despite differences in chemical profiles evident from GC analysis. Nor was there a difference in percentage of boring (interpreted as host recognition/acceptance) among the cultivars presented in no-choice tests. Mayfield et al. (2008) evaluated four different cultivars ('Hass', Guatemalan-Mexican hybrid; 'Monroe', Guatemalan-West Indian hybrid; 'Winter Mexican' Mexican; and 'Catalina', Guatemalan-West Indian hybrid) as young potted trees in no-choice tests and found no differences in boring of *X. glabratus* or in transmission of the *Raffaelea* pathogen. As a generalist on woody hosts in the Lauraceae, *X. glabratus* did not appear to distinguish among differences in avocado genotypes (intraspecific variation in secondary metabolites). In all of our laboratory bioassays (and in avocado bolts deployed in field tests), we observed that the majority of boring took place along the cut surface of the bolts, suggesting that host trees would be most susceptible to attack by *X. glabratus*

immediately following pruning activities, when there would likely be high release of host volatiles.

Of the wood substrates evaluated, lychee was the most attractive to dispersing female *X. glabratus,* outcompeting avocado in field tests. In two-choice bioassays, lychee bolts were more attractive than avocado initially, but over time a higher percentage of females bored into avocado bolts. This response suggests that lychee wood provides an initially more powerful olfactory/visual cue than avocado; but after settling on lychee, it may be a suboptimal substrate, and thus the beetles continue to forage until they find a more suitable host (avocado) for long-term settling based on other sensory modalities, including gustation. However, when not given a choice, more than half of the females tested did bore into lychee bolts. Although not in the family Lauraceae (like all confirmed U.S. hosts of *X. glabratus*), lychee should be evaluated for host status and susceptibility to laurel wilt. Since lychee is another subtropical fruit tree grown in the same areas as commercial avocado groves, lychee could serve as a potential reservoir for *Raffaelea* even if it is not susceptible to laurel wilt. The latter would not be unexpected since lychee is native to Southeast Asia and occurs sympatrically with endemic populations of *X. glabratus*. In its native regions, *X. glabratus* is not restricted to the family Lauraceae, and has been recorded from hosts in the Dipterocarpaceae, Fagaceae, and Fabaceae, in addition to Lauraceae (Rabaglia et al., 2006).

Chemical analysis of our test substrates identified three sesquiterpenes that were correlated positively with field captures of *X. glabratus*—α-copaene, β-caryophyllene, and α-humulene. β-Caryophyllene and α-humulene (synonymous with α-caryophyllene) have not been evaluated previously for *X. glabratus*, and need further study as potential attractants. The high levels of α-copaene measured from lychee wood support the conclusion of Hanula and Sullivan (2008) that this sesquiterpene functions as a primary host attractant. The same authors identified calamenene as an attractant in native redbay trees; however, calamenene was detected at low levels in our wood substrates (particularly the West Indian avocado) and did not appear to play a role in attraction to avocado or lychee. Quantification of calamenene was also low in the phoebe oil lure that had been aged in the field for 1 wk. Direct evaluations of α-copaene and calamenene as field lures have yet to be done, due to lack of commercial availability in quantities suitable for field tests. Interestingly, α-copaene, β-caryophyllene, and α-humulene have also been implicated as potential attractant semiochemicals for males of the Mediterranean fruit fly, *Ceratitis capitata* (Wied.) (Diptera: Tephritidae) (Niogret et al., 2011, and references therein). In addition to sesquiterpenes, we detected two monoterpenes, α- and β-pinene, in significant quantities from the avocado cultivars, but not from lychee or live oak (data not shown). Pinenes are known attractants for other species in the Xyleborini, including *Xyleborus pubescens* Zimmermann (Miller and Rabaglia, 2009) and *Xyleborinus saxesenii* (Ratzeburg) (Petrice et al., 2004), and may function as host (Lauraceae) attractants for *X. glabratus* as well.

The unique peak detected in lychee (RI=1504) also needs further evaluation. Unfortunately, the chemical could not be identified even tentatively in this study due to lack of consistent matches in the NIST mass spectral library. Further work is needed for structural confirmation of the chemical and for evaluation of its potential role as an attractant (or possible synergist to α-copaene). Insight into potential attractants for *X. glabratus* may be gained from comparative studies of substrates like lychee and known hosts, including analysis of sesquiterpene content and evaluation of relative attractiveness in field tests or bioassays. However, identification of specific attractants could be facilitated by coupled electroantennography-chromatographic separation (electroantennal detection or EAD) of host volatiles. Future research efforts will be directed toward applying EAD techniques to *X. glabratus* for evaluation of α-copaene, calamenene, β-caryophyllene, α-humulene, and the unidentified peak from lychee.

In summary, our study revealed that the standard detection system for *X. glabratus* (Lindgren funnel trap baited with manuka oil lures) is suboptimal, apparently due to limited longevity of the field lure. Phoebe oil lures were more effective, but their future availability is uncertain. Female *X. glabratus* showed no preference among avocado cultivars (West Indian, Mexican, and Guatemalan races) and preferred to bore into freshly-cut surfaces. This suggests that avocado trees would be most susceptible to attack immediately following pruning activities. Chemical analysis of wood substrates provided supporting evidence that α-copaene is a primary host attractant. Volatiles from lychee wood were more attractive to *X. glabratus* than volatiles from host avocado wood, and lychee may be a source of novel attractants for development of improved detection and control strategies for *X. glabratus*.

Acknowledgments We gratefully acknowledge Jorge Sanchez, David Long, Ricardo Joseph, Mike Winterstein (USDA-ARS; Miami, FL), and Stephen McLean (Univ. Florida; Gainesville, FL) for technical assistance; Kate Okins and Patti Anderson (FDACS-DPI; Gainesville, FL) for identifications of ambrosia beetles and *Persea*, respectively; Ray Schnell (USDA-ARS; Miami, FL) for advice on avocado germplasm samples; Bud Mayfield (USDA-Forest Service; Asheville, NC), Lukasz Stelinski (Univ. Florida; Lake Alfred, FL), and two anonymous referees for critical reviews of the manuscript; and Connie Rightmire (St. John's River Water Management District; Palatka, FL) for assistance in obtaining a special use permit for the Lochloosa Wildlife Conservation Area. This work was supported in part by the USDA-ARS National Plant Disease Recovery System, a NIFA Critical Issues Grant, and the Florida Avocado Administrative Committee. This report presents the results of research only; mention of a proprietary product does not constitute an endorsement by the USDA.

All sawflies sequestering plant secondary metabolites are considered specialists in that they feed on a narrow set of plant species belonging to one genus or family. A restricted diet is also typical for sawflies taken as a whole, with the exception of members of the subfamily Tenthredininae (Tenthredinidae), which includes both specialists and generalists (Taeger et al., 1998; Lacourt, 1999). Little is known about the sequestration ability of Tenthredininae larvae. The iridoid glycoside catalpol was detected in total extracts of larvae, prepupae and exuviae of *Tenthredo grandis* (Tenthredininae), a specialist on *Chelone glabra* (Scrophulariaceae) (Bowers et al., 1993). In the current study, we analyzed several organs from immature stages of *Tenthredo zonula* Klug, a specialist on common St. John's wort *Hypericum perforatum* L. (section *Hypericum*, Hypericaceae). A field population of *T. zonula* was found on common *H. perforatum*, but also on hairy St. John's wort (*Hypericum hirsutum* L., section *Taeniocarpium*). To our knowledge, this represents the first observation that the latter species also serves as a host plant for *T. zonula*.

The contemporary use of *H. perforatum* is as an alternative herbal treatment for mild to moderate depression in North America and Europe. This has resulted in its increased cultivation in several countries (e.g., Canada, the United States, Germany, Poland, France) and collection from the wild in others (e.g., Romania, Serbia, Hungary). The naphthodianthrones hypericin and pseudohypericin, which have been isolated only from certain species of *Hypericum*, along with flavonoid glycosides such as rutin, hyperoside, isoquercitrin, and quercitrin, may contribute to the bioactivity of the extracts (Nahrstedt and Butterweck, 2010). Flavonoid glycosides are found in both leaf and floral tissues of *Hypericum* species, and make up 2-4% of the dry weight (Hölzl and Petersen, 2003). In *Hypericum*, exudate-containing glands appear as lines or dots, and are of two types: translucent (pale yellow to amber in color) and dark (red to nearly black), found variously on the stems, leaves, sepals, petals, and the anther connective (Robson, 2002). Anatomical and histochemical studies of *H. perforatum* have shown that the translucent glands are actually subepidermal cavities, lined with two layers of flattened, thin-walled secretory cells (Ciccarelli et al., 2001a). Evidence suggests that essential oil components and acylphloroglucinol derivatives (i.e., hyperforin) are biosynthesized in these secretory cells and exuded into the cavities (Soelberg et al., 2007). Dark glands (more correctly called "nodules"), meanwhile, are specialized clusters of cells containing wax and the intensely red naphthodianthrone pigments hypericin and pseudohypericin (Ciccarelli et al., 2001b). The concentrations of the naphthodianthrones vary according to the species, but generally range from 0.1-0.3% of the dry tissue weight (Hölzl and Petersen, 2003). *Hypericum perforatum* plants have black nodules scattered on the leaf, petal, and sepal surface, within the leaf, petal and sometimes sepal margin, and on the stamen connective tissue (Robson, 2002). On *H. hirsutum* plants, reddish nodules appear occasionally on the stems; and black nodules are scattered on the leaf and petal surface, as well as within the sepal and petal margin. Those on the sepal margin in this species can be either sessile or on cilia, while in *H. perforatum*, they are always sessile (Robson, 2002, 2010).

The localization of the naphthodianthrones in tissues of *Hypericum* is of interest because these compounds can cause phototoxic effects in grazing insects and mammals that feed on the plants (Knox and Dodge, 1985a). These compounds are photoreactive and when activated by light they catalyze the formation of singlet oxygen, which has damaging effects on enzymes (i.e., inactivation), cell membranes (i.e., disruption through lipid peroxidation) and DNA tertiary structure (Knox and Dodge, 1985b; Berenbaum, 1987). Insects such as leaf beetles and moth caterpillars that feed on *Hypericum* possess behavioral and physiological adaptations that prevent these damaging effects (Larson, 1986; Sandberg and Berenbaum, 1989; Aucoin et al., 1990, 1991, 1995; Duffey and Pasteels, 1993; Guillet et al., 2000).

We observed larvae of *T. zonula* feeding on *H. perforatum* and *H. hirsutum*, actively consuming leaf tissues containing both translucent glands and dark nodules. We were interested in exploring whether this species sequesters the bioactive metabolites from its host-plant, and if so, in which organs and what amounts. Furthermore, we proposed to compare the physiology and ecology of *T. zonula* with that of other insects that feed on *Hypericum*. We determined the amounts of specific flavonoid glycosides (rutin, hyperoside, isoquercitrin, and quercitrin), as well as the naphthodianthrones hypericin and pseudohypericin, in *H. perforatum* and *H. hirsutum*, and analyzed the distribution of these compounds in several organs of larvae and prepupae of *T. zonula*.

Methods and Materials

Plant and Insect Material A population of *T. zonula* was found in the field (Dinant, Belgium; July 2007) feeding on sympatric *H. perforatum* and *H. hirsutum* plants, which grew in monospecific or mixed clusters on the logged edge of a forest. All plant and insect samples used were collected in this location and were identified by using the taxonomic keys published in Robson (2002, 2010) and Lorenz and Kraus (1957), respectively.

Ten aerial branches of *H. perforatum* and six of *H. hirsutum* were collected in the field (on July 05, 2007), and individually marked. The cut branches were placed in

water, while one additional plant of each species was transplanted to a pot. All plants were brought to the laboratory and maintained at 10°C and exposed to natural daylight conditions. For chemical analysis, 5–10 cm long twigs (comprising leaves and flowers) were taken from each of the 10 *H. perforatum* and 6 *H. hirsutum* branches on three dates (July 6th, 13th, and 20th) as well as from the 2 potted plants. Twigs were dried in the dark to a moisture content of less than 2% and stored at room temperature until extraction was conducted. We established that 100 mg of dried plant material were equivalent to 1 g of fresh plant material (1:10 w/w). Voucher specimens of the plants are deposited at the Institute for Pharmaceutical Sciences (Karl-Franzens-University, Graz, Austria).

Tenthredo zonula larvae (Fig. 1a) were collected in the field by gently beating plant clusters above a square net placed horizontally on the ground. Larvae were approximately four times more numerous on *H. perforatum* than on *H. hirstutum*. The density of the larvae on the plants was variable: ca. 50-70% of plant clusters had 1–3 larvae, while the others had none. A few prepupae were collected as well, which indicates that this stage (Fig. 1b) remains without feeding on the plant for a period of time, before pupation in the soil. Most prepupae used in this study, however, were obtained by rearing the field-collected larvae (Fig. 1c). The general feeding behavior of the sawflies was observed while larvae were reared for 2–6 d on leaves taken from plant material from both cut aerial branches and potted plants (see above) until the last larval instar, or prepupal stage. For chemical analyses, 4 to 7 individuals were pooled when they reached either the last or penultimate larval instar, or prepupal stage, whereas excrement from more numerous larvae, at several instars, was combined as one sample. Hemolymph droplets were collected in glass capillaries by gently piercing the integument with forceps, and were deposited in vials after measuring the volumes. Average amounts of hemolymph per individual were 8 µl for larvae and 7 µl for prepupae, but the maximal amount collected from an individual (i.e., 13 µl and 11 µl, respectively) was used to calculate their amounts in µg/individual; values in µmol/g fresh weight (FW) were obtained by considering 1 µl hemolymph as equivalent to 1 mg FW. The individuals were frozen prior to the dissection, at 4°C, of several organs: the digestive tract (its anterior and median parts); the salivary glands; and miscellaneous organs (i.e., integument, muscles, and fat body). The salivary glands (Fig. 1d) were sometimes absent or poorly developed and were discarded. The prepupa is a non-feeding stage, so its digestive tract is empty and was not collected. All samples were immediately stored in the dark, at −20 or −30°C until chemical analysis. Voucher specimens of sawfly immature stages are deposited at the Royal Belgian Institute of Natural Sciences (Brussels, Belgium).

HPLC Analysis Ammonium acetate and glacial acetic acid, as well as acetonitrile (ACN) and methanol (MeOH), were of HPLC grade and purchased from Carl Roth GmbH (Karlsruhe, Germany). Dried plant material was ground to a

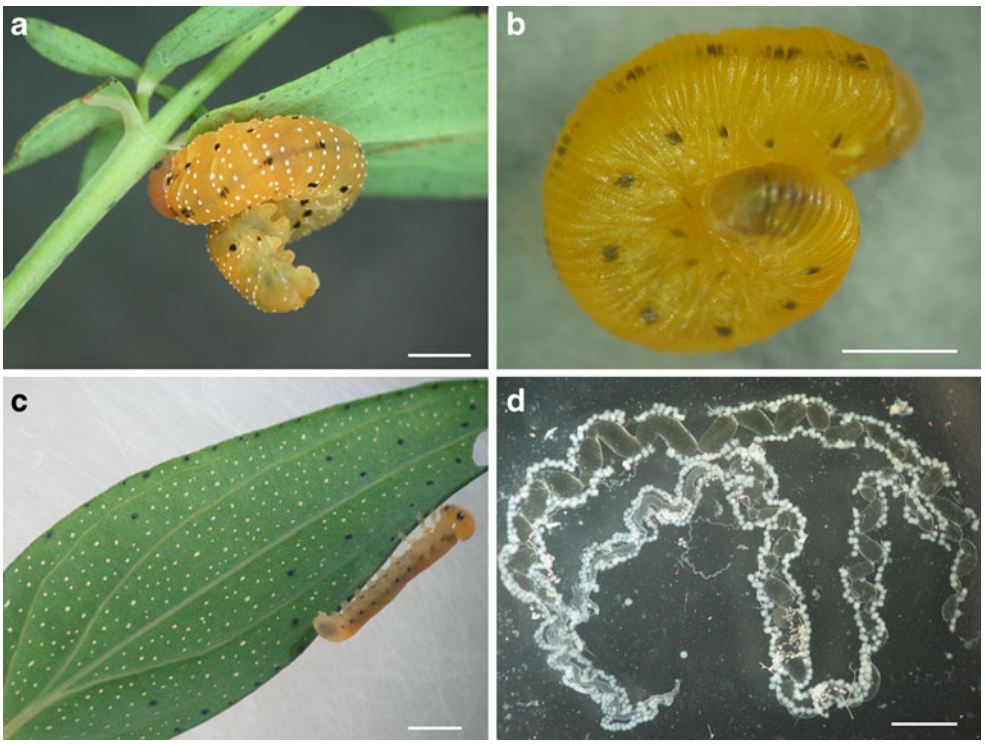

Fig. 1 Sawfly *Tenthredo zonula*. **a** Last instar larva attached to the underside of a leaf of *Hypericum perforatum*; when not feeding, the larva maintains its abdomen typically curled. **b** Prepupal stage; a prepupa never feeds. **c** Young larva on a leaf of *H. perforatum* where translucent and dark glands are visible on its underside. **d** Dissected salivary glands from a prepupa. Bar=2 mm. Photographed by J-L Boevé

fine powder and 250 mg of the powder were extracted four times with 2.5 ml aliquots of MeOH with sonication for 10 min. After 5 min centrifugation at 792 x *g*, the extracts were combined in a 10-ml volumetric flask and filled up to the final volume with MeOH. A 1 ml subsample of this solution was filtered through a 0.45 μm PTFE filter (Carl Roth GmbH), dried under nitrogen, and stored in an amber glass vial at −20°C until analysis, at which time each sample was re-dissolved in 1 ml MeOH. Each insect sample (hemolymph, digestive tubes, salivary glands, and miscellaneous organs) was extracted with 1 ml MeOH with sonication for 10 min and centrifuged for 5 min at 792 x *g*. The clear supernatants were pipetted into 1-ml volumetric flasks and filled to the final volume with MeOH, filtered through a 0.45 μm PTFE filter (Carl Roth GmbH), and directly analyzed. Each sample solution was injected in triplicate.

The identity and purity (>95%) of rutin, hyperoside, isoquercitrin, quercitrin, pseudohypericin, and hypericin standards (Fig. 2) (Chromadex, Inc., Irvine, CA, USA) were confirmed by chromatographic (high pressure liquid chromatography-diode array detection, HPLC-DAD), spectral (1D- and 2D-nuclear magnetic resonance, NMR), and electrospray ionization mass spectrometry (ESIMS) methods. Stock solutions of each standard were prepared at concentrations of 1.0 mg/ml in MeOH and serial dilutions were made with MeOH. Within the range of concentrations injected (0.025-100 μg/ml), the detector response was linear (correlation coefficient R^2=0.998).

All data were recorded and processed using Agilent 1100 Chemstation software (Agilent Technologies, Santa Clara, CA, USA). HPLC analysis was performed on an Agilent 1100 Separations Module equipped with a DAD (Agilent Technologies), using a Synergi MAX-RP 80 Å column (150 x 2.1 mm, 4 μm particle size) from Phenomenex (Torrance, CA, USA) at a flow rate of 300 μl min^{-1}, 5 μl injection per sample (Ganzera et al., 2002). Briefly, the mobile phases consisted of 10 mM ammonium acetate buffer adjusted to pH 5.0 with glacial acetic acid (A) and a 9:1 mixture of ACN and MeOH (B). Gradient elution was performed as follows: linear gradient from 13% B to 17% B over the first 10 min, followed by a gradient to 100% B over the next 25 min, followed by re-equilibration for 7 min. All separations were performed at 40°C. Peaks were assigned by spiking selected samples with standard compounds, and comparison of the UV spectra and retention times. HPLC–DAD/ESIMS (positive and negative modes) was performed on a Thermo Finnigan Surveyor liquid chromatography instrument with Thermo Quest Surveyor photodiode array detector, autosampler, and MS pump, and a Thermo Finnigan LCQ-XP mass detector equipped with an ESI source run by Xcaliber software (Thermo Fisher Scientific, Waltham, MA, USA). Mass spectra were detected and recorded in a scan range of *m/z*=100 to 1,000, using a transfer capillary temperature of 350°C, a spray voltage of 5.00 kV and a sheath gas flow of 70 units.

Results

The amounts of flavonoid glycosides (rutin, hyperoside, isoquercitrin, and quercitrin) and naphthodianthrones (pseudohypericin and hypericin) measured in *H. perforatum* and *H. hirsutum* are given in Fig. 3. All compounds were found

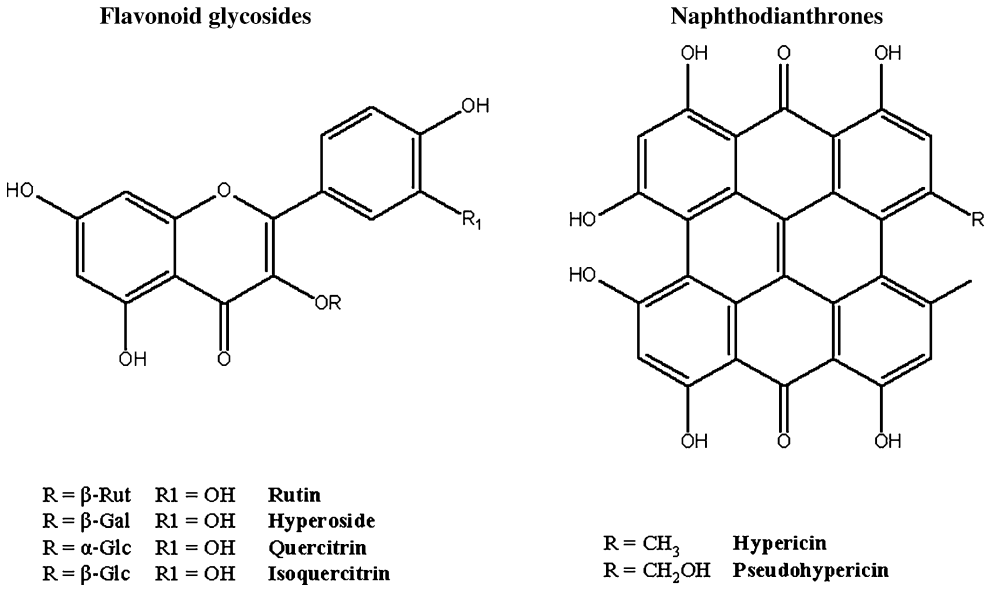

Fig. 2 Flavonoid glycosides and naphthodianthrones found in the plants *Hypericum perforatum* and *H. hirsutum*, and the sawfly *Tenthredo zonula*

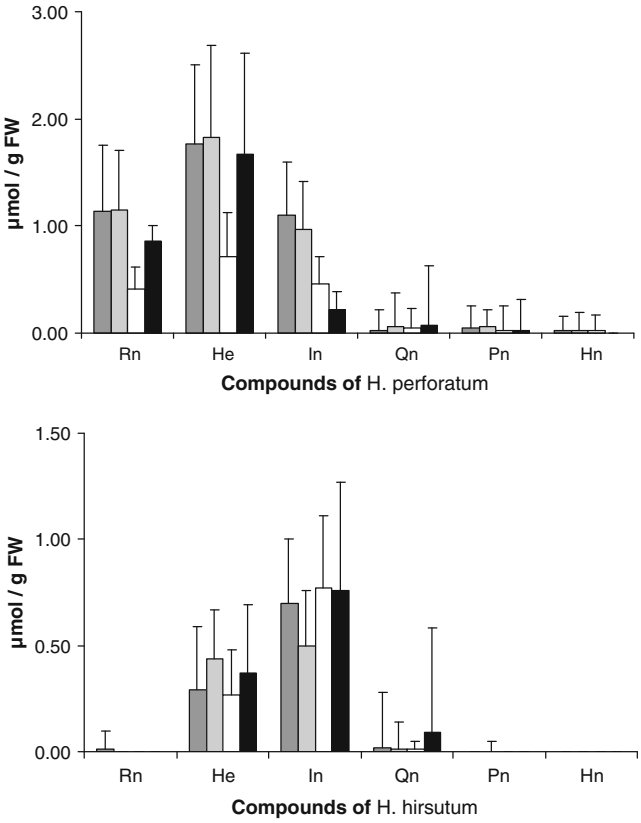

Fig. 3 Concentrations of flavonoid glycosides and naphthodianthrones in *Hypericum* samples. The compounds are: rutin (Rn), hyperoside (He), isoquercitrin (In), quercitrin (Qn), pseudohypericin (Pn), and hypericin (Hn). Values are given in µmol/g FW and as means±SD, $N=3$ technical replicates for each plant sample. From 10 *H. perforatum* and 6 *H. hirsutum* branches having been cut in the field and maintained at the laboratory, leaves and inflorescences were taken from them after 1, 8, and 15 d (i.e., *dark grey*, *light grey*, and *white bars*, respectively, for each compound), and from one potted plant of each species (*black bar*)

in both species, although not in every sample of each species. Two samples of *H. perforatum* differed from the other samples of this species in that they lacked rutin. The major flavonoid glycoside detected was hyperoside in *H. perforatum* (ca. 1.7 µmol/g FW) and isoquercitrin in *H. hirsutum* (ca. 0.7 µmol/g FW). Overlapping peaks were observed in many samples of *H. hirsutum* in the chromatographic region where quercitrin would have appeared, preventing quantification of this compound in some cases. Rutin in *H. hirsutum* and naphthodianthrones in both plant species were infrequently detected, and when detected, they generally were present as minor constituents (0.01 to 0.05 µmol/g FW).

Amounts of the six plant metabolites detected in extracts of specific body parts (hemolymph; digestive tract; salivary glands; pooled miscellaneous organs) of dissected *T. zonula* larvae and prepupae are presented in Table 1. All compounds were detected at some level in the sawflies, although not in all samples or in all body parts. In particular, the concentrations of the flavonoid glycosides were highly variable. The detection of the six compounds was as frequent for larvae reared on one of the cut branches (24 out of 96 potential detections) as for those reared on a potted plant (8 out of 48) ($P=0.29$, Fisher exact probability test), but their detection was associated with the sawfly stage, since a lower frequency of detections was observed in larvae (32 out of 144) than in prepupae (11 out of 18) ($P=0.001$; individuals reared on *H. perforatum*; Table 1).

The highest levels of flavonoid glycosides in the hemolymph were detected in prepupae that had fed during the larval stage on *H. perforatum* (as high as an absolute value of 10 µg/individual=0.45 µmol/g FW of isoquercitrin). In contrast, the four flavonoid glycosides generally were not detected in the hemolymph of larvae although the results for quercitrin were unclear due to overlapping peaks. Flavonoid glycosides also were detected infrequently in the digestive tracts of the larvae. However, the salivary glands of prepupae that had fed as larvae on *H. perforatum* had high concentrations of rutin (41 µg/individual) and isoquercitrin (32 µg/individual). The highest amounts of quercitrin were detected in several of the samples of miscellaneous organs from larvae that had fed upon *H. perforatum*. The naphthodianthrones pseudohypericin and hypericin were detected more often in larvae and prepupae reared on cut branches (15 out of 38 potential detections) than on those reared on potted plants (2 out of 22) ($P=0.01$, Fisher exact probability test). Pseudohypericin was detected most frequently in the digestive tract and/or miscellaneous organs with a maximum for the digestive tract of 0.25 µg/individual. Hypericin was found only in sawflies that had fed upon cut branches of *H. perforatum*.

Pseudohypericin and hypericin were the only screened metabolites detected in the excrement of larvae reared on *H. perforatum*, at concentrations of 0.11 and 0.12 µg/mg DW excrement, respectively, which indicates that the major portions of the ingested naphthodianthrones were excreted without undergoing chemical changes. The presence of both of these naphthodianthrones in the excrement was confirmed by further analysis of this extract using HPLC–DAD/ESIMS (negative mode), but this revealed several additional peaks with UV spectra and mass fragmentation patterns that shared some characteristics with hypericin and pseudohypericin (Fig. 4; Table 2).

Discussion

Amounts of flavonoid glycosides and naphthodianthrones measured in *H. perforatum* and *H. hirsutum* during this study (Fig. 3) are in agreement with those measured during previous studies (Ganzera et al., 2002; Crockett et al., 2005). The primary goal of the current research was to

For eight batches of 4–7 individuals, hemolymph (Hem.) was collected prior to dissection of digestive tract (Dig. tr.), salivary glands (Sal. gl.), or remaining, miscellaneous organs (Misc. org.). The quantity in µl, or number of organs, is indicated in the column headed **Qtt**. Data are given as mean±SD of three technical replicates, in µg/individual. Values of hemolymph are also given in µmol/g FW (Hem.[a], in brackets). If the compound was present at <0.005 of the given concentration unit, it is recorded as *TR*, and if it was not detected it is indicated with a dash (−). *OV* indicates overlapping peaks, which made quantification impossible. The compounds are: rutin (Rn), hyperoside (He), isoquercitrin (In), quercitrin (Qn), pseudohypericin (Pn), and hypericin (Hn)

determine whether these secondary metabolites could be detected in larvae and prepupae of *T. zonula*, and to examine the body distribution of these compounds. While all compounds were observed at some amount in one or more insect samples, our results indicate a patchy distribution in the sawfly body parts. Their occurrence, nonetheless, seems to be influenced by the host-plant's chemical profile and by the developmental stage at which the sawfly specimens were analyzed.

Our study reveals that *T. zonula* is able to sequester flavonoid glycosides, since these compounds were detected in body parts other than the digestive tract. For example,

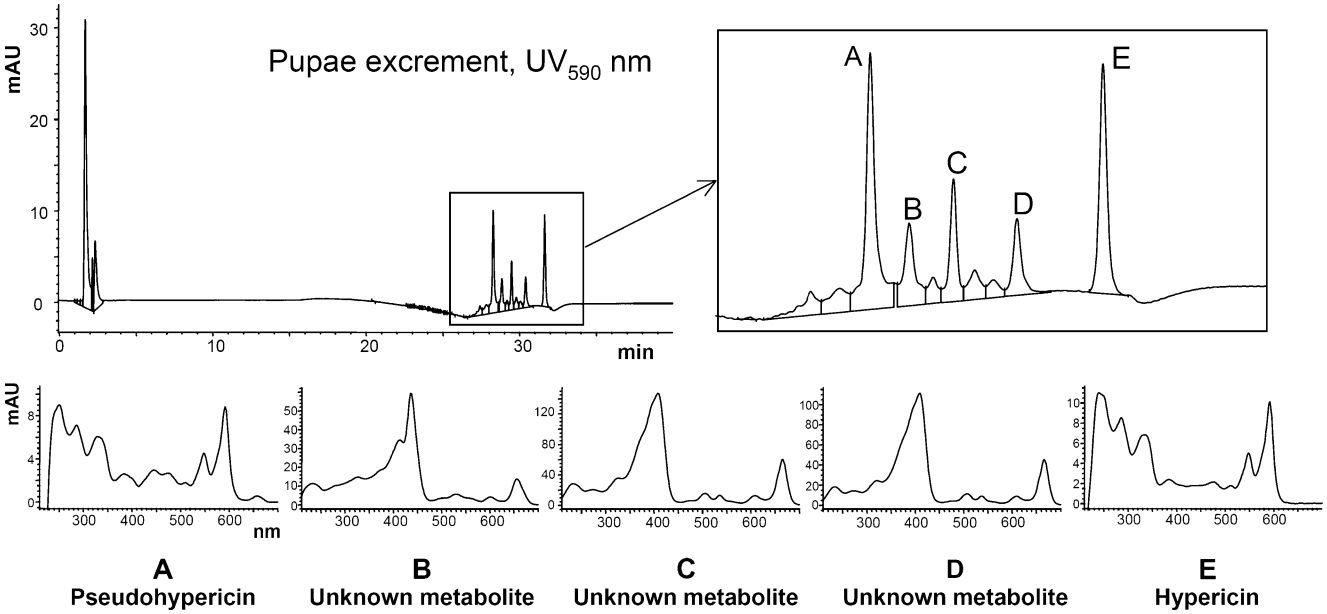

Fig. 4 UV–Vis absorbance spectra from peaks corresponding to the known naphthodianthrones, pseudohypericin **A** and hypericin **E**, and to as-yet-unidentified, but related, lipophilic compounds **B**–**D**

the compounds were found in the larval integument, which formed a main part of the dissected 'miscellaneous organs', as well as in the prepupal hemolymph and salivary glands. Among the isolated organs, only the hemolymph could be weighed, but these measurements allowed comparisons to be made between compound concentrations in plant and sawfly samples. For instance, the concentration of isoquercitrin was about 1 μmol/g FW in *H. perforatum* (Fig. 3) and 0.5 μmol/g FW in the prepupal hemolymph (Table 1). The latter concentration is equal to about 10 μg/individual, and the compound occurred at 32 μg/individual in the salivary glands. As compared to concentrations measured in the plant tissue, isoquercitrin is approximately half as concentrated in the hemolymph of prepupae, and 1.5 times more concentrated in the salivary glands. In the case of prepupae, we conclude that sequestration occurs because this non-feeding stage, which always has an empty digestive tract, can only accumulate plant compounds from the earlier (larval) instars.

Table 2 Negative and positive quasi-molecular and collision induced fragment ions of peaks A-E detected in excrement of *Tenthredo zonula* larvae

Not detected (−)

Tenthredo grandis is the only other *Tenthredo* species that has been studied previously for the possible sequestration of plant metabolites (Bowers et al., 1993). In that study, total extracts of the prepupae contained the iridoid glycoside catalpol at a level up to 3.86% DW, and this compound reached 1.87% DW in leaves of the host plant, *C. glabra*. Thus, both *Tenthredo* species are able to sequester glycosides, at least at the prepupal stage, and we suggest for *T. zonula* larvae that quercitrin is selectively sequestered in the integument, and rutin and isoquercitrin, in the salivary glands. Larval hemolymph may be another storage site for quercitrin, but a methodological problem of overlapping peaks did not always allow quantification. Furthermore, not every flavonoid glycoside was detected in the analyzed batches of larvae. Thus, one should be cautious when discussing the ecological role of these sequestered metabolites as chemical defenses.

Several fates are known for plant metabolites ingested by sawfly larvae, even within one species. For instance, larvae of *Rhadinoceraea nodicornis* (Tenthredinidae, Blennocampinae) sequester some steroidal alkaloids from the host plant, *Veratrum*, in the hemolymph, either directly or after metabolism. However, the larvae excrete or degrade other steroidal alkaloids (Schaffner et al., 1994). In this sawfly species, zygadenine and 3-acetyl-zygadenine are present in the hemolymph at a total concentration of 1.18 μg/mg DW (= 24 μg/individual), whereas 1.77 μg/mg DW of their common precursor, 3-angeloyl-zygadenine, is found in the plant leaves. Larvae of other Blennocampinae species belonging to the genus *Monophadnus* sequester two furostanol saponins in the hemolymph (1.6 and 17.5 μmol/g FW). These compounds are present in the host plant, *Helleborus*, at much lower concentrations (0.008 and 0.268 μmol/g FW) (Prieto et al., 2007). Similarly, glucosinolates and iridoid glucosides are sequestered in the hemolymph by members of the Tenthredinidae genus *Athalia* (Müller et al., 2001; Opitz et al., 2010). Thus, sequestration of plant metabolites occurs repeatedly in Tenthredinidae sawfly larvae. Sequestration renders the hemolymph highly repellent and sometimes toxic to natural enemies such as ants, and provides these species with an efficient chemical defense.

Many classes of secondary metabolites, including naphthodianthrones, can be induced in *H. perforatum* in response to feeding damage from both generalist and specialist herbivores (Sirvent et al., 2003), but also to mechanical wounding such as cutting the plant stem (Lawton and Lamb, 1987). Both naphthodianthrones were found in *T. zonula* larvae that had been fed on cut branches as well as potted plant material, but pseudohypericin was detected more often and in higher amounts than hypericin, and only pseudohypericin was detected in the digestive tract (0.02 to 0.25 μg/individual). The excrement collected from larvae contained 0.11 μg/mg of pseudohypericin, and 0.12 μg/mg of hypericin, but no flavonoid glycosides. These results support the hypothesis that naphthodianthrones are specifically excreted from *T. zonula* larvae. There may be several reasons why only pseudohypericin is detected in the digestive tract. First, the ingested plant material generally contains more pseudohypericin than hypericin. If one assumes a daily consumption of a 36 mm^2 piece of *H. perforatum* leaf tissue (= 18 mg fresh plant material; SLC, personal observation), a larva would ingest about 0.1 – 0.8 μg of hypericin and 0.1 – 1.1 μg of pseudohypericin, which are amounts roughly in the range of those detected in the digestive tract. Second, hypericin may be metabolized to pseudohypericin through the activity of microsomal detoxification enzymes often associated with gut tissues such as cytochrome P450 enzymes, which hydroxylate the substrate (Feyereisen, 1999). Since equivalent amounts of pseudohypericin and hypericin could be identified in the larval excrement, it is likely that hypericin is only partially converted to pseudohypericin in the gut. Third, due to the more apolar nature of pseudohypericin, it does not pass through the gut wall as easily as hypericin (Menn, 1978). However, hypericin as well as pseudohypericin were rarely found in other body parts than the digestive tract, but were clearly present in the excrement.

In the excrement, three additional peaks with similar, but not identical, spectral and mass fragmentation pattern characteristics were seen in the HPLC profiles and were absent from all other insect and plant samples (Fig. 4; Table 2). While the naphthodianthrones hypericin and pseudohypericin exhibit UV maxima at 545 and 590 nm, these compounds displayed intense absorbance peaks between 400–430 nm, and secondary maxima at 660–670 nm. For hypericin, typically observed collision-induced fragment ions of the parent species $[M\text{-}H]^-$ include $[M\text{-}H\text{-}CH_4]^-$ (−16 from parent ion, *m/z* 487) and $[M\text{-}H\text{-}CH_2{=}C{=}O\text{-}H_2O]^-$ (−60 from parent ion, *m/z* 443); for pseudohypericin, such ions include $[M\text{-}H\text{-}CO_2]^-$ (−44 from parent ion, *m/z* 475), $[M\text{-}H\text{-}CH_2{=}C{=}O\text{-}H_2O]^-$ (−60 from parent ion, *m/z* 459) and $[M\text{-}H\text{-}3CO\text{-}H_2O]^-$ (−101 from parent ion, *m/z* 417). The fragmentation patterns observed for peaks B, C, and D showed interesting similarities that could correlate to a loss of $[-CH_2{=}C{=}O\text{-}H_2O]^+$ for peak B (−60 from the parent ion, *m/z* 534); a loss of $[-3CO\text{-}H_2O]^+$ for peak C (−101 from the parent ion, *m/z* 435); and a loss of both $[-CO_2]^+$ (−44 from the parent ion, *m/z* 489) and $[-CH_2{=}C{=}O\text{-}H_2O]^+$ (−60 from the parent ion, *m/z* 473) (Table 2). Although further isolation and structural elucidation are needed to fully clarify the structures of these compounds, it is intriguing to note that several fragment ions seen in the molecular ion pool are 2 mass units greater than several seen in the ion pools of hypericin and pseudohypericin, suggesting that a reduction has taken place. Additionally, the mass of peak D (533)

could be reached by the addition of two methyl groups to hypericin, and the mass of peak C (536), by the addition of a single methyl group to pseudohypericin. These results could indicate either that partial metabolism of hypericin and/or pseudohypericin has occurred in the gut, in which case we hypothesize that the compounds represented at least by peaks C and D present in the excrement extract are metabolites of these compounds, or that the compounds may be the result of post-excretory degradation. These data taken together suggest that *T. zonula* larvae have developed physiological mechanisms that enable them to reduce the absorption of the phototoxic naphthodianthrones by an efficient elimination as a waste by-product.

Other insects, in particular the leaf beetles (e.g., *Chrysolina brunsvicensis, C. geminata, C. hyperici,* and *C. varians*; Coleoptera, Chrysomelidae), possess similar biochemical and physiological adaptations, and also display a specialized feeding behavior that allow them to ingest plant material containing naphthodianthrones without negative effects (Larson, 1986; Duffey and Pasteels, 1993). Analyses of the body distribution of hypericin in *C. brunsvicensis* support the hypothesis that this species contains the majority of hypericin within the gut lumen, and then rapidly eliminates it through the feces (Duffey and Pasteels, 1993). Particular cuticular pigments and, to a lesser extent, cuticle thickness also have been demonstrated to confer protection against the phototoxicity of hypericin in adult *Chysolina* beetles (Berenbaum, 1987; Fields et al., 1990). To block the phototoxic activity of ingested naphthodianthrones, *C. hyperici* is believed to sequester the natural antioxidant molecule β-carotene, in part responsible for the yellow coloration of *Hypericum* petals (Aucoin et al., 1990). Furthermore, elevated levels of antioxidant enzymes such as catalase and glutathione peroxidase have been measured in larvae of the *H. perforatum* specialist *Anaitis plagiata* (Lepidoptera, Lepidopteridae) when fed leaf discs treated with hypericin or reared strictly on *H. perforatum* tissue (Aucoin et al., 1991, 1995). Higher constitutive levels of enzymes such as glutathione reductase and glutathione S-transferase have not been demonstrated for the chrysomelid specialists although they have been measured in two generalist orthopterans, *Tettigonia viridissima* and *Conocephalus discolor*, which only occasionally feed on *H. perforatum* (Guillet et al., 2000). Some insects, such as the larvae of *Platynota flavedana* (Tortricidae), are protected from phototoxic effects through a behavioral adaptation, tying together leaves to form a shaded shelter within which they feed (Sandberg and Berenbaum, 1989). We do not know whether larvae of *T. zonula* have a particularly thickened cuticle or specific cuticular pigments that would potentially protect them against the phototoxic effects of the naphthodianthrones. The larvae do avoid light, displaying a negative phototropism in response to daylight/windows and the cold light source of a binocular microscope (JLB, personal observation). Moreover, in the field, they often are found settling on the underside of a leaf (Fig. 1a), but this behavior is frequently observed in sawfly larvae, regardless of their host plant species. More studies are necessary to fully understand the etho-physiological adaptations in *T. zonula*, and to assess the ecological role of flavonoid glycosides and naphthodianthrones as chemical defense metabolites in this species.

Acknowledgments We thank three anonymous reviewers for their helpful comments. Funding for SLC was provided through a Hertha Firnberg Stipendium (T345-B05) from the *Fonds zur Förderung der Wissenschaftlichen Forschung* (FWF) in Austria.

to the two enantiomers is known (Lanier et al., 1980; Slessor et al., 1985).

Whitten et al. (1988) found that ipsdienol of unknown stereochemistry is a major component of the floral scents of several species of neotropical orchids and one species of aroid (see also Schwerdtfeger et al., 2002). The majority of these species are, or are presumed to be, pollinated by fragrance-collecting male orchid bees (Whitten et al., 1988). Ipsdienol of unknown stereochemistry also has been found in the hind tibial pouches of male euglossines [e.g., *E. tridentata*, (Eltz et al., 1999); *Eulaema bombiformis,* (Zimmermann et al., 2006), *Euglossa cyanura*, T. Eltz, pers. obs.]. These species, among others, have been observed to collect racemic (synthetic) ipsdienol from baits (Williams and Whitten, 1983; Whitten et al., 1988; Ramírez et al., 2002). Among the bee species visiting the synthetic baits, the frequent capture of *Euglossa cyanura* (Whitten et al., 1988) is remarkable, because this species is rarely attracted during standard baiting assays (Roubik and Hanson, 2004).

There is a considerable number of publications on substances attractive to Euglossini and how efficient these are for baiting in particular regions of the neotropics (Ramirez et al., 2002; Roubik and Hanson, 2004). However, it rarely has been investigated whether or not the bees are able to distinguish between different optical isomers, even though several of the known attractants are chiral (see Williams and Whitten, 1983 and discussion). Chirality may add another level to the chemical specificity evident in odors of euglossophilous plants, as well as in the perfumes of male euglossine bees themselves (Zimmermann et al., 2009).

Using gas chromatography coupled with electroantennography (EAG), Eltz et al. (2006) studied the responses of males of three different *Euglossa* species to hindtibial extracts of *E. tridentata* which, among other components, contained ipsdienol of unknown stereochemistry. The antennae of all tested species responded to ipsdienol, suggesting that the bees are able to smell this compound. In the present study, our aim was to find out whether euglossine males can distinguish between (+)- and (−)-ipsdienol, by testing (1) their behavioral preferences, and (2) their peripheral olfactory receptor responses to the enantiomers and racemate. With regard to behavioral preferences, we further sought to elucidate whether the less preferred enantiomer acts as a repellent or as an attractant in the racemate.

Methods and Materials

Chemicals Ipsdienol of three different optical purities was purchased in slow-release devices (bubble caps) from Phero Tech Inc. (7572 Progress Way, Delta, British Columbia, V4G 1E9 Canada): racemic ipsdienol [50:50 mixture of (+)- and (−)-isomers], (+)-ipsdienol (97:3), and (−)-ipsdienol (3:97). Each bubble cap contained 40 mg of the respective isomer(s) and released about 0.2 mg of ipsdienol/day at 25°C (J. P. L. Lafontaine, pers. comm.). In most field bioassays, these bubble caps were used directly as odor releasers (see below). In addition, we used aliquots of racemic ipsdienol (Bedoukian Research Inc.) dissolved in hexane (1 g/ml), and pure hexane (p.a.) as solvent control. Chemicals were kept on ice or in a freezer for most of the time.

Field Tests All field bioassays were conducted during May and June 2009 in forests in the state of Veracruz, Southern Mexico, mainly near the "Estacion Biologica Los Tuxtlas" in the biosphere reserve of Los Tuxtlas (18°30′ N, 95°8′ W), and near the village Poza Azul (17°23′N, 94°11′W). Baits were suspended from vegetation at heights between 1.7 and 2.0 m above ground during standardized time periods (9:30–12:30 and 16:00–17:30). Any bee landing on a bait was captured, and only released again if marked by a dot of acrylic paint on the thorax. This was done to avoid pseudoreplication and to minimize potential local enhancement effects reported in foraging bees and wasps (Jarau and Hrncir, 2009). Bees were caught either by entomological nets or by aspirators.

Baits A bait consisted of three parts: 1) an odor releaser; 2) a nylon net (mesh size ~1 mm) covering the odor releaser to minimize direct contact by bees; and 3) a nylon thread (~20 cm) for suspending the bait. For odor releasers, we either used the bubble caps directly or four sheets of unused coffee filter paper (size: ~9×5 cm) to which we added test solution (see below). If not mentioned otherwise, the nylon net covering the odor releaser was replaced after each experiment. During multiple-bait bioassays, the exact position of baits was swapped every 5 min to minimize position bias.

Single-substance Bioassays One bubble cap of (+)-ipsdienol, (−)-ipsdienol, or racemate was presented singly for periods of 40 min. (N>6 per substance). Additionally, hexane (30 µl on filter paper) was used as a control (N=6).

Multiple-choice Bioassays – Equal Concentrations One bubble cap of each of (+)-ipsdienol, (−)-ipsdienol, and racemate were presented simultaneously for intervals of 40 min. (N=14). The baits were normally placed between 2–5 m from each other (min=50 cm; max=7 m). To test whether or not males would switch to forage for the less attractive ipsdienol enantiomer after the attractive enantiomer was depleted, we occasionally (N=9) continued the bioassay for another 40 min with all but the (+)-ipsdienol bait removed.

Multiple-choice Bioassay – Different Concentration Baits included the same as described above (bubble caps) plus an additional filter paper bait with 30 μl aliquots of racemic ipsdienol in hexane, and a filter paper bait with 30 μl of hexane as a control. Although this was not quantified, the filter paper bait was expected to release much more [order (s) of magnitude more] racemic ipsdienol per unit time than the bubble cap.

Sequential Bioassays We tested whether euglossine males leave chemical cues on visited odor sources that could potentially influence foraging behavior of themselves or conspecifics. We used two baits of the filter paper type, which we presented simultaneously during sequential experiments. Each sequential experiment consisted of two periods: During the first 20 min. we presented one bait containing 30 μl hexane, and another bait with 30 μl racemic ipsdienol. Different from other bioassays and the second phase of the sequential bioassays, we did not capture bees landing on the ipsdienol bait, but allowed males to collect on the mesh until the end of the first period. This allowed for the accumulation of any chemicals left by males on the mesh. During the second period, we again presented two baits for 20 min. This time, both baits contained 30 μl of racemic ipsdienol. Whereas the odor of both baits was new, we reused mesh and clips of the baits from the first period. Consequently, both baits differed in that one had traces of chemical substances left previously by odor-collecting males, while the other (previously unvisited) lacked any such substances.

Electroantennography Antennae of male *E. cyanura and E. mixta* (N=10 individuals each) were cut at the base of the flagellum, and mounted between two glass capillaries containing insect physiological solution and silver electrodes. A Syntech (Hilversum, The Netherlands) signal amplifier (IDAC-232) and Syntech EAG)software were used to amplify and record antennal responses to chemicals. A constant stream of humidified clean air, into which we introduced the test stimuli, flowed over the antennal preparation. Five microliters of test solution (see below) were applied to a strip of filter paper (5×10 mm), and the filter paper placed inside a clean pipette tip. Two hundred microliters of air were puffed through the tip and into the air stream using an electronic pipette (Biohit *e*line 50–1,000 ml). Test substances were applied once per antenna in the same order, except for the hexane, which was applied at the beginning and end of each antennal test series.

Test Solutions (+)-Ipsdienol and (−)-ipsdienol were extracted from the bubble caps with hexane, yielding solutions of 2.31 mg/ml of (+)-ipsdienol, and 1.75 mg/ml of (−)-ipsdienol), as quantified by gas chromatography with flame ionization detection. These were further diluted to 1:10, 1:100, 1:1.000, and 1:10.000. Accordingly, the (+)-ipsdienol stimulus was always at a slightly higher concentration than the respective (−)-ipsdienol stimulus, at all dilutions. For comparison and standardization of response data (see below), we also tested solutions of methyl 2-phenylacetate, eucalyptol (1,3,3-trimethyl-2-oxabicyclo [2.2.2.] octane), eugenol (4-allyl-2-methoxyphenol), *R*-limonene [(*R*)-1-methyl-4-(1-methylethenyl)-cyclohexene], and geraniol [(*E*)-3,7-dimethyl-2,6-octadien-1-ol]. All standard solutions were 0.0667 mg/ml. Standardization in relation to the control stimulus was necessary because *E. cyanura* and *E. mixta* differ slightly in size. As EAG response amplitude is influenced by the size of the antenna (Roelofs, 1984), absolute responses could not be compared between species. Instead, we compared relative responses, standardized in relation to the control stimulus (hexane).

Data Analysis For data from single-substance bioassays, we used the Kruskal–Wallis H-tests, followed by Dunn's test for multiple comparisons. For multiple-choice bioassays, we used one-way ANOVA, followed by a Student-Newman-Keul's multiple comparison test for normally distributed data of equal variance or, in case the assumption of normality was not met, Kruskal–Wallis H-tests (again followed by Dunn's multiple comparison test) or Mann–Whitney rank sum test. For sequential bioassays, we used the Wilcoxon signed-rank tests to test for differences between the periods. The Mann–Whitney rank sum test was applied to test for significant differences within a period. We used the two-side paired t-test for comparing EAG responses (amplitude of rapid negative baseline deflection in mV) to different ipsdienol isomers within species, and the two-side unpaired t-test for comparisons of responses between species. For between-species comparisons we standardized the absolute EAG responses in relation to responses to the set of reference substances (see above, in %), to compensate for differences in size between *E. mixta* and *E. cyanura*. The relative response (%) to an ipsdienol isomer was calculated as the absolute response divided by the mean response to the set of reference substances used. For relative responses to the reference substances themselves, the relative response for each reference substance was computed in the same way, except for a reduced set of remaining reference substances (not including the ipsdienol solutions).

Results

Among the 20+ species of Euglossini occuring in the study area, only two were attracted regularly to our ipsdienol baits, and both had a near-exclusive preference for (−)-

ipsdienol and the racemate (see below). *Euglossa cyanura* (Fig. 1) males were attracted in large numbers at all sites, and consequently were subject to all of the analyses below. Additionally, male *Euglossa tridentata* were regularly attracted to racemic and (−)-ipsdienol at Poza Azul, where they were subjected to multiple-choice and sequential bioassays (in addition to *E. cyanura*). *Euglossa mixta* was never attracted to any ipsdienol bait, irrespective of the time of the day, enantiomeric composition, or baiting locality.

Single Substance Bioassays Male *E. cyanura* were most frequently observed on (−)-ipsdienol (6.83±2.64 SD bees in 40 min) and racemic ipsdienol baits (5.67±1.63 SD bees in 40 min). Only a single male was ever observed to visit an (+)-ipsdienol bait, and no bee came to the control (Fig. 2). Overall, there was a difference among visits to the four stimuli (H=27.9, $d.f.$=3, P<0.001).

Multiple-choice Bioassay – Equal Concentrations Male *E. cyanura* preferred (−)-ipsdienol over racemic and (+)-ipsdienol, when all stimuli were tested simulatenously at the same concentration (H=35.10, d.f.=2, P<0.001; Fig. 3a). When (−)- and racemic ipsdienol baits were removed after 40 min, only a few males behaved opportunistically and switched to the remaining (+)-ipsdienol baits (median=3.85%, 1st quartile=0.00%; 3rd quartile=12.95%, N=9, N=88 bees).

Multiple-choice Bioassay – Different Concentrations When racemic ipsdienol was presented in a high concentration simultaneously with a lower concentration of (−)-ipsdienol from bubblecaps, males of both *E. cyanura* and *E. tridentata* preferred racemic ipsdienol over (−)-ipsdienol (Fig. 3b, c), and neglected the remaining baits. Overall, the number of visiting bees per bait was different (ANOVA $F_{cyanura}$=337.4, $d.f.$=4, P<0.001; ANOVA $F_{tridentata}$= 838.2, $d.f.$=4, P<0.001).

Sequential Bioassays As expected from previous multiple-choice bioassays, there was a clear preference for the racemic ipsdienol bait (bait A in Fig. 4), compared to the control bait to which no bee was attracted (bait B in Fig. 4), for both species (Mann-Whitney $U_{cyanura}$=0, P<001; Mann-Whitney $U_{tridentata}$=0, P<0.001). When ipsdienol was added at the beginning of the second experimental period to the former control bait (bait B in Fig. 4), bees immediately started to land on this bait. Both baits possessed equal amounts of ipsdienol (racemate) and, on average, were visited in similar percentages by both *E. tridentata* and *E. cyanura* males. Thus, any chemical traces of odor-foraging males left on one of the baits had no effect on the subsequent preferences of bees (Mann-Whitney $U_{cyanura}$=24, P>0.10; Mann-Whitney $U_{tridentata}$=19, P> 0.10). Consequently, the percentages of bees that landed on one of the two baits (Fig. 4) changed between the two periods for both species and baits (Wilcoxon Signed Rank Test, P<0.02 for both baits and species).

Electroantennography The EAG results reflected the behavioral results in the sense that *E. cyanura* showed (i) stronger absolute EAG responses to (−)-ipsdienol than to (+)-ipsdienol at all except the lowest concentrations (Fig. 5), and (ii) stronger relative EAG responses to (−)-ipsdienol than *E. mixta* males, again at all except the lowest concentration (Fig. 6b). In contrast, relative EAG responses to (+)-ipsdienol, were not different between the two species at any concentration (Fig. 6a). There was also no difference in relative EAG responses to any of the reference substances between the two *Euglossa* species (unpaired t-test or Mann-Whitney U; P>0.05).

Discussion

We demonstrated that male *Euglossa cyanura* discriminate between optical isomers of ipsdienol by showing that they exhibit a near-exclusive preference for (−)-ipsdienol over (+)-ipsdienol. Corresponding results were obtained for *E. tridentata*, the only other euglossine species attracted regularly to ipsdienol in the study area. This suggests that

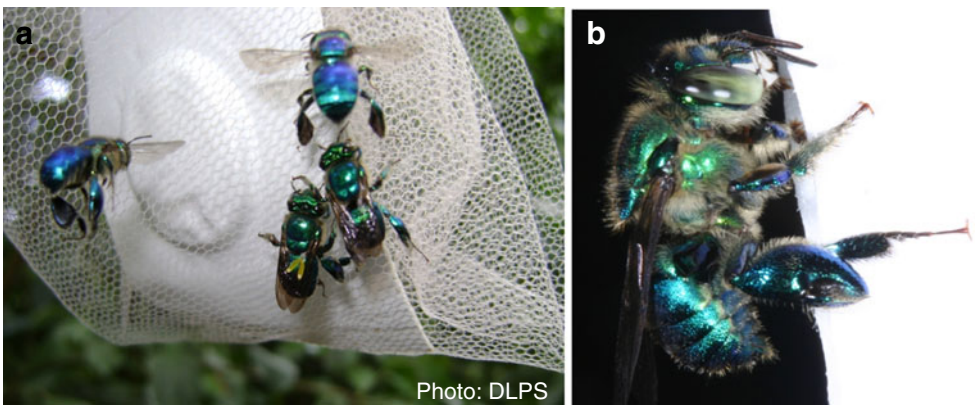

Fig. 1 **a** Male *Euglossa cyanura* (body length ~1.1 cm) arriving at a bubble cap bait, containing ipsdienol, near the Los Tuxtlas biological station, Veracruz, southern Mexico (one of the males is carrying a pollinarium of a *Gongora* orchid). **b** Close up of an ipsdienol-collecting male

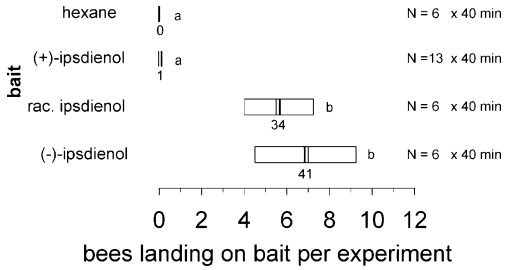

Fig. 2 Single-substance bioassays. Average number of male *Euglossa cyanura* landing on various ipsdienol and control (hexane) baits. Boxplots indicate the inter-quartile range (box), the median value (vertical line) and the arithmetic mean (bold vertical line). Numbers below the bold mean line represent the total number of bees. Treatment means followed by the same letters indicate those that are not different from each other (α=0.05)

enantioselectivity plays an important role in the fragrance collection behavior of male euglossines, which appear to have replaced endogenous pheromones with environmental odors (Zimmermann et al., 2006, 2009). To achieve pollination, a considerable number of orchid and other plant species of the neotropics take advantage of the attraction of euglossine males to volatile chemicals. Ipsdienol occurs in floral scents of orchids and aroids (Whitten et al., 1988; Schwerdtfeger et al., 2002; Knudsen et al., 2006), and it appears that it often occurs with its putative precursor, β-myrcene (Knudsen et al., 1999, 2006; Raguso, 2008). Unfortunately, it is not known whether or not (−)-ipsdienol is the predominant enantiomer in those neotropical plants (M. Whitten and J. Knudsen, personal communication). Other chiral compounds are attractive to male euglossines, and attraction may, in fact, be selective to one optical isomer. For example, of the 34 compounds listed by Roubik and Hanson (2004), 13 are chiral and, in at least one of them (α-pinene), attraction is mediated exclusively by one isomer [(−)-⟨-pinene] (Williams and Whitten, 1983). Another possible case of stereoselective attraction of male orchid bees is to hexahydrofarnesyl acetone, in which the *R,R*-isomer is more attractive than the racemate (Eltz et al., 2010).

In *Euglossa cyanura*, the observed preference to (−)-ipsdienol is associated with increased sensitivity of male antennae to this enantiomer. Previous EAG studies on orchid bees (Schiestl and Roubik, 2003; Eltz and Lunau, 2005; Eltz et al., 2006) found that the antennal chemosensory apparatus of euglossines responds to a broad range of compounds, in a rather generalized way; i.e., there was little evidence for component-specific antennal specialization. One notable exception is the antennal sensitivity of male *E. dilemma* to 2-hydroxy-6-nona-1,3-dienylbenzaldehyde, a high molecular weight compound that is both behaviorally attractive and present in large quantities in *E. dilemma* perfumes (Eltz et al., 2008). (−)-Ipsdienol is the first low molecular weight compound that has been found to elicit stronger antennal responses in males of an attracted species (*E. cyanura*) than in males of a non-attracted species (*E. mixta*). Thus, our findings strengthen the idea that antennal responses, to some extent, reflect behavioral preferences for certain odors by males. However, it remains unknown whether the increased antennal sensitivity of male *E. cyanura* is a cause or a consequence of (−)-ipsdienol preference. Both alternatives may apply but, perhaps, it is most parsimonious to assume that increased sensitivity

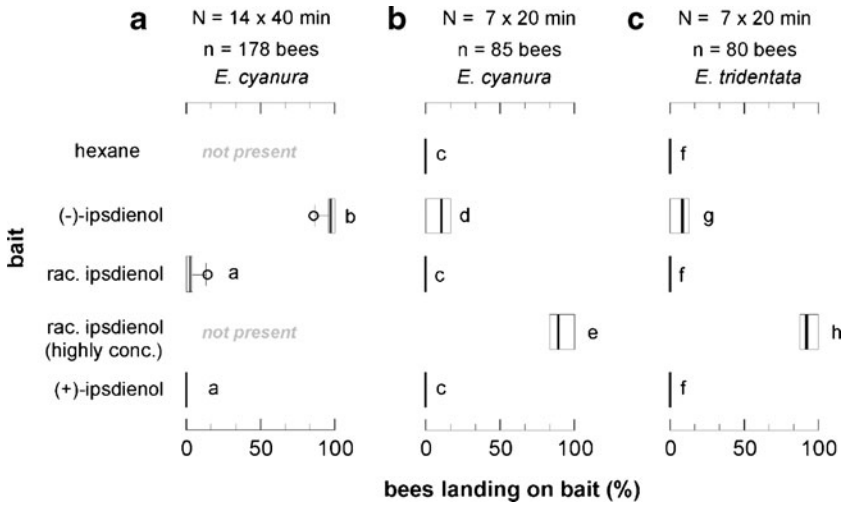

Fig. 3 Multiple-choice bioassays. Average percentages of male *Euglossa* species landing on various treatments. **a** *E. cyanura* on various bubble cap ipsdienol baits, all at the same concentration, plus a hexane control; **b** *E. cyanura* and **c** *E. tridentata* on the various bubble cap ipsdienol baits, all at the same concentration, plus a more concentrated racemate bait on filter paper, plus hexane control. Treatments with the same letters indicate those that are different from each other (α=0.05)

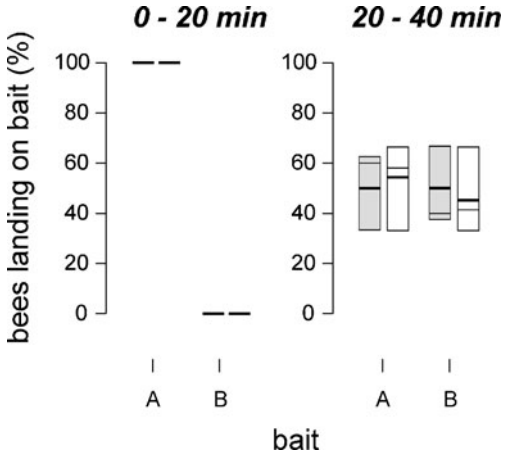

Fig. 4 Sequential bioassays. Test for intraspecific chemical cues. Percentages of bees landing on either of two baits (A, B). During the first 20-minute period ($N_{cyanura,\ 0–20\ min}$=7, N=46 bees; $N_{tridentata,\ 0–20\ min}$=7, N=38), bait A contained racemic ipsdienol and bait B hexane (control). During the second 20-minute period ($N_{cyanura,\ 20–40\ min}$=7, N=59 bees; $N_{tridentata,\ 20–40\ min}$=7, N=39), both baits had the same amount of ipsdienol, but bait A was distinguished from bait B by the presence of chemical traces left by odor-visiting bees during the first period. Boxplots (*Euglossa cyanura* = grey; *E. tridentata* = white) indicate the inter-quartile range (box), the median value (horizontal line), and the arithmetic mean (bold line). In the second period, there were no differences in landings to the two baits

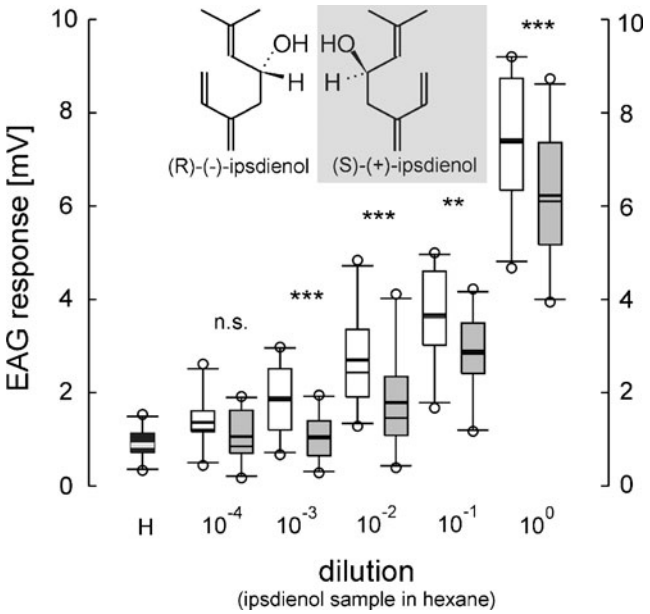

Fig. 5 Electroantennographic (EAG) responses of male *Euglossa cyanura* (N=10 bees) to different concentrations of the two enantiomers of ipsdienol. Boxplots indicate the inter-quartile range (box), the median value (horizontal line), the arithmetic mean (bold line), 95% range (whiskers) and outliers. Significant differences in responses to the two enantiomers are indicated by asterisks (*/**/***=P<0.05/0.01/0.001; n.s. = not significant = P>0.05). H = hexane (control). All responses to the enantiomers were larger than those to the hexane control (Paired T-tests; P<0.05), except for responses to (+)-ipsdienol at 10^{-4} and 10^{-3} dilutions (P>0.1)

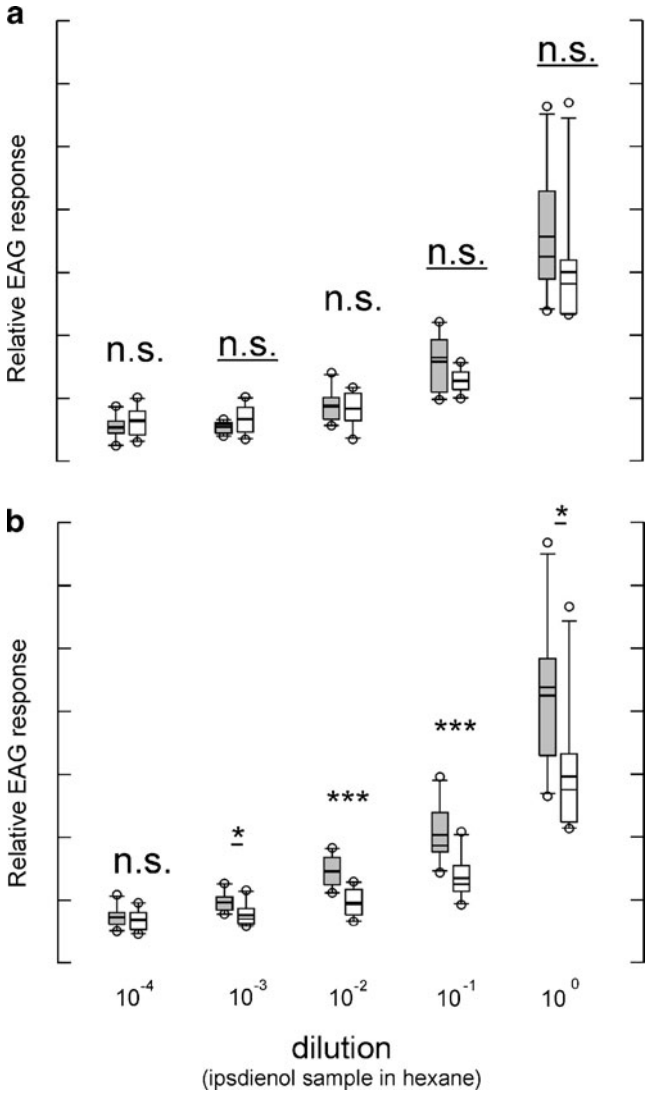

Fig. 6 Standardized electroantennographic (EAG) responses of male *Euglossa cyanura* (grey bars, N=10) and *E. mixta* (white bars, N=10) to different concentrations of (+)-ipsdienol (**a**) and (−)-ipsdienol (**b**). Boxplots indicate the inter-quartile range (box), the median value (horizontal line), the arithmetic mean (bold line), 95% range (whiskers), and outliers of the responses. Significant differences in standardized responses between the two species are indicated by asterisks (*/***=P<0.05/0.001; n.s. = not significant = P>0.05). The statistically relevant abbreviations are underlined when non-parametric statistics were applied

evolved as a consequence of an already existing behavioral preference. Ipsdienol is likely rare in the natural habitat, necessitating a highly responsive olfactory system to detect and locate a source. That male *E. cyanura* are highly responsive to this compound is supported by the observation that males were extremely quick to locate our baits. Often, it took the first males only 1–3 min to appear following bait exposure, surprising given the very low quantities of substance released from the bubble caps.

Whether or not male *E. cyanura* possess a class of (−)-ipsdienol-specific olfactory neurons on their antennae, as found in *Ips* bark beetles (Mustaparta et al., 1984), needs to be determined by single cell recording techniques. However, if they do possess such neurons, this could explain why they are not repelled by the presence of (+)-ipsdienol in an odor source. Males of both *E. cyanura* and *E. tridentata* preferred racemic ipsdienol whenever it was presented in concentrations greater than that of purified (−)-ipsdienol. Thus, it appears that it is the absolute amount of (−)-ipsdienol that matters, not whether (+)-ipsdienol is present or not; i.e., (+)-ipsdienol is neither a repellent nor an attractant. This would also explain why *E. cyanura* sometimes visited (+)-ipsdienol bubble caps containing trace proportions (3%) of (−)-ipsdienol during single-substance bioassays or after racemic and (−)-ipsdienol baits were removed. The behavioral indifference with regard to (+)-ipsdienol is surprising given that males perceive (+)-ipsdienol. The mechanisms by which males respond to small amounts of attractive (−)-ipsdienol, in mixtures with large amounts of (+)-ipsdienol, warrant further investigation. It is noteworthy that the situation is different for α-pinene, in which males are attracted only to the (−)-isomer. Here, the racemate is unattractive, suggesting that (+)-α-pinene acts as a repellent (Williams and Whitten, 1983).

No Signals and Cues Left on Visited Odor Sources In insects, there is mounting evidence for detection of chemical traces left by visitors to flowers and other resources (Schmidt et al., 2005; Wilms and Eltz, 2008; Goulson, 2009). Several species use these traces as cues when foraging to judge and detect the availability and profitability of particular odor sources. Since neither ipsdienol-collecting *E. tridentata* nor *E. cyanura* males preferred visited to unvisited ipsdienol baits, we conclude that these euglossines do not utilize such intraspecific chemical signals during odor collection. Presumably, odor originating from the resource alone represents sufficient information for males to detect the presence and profitability of an odor source. This is different to other resources like nectar and pollen advertised by entomophilous plants, in which odor quantity or quality do not necessarily match the actual amount of available resources; in such cases, it makes sense for the seekers to "watch out" for additional indicators of profitability. Whether euglossines utilize chemical cues left by previous flower visitors under such circumstances remains to be unveiled.

Acknowledgements We thank Rosamond Coates and the staff of the Los Tuxtlas Biological station for their hospitality, as well as technical and advisory support. Ricardo Ayala kindly provided a collecting permit for euglossine specimens in Mexico. Many thanks also to Klaus Lunau and the Sensory Ecology group at the University of Düsseldorf. the recent shift of the fly from its native host downy hawthorn, *Crataegus mollis* Sheele (Rosales: Rosaceae), to introduced Eurasian apple, *Malus domestica* Mill. (Rosales: Rosaceae) in the northeast United States about 160 years ago is often cited as an example of sympatric host race formation in action in the face of gene flow (Bush, 1966, 1969; Berlocher et al., 1993; Berlocher and Feder, 2002; Coyne and Orr, 2004; Smadja and Butlin, 2009). Genetic analysis (Feder et al., 1988; McPheron et al., 1988; Michel et al., 2010) and field studies (Feder et al., 1993, 1994) have confirmed the status of apple and hawthorn flies as partially ecologically reproductively isolated host races, the hypothesized first stage in sympatric speciation. Significant allele frequency, but not fixed, genetic differences have been documented for a number of loci between the apple and hawthorn fly races (Michel et al., 2010). In addition, mark-release-recapture studies in the field have shown that host fidelity while strong, is not absolute, and currently inter-host migration between apples and hawthorns occurs at a rate of ~4–6% per generation (Feder et al., 1994). Apple and hawthorn flies readily mate with each other in the lab and produce viable and fertile offspring (Dambroski et al., 2005). Consequently, there appears to be no obvious intrinsic post-zygotic reproductive isolation between the host races, and apple and hawthorn flies are primarily, if not exclusively, isolated by ecological barriers to gene flow.

Two host-related adaptations are important traits that facilitate the host shift of *R. pomonella* to apple and contributing to partial ecological reproductive isolation between the apple and hawthorn fly races. The first involves diapause life history adaptation matching the eclosion time of emerging adult flies to a difference in the fruiting times of apples vs. hawthorns (apple varieties favored by the fly generally bear fruit ~3–4 weeks earlier than hawthorns) (Bush, 1969; Feder et al., 1993, 1994). The difference in eclosion time generates allochronic mating isolation between the host races (Feder et al., 1993; Filchak et al., 2000). The second trait involves host-plant choice. Apple and hawthorn flies prefer to mate on or near the fruit of their respective host plants (Prokopy et al., 1971, 1972). Hence, differences in host plant choice translate directly to mate choice and generate premating reproductive isolation (Feder et al., 1994). One such difference involves volatile compounds emitted by ripening host fruit that are used to recognize and distinguish among alternative host plants (Linn et al., 2003; Forbes et al., 2005). Not only do apple and downy hawthorn flies preferentially orient to their respective natal fruit volatiles, but their upwind-directed flight also is antagonized (arrested) by non-natal volatiles (Forbes et al., 2005; Linn et al., 2005a). Antagonism is important because it indicates that when flies shift to a new host plant, not only do they rapidly evolve and positively behaviorally respond to the volatile profile of the new fruit (where offspring survivorship is higher) but also avoid certain volatiles of the ancestral host fruit (where fitness is lower).

Divergence along these two axes: eclosion phenology and host odor response, has led to considerable, but still incomplete reproductive isolation between races. Mark-recapture studies estimate a migration rate of ~4–6% at sympatric sites (Feder et al., 1994), more than enough to homogenize allele frequencies of the races in the absence of selection (Feder, 1998). While F_1 hybrids between races are intrinsically viable (Reissig and Smith, 1978), they are ecologically unfit due to life history tradeoffs (Filchak et al., 2000) and diminished olfactory response to either parental host fruit (Linn et al., 2004). Thus, genetic differences between races (Feder et al., 1988; McPheron et al., 1988; Michel et al., 2010) are actively maintained by divergent selection on these two key ecological traits.

In contrast to the northern USA, *R. pomonella* infests an array of different hawthorn species in the South (Note: domesticated apple does not thrive in the southern USA, and so the apple race is limited in its distribution to the Northeast, Midwest, and Appalachian Mountains). In this regard, it has been suggested that perhaps the apple race did not originate via a sympatric host shift from the endemic downy hawthorn in the Northeast but from migration of a geographically differentiated, hawthorn-infesting form of the fly from the South (Carson, 1989; although see Bush et al., 1989). This would imply that in the southern USA, a "pre-adapted" hawthorn-infesting population of *R. pomonella* exists that preferentially responds to apple fruit volatiles and is antagonized by downy hawthorn fruit volatiles. It also is possible, however, that *R. pomonella* has formed a series of sympatric host races on the various species of native hawthorn present in the South (Berlocher and Enquist, 1993). Indeed, the five major hawthorn hosts of *R. pomonella* in the South (western mayhaw, *C. opaca*; eastern mayhaw, *C. aestivalis*; blueberry hawthorn, *C. brachyacantha*; green hawthorn, *C. viridis*; and downy hawthorn, *C. mollis*) generally overlap in their geographic ranges, but differ in key traits such as fruiting time, host fruit color and size, and potentially fruit volatiles, thus presenting the opportunity for host-related divergence. In this case, the southern hawthorn races would represent an example of a natural sympatric radiation onto a suite of native host species, complimenting the documented historical shift of the fly onto domesticated apple in recent times.

To investigate the possibilities of preformed apple vs. native hawthorn host races in the South, we initiated studies of the fruit volatile profiles and behavioral responses of *R. pomonella* to the major hawthorn hosts in the southern USA. Here, we focus on three related *Crataegus* species in the series *Aestivales* collectively known under the common name of "mayhaw". *Rhagoletis pomonella* infests both a western (*C. opaca*) and eastern (*C. aestivalis*) distributed

species of mayhaw in the South. The range of *C. opaca* extends from eastern Texas, through all of Louisiana to southwestern Mississippi, with a northern limit in extreme southern Arkansas (Fig. 1). *Crataegus aestivalis* is found from southern Alabama through southern Georgia and central Florida, as well as along the Atlantic coast to North Carolina. Both *C. aestivalis* and *C. opaca* are grown commercially in their respective regions; the fruit is used to make jelly, syrup, and wine. The two species have an early fruiting phenology (mid April to late May), large edible fruits, and a requirement for damp and often flooded soil. The mayhaws are distinguished morphologically by the eastern *C. aestivalis* in having more glabrous oblong-ovate leaves, as opposed to the more cuneate leaves of the western *C. opaca* (Sargent, 1933). The fruit of *C. aestivalis* is smaller and more oblong in shape than *C. opaca*, which has a more depressed, globose fruit. A third described species, *C. rufula*, occurs primarily at the intersection of the eastern and western species' ranges between the lower Pearl River and Pascagoula River drainages in Mississippi. It is intermediate between *C. opaca* and *C. aestivalis* in both fruit and leaf morphology, and may represent a hybrid species. Collection of ripe *C. rufula* fruit from four field sites in this region of Mississippi from 2008 to 2010 failed to yield any *Rhagoletis* infestation.

The distinctive early fruiting time of southern mayhaws makes them prime candidates for the source of a potential shift to apple in the North. To assess this possibility, we developed volatile blends for the three mayhaw species through a combination of gas chromatography/electroantennographic detection (GC-EAD) and gas chromatography/mass spectrometric (GC-MS) analysis of both solid phase microextraction (SPME) and adsorbent samples collected from fruit headspace. Behavioral flight tunnel assays also were conducted using the different adsorbent extracts, mayhaw blends, and our previously developed apple, downy hawthorn, and flowering dogwood (*Cornus florida*) blends to test for possible olfactory pre-adaptation of mayhaw flies to apple. We report results showing that while mayhaws share some fruit volatiles in common with apple, the fruit odor profiles also differ in several key volatiles. Moreover, while eastern and western mayhaw flies preferentially oriented to their respective natal mayhaw blends, they were less responsive to the apple and downy hawthorn blends. Our findings are, therefore, consistent with the possibility of southern USA hawthorn-infesting host races of *R. pomonella*.

Methods and Materials

Insects Flies were collected, from a total of four different mayhaw sites (Fig. 1; Table 1), as larvae in infested host fruit and reared to adulthood in the Notre Dame laboratory

using standard *R. pomonella* husbandry techniques (Neilson, 1965; Dambroski and Feder, 2007). Adult flies were shipped to the Cornell lab and kept in a walk-in environmental chamber at 23-24°C, 16 L:8D photoperiod, and 65–70% r.h., on an artificial diet made of water, sugar, vitamins, casein hydrolysate, and salt mixture prior to testing (Fein et al., 1982). Adult flies at 0–7 and 10–21-d-old were used for GC-EAD analyses and flight-tunnel behavior tests, respectively. Younger flies were used for the GC-EAD analyses because they are more robust and stable in the EAD apparatus than older flies (Nojima et al., 2003a). In contrast, *R. pomonella* flies do not respond behaviorally to volatiles until they reach reproductive maturity at > 8d post-eclosion (Fein et al., 1982).

Fruit Western mayhaw (*C. opaca*) fruit came from two locations: the Louisiana State University Idlewild Experimental Field Station, East Feliciana Parish, LA, USA, and the H.W. Jackson Farm, Polk Co., TX, USA (Fig. 1; Table 1). Eastern mayhaw (*C. aestivalis*) fruit also came from two sites: the USDA southern fruit and nut station, Byron, GA, USA, and Crisp Co., GA, USA (Fig. 1; Table 1). Fruit from the morphologically intermediate *C. rufula* were collected from Parker Lake in the Pascagoula Wildlife Management Area, Jackson Co., MS, USA (Fig. 1; Table 1). Fruit were collected from off of trees in the field and shipped overnight to the Cornell lab for volatile characterization. While it is possible that fruit on trees emit a different blend than newly picked fruit, this is an inherent methodological constraint of volatile collection. In this regard, we note three points. First, our goal was not to directly determine the exact volatile profile of fruit on trees, but rather to identify the key behaviorally active compounds inducing fly response, and to develop synthetic blends that elicit levels of orientation at least as high as whole fruit extracts. Candidate compounds were identified by GC-EAD analysis. Thus, while the composition of eluded compounds from newly picked fruit may differ from unpicked fruit on trees, the key volatiles for behavior should still be present and identified by GC-EAD. Second, previous studies have shown that *Rhagoletis* flies do not respond to all the volatiles emitted by fruit but a crucial subset of compounds (Zhang et al., 1999; Nojima et al., 2003a, b; Linn et al., 2003). Thus, determination of the exact composition of volatiles emitted by fruit on trees is not as important as identification of the subset of key compounds. Third, we eluted volatiles from activated charcoal adsorbent filters in collecting chambers every 24 h for a given fruit sample, and we combined the elution across 5 collecting days, as well as performing SPME sampling on the day following fruit collection. Thus, we sampled volatiles encompassing a period as close as we could following fruit collection in a manner to best ensure that all compounds were sampled in sufficient quantity to be detected by GC-EAD analysis.

Adsorbent Sampling Headspace volatiles were collected from whole fruit by using 2.4 l closed volatile collection chambers (ARS, Inc., Gainesville, FL, USA; glass shop, Cornell University, Ithaca, NY, USA) with one air inlet adapter (7 mm ID) on the top and an outlet adapter (7 mm ID) on the bottom wall. Field collected fruit (500–800 ml in volume) were cleaned gently with distilled water, thoroughly dried, and then immediately put into a collection chamber. Clean air from a filtering and delivery system (ARS Inc., Gainesville, FL, USA) was pushed into the chamber at 0.7 L min^{-1} through the top inlet port, and volatiles from fruit were pushed out through volatile traps (activated charcoal adsorbent filters, ORBO32-small, Supelco Inc., Bellefonte, PA, USA) on the bottom of the chamber. An additional ORBO filter was used to ensure that no breakthrough occurred. For each sample of fruit, adsorbent collections were made over a 5 d period at room temperature using the same volatile trap. For each new fruit sample, the chambers were washed with acetone, purged with clean filtered air for 24 h, and new ORBO filters were put in place. Volatiles were eluted with 500 µl methylene chloride every 24 h from the filters of a given fruit sample and combined across the 5 collecting days. The combined extract was kept at −20°C and subjected to GC-EAD, GC-MS, and flight tunnel analyses.

SPME Sampling A glass jar (500 ml) with Teflon liner screwcap (Wheaton, Milliville, NJ, USA), containing ca. 150 g of fruit, was used for SPME sampling. A carboxen–polydimethylsiloxane-coated SPME fiber (film thickness 85 μm, Supelco) was conditioned in the GC injector (280°C) for 5 min, and then passed through the small hole on the cap into the headspace of the jar. After a 10 to 20-min exposure, collected volatiles on the fiber were immediately subjected to GC-EAD analysis. The sampling container was washed with acetone before sampling new fruit.

Coupled Gas Chromatographic-Electroantennographic Detection (GC-EAD) Analysis Coupled GC-EAD analysis was performed as described previously (Zhang et al., 1999; Nojima et al., 2003a,b; Cha et al., 2008) using a Hewlett Packard 5890 Series II gas chromatograph equipped with a non-polar EC-1 capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; Alltech Associates, Inc., Deerfield, IL, USA) or a Shimadzu GC-17A gas chromatograph equipped with a polar EC-Wax Econo-Cap capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; Alltech) in the splitless mode. The oven temperature was programmed at 40°C for 5 min, then increased by 15°C/min to 250°C, and held for 5 min. Injector and detector temperatures were set at 280°C and 270°C, respectively. Nitrogen gas was the carrier at a flow of 2 ml/min. The column effluent was split 1:1 in the oven via a "Y" glass splitter (Supelco). One arm of the splitter led to the flame ionization detector (FID) (270°C) and the other to the heated EAD port (270°C).

Whole head preparations were made of individual flies for GC-EAD analysis (Nojima et al., 2003a). The head was separated from the body and its antennae positioned between two gold wire electrodes immersed in saline-filled (*Drosophila* ringer solution; 46 mmol NaCl, 182 mmol KCl, 3 mmol $CaCl_2$, and 10 mmol Tris HCl at pH 7.2) micropipettes in an acrylic holder. The antennal holder was placed inside a humidified condenser and maintained at 5°C. The output signal from the antenna was amplified by a customized high input impedance DC amplifier and recorded on an HP 3390A integrator.

Chemical Analysis GC-MS was carried out as previously described (Zhang et al., 1999; Nojima et al., 2003a,b; Cha et al., 2008) with a Shimadzu GCMS-QP5050A quadrupole mass spectrometer in EI (at 70 eV) scan mode coupled with a Shimadzu GC-17A equipped with a nonpolar DB-1 ms capillary column or a polar EC-Wax Econo-Cap capillary column. Helium was the carrier gas (54 kPa at 1.1 ml/min). GC conditions and temperature program were as for the GC-EAD analyses. The interface temperature was set at 260°C. Volatile compounds were identified by comparison of chromatographic retention times and mass spectra with those of authentic standards analyzed on the same instrument. The identification was further verified by antennal responses in the GC-EAD analyses to the standard compounds. Quantification of the relative ratio of the compounds that elicited EAD responses was made from the adsorbent collection based on total ion abundances from GC/MS analyses. As we did not add an internal standard to adsorbent samples for behavioral testing purposes, standard solutions containing 0.1, 1, 10, and 100 ng of the each compound that elicited EAD responses in 1 μl of methylene chloride were prepared and analyzed to obtain calibration curves.

Chemicals The compounds pentyl hexanoate, hexyl butanoate, butyl hexanoate, propyl hexanoate, pentyl butanoate, butyl butanoate, 1-octen-3-ol, 3-methylbutan-1-ol, 3-methylbutyl acetate, dimethyl trisulfide, β-caryophyllene (purities>98%), and dihydro-β-ionone (> 90%) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Butyl acetate (> 99%) and pentyl acetate (> 98%) were purchased from TCI America (Portland, OR, USA), and ethyl acetate (99.9%) was purchased from Fischer Scientific (Pittsburgh, PA, USA). The compound (3*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) was synthesized by oxidation of geraniol and then by Wittig reaction with methylenetriphenylphosphorane (Greenwald et al., 1963) and purified (> 97% with> 97% *E*-isomer by GC/MS) using flash chromatography on silica gel. The synthesis product was eluted with hexane and then subjected to Kugelrohr distillation.

Synthetic Blends and Flight Tunnel Sources We prepared synthetic blends for western, eastern, and hybrid mayhaw based on the EAD active volatile compounds identified from GC-EAD and GC-MS analyses (Fig. 2). The synthetic blends for apple, downy hawthorn, and flowering dogwood were based on Zhang et al. (1999) and Nojima et al. (2003a, b). Table 2 shows the proportion of each compound in the respective blends. The western mayhaw, eastern mayhaw, hybrid mayhaw, and apple blends were prepared such that the concentration of the total volatile mixture was 1 μg/μl in hexane. Downy hawthorn and flowering dogwood blends were prepared as described in Nojima et al. (2003a,b). As in our previous flight tunnel studies, we applied 200 μl of a synthetic blend to a red rubber septum (hexane-washed; Thomas Scientific, Swedesboro, NJ, Cat. No. 1780 J07) as the corresponding doses elicited maximal levels of upwind flight (Zhang et al., 1999; Linn et al., 2003; Nojima et al., 2003a,b). The septum sources were prepared 60 min prior to a test and were clipped onto the bottom of a 7.5 cm red plastic sphere (Gempler's Inc., Mt. Horeb, WI, USA). Fresh sources and red spheres were used for each replicate. For adsorbent extracts, we adjusted (either by diluting with hexane or concentrated under a gentle stream of nitrogen gas) the concentration (GC peak

size) of GC-EAD active volatiles to match the GC profiles of the synthetic blend at 1 μg/μl concentration, and applied 200 μl of the extract to a rubber septum.

Modified Synthetic Blends Based on the similar high response levels of flies to whole fruit adsorbent extracts and synthetic blends (see next section below), we prepared three modified blends by adding and/or subtracting compounds from the complete blends, to determine the relative importance of individual volatiles in the blend, or those that might function as inter-specific behavioral antagonists (Table 3). Because of the limited availability of flies, we concentrated our effort on the compounds butyl acetate, found in the eastern mayhaw blend but not in the western blend, and 3-methylbutan-1-ol, previously demonstrated to be an essential volatile for the upwind flight response of northern downy hawthorn flies (Linn et al., 2005b) and functioning as a behavioral antagonist for apple-origin flies. Blend W1 represented the complete 6-component western blend (Wc) with butyl acetate added. Blends E1 and E2 represented the complete 8-component eastern blend (Ec) with butyl acetate removed, and with both butyl acetate and 3-methylbutan-1-ol removed, respectively. The modified blends were prepared so that each compound was always in the same amount as in the corresponding complete blends, thus eliminating the potential effect of variation in concentration. For flight tunnel testing, we applied 200 μl of the modified blends to a rubber septum. The concentration of each modified blend is listed in Table 3.

Flight Tunnel The response of flies to host fruit volatiles was measured in a sustained-flight tunnel (Nojima et al., 2003a). Flight-tunnel conditions were 23-24°C, 50-70% r.h., 35 cm/s wind speed, 1500 lux light intensity. Sexually mature adult flies (males and females) 10-21-d-old post-eclosion that had never been previously exposed to the fruit volatile blends (i.e., fruit odor-naïve flies) were tested during the 3rd to 11th h of the 16 h photophase period in the flight tunnel. Flies were selected from holding cages located in a separate, environmentally controlled room, placed singly in glass vials, taken to the room housing the flight-tunnel, and then allowed to acclimate for at least 30 min before testing. Individual flies were transferred to a screen holding cage, which was then placed on a release stand such that the open end of the cage faced upwind at a distance of 1 m to the odor source. Flies were given 1 min to respond, and scored by a human observer for the following behaviors: 1) remain in release cage = fly did not take flight, but remained in the release cage, generally walking and grooming; 2) taking flight = flight from the release cage to the sides, top or floor of the tunnel; and 3) upwind-directed flight = fly faced upwind, walked to the edge of the release cage (100 cm from source), took flight and initiated upwind oriented flight in the odor plume. An upwind flight response was scored as positive if the fly exhibited plume-oriented flight for at least 50 cm toward the sphere [we previously showed that at this distance flies are not attracted to the red sphere alone with no odor source (Linn et al., 2003)]. In some cases, flies made complete flights to the red sphere, but mostly their upwind oriented flights ended within 20–25 cm of the sphere with the fly landing on the floor or side walls of the tunnel. We suspect this was due to negative visual effects of the red sphere at close range. Large red spheres simulate an apple fruit, or cluster of dogwood and red hawthorn (*C. mollis*) fruit, but may not be an optimal visual stimulus for mayhaw flies. The red sphere was retained in the present study to provide a consistent assay environment between the current experiments and previous studies (Linn et al., 2003). Also, in the following sections, reference to 'agonist' volatiles refers to those that contributed to the positive upwind directed flight response to a particular blend, and 'antagonist' refers to a non-natal host volatile that, when added to a blend resulted in a significant reduction in upwind directed flights. The effect of the antagonist was characterized by flies exhibiting arrested flight within 25 cm of the release cage, hovering (1–2 s) in the plume, followed by cross-wind casting, then turning and flying in a downwind direction and landing on the floor or side walls of the tunnel. These behaviors were strikingly similar to the pattern observed for behavioral antagonists in moth sex pheromone blends (Linn and Roelofs, 1995; Cardé and Haynes, 2004).

For each of the host plants, our experimental protocol involved first testing adsorbent extracts in the flight tunnel, with the expectation that response levels should be high, indicating that the behaviorally active blend was contained in the extract, and that no potential deterrent compounds were present, such as might occur with over-ripe or rotting fruit. Given a high response level to the extract, we then tested the candidate synthetic blends that were selected from the GC-EAD profiles based on the consistency of the responses over the majority (>75%) of the profiles. Again, the expectation was that response levels should be high and equivalent to those observed with the extracts. We then tested flies to modified blends that had volatiles subtracted or added to the complete blends to determine whether all of the compounds identified from the GC-EAD profiles were required for maximal response (upwind directed flight). For each extract or synthetic blend, different sets of flies were

tested as the flies became available from field collections of infested fruit. For each set of experiments, almost all of the flies were tested to all of the treatments, usually over a continuous period of 2–4 d, with no more than 3 treatments being tested on a given day. In previous studies, we have shown that *R. pomonella* flies can be repeatedly tested without affecting odor preference as displayed in the flight tunnel (Dambroski et al., 2005). Differences in the frequency of upwind flight were compared using Fisher's Exact Test in R (R development core team, Vienna, Austria).

Table 3 Relative ratio (%) of volatile compounds in the complete western mayhaw (Wc) and eastern mayhaw (Ec) synthetic blends and their modified blends (W1, E1, and E2). We prepared the modified blends so that the same compound was always in the same amount as in corresponding complete blends, thus eliminating the potential effect of variation in concentration. For flight tunnel tests, 200 μl of Wc or Ec (prepared at 1.0 μg/μl), thus 200 μg of total volatile compounds, were loaded onto a rubber septum. The ratio and concentration of modified blends (W1, E1, and E2) were formulated as found in Wc or Ec. For flight tunnel tests of the modified blends, we also loaded 200 μl of W1, E1, or E2 to a rubber septum. Bold characters indicate the modified compounds

Results

Identification of Volatiles from Western, Eastern, and C. rufula Mayhaw Fruit Mayhaw fruit was analyzed using SPME and adsorbent extracts with GC-EAD and GC-MS. Figure 2 a-c shows GC-EAD recordings from the antennae of a fly from each mayhaw-origin population exposed to the whole fruit extract at a stage when >90% of the fruit was ripe. We note that whereas the traces indicate the presence of some unidentified peaks with EAD responses, these responses were not present in the majority (>75%) of GC-EAD runs examined. The relative ratio of compounds that elicited EAD responses from flies in each geographic location estimated with GC-MS are listed in Table 2.

For western mayhaw (*C. opaca*), fruit was analyzed from two samples collected in 2007 (Idlewild, East Feliciana Parish, LA, USA, and Polk Co., TX, USA). A total of 12 different antennal pairs of 9 female and 3 male flies (1–10 replicate runs/pair) were used for the GC-EAD analysis. All of the flies were of western mayhaw-origin from Dewey Wills, LaSalle Parrish, LA, USA. Compounds that consistently elicited EAD responses were identified as (**Ia**) 3-methylbutan-1-ol, (**IIa**) pentyl acetate, (**IIIa**) butyl butanoate, (**IVa**) propyl hexanoate, **(Va)** butyl hexanoate, and (**VIa**) hexyl butanoate. Two adsorbent extracts of volatiles from whole mayhaw fruit from each location that were made for quantitative analysis of key volatiles (GC-MS) and flight tunnel analysis were identical.

For eastern mayhaw (*C. aestivalis*), fruit collected in 2007 from Byron, GA, USA and in 2010 from Crisp Co., GA, USA, was analyzed. A total of 7 different antennal pairs of 5 female and 2 male flies (all from Byron; 1–10 replicate runs/pair) were used for the GC-EAD analysis. The corresponding compounds that consistently generated EAD responses from tested flies were identified as (**Ib**) 3-methylbutan-1-ol, (**IIb**) butyl acetate, (**IIIb**) pentyl acetate, (**IVb**) butyl butanoate, (**Vb**) propyl hexanoate, **(VIb)**, butyl hexanoate, (**VIIb**) hexyl butanoate, and (**VIIIb**) pentyl hexanoate.

Fruit from the potential hybrid mayhaw, *C. rufula*, was analyzed from a 2010 collection made at Parker Lake, MS, USA. A total of 7 different antennal pairs of 5 female and 2 male eastern mayhaw-origin flies (1–10 replicate runs/pair) from Byron, GA, USA, were used for the GC-EAD analysis. The corresponding compounds that consistently generated EAD responses from tested flies were identified as (**Ic**) 3-methylbutan-1-ol, (**IIc**) butyl acetate, (**IIIc**) 3-methylbutyl acetate (**IVc**) butyl butanoate, (**Vc**) propyl hexanoate, **(VIc)** hexyl propionate, (**VIIc**) butyl hexanoate, (**VIIIc**) hexyl butanoate, and (**IXc**) pentyl hexanoate.

Behavioral Responses of Mayhaw-Origin Flies to Natal Adsorbent Extracts and Non-natal Northern Volatile Blends Western and eastern-origin flies were tested first in the flight tunnel to western, eastern, and *C. rufula* adsorbent extracts and to the previously developed apple, northern downy hawthorn (DH), and flowering dogwood (DW) blends (Fig. 3). A total of 30 western flies from *C. opaca* fruit collected from La Salle Parish, (N=17) and Grant Parish (N=13), LA, USA, were tested to the western (W-MH) and eastern mayhaw (E-MH) adsorbent extracts, and 13 of the western mayhaw flies from La Salle Parish also were tested to the extract of the hybrid (H-MH) (Fig. 3a). A higher proportion of western flies displayed upwind flight to the western extract (67%) than to the eastern extract (10%; P<0.001, 1 *df*), hybrid extract (0%; P<0.001, 1 *df*), apple blend (3%; P<0.001, 1 *df*), northern downy hawthorn blend (30%; P=0.009, 1 *df*), and flowering dogwood blend (0%; P<0.001, 1 *df*).

For eastern mayhaw, a total of 27 flies from *C. aestivalis* fruit collected from Byron, GA, USA, were tested (Fig. 3b).

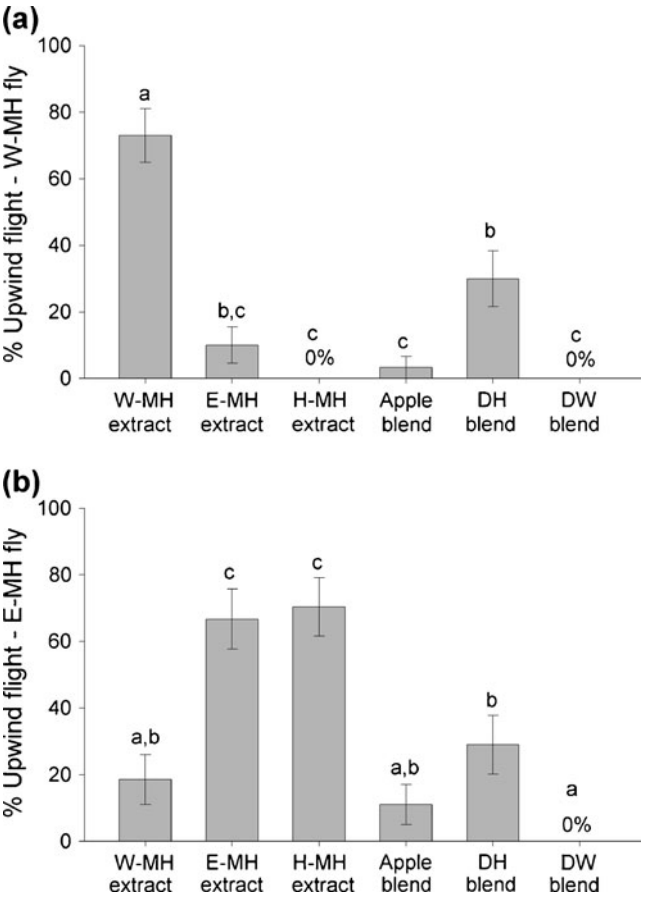

Fig. 3 Upwind flight responses (%±1 *SE*) of **a** western mayhaw-origin flies and **b** eastern mayhaw-origin flies to western, eastern and hybrid mayhaw whole fruit adsorbent extracts and previously developed volatile blends for 3 northern host plants: apple, downy hawthorn, and flowering dogwood. List of abbreviations used and what they stand for: W-MH, western mayhaw; E-MH, eastern mayhaw; H-MH, hybrid mayhaw; DH, downy hawthorn; DW, flowering dogwood. Different letters on bars indicate significant differences (P<0.05)

As was the case for western flies, a higher proportion of eastern flies exhibited upwind flight to the eastern extract (63%) compared to the western extract (19%; $P=0.002$, 1 *df*), the apple blend (11%; $P<0.001$, 1 *df*), and the flowering dogwood blend (0%; $P<0.001$, 1 *df*). The difference between levels of upwind flight of eastern flies to their natal extract and the downy hawthorn blend was marginally significant (63 vs. 30%; $P=0.055$, 1 *df*). However, eastern mayhaw flies did not differ significantly in levels of upwind flight between their natal eastern extract vs. the hybrid *C. rufula* extract (63 vs. 70%, respectively; $P=0.610$, 1 *df*).

Behavioral Responses of Mayhaw Flies to Synthetic Mayhaw Blends Eastern and western mayhaw flies next were tested to synthetic blends of the complete set of GC-EAD active volatiles identified for western (designated Wc) and eastern mayhaw (designated Ec) (Table 2). The proportion of western flies displaying upwind flight to the 6-component Wc blend was 75% (Fig. 4a) and not significantly different from the 67% value exhibited by western flies to the *C. opaca* extract ($P=0.814$, 1 *df*). Similarly, the proportion of eastern flies displaying upwind flight to the 8-component Ec blend was 74% (Fig. 4b), a level equivalent to and not significantly different from the 63% value exhibited by eastern flies to the *C. aestivalis* extract ($P=0.419$, 1 *df*). These two results support the hypothesis that the Wc and Ec blends contain all of the key volatiles found in the extracts that elicit maximal response levels for western and eastern fly behavior, respectively. However, western and eastern flies displayed significantly reduced levels of upwind flight to their respective non-natal blends. The response level for western flies to the eastern Ec blend was 8% upwind flight (Fig. 4a), while the response level for eastern flies to the western Wc blend was 12% upwind flight (Fig. 4b).

We also tested eastern and western mayhaw-origin flies to a 9-component *C. rufula* hybrid blend (designated Hc) (Fig. 4a and b). The results were similar to those observed for the *C. rufula* adsorbent extract. Once again, western flies showed a low level of response to the Hc blend (8% upwind flight), while eastern flies responded in high proportion to the Hc blend (60% upwind flight).

Behavioral Responses of Mayhaw Flies to Modified Blends To better determine the impact of potential key volatile compounds responsible for the agonist and antagonist behavioral responses of mayhaw flies to natal and non-natal fruit volatiles, we tested three different modified blends with a focus on 3-methylbutan-1-ol and butyl acetate (Table 3). A total of 62 western mayhaw-origin flies (La Salle Parish, LA, USA, $N=27$; Grant Parish, LA, USA, $N=17$; Nacagdoches Co., TX, USA, $N=18$) were

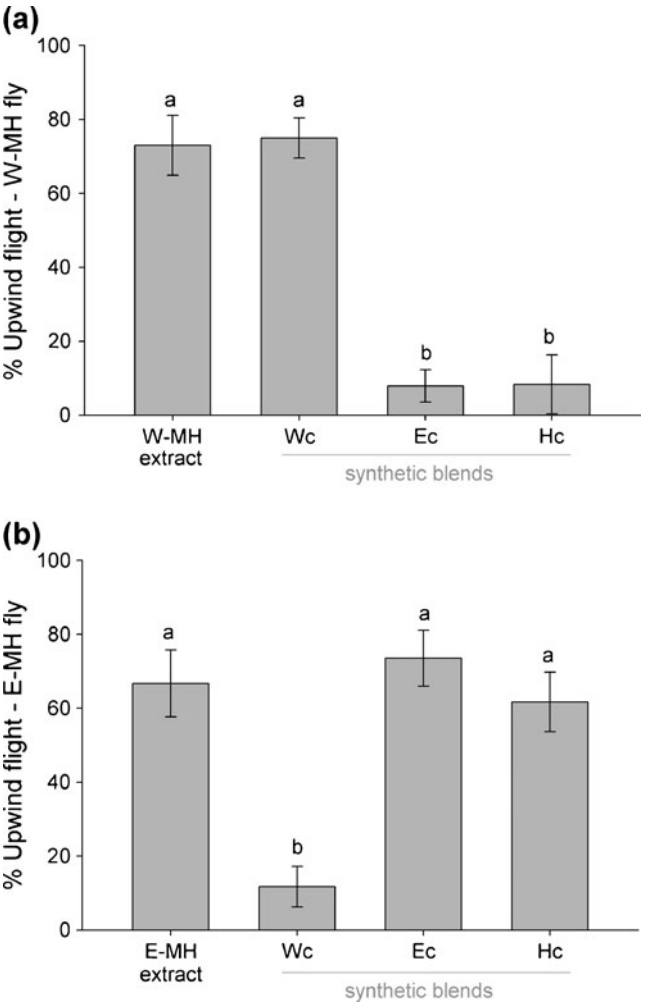

Fig. 4 Upwind flight responses (%±1 *SE*) of **a** western mayhaw-origin flies and **b** eastern mayhaw-origin flies to their natal whole fruit adsorbent extract and volatile blends of western (Wc), eastern (Ec), and "hybrid" mayhaw (Hc). W-MH and E-MH stand for western mayhaw and eastern mayhaw, respectively. Different letters on bars indicate significant differences ($P<0.05$)

tested to the modified mayhaw blends (Fig. 5). Western flies displayed reduced levels of upwind flight to the W1 (Wc plus butyl acetate) blend (10 vs. 75% upwind flight, respectively; $P<0.001$, 1 *df*), indicating that butyl acetate functions as an inter-specific behavioral antagonist on western fly behavior. Consistent with this hypothesis, western fly response to the eastern blend E1 (Ec minus butyl acetate) was not statistically different from that to the complete Wc blend (68 vs. 75%; $P=0.647$, 1 *df*). The critical importance of 3-methylbutan-1-ol was evidenced by the fact that no western flies exhibited upwind-directed flight to the modified E2 blend (E1 minus 3-methylbutan-1-ol). The tests with the modified blends also suggested that the compound pentyl hexanoate did not greatly affect flight behavior of western flies. Although pentyl hexanoate, like butyl acetate, is present in the eastern, but not western,

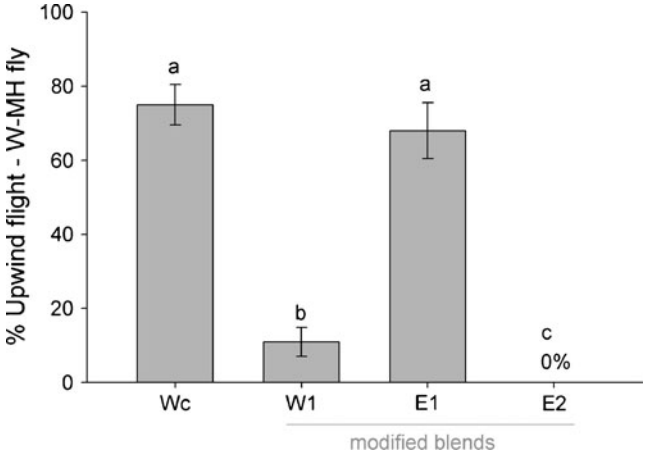

Fig. 5 Upwind flight responses (%±1 *SE*) of western mayhaw-origin flies to the complete western volatile blend (Wc), modified blend W1 (Wc plus butyl acetate), E1 (complete eastern mayhaw blend minus butyl acetate), and E2 (E1 minus 3-methylbutan-1-ol). W-MH stands for western mayhaw. Different letters on bars indicate significant differences ($P<0.05$)

blend (Table 3), western flies responded in high proportions (68%) to the modified eastern blend E1 that had butyl acetate removed, but still contained pentyl hexanoate.

A total of 34 eastern flies from Byron, GA, USA, were tested to the E1 and E2 blends (Fig. 6). Eastern flies exhibited a reduced level of upwind-directed flight to the E1 (Ec minus butyl acetate) blend (7% upwind flight) compared to the complete 8-component Ec blend (74% upwind flight; $P<0.001$, 1 *df*), suggesting that butyl acetate is a critical volatile for maximal response by eastern flies. Eastern flies showed no response (0% upwind-directed flights) to the E2 blend that lacked both butyl acetate and 3-methylbutan-1-ol.

Discussion

We developed synthetic volatile blends of western (*C. opaca*) and eastern (*C. aestivalis*) mayhaw fruit using GC-EAD and GC-MS analysis of SPME and whole fruit adsorbent collections. Western and eastern flies displayed high levels of upwind directed flight to their respective natal blends and a reduced response to almost all of the non-natal blends in flight tunnel assays, the lone exception being eastern mayhaw flies acceptance of the hybrid *C. rufula* blend. A key difference between the eastern and western blends is the presence of butyl acetate in the eastern blend. Addition or subtraction of butyl acetate to the synthetic blends demonstrated the critical importance of this volatile for stimulating upwind directional flight in eastern flies and for antagonizing (arresting) the upwind flight of western flies. This sharp contrast in preference behavior indicates that *R. pomonella* flies infesting western and eastern fruit differ in their host odor response phenotypes. The results for butyl acetate also can help to explain the behavioral responses of mayhaw flies to the fruit volatiles of the morphologically intermediate *C. rufula*, which may represent a hybrid between *C. opaca* and *C. aestivalis* in the state of Mississippi. We found that *C. rufula*, like the eastern mayhaw, *C. aestivalis*, contains butyl acetate in high levels. As a consequence, eastern flies tested against the *C. rufula* blend showed a similar level of upwind flight compared to their natal blend, while the upwind flight of western flies was antagonized by the hybrid blend (Fig. 4a and b). The apparent lack of *R. pomonella* infestation of *C. rufula* in Mississippi may thus be due to inadequate sampling of host fruit or some other abiotic or biotic factor such as dramatic year-to-year variability in the timing or amount of fruit set, and/or high interspecific competition, as the fruit of *C. rufula* would appear to present no olfactory barrier to colonization by eastern mayhaw flies.

A principal motivation for the current study was to investigate a potential role for southern mayhaw flies in the formation of the apple host race in the northern USA. In particular, it has been hypothesized that the introduction of a geographically differentiated, hawthorn-infesting form of *R. pomonella* from the South could be the source of the apple-infesting race in the North (Carson, 1989; although see Bush et al., 1989). This would imply that in the southern USA, a "pre-adapted" hawthorn-infesting population of *R. pomonella* exists that preferentially orients to apple fruit volatiles and is antagonized by downy hawthorn (*C. mollis*) fruit volatiles. However, in the current study, flies collected from both eastern and western fruit exhibited low response levels with the apple blend in flight tunnel assays (6 and 10% upwind flight, respectively). Indeed, the proportion of upwind flight exhibited by southern mayhaw

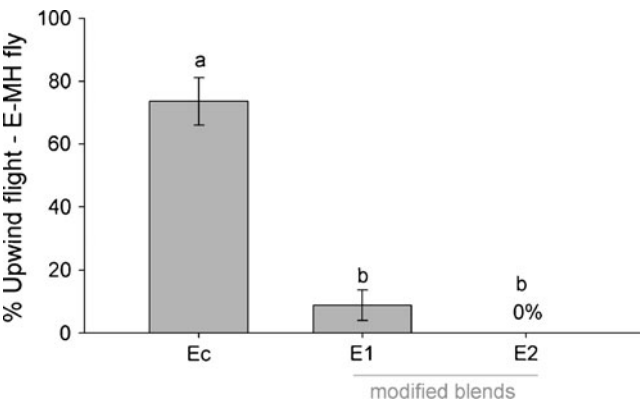

Fig. 6 Upwind flight responses (%±1 *SE*) of eastern mayhaw-origin flies to the complete eastern mayhaw blend (Ec), E1 (Ec minus butyl acetate), and E2 (E1 minus 3-methylbutan-1-ol). E-MH stands for eastern mayhaw. Different letters on bars indicate significant differences ($P<0.05$)

flies to the apple blend was lower than that shown for the northern downy hawthorn blend (Fig. 3). Further, all of these apple-responding flies also responded to their natal fruit extract or synthetic blend, indicating that they are examples of broadly responsive flies, ones that do not exhibit a high degree of response specificity for blend quality. Mayhaw infesting populations from the South, therefore, do not preferentially orient to apple and are not "pre-adapted", direct precursors to the apple race in the North. However, western and eastern mayhaw blends from the South do contain certain compounds present in the apple blend and absent in northern downy hawthorn blend (Table 2). In particular, both mayhaw blends and the apple blend contain butyl butanoate, propyl hexanoate, and hexyl butanoate, and eastern mayhaw and apple further share pentyl hexanoate. Mayhaw flies are thus capable of detecting certain components of the apple blend, and some southern flies are capable of responding to both hawthorn and apple blends, supporting the hypothesis that odor response phenotypes in the South may have contributed to pre-standing variation in northern hawthorn populations facilitating a rapid, sympatric shift to apple. Perhaps most importantly, northern downy hawthorn and both mayhaw blends share 3-methybutan-1-ol in common. 3-Methybutan-1-ol is not present in the apple blend (Table 2), and is an antagonist of upwind flight by apple-origin flies when added to the apple blend (Linn et al., 2005a). The lack of response of both eastern and western flies to modified blends lacking 3-methylbutan-1-ol, together with our previous findings for northern downy hawthorn flies (Linn et al., 2003; 2005a), supports the hypothesis that this compound functions as a critical volatile for hawthorn fly host discrimination.

Rather than a direct shift of southern mayhaw flies to apple to form the northern apple fly race, our current results instead provide evidence for the possible existence of differentiated host races (or even sibling species) of hawthorn-infesting *R. pomonella* in the South. Neither western nor eastern flies were attracted greatly to the northern downy hawthorn blend or to their respective non-natal mayhaw blend. These findings are consistent with differences in olfactory preference and discrimination of volatile mixtures contributing to prezygotic reproductive isolation between these populations if they were to come in geographic contact. In an accompanying study (Cha et al., 2011, this issue), we report fruit volatile and fly response differences for two additional hawthorn species in the South (the blueberry hawthorn, *C. brachyacantha*, and the green hawthorn, *C. viridis*), further supporting the hypothesis of southern hawthorn-infesting races of *R. pomonella*.

We now have developed active volatile blends for six different host fruit of *R. pomonella* group flies. Previously, we optimized volatile blends for apple (Zhang et al., 1999), northern downy hawthorn (Nojima et al., 2003a), and flowering dogwood (Nojima et al., 2003b). The addition of the three new western, eastern, and hybrid mayhaw blends in the current study will allow us to further characterize phenotypic patterns and elucidate the genetic architecture of host plant preference in the model *R. pomonella* system, thus leading to a greater understanding of the role that host volatile recognition plays in phytophagous insect speciation. Studies that compare the behavior of southern mayhaw flies to those of other southern *Crataegus* infesting populations will give us insight into the generality of host odor recognition as an isolating mechanism in the *R. pomonella* species complex and into the nature of fitness trade-offs posed by blends composed of overlapping components (Cha et al., 2011, this issue). Additionally, the importance of pre-standing variation in hawthorn flies to recognize certain specific fruit volatiles in apple may become clearer as we form a complete picture of host race formation among southern *R. pomonella* populations.

Acknowledgments We thank Tracy Arcella, Stewart Berlocher, Scot Egan, Andrew Forbes, Glen Hood, Dave Costello, H. W. Jackson, Jim Stevens, and Sheina Sim for help in collecting fruit and fly samples, thoughtful discussion, and/or assistance in helping prepare the manuscript for publication. We also thank Callie Musto, Kathy Poole, and Paula Fox for maintaining the flies received from Notre Dame, and Harvey Reissig, Cynthia Smith, and Dave Combs for use of the Geneva, New York, apple maggot colony. We also thank Aijun Zhang for the synthesis of (3*E*)-4,8-dimethyl-1,3,7-nonatriene. The research was supported by grants to J.L.F. and C.L. from the National Science Foundation and to J.L.F. from the USDA.

However, the situation is different in the southern USA, where *R. pomonella* infests an array of several different hawthorn species that generally overlap in their geographic ranges, but differ in key traits such as fruiting time, host fruit color and size, and potentially fruit volatiles, thus presenting the opportunity for host-related divergence.

In a companion paper, we investigated the fruit volatile profiles for three related *Crataegus* species in the series *Aestivales*, collectively known under the common name of "mayhaw" in the South. Two of these species, the western mayhaw (*C. opaca*) and the eastern mayhaw (*C. aestivalis*), are infested by *R. pomonella*. A third described species, *C. rufula*, occurs primarily at the intersection of the eastern and western species' ranges between the lower Pearl River and Pascagoula River drainages in Mississippi and may represent a hybrid species; *C. rufula* does not appear to be infested by *R. pomonella* (Cha et al., 2011b, this issue). Our results are consistent with the possibility of endemic southern hawthorn-infesting host races of *R. pomonella* and do not support a "pre-adapted" apple race of the fly being present in the South (Cha et al., 2011b).

There are other hawthorn hosts of *R. pomonella* in the South, however, that could serve as a source for a pre-assembled apple race and/or shed additional insight into the evolutionary origins of apple volatile attraction. The fly also infests blueberry hawthorn, *C. brachyacantha* Englem. and Sarg. and green hawthorn, *C. viridis* L., as principal hosts. The blueberry hawthorn is so named for its characteristic dark blue, subglobose fruit. It is one of the tallest southern species in *Crataegus*, and is further distinguished by its small, waxy, crenulate-serrated leaves and small curved thorns (Sargent, 1933). Blueberry hawthorn fruit typically ripens from late August through September. Blueberry hawthorns are found in moist soil on the edge of forests bordering on low-lying prairies (Correll and Johnston, 1970). Its natural range is the "piney woods" region of eastern Texas through much of Louisiana, barely extending into adjacent counties in Arkansas and Mississippi.

The green hawthorn, *C. viridis*, has a broader range. It is found from southern Illinois southward to the coastal plain of Texas, eastward to the Florida panhandle and as far north as the Virginia piedmont. It is sparsely distributed through much of this range, only occurring in high densities west of the Mississippi River (Sargent, 1890). Green hawthorn is comprised of a complex of both sexual and apomictic individuals (Talent and Dickinson, 2005), and is distinguished from other hawthorns by dark green, acute, ovate leaves and small red-orange fruit (Vines, 1977). Green hawthorn has the latest fruiting phenology of southern hawthorns, with ripening not occurring until November. Unlike many hawthorn species, whose fruit abscises shortly after ripening, uninfested green hawthorn fruit often remains on the tree through winter. For this reason, a cultivar of green hawthorn known as "Winter King" has recently become popular with horticulturalists outside its native range.

Here, we expand on our previous studies and report on the identification of volatile blends for blueberry and green hawthorns through a combination of gas chromatography-electroantennographic detection (GC-EAD) and gas chromatography–mass spectrometric (GC-MS) analysis of solid phase microextraction (SPME) and adsorbent volatile collection samples from whole fruit. Behavioral flight tunnel assays also were conducted using the blueberry and green hawthorn blends and our previously developed apple, downy hawthorn, and flowering dogwood blends to test for possible olfactory pre-adaptation of flies that infest these two southern hawthorn species to apple. We report results showing again that both blueberry and green hawthorn-origin flies respond maximally to their natal fruit volatile blends and are relatively unresponsive to the alternative non-natal blends, consistent with endemic host race formation of *R. pomonella* on native southern hawthorns. The results also show that the volatile blend for green hawthorn flies, in particular, contains volatiles used by northern downy hawthorn and apple flies, and thus could be a potential source for genetic variation, thus contributing to olfactory fruit odor discrimination and host race formation in the North.

Methods and Materials

Details concerning methods and procedures for fruit volatile adsorbent and SPME sampling, GC-EAD and chemical analyses, synthetic blend development, and flight tunnel behavioral testing, can be found in the companion paper (Cha et al., 2011b, this issue). As done previously in Cha et al. (2011b), differences in the frequency of upwind flight in the tunnel were compared using Fisher's Exact Test in R (R development core team, Vienna, Austria).

Insects Flies used in the study were collected as larvae in infested host fruit from three different blueberry and seven different green hawthorn sites in the South (Fig. 1; Table 1) and reared to adulthood in the Notre Dame laboratory (Neilson and McAllan, 1965; Dambroski and Feder, 2006). Upon eclosion, adult flies were kept in a walk-in environmental chamber on an artificial diet (Fein et al., 1982). Adult flies at 0–7 and 10–21-d-old were used for GC-EAD analyses and flight-tunnel behavior tests, respectively.

Fruit Blueberry hawthorn fruit was collected from Monroe, LA, USA, in 2007 (Fig. 1; Table 1). Green hawthorn fruit was collected from Dewey Wills Wildlife Management

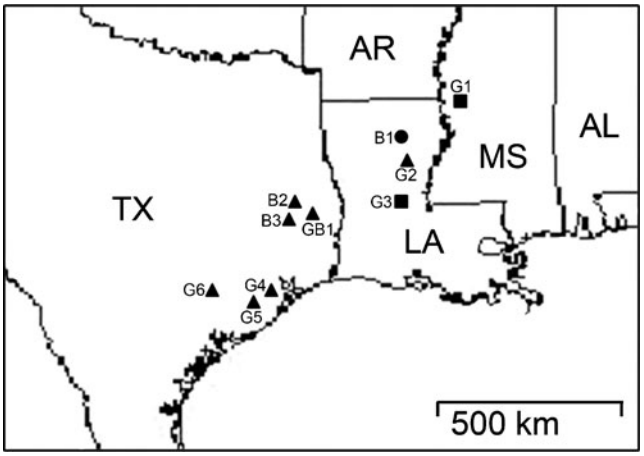

Fig. 1 Map of collection sites for blueberry hawthorn (B) and green hawthorn (G) fruit (*circles*), flies (*triangles*), or both (*squares*). Abbreviations for each of the southern States indicated are: AL, Alabama; AR, Arkansas; LA, Louisiana; MS, Mississippi; TX, Texas

Area, LA, in 2007 and Rolling Fork, MS, USA, in 2008 (Fig. 1; Table 1). Fruit collections were made off of trees in the field and shipped overnight to the Cornell lab for volatile characterization.

Chemicals Pentyl hexanoate, hexyl butanoate, butyl hexanoate, propyl hexanoate, pentyl butanoate, butyl butanoate, 1-octen-3-ol, 3-methylbutan-1-ol, 3-methylbutyl acetate, dimethyl trisulfide, β-caryophyllene (purities >98%), and dihydro-β-ionone (>90%) were purchased from Sigma-Aldrich (St. Louis, MO, USA); butyl acetate (>99%) and pentyl acetate (>98%) from TCI America (Portland, OR, USA); ethyl acetate (99.9%) from Fischer Scientific (Pittsburgh, PA, USA). The compound (3*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) was synthesized by oxidation of geraniol and then by Wittig reaction with methylenetriphenylphosphorane (Greenwald et al., 1963) and purified (>97% with >97% *E*-isomer by GC/MS) using flash chromatography on silica gel. The synthesis product was eluted with hexane and then subjected to Kugelrohr distillation.

Modified Synthetic Blends To determine the relative importance of individual volatiles in the blend, or those that might function as inter-specific behavioral antagonists for green and blueberry hawthorn-origin flies, we prepared six modified blends by adding and/or subtracting volatile compounds from the complete blends (Table 2). We concentrated on five different compounds: 3-methylbutan-1-ol, butyl acetate, propyl hexanoate, DMNT, and 1-octen-3-ol. Previous studies have shown that 3-methylbutan-1-ol is an essential volatile inducing agonistic behavior for northern downy hawthorn flies (Linn et al., 2005b) and also for southern mayhaw flies (Cha et al., 2011b, this issue). Butyl acetate was examined because it is present in the blueberry hawthorn, but not common in other hawthorn species found in blueberry hawthorn growing regions (e.g., western mayhaw, *C. opaca*). DMNT, 1-octen-3-ol, and propyl hexanoate are all compounds that are important for the northern apple, downy hawthorn, and dogwood host races. DMNT is unique to green hawthorn in the South and was previously shown to be essential for maximal upwind flight by northern downy hawthorn flies (Nojima et al., 2003a). The volatile 1-octen-3-ol is in both green and blueberry hawthorn, and is an essential volatile in the dogwood blend (Nojima et al., 2003b) but an antagonist to apple flies (Linn et al., 2005a). The modified blends were prepared so that each compound was always in the same amount as in corresponding complete blends, thus eliminating the potential effect of variation in concentration. For flight tunnel testing, we applied 200 μl of the modified blend to a rubber septum. The concentration of each modified blend is listed in Table 2.

Results

Identification of Volatiles from Green and Blueberry Hawthorn Fruit Green and blueberry hawthorn fruit were analyzed by using SPME and adsorbent extracts with GC-

Table 1 Collection sites for green hawthorn (*Crataegus viridis*) and blueberry hawthorn (*Crataegus brachyacantha*) fruit and flies as marked in Fig. 1

Map Name	Host plant species	Location	Latitude	Longitude
B1	*C. brachyacantha*	Co. Rd 841, Ouachita Parish, LA	32° 19′ N	90° 55′ W

Table 2 Relative ratio (%) of volatile compounds in the complete green (Gc) and blueberry (Bc) synthetic blends and their modified blends (G1, G2, B1, B2, B3 and B4). We prepared the modified blends so that the same compound was always in the same amount as in corresponding complete blends, thus eliminating the potential effect of variation in concentration. For flight tunnel tests, 200 μl of Gc or Bc (prepared at 1.0 μg/μl), thus 200 μg of total volatile compounds, were loaded to a rubber septum. Ratio and concentration of modified blends (G1, G2, B1, B2, B3 and B4) were formulated as found in Gc or Bc. For flight tunnel tests of the modified blends, we also loaded 200 μl of G1, G2, B1, B2, B3 or B4 to a rubber septum. Bold characters indicate the compounds modified. DMNT indicates (3*E*)-4,8-dimethyl-1,3,7-nonatriene

EAD and GC-MS. Figure 2a and b shows GC-EAD recordings from the antennae of a representative green or blueberry hawthorn-origin fly exposed to an extract sample from ripe fruit. We note that whereas the trace indicates the presence of some unidentified peaks with EAD responses, these responses were not present in the majority (>75%) of GC-EAD runs examined. The relative ratio of the EAD active compounds estimated by GC-MS for the whole green and blueberry hawthorn fruit adsorbent extracts is given in Table 3.

For green hawthorn (*C. viridis*), fruit collected from two sites (Dewey Wills, LA, USA 2008; Sharkey Co., MS, USA 2008) were analyzed. A total of 24 different antennal pairs of 21 female and three male green hawthorn-origin flies (1–10 replicate runs/pair) was tested. The compounds that consistently elicited EAD responses were identified as (Ia) 3-methylbutan-1-ol, (IIa) 1-octen-3-ol, (IIIa) butyl butanoate, (IVa) pentyl butanoate, (Va) propyl hexanoate, (VIa) (3*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), (VIIa) butyl hexanoate, (VIIIa) hexyl butanoate, and (IXa) pentyl hexanoate (Table 3).

For Blueberry hawthorn (*C. brachyacantha*), fruit collected at Ouachita Parish, LA, USA, in 2007 was analyzed. A total of seven different antennal pairs of 5 female and 2 male blueberry hawthorn-origin flies (1–6 replicate runs/pair) was tested using SPME and the extract in the GC-EAD analysis of *C. brachyacantha* volatiles. The corresponding compounds eliciting consistent EAD activity were identified as (Ib) 3-methylbutan-1-ol, (IIb) butyl acetate, (IIIb) 1-octen-3-ol, (IVb) butyl butanoate, (Vb) pentyl butanoate, (VIb) butyl hexanoate, (VIIb) hexyl butanoate, and (VIIIb) pentyl hexanoate (Table 3).

Behavioral Responses of Green and Blueberry Hawthorn-Origin Flies to Natal Adsorbent Extracts and Non-Natal Northern Volatile Blends A total of 26 green hawthorn-origin flies from Fort Necessity, LA, USA (N=5), Brazos Bend, TX, USA (N=4), and Rolling Fork, MS, USA (N=17) and 17 blueberry hawthorn flies from the Stephen Austin Experimental Forest, near Nacogdoches, TX, USA were tested in the flight tunnel to adsorbent extracts from green and blueberry hawthorn, and to 200 μg of the previously developed apple, downy hawthorn, and flowering dogwood blends (Fig. 3). For green hawthorn-origin flies, the response patterns were not statistically different among the three sites for any of the host volatiles tested, and so we present the combined results. A higher proportion of green hawthorn-origin flies displayed upwind directed flight to the green hawthorn extract (69%) than to the blueberry hawthorn extract (34%; P=0.002, 1 *df*), the apple blend (4%; P=0.005, 1 *df*), and the downy hawthorn blend (23%; P=0.002, 1 *df*) (Fig. 3a). No green hawthorn-origin fly responded to the dogwood blend. Similarly, a higher proportion of blueberry hawthorn-origin flies displayed upwind directed flight to the blueberry hawthorn extract (76%) than the green hawthorn extract (24%; P=0.0121, 1 *df*), the downy hawthorn blend

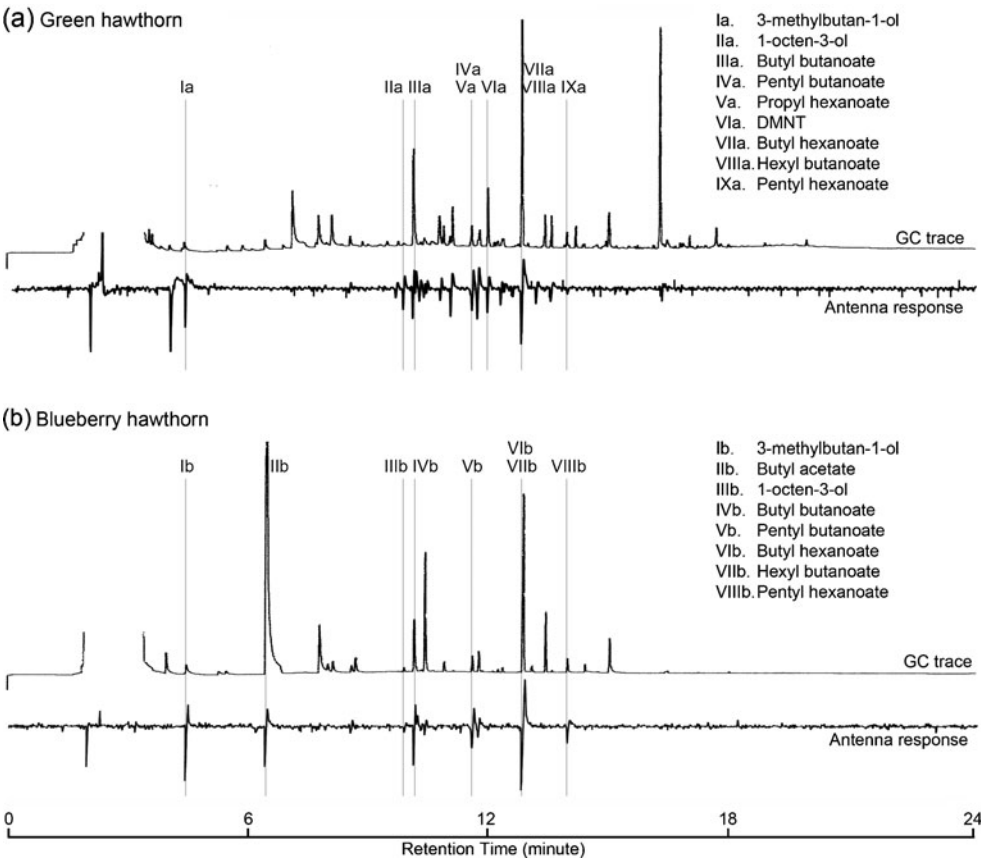

Fig. 2 Simultaneous recorded GC-EAD responses of adult green and blueberry hawthorn fly antennae to adsorbent samples of green and blueberry hawthorn, respectively. Different traces indicate antennal response of (**a**) green hawthorn-origin flies to green hawthorn fruit adsorbent samples and (**b**) blueberry hawthorn-origin flies to blueberry hawthorn fruit adsorbent samples. DMNT indicates (3*E*)-4,8-dimethyl-1,3,7-nonatriene

Table 3 The relative ratios (%) of volatile compounds used in different synthetic blends. Ratios of the green and blueberry hawthorn blends were based on GC/MS analyses of volatile adsorbent samples collected from green and blueberry hawthorn fruits, respectively. The ratio of apple, red hawthorn and dogwood blends were previously developed by Zhang et al. (1999) and Nojima et al. (2003a,b). DMNT indicates (3*E*)-4,8-dimethyl-1,3,7-nonatriene.

Chemicals	Synthetic blends (%)				
	Green hawthorn (Gc)	Blueberry hawthorn (Bc)	Apple	Downy hawthorn	Flowering dogwood
3-methylbutan-1-ol	5	0.6		4	27.5
Butyl acetate		50			
Pentyl acetate		3.5			
Butyl butanoate	19.5	9	10		
Propyl hexanoate	1.5		4		
Butyl hexanoate	24	16.8	37	0.01	
Hexyl butanoate	24	16.8	44		
Pentyl hexanoate	2.5		5

1-octen-3-ol	0.5	0.3			9.1
β-caryophyllene					5.8

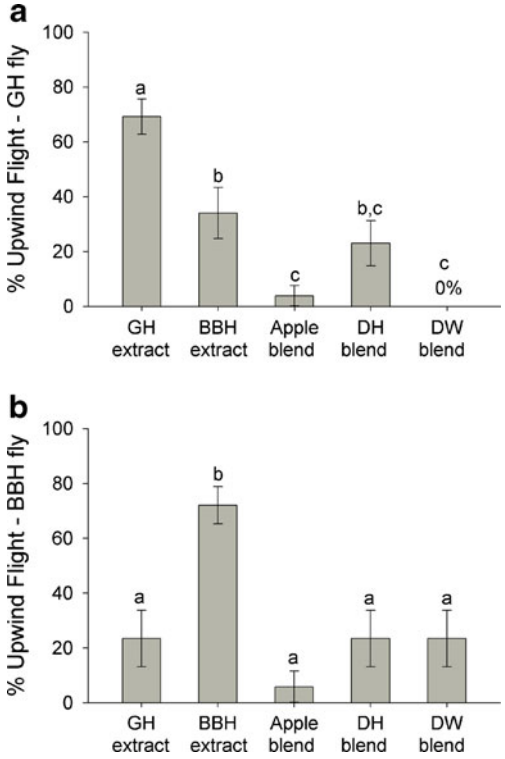

Fig. 3 Upwind flight responses (% ± 1 *SE*) of (**a**) green hawthorn-origin flies and (**b**) blueberry hawthorn-origin flies to green and blueberry hawthorn fruit adsorbent extracts as well as previously described synthetic volatile blends for three northern USA host plants: apple, downy hawthorn, and flowering dogwood. List of abbreviations used and what they stand for: GH, green hawthorn; BBH, blueberry hawthorn; DH, downy hawthorn; DW, flowering dogwood. Different letters on bars indicate significant differences ($P<0.05$)

(24%; $P=0.0121$, 1 *df*), and the flowering dogwood blend (24%; $P=0.0121$, 1 *df*). Only one of the 17 blueberry hawthorn-origin flies (6%) responded to the apple blend (Fig. 3b).

Behavioral Response of Green and Blueberry Hawthorn-Origin Flies to the Synthetic Blends A total of 26 green hawthorn-origin flies from four different sites (Fort Necessity, LA, USA [$N=8$]; Rolling Fork, MS, USA [$N=13$]; Brazos Bend, TX, USA [$N=1$]; and Cedar Lane, TX, USA [$N=4$]) were tested to both the green hawthorn extract and the 9-component synthetic blend developed for green hawthorn fruit (designated Gc). A total of 26 blueberry hawthorn-origin flies from two different sites (Nacogdoches, TX, USA [$N=19$]; and Marion Ferry, TX, USA [$N=7$]) were tested to the blueberry hawthorn extract and to an 8-component synthetic blend of the complete set of EAD active volatiles identified from fruit (designated Bc). For both fly host populations, there was no difference in the level of upwind directed flight with the Gc or Bc blend compared to the respective extracts (for green hawthorn 81 vs. 69%, respectively, $P=0.523$, 1 df; for blueberry 88 vs. 65%, respectively, $P=0.098$, 1 *df*). These results support the hypothesis that the Gc and Bc blends contain all of the key volatiles required for maximal levels of green and blueberry hawthorn upwind flight behavior. We, therefore, used the Gc and Bc blends as a baseline for comparison in subsequent tests to investigate the behavioral responses of flies to specific volatile compounds (see section below on Behavioral Responses of Flies to Modified Blends).

Behavioral Responses of Flies to Modified Blends Analysis of the flight responses of green and blueberry hawthorn-origin flies to two complete synthetic (Gc and Bc) and six modified blends (G1, G2, B1, B2, B3, and B4; Table 2) provided evidence for DMNT as a behavioral agonist for green hawthorn flies and a behavioral antagonist for blueberry hawthorn flies, and butyl acetate as a behavioral agonist to blueberry hawthorn flies and a behavioral antagonist for green hawthorn flies (Figs. 4 and 5). There also was evidence for 3-methylbutan-1-ol as an important volatile for maximal upwind flight levels by both green and blueberry hawthorn flies, while 1-octen-3-ol (a critical volatile for the dogwood flies; Linn et al., 2005b) and propyl hexanoate (found in the apple blend) had little influence on fly behavior.

For the 85 green hawthorn flies from Dewey Wills, LA, USA ($N=20$); Fort Necessity, LA, USA ($N=26$); Rolling Fork, MS, USA ($N=28$); Brazos Bend, TX, USA ($N=4$); and Cedar Lane, TX, USA ($N=7$), there was no significant difference in the level of upwind directed flight between the complete Gc blend and the G1 blend (Gc minus 1-octen-3-ol and propyl hexanoate) (73 vs. 78%; $P=0.594$, 1 *df*), suggesting that 1-octen-3-ol and propyl hexanoate were not essential for maximal upwind flight responses by green hawthorn flies (Fig. 4a). Of the 85 flies, 40 (Dewey Wills, LA, USA [$N=20$]; Fort Necessity, LA, USA [$N=11$]; Rolling Fork, MS, USA [$N=6$]; and Brazos Bend, TX, USA [$N=3$]) also were tested against blend G2 (Gc minus 3-methylbutan-1-ol), with upwind directed flight responses significantly lower than with Gc (10 vs. 78%; $P<0.001$, 1 *df*). In addition, the same 26 green hawthorn flies tested above to both the green hawthorn adsorbent extract and Gc were tested to the complete blueberry hawthorn blend (Bc) and modified B1 (Bc minus 1-octen-3-ol). Green hawthorn flies exhibited low response levels to both Bc and B1 (23 and 4% upwind flight behavior; Fig. 4b).

To test the effect of butyl acetate and DMNT on green hawthorn-origin flies, we performed the following comparisons. The 85 green hawthorn flies tested above to Gc and G1 also were tested to modified blueberry hawthorn blend B2 (B1 minus butyl acetate), to which they showed an increased level of upwind directed flight compared with Bc (47 vs. 24%; $P=0.04$; Fig. 4b), suggesting that butyl

acetate, a unique compound to blueberry hawthorn fruit among the southern hawthorn species, functions as an inter-specific behavioral antagonist on the flight behavior of green hawthorn flies. A total of 56 additional green hawthorn flies from Brazos Bend, TX, USA (N=31), Dewey Wills, LA, USA (N=18), Marion Ferry, TX, USA (N=5), and Palmetto State Park, TX, USA (N=2), were tested to the modified blueberry blend B3, as well as to B2 and G1 (Fig. 3c). Modified blend B3 represented blend B2 with the compound DMNT added, making B3 very similar in composition (except for pentyl acetate in B3) to the modified G1 blend. For these 56 green hawthorn flies, the upwind directed flight response to B3 (68%) was higher compared to B2 (38%; $P<0.001$, 1 *df*) and was similar to that for G1 (73%; $P=0.66$), suggesting that DMNT is a critical volatile in the blend that green hawthorn flies use to locate green hawthorn trees (Fig. 4c).

To test the effect of 1-octen-3-ol, butyl acetate, and DMNT on blueberry hawthorn flies, we performed the following comparisons. For the 26 blueberry hawthorn-origin flies tested above from Nacogdoches, TX, USA (N=19), and Marion Ferry, TX, USA (N=7), there was no significant difference in the level of upwind directed flight between the complete Bc blend and the modified B1 blend (Bc minus 1-octen-3-ol) (88 and 85% upwind flight, respectively), suggesting that 1-octen-3-ol does not greatly affect upwind flight by blueberry hawthorn flies (Fig. 5a). However when butyl acetate was removed from the B1 blend to create blend B2, fewer blueberry hawthorn flies exhibited upwind directed flights (8%) compared with B1 (88%; $P<0.001$, 1 *df*), supporting the essential role of butyl acetate for blueberry hawthorn flies (Fig. 5a). Further support for a major role of butyl acetate came from a test of 28 blueberry flies collected from Lufkin, TX, USA in 2009. These flies also displayed a dramatic decrease in response when butyl acetate was not present in the blueberry hawthorn blend (75% upwind flight to B1 vs. 0% to B2; $P<0.001$, 1 *df*) (Fig. 5b). Moreover, addition of DMNT to B1 to create modified blend B4 also reduced upwind directed flight behavior for the 28 Lufkin, TX, USA, flies (75% upwind

flight to B1 vs. 18% to B4; $P<0.001$, 1 *df*), suggesting that blueberry hawthorn-origin fly flight behavior was antagonized by the presence of DMNT, a key green hawthorn volatile (Fig. 5b) in the mixture.

Discussion

We developed synthetic volatile blends for green (*C. viridis*) and blueberry hawthorn (*C. brachyacantha*) fruit using GC-EAD and GC-MS analysis of SPME and adsorbent samples. In the flight tunnel, green and blueberry hawthorn-origin flies displayed maximal levels of upwind directed flight to their respective natal blends and reduced response levels to their non-natal blends. The reduced response levels were due to differences in key volatiles that comprised the behaviorally active blend for each host, and to the presence of non-natal fruit volatiles that function as behavioral antagonists.

Two key differences were discovered between the green and blueberry hawthorn blends. The first was the presence of DMNT in the green hawthorn blend and its absence from the blueberry hawthorn blend. Addition and subtraction of DMNT to synthetic green and blueberry hawthorn blends demonstrated the critical importance of the compound for stimulating upwind oriented flight for green hawthorn-origin flies and for antagonizing the upwind flight of blueberry hawthorn flies. The compound DMNT has not been found in the fruit of other southern hawthorn species besides green hawthorn (blueberry hawthorn and three mayhaw species; Cha et al., 2011b, this issue), suggesting that it may be a unique volatile in the blend distinguishing *C. viridis*. The second difference is the presence of butyl acetate in the blueberry hawthorn blend and its absence from the green hawthorn blend. Addition and subtraction of butyl acetate to the respective synthetic blends showed the critical importance of this volatile for stimulating upwind oriented flight in blueberry flies and for antagonizing the upwind flight of green hawthorn flies. The striking contrast in preference behavior indicates that southern *R. pomonella* flies that infest green vs. blueberry hawthorn differ in their host odor response phenotypes. Butyl acetate has not been found in the fruit of other southern hawthorn species that co-occur with the blueberry hawthorn across its range in eastern Texas and Louisiana (e.g., western mayhaw, *C. opaca*), although the compound is present in the more eastern distributed mayhaws, *C. aestivalis* and *C. rufula* (Cha et al., 2011b, this issue). Butyl acetate may, therefore, be a key compound in the blend that distinguishes *C. brachyacantha* throughout its geographic distribution in the South. The results for DMNT and butyl acetate continue a pattern we first observed in northern *R. pomonella* populations (Linn et al., 2005a, b) involving positive orientation of flies to key mixtures of volatile components present in the adsorbent extract profiles of their natal host fruit, and antagonism or arrestment of upwind flight when unique compounds found in alternative non-natal fruit are added to the natal blend. Antagonism is important because it indicates that when flies shift to a new host plant, not only do they evolve to positively behaviorally respond to the volatile profile of the new fruit (where offspring survivorship is presumably higher) but also to avoid certain volatiles of other, alternative host fruit (where fitness should be lower).

The green hawthorn and blueberry hawthorn synthetic blends also showed similarities. Perhaps noteworthy, both blends, as well as the northern downy hawthorn, the dogwood blend, and the three southern mayhaw blends, share 3-methybutan-1-ol in common. Moreover, 3-methybutan-1-ol is not present in the apple blend, and is a potent behavioral antagonist for apple-origin fly flight behavior (Linn et al., 2005a). Our current results, therefore, further underscore that 3-methybutan-1-ol may be an essential component of behaviorally active volatile blends for hawthorn infesting *R. pomonella* flies. In comparison, the volatile 1-octen-3-ol that we previously showed to be a key agonist volatile for dogwood fly behavior and a behavioral antagonist for apple flies (Linn et al., 2005a), while present in both the green hawthorn and blueberry hawthorn blend, did not significantly affect the upwind flight of green or blueberry hawthorn flies.

Because of limitations in the number of available flies, we were not able to conduct exhaustive subtraction assays for all of the compounds in the respective natal blends. Thus, it is not possible to definitively say whether any of the remaining compounds in the green hawthorn and blueberry hawthorn synthetic blends (e.g., butyl hexanoate and hexyl butanoate) are essential for behavioral activity and discrimination. We also recognize that important differences in the ratio of common compounds could be important (e.g., Cha et al., 2011a). For example, butyl hexanoate is an important volatile for the northern downy hawthorn (*C. mollis*) flies, but is present in very low quantities compared to the apple blend (<1 vs. 44%; Nojima et al., 2003a), and high proportions of butyl hexanoate in the northern downy hawthorn blend have been shown to act antagonistically on upwind flight responses (Linn et al., 2005a).

Coupled with our results for three mayhaw host plants in the southern USA (Cha et al., 2011b, this issue), the current study does not support the hypothesis that the introduction of a geographically differentiated, southern hawthorn-infesting form of *R. pomonella* was the direct source of the apple-infesting race of the fly in the North (Carson,

1989; see Bush et al., 1989). In the current study, flies collected from both green and blueberry hawthorn fruit exhibited low response levels with the apple blend in flight tunnel assays (0 and 6% upwind directed flight, respectively). Indeed, the proportion of upwind directed flight exhibited by southern green hawthorn and blueberry hawthorn-origin flies to the apple blend was lower than that shown for the downy hawthorn blend (27 and 25%, respectively). Green and blueberry hawthorn-infesting populations of *R. pomonella* therefore do not preferentially orient to apple and are not "pre-adapted", direct precursors to the apple race in the North. However, just like southern mayhaws (Cha et al., 2011b, this issue), both green and blueberry hawthorn fruit from the South also contain certain compounds present in the apple blend and absent in the fruit of the downy hawthorn, the major hawthorn host attacked by *R. pomonella* in the North. In particular, mayhaw, green hawthorn, and the apple blend all contain butyl butanoate, propyl hexanoate, butyl hexanoate, hexyl butanoate, and pentyl hexanoate. Blueberry and green hawthorn flies are thus capable of detecting certain components of the apple blend, and some southern flies are capable of responding to both hawthorn and apple blends, supporting the hypothesis that odor response phenotypes in the South may have contributed to pre-standing variation in northern hawthorn populations facilitating a rapid, sympatric shift to apple. Rather than a pre-adapted apple race in the South, our results instead provide more evidence for the possible existence of differentiated races (or even sibling species) of hawthorn-infesting *R. pomonella* in the South.

We now have developed active synthetic blends for eight different host fruit of *R. pomonella* group flies. With the addition of the green hawthorn and blueberry hawthorn blends in the current study, we have now characterized fruit volatile profiles for most of the major hawthorn hosts infested by *R. pomonella* across the northern and southern USA. Development of these blends will allow us to further characterize phenotypic patterns and elucidate the genetic architecture of host plant preference in the classic *R. pomonella* system, leading to a greater understanding of the role that host volatile recognition plays in phytophagous insect speciation (Smadja and Butlin, 2009). The importance of pre-standing variation in hawthorn flies to recognize certain specific fruit volatiles in apple may now become clearer as we approach a complete picture of host race formation among southern *R. pomonella* populations.

Acknowledgments We thank Tracy Arcella, Stewart Berlocher, Scot Egan, Andrew Forbes, Glen Hood, Andy Michel, Matt Michel, Jim Stevens, Sheina Sim, and David Riskind of Texas State Parks for help in collecting fruit and fly samples, thoughtful discussion, and/or assistance in helping us prepare the manuscript for publication. We also thank Callie Musto, Kathy Poole, and Paula Fox for maintaining the flies received from Notre Dame, and Harvey Reissig, Dave Combs, and Cynthia Smith for use of the Geneva, NY apple maggot colony. We also thank Aijun Zhang for the synthesis of (3*E*)-4,8-dimethyl-1,3,7-nonatriene. The research was supported by grants to J. L.F. and C.L. from the National Science Foundation and to J.L.F. from the USDA.

converted by glucosidases to the more reactive aglycones when plant cells are damaged by insect herbivory and pathogen infection (Niemeyer 2009).

While largely viewed as constitutive defenses, individual benzoxazinoid pools can be influenced greatly by biotic stresses. For example, insect herbivory can increase DIMBOA levels in wounded leaves and shoots of maize (Gutierrez et al. 1988; Erb et al. 2009). In other studies, DIMBOA-Glc [2-(2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one)-β-D-glucopyranose] levels decreased with insect and pathogen infection, but there was a corresponding increase in the concentration of HDMBOA-Glc [2-(2-hydroxy-4,7-dimethoxy-1,4-benzoxazin-3-one)-β-D-glucopyranose] (Oikawa et al. 2004). Increases in HDMBOA-Glc result from the methylation of existing pools of DIMBOA-Glc by a DIMBOA-Glc 4-O-methyltransferase (Oikawa et al. 2001, 2002), but there also is evidence for *de novo* biosynthesis of HDMBOA-Glc in response to endogenous peptide defense signals (Huffaker et al. 2011). Similar to DIMBOA, HDMBOA has been shown to have a negative impact on insect growth and development. When incorporated into artificial diet, HDMBOA-Glc effectively decreased the survival and fecundity of the aphid, *Metopolophium dirhodum* (Walker) at concentrations as low as 1 mM (Cambier et al. 2001). In a nitrogen restricted diet, HDMBOA-Glc completely inhibited the growth of southwestern corn borers (*Diatraea grandiosella* Dyar) (Hedin et al. 1993). Although there is evidence that benzoxazinoids function in insect defense, little is known regarding their function with respect to ECB stem herbivory.

In maize leaves, the plant defense hormone, jasmonic acid (JA) previously has been shown to regulate the concentration and composition of benzoxazinoids (Oikawa et al. 2001). Treating leaves exogenously with JA resulted in increased HDMBOA-Glc and decreased DIMBOA-Glc levels similar to those observed with biotic stresses. JA is a long established endogenous regulator of induced plant defenses, including proteins that can have anti-nutritive or toxic effects on insects (Howe and Jander 2008).

Plant defense signaling often involves cross talk among multiple endogenous phytohormones that provides resistance against invading pathogens and insects while reducing fitness costs to the plant (Koornneef and Pieterse 2008). JA frequently works synergistically with the phytohormone ethylene (ET) in regulating defense responses in plants. For example, kauralexins, a class of maize diterpenoids, are induced in young maize stems in response to the combination of JA and the ethylene releasing compound, ethephon, but not JA alone (Schmelz et al. 2011). Kauralexins also increased in response to ECB stem herbivory. In a choice assay, ECB avoided stem tissues treated with kauralexins, thus indicating that these compounds have anti-feedant activity (Schmelz et al. 2011). Contrary to ET, phytohormones such as salicylic acid (SA) and indole-3-acetic acid (IAA) generally negatively regulate JA signaling (Koornneef and Pieterse 2008).

Although herbivore induced defenses in leaves have been studied widely in crop plants, much less is known concerning insect induced defenses in stems. In the current study, we characterized chemical changes that occur in maize stem internode tissues in response to ECB herbivory. We measured changes in concentrations of the defensive compounds, benzoxazinoids and kauralexins. We also measured changes in phytohormones in an effort to understand how these signals may influence the expression of maize defenses. Additionally, we determined the impact of ECB-induced maize defenses on the growth of ECB.

Methods and Materials

Plant and Insect Materials. Zea mays var. Golden Queen seeds were germinated in three gallon pots, 4 plants per pot, in MetroMix 200 (Piedmont Pacific, Statham, GA, USA) containing 1.9 gl^{-1} 14-14-14 Osmocote (Scotts, Marysville, OH, USA). Plants were maintained in a greenhouse supplemented with 400 W high pressure sodium lamps (Higuchi Inc., Plano, TX, USA) and multi-vapor lamps (GE, Cleveland, OH, USA) for a 12-h photoperiod. Relative humidity was 70%, and temperature was maintained at 24°C: 28°C (night: day). Plants were watered daily and fertilized weekly with 1.25 mg L^{-1} Peters 20-20-20 water soluble fertilizer (Scotts). Plants used for studies were approximately 30 d-old and had 11–13 leaves. ECB were supplied by Benzon Research (Carlisle, PA, USA). Prior to infesting plants with ECB, newly molted fifth instar larvae were fed maize whorl tissue overnight.

Experimental Treatments For controlled establishment of ECB herbivory, a hole was made with a #1 cork borer in the internode tissue in the middle of the 2nd and 3 rd nodes from the base of the stem. ECB were introduced by using a modified 200 μl pipette tip; 2 cm of the narrow end of the tip was removed to allow the ECB to move into the stem, which promoted feeding at this site. At indicated time points, approximately 2 cm stem sections were collected around the initial site of wounding. As a damage control, plants were wounded with a cork borer as described above, and samples were collected around the wound site during the same sample periods. Corresponding tissue samples also were collected from plants that were not previously damaged. For time course studies, three biological replicates were collected, and each replicate was comprised of tissue pooled from 3 different plants.

For the no choice feeding assay, fifth instars were introduced above the second node as described above. An

equal number of plants were wounded using the cork borer or were left undamaged. After 24 h, 2 cm stem sections surrounding the initial damage site were collected for both the ECB and wound treatments. Developmentally similar tissue was collected from the non-treated control plants. To estimate concentrations of benzoxazinoids and kauralexins present at 24 h, samples were collected and analyzed from 6 representative plants for each treatment.

To examine the effects of exogenously applied JA and ET precursor, 1-aminocyclopropane-1-carboxylic acid (ACC), a hole was made with a #1 cork borer in the middle of the 2nd and 3rd nodes from the base of the stem and a 60 µl solution of JA–Na^+, [methyl jasmonate (Bedoukian Research, Danbury, CT, USA) was saponified with 10 M NaOH, diluted with excess H_20, passed through C18 solid phase extraction column, washed with H_20, eluted with 4:1 MeOH:H_20 and evaporated to yield JA–Na+], ACC (Sigma-Aldrich Corp., St. Louis, MO, USA), or a combination of JA–Na^+ and ACC prepared in water was applied to the wound site. Total applied amounts were 660 nmol $plant^{-1}$ JA–Na^+ and 300 nmol $plant^{-1}$ ACC. The wound site was sealed with parafilm to prevent drying and samples (N=5) were collected after 24 h.

Biochemical Analysis of Defense Metabolites and Phytohormones Concentrations of the defense metabolites, anthranilate, indole, and kauralexins, and the phytohormones, JA, SA, and IAA were measured using the vapor phase extraction method described by Schmelz et al. (2004). Concentrations of kauralexins A1–A3 and B1–B3 (Schmelz et al. 2011) were combined and reported as total kauralexins. Concentrations of total JA were calculated as a sum of the concentrations of *trans*- and *cis*-JA isomers. Benzoxazinoids were measured using HPLC as previously described (Huffaker et al. 2011). Ethylene emission was measured by sampling 1 ml of headspace from maize stem sections sealed in 27 ml plastic tubes followed by GC analysis (Schmelz et al. 2003a).

Gene Expression Analysis RNA from approximately 200 mg of stem tissue was extracted using a modified TRIzol® reagent (Invitrogen, Carlsbad, CA, USA) protocol. To help remove contaminants, the chloroform phase separation step was completed two times. RNA was precipitated using 350 µl isopropanol, and samples were washed twice with 75% (v/v) ethanol. Two µg of RNA were reverse transcribed into cDNA using RETROscript® First Strand Synthesis Kit (Applied Biosystems, Carlsbad, CA, USA). Quantitative real-time PCRs consisted of 1x Power SYBR Green Master mix (Applied Biosystems), 300 nM each of forward and reverse primers, 0.8 µl of cDNA template and nuclease-free ddH_2O to a final volume of 20 µl. Amplification was performed using the ABI 7300 sequence detection system (Applied Biosystems) following standard thermal profile conditions: 50°C for 2 min, 95°C for 10 min, followed by 40 cycles of 95°C for 15 sec and 60°C for 1 min. Data were analyzed with SDS 1.3.1 software (Applied Biosystems). Relative expression levels were determined for three independent biological replicates that consisted of a pool from 3 plants, and all the reactions were run in triplicate. Threshold cycle (Ct) values for *anthranilate synthase subunit 2* (*ASsub2*), *anther ear 2* (*An2*), and *allene oxide synthase* (*AOS*) were normalized to *elongation factor 1α* (*EF 1α*) and the values for *1-aminocyclopropane-1-carboxylate oxidase* (*ACC Ox*) was normalized to the housekeeping gene encoding *ribosomal protein 17* (*RPL17*). As per Livak and Schmittgen (2001), ΔC_T *vs*. log input amount of RNA were plotted to determine which primer pairs had equivalent efficiencies (Supplemental Fig. 1). The levels of each gene transcript were calculated relative to its corresponding untreated control. Fold-changes of RNA transcripts were calculated by the $2^{-\Delta\Delta Ct}$ method (Livak and Schmittgen 2001). The specificities of real-time PCR products were verified on 1% agarose gels. The gene-specific oligonucleotides that were designed to span an exon-exon junction to avoid amplication of genomic DNA are listed in Table 1.

No Choice Feeding Assay with ECB As described above, stem sections (2 cm) were collected from control, wound, and ECB damaged tissues, weighed, and placed into sterile 12-well tissue culture plates (Fisher Scientific, Vernon Hills, IL, USA). For each stem section, a newly molted 5th instar ECB that had been previously maintained on maize leaf tissue was weighed and then placed in the well with the stem tissue. Newly molted final instars were used because typically older larvae tunnel into maize stems, whereas younger larvae feed on leaves. After 24 h, both the stem tissue and ECB larvae were weighed to determine the amount of tissue consumed and the percent weight gain for each ECB. A total of 13 ECB were used for each treatment.

Statistical Analyses With the exception of the percent weight gain data, all data were square-root transformed prior to statistical analysis (Zar 1999). The percent weight gain data were arcsine square root transformed (Zar 1999). Analysis of variance (ANOVAs) and Tukey HSD tests were used to make multiple comparisons among control, wound, and ECB samples. All statistical analyses were performed with JMP 4.0 (SAS Institute, Cary, NC , USA).

Results

ECB Stem Herbivory Induces Accumulation of Maize Chemical Defenses. Transcript levels of *ASsub2*, a gene predicted to encode an anthranilate synthase (Huffaker et al.

Table 1 Primer sequences used to amplify biosynthetic enzymes

2011), were significantly upregulated as early as 3 h after initiation of ECB feeding, and remained elevated over the entire 24 h time course (Fig. 1a). Induction of *ASsub2* preceded the induction of anthranilate. Anthranilate levels increased approximately 30-fold at 12 h and 100-fold at 24 h as compared to control tissue (Fig. 1b). Indole also accumulated in ECB damaged tissue, but levels peaked at 3 h and returned to basal levels by 12 h (Fig. 1c). The benzoxazinoid profile was altered significantly by ECB stem herbivory at 24 h (Fig. 1d). Levels of DIMBOA-Glc decreased three-fold in ECB damaged tissue as compared to control tissue. In wounded and ECB damaged tissues, an additional benzoxazinoid, HDMBOA-Glc, was detected. Levels of HDMBOA-Glc were 2.2-fold greater in ECB damaged tissue as compared to wound tissue. Overall total benzoxazinoid levels increased from 765 ng g^{-1} FW in control tissue to 1081 and 1350 ng g^{-1} FW in wounded and ECB damaged tissue, respectively.

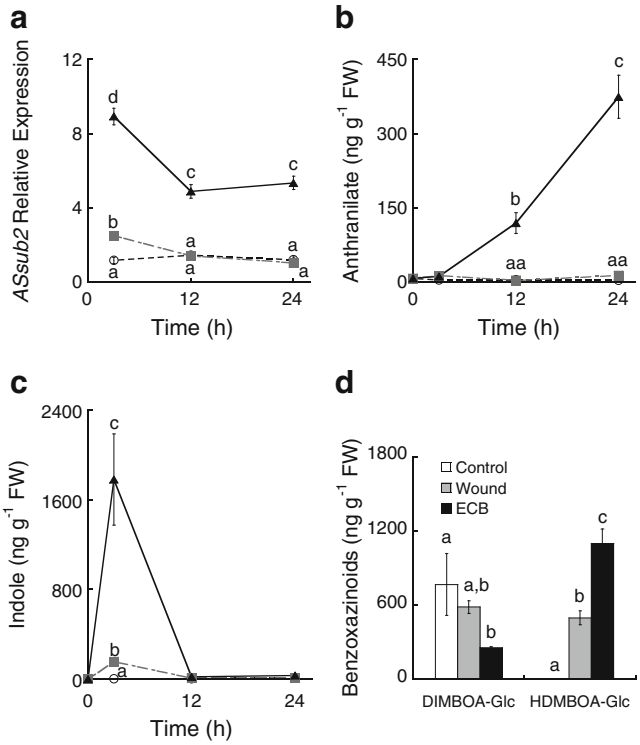

Fig. 1 European corn borer (ECB) herbivory in maize stems induces changes in benzoxazinoids and their precursors. **a** Average relative expression of the *anthranilate synthase subunit 2* (*ASsub2*) gene over time in maize stems that were untreated (○), wounded (■), or infested with ECB (▲;*N*=3, ±SEM). Average concentrations of (**b**) anthranilate and (**c**) indole over time (*N*=3, ±SEM). **d** Comparison of average concentrations of 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one)-β-D-glucopyranose (DIMBOA-Glc) and 2-(2-hydroxy-4,7-dimethoxy-1,4-benzoxazin-3-one)-β-D-glucopyranose (HDMBOA-Glc) at 24 h between control (white bars), wounded (gray bars), and ECB infested stems (black bars; *N*=6, ±SEM). Different letters (a-c) represent significant differences ($P<0.01$ for all ANOVAS; $P<0.05$ for Tukey test corrections for multiple comparisons)

Expression of *An2*, a gene encoding an *ent*-copalyl diphosphate synthase associated with kauralexin synthesis (Schmelz et al. 2011), is significantly upregulated in both wounded and ECB treated tissues as compared to control tissues (Fig. 2a). At 24 h, *An2* transcript levels displayed 9.8- and 31-fold increases in wounded and ECB damaged tissues, respectively. When comparing concentrations at 24 h, total kauralexin levels displayed 2.3-fold greater increases in ECB damaged tissue compared to wounded tissue alone (Fig. 2b).

JA and ET Levels Are Upregulated in Response to ECB Herbivory To examine defense signaling in maize stems, we analyzed ECB induction of the phytohormones JA and ET and transcript levels of their key biosynthetic enzymes. Allene oxide synthase (AOS) is the first dedicated enzyme in the biosynthesis of JA (Wasternack and Kombrink 2010), and the expression of the *AOS* gene is significantly upregulated in response to wounding, and to an even greater extent, ECB feeding as early as 3 h (Fig. 3a). *AOS* transcript levels remained elevated at 12 h in ECB damaged tissues before decreasing at 24 h. In wounded tissue, *AOS* expression levels sharply declined at 12 h and remained low throughout the remainder of the time course. Even though *AOS* increased in both treatments, JA levels significantly increased only in ECB damaged tissue (Fig. 3b). JA levels peaked at 3 h in ECB damaged tissue with a 6.8-fold and 3.7-fold increase as compared to control and wounded tissue, respectively. JA levels remained elevated in ECB damaged tissue, although levels did slightly decrease at 12 h.

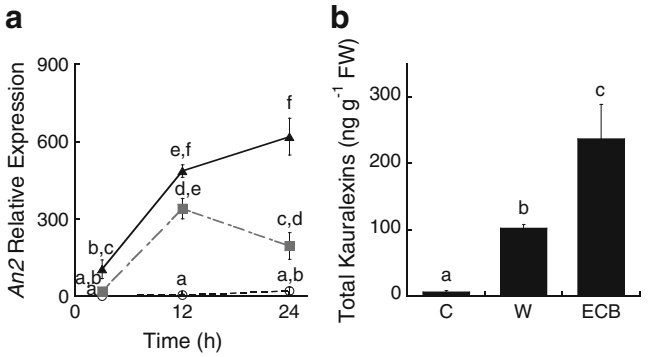

Fig. 2 European corn borer (ECB) herbivory elicits an accumulation of total kauralexins. **a** Average relative expression of the *anther ear 2* (*An2*) gene over time in maize stems that were left undamaged (○), wounded (■), or infested with ECB (▲; N=3, ±SEM). **b** Comparison of the average concentration of total kauralexins at 24 h between control (C), wounded (W), and ECB infested stems (N=6, ±SEM). Different letters (a–f) represent significant differences (P<0.01 for all ANOVAS; P<0.05 for Tukey test corrections for multiple comparisons)

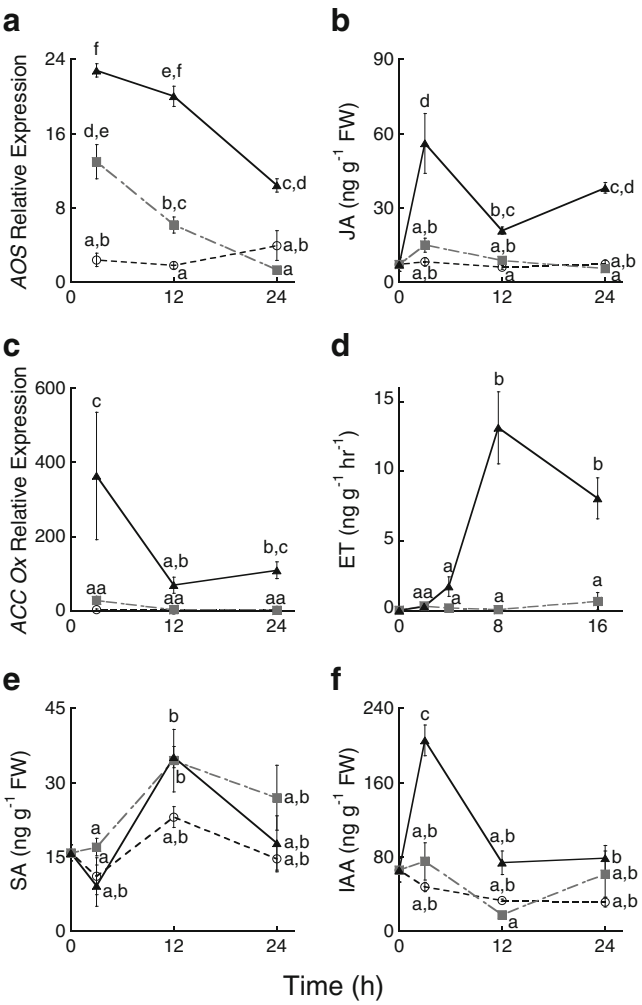

Fig. 3 Changes in phytohormones in response to European corn borer (ECB) herbivory. **a** Average relative expression of the *allene oxide synthase* (*AOS*) gene over time in control (○), wounded (■), and ECB damaged maize stems (▲). **b** Average concentration of jasmonic acid (JA) over time. **c** Average relative expression of the *1-aminocyclopropane-1-carboxylate oxidase* (*ACC Ox*) gene over time. Average concentrations of (**d**) ethylene (ET), (**e**) salicylic acid (SA), and (**f**) indole-3-acetic acid (IAA) over time. Within each panel, different letters (a–f) represent significant differences (P<0.01 for all ANOVAS; P<0.05 for Tukey test corrections for multiple comparisons). For all graphs; N=3, ±SEM

Transcript levels of the gene encoding the ethylene biosynthetic enzyme, 1-aminocyclopropane-1-carboxylic acid oxidase (ACC Ox), also were significantly higher in ECB damaged tissue. At 3 h, transcript levels were 107- and 13-fold greater than control and wound samples, respectively (Fig. 3c). Even though levels of the *ACC Ox* transcript significantly decreased in ECB damaged tissues after 3 h, the average transcript levels remained consistently higher than control and wounded samples over the 24 h time course. Ethylene emission in ECB damaged stem tissue peaked at 8 h (Fig. 3d). Compared to the time zero sample, there was no increase in ET emission detected in wounded tissue at any time point.

In addition to JA and ethylene, salicylic acid (SA), and indole-3-acetic acid (IAA) levels were measured in control, wound, and ECB damaged tissues. There was no significant difference observed for SA levels when comparing the three treatments at 3, 12, and 24 h (Fig. 3e). There was, however, a significant increase in IAA detected in ECB damaged tissues at 3 h (Fig. 3f). As compared to control and wounded samples, IAA was induced 4.3- and 2.7-fold, respectively. IAA levels then decreased to basal levels at 12 h.

JA and ET Regulate Changes in Benzoxazinoids To test whether JA and ET may have a role in regulating ECB-induced responses in stems, JA and the ET precursor, (ACC), were applied to mechanically wounded maize stems, and levels of benzoxazinoids and kauralexins were measured. Similar to the trend observed with ECB feeding, exogenous application of JA alone or in combination with ACC resulted in decreases of DIMBOA-Glc as compared to control and wounded plants (Fig. 4). However, only the combination of JA and ACC resulted in significant increases in HDMBOA-Glc above wounding alone as evidenced by 3.2-fold higher concentrations. Treatment with ACC did not result in any changes that were significantly different from wounding alone. HDMBOA-Glc was not detected in unwounded control plants.

Treating stem internode tissues exogenously with JA, ACC, or the combination of JA and ACC did not significantly affect levels of kauralexins (Supplemental Fig. 2). However, the concentration of total kauralexins was significantly increased in wounded tissue as compared to control tissue.

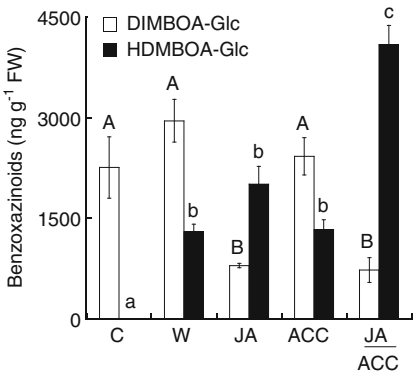

Fig. 4 In maize stem internode tissue, treating with a combination of jasmonic acid (JA) and the ethylene (ET) precursor, aminocyclopropane-1-carboxylic acid (ACC), elicits changes in benzoxazinoids similar to those observed with European corn borer (ECB) feeding. Comparison of average concentrations of 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one)-β-D-glucopyranose (DIMBOA-Glc, white bars) and 2-(2-hydroxy-4,7-dimethoxy-1,4-benzoxazin-3-one)-β-D-glucopyranose (HDMBOA-Glc, black bars) at 24 h between control (C), wounded (W), JA, ACC, and JA and ACC treated stems (N=5, ±SEM). Upper case letters (A–B) represent significant differences in DIMBOA-Glc levels and lower case letter (a–c) represent significant differences in HDMBOA-Glc levels (P<0.01 for all ANOVAS; P<0.05 for Tukey test corrections for multiple comparisons)

ECB Growth not Affected by Chemical Defenses in Maize Stems To determine if ECB-induced maize defenses could effectively inhibit the growth of ECB, final instars were allowed to feed on stem tissues that had previously experienced no treatment, wounding, or ECB damage for 24 h. After 24 h of feeding on these tissues, no significant differences were observed between the percent weight gains (Fig. 5a) or tissue consumption (Fig. 5b) of ECB feeding on control, wounded, and ECB damaged stem tissues. This suggests that ECB larvae are largely unaffected by short-term changes in maize defenses.

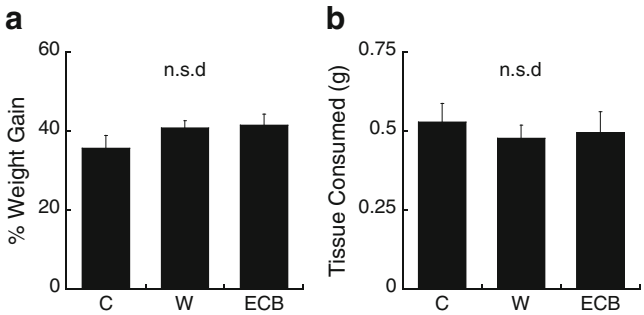

Fig. 5 European corn borer (ECB) growth is not affected by the presence of maize chemical defenses. **a** Average percent weight gain for ECB fed for 24 hrs on tissues previously subjected to either no treatment (C), wounding (W), or ECB stem herbivory (ECB). **b** Average amount of tissue consumed by ECB over the 24 hr feeding period. Not statistically different (n.s.d) indicates P>0.05 for all ANOVAs. For both graphs; N=13, ±SEM

Discussion

ECB are one of the most important insect pests of maize (Ostlie et al. 1997); however, surprisingly little is known about ECB-induced chemical defenses in maize stems. For example, DIMBOA is a constitutively expressed phytoanticipan known to function in defense against ECB herbivory in leaves (McMullen et al. 2009; Niemeyer 2009), but the dynamics of benzoxazinoids in maize stems in response to ECB herbivory has not been well studied. For leaves of young maize seedlings, biotic cues, including fungal infection and insect herbivory, have been shown to promote the synthesis of the benzoxazinoid, HDMBOA-Glc with a corresponding decrease in DIMBOA-Glc levels (Oikawa et al. 2001, 2004). In this study, we observed a similar pattern, thus demonstrating that insect inducible benzoxazinoid production continues to occur in mature plants and importantly in stem tissues.

In an effort to understand how defenses like benzoxazinoids are regulated in response to ECB stem herbivory, levels of plant hormones were analyzed in control, wounded, and ECB damaged tissues. Significant increases were observed for JA and ET in response to ECB feeding indicating that these two hormones may be involved in regulating the expression of maize stem defenses. Applying JA and the ET precursor, ACC, concurrently to stem internode tissue mimicked the HDMBOA-Glc accumulation observed with ECB feeding, and provided additional support for this hypothesis. While similar, these results appear to differ with the plant hormonal regulation of maize benzoxazinoids in leaves where the application of JA alone to maize leaves triggers HDMBOA-Glc accumulation (Oikawa et al. 2001). It is possible that different signaling mechanisms may be utilized in different plant tissues. A similar discrepancy was observed when analyzing total kauralexins, a class of diterpene phytoalexins that have ECB anti-feedant properties (Schmelz et al. 2011). Concentrations of kauralexins were upregulated significantly when young, actively growing stem tissue was treated with a combination of JA and ethephon or JA and ACC (Schmelz et al. 2011). In the current study, when stem internode tissue (tissue that is not actively growing or differentiating) was treated with JA, ACC, or the combination of JA and ACC, the levels of kauralexins were not significantly altered. However, total kauralexins did increase in stem internode tissue when subjected to ECB herbivory, indicating a requirement for additional, currently unknown stimuli beyond JA and ET. Thus, the hormonal regulation of benzoxazinoids and kauralexins appears to be tissue dependent, and although both classes of defensive compounds are induced in response to ECB stem herbivory, they appear to require different combinations of phytohormone signals within the same tissue.

In addition to JA and ET, the phytohormone IAA also may be involved in regulating the induction of defensive com-

pounds in maize stems. IAA generally is considered an antagonist of JA, and it can suppress the induction of defensive compounds such as protease inhibitors and nicotine (Baldwin et al. 1997; Saniewski et al. 2002). Generally, IAA decreases in response to wounding (Thornburg and Li 1991, Schmelz et al. 2003b), however, it rapidly and significantly increased in maize stems in response to ECB herbivory. We are currently in the process of trying to understand how IAA may function in the maize defense response.

Both benzoxazinoids and kauralexins have anti-insect properties (McMullen et al. 2009; Niemeyer 2009; Schmelz et al. 2011), yet it is unknown how these compounds function *in planta* against ECB stem boring. DIMBOA functions in defense against ECB feeding on maize leaves (McMullen et al. 2009; Niemeyer 2009), but the levels of DIMBOA are much lower in stem tissue (Niemeyer 2009), and the levels decrease even further with ECB stem herbivory. As compared to DIMBOA levels in young leaves, the low levels in stems likely fail to afford sufficient protection. We demonstrate that ECB and the concurrent application of JA and ACC induces HDMBOA-Glc in stems, but far less is known regarding the activity of this compound, in part because benzoxazinoids such as HDMBOA are highly unstable (Woodward et al. 1978; Grambow et al. 1986). There are studies suggesting that HDMBOA can have anti-insect activity (Hedin et al. 1993; Cambier et al. 2001), but the effect of HDMBOA on ECB has not yet been investigated. Unlike HDMBOA, the effect of kauralexins on ECB has been studied, and these compounds have ECB anti-feedant activity when applied to stem sections at 50 $\mu g\ \mu g^{-1}$ FW (Schmelz et al. 2011). This treatment is consistent with the concentration of kauralexins induced by fungal pathogens (Schmelz et al. 2011), but it is much higher than the concentration in ECB damaged stem sections that occurs at 24 h (0.2 $\mu g\ \mu L^{-1}$). However, similar to benzoxazinoids, kauralexins can be unstable and, therefore, the biological activity detected in the ECB choice feeding assay (Schmelz et al. 2011) may be a conservative estimate due to degradation.

To minimize the degradation of benzoxazinoids and kauralexins, we fed ECB previously treated stem tissue instead of artificial diet supplemented with purified products. In addition to known phytochemicals, the tissue would have an array of other inducible defenses present, which could potentially function synergistically in defense against ECB herbivory. Inducible plant defenses often effectively increase resistance against insect feeding by reducing insect growth and decreasing fecundity (Agrawal 1999; Bruinsma et al. 2007; Abe et al. 2008, 2009; Stout et al. 2009; Brunissen et al. 2010). In contrast, plants that are deficient in JA signaling and have a compromised defense response are far more susceptible to insect feeding (Halitschke and Baldwin 2003; Abe et al. 2008, 2009; Scott et al. 2010). Although maize stems accumulated significant quantities of defensive compounds 24 h after the initiation of ECB feeding, the growth of ECB was not affected. It is possible that long-term exposure to these defenses beginning at an earlier developmental stage could have a significant impact on the growth and development of ECB; however, our current findings suggest that ECB may have mechanisms to cope with maize chemical defenses. In the related Asian corn borer [*Ostrinia furnacalis* (Guenée)], larvae can withstand low levels of hydroxamic acids, most likely by enzymatically degrading them (Kojima et al. 2010). In contrast, the rice armyworm [*Mythimna separata* (Walker)] glycosylates benzoxazinoids making them less reactive (Sasai et al. 2009). ECB may have similar detoxification strategies, or alternatively, defenses other than the ones studied here may be more important in stem resistance against ECB feeding in the stem (McMullen et al. 2009). For example, transgenic maize expressing a wheat oxalate oxidase gene had decreased DIMBOA levels, but increased resistance that was positively correlated to increases in concentrations of soluble phenolic acids (Mao et al. 2007). Although the defenses induced by ECB in maize stems appear not to be effective against ECB, they may function against subsequent threats by invading fungal pathogens. In addition to anti-insect activity, both benzoxazinoids and kauralexins have been shown to have anti-fungal properties (Niemeyer 2009; Schmelz et al. 2011).

The current study provides a basis for understanding inducible defenses in maize stems and in part, how these defenses are regulated. ECB growth does not appear to be affected by these defenses, leading to many interesting questions as to how ECB subverts or tolerates maize defenses.

plant's natural development. Thus, ontogenetic trajectories in plant constitutive defenses can interact with herbivore-induced defenses leading to changes in the occurrence and strength of induction in unpredictable ways. This question is of particular interest for annual and/or short-lived perennial plant species, whose responses to single or multiple damage events over a growing season are likely to interact with ontogenetic constraints in affecting a plant's ability to respond to herbivory. Yet, empirical tests that assess the combined role of multiple damage events and age-dependent constraints on the ability of plants to induce defenses are scarce.

Constitutive defenses have been shown to vary as a function of plant development, with defensive traits increasing or decreasing over time as resource allocation constraints and plant functional priorities change (Boege and Marquis, 2005). Furthermore, dissimilar ontogenetic trajectories in constitutive chemical defenses have been reported among plant tissues, such as between above- and below-ground tissues (Williams and Ellis, 1989; Bellostas et al., 2007). These ontogenetic trajectories can encompass small to large qualitative and quantitative changes in defensive traits, which may in turn influence the identity of herbivores associated with different plant developmental stages (Waltz and Whitham, 1997; Thomas et al., 2010). Despite the increasing interest in documenting developmental variation in constitutive defenses, the role of plant age in explaining herbivore induced defenses within and among tissues continues to be largely unexplored. In those systems where age-dependent induction of defenses was assessed, however, the ability of plants to resist or tolerate herbivory has been shown to strongly depend on plant developmental stage (Van Dam et al., 2001; Warner and Cushman, 2002; Boege et al., 2007; Muola et al., 2010).

Physiological and morphological constraints during plant ontogeny can lead to strong age-dependent induced responses to herbivory, with opposite trends being predicted for resistance and tolerance. Induced chemical defenses, usually considered a cost-saving strategy for plants, are associated with scenarios where resource allocation constraints limit constitutive defenses or are dependent on actively growing and differentiating tissues (Karban and Baldwin, 1997; Cipollini et al., 2003). Because younger plant stages often are more susceptible to herbivory, have lower levels of constitutive defenses, and proportionally more undifferentiated and actively growing tissues than older plant stages, the ability of plants to induce defenses is predicted to be greater in younger developmental stages and to lessen as plants mature (Karban and Baldwin, 1997). Alternatively, secondary growth that aims to compensate for lost tissue requires the reallocation of resources stored in undamaged tissues, as well as the enhancement of photosynthetic rates and nutrient uptake from the soil. Therefore, tolerance to herbivory is predicted to increase with plant age due to greater capacity to acquire resources and/or higher probability to have already stored reserves (Strauss and Agrawal, 1999; Haukioja and Koricheva, 2000). While there is some support for such patterns (Boege and Marquis, 2005; Barton and Koricheva, 2010), this is mostly based on comparisons of single herbivore damage events during plant development, and as such, do not reflect potential plant responses due to natural variation in multiple and successive damage events over the course of development.

Sequential damage over a growing season can alter age-dependent induced responses to herbivory in two ways. First, repeated damage events by an herbivore species can induce an enhanced response as compared to a single damage event (e.g., Ruuhola et al., 2007; Roitto et al., 2009), as a result of what has been called 'immunological memory' (Baldwin and Schmelz, 1996). Alternatively, plant responses to a previous damage event may reduce the ability of a plant to defend itself against a later attacker (e.g., Viswanathan et al., 2007; Poelman et al., 2008). This pattern, usually termed 'priority effect', can arise as a consequence of physiological limitations such as negative cross-talk between pathways elicited by different herbivores (Verhage et al., 2010) or because of resource limitations if resources used during an initial response are unavailable for use in later responses. Thus, history of damage over a season or throughout plant development can strongly enhance or diminish expected age-dependent induced responses, potentially altering key plant-herbivore interactions. Furthermore, because allocation patterns and synthesis of chemical defenses may vary within and among tissues over time as a response to plant development and history of damage (Williams and Ellis, 1989; Van Dam et al., 2001; Bellostas et al., 2007; Kaplan et al., 2008), it is essential that we incorporate both above- and below-ground plant responses to current and past damage to fully understand the complexity of factors that shape plant defenses and, as a consequence, plant-mediated herbivore interactions.

Here, by using *Plantago lanceolata* L. (Plantaginaceae) and one of its specialist chewing herbivores, *Junonia coenia* Hübner (Lepidoptera: Nymphalidae), we examined the effect of plant ontogeny (two developmental stages) and history of damage (single and multiple damage events early or late in the season) on plant responses to herbivory in both above- and below-ground tissues. We specifically ask the following questions: 1) Do levels of constitutive defenses, as well as induced defenses and compensatory regrowth following leaf damage by a specialist chewing herbivore, vary with plant age?, 2) For mature plants, does variation in frequency and intensity of herbivory early

during a growing season influence plant induced chemical defenses and compensatory regrowth later in the season?, and 3) To what extent do changes in above-ground plant responses to leaf chewing damage, due to plant age or previous history of damage, translate into changes in below-ground biomass and defenses?

Methods and Materials

Study System Plantago lanceolata L., narrowleaf or ribwort plantain, (Plantaginaceae) is a common short-lived weed (annual or facultative perennial) introduced to North America from Eurasia ca. 200 years ago (Cavers et al., 1980). This species forms natural populations with diverse age structures (Shefferson and Roach, 2010) and thus, herbivore communities are naturally exposed to a wide diversity of host age classes in wild populations. *Plantago lanceolata* produces iridoid glycosides (IGs) (Rønsted et al., 2000) as its primary allelochemicals that influence feeding preferences of generalist and specialist rhizophagous and folivorous herbivores. For example, several laboratory and field experiments have shown that specialist lepidopterans use iridoid glycosides as oviposition and feeding stimulants (Bowers, 1983, 1984; Talsma et al., 2008), and that larvae of these herbivores grow better on diets with higher concentrations of IGs (e.g., Bowers and Puttick, 1989; Harvey et al., 2005; Saastamoinen et al., 2007). In contrast, generalist herbivores and pathogenic fungi that damage below- or above-ground tissues usually are deterred by high concentrations of IGs (Bowers and Puttick, 1989; Strohmeyer et al., 1998; Biere et al., 2004; De Deyn et al., 2004; Harvey et al., 2005; Wurst and van der Putten, 2007). *Plantago lanceolata* produces primarily two IGs, aucubin and catalpol, and amounts of these compounds may be as high as 10–12% dry weight (Bowers and Stamp, 1993). Because aucubin is the biosynthetic precursor of the more toxic catalpol (Rønsted et al., 2000), high relative concentrations of catalpol indicate not only a greater biosynthetic investment of the plant, but also may be important in determining how generalist and specialist herbivores respond to the plant. Finally, constitutive concentrations of IGs have been shown to increase non-linearly during plant ontogeny (Fuchs and Bowers, 2004; Quintero and Bowers, 2011) leading to significant seasonal variation. The variation in constitutive defenses in both above- and below-ground tissues can be as much as an order of magnitude, even during relatively short periods of time (Bowers and Stamp, 1993; Fuchs and Bowers, 2004; Barton, 2007; Quintero and Bowers, 2011), which can lead to significant variation in a plant's ability to induce chemical defenses within and among tissues.

The common Buckeye butterfly (*Junonia coenia* Hübner, Nymphalidae) is a New World butterfly that can have one to three broods per year under temperate conditions, or more in the tropics where it can breed year-round (http://www.nearctica.com/butter/plate17/Jcoenia.htm). The larvae feed on members of four plant families: Cornaceae, Plantaginaceae, Scrophulariaceae, and Verbenaceae, and this species is considered a specialist on plants containing iridoid glycosides (Bowers, 1984). In *P. lanceolata*, the two major IGs, aucubin and catalpol, serve as feeding and oviposition stimulants for Buckeyes (Bowers, 1984; Pereyra and Bowers, 1988). In addition, Buckeye larvae not only sequester IGs from their hosts, but larval IG content also is positively correlated with plant IG content (Camara, 1997; Prudic et al., 2005); thus, caterpillar performance and predation risk can strongly depend on levels of host plant defenses (Dyer and Bowers, 1996; Theodoratus and Bowers, 1999). Nevertheless, high concentrations of IGs also may have some detrimental effects by decreasing larval performance (Adler et al., 1995; Camara, 1997) and/or by enhancing larval susceptibility to parasitoid attack (Smilanich et al., 2009).

Plant and Caterpillar Colony Maintenance The study was performed at the University of Colorado during spring-summer 2006. Seeds were collected from >20 maternal *P. lanceolata* plants from several populations in Boulder County, Colorado, and mixed before the experiment started. Seedlings were germinated in Fafard mix on April 26th and transplanted after 15 d to a 1.5 L plastic pots containing growth medium of equal parts Metro Mix 350™, sterilized sand, and turface. These extra-deep pots were used in order to ensure natural growth of root as well as shoot tissues and to prevent pot-binding, which can affect both compensatory regrowth and plant secondary metabolite production (Karban and Baldwin, 1997). All seedlings used were selected to be equivalent in size and number of leaves at the time of transplanting. Buckeye larvae used were from a laboratory colony reared at the University of Colorado at Boulder. Larvae were fed on a mix of *P. lanceolata* leaves and kept in growth chambers with a photoperiod of 14 h day: 10 night, and day-night temperatures of 27°C /22°C.

Plant Age and Responses to Herbivory To assess the effect of plant age on plant induced responses to herbivory, juvenile and mature *P. lanceolata* plants were damaged by *J. coenia* caterpillars when plants were 9- and 14-wk-old, respectively. We chose 5 wk as a meaningful period between age classes because this is a good approximation of the average generation time of *J. coenia* (personal observation). In addition, 9- and 14-wk-old age classes were *a priori* selected to represent two distinct but still comparable developmental stages. These stages are

comparable in the sense that both are already independent from reserves stored in the seed, contain several new and intermediate leaves but lack mature leaves, and show no significant variation in terms of nutritional quality and physical defenses (i.e., <1% difference in nitrogen content, <4% difference in water content, and <10% difference in leaf toughness; unpublished data). However, while 9-wk-old plants, designated juvenile plants, still have a high relative growth rate and lower constitutive levels of IGs, 14-wk-old plants, designated mature plants, usually are reaching the onset of flowering, have started to decrease their vegetative growth rate, and constitutive defenses are often double those of juvenile stages (see "Results").

At both age classes, 40 previously undamaged plants were randomly assigned to one of two treatments: no herbivore (C: control) or damage by *J. coenia* caterpillars (H: herbivore). In order to account for potential differences between treatments before the experiment started, initial plant size of all plants at the beginning of the herbivory treatments was measured as the product of the length of the longest leaf and the total number of leaves, which provides a good index of plant size (Jarzomski et al., 2000). To confine caterpillars on the plants, control and treatment plants were caged using mesh bags constructed of Remay™. For juvenile plants, two newly molted 4th instars per plant were placed in the center of the plants in the herbivory treatment. For mature plants, we applied from four to seven 4th instars per plant in order to reach approximately 50% damage during an equivalent period of time. In both cases, 2 d after larvae were placed on plants or when larvae had eaten approximately 50% leaf tissue, all caterpillars and mesh bags were removed. Since induction of IGs was estimated to reach its highest point 6 d after damage (Fuchs and Bowers, 2004), to test for short-term plant induced defenses as a function of plant age, all plants per treatment per age class were harvested 7 d after herbivore removal.

Harvested plants were separated into above- and below-ground tissues. Above-ground tissues consisted of new and intermediate leaf age classes (see Bowers and Stamp, 1993) for both juvenile and mature stages. Thus, although we did not asses variation in plant defenses within different leaf age classes, we kept equal representation of leaf ages classes across plant developmental stages. Root tissues were washed until roots were totally clean from remaining soil material. Due to time constraints, root tissues from only half of the plants were processed (N=10 per treatment). Harvested tissues were weighed fresh, oven-dried at 50°C for 48 h to a constant mass, and weighed again to the nearest hundredth of a gram. By the time plants reached their mature stage (14-wk-old plants), a few plants per treatment had started flowering. However, because inflorescence biomass was usually <10% of the total above-ground biomass and because the proportion of plants flowering did not vary among treatments (P>0.05), we added data obtained from reproductive tissue data to leaf data in order to report overall above-ground (i.e., shoot) values for biomass and chemical defenses. Furthermore, we ran all analyses for the complete data set as well as separately, using just flowering or non-flowering individuals; but because trends were not significantly different (data not shown), we present here the results for the complete data set.

To assess variation in concentrations of IGs, dried shoots and roots were ground into a fine powder, and subsamples of 25 to 50 mg were processed for IG extraction and analyzed by gas chromatography following previously described methods (Bowers and Stamp, 1993; Jarzomski et al., 2000). Briefly, samples were extracted overnight in 95% methanol, and then partitioned between water and ether to remove hydrophobic compounds, using phenyl-β-D-glucose (PBG) as our internal standard. An aliquot of the solution was derivatized with Tri-Sil-Z™ (Pierce Chemical Company) and injected into an HP 7890A gas chromatograph (Agilent Technology) using an Agilent DB-1 column (30 m, 0.320 mm, 0.25 μm particle size). Amounts of aucubin and catalpol were quantified using ChemStation B-03-01 software, and they are presented as percent dry weight for comparative purposes (e.g., Fuchs and Bowers, 2004; Barton, 2007; Wurst and van der Putten, 2007).

Independent sample *t-tests* were used to test for possible differences in initial plant size between treatments of 9- or 14-wk-old plants before the herbivory treatments were applied. Plant responses to herbivory (C vs. H) at juvenile or mature plant stages were assessed as changes in shoot and root biomass (dry mass), total concentration of IGs (% dry weight), and proportion of catalpol/total IGs. We used a series of two-way analyses of variance (ANOVA) with age and treatment as the main effects and an interaction term included. Iridoid glycoside concentration data were arcsine-square root transformed for statistical analyses, but biomass data did not require transformation. Separate two-way ANOVAs were performed for shoot and root tissues since root tissues were available for only half of the plants (N=10 for roots and N=20 for shoots for each herbivory : age treatment combination). When the herbivory treatment effect was significant, we followed with single degree of freedom contrasts to assess differences between treatments (C vs. H) at the two different age classes.

History of Damage and Plant Responses to Herbivory To determine how variation in the frequency and intensity of damage might affect plant performance and IG concentration, plants received a combination of damage and non-

damage events early and later in the season. First, 80 juvenile plants (i.e., 9-wk-old) were divided in two treatments: control and herbivory (N=40 for each) as described above. Five weeks following the first damage event to juvenile plants (50% damage), 14-wk-old plants (N=40 undamaged and 40 previously damaged plants) were exposed to a second generation of Buckeye caterpillars (50% damage). Thus, for this experiment there were 4 treatments: 1) plants that were never damaged (control-control: CC); 2) plants damaged by the first generation of Buckeyes but not by the second generation (herbivory-control: HC); 3) plants not damaged by the first generation of Buckeyes but damaged by the second generation (control-herbivory: CH); and 4) plants damaged by both generations of Buckeyes (herbivory-herbivory: HH), with 20 replicates per treatment. As before, when caterpillars achieved 50% damage during both first and second damage events, all caterpillars and exclusion cages from control and treatment plants were removed. Seven days after the last damage event, all plants per treatment were harvested and separated into shoot and root tissues to assess differences in plant biomass and induced defenses as explained above.

To assess the effect of previous herbivory on subsequent plant responses to damage, 1 wk after the second generation of damage, differences in biomass, total concentration of iridoid glycosides, and proportion of catalpol/total IGs in shoot and root tissues were evaluated using one-way ANOVAs. Because sample sizes were different between root and shoot tissues (see above) these data were analyzed separately. In all cases, when significant effects were detected by ANOVAs, we followed up with *a priori* contrasts comparing (1) control vs. herbivory treatments (CC vs. HC + CH + HH), (2) plant responses to damage received early vs. late in the season (HC vs. CH), and (3) mature plant responses to a single herbivory event vs. multiple events (CH vs. HH).

Results

Plant Age and Responses to Herbivory At the beginning of the experiment, above-ground size of plants in the two herbivory treatments (C and H) were not significantly different from each other for either juvenile plants ($t_{1,38}$ −0.07; P=0.51), or for mature plants ($t_{1,38}$ 5.6; P=0.13). Based on the subset of plants harvested the same day that treatments started, juvenile plants at the beginning of the experiment had, on average, 12 leaves, their average above-ground biomass (dry weight) was 0.5±0.04 g, and their below-ground biomass was 0.13±0.01 g. Mature plants had, on average, 56 leaves, their above-ground biomass was 6.05± 0.29 g, and their below-ground biomass was 4.14±0.24 g (dry weight).

One week following the first generation of damage, above-ground plant responses to herbivory were strongly influenced by plant age (Table 1, Fig. 1). Above-ground biomass was significantly higher in control plants and older plants, but no interaction was observed (Table 1). Thus, 1 wk following 50% leaf tissue removal, damaged plants in both age classes were unable to compensate for the lost tissue (Fig. 1a), with damaged plants being on average 46% and 24% smaller than control plants for juvenile and mature plants, respectively (juvenile: $F_{1,76}$ 6.5, P=0.013; mature: $F_{1,76}$ 24.5, P<0.001). Therefore, although there was no significant interaction between age and herbivory, mature plants were better than juvenile plants at compensating for the lost tissue 1 wk following damage. In turn, induced defenses after herbivory in above-ground tissues were observed only for proportion of catalpol but not for total levels of IGs (Table 1). Total levels IGs were 16 times greater in mature plants when compared to juvenile plants; but they did not significantly vary between control and herbivory treatments in either age class (Fig. 1b). In contrast, the proportion of catalpol not only varied with plant age, showing an average decrease of 47% from

juvenile to mature plants, but also the ability of a plant to induce above-ground chemical defenses depended on host plant age (Table 1). Single degree of freedom contrasts showed that 1 wk following 50% tissue removal, damaged juvenile plants showed a 45% increase in their levels of catalpol/total IGs ($F_{1,76}$ 9.7, P=0.003), while mature plants did not differ from control plants in the proportion of catalpol (Fig. 1c) ($F_{1,76}$ 0.3, P=0.58). This difference is illustrated by a significant interaction between plant age and treatment in above-ground proportion of catalpol (Table 1).

In contrast, although below-ground tissues followed similar patterns to the ones seen for above-ground tissues, ANOVA results showed only a significant effect of plant age on root biomass and defenses; but leaf damage by Buckeye caterpillars did not translate into changes in root biomass or chemical defenses between control and herbivory treatments one week following damage (Table 1, Fig. 1).

History of Damage and Plant Responses to Herbivory One week following the second generation of damage by Buckeye caterpillars, ANOVA results showed that herbivory treatment had a negative effect on shoot biomass ($F_{3,76}$=21.46, P<0.001) and a nearly significant negative effect on root biomass ($F_{3,36}$ 2.77, P=0.056) (Fig. 2a). Therefore, compensatory regrowth was not achieved 1 wk or even 5 wk following herbivore damage. Single degree of freedom contrasts showed that a decrease in shoot biomass was observed between undamaged control plants and damaged plants (CC vs. HC + CH + HH): $F_{1,76}$ 44.9, P<0.001), as well as between mature plants damaged once vs. those damaged twice (CH vs. HH: $F_{1,76}$ 18.7, P<0.001) (Fig. 2a). However, no difference in shoot biomass was observed between plants with one single damage event early vs. late in the season (HC vs. CH: $F_{1,76}$ 2.1, P=0.15) (Fig. 2a).

In contrast, we did not observe any significant changes in plant IGs as a response to different histories of damage: production of total IGs and proportion of catalpol/total IGs did not vary with history of damage either for above-ground tissues ($F_{3,76}$=0.99, P=0.40 and $F_{3,76}$=2.39, P=0.08, respectively) or below-ground tissues ($F_{3,36}$=0.13, P=0.94 and $F_{3,36}$=0.59, P=0.63, respectively). Thus, mature plants that

Bars represent the combination of first and second damage events, leading to four treatments: 1) plants that were never damaged (CC); 2) plants damaged by the first generation of Buckeyes but not by the second generation (HC); 3) plants not damaged by the first generation of Buckeyes but damaged by the second generation (CH); and 4) plants damaged by both generations of Buckeyes (HH), with N=20 replicates per treatment. Original data were arcsine-square root transformed for statistical analyses, percentage data are shown for illustrative purposes only. Lowercase letters represent mean group differences among treatments as tested by Bonferroni post-hoc tests (P<0.05)

varied in intensity and frequency of herbivory, had similar levels of defenses across all four damage treatments, and induction of defenses was not observed (Fig. 2b, c).

Discussion

This study revealed novel patterns regarding the extent to which plant age and history of damage over a growing season can modify *Plantago lanceolata*'s ability to respond to herbivory. Most notably, we showed that while constitutive concentration of IGs markedly increased as plants matured, plant ability to induce chemical defenses was limited to juvenile, but not mature, plant stages. In addition, induced defenses observed 7 d following herbivory in juvenile plants disappeared five weeks after the first herbivory event, and mature *P. lanceolata* plants that varied considerably in the absolute amount and frequency of damage received over 5 wk, did not significantly differ in their levels of chemical defenses. Finally, contrary to what we expected, we did not observe changes in below-ground tissues' defenses or biomass a week following 50% removal of above-ground tissues at either age class or history of damage. Together, these results suggest that in *Plantago lanceolata* and perhaps other systems, ontogenetic trajectories in plant growth and defenses can play a stronger role in mediating plant-herbivore interactions than history of damage.

Plant ontogeny strongly influenced plant defenses in both above- and below-ground tissues. Synthesis and accumulation of constitutive IGs increased 13 times in above-ground tissues and doubled in below-ground tissues from juvenile to mature stages. In addition, plant allocation patterns also varied considerably from almost equal investment in total IG concentrations between shoot and root tissues during the juvenile stage to a large increase in plant total IGs in shoots as compared with roots during the mature stage (i.e., ratio of total levels of IGs between shoot and root tissues varied from roughly 1:1 in juveniles to 8:1 ratio in mature plants) (Fig. 1). Comparable trends in constitutive defenses within and among tissues as plants age have been reported previously for *P. lanceolata* (Darrow and Bowers, 1999; Fuchs and Bowers, 2004; Quintero and Bowers, 2011) as well as for other IG-containing plants (Hogedal and Molgaard, 2000; Beninger et al., 2007; Jamieson and Bowers, 2010). These shifts suggest that, even in the absence of damage, plant palatability can dramatically change in a short period of time with strong implications for plant-herbivore interactions and plant fitness. For instance, even smaller differences in concentration of IGs in *P. lanceolata* as the ones reported here have shown to significantly decrease leaf consumption and growth rate of generalist herbivores and pathogens as iridoid content increases (Biere et al., 2004). As a result, herbivore pressure may be higher on younger developmental stages, decreasing their chances of survival or future reproductive output (e.g., Shefferson and Roach, 2010).

While the role of ontogenetic trajectories in constitutive defenses has received considerable attention, our knowledge regarding the role of plant age in explaining herbivore induced defenses is still limited. A recent meta-analysis that summarized ontogenetic patterns in plant defense traits illustrated that, in the case of herbaceous plants, ability to induce defenses after damage usually decreased with plant age, while no significant differences in tolerance were observed across plant development (Barton and Koricheva, 2010). In accordance with this trend, we show that a week following damage, juvenile *P. lanceolata* plants were significantly more capable of induction (i.e., 45% increase in the proportion of catalpol/total IGs) than mature plants, but no significant differences were observed for compensation to herbivory. Nevertheless, lack of differences in compensatory regrowth between age classes should be interpreted carefully since we only assessed changes in biomass between treatment and control plants a week following 50% damage, and thus, this short-term responses may not reflect long-term compensatory regrowth strategies nor be indicative of potential fitness consequences. In terms of induction, because the defensive properties of iridoid glycosides have been well documented (reviewed by Bowers, 1991), our data suggest that increased ability to induce defenses at the juvenile stage is likely to increase plant resistance to generalist herbivores. Increased levels of iridoid glycosides, especially catalpol, usually deter generalist herbivores and/or decrease consumption rate (Bowers and Puttick, 1989; Biere et al., 2004; De Deyn et al., 2004; Wurst and van der Putten, 2007), potentially allowing induced juvenile plants to decrease subsequent damage by generalist herbivores. However, this increase in defenses also may enhance *P. lanceolata* susceptibility to specialist herbivores such as buckeye butterflies (Bowers, 1984; Pereyra and Bowers, 1988; Prudic et al., 2005; Talsma et al., 2008). Therefore, whether high induction capabilities at younger life stages in *P. lanceolata* is adaptive remains to be tested, but may strongly depend on the community structure of antagonist species present in the habitat. Alternatively, mature plant stages with already 16 times more constitutive defenses than juvenile stages may not benefit by investing in induced defenses. Thus, as seen in other plant species, age-dependent induced defenses in *P. lanceolata* may respond to variable cost and benefits of these defensive strategies as plants develop (Ohnmeiss and Baldwin, 2000; Van Dam et al., 2001; Boege et al., 2007; Orians et al., 2010).

Plant responses to sequential damage over a growing season may depend on and/or interact with age-dependent induced responses to herbivory. Two alternative scenarios can be expected, one where age-dependent induced responses can prevail over plant responses to sequential damage or, the opposite, where herbivore-induced indirect interactions alter plant defenses beyond the expected age-dependent induced response. To our knowledge, we currently lack empirical data testing these opposite scenarios. On one hand, recent empirical studies have shown strong age-dependent induced responses to herbivory (Van Dam et al., 2001; Boege et al., 2007; Barton, 2008; Tucker and Avila-Sakar, 2010), but these studies usually lack a consideration of the role of multiple and successive damage events over the course of plant development. Alternatively, studies that assess the effects of previous history of damage on plant responses to herbivory have shown both that previous damage events can increase plant induced responses after subsequent damage (Ruuhola et al., 2007; Roitto et al., 2009), or decrease plant ability to mount a localized or systemic induced response following subsequent damage (van Zandt and Agrawal, 2004; Viswanathan et al., 2007; Poelman et al., 2008; Erb et al., 2011). Although these latter studies assess the role of history of damage over extended periods of time, where plant ontogeny may interact with herbivore-induced indirect interactions, conclusions on the independent or combined effects of these factors on plant induced responses are hard to draw. Most of these studies vary widely in terms of plant life form (i.e., annual or perennial), herbivore-mediated indirect interactions (i.e., conspecific or heterospecific interactions), and time elapsed between initial and subsequent damage (i.e., from 48 h to >5 yr); making it difficult to assess whether changes in plant defense phenotypes and/or subsequent herbivore communities are the product of immunological memory and/or priority effects, age-dependent induced responses, or a combination of both. Our results show, that a week following the second damage event, mature plants with diverse frequency and intensity of damage (i.e., CC, CH, HC, HH) all had similar levels of defenses. Thus, for this plant-herbivore system and considering potential conspecific interactions occurring over successive generations (i.e., 5 wk), plant age seems to influence plant allocation of resources to defense more than past history of damage.

Evaluating changes in plant induced responses within and between above- and below-ground tissues as a function of plant age or history of damage is essential to understand temporal variation in plant-herbivore interactions. Herbivore-induced defenses not only may change the palatability and nutritional quality of a tissue for future herbivores, but also may lead to altered phytochemical expression across multiple plant tissues (Ohgushi, 2005; Kaplan et al., 2008). However, in this study, *P. lanceolata*'s short-term responses to 50% above-ground tissue removal by a specialist caterpillar did not translate into significant changes in root biomass or defenses (as also found in Darrow and Bowers, 1999). In accordance with our data, a recent meta-analysis of plant induced defenses within and across tissues following leaf and root herbivory demonstrated that herbivore damage to above-ground tissues usually results in stronger induced responses in leaves than in roots (Kaplan et al., 2008). Thus, if these observed short-term responses hold true throughout the growing season, then we should expect stronger temporal changes in above-ground herbivore population and/or community structure following leaf damage (especially in the case of juvenile plants) than in below-ground communities. Nevertheless, it is important to emphasize that the patterns described here may be system-specific. Here, we only assessed *P. lanceolata* responses to variable timing and severity of damage by a single specialist leaf-chewing herbivore, larvae of the Buckeye butterfly. It is the case for *P. lanceolata* that induced defenses within and across tissues can vary considerably as a function of herbivore identity. For instance, Bowers and Stamp (1993) showed that *P. lanceolata* damaged by the specialist *J. coenia* induced higher levels of iridoid glycosides than plants damaged by the generalist *Spilosoma congrua* (Arctiidae). Similarly, Wurst and van der Putten (2007) demonstrated not only that induction of iridoid glycosides depends on herbivore identity but also that herbivore-induced indirect interactions can vary as a function of initial and subsequent above- and below-ground herbivore species. Therefore, the patterns reported here may differ for different herbivore species and/or a combination of multiple antagonists damaging above- and below-ground tissues over time. Hence, future studies that assess the ecological consequences of history of damage and plant age-dependent induction within and across tissues for a wide diversity of above- and below-ground antagonists as well as more plant developmental stages will shed light on the ubiquity of the patterns observed here.

In summary, these results suggest that plant ontogeny not only dictates important shifts in plant investment in constitutive defenses, but it can also influence the ability of a plant to respond to herbivory, making ontogenetic trajectories a key feature in mediating plant-herbivore interactions. In contrast, variable frequency and intensity of damage in mature plant stages did not affect plant investment in defenses within as well as between tissues. This suggests that plant-mediated herbivore interactions throughout a season may depend strongly on plant age during initial and subsequent damage. For example, age-dependent induced resistance may shift the relative abundance or performance of generalist and specialist herbivores following initial damage to juvenile stages but not mature plant stages. Thus, in *P. lanceolata* and perhaps other systems, it is possible that ontogenetic trajectories in plant

growth and defenses leading to strong age-dependent induced responses may prevail over herbivore-induced indirect interactions. Yet, because herbivore-induced indirect interactions also vary as a function of herbivore identity and the lag of the localized and/or systemic induced response over time (van Zandt and Agrawal, 2004; Muola et al., 2010), more studies that address the effect of sequential damage by multiple shoot and root herbivores on plant defense phenotype and subsequent herbivore community structure throughout plant development are needed.

Acknowledgments We thank E.C. Lampert, A. Trowbridge, J. Paritsis, and S. Whitehead for valuable comments and suggestions on this manuscript. In addition, we acknowledge A. Hill, L. Mulder, E. Burke, and M. Tapy for greenhouse and laboratory assistance; and K. E. Barton for the seeds provided for this study. Funding for this project was provided by the UROP program and the Department of Ecology and Evolutionary Biology at the University of Colorado, and Dissertation Improvement Grant NSF grant DEB 0909717.

genetic control of plant secondary chemistry are of importance to plant breeders, researchers, and forest managers, few studies have focused on forest trees, and fewer yet have investigated the interaction of a biotic agent and environment on plant defense responses. However, Hanover (1966) studied the heritability of five terpenoids present in pine, and Yanchuk et al. (2007) quantified tree defensive responses to insect attack. The reason for the dearth of studies on the heritability of tree secondary compounds and the response to biotic agents likely is due to the need for spatially replicated field trials of trees with known pedigree structure, that are of an appropriate age for biotic challenges of interest.

Mountain pine beetle, *Dendroctonus ponderosae* Hopkins (Coleoptera: Scolytidae), is an obligate herbivore that has coevolved with lodgepole pine, *Pinus contorta* Douglas ex Louden var. *latifolia* Engelm. ex S. Watson (Pinales: Pinaceae) (Raffa and Berryman, 1983). Two ophiostomoid blue stain fungi, including *Grosmannia clavigera* (Robinson-Jeffrey and Davidson) Zipfel, de Beer and Wingfield, are associated with *D. ponderosae* (Safranyik and Carroll, 2006). Beetles transport the fungi to the tree by either surface contact (fungi on exoskeleton) or via mycangia (specialized invaginations on beetle exoskeleton) (Paine et al., 1997; Krokene and Solheim, 1998). The blue stain fungi present an often lethal challenge for the host tree (Krokene and Solheim, 1998). Blue stain fungi grow throughout a tree's parenchyma cells, act to plug tracheids, and block nutrient and water flow. Trees typically respond to the fungi by allocating terpenoids to the site in an attempt to stop the growth of the fungi (Krokene et al., 2000; Huber and Bohlmann, 2006). For example in Petri dish assays, γ-terpinene, α-pinene, and abietic and isopimaric acids inhibited germination and growth of Ophiostomatales (Klepzig et al., 1996; Kopper et al., 2005). However, when bark beetle populations and their corresponding inocula are high due to mass attack, the defense system of healthy live trees do not inhibit the germination and growth of Ophiostomatales (Raffa and Berryman, 1983), which contributes to the mortality of the tree. Several important interactions play a role in this phenomenon.

During outbreaks of *D. ponderosae*, not all trees in the landscape, regardless of vigor, age and/or size will be mass attacked and killed by beetles. There are trees that are not landed upon; are landed upon but are not attacked; or are attacked but unsuccessfully colonized (Safranyik et al., 2004). The reasons that certain trees survive major outbreaks generally are unknown; however, as reported in other *Dendroctonus* spp-pine interactions, the environment strongly affects overall tree vigor (Ayres and Lombardero, 2000; Lombardero et al., 2000). However, genetic characteristics of the tree, and their interaction with the environment, also strongly affect any expression of resistance mechanisms of loblolly (Strom et al., 2002) and lodgepole pine (Yanchuk et al., 2007)

The *D. ponderosae* outbreak in British Columbia *P. c. latifolia* forests, and the tree breeding progeny trials established in the past by the British Columbia Forest Service, provided a rare opportunity to study the complex interactions of the host tree genetics, the insect, and a symbiotic, pathogenic fungus under replicated conditions in the field. We used 45 half-sibling families at two experimental sites, to study the effect of genotype and environment on the terpenoid chemical responses of *P. c. latifolia* to *G. clavigera*. Understanding host defense mechanisms involved in successful and unsuccessful *D. ponderosae* attacks and colonization may help expand our knowledge of why some trees appear to be resistant or tolerant to *D. ponderosae* attack. Our objectives were: (1) to examine the phenotypic variation in constitutive and induced secondary chemistry among half-sibling families and variations within individual trees; and (2) to estimate heritabilities for aspects of *P. c. latifolia* secondary metabolite defense resin chemistry.

Methods and Materials

Study Area Progeny trials for lodgepole pine were established in 1986 (prior to our study) at three sites in north central British Columbia, Canada. The sites were located near Prince George (Long. W 121° 35′ 18″ Lat. N 53° 29′ 18″, UTM Zone 10 East 593630 North 5927586), Wells (Long. W 121° 27′ 57″ Lat. N 53° 15′ 30″, UTM Zone 10 East 602371 North 5902142), and Williams Lake (Long. W 121° 21′ 42″ Lat. N 52° 09′ 11″, UTM Zone 10 East 612087 North 5779327). Plots will be referred to as Indian Point Creek (Indian Point), Bowron Lake (Bowron), and Moffat Creek (Moffat), respectively. Each plot was set-up in a randomized complete block design. In each plot, trees were grid planted at one meter by one meter spacing, in rows of four trees per family, with eight replication blocks per site. Plots were systematically thinned to one half the stocking density 10 yr prior to this study. Half-sibling open-pollinated families were common to all three sites, with varying local control wild stand seed lots also included. The seeds for families were sourced from local and non-local provenances, ranging from the north (Lat. N 53° 58′) to south (Lat. N 50° 42′).

Prior work at Indian Point provided preliminary information on the range of resistance parameters (antixenosis, antibiosis, and tolerance) to colonization by *D. ponderosae* (Yanchuk et al., 2007). Data reported in Yanchuk et al. (2007) were used to select families for this research on heritability of host responses to *G. clavigera*. We selected families in which 0–75% of the individuals showed signs of attack by *D. ponderosae*.

In addition to information from Yanchuk et al. (2007), family selections at Bowron and Moffat were based on direct observations of abiotic and biotic damage to individual trees. Trees were not used in this study if they had signs or symptoms of *D. ponderosae*; pine engraver, *Ips pini* (Say) (Coleoptera: Scolytidae); western gall rust, *Endocronartium harknessii* Hirats (Uredinales: Cronartiaceae); comandra blister rust, *Cronartium comandrae* Peck (Uredinales: Cronartiaceae); atropellis canker, *Atropellis piniphila* (Weir) Lohman & Cash (Helotiales: Dermateaceae); and/or stalactiform blister rust, *Cronartium coleosporioides* J.C. Arthur (Uredinales: Cronartiaceae). Families with greater than 50% of individuals showing signs and/or symptoms of these pest and pathogen agents were not included in the study.

In total, forty-five families were selected for this study. The number of individuals per family ranged from 16 to 26 across the two sites, for a total of 482 trees at Bowron and 405 trees at Moffat. Trees in the study had diameters measured at 1.4 m from the base of the tree (DBH), ranging from 5.8 to 16.7 cm. The treatments described below were conducted on individual trees prior to the *D. ponderosae* flight period in July 2006.

Fungal Cultures and Challenge Inoculations The fungus, *G. clavigera*, was isolated from adult *D. ponderosae* collected from Indian Point in August 2005. Samples were cultured by using methods described by Raffa and Smalley (1995) and Wallin and Raffa (2001). Cultures were grown in Petri plates on potato dextrose agar at 22°C and 85% relative humidity for 14–20 d and were used as the source for hyphal tip transfer. After establishing a pure culture, the number of transfers were limited to <10 transfers per dish, and visual inspections were used to prevent possible mutations. To obtain ample inoculum for field inoculations, ~600 1.5 mm agar samples with hyphal tips present were transferred to agar plates.

In July 2006, trees were inoculated with *G. clavigera* on the east and west side of the main stem at a point 1.4 m from the base of the tree. A 10 mm diam cork borer was used to excise bark and phloem. Inoculum containing hyphal tip material was removed from the petri dishes with a 4 mm diam cork borer. The inoculum was placed onto the exposed xylem tissue. The bark patch was re-secured to prevent desiccation and to promote propagation of the fungus. Prior to inoculation, each tree was sampled for constitutive terpenoids by using a 10 mm diam cork borer to remove undamaged phloem tissue. Host response was measured at 7 (sampled on the east side of each tree) and 12 (sampled on the west side of each tree) days following the initial inoculation. Post-inoculation sampling time points will be referred to hereafter as d 7 and d 12. At d 7 and 12, bark was removed from around the inoculation site, and the length of necrotic lesion was measured on the xylem. A 10 mm diam cork borer was used to remove phloem sample from the necrotic lesion. Samples were transported to a UNBC laboratory on dry ice and then stored in a −80°C freezer until it was shipped (also on dry ice) to the British Columbia Forest Service laboratory in Victoria, British Columbia where they were stored in liquid nitrogen until they were processed for terpenoid analysis.

Extraction of Terpenoids Constitutive and induced terpenoids were quantified from all 887 study trees in July 2006. Terpenoid quantity and composition were analyzed by gas chromatography with flame ionization detection (GC-FID). Outer bark tissue was separated from phloem tissue. The phloem was chopped to increase sample surface area before being placed into a vial with 4 ml of 240.5 ppm pentadecane solution as an internal standard (Sigma-Aldrich, 99% purity, Oakville Ontario, Canada). Pentadecane served as the internal standard since it is not present in *P. c. latifolia* phloem resin and is easily separated from the naturally present terpenoids (Hampel et al., 2005). After 48 h in solution, each vial was inverted to mix contents and then allowed to settle for an additional 24 h. Extracts (0.5 ml) were removed by using an air pipettor and placed into a 2 ml auto-sampler vial for GC-FID analysis.

The gas chromatograph (Perkin Elmer Clarus 500) was calibrated for all terpenoid standards and pentadecane at the British Columbia Ministry of Forests, Forestry and Technical Services Section, Research Branch Laboratory, Victoria, British Columbia, Canada. Samples were injected and volatized immediately at 200°C. The carrier gas, helium, flowed at a rate of 0.91 ml/min, into a split flow valve, which delivered the sample into the column. Compounds were separated with INNOwax column (J&W, 25 m in length a 0.2 mm i.d., 0.4 μm film thickness). The initial column temperature was 60°C and increased by 3.0°C/min to 85°C, then increased by 8.0°C/min to 170°C. The final step increased the temperature by 20.0°C/min to 250°C where it was held constant for 7 min. Peak areas were used to quantify terpenoids where the ratio of the area of a terpenoid was compared with the area of the internal standard. Following extraction, phloem samples were oven-dried and weighed. Total terpenoids were corrected based on dry weight per gram of sampled tissue.

Statistical Analyses Differences in terpenoid concentrations were assessed by using ANOVA in SAS (SAS Institute, version 8.2, Cary, NC 1999–2001). Individual and total terpenoid levels were analyzed for all trees and within individual trees by using repeated-measures ANOVA (among days after inoculation) with a model incorporating sites, replications within site, families, and the interaction of family and site. Homogeneity of variance and normality were tested with residual plots. Data were transformed as

necessary [log(x + 1)] to meet assumptions of tests prior to analyses, however, data for Δ-2-carene could not be transformed to meet assumptions.

Heritabilities (h^2) of all compounds were estimated as $h^2 = V_A / V_P$; V_A representing the additive genetic variance and V_P the total phenotypic variation. V_A is the family variance (V_F) multiplied by four and V_P is the sum of error variance, family variance and the family by site interaction. Family variance was multiplied by four to estimate additive genetic variance because variance among families in half-sibling trials account for only one-quarter of the additive genetic variance (Falconer, 1981). All heritability values were calculated by using the variance components obtained with the PROC MIXED procedure in SAS, with an auto regressive model; i.e., repeated-measures within trees were accounted for by the auto-regressive covariance parameter estimates (here tree families represented by the family variance and environmental variance was the sum variances of tree families, replication within site, and the errors from random effects). Heritability of non-repeated host defense parameters were calculated in the same manner, but without the auto-regressive repeated measure. Standard errors for all heritability values were estimated by adding the statement COVTEST to the PROC MIXED procedure after the dataset was identified (Becker, 1975). COVTEST displays estimated standard errors for the variables. Although the families in the study were not truly random effects, they were chosen to represent a broad cross section of families in the test that had differential *D. ponderosae* attack rates. It is assumed that the bias was minimal for the attributes that were measured and adequately represent genetic variation in this population.

Results

Variation in Constitutive and Induced Secondary Chemistry within Half-Sibling Families Constitutive terpenoid levels were measured at day 0 and induced terpenoids were measured at seven and 12 days post-inoculation with *G. clavigera*. Twenty-six terpenoids were identified from the phloem extracts; borneol, bornyl acetate, camphene, camphor, Δ-2- and Δ-3-carene, α-caryophyllene, α-copaene, α-cubebene, p-cymene, α-humulene, limonene, linalool, myrcene, ocimene, α-phellandrene, β-phellandrene, α- and β-pinene, pulegone, sabinene, α- and γ-terpinene, terpineol, terpinolene, and α-thujone; however, we focused on the seven terpenoids that comprised 94.19 to 95.78% of the total amount of monoterpenoids in constitutive and induced phloem tissue, respectively (Table 1). In order of descending abundance for constitutive tissue, the seven monoterpenoids were β-phellandrene, β-pinene, Δ-3-carene, α-pinene, limonene,

[a] Percentage change measured as [%Δ = (day/previous day * 100) − 100]; data were taken at 0, 7, and 12 d following inoculation with *G. clavigera* at Bowron Lake and Moffat Creek, near Wells and Williams Lake, British Columbia, respectively

myrcene, and terpinolene (Table 1). In induced tissue, the order of decreasing abundance was β-phellandrene, Δ-3-carene, β-pinene, α-pinene, limonene, myrcene, and terpinolene (Table 1).

Although the relative proportions of the 26 terpenoids were impacted by the simulated *D. ponderosae* attack, β-phellandrene, although somewhat variable, remained the most abundant terpenoid extracted from the phloem (Table 1). Similar to the constitutive tissue, β-phellandrene also was the most abundant monoterpenoid extracted from induced tissue at both times. Larger changes occurred at day 7, relative to the changes at day 12.

For the analyses where all three measurement periods had terpenoid levels 'pooled', there were significant differences in terpenoid levels between the two sites for Δ-3-carene, terpinolene, borneol, bornyl acetate, camphor, linalool, α-terpinene, γ-terpinene, terpineol, α-thujone, α-cubebene, and α-humulene. Quantities of all terpenoids were significantly influenced ($P \leq 0.05$) by replicates within sites with the exception of β-pinene, Δ-2-carene, ocimene, and α-thujone (Table 2). Family significantly impacted quantities of all terpenoids except for Δ-2-carene and α-thujone. Family by site interaction was only significant for the quantity of α-cubebene.

Analysis of variance revealed that all terpenoids varied with time of induction and replications within site, except for borneol, bornyl acetate, Δ-2-carene, and α-thujone. The interaction of tree (i.e., the repeated measure within tree) and site significantly impacted the quantities of Δ-3-carene, bornyl acetate, camphene, camphor, p-cymene, linalool, pulegone, sabinene, α-terpinene, γ-terpinene, α-thujone, α-caryophyllene, and α-humulene (Table 3). The amounts of terpenoids significantly increased or decreased by tree and family for all chemicals except for borneol, camphor, Δ-2-carene, pulegone, terpineol, α-thujone, α-caryophyllene, and α-cubebene. There were significant interactions ($P \leq 0.05$) among tree, family, and site in terms of the amounts of camphene extracted from the phloem tissue. No other terpenoids showed significant variation for this interaction. Constitutive effects on days 7 and 12 post-inoculation significantly influenced the amount of all terpenoids, except for Δ-2-carene; therefore, each time point after inoculation was treated separately (Table 4a-c).

Analysis of variance of the seven most abundant constitutive terpenoids prior to inoculation indicates that site and replication within site had significant effects on the amount of myrcene and terpinolene present in phloem tissue (Table 4a), but Δ-3-carene varied for site only. Family significantly impacted all seven of the most abundant terpenoids and no statistically significant interaction of family and site occurred (Table 4a).

For terpenoids induced seven days post-inoculation, replication within site and site significantly impacted seven and two, respectively, of the seven most abundant terpenoids (Table 4b). Similar to the pattern of variation in constitutive phloem tissue, quantities of all seven terpenoids were significantly influenced by family, but not significantly influenced by the interaction of family and site (Tables 4b). On day 12 post-inoculation with *G. clavigera*, terpenoids were influenced by all four sources of variation (Table 4c). In comparison to constitutive (Table 4a) and seven days post-inoculation (Table 4b),

[a] Variables were the individual tree (TREE); the family of half-sibling *P. contorta latifolia* (FAM); and the location of either Bowron Lake or Moffat Creek, near Wells and Williams Lake, British Columbia, respectively (SITE); there were eight replications within a site [REP(SITE)] and the quantities of terpenoids (ppm/g) were measured 0, 7, and 12 d post inoculation with *G. clavigera*

quantities of all of the seven terpenoids were significantly different for family but again not for the interaction of family and site (Table 4c).

Variation Among Families Quantitative changes in terpenoid abundance that occurred during induction from day 0 to day 7 varied between Bowron and Moffat, but there were some general trends; i.e., all 7 of the most abundant terpenoids increased at both sites. As such, total monoterpenoids extracted from phloem tissue of study trees also increased at both sites (Table 1).

Quantitative changes in terpenoid abundance varied much more between sites during induction from day 7 to day 12 (Table 1). β-Phellandrene decreased at Bowron and Moffat. β-pinene also decreased in the phloem of trees at Bowron, but increased at Moffat. Δ-3-Carene decreased in phloem tissue at Bowron, but increased at Moffat. During this induction the amount of α-pinene, limonene, and myrcene decreased in study trees at Bowron, but increased at Moffat. Similar to β-phellandrene, terpinolene decreased at both sites. Total monoterpenoids decreased in samples taken at Bowron, but increased at Moffat.

During the first induction period (day 0 to 7), families had variable changes in quantities of terpenoids; however, there were similar trends among the seven terpenoids that make-up the majority of the total monoterpenoid profile. For example, all 45 families had higher amounts of β-phellandrene, β-pinene, Δ-3-carene, α-pinene, and terpinolene at day 7 compared to the constitutive profile. Mean percent of limonene increased from day 0 to day 7 in 41 of 45 families at Bowron, and similarly, mean proportion of limonene increased in 43 of 45 families at Moffat. Myrcene levels increased in every case but two; only one family at Bowron, and one at Moffat. Terpineol was the only monoterpenoid to decrease from day 0 to 7 at Bowron and Moffat (Ott, 2010). At Bowron and Moffat, 98 and 89% of families, respectively, showed decreases in the amount of terpineol in their phloem resin. During the same time period, 67% of families at Bowron and 89% at Moffat decreased in total sesquiterpenoids (Table 1).

Unlike the first induction period from day 0 to day 7, the second period from day 7 to day 12 showed fewer consistent changes among families. This was not too surprising, considering the much smaller % change that occurred between day 7 and 12, vs. day 0 and 7 (Table 1). For example, twenty-nine percent of families and 42% of families increased in mean percent of β-phellandrene at Bowron and Moffat, respectively. Thirty-three and 51% of families at Bowron and Moffat, respectively, increased in mean percent of β-pinene and α-pinene. Levels of Δ-3-carene increased in 27% of families at Bowron and 40% of families at Moffat. Limonene increased in 51% of families at Bowron and 56% of families at Moffat. Myrcene increased in 29% and 44% of families at Bowron and Moffat, correspondingly. Mean amounts of terpinolene increased in 38% of families at both sites. Showing a trend contrary to the majority of monoterpenoids, terpineol increased in 98% of families at both sites. Total sesquiterpenoids increased in 80% of families at Bowron and 91% at Moffat from day 7 to 12.

[a] Terpenoid quantities (ppm/g) were measured 0, 7, and 12 d post inoculation with *G. clavigera*; variables were the location of either Bowron Lake or Moffat Creek, near Wells and Williams Lake, British Columbia, respectively (SITE); the family of half-sibling *P. contorta latifolia* (FAM) and there were eight replications within a site [REP(SITE)]

Heritability Estimates of Secondary Chemistry Analysis of *P. c. latifolia* host defense traits revealed that most measured traits responded to simulated *D. ponderosae* attack, and that the majority of these traits possessed significant additive genetic variation (Table 5). There was a large range of h^2 values estimated for *P. c. latifolia* primary and secondary defensive responses to simulated *D. ponderosae* attack (Table 5).

Δ-3-Carene levels had a heritability estimated at $h^2=0.48$ (s.e.=0.12), which was the highest estimated heritability value of all terpenoids (Table 5). Limonene, β-pinene, and terpinolene levels also had heritability estimates above 0.25 (Table 5). Of the seven most abundant terpenoids, α-pinene, β-phellandrene, and myrcene levels all had low heritability values compared to the others (Table 5). Total terpenoids, monoterpenoids, and sesquiterpenoids all had heritabilities

Table 5 Estimates of heritability (h^2) over time for the seven most abundant monoterpenes, total terpenoids, and the ratios between selected monoterpenes from phloem tissue of families of 45 half-sibling lodgepole pines, *Pinus contorta latifolia*, inoculated with *Grosmannia clavigera* at two sites in British Columbia, Canada[a]

Variable	h^2	s.e.
β-Phellandrene	0.20	0.06
β-Pinene	0.37	0.11
Δ-3-Carene	0.48	0.12
α-Pinene	0.22	0.07
Limonene	0.44	0.11
Myrcene	0.16	0.05
Terpinolene	0.29	0.08
Total Terpenoids	0.12	0.04
Total Monoterpenes	0.12	0.04
Total Sesquiterpenes	0.19	0.06
β-Pinene/Δ-3-Carene	0.58	0.15
Terpinolene/Myrcene	0.39	0.11

[a] Terpenoid quantities (ppm/g) were measured from *P. contorta latifolia* families at either Bowron Lake or Moffat Creek, near Wells and Williams Lake, British Columbia, respectively; estimates were based on covariance parameter estimates from tree families, replications within sites, and the errors (Falconer, 1981)

estimated to be lower than $h^2=0.25$. The estimated heritability of the ratio of β-pinene to Δ-3-carene was $h^2=0.58$ (s.e.=0.15). The estimated heritability of the ratio of terpinolene to myrcene was $h^2=0.39$ (s.e.=0.11). None of the sesquiterpenoids had heritability values estimated to be greater than 0.25.

Discussion

This study examined the genetic and environmental variation of tree chemical defenses against *D. ponderosae*, an insect that invades pine subcortical tissue, and one of its symbiotic fungi. We quantified changes in terpenoid abundance following simulated *D. ponderosae* attack and fungal invasion of subcortical tissue. Variations in defense parameters observed at different times following inoculation suggest a change in the allocation of carbon-based resources due to simulated attack by *D. ponderosae*. Constitutive and induced terpenoid levels were significantly affected by family, and low to medium heritabilities are involved in the expression of these responses.

Wounding and inoculating trees with *G. clavigera* resulted in necrotic lesions in phloem and xylem tissue. The formation of necrotic lesions following simulated bark beetle attack has been shown in many other studies and systems (Cook and Hain, 1986; Raffa and Smalley, 1988; Klepzig et al., 1996). Wounding and inoculation with *G. clavigera* significantly affected the abundance and quantity of terpenoids within the necrotic lesions at day 7 and day 12 post-inoculation. The levels of induction agree with those reported in Klepzig et al. (1996) and Raffa and Smalley (1988), i.e., the quantity of total terpenoids was higher in induced tissue than in constitutive tissue. The seven monoterpenoids that made up the major fraction of the total terpenoids in the tissue showed similar trends in how they changed over time, from day 0 to day 7 and day 7 to day 12 (Table 1).

The overall trend for the seven most abundant terpenoids was for them to increase by day 7 following inoculation. Monoterpenoid abundances were positively related as induction occurred from day 0 to day 7. However, this trend did not remain by day 12 post-inoculation. By day 12, most monoterpenoids at Bowron and Moffat had decreased or remained relatively stable. While it appears in the short-term that an attack by *D. ponderosae* induces and increases tree monoterpenoids appropriate for defense, this may indicate an immediate increase in defense related to the *D. ponderosae* threat, followed by a leveling off or even a return to the pre-induced state after the rapid response. This reduced level of response after day 7 also may be due to the limited challenge that we presented to the trees, i.e., most *D. ponderosae* attacks comprise many more sites of inoculation than did our experimental treatments.

Mass attack by *D. ponderosae* usually occurs within a short period of time following the onset of successful beetle colonization. This suggests that once an initial threat has been eliminated the tree may return to normal constitutive defensive levels and its regular functions. Somewhat contrary to this hypothesis, Klepzig et al. (2005) reported the amount of resin-based defenses of loblolly pines, *Pinus taeda* L., to be induced 105 days after simulated attack by southern pine beetle, *Dendroctonus frontalis* Zimmermann. However, both studies support the initial increase and trade-offs for the induction of defenses.

Differential expression of certain genes may regulate terpenoid expression due to herbivory or particular stress. For example, the mevalonic acid pathway (MVA) may be shut down or have isopentenyl diphosphate (IDP) (a building block of terpenoids) shunted away to promote the non-mevalonate pathway (MEP). This is due to the MVA producing primarily sesquiterpenoids, whereas the MEP produces primarily monoterpenoids, especially monoterpenoids of interest such as Δ-3-carene, myrcene, and α-pinene (Huber et al., 2004). All three of these particular monoterpenoids as well as others increased with induction by fungal inoculation. The hypothesis of trade-offs for induction of defenses may be further supported by sesquiterpenoids not being associated with *P. c. latifolia* defenses against *D. ponderosae* because sesquiterpenoids decreased due to simulated *D. ponderosae* attack.

The seven most abundant monoterpenoids that increase with induction have been shown to provide defense against bark beetles and other coniferous herbivores (Lindgren et al., 1996; Rocchini et al., 2000) or to affect pheromone-mediated aggregation and anti-aggregation (Pureswaran and Borden, 2005). In particular, Δ-3-carene is toxic to many conifer-invading insects (Cook and Hain, 1988; Rocchini et al., 2000; Fäldt et al., 2003; Carlow et al., 2006; D. W. Ross, Oregon State University, personal correspondence). In comparison to other terpenoids, Δ-3-carene occurs in relatively high concentrations in *P. c. latifolia*. This is also the case for β-pinene. However, the ranking of abundance of these two monoterpenoids changes with the onset of induction. Following inoculation, Δ-3-carene increased to a higher level than β-pinene. The change in proportion of these two terpenoids from the less toxic β-pinene to the more toxic Δ-3-carene strongly suggests that higher ratios of Δ-3-carene to β-pinene may provide a greater level of defense against *D. ponderosae*.

Myrcene has been shown to be important in the behavioral activity or synthesis of aggregation and anti-aggregation pheromones produced by *D. ponderosae* (Borden, 1982; Raffa and Berryman, 1983; Safranyik and Carroll, 2006). Raffa and Berryman (1983) reported that levels of terpenoids active in the aggregation response increase along with toxic terpenoids. This is an unintentional by-product of induction that *D. ponderosae* has adapted to and has used to its advantage. Myrcene has been shown, in conjunction with α-pinene, to be used to enhance the response of *D. ponderosae* to potential hosts and traps (Borden, 1982; Raffa, 2001; Pureswaran and Borden, 2005). Seybold et al. (2004) reported that in the Rocky Mountains, specific populations of *D. ponderosae* respond at higher rates when the aggregation attractant contains terpinolene vs. myrcene. Borden and colleagues tested the relative effects of these monoterpenes in British Columbia under laboratory (Borden and Pureswaran, 2006) and field (Borden et al., 2008) conditions. In the field, there was a synergistic effect of combining terpinolene with myrcene as part of the aggregation attractant for *D. ponderosae*. In our study, myrcene and terpinolene were induced at both sites. Terpinolene increased ~200% from the constitutive level, whereas myrcene increased by ~110-150%.

One challenge in estimating genetic variation in pest resistances is that there must be sufficient challenges by the pest to assess variation in the resistance traits of interest. Therefore, we simulated the challenge posed by the pest to assess complex interactions of the host tree genetics under replicated conditions in the field. The results support previous findings that there is large variation within and among trees for expression of these chemicals, but this variation also is composed of significant additive genetic effects in the population. In order to describe genetic variation of these defensive traits, it is important to offer a contextual framework of heritable traits provided by previous studies. Some studies categorize heritability values as high if the estimated value is ≥0.45 (King et al., 1997; Alfaro et al., 2000). Quencez and Bastien (2001) characterize moderate levels of heritability as between h^2=0.30–0.54. Whereas Roberds et al. (2003) state moderate levels of heritability are h^2=0.44 to 0.59, Hamilton et al. (2001) stated that the degree of genetic control or heritability of secondary defenses varies widely among plant species, but that it is generally thought to be in the order of 0.3. Zangerl and Berenbaum (2004) reported heritabilities of primary and secondary metabolites in their study that range between 0.048 and 0.728, with an average of approximately 0.3, similar to results shown by Hamilton et al. (2001). Within the context of the other studies discussed, heritabilities in our study were considered low (ranging from 0 to 0.25), moderate (0.25 to 0.5), or high (>0.5).

Our findings suggest that the majority of terpenoid variation within and among trees can be most consistently explained by family variation, relative to the other main effects or interaction. It was rare for terpenoids to vary significantly by site, which indicates a strong genetic factor influencing the levels secondary metabolites in this system. For example, only α-cubebene at day 0, bornyl acetate at day 7, and pulegone at day 7 varied significantly by the interaction of site and family—none of which are major terpenoid constituents of *P. contorta latifolia* resin. Moreover, the majority of changes from day 0 to day 7 and day 12 were primarily influenced by family and rarely by site. These findings should have important ramifications when considering *D. ponderosae* dispersal and host selection dynamics.

Heritability estimates for the seven most abundant terpenoids show four of the seven to have moderate heritability values [β-pinene, Δ-3-carene, limonene, terpinolene], and the other three to have low heritability values [β-phellandrene, α-pinene, myrcene]. However, they were all significant in that heritability estimates were greater than their standard error estimates.

While individual terpenoids have significant heritabilities, the ratios of particular terpenoids may be important. The ratio of β-pinene to Δ-3-carene abundance changed between the two variables. The ratio over the sampling period for these two terpenoids had the highest estimated heritability value at 0.58 (s.e.=0.15). This higher level of specific terpenoids or ratios between terpenoids may provide some advantage to individual trees, for example, when discussing possible anti-aggregation effects. The ratio of terpinolene to myrcene had a moderate heritability at h^2=0.39 (s.e.=0.11). This supports the idea of terpinolene as an important variable for attack by *D. ponderosae*, resulting in the beetle colonizing trees with higher levels of terpinolene, or terpinolene acting synergisti-

cally with myrcene to elicit higher flight responses to the *D. ponderosae* pheromone components (Borden et al., 2008).

Defensive traits that comprise constitutive and induced terpenoids are based primarily on quantities of secondary chemicals. Here, we have shown not only that *P. c. latifolia* have significant genetic variation in constitutive bark terpenoids, but also that genetic variation is present for chemical changes in response to attack, or at the very least, challenge from the fungal associate with *D. ponderosae*. This may have arisen from a long history of *D. ponderosae*, or other insects and diseases, and a complex of various selective pressures that have maintained low to moderate levels of genetic variation in defenses chemicals. While we have been able to show that monoterpenoid abundances are under significant genetic control, it is important to test defense hypotheses by linking these traits with negative impacts on the attacking species and/or host mortality, and further work is underway to document these relationships in *P. c. latifolia*. Also, while some traits may provide adequate defense during endemic or localized outbreaks of *D. ponderosae*, the current *D. ponderosae* population in British Columbia has killed a large proportion of the mature *P. c. latifolia* across the landscape. Yet, even in the midst of massive die off, some trees have not been killed. The results from this study provide a framework under which some traits for bark beetle defense can be considered—as well as the selection of families with less mortality/attack, or individuals that survived. This will be important in the future management plans and strategies for *D. ponderosae* system resistance, resilience, and tolerance, especially in the context of climate change, genetic improvement, population shifts, and landscape wide epidemic outbreaks.

new areas in northern Alberta (Carroll et al., 2006), MPB has spread across the lodgepole×jack pine hybrid zone into stands of pure jack pine (Cullingham et al., 2011). Studies show that beetles can reproduce and develop in jack pine (Cerezke, 1995), as do its fungal associates (Rice et al., 2007). Jack pine is the most abundant pine species in the boreal forest which potentially could lead to the spread of MPB across the boreal forest to eastern Canada.

Global climate change might allow MPB to expand its range into formerly unoccupied lodgepole pine habitat and also enable further eastward invasion of jack pine (Williams and Liebhold, 2002). Climate change is expected to produce longer and more frequent droughts in many regions of the world (Breshears et al., 2009) that may influence the ability of trees to defend themselves against invading insects and diseases (reviewed in Franceschi et al., 2005). For plant species that are conservative water users, prolonged droughts will decrease carbon dioxide uptake and associated photosynthetic carbon assimilation due to stomata closure. Reduced carbon gain can result in the depletion of carbohydrate reserves for biosynthesis of defensive compounds, particularly carbon-based compounds such as terpenoids that could make trees more susceptible to biotic stress factors, such as bark beetles (McDowell et al., 2008; Breshears et al., 2009). Water deficit is one of the climatic variables used in climate-suitability models for MPB populations; in these models, it reduces the resistance of lodgepole pine to attack and subsequent development and survival of the beetle (Safranyik et al., 2010).

Increasing temperature predicted under a global climate change scenario also could alter volatile emission by potential host trees, since monoterpene emission is temperature dependent (Kesselmeier and Staudt, 1999), and might influence host finding by MPB. Two mechanisms are proposed to explain host finding by pioneering MPB. Beetles could visually orient towards and randomly land on potential host trees and then use gustatory cues to assess the suitability of the host (Raffa and Berryman, 1982). Alternatively, recognition and direct flight towards a host could be based on orientation to volatile organic compounds (VOC) emitted from the host (Moeck and Simmons, 1991) in combination with visual cues. MPB is able to detect and avoid non-hosts, which supports the hypothesis of direct flight as a host finding mechanism (Huber et al., 2000). Both mechanisms might act together; differences in VOC emission from different host trees grown under different conditions and with different levels of beetle infestation may be an indication of host suitability to orienting beetles. Successful attack and colonization of the host may be further influenced by the chemical composition of the bark of the host tree (Faccoli et al., 2005; Raffa et al., 2005).

Once a suitable host is found by a female pioneer beetle, α-pinene-one of the most abundant host monoterpenes in most pine species examined to date-is hydroxylated into the major aggregation pheromone *trans*-verbenol that attracts both sexes of MPB to initiate a mass attack (Pitman et al., 1968; Blomquist et al., 2010). As the colonization progresses, arriving males produce *exo*-brevicomin that attracts additional females until the optimum attack density is achieved, at which point both male and female beetles emit anti-aggregation pheromones that prevent further recruitment to the host tree (Rudinsky et al., 1974; Ryker and Libbey, 1982).

At least two MPB associated blue stain fungi, *Grosmannia clavigera* and *Ophiostoma montium*, also deplete tree defenses and kill their host (Reid et al., 1967; Rice et al., 2007) during the host colonization process. *Grosmannia clavigera* is more virulent than *O. montium* (Yamaoka et al., 1990) and often is used experimentally to stimulate tree defenses (Reid et al., 1967; Lieutier et al., 2009).

Trees that are mass attacked by the bark beetle plus associated fungi are defended with resin, a mixture of monoterpenes, sesquiterpenes, diterpenoid resin acids, and phenolic compounds characteristic of conifers (Keeling and Bohlmann, 2006) that act as physical and chemical defenses. Resin monoterpene composition differs between species, and the composition of individual trees in various pine species correlates with resistance to bark beetle attack (Sturgeon, 1979; Gollob, 1980).

In order to test the hypothesis that tree responses differ between lodgepole and jack pine trees, and also are affected by environmental conditions, we conducted a controlled environment experiment on seedlings subjected to water deficit (simulating drought conditions) and used the MPB fungal associate *Grosmannia clavigera* in conjunction with wounding to stimulate tree defenses.

The objectives were to: (1) develop a chemical profile of volatiles released from the two different host tree species; (2) evaluate if volatile chemical profiles vary within and between tree species when subjected to different environmental (water deficit vs. well watered) and biological (fungal inoculation, mechanical wounding, and control) treatments; and (3) determine if the monoterpenoid content of tissues is affected by the treatments and differs between tree species.

Methods and Materials

Seedling Source and Treatments Seedlings in their second growth cycle were used for all experiments. Lodgepole pine (*Pinus contorta* var. *latifolia* Engelm. ex Wats.) originated from west-central Alberta, while jack pine was from provenances in north-central Saskatchewan. Seedlings were grown through their first growth cycle under near-identical conditions at PRT Vernon, then packaged and placed in cold storage for approximately 3 month to satisfy dormancy requirements.

Dormant seedlings were shipped overnight to Edmonton, where $N=84$ seedlings per species were planted (pot size: 15×18 cm) in Sunshine Mix #4 (Sungro, Vancouver BC Canada) and maintained throughout the experiment in a walk-in growth chamber, with 16 L/8 h D, 200 μmol m^{-2} full spectrum light intensity, 20°C constant temperature and approximately 50% humidity. Fertilizer was applied with irrigation weekly (0.5 g/l 20 N -20 P -20 K), with additional watering provided as necessary until 1 week before the start of the experiment at which point both species had completed shoot elongation with an average height of 21.5 cm (±2.9 S.D) for lodgepole pine and 32.5 cm (±4.0 S.D) for jack pine seedlings.

Once terminal bud formation had been initiated, seedlings of each species were randomly divided into two groups and received one of two water regimes: water deficit or well watered. Seedlings in the water deficit group received 50 ml of water and those in the other group received 400 ml twice a week for the duration of the 6-wk experiment. In order to ensure that the water deficit seedlings were experiencing mild water stress conditions at the onset of the 6-wk experiment, water was withheld from these seedlings prior to the application of the fungal treatments. Seedlings in both water treatment groups were assigned randomly to one of three treatments: (1) mechanical wounding plus inoculation with *G. clavigera*; (2) mechanical wounding alone; and (3) untreated control. The aim of the first treatment was to stimulate tree defenses with the MPB fungal associate, and the last two treatments were positive and negative control treatments, respectively. Seedlings were inoculated with 5 μl of a *G. clavigera* spore suspension injected into a pouch made with a 23G1 PrecisionGlide™ needle. The spore suspension was prepared by using a sterile inoculation loop and transferring two loopfuls (20 μl) of spores of *G. clavigera* from a well sporulating strain collected from Fox Creek Alberta (54°24'N, 116°48'W) into sterile saline. Seedlings were inoculated at three points, equally distributed along the whole length of the stem. Mechanical wounding was applied in a similar manner but without the fungal inocula (Fig. 1).

For each tree species and water x biological treatment combination, four seedlings were randomly selected (total of 24 seedlings per species) and monitored for volatile emission, photosynthetic rate, stomatal conductance, and soil water content the day before inoculation ($t=0$), and at five time points post inoculation ($t=1$ day, $t=1$ week, $t=2$ week, $t=4$ week, and $t=6$ week). Twelve of the remaining seedlings of each treatment combination per species were destructively harvested at each time point ($N=2$) for chemical analysis of the bark (primarily constituting phloem tissue) of the current year and previous growth of the stem (referred to as current year and previous year bark) and needles. After 6 week, we harvested the seedlings that were used for acquiring volatile emission and physiology data for tissue analyses (below).

Soil Water Content and Gas Exchange Parameters Soil water content was measured using time domain reflectrometry (TDR) (Hillel, 1998). We measured the apparent dielectric constant of the soil with a Tektronix 1502B (Beaverton, OR, USA) and used the empirical equation for organic soils in Robinson et al. (2003) to relate it to water content. Rate of photosynthesis and stomatal conductance were measured using a LI-6400 (LI-COR Biosciences, Lincoln, NE, USA). The instrument settings were: leaf area 1.5 cm^2, flow 300 μmol/sec, and Quantum flux lamp at 200 μmol/m^2sec (equivalent to light intensity in growth chamber).

Volatile Collection Volatile organic compounds (VOCs) released from seedlings were collected 1 day after the physiological data were recorded from the same plant. An oven bag (LOOK®, 45×55 cm) was imposed over the

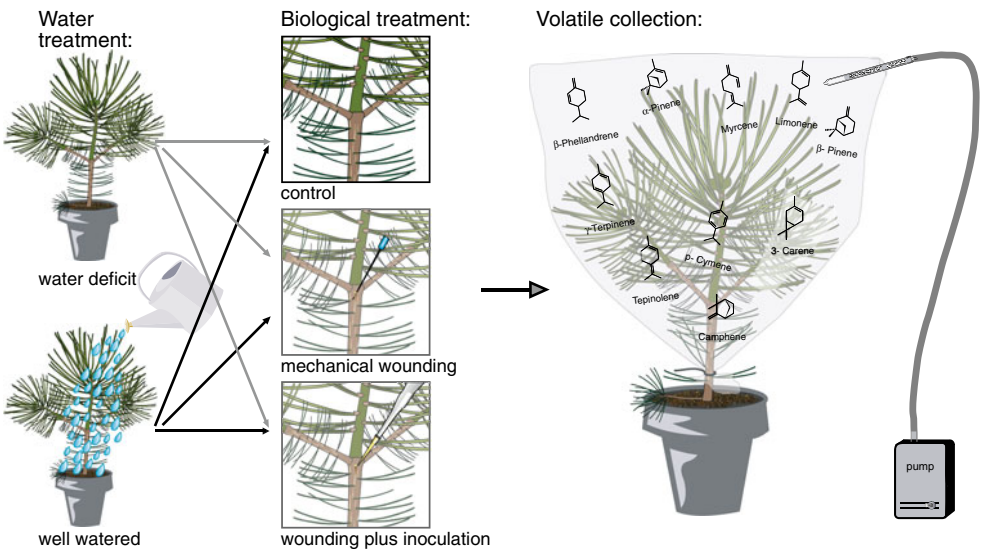

Fig. 1 Methodology scheme showing the two different water treatments: water deficit and well watered, the three biological treatments: control, mechanical wounding and wounding plus inoculation with *Grosmannia clavigera*, and collection of VOCs

whole seedling and closed near the base of the stem with a cable tie. An absorbent tube [Porapak Q (OD 6 mm, length 110 mm; absorbent: front layer 150 mg, back up layer 75 mg; separated by glass wool) SKC Inc., PA, USA] was inserted into the bag at the top of the seedling and affixed with Parafilm®. A small hole was placed on the other side of the oven bag to maintain constant air pressure inside the bag. Volatile emissions were collected for 4 h at a constant flow rate of 200 ml/min. After collection, the sorbent tubes were capped and stored at −40°C until extraction. Air samples were collected at two locations of the growth chamber to control for possibility of contamination with chamber air.

Porapak Q tubes were extracted with 1 ml of dichloromethane (Sigma-Aldrich, St. Louis, MO, USA) spiked with 0.01% (v/v) tridecane (Sigma-Aldrich, St. Louis, MO, USA) as surrogate standard and subsequently stored at −40°C before GC analysis.

Tissue Extracts Seedlings were harvested outside of the chamber in which VOCs were collected. During seedling harvest, bark and needle samples were frozen rapidly in liquid nitrogen, and stored at −40°C prior to extraction. Tissue was ground in liquid nitrogen, and 100 mg of the tissue were transferred to a 1.5 ml microcentrifuge tube. Samples were extracted twice with 0.5 ml dichloromethane and 0.01% tridecane as surrogate standard. After adding solvent, samples were vortexed for 30 sec, sonicated for 10 min, subsequently centrifuged at 13,200 rpm and 0°C for 15 min, and placed in a freezer for at least 2 h to let the pellet freeze. Extracts were transferred into an amber GC vial and stored at −40°C before GC analysis.

GC Analysis Samples (1 μl) were injected in an Agilent 7890A Gas Chromatograph (Agilent Technologies, Santa Clara, CA, USA) with an HP Innowax (Agilent Technologies) column (I.D. 0.32 mm, length 30 m), helium carrier gas flow at 1.8 ml/min, temperature 50°C for 2 min, increased to 160°C by 5°C per min, and then to 250°C by 20°C.

Peaks were identified using the following standards: Borneol, pulegone, α-terpinene, γ-terpinene, α-terpineol (Sigma-Aldrich, St. Louis, MO, USA), camphor, 3-carene, α-humulene, terpinolene, α-thujone and β-thujone, (-)-α-pinene, (-)-β-pinene, (S)-(-)-limonene, sabinene hydrate, myrcene, (-)-camphene, *p*-cymene (Fluka, Sigma-Aldrich, Buchs, Switzerland), bornyl acetate, *cis*-ocimene (SAFC Supply Solutions, St. Louis, MO, USA), β-phellandrene (Glidco Inc., Jacksonville, FL, USA).

Calibration with standards allowed for analysis of quantitative differences among samples of differently treated seedlings at different time points. For all samples, peaks were integrated and peak area was compared for qualitative and quantitative differences among samples of differently treated seedlings at different time points.

After all samples were analyzed with the GC, subsequent analysis with GC-mass spectrometry showed that our method was unable to separate myrcene and α-phellandrene. From a different experiment, we know that α-phellandrene hardly occurs in jack pine seedlings and makes up to 35% of the peak in lodgepole pine seedlings.

Statistical Analyses The VOC emission data and the seedling physiology data collected from the same trees were analyzed using the R statistical language (R development core team, 2010). In order to address how volatile emission of the seedlings changed due to the environmental and biological treatments and their associated change in physiology, we carried out a canonical redundancy analysis (RDA; Legendre and Legendre, 1998) using the rdaTest package (Legendre and Durand, 2010). RDA axes were tested for significance by permutations with the vegan package (Oksanen et al., 2010) also through the R statistical language. Explanatory variables included water and biological treatments, as well as soil water content, photosynthesis and stomatal conductance. Total and individual monoterpenes of all time points were the response variables. Due to technical difficulties during the extraction process, two time points (weeks 1 and 6) were discarded from the jack pine dataset. In order to evaluate whether the resulting lack of correlation between soil water content and physiological parameters in jack pine was due to the missing two time points, we also carried out an RDA for lodgepole pine with the same time points omitted, the results remained the same.

To assess the effect of environmental treatments on total monoterpene emission from both tree species over time, Mann–Whitney *U* tests were used. The effect of the biological treatments was assessed using repeated measures ANOVAs with subsequent pairwise comparison with Bonferroni correction on water deficit and well watered seedlings separately using SPSS Statistics 17.0. Soil water content and plant physiology results are presented using bar graphs with error bars showing 95% confidence intervals, non-overlapping bars represent a significant difference.

All tissue extract data were analyzed using SPSS Statistics 17.0. Total monoterpenes were analyzed using repeated measure ANOVA. Individual monoterpene data were transformed with log(x+1) to meet the assumptions of normality and analyzed for all tissues separately using ANOVA. In cases in which the data violated the assumptions of an ANOVA, non parametric tests were conducted on non transformed data. Interspecific differences were analyzed using *t*-test.

Results

Soil Water Content and Gas Exchange Parameters The water deficit seedlings were not watered the week before

the experiment started; therefore, there was a significant difference in soil water content between the well watered and water deficit seedlings on the first day of the experiment (Fig. 2). Through the duration of the experiment, the water content of the soil in the water deficit treatment decreased to almost 0%, whereas soil water content of well watered seedlings stayed constant between 20% and 30%.

Independent of the biological treatments, the photosynthesis rate in lodgepole pine decreased over time in the water deficit group, but not in the well watered group (Fig. 3a). In jack pine, neither the biological nor the water treatments had an effect on photosynthesis rate. Stomatal conductance was generally higher in lodgepole than jack pine but it decreased sooner due to water stress in lodgepole pine and reached 1/3 of the jack pine stomatal conductance by the end of the experiment (Fig. 3b).

Chemical Profiles The main differences in the chemical profile emitted by seedlings of the two pine species are that lodgepole pine (LP) emits a higher percentage of β-phellandrene (27%±2.25 SE) than jack pine (1%±0.26 SE) and jack pine (JP) releases more α-pinene (27%±3.25 SE) than lodgepole pine (7%±0.80 SE) (Fig. 4). 3-Carene makes up more of the volatile chemical profile in jack pine than lodgepole pine (21%±3.99 SE in JP, 7%±1.76 SE in LP).

Volatile Emission The first axis of the lodgepole pine redundancy analysis (RDA) ($P<0.001$) and of the jack pine RDA ($P=0.006$) was significant. RDA triplots (Fig. 5) illustrate the relationship between the gas exchange parameters and volatile emission of the seedlings and water stress and biological treatments for each tree species.

In both species, 3-carene emission correlated with fungal inoculation. Emission of the major compounds, β-phellandrene in lodgepole and α-pinene in jack pine correlated with the physiological state (photosynthesis and stomatal conductance) of the seedling. The physiological parameters of stomatal conductance and photosynthesis correlated positively with soil water content in lodgepole but not jack pine seedlings.

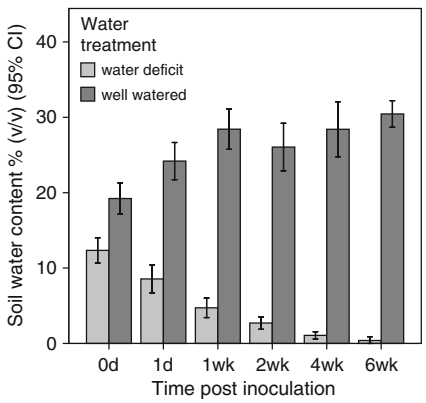

Fig. 2 Soil water content over time measured for pots containing lodgepole and jack pine seedlings. For each time point, data for the two species were combined. Error bars represent the 95% confidence interval. Bars with non overlapping error bars are significantly different from each other

In both lodgepole pine and jack pine, water deficit seedlings released significantly lesser amounts of total monoterpenes starting at week 4 of the experiment (Mann–Whitney U, lodgepole pine: $U=21$, $z=-2.94$, $P=0.003$; jack pine: $U=26$, $z=-2.66$, $P=0.008$) and thus, all further analyses were conducted on water deficit and well watered seedlings separately. Biological treatments had a significant effect on total monoterpene emission in water deficit lodgepole pine seedlings [repeated measures ANOVA, $F(2,8)=6.329$, $P=0.022$; Fig. 6]. Subsequent pairwise comparison with Bonferroni correction of the timepoints revealed that 1 day after biological treatment application greater amounts of VOCs were emitted from lodgepole pine than at any other timepoint ($P=0.006$; Fig. 6). Further, pairwise comparison of the biological treatments showed that lodgepole pine seedlings that were inoculated with *G. clavigera* emitted significantly greater amounts of monoterpenes than controls ($P=0.029$). Mechanically wounded seedlings also emitted greater amounts of volatiles than control seedlings but not at a significant level ($P=0.066$). Well watered lodgepole pine demonstrated the same trends but showed no significant differences. In jack pine, the biological treatments had no significant influence on VOC emission. Lodgepole pine seedlings emitted lesser amounts than jack pine but the difference was not significant.

Tissue Extracts The number of detectable monoterpenes in the tissue extracts of both species was higher than in the volatile profiles (Table 1). Sabinene hydrate, *cis*-ocimene, α-thujone, and pulgeone occurred only in lodgepole pine and were never detected in jack pine.

The overall needle monoterpene content in lodgepole pine seedlings is lower compared to previous year and current year growth bark [repeated measures ANOVA, $F(1.80,127.70)=118.37$, $P<0.001$; Fig. 7]. *cis*-Ocimene is the only terpenoid that did not follow this pattern and it occurred in higher concentration in the needles. All further analyses were conducted on the different tissues separately. The environmental treatment affected terpinolene, which occurred in higher concentrations in the current year and previous year bark of watered seedlings [ANOVA, $F(1,70)=3.999$, $P=0.028$ and $F(1,70)=5.059$, $P=0.049$, respectively] than in the water deficit seedlings. Less bornyl acetate occurred in the previous year's bark of watered seedlings [ANOVA, $F(1,70)=5.265$, $P=0.025$] compared to seedlings subjected to water deficit. The biological treatments had no effect on any of the measured terpenoids in the tissue extracts.

Like lodgepole pine, jack pine needles had a significantly lower overall monoterpene content than current year or previous year bark [repeated measures ANOVA, $F(2,142)=$

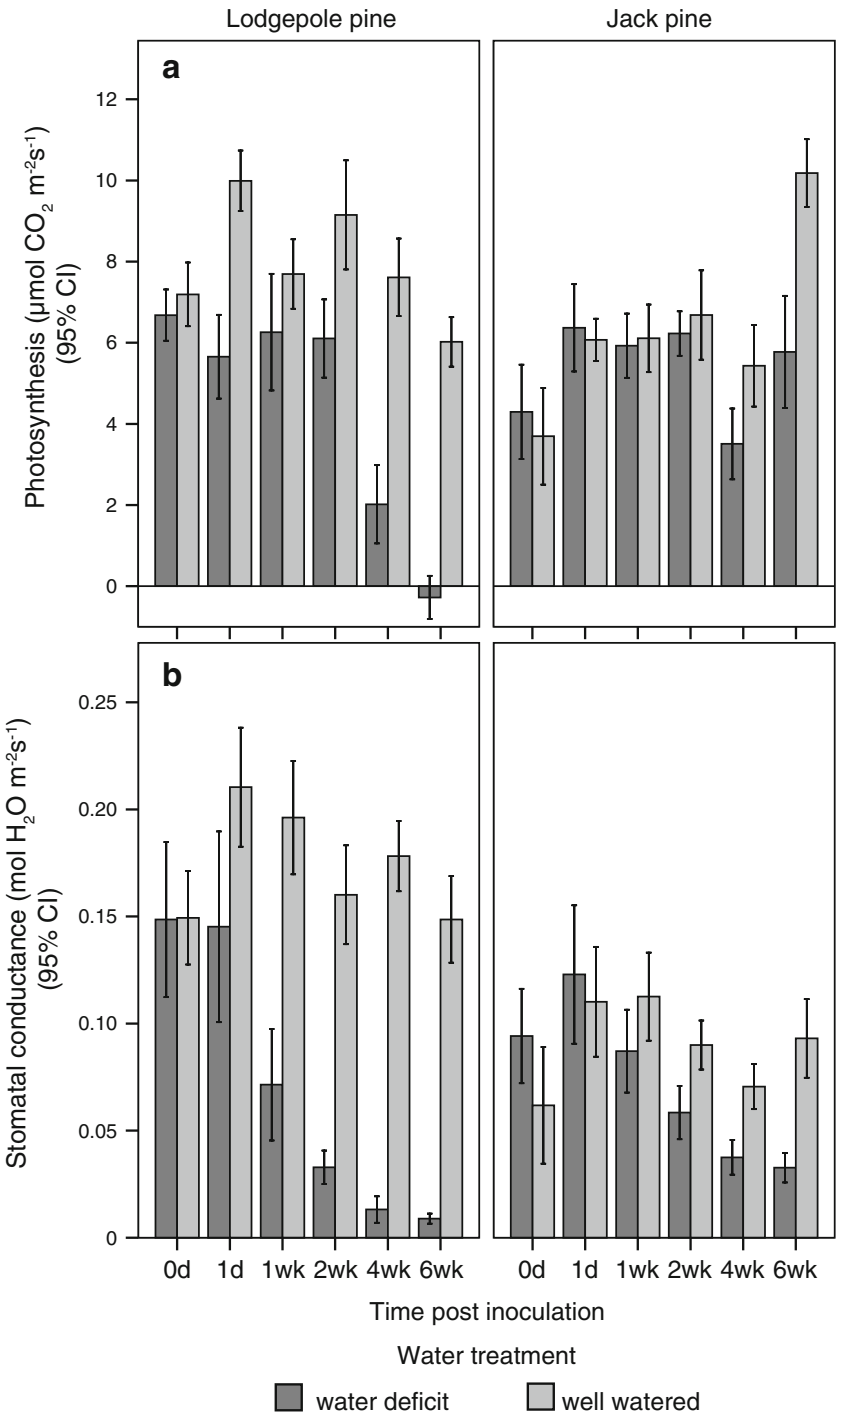

Fig. 3 Changes in gas exchange parameters over time shown for both water treatments in lodgepole and jack pine seedlings (**a**) rate of photosynthesis (**b**) stomatal conductance. Error bars represent the 95% confidence interval. Bars with non overlapping error bars are significantly different from each other

115.66, $P<0.001$; Fig. 7]. The environmental treatment had no effect on monoterepene content of jack pine tissues. The bornyl acetate content in the previous year bark of fungal-inoculated seedlings was higher than in wounded seedlings [Kruskal-Wallis, $H(2)=16.467$, $P<0.001$; Fig. 8].

The overall monoterpene content of all tissues increased in both species over time independent from any manipulation (Fig. 9). Both species exhibit similar terpenoid content in collected bark tissues, but jack pine needles contain more terpenoids compared to those from lodgepole pine [*t*-test, $t(117.664)=3.413$, $P=0.001$; Fig. 7].

Discussion

Water regime manipulation and stimulation of plant defenses affected the emission of VOCs differently in the two studied

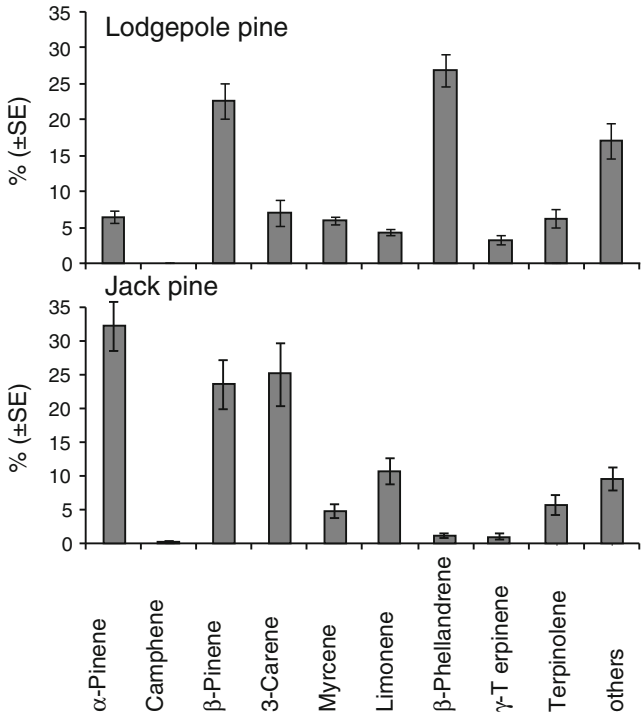

Fig. 4 Chemical profiles presented as percent of volatile organic compounds emitted from lodgepole pine and jack pine seedlings based on peak area in GC analysis. Error bars indicate standard errors

pine species. In general, jack pine emitted higher amounts of 3-carene (21%), compared to lodgepole pine (7%) while lodgepole pine released higher amounts of β-phellandrene (27%) than jack pine (1%) (Fig. 4). β-Phellandrene is the only monoterpene that attracts MPB in the absence of aggregation pheromones when released at high doses (Miller and Borden, 1990), which could mean that pure jack pine stands might fail to attract pioneer beetles flying actively into the region compared to lodgepole pine stands.

The chemical profile of jack pine seedlings tested in our study contained 21% of 3-carene on average, similar to previous reports of jack pine from central Saskatchewan, Canada (Pauly and von Rudolff, 1971) and consistent with the profile of mature jack pine in the Smoky Lake region of Alberta (unpublished data). Within the wide range of jack pine in North America, there are surprisingly few records available on chemical profiles of jack pine, and almost all records are from the most southern extension of the jack pine forest in Wisconsin, USA. In those studies, the chemical profiles consist primarily of α- and β-pinene; 3-carene was either not found or occurred only in trace amounts (Zavarin et al., 1969; Wallin and Raffa, 1999; Erbilgin et al., 2001; Aukema et al., 2010). An early study that directly compared resin monoterpene composition among lodgepole pine, jack pine, and their hybrids found 3-carene to be a signature compound in lodgepole pine that could distinguish it from jack pine (Zavarin et al., 1969). This large variability of 3-carene in jack pine monoterpene profiles suggests either that there are two or more phytochemical phenotypes in jack pine, similar to lodgepole pine (Forrest, 1980), or that there is a greater degree of introgression of lodgepole pine genes into jack pine in the western extent of the jack pine range than originally assumed. A similar variability of 3-carene content occurs in Scots pine seedlings from different provenances in Turkey and Finland (Semiz et al., 2007), suggesting that terpenoid synthesis is under genetic control and differs by geographical origin of the seeds. Clarification of the role, if any, of 3-carene in jack pine profiles is essential in order to predict the potential interaction between MPB and jack pine in the boreal forest.

The chemical profile measured from lodgepole pine seedlings in our study is in agreement with existing published profiles (Zavarin et al., 1969; Pauly and von Rudolff, 1971; Pureswaran et al., 2004a). The consistency in monoterpene profiles of lodgepole pine resin has enabled the use of chemosystematics across the geographic range of the species (Forrest, 1980). Chemical profiles are used to distinguish subspecies/varieties of lodgepole pine, which are: subsp. *contorta*, *bolanderi*, *murrayana*, and *latifolia* (Critchfield, 1957). Chemotyping only failed to distinguish the lodgepole pine subspecies *murrayana* and *latifolia* (Forrest, 1980; Bohm, 2009). Our results underscore the need for a thorough study to chemotype jack pine trees across its broad range.

Seedlings of both species emitted an overall lower quantity of VOCs under water deficit conditions, which was evident at day one of the experiment but significant at week four (Fig. 6). Although emission of VOCs is not thought to be controlled by stomatal conductance (Sharkey, 1991; Kesselmeier and Staudt, 1999; Blanch et al., 2007), in our study stomatal conductance may have indicated the general condition of seedlings and thus indirectly affected the efficiency of monoterpene synthesis in the plant to increase monoterpene emission rates. Similarly, VOC emission was strongly reduced by severe drought conditions and linked to stomatal closure in common Mediterranean woody species including *Pinus halepensis* (Llusià and Peñuelas, 1998). Although in a similar study, *Pinus halepensis* seedlings exposed to moderate drought conditions exhibited no change in VOC emission as a result of water deficit (Blanch et al., 2007). In our study, stomatal conductance explained the release of some of the most abundant monoterpenes in lodgepole pine and jack pine. Likewise, Niinemets et al. (2002) concluded that stomatal conductance in *Pinus pinea* affected the emission of alcohols, aldehydes, carboxylic acids, and oxygenated monoterpenoids. This finding should be considered in monoterpenoid emission models that currently use a simple equation that relies mainly on temperature to describe the monoterpene efflux from foliage (Guenther et al., 1991) and does not consider any role of

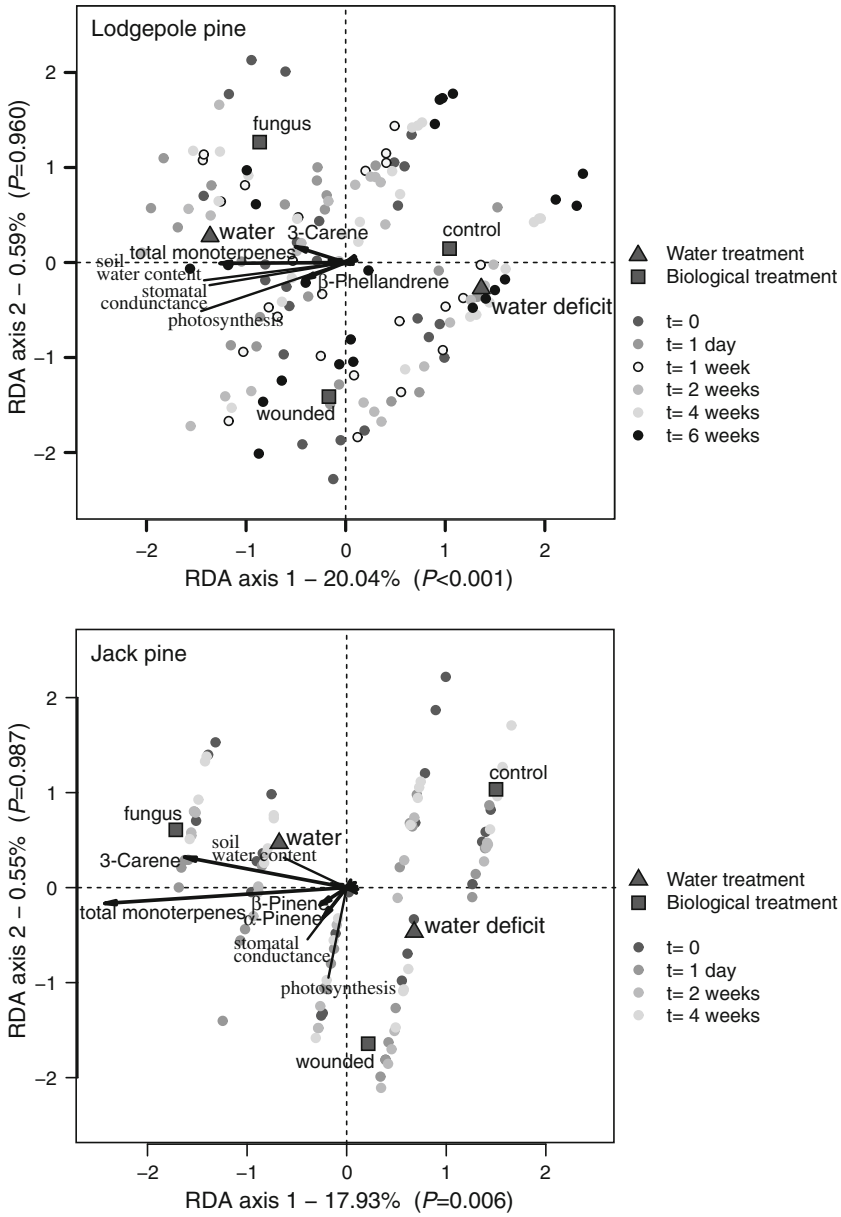

Fig. 5 Canonical redundancy analysis (RDA) triplots (scaling 2) illustrating the effect of environmental and biological treatments as well as seedling physiology on volatile emission of individual and total monoterpenes in lodgepole and jack pine

stomatal conductance in VOCs emission (Sharkey, 1991; Kesselmeier and Staudt, 1999).

Stomatal conductance and the resulting gas exchange that is essential for the carbon reactions of photosynthesis depend on the water transport from soil to leaf. Plant species categorized as isohydric exhibit tight control over stomatal aperture in response to soil water deficit as a means to regulate water loss; whereas species classified as anisohydric do not (Tardieu and Simonneau, 1998; McDowell et al., 2008). Stomatal conductance in lodgepole pine seedlings in the current study was higher than that in jack pine and responded more quickly to a decrease in soil water content (Fig. 3). Jack pine appears to be better adapted to low water availability than lodgepole pine, which is consistent with the success of jack pine in dry and nutrient poor soils across its natural range (Vidaković, 1991). In our study, soil moisture content influenced the physiological state of pine species differently. The RDA results (Fig. 5) support the findings that jack pine is better adapted to water deficit conditions, as the physiological state of lodgepole pine but not that of jack pine was correlated with soil water content.

Fungal inoculation of seedlings with an MPB associated fungus also altered the VOC emissions in both pine species. 3-Carene emission increased and was correlated with fungal inoculation in both lodgepole and jack pine (Fig. 5). Mature jack pine trees inoculated with the pine engraver, *Ips pini*, associated fungus *Ophiostoma ips* had increased 3-carene phloem content (Raffa and Smalley, 1995). Jost et al. (2008) inoculated mature lodgepole and jack pine trees as well as their hybrids with MPB associated fungi and collected bark

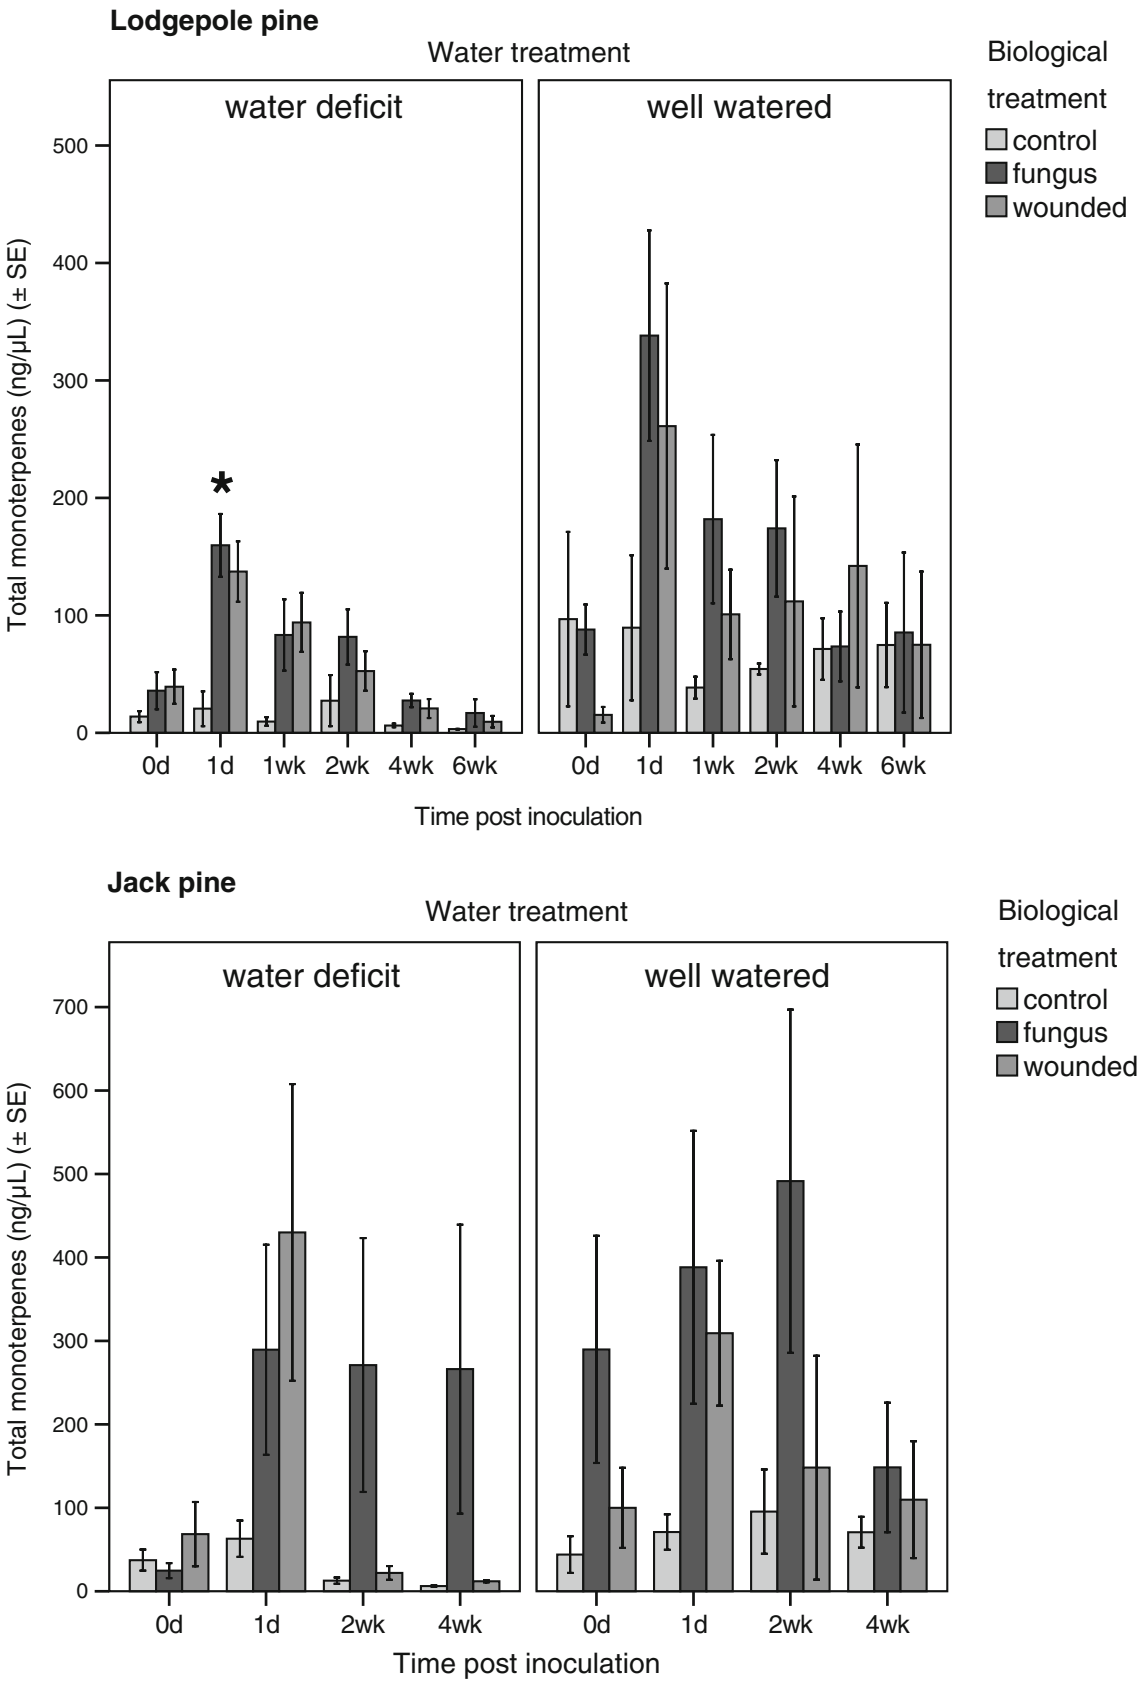

Fig. 6 Effect of water and biological treatment on total monoterpene emission by lodgepole and jack pine seedlings over time. Error bars indicate standard errors. The asterisk indicates the significant difference of total monoterpene emission in fungal inoculated water deficit lodgepole pines compared to the control treatment (P=0.029)

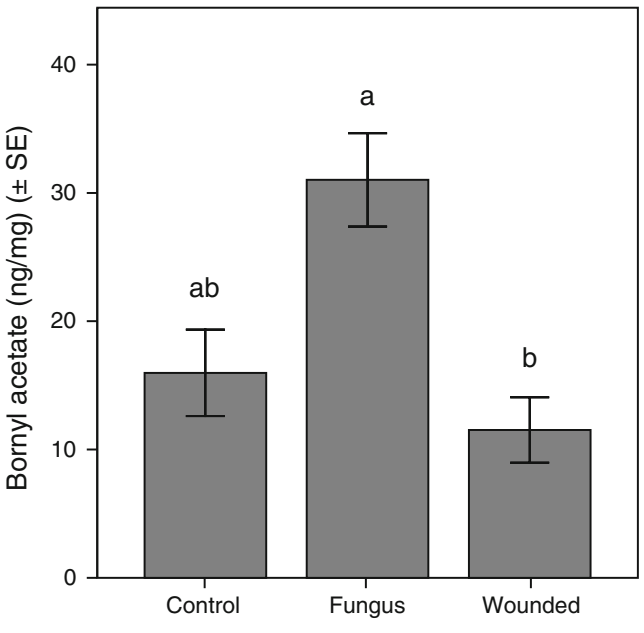

Fig. 8 Different bornyl acetate concentrations in previous year's bark of jack pine caused by the biological treatments. Kruskal-Wallis test was used followed up by Mann–Whitney *U* tests. A Bonferroni correction was applied and so all effects are reported at a 0.025 level of significance. Different lowercase letters indicate a statistically significant difference

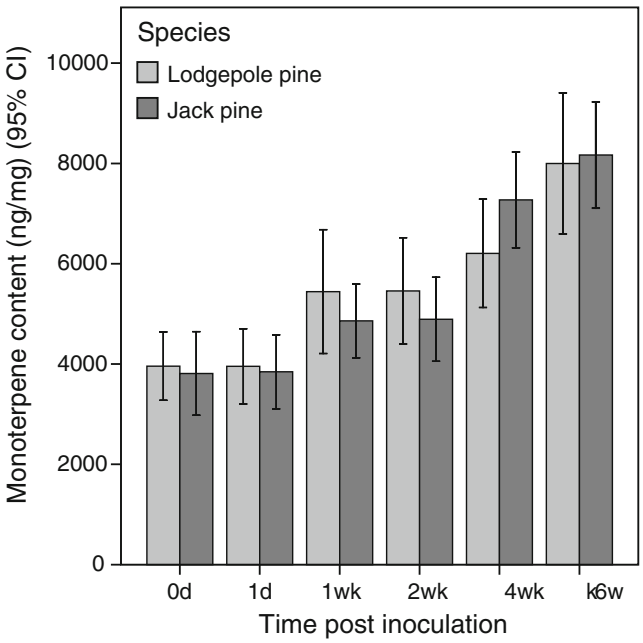

Fig. 9 Total monoterpene increase over time in all tissues of lodgepole and jack pine seedlings across all treatments. Error bars represent the 95% confidence interval. Bars with non overlapping error bars are significantly different from each other

volatiles after a 6-week inoculation period. Unfortunately, they did not measure 3-carene, and the only significant difference they found was a strong reduction in α-pinene emission in fungal inoculated lodgepole pine. Direct comparison of the two studies is difficult since they did not quantify their results but only compared ratios. During our experiment, the fungal inoculated lodgepole pine seedlings always released more α-pinene than the controls. Resin monoterpenes from ponderosa pine including α- and β-pinene, 3-carene, limonene, and terpinolene have anti-fungal properties (Himejima et al., 1992). Monoterpenes and other chemical compounds in the resin of host pine inhibit the growth of bark beetle-associated fungi in the southern US coniferous system (Bridges, 1987; Klepzig et al., 1996). There is growing evidence that plants respond to microbial attack by releasing volatiles, which initiates defense mechanisms by signaling within as well as possibly between plants (Kesselmeier and Staudt, 1999). Volatile organic compounds released from inoculated plants induce the resistance to fungi in *Arabidopsis* (Kishimoto et al., 2006), but little is known about plant communication in conifers (Heil and Karban, 2009). The increased emission of 3-carene after fungal inoculation in our study might be due to allocation of that compound towards the inoculation site by the plant, thus fighting the fungus and the wound facilitating its release. In particular, damaged bark can be a major source for VOC emission in conifer seedlings (Heijari et al., 2011).

In the current study, we sampled both volatile and tissue chemistry of both pine species in response to water stress and biological treatments. There are fewer detectable monoterpenes in the seedling volatile profiles compared to monoterpene content in bark and needles. Monoterpene concentration in bark (phloem) and needles also can respond to drought stress (Hodges and Lorio, 1975; Llusià and Peñuelas, 1998). Monoterpenes and resin acids in the woody tissue of Scots pine and Norway spruce seedlings significantly increased as a result of drought exposure (Turtola et al., 2003). In our study, water deficit had no effect on overall monoterpene content in either tissue type. In fact, terpinolene concentration decreased in the bark as a result of water deficit in the lodgepole pine seedlings. The only compound that significantly increased due to water deficit was bornyl acetate in the previous year's bark of lodgepole pine seedlings. The levels of bornyl acetate also was associated with fungal inoculation in jack pine previous year's bark (Fig. 8). Increased bornyl acetate concentrations in the resin of lodgepole pine are associated with Armillaria root disease (*Armillaria mellea*) (Nebeker et al., 1995). Bornyl acetate levels also increase in root and stem tissue of Douglas-fir seedlings (*Pseudotsuga menziesii*) treated with methyl jasmonate, a phytohormone implicated in mediating defense responses (Huber et al., 2005). In some areas, MPB attack is linked to pines infested with *A. mellea* (Tkacz and Schmitz, 1986). Mountain pine beetle antennae do not respond to bornyl acetate (Pureswaran et al., 2004b), but it is possible that it can taste this compound since olfactory and gustatory information are processed in different areas of the insect brain (DeBruyne and Warr, 2006). Gustatory assessment could be way for MPB to evaluate the health status of a host tree and to determine how well defended it is.

The primary goal of our study was to evaluate the chemical profiles of jack pine and lodgepole pine trees and to make reasonable assumptions about jack pine suitability as a potential host to MPB based on its chemistry. All volatile monoterpenes emitted by lodgepole and jack pine seedlings in the study can be detected by the MPB (Huber et al., 2000; Pureswaran et al., 2004b). Some of these host monoterpenes synergize MPB response to the aggregation pheromones *trans*-verbenol and *exo*-brevicomin in trapping studies (Borden et al., 2008). There is strong evidence that myrcene, 3-carene, terpinolene, and α-pinene synergize MPB aggregation pheromone response (Borden et al., 2008). In olfactometer tests, 3-carene was most attractive to MPB out of 20 tested compounds (Conn, 1981). In our study, 3-carene emission increased with plant defense stimulation by *G. clavigera.* This compound might function as an indicator of a weakened tree and could support the aggregation of beetles on susceptible hosts. MPB is able to distinguish between host and non-host volatiles, and may

also use host volatiles to identify weak hosts and avoid the risks associated with trying to overcome tree defenses of a healthy host (Keeling and Bohlmann, 2006). Jack pine emits about three times more 3-carene than lodgepole pine, suggesting that it may be more prone to MPB attacks (Conn, 1981; Borden et al., 2008). Further, jack pine bark contains higher concentrations of α-pinene than lodgepole pine, and α-pinene can be a synergist for the MPB aggregation pheromone, and it is also a precursor for production of *trans*-verbenol, the primary component of MPB aggregation pheromone (Borden et al., 2008).

This study enabled us to compare VOC emission and monoterpene content between lodgepole and jack pine exposed to water stress and different biological treatments under controlled and easy to manipulate conditions. The results suggest that monoterpenes that play a role in pine-MPB interactions differ between lodgepole and jack pine, and also that they are affected by water availability. Shrimpton and Watson (1971) recommended the use of lodgepole pine seedling for studying wound response, since seedlings and mature trees are identical in their resistant response. Nevertheless, inferences made from our study to MPB host use are limited as beetles do not attack trees at the seedling stage. The results from this study, however, are useful for developing the models that guide rational design of field studies, with their inherently greater degree of difficulty and experimental variance. Additional field experiments to understand chemically-mediated interactions among MPB, its associated fungus, and its pine hosts under water deficit conditions are currently being conducted in mature lodgepole, jack and hybrid pine stands. Future studies will assess the behavioral importance of the host monoterpenes from the two species in host detection and acceptance by MPB.

Acknowledgements We thank two anonymous reviewers for helpful suggestions on an earlier version of this manuscript. We acknowledge the lab members of Janice E. K. Cooke as well as Boyd Mori for help potting the seedlings; Miles Dyck for providing us with the TDR equipment; Celia Boone for sharing β-phellandrene; Patrick James for an introduction to R; and Joanne Mann (West Fraser Mills Ltd., Hinton Wood Products), Michael Bendzsak (Saskatchewan Forest Centre), and Glenn Goodwill, Candace Kent and Stewart Haywood-Farmer (PRT) for providing seedlings. We particularly acknowledge Adrianne Rice for providing fungal culture and knowledge, and Jeremiah Bolstad and Andrew Ho for the help during the sample extraction process.

Funding for this research has been provided through grants from the Government of Alberta through Genome Alberta, the Government of British Columbia through Genome BC and Genome Canada in support of the Tria 1 and Tria 2 projects (http://www.thetriaproject.ca) of which MLE, JEKC, and NE are co-investigators.

which in turn affects worker behavior (Richard et al., 2007). Honey bee queens typically mate with multiple males, but the number of matings is highly variable (Tarpy and Nielsen, 2002). Extreme polyandry in honey bees results in greater genetic variability within the colony, which has been associated with healthier colonies (Tarpy and Seeley, 2006), as well as greater productivity and fitness (Mattila and Seeley, 2007). However, according to kin selection theory, lower relatedness among colony members should reduce altruistic and social behavior (Bourke, 1988). Thus, it is expected that queen pheromone composition would reflect her mating history, and that workers should be able to detect these differences. The relationships among multiple matings by the queen, her pheromone composition, and worker behavior have important implications for the evolution of social behavior in honey bees.

The Dufour's gland, previously called the alkaline gland, is an abdominal gland ubiquitous in the Hymenoptera. The gland is associated with the venom, sting sheath, and Koschevnikov glands in the sting apparatus (Martin et al., 2005) (see Fig. 1). Despite several studies, the precise role of the Dufour's gland in honey bees remains unclear. The chemical composition of the gland is affected by caste, task, and age of the bees (Le Conte and Hefetz, 2008). While both queen and worker glands produce hydrocarbons, queens also produce esters (Katzav-Gozansky et al., 1997a). However, the Dufour's gland of workers with developed ovaries also synthesizes queen-like esters (Katzav-Gozansky et al., 1997a), suggesting that the chemical profiles are linked to ovary development and reproductive potential. Previous studies on the effects of mating and reproduction on queen Dufour's gland content have been inconclusive (Katzav-Gozansky et al., 1997b); although newly mated and one-year-old mated queens tended to have lower quantities of Dufour's gland components than virgins, the differences were not statistically significant. Similarly, glands of mated queens tended to contain higher proportions of esters (compared to hydrocarbons) than virgins, but these differences also were not statistically significant. Finally, and contrary to analyses of gland contents, *in vitro* assays of ester and hydrocarbon production by using radiolabeled precursors revealed that mated queens produced significantly higher proportions of hydrocarbons than esters compared to virgin queens. However, these assays likely were confounded by age differences among the queens; other studies have demonstrated that production of queen mandibular pheromone (QMP) varies greatly with age (Plettner et al., 1997).

Fig. 1 Dufour's gland location in honey bees (in red)

The Dufour's gland may serve different functions in different species (Hölldobler and Wilson, 1990). It can produce a trail-marking pheromone, recruitment pheromone, sexual pheromone, or queen control pheromone (Hölldobler and Wilson, 1990; Le Conte and Hefetz, 2008). In honey bees, it has long been debated whether or not the Dufour's gland produces an egg-marking pheromone (Ratnieks, 1995). Selective oophagy of worker-laid eggs (also called 'workers policing') strengthens the functional sterility of their nestmates (Ratnieks and Visscher, 1989). Thus, the switch to queen-like Dufour's gland composition by laying workers may be an attempt to mimic the queen. Indeed, Dufour's gland chemicals have been found on eggs (Katzav-Gozansky et al., 2001). Worker-laid eggs treated with either whole Dufour's gland extracts or the ester fraction—at significantly higher quantities than naturally occurring levels—were removed more slowly than untreated worker-laid eggs, and no difference was observed when eggs were treated with the hydrocarbon fraction (Martin et al., 2002). However, another study that used more natural levels did not demonstrate an effect of Dufour's gland extracts on egg-removal and worker policing (Katzav-Gozansky et al., 2001). Thus, it is unclear whether or not the Dufour's gland in honey bee queens is a significant source of egg-marking cues. However, the Dufour's gland secretions are attractive to workers, suggesting that this gland plays a role in modulating worker behavior and perhaps in colony organization. Attracted workers antennate and groom the queen (Pankiw et al., 1994, 1995), and subsequently spread the queen pheromone through the colony; thus, attraction to the queen plays a role in colony social organization. The Dufour's gland extracts of queens and laying workers are significantly more attractive to workers than extracts of non-reproductive worker bees (Katzav-Gozansky et al., 2001, 2003). Furthermore, the esters, rather than the hydrocarbons, appear to mediate this attraction (Katzav-Gozansky et al., 2003). Finally, exposing bees to both QMP and Dufour's gland extracts has a greater inhibitory effect on worker ovary development than QMP alone (Katzav-Gozansky et al., 2006), suggesting that these chemicals may also serve as a primer pheromone.

Previous studies have demonstrated that chemical composition of the queen mandibular gland is affected by reproductive state and insemination quantity (Richard et al., 2007; Kocher et al., 2008, 2009). Here, we examined the effect of both instrumental insemination and insemination with one or multiple drones on the Dufour's gland. We monitored the attraction of caged workers to the Dufour's gland extracts of virgin, single-drone inseminated (SDI), and multi-drone inseminated (MDI) queens. The chemical profiles of the Dufour's glands of these queens were then characterized by using gas chromatography-mass spectroscopy (GC-MS). We analyzed the quantities and relative proportions of esters and hydrocarbons, since previous studies indicated that mated queens may have lower total quantities of compounds and synthesize higher proportions of hydrocarbons than virgins (Katzav-Gozansky et al., 1997b). Furthermore, since previous studies indicate that the Dufour's gland is linked to ovary development in workers and, thus, might be an indicator of fertility, we also monitored levels of *vitellogenin* expression in the fat body of queens. *Vitellogenin* is an egg-yolk protein precursor, and expression of this gene is higher in recently mated, laying queens than in same-aged virgins (Kocher et al., 2008).

Methods and Materials

General Bee Rearing Colonies headed by SDI queens (*Apis mellifera carnica*, Glenn Apiaries, CA, USA) were maintained at the NCSU Lake Wheeler Honey Bee Research Facility (Raleigh, NC, USA). These colonies were used to produce super-sister queens for the experiments. Due to the haplodiploid sex determination of Hymenoptera, female progeny of SDI-queens have a genetic relatedness of G=0.75. Additionally, colonies headed by naturally mated *Apis mellifera ligustica* or Buckfast-SMR queens (B. Weaver, TX, USA) were used to provide drones for the semen collections and workers for the cage experiments.

Queen Rearing Super-sister queens were produced by grafting young larvae (<24 h) from a single source colony headed by an SDI queen, and rearing them as queens in a queenless colony (Laidlaw, 1977). Capped queen cells were transferred to a dark incubator at 33°C and ~40% relative humidity. One to two days prior to emergence, each capped queen cell was placed into an individual Plexiglas cage (10×10×7 cm) with ~100 1-d-old workers and fed a 50% sucrose solution and honey/pollen paste (45% honey, 45% pollen, 10% sucrose) *ad libitum*. Five days after emergence, some queens (those that were to be inseminated) were treated with CO_2 for 4.0 min (Laidlaw and Page, 1997), while others (those that were to remain virgins) were left untreated. Two days later, queens were treated again with CO_2 for 4.0 min, during which time they were inseminated with semen from either one drone (SDI) or 10 brother drones (MDI) following standard insemination protocols (Laidlaw, 1977). The average drone produces approximately 1 μl of semen, and thus the total insemination volume of each queen was approximately 1 μl for SDI queens and 10 μl for MDI queens. There is obviously variation between different drones, however, and thus volume was not precisely controlled in this study. Note that we are studying the effects of the instrumental insemination procedure (which includes CO_2 treatment, manipulation with the insemination device, and insemination with semen), and the effects of insemination with different numbers of drones. Additional studies on the specific effects of CO_2 and physical manipulation are in preparation. Queens were returned to their respective cages and collected 5 d later onto dry ice and stored at −80°C. A total of 12 virgin, 12 SDI, and 9 MDI queens were produced. Queens were reared in two separate cohorts from the same colony, approximately 1 wk apart (Cohort 1: 7 SDI and 4 MDI; Cohort 2: 12 virgin, 5 SDI, and 5 MDI), but queens from different cohorts were combined in behavioral assays, gene expression studies, and chemical analyses.

Dufour's Gland Extraction Abdomens were dissected in ice-cold RNAlater (Qiagen, Valencia, CA, USA). The Dufour's glands were dissected (Fig. 1) and extracted in 50 μl of pentane containing 0.4 μg/μl of hexadecane (Sigma). Gland extracts were stored at −20°C until they were used for GC analysis or behavioral assays (see below). Internal organs of the abdomen were removed, and the carcass (with attached fat body) was stored at −80°C for gene expression analysis.

Worker Attraction to Dufour's Gland Extracts We compared the responses of adult workers to Dufour's gland extracts of virgin, SDI, and MDI queens. The glands were extracted from each super-sister queen produced as outlined above. Since the internal standard was introduced to each sample, the hexadecane was not expected to contribute to differences in behavioral responses among the sample groups. Previous studies also demonstrated no worker attraction to hexadecane (data not shown). Frames of brood were removed from a single colony headed by a naturally mated queen and incubated at 33°C. One day old workers were collected from the brood frames, and 30 bees were placed into Plexiglas cages (10×10×7 cm). Bees were provisioned with food as described above. Cages were kept in a 33°C incubator with ~40% relative humidity, and manipulations and observations were performed under red light to mimic natural conditions in the hive. In total, 34 cages were maintained for 5 d.

Since worker maturation is altered in the absence of queen pheromone (Morgan et al., 1998; Grozinger et al., 2003), we reared these workers with QMP to mimic natural colony conditions. Bees were exposed to 0.1 queen equivalents (Qeq) of synthetic QMP (Pherotech, Canada). Every day, 10 µl of QMP (0.1 Qeq) in hexane was placed on a glass microscope slide, and the solvent was allowed to evaporate before the slide was placed into the cage. This amount of QMP mimics a live queen in assays of worker behavior and physiology (Slessor et al., 1998, 2005; Hoover et al., 2003).

On the fifth day of the experiment, 30 workers were presented with two microscope slides containing equal quantities of pooled Dufour's gland extract (0.33 Qeq) to compare their responses in binary choices of virgin vs. SDI queens (N= 13 replicates), virgin vs. MDI queens (N= 10 replicates), or SDI vs. MDI queens (N= 11 replicates). The number of workers contacting each slide was counted every 5 min for 15 min after slide presentation. Each cage was only tested once, and the 3 data points per slide were summed as a cumulative measure of worker response.

Data are presented as mean ± SEM. The worker preferences between the two slides of the 34 cages were evaluated with a non-parametric Wilcoxon test.

Chemical Analysis of Dufour's Gland Extracts A 2 µl portion of the 50 µl Dufour's gland extract from each individual queen was analyzed by using GC on an HP 5890 equipped with a capillary DB-5 column (30 m×0.25 mm ID×0.5 µm film thickness, J&W Scientific, Folsom, CA, USA) in splitless mode. Helium was used as carrier gas at a head pressure of 124 kPa (1.3 ml/min). The GC temperature was held at 150°C for 2 min and then increased at 15°C/min to 250°C (5 min), followed by an increase of 3°C/min to 300°C (30 min). Injector and FID were both set at 300°C. We analyzed the Dufour's gland extracts from each of the queens in the study (12 virgin, 12 SDI, and 9 MDI queens).

Compounds were identified using selected samples by splitless capillary GC-MS using a Hewlett-Packard 6890 GC and a model 5973A MSD with an electron impact ion source and an HP-5 ms capillary column (30 m×0.25 mm ID×0.25 µm film thickness). Compounds were identified by using diagnostic ions, comparisons with standard MS databases, and by determination of Kovats indices (Lommelen et al., 2006).

For assessing profile similarity based on the relative proportion of the constituent compounds, a stepwise discriminant analysis was employed using only peaks that were reliably and reproducibly quantifiable (i.e., peaks that were consistently below 0.1% of the total were omitted; Statistica 6.0. StatSoft® Inc.).

Quantification of Vitellogenin RNA Levels by Quantitative Real-time PCR Total RNA was isolated from eviscerated abdominal carcasses (which contained fat bodies) from individual queens using an RNeasy RNA extraction kit (Qiagen, Valencia CA, USA), yielding 0.6–1.5 µg/individual. cDNA was synthesized from 150 ng RNA using Arrayscript reverse transcriptase (Ambion, CA, USA). Abundance of *vitellogenin* transcript was measured using quantitative real-time RT-PCR (qRT-PCR) with an ABI Prism 7900 sequence detector and the SYBR green detection method (Applied Biosystems, Foster City, CA, USA). *eIF3-S8* and *actin* were used as loading controls; both have been used in previous studies of fat body *vitellogenin* expression (Amdam et al., 2006; Grozinger and Robinson, 2007). For each sample, triplicate qRT-PCR reactions were performed and averaged. A standard curve was generated for each primer using dilutions of genomic DNA to calculate the relative quantity of mRNA for each sample. A dissociation curve and negative control (cDNA reaction without RT-enzyme) were used to ensure primer specificity and lack of contamination. *eIF-S8* primers were as in Grozinger and Robinson (2007). *Vg* and *actin* primers were as in Amdam et al. (2006)

We evaluated *vitellogenin* expression in 9 virgin, 10 SDI, and 9 MDI queens. For each individual sample, the ratio of the expression level of *Vg* to that of the geometric mean of the quantities of both reference genes (*eIF3-S8* and *actin*) was calculated. For graphical representation, the samples were normalized to the mean levels in virgin queens. Data are presented as mean ± SEM. The expression level of *vitellogenin* was evaluated with a non-parametric Kruskal-Wallis test, followed by a Mann-Whitney *U*-test.

Results

Worker Attraction to Dufour's Gland Extracts Worker attraction to the Dufour's gland extracts of virgin, SDI, and MDI queens was tested in cages containing 5-d-old bees. Out of 30 bees only a small fraction were attracted by to the different Dufour's gland extracts, which is consistent with previous studies (Slessor et al. 1988; Richard et al., 2007). Worker bees simultaneously exposed to two different Dufour's gland extracts were more attracted to the gland extracts from SDI and MDI queens than to extracts from virgins (t=5.5, P=0.005 and t=1, P=0.027, respectively, Fig. 2), and in a binary choice, they preferred MDI extracts to SDI extracts (t=6, P=0.016).

Insemination Quantity Affects the Relative Proportion of Compounds in the Dufour's Gland The queen Dufour's gland contains a complex mixture of hydrocarbons and esters. Fifty seven compounds were identified, 32 of which were found at relative proportions greater than 0.1% of the total (Table 1). These 32 peaks were used for all of the

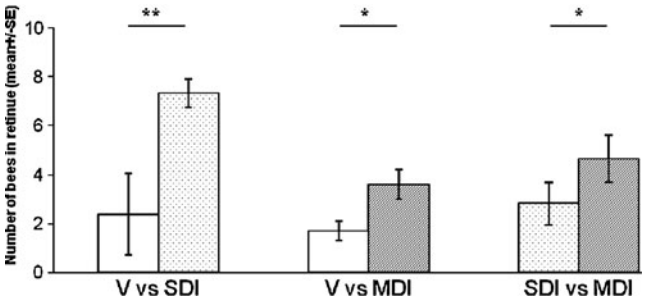

Fig. 2 Worker attraction to Dufour's gland extracts is affected by insemination and insemination quantity. Caged workers were exposed to Dufour's gland extracts of two different queens simultaneously, and the retinue response to each extract was monitored. Worker attraction was compared with a non-parametric Wilcoxon test. (*: $P<0.05$; **: $P<0.01$). *V* Virgin, *SDI* single-drone inseminated queen, *MDI* multi-drone inseminated queen

following analyses. We performed a forward stepwise discriminant analysis to determine if there was significant variation in the relative proportions of these compounds associated with insemination quantity. We also demonstrated a separation between virgin, SDI, and MDI queens ($F_{24,38}$=4.77, $P<10^{-3}$; Fig. 3). All three groups exhibited different chemical profiles (Mahalanobis distances, $P<0.01$).

Insemination Quantity Affects the Quantities of Hydrocarbons and Esters in the Dufour's Gland The total combined quantity of hydrocarbons and esters in the Dufour's glands in all three groups was compared; there were significant differences in total hydrocarbon and ester quantities ($F_{2,32}$= 2.1, $P<0.01$). Pairwise comparisons of the three groups revealed that virgin queens had higher quantities of hydrocarbons and esters than MDI queens (Least Significant Difference, LSD, $P<0.05$; Fig. 4), while SDI queens had intermediate amounts and were not significantly different from either virgin or MDI queens (LSD, $P>0.05$).

The total quantity of hydrocarbons and esters, tested by class, followed a similar pattern. When all three groups (virgin, SDI, and MDI) were compared separately, there were also differences in quantities (hydrocarbons, $F_{2,32}$= 4.23, $P<0.05$; esters, $F_{2,32}$=7.63, $P<0.01$). Pairwise comparisons revealed higher quantities in virgin than in MDI queens (hydrocarbons, LSD, $P<0.05$, esters, LSD, $P<0.05$) while SDI queens had intermediate levels for both hydrocarbons and esters, which were not different from total hydrocarbons in virgin and MDI queens (LSD, $P>0.05$).

Insemination Quantity Differentially Affects the Relative Proportions of Hydrocarbons and Esters in the Dufour's Gland The relative proportion of hydrocarbons in the Dufour's gland among virgin, SDI, and MDI queens revealed differences across the three groups ($F_{2,32}$=3.67, $P<0.05$). Pairwise comparison revealed a higher relative proportion of hydrocarbons in SDI queens than in virgin queens (LSD, $P<0.05$). However, the relative proportion of the hydrocarbons in MDI queens was intermediate and not significantly different from either virgin or SDI queens (LSD, $P>0.05$).

The relative proportion of esters in the Dufour's gland among virgin, SDI, and MDI queens revealed differences across the three groups ($F_{2,32}$=3.67, $P<0.05$). Pairwise comparisons revealed a lower relative proportion of esters in SDI queen Dufour's glands than in virgin queens (LSD, $P<0.05$). However, the relative proportion of esters in Dufour's glands of MDI queens were intermediate and not significantly different from either virgin or SDI queens (LSD, $P>0.05$).

Effect of Insemination Quantity of Vitellogenin Expression We used qRT-PCR to measure *vitellogenin* expression in the queens' eviscerated abdomens. *Vitellogenin* expression was higher in virgin than in MDI queens, using *eIF-S8* and *actin* as loading controls (H(2, N= 29)=10.78, P=0.004; Fig. 5). *Vitellogenin* expression was intermediate in SDI queens and not significantly different from that in either virgin or MDI queens.

Discussion

We instrumentally inseminated honey bee queens with semen from one or 10 drones and compared them to uninseminated virgin queens. These studies allowed us to examine the effects of the instrumental insemination procedure (which includes CO_2 treatment, physical manipulation, and insemination substance) as well as insemination quantity (via the comparison of the SDI and MDI queens) on Dufour's gland composition and gene expression under controlled environmental conditions. Our results clearly demonstrate that both the instrumental insemination procedure and insemination quantity alter queen Dufour's gland composition, which results in differences in worker behavior. Honey bee workers were more attracted to Dufour's gland extracts from inseminated queens than from virgin queens, and to extracts of MDI queens than to SDI queen extracts. Moreover, the overall comparison of Dufour's gland chemical profiles revealed a significant separation between virgin and inseminated queens and between SDI and MDI queens. A small number of esters and hydrocarbons were in higher proportions in MDI queens, while others were significantly lower. It remains to be determined which of the Dufour's gland constituents are most important for eliciting worker attraction to Dufour's gland extract in honey bee queens. Finally, we found a decrease in *vitellogenin* gene expression in MDI queens compared to

virgin queens. However, additional studies are necessary to examine the effects of specific aspects of the instrumental insemination protocol (CO_2 anesthetization, physical manipulation of the reproductive tract).

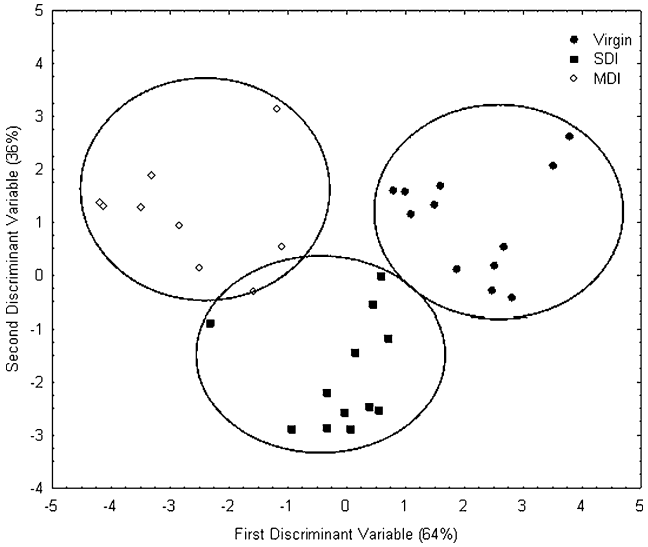

Fig. 3 Insemination quantity significantly alters the chemical profile of the Dufour's gland. Chemical composition of Dufour's gland extracts of virgin, single-drone inseminated (SDI), and multi-drone inseminated (MDI) queens were analyzed using gas chromatography. Discriminant analysis was used to determine if there were significant differences in their Dufour's gland profiles, based on the relative proportion of each compound ($F_{24,38}$=4.77, $P<10^{-4}$). Mahalanobis distances, $P<0.01$. Ellipses were drawn to emphasize the categories, but have no specific statistical meaning

It is important to note that significant changes in the chemical composition of both the Dufour's and mandibular glands occur relatively rapidly, within 5 days after insemination (Richard et al., 2007). While these changes

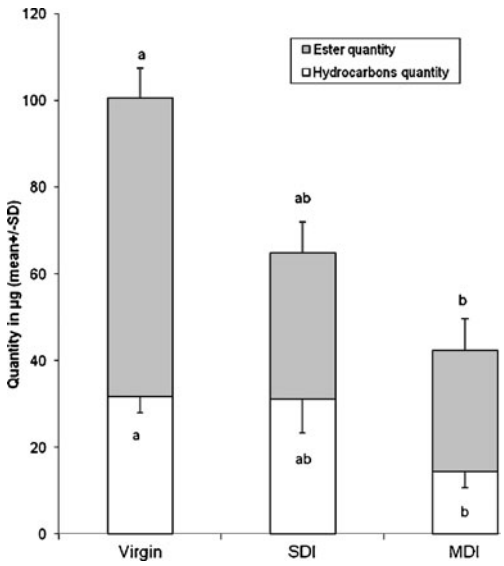

Fig. 4 Insemination quantity significantly alters contents of the Dufour's gland. The quantity of esters and hydrocarbons are significantly different among virgin, single-drone inseminated (SDI), and multi-drone inseminated (MDI) queens (respectively: Kruskal-Wallis: $H_{2,32}$=7.63, p<0.01; $H_{2,32}$=4.23, $P<0.01$)

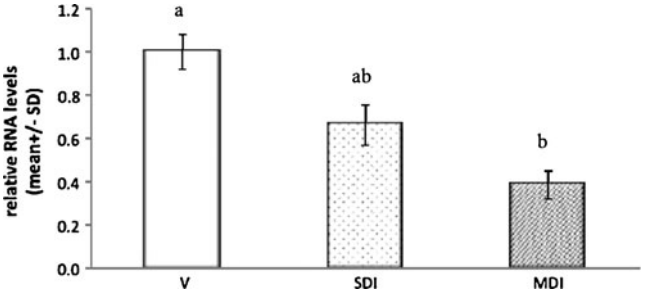

Fig. 5 Expression of *vitellogenin* in the fat body is affected by insemination quantity. Expression of *Vg,* using *eIF3-S8* and *actin* as controls, was monitored using quantitative real-time PCR using individual bees [virgin: $N=9$; single-drone inseminated (SDI): $N=10$; multi-drone inseminated (MDI): $N=9$]. Bars with different letters are significantly different (Kruskal-Wallis: $H_{2,29}$=10.79, P=0.004)

could be due to artificial aspects of the instrumental insemination protocol (such as treatment with CO_2), studies with naturally mated queens have demonstrated that mandibular gland pheromone profiles begin to change before behavioral changes are observed (Kocher et al., 2008). In other insect species, stretch receptors in the bursa, oviducts, or spermatheca, or seminal proteins in male semen are involved in stimulating post-mating changes in females (Sugawara, 1979; Wolfner, 2002, 1997). Both types of mechanisms appear to be operating in honey bee queens (unpublished data), but it remains to be determined if these rapid changes in pheromone production and gene expression are triggered by mechanosensory pathways, chemosensory pathways, or both. Recent studies suggest that insemination volume is an important cue that triggers immediate changes in pheromone production, while semen or seminal fluid may trigger behavioral and brain expression differences over a longer time scale (Kocher et al., 2008; Richard et al. unpublished). However, we note that our MDI queens differed from SDI queens in two regards: they were inseminated with a 10-fold greater volume than SDI females, and they received semen from more genetically diverse sources (ten drones rather than a single drone). Therefore, our experimental design does not allow us to separate the effects of semen volume, sperm number, quantity of semen constituents, or other possible effects of genetic diversity.

While mating stimuli, such as stretch receptors or seminal proteins, may play a role in triggering changes in Dufour's gland composition, the pathways that translate these stimuli into physiological changes in the queen remain to be determined. We observed a quantitative decrease, but not statistically significant, in both *Vg* gene expression and Dufour's gland content in MDI compared to SDI queens, suggesting that these two phenotypes may be regulated by a common pathway. In *Bombus* and *Apis,* the Dufour's gland size and secretion activity in workers

increase with ovary activation (Abdalla et al., 1999a, b). In bumble bees, ovary activation is positively mediated by juvenile hormone (Bloch et al., 2000), but the role of JH in honey bee reproduction is not fully understood (Robinson and Vargo, 1997). In fact, *Vg* expression and JH levels are negatively correlated in honey bees (Pinto et al., 2000; Guidugli et al., 2005; Corona et al., 2007). Thus, while JH may mediate both Dufour's gland secretion and ovary activation in bumble bees (reviewed in Abdalla and Cruz-Landim, 2001), it is likely that an alternative mechanism is operating in honey bees.

The total quantity of compounds in the Dufour's glands decreased following insemination. This decrease may be simply an artefact of the instrumental insemination process. Since our study used same-aged queens, the changes in gland contents are directly linked to the effects of insemination on queen physiology. There are several possible explanations for why insemination would cause a reduction in gland quantities. A high quantity of compounds in the Dufour's gland of virgin queens could be involved in other aspects of reproduction, such as attracting drones during mating flights. Alternatively, the chemical profiles of virgins may deter workers from attacking the queen (see Gilley et al., 2003; Tarpy et al., 2004).

Assuming that instrumental insemination (which includes CO_2 treatment, physical manipulation, and the introduction of semen) mimics natural mating, a third hypothesis is that there is a negative impact of mating on the physiology of the queen. Indeed, in *Drosophila* females, mating stimulates an immune response, suggesting that the introduction of novel male-specific proteins or sperm has effects on the females. Baer et al., 2006 found that newly mated queens of leaf-cutting ants up-regulated their immune responses 9 days after their mating flight. Mating also could be metabolically costly because the female needs to activate processes involved in sperm storage and maintenance of live sperm in the spermatheca. For example, expression levels of antioxidant enzymes increase in the spermathecae of mated queens compared to virgins, suggesting that the mated queens must produce an additional repertoire of proteins to increase sperm longevity (Collins et al., 2004). The cost of mating could explain the short-term effect that we observed before long-term reproductive success. Indeed, we also observed a reduction in *vitellogenin* levels after insemination, despite the fact that *Vg* is necessary for egg-maturation, which suggests that inseminated queens may be negatively affected by mating. Alternatively, there may be a period of physiological remodelling after mating, before egg-production can be fully stimulated. In naturally mated queens (Kocher et al., 2009), these changes occur quickly, while in inseminated queens, changes may occur more slowly.

Previous studies have compared Dufour's gland compounds among non-reproductive virgin, newly mated, and one-year-old mated queens without finding a significant difference in the relative proportion of hydrocarbons and esters (Katzav-Gozansky et al., 1997b). However, analysis of the biosynthesis of Dufour's gland constituents have revealed that the relative proportion of newly synthesized hydrocarbons was significantly higher in mated queens than in virgins, while for esters the pattern was reversed (Katzav-Gozansky et al., 1997b). We found that the relative proportion of hydrocarbons in inseminated queens is significantly higher than in virgins. However, when the three groups of queens were compared separately, hydrocarbon levels of MDI queens were intermediate between the SDI and virgin queens. Thus, insemination appears to have a significant effect on the relative proportions of the hydrocarbons and esters, but insemination volume seems to have additional effects.

Interestingly, workers can discriminate between the Dufour's glands of queens in different mating states. They were more attracted to the gland extracts of inseminated queens than virgin queens, and more attracted to the glands of MDI queens than SDI queens. Previous studies found that queen-like esters, rather than hydrocarbons, seem to play an important role in eliciting this behavior. However, in our studies, the proportion of esters was *lower* in the more attractive blends; thus, the attractive cue may be more specific than a simple increased quantity or proportion of all esters. Some esters were more represented in MDI queens, while others were significantly lower in MDI queens. Similarly, significant differences were seen in individual hydrocarbon compounds.

In summary, both the instrumental insemination procedure and quantity have profound impacts on queen physiology, queen worker interactions, and gene expression in honey bees. Importantly, workers are more attracted to both mandibular gland (Richard et al., 2007) and Dufour's gland extracts (present study) from MDI queens compared to SDI or virgin queens. These behavioral differences are elicited by changes in the chemical profiles that appear to signal the reproductive state of the queens to the workers. Our results suggest that post-mating changes in honey bee queens involve complex processes that are regulated by multiple parameters.

adaptations, according to species. These include a hardened cuticle (sclerotized or mineralized), protective setae, hard roof-like or wing-like projections (tecta) that protect vulnerable articulations, special body forms such as ptychoidy, in which legs can be retracted to form a sphere of seed-like appearance (Sanders and Norton, 2004; Schmelzle et al., 2009), and even jumping capabilities (Wauthy et al., 1998). In addition, strong claws might give some protection, by preventing detachment from the substrate and thereby avoiding presentation of the vulnerable ventral region (Heethoff and Koerner, 2007). Some of these morphological and behavioral adaptations appear to be effective against small predatory mites (Peschel et al., 2006; but see also Schneider and Maraun, 2009), but have been assumed to have limited value against larger predators such as amphibians (Norton and MacNamara, 1976), ants (Masuko, 1994), and a specialized group of oribatid mite-feeding staphylinoid beetles, the Scydmaenidae (Mollemann and Walter, 2001).

Still, most large arthropod predators in soil seem to consume oribatid mites rarely, or not at all, and this may be related to chemical defense. Most species (the 'glandulate' Oribatida) possess a pair of exocrine oil glands, technically the opisthonotal glands or latero-abdominal glands (Fig. 1), on the hysterosoma ('abdomen'). These have been long assumed to have a defensive function (Oudemans, 1916), although other biological functions, such as lubrication, osmoregulation, or thermoregulation also have been hypothesized (Raspotnig, 2010 and included references). Oribatid oil gland secretions may contain a mixture of aromatics, terpenes, hydrocarbons, and alkaloids of which, collectively, more than 100 specific compounds have been reported (Raspotnig, 2010; Raspotnig et al., 2011a, b). The precise biological function of these compounds remains mostly unstudied. Raspotnig (2006) found that exposure to hexane-soluble compounds from oil gland secretions of the oribatid mite *Collohmannia gigantea* were repellent to the scydmaenid beetle *Euconnus (Tetramelus) oblongus*. In addition, some compounds of oribatids function as alarm-pheromones that initiate escape behavior (Shimano et al., 2002; Raspotnig, 2006). In all other cases, literature reference to secretions being 'pheromones' or 'allomones' is based only on indirect inference.

Considering the abundance of glandulate oribatid mites and their potential predators, knowing the biological function of gland secretions seems crucial for a sound understanding of trophic interactions in soil food webs. The absence of any direct experimental investigation is probably due to the small size of oribatid mites (mostly in the range of 0.2–1 mm), which renders it difficult to test the function of glands by manipulation, such as emptying content or inhibiting discharge.

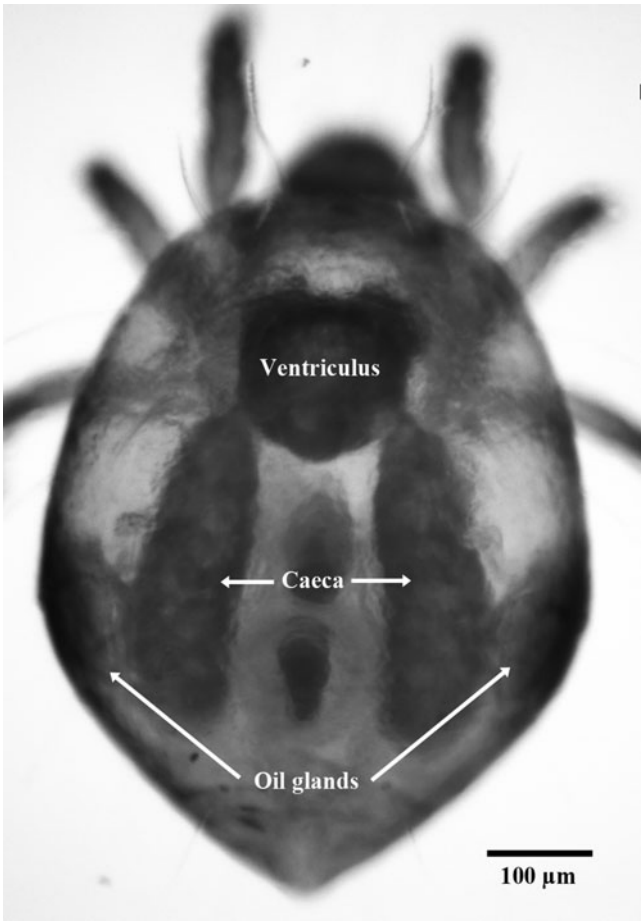

Fig. 1 Micrograph of *Archegozetes longisetosus* showing large oil glands and reservoirs. Image taken under very bright light in phosphate buffered saline to enable view of internal organs

Here, we established a protocol to chemically 'disarm' the oribatid mite *Archegozetes longisetosus* by manipulative emptying of the oil glands, and showed that oil gland secretions, rather than morphological properties, effectively protect the mites from large (~35 times greater body mass) predaceous rove beetles of the genus *Stenus*. This is the first predator–prey bioassay experiment with oribatid mites that tests the function of oil gland secretions, and the first evidence of the adaptive value of these secretions for predator defense.

Methods and Materials

Animals Archegozetes longisetosus was chosen as prey because it is a model chelicerate, and the best-studied oribatid mite (Heethoff et al., 2007; Alberti et al., 2011 and included references). In particular, the oil gland secretions of *A. longisetosus* are well characterized, comprising a set of terpenes, aromatics, and hydrocarbons, the so-called 'Astigmata-compounds' (sensu Sakata and Norton, 2001;

Heethoff and Raspotnig, 2011; Heethoff et al., 2011), which are considered synapomorphic for the glandulate Oribatida (including the clade known as Astigmata; Sakata and Norton, 2001). Moreover, the glands are of special interest for understanding mite evolution and phylogeny (Norton, 2007). Adults of *A. longisetosus* also have limited morphological defenses, including a lightly sclerotized cuticle and moderately long setae that might help to keep some predators at a safe distance. Adult specimens from the laboratory strain of *A. longisetosus* (Heethoff et al., 2007) were cultured as described in Heethoff and Raspotnig (2011).

Two species of the rove beetle genus *Stenus* were chosen as predators, because they are polyphagous and feed mainly on small spiders, mites, aphids, springtails, flies and hymenopterans (Betz, 1998). Besides using the mandibles for prey capture, *Stenus* bears a highly modified labium that can be rapidly protruded, like a harpoon, for catching prey over a distance of up to several millimeters. Using the labium, the prey is attacked without any *a priori* tactile information about quality. Betz et al. (2009) showed that *Stenus* will even attack dummies (plastic heads of insect pins) with the labium, as long as the dummies are moving and are of appropriate size. Specimens of *S. juno* Paykull ($N=23$) and *S. clavicornis* Scopoli ($N=6$) were collected from the reed zone of a small pond near Tübingen (Germany; 48°31′30.74″ N; 9°00′46.53″E), and kept in the laboratory in plastic boxes on a moist mixture of plaster of Paris and charcoal, and allowed to feed on live springtails. Beetles were starved for 5 days prior to the experiments. Experiments were conducted with both species but, due to the low number of specimens, results for *S. clavicornis* were used only for general behavioral comparison with data from *S. juno*, and were not subjected to statistical analysis.

Extraction of Oil Gland Secretion and Gas chromatography–Mass Spectrometry Analyses To determine oil gland contents, control and experimental mites were transferred into 50 µl of hexane for 3 min. to release secretions into the solvent. Gas chromatography–mass spectrometry (GC-MS) analyses and quantification of secretions were performed as described in Heethoff and Raspotnig (2011).

Experimental Discharge of Oil Glands Discharge of oil glands was evoked by dipping live adult mites for 60 sec. into hexane, followed by 1 hr of recovery (with food and water, at 28°C) for the mite, and then a second cycle of 60 sec. in hexane, followed again by 1 hr of recovery. The survival rate from this treatment was >95%, and all specimens discharged their oil glands, with remaining secretions constituting <2% (checked by GC-MS analyses of 100 individuals) of the amount in untreated individuals. There was no difference in moving, feeding, survival, or reproductive rate between hexane-treated and untreated specimens (data not shown).

Bioassays Circular, plastic cuvettes (2.1 cm diam., 2.2 cm height) were used for bioassay-arenas. The floor was covered with plaster of Paris (0.5–1 cm high), which was kept moist during experiments. Fifteen mites, from either the control (fresh mites from the culture) or treated (mites with emptied glands) groups, were placed inside the arena and left for a few min. to acclimate and start moving. An individual *Stenus* was introduced into the arena and observed for 5 min. Mites were replaced (and discarded) and beetles replaced (but retained in individual isolation) after each experiment. Over a period of 3 days, each individual beetle was used for 20 trials, being tested with either control (10 times) or treated (10 times) mites, in random order. Attacks were recorded as successful, if a mite was caught and fed upon, or as unsuccessful, if a mite was released after the attack and survived. Videos were recorded sporadically to demonstrate typical prey capture and feeding behavior (see supplementary video).

Results

Of the 23 *Stenus juno* tested, 10 completely ignored *A. longisetosus* as a food source, regardless of whether mites were controls or treated. The remaining 13 beetles attacked mites from the control group a total of 78 times (28 times with the labium and 50 times with the mandibles; Table 1, Fig. 2). In two cases (both with the same beetle specimen), capture of a control mite was partially successful (outlier in Fig. 2). These mites were caught by the legs or gnathosoma and killed quickly during the attack, which presumably prevented the mites from emitting effective amounts of oil gland secretions. The prey was always immediately released when the beetle manipulated the mites and the mouthparts came into contact with the glandular region on the hysterosoma (see supplementary video). In these two cases of successful capture, the hysterosoma remained almost intact. Remnants of both bodies were extracted in hexane after release from the beetle, and the extracts analyzed by GC-MS: 123% and 184% relative amounts (compared to the internal standard; Heethoff and Raspotnig, 2011) of secretions were observed, compared to the 200–700% relative amounts that are usually observed in secretions of control specimens (data not shown). As the two mites were killed, and a part of their prosoma consumed before the mites were released, these attacks were recorded as successful. Hence, a relative predation success of <3% was recorded for the control group. Generally, contact of the beetle's mandibles or labium with

Table 1 Prey-capturing behavior (number of attacks using the eversible labium or the mandibles for attacking prey) and relative feeding success of *Stenus juno* on *Archegozetes longisetosus* adults with (control) and without (disarmed) oil gland secretions

the glandular region led to intense cleaning of the mouthparts; a direct bite into the oil glands led to a skittish release of the prey, and sometimes a disorientation of the beetle, followed by scrubbing of mouthparts on the substrate (see supplementary video).

The treated mites were attacked 75 times (20 times with the labium, 55 times with the mandibles; Table 1, Fig. 2), with 21 of these mites eaten. This relative feeding success rate of 28% was higher than that of the control group (Wilcoxon rank-sum test, $P<0.01$). After capturing a treated mite, the beetles immediately started to feed, and showed no obvious preference for a starting location. While manipulating the mite, the hysterosoma was not avoided, nor did the cuticular remnants indicate that any body region was preferred or avoided (see supplementary video).

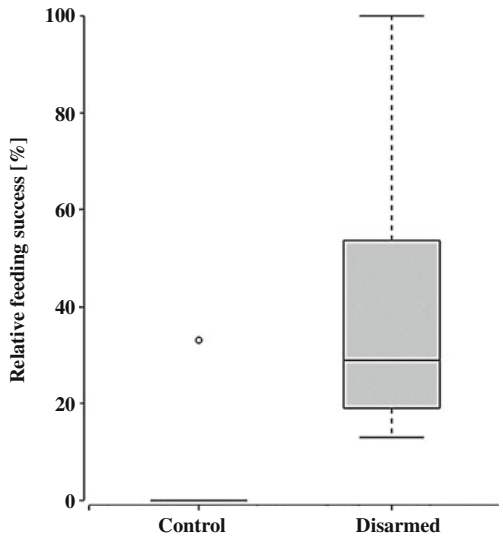

Fig. 2 Boxplot of individual relative feeding success by *Stenus juno* on *Archegozetes longisetosus*. Control = untreated mites taken from culture; Disarmed = hexane-treated mites with empty oil glands. Circle in the control group indicates an outlier

When attacking, the mandibles were used more often than the labium, against both the control ($P<0.05$) and the treated ($P<0.01$) prey groups. There was no difference in how these two capture strategies were applied to prey type (control vs. disarmed: $P>0.2$ for labium; $P>0.5$ for mandibles).

Stenus clavicornis beetles behaved in a similar way with respect to prey capture, handling, and general feeding behavior. Mouthpart-cleaning behavior after contact with the glandular region also was similar. Although the low number of specimens and attacks does not allow meaningful statistical analysis, the trend is similar to that for *S. juno* (2 of the 6 specimens ignored the mites as a prey; 4% and 27% of successful feeding in the control group and the disarmed group, respectively).

Feeding on springtails, a major prey of *Stenus* in nature, was observed and recorded (see supplementary video) for comparison. There were no apparent differences between how springtails and disarmed mites were attacked or eaten (a detailed overview of prey capture and feeding behavior of *Stenus* spp. is given in Betz, 1998).

As capture strategy was essentially the same, behavioral differences of beetles to control and treated mites first became obvious after the attack. Springtails and treated mites were consumed immediately after capture; the beetles remained motionless most of the time during feeding, occasionally turning the prey using the mandibles (see supplementary video). In some cases, the prey was released to the ground after some minutes of mastication and then taken up again with the mandibles for further feeding.

Cuticular remnants of consumed mite specimens were mostly torn to pieces. In contrast, mites from the control group were released immediately if attacked on the hysterosoma. If mites were captured by the legs or the gnathosoma, the beetles started to feed or remained motionless (without feeding) with the prey held in the mandibles. In these cases, mites were released after a few seconds, and beetles cleaned their mouthparts afterward. Mites were released immediately in all cases that they were turned in such a way that the beetle's mouthparts came into contact with the glandular region of the hysterosoma, and this was followed by intense cleaning of the beetle's mouthparts.

Discussion

Chemical defense is a widespread protective strategy among arthropods (Eisner, 2003). While best studied in insects, chemical defense is also well known from chelicerates (e.g., Eisner et al., 1961), with most of this work focused on opilionids (Roach et al., 1980; Raspotnig et al., 2010). Our experiments demonstrate, for the first time, that oil gland secretions of oribatid mites provide protection from predation by arthropod predators.

Predation on Oribatid Mites Peschel et al. (2006) showed that adults of the oribatid species *Eupelops plicatus*, *Steganacarus magnus*, and *Damaeus riparius* were completely rejected as food by the predatory gamasid mite *Pergamasus septentrionalis*. Furthermore, *Achipteria coleoptrata*, *Nothrus silvestris*, and *Liacarus coracinus* also seemed to be well protected (respectively, 71, 57, and 43% of tested individuals survived 30 days of continuous exposure to *P. septentrionalis*). The authors concluded that adult oribatid mites live in an 'enemy-free space', and attributed this to morphological defenses, particularly to the hardened cuticle. Unfortunately, the role of oil gland secretions was not explored in that study, though these secretions are present in many of the tested prey species. *Steganacarus magnus,* like all members of the Phthiracaridae, does not possess oil glands, and its protection from predation probably derives only from a mineralized cuticle and its ptychoid body form. *Damaeus riparius* and *E. plicatus* possess only very small, perhaps vestigial, oil glands that probably contain little secretion (Günther Raspotnig, unpublished data). However, both species have a hard cuticle, and a waxy cuticular covering (cerotegument) or tecta covering vulnerable articulations. These defenses may be sufficient for protection from *P. septentrionalis*, but possibly not from larger predators (as also discussed in Peschel et al., 2006), though direct evidence is lacking. Nothing is known about the oil gland chemistry of *A. coleoptrata*, but secretions of *N. palustris* (and also *N. silvestris*) contain high amounts of geranial, which acts as an alarm pheromone, at least in the former species (Shimano et al., 2002), and possibly as a defensive allomone. Oil gland secretions of *L. coracinus* may contain several acids and their glycerol esters, but these probably function as anti-wetting agents rather than as allomones (Raspotnig and Leis, 2009). However, the high amount of caprylic acid found in *L. subterraneus* might serve as an allomone, as was demonstrated for similar acids for the whipscorpion *Mastigoproctus gigantaeus* (Eisner et al., 1961).

As some of the species investigated by Peschel et al. (2006) produce putative defensive secretions, and as these mites succumbed only after a delay of some days, we suggest that *N. silvestris* and *L. coracinus* were eaten only after they were depleted of chemical defenses. The mites were presumably attacked repeatedly over the course of several days, and the production of secretions may not have been fast enough to counter constant exposure to predators over such a long period. Chemically disarming these species and repeating the experiments with *P. septentrionalis* would test this hypothesis.

Masuko (1994) reported specialized predation on oribatid mites by two species of the ant genus *Myrmecina*. Oil gland composition data are available for only one of these species, *Rhysotritia ardua* (Raspotnig et al., 2011a). This mite produces chrysomelidial, which is known as a defensive secretion of the oribatid *Oribotritia berlesei* (Raspotnig et al., 2011a). Predation on *R. ardua* was inferred by finding remains of this species in the refuse dumps of field nests of *M. flava* and was not observed directly; it was rejected when offered as direct food. Hence, it remains to be elucidated if and how these ants can overcome the chemical and morphological defenses of *R. ardua* (it also has a ptychoid body form; Schmelzle et al., 2009).

Scydmaenid beetles are well-known predators of oribatid mites (Mollemann and Walter, 2001). These beetles typically lift oribatid mites and cut off their legs before turning the mites to start feeding on the gnathosoma (Mollemann and Walter, 2001). Their prey consists of numerous oribatid mite species, some of which possess large oil glands. It is unlikely that scydmaenids are not affected by the oribatid secretions, as Raspotnig (2006) reported escape behavior, intense cleaning of antennae, and narcosis or death following exposure of the scydmaenid *Euconnus (Tetramelus) oblongus* to components from oil gland secretions of *Collohmannia gigantea*. Perhaps, instead, these scymaenids inhibit expulsion of the oil gland secretions, as do predaceous larvae of the beetle *Phengodes laticollis* when feeding on the millipede *Floridobolus penneri* (Eisner et al., 1998)?

In recent years, oribatid mite oil gland secretions have been discussed in a different ecological context. Numerous poison frogs seem to feed specifically on oribatid mites and use their pumiliotoxins and other lipid-soluble alkaloids as 'cleptotoxins' to increase the toxicity of their own skin (Rodriguez et al., 2010; Raspotnig et al., 2011b). In this case, the defensive function of oil gland secretions was functionally sequestered, with the frogs profiting. It is tempting to speculate that the frogs can actually detect oribatid mites through the oil gland secretions (e.g., through taste or olfaction), and hence use these secretions as kairomones.

Stenus *as a Model Predator for Oribatid Mites.* Several species of the genus *Stenus* have been investigated for prey capture and feeding behaviors. Betz (1998) defined three phases in the behavioral sequence associated with preying on springtails: orientation, approach, and prey capture. When attacking *A. longisetosus*, *S. juno* and *S. clavicornis* exhibited all three phases, and no differences were observed during preying on chemically defended or disarmed mites. The rare behaviors of moving sideways while approaching the prey or touching the prey with the antennae, as described for some other *Stenus* species (Betz 1998), were not observed.

Betz (1998) found that use of mandibles by *S. juno* increased with prey size: use of the labium was preferred when attacking small springtails (about 0.5–0.8 mm), while the labium and mandibles were used equally for capturing larger springtails (about 1.2–1.5 mm). As *A. longisetosus* has an intermediate size of 0.9–1 mm, we expected that either the labium would be used preferentially, or both attack types would be used equally. However, we found that *S. juno* used the mandibles more often than the labium. This might be explained by the relative speeds of the respective prey. While springtails are fast moving and can escape by jumping, *A. longisetosus* move slowly and may not be able to escape an attack by the mandibles of *S. juno*. This hypothesis is supported by the fact that *S. juno* uses its mandibles more frequently when feeding on slow-moving aphids (Betz, 1998). The relative feeding success of *S. juno* using the labium was 100% on small, and slightly above 25% on large, springtails. In contrast, when using the mandibles, feeding success was reduced to about 30% and almost 0% in small and large springtails, respectively (Betz, 1998). This is in the same range as the relative feeding success reported here on disarmed (treated) *A. longisetosus*.

Oil Gland Secretions of Archegozetes longisetosus**.** *Archegozetes longisetosus* produces 2-hydroxy-6-methylbenzaldehyde (2,6-HMBD), neral, geranial, neryl formate, γ-acaridial (3-hydroxybenzene-1,2-dicarbaldehyde), tridecane, pentadecene, pentadecane, heptadecadiene, heptadecene, and heptadecane in the oil glands (Heethoff and Raspotnig, 2011 and references therein). The hydrocarbons probably are important as solvents and carrier agents, but some also might have an allomonal function. Most of the compounds have been demonstrated to act as allomones in other arthropod species. Raspotnig (2006) showed that 2,6-HMBD, neral, geranial, neryl formate, tridecane, and pentadecane repel the predaceous scydmaenid beetle *Euconnus (Tetramelus) oblongus.* The aromatic γ-acaridial is specific to oribatid and astigmatid mite oil gland secretions. Its behavioral function is unknown, but it could have an allomonal effect.

Chemical Defense of Oribatid Mites We have shown here for the first time that oil gland secretions of oribatid mites can have an adaptive value for chemical defense against large arthropod predators. We also have shown how other reports of predation on oribatid mites can be viewed in the context of both morphological and/or chemical defense. Taking all evidence into account, we conclude that the 'enemy-free space' hypothesis for adult oribatid mites (Peschel et al., 2006) is supported, but that the importance of chemical defense against predators by oil gland secretions has been underestimated. It is unlikely that cuticular compounds (soluble in hexane and, therefore, likely removed by our extractions) on the mites were responsible for protection, as our GC-MS analyses of extracts showed no compounds other than those from the oil glands. In addition, *Stenus* beetles avoided only the glandular region of untreated mites, and not other cuticular regions.

Of course, 'enemy-free space' is not 'free' to acquire. We do not know the energetic costs of forming morphological defenses or of maintaining a supply of oil gland secretions, but each must be significant. As the selective pressure of predation is unrelenting, such costs probably comprise an evolutionary tradeoff against higher secondary production in a group of mites in which most species grow and reproduce slowly (Norton, 2007).

including *Pseudoroegneria*, *Stipa*, *Koeleria*, and *Festuca* (Callaway et al., 2005b; Pollock et al., 2009) and has also been reported to impact soil microorganisms *in vitro* (Callaway et al., 2005a). Other evidence has demonstrated that *Centaurea stoebe* growth is facilitated by either promoting beneficial fungal interactions (Callaway et al., 2004b) or by avoidance of harmful microbes normally found in its native range of Europe (Callaway et al., 2004a). Thus, important plant-microbe interactions could be disrupted by the presence of (±)-catechin in soil. However, research to date has not attempted to elucidate the effects that catechin has on specific soil microbial populations or the microbial community in general, nor the specific mechanisms by which it might exert such effects.

To understand how catechin affects soil and root zone microbial communities, we investigated its overall impact on bacterial communities from Romanian (native range) and Montanan (both invaded and non-invaded) soils, as well as on individual soil bacterial isolates (populations) from these same soils. Additional experiments examined the effect of various catechin concentrations on bacterial growth kinetics, as well as the effect of removing catechin from the system in these inhibition studies. The relationship between catechin concentration and its impact on various bacterial soil isolates is discussed.

While there has been a tendency to rely heavily on molecular techniques to examine microbial community phenomena in recent years, with the exception of 16S rRNA gene classification of isolates, we employed simple culture-based most-probable-number (MPN) assays and growth kinetics studies to establish that (±)-catechin has a general suppressive effect on the culturable aerobic, heterotrophic soil bacterial community in all soils. Further, we showed that this suppression is manifested at the population-level as dose-dependent bacteriostatic (i.e., reversible) inhibition that varied between the populations analyzed. These results suggest that catechin exuded by spotted knapweed will have differential effects at the bacterial population-level, which may interfere with or enhance important plant:microbe or microbe:microbe interactions and thus play a role in the invasive success of this aggressive noxious weed.

Methods and Materials

Bacterial Growth Media and Chemicals R2 broth (Difco, Detroit, MI, USA) was prepared according to the manufacturer's suggested protocol and, after autoclaving and cooling to 65°C, amended to a final concentration of 300 μg ml^{-1} cycloheximide (to inhibit fungal growth) by addition of 10 ml of a 30 mg ml^{-1} stock solution (in 100% ethanol) to 1 l R2 broth. R2A plates were prepared in the same fashion as R2 broth, except that 15 g Bacto-agar (Becton Dickinson, Sparks, MD, USA) were added prior to autoclaving. Where minimal medium plus glucose was employed, MMO minimal salts medium was prepared as described previously (Stanier et al., 1966) and amended with 500 μg·ml^{-1} glucose and 300 μg ml^{-1} cycloheximide. Whenever (±)-catechin was amended to liquid or agar media for use in community- and population-level analyses, these were prepared as described below.

(±)-Catechin hydrate (>99% purity) (hereafter referred to simply as catechin) was obtained from Shivambu International (New Delhi, India), and all other chemicals were obtained from Sigma (St. Louis, MO, USA). Due to its limited solubility in water, stock solutions of catechin (150 mg ml^{-1}) in 100% methanol were made fresh for use in community- and population-level inhibition experiments (see below). All liquid and agar media were stored in the dark prior to and during use in experiments. Liquid and agar media amended with various concentrations of catechin were made by adding (after autoclaving and cooling the media to 65°C) the appropriate volume of catechin stock solution, along with the appropriate volume of 100% methanol, so that a constant volume of methanol (20 ml l^{-1}) was added to all media, and only catechin varied in concentration between 0 and 3,000 μg ml^{-1}. This was done to normalize for any methanol-based effects on bacteria, although these are unlikely since the methanol was assumed to have evaporated from media prior to use in experiments.

Source of Soil Samples and Soil Microorganisms Soil was obtained from a native grassland plant community including spotted knapweed in Timisesti, Romania (47.13°N/26.29°E) to represent the soil microbial community in the native range of *C. stoebe* and was collected on March 24, 2005. This sample was comprised of 5 individual soil samples (0–10 cm depth from the A horizon) from random locations within the grassland plot that were composited, mixed thoroughly, and sieved (2 mm) to provide a representative sample hereafter referred to as "native". The soils at this site are classified as Entic Hapludolls and Chernozems. Two different soils (both collected in mid-June of 2005) from western Montana were used to represent invaded and non-invaded soil microbial communities, respectively. Soil from the Bandy Ranch, near Ovando, Montana (47.06°N/113.26°W), classified as Perma gravelly loam, was collected, pooled, and sieved as described above to represent a typical, heavily-infested, spotted knapweed-invaded site, hereafter referred to as "invaded". Similarly, soil from the Clearwater Game Range, near Clearwater Junction, Montana (47.08°N/113.04°W), classified as a Winkler gravelly loam, was collected, pooled and sieved to represent a non-invaded Montana soil that has

never experienced spotted knapweed invasion, nor been treated to prevent it (M. Thompson, *personal communication*). This sample is hereafter referred to as "non-invaded". Multiple bacterial isolates representing phenotypically diverse (based on colony morphology) populations were obtained from each soil type using R2 broth and R2A agar as described below for use in population-level catechin inhibition experiments.

Two other Montana soil samples: one from the root zone of spotted knapweed plants within the Bob Marshall Wilderness (47.80°N/113.03°W) collected on April 6, 2005; and the other from the root zone of spotted knapweed plants on Waterworks Hill near Missoula, Montana (46.88°N/113.98°W) on April 5, 2005 were the source of additional catechin-sensitive and -resistant root zone bacterial strains. As soil had to be air-dried for shipment at 4°C from Romania to the USA, all other soil samples were also air-dried and held at 4°C prior to analysis for consistency between samples. Soil samples were sent to the Soil, Water, & Forage Testing Lab (College Station, TX, USA) for typical soil chemical analysis, the results of which are reported in Table 1.

Pure culture isolates were recovered from the root zone of knapweed plants at the Waterworks Hill and Bob Marshall Wilderness sites via initial growth on R2A+ cycloheximide (300 μg ml^{-1}) and subsequently restreaked onto R2A to ensure purity. Sixteen pure isolates were shown to represent diverse genera and species based on 16S rRNA gene affiliation (see below), and were used to test for catechin sensitivity and recovery from inhibition. Of the sensitive strains, *Burkholderia* strain G-5 was selected for use in detailed growth kinetics experiments to further elucidate the bacteriostatic effects of catechin.

Identification of Bacterial Isolates Based on 16S rRNA Gene Affiliation To ensure the phylogenetic diversity of the isolates used for catechin sensitivity and recovery assays, their 16S rRNA gene was PCR amplified, sequenced, and compared to known 16S rRNA genes by using standard techniques. Briefly, PCR was performed using the generally conserved 16S rRNA gene primers 27f (5′-AGAGTTTGATCMTGGCTCAG-3′), 536f (5′-CAGCMGCCGCGGTAATWC-3′), 907r (5′-CCGTCAATTCMTTTRAGTTT-3′), and 1492r (5′-TACGGYTACCTTGTTACGACTT-3′) as described previously (Holben et al., 2004). PCR amplicons were purified using the QIAquick PCR purification kit (Qiagen, Valencia, CA, USA) and the manufacturer's recommended protocol, and then were sequenced by using the Sanger dideoxy method at the University of Montana Murdock Molecular Biology Facility. The near full-length sequences obtained (i.e., positions 27–1492 based on *E. coli*) were compared with their closest phylogenetic matches based on S_{ab} scores determined using the Sequence Match function of the RDP II website (Cole et al., 2005).

Community-Level Inhibition of Bacteria by Catechin To examine general inhibition of the total cultivable bacterial community by catechin, non-invaded soil was used to enumerate the fraction of the total bacterial community capable of aerobic, heterotrophic growth on general medium in the presence, absence, and following removal of catechin. The numbers of bacteria that grew in R2 broth (containing cycloheximide) with or without catechin were determined by using the three-tube most-probable-number (MPN) approach (Banwart, 1981). To achieve this, non-invaded soil was split into four equal proportions (11.23 g dry weight each) and placed into four sterile 50 ml screw-top flasks. All four subsamples were hydrated drop-wise with sterile double distilled water (ddH_2O) to 40% water holding capacity. These were amended subsequently with stock solutions of catechin in 10 ml of 10% methanol to yield final soil concentrations for catechin of 500, 1000, and 3000 μg g^{-1}. Control treatments with 0 μg g^{-1} catechin were similarly amended with 10 ml of 10% methanol for the reason described above. All treatments were brought to 100% water holding capacity following catechin addition. After 8 days of incubation in the dark at room temperature, 500 mg aliquots from each flask were added to 4.5 ml of

[c] Non-invaded Montanan soil

R2 broth amended with either the same concentration of catechin that was present in the original incubation (0, 500, 1000, or 3000 μg ml^{-1}, respectively) to simulate continuous exposure to catechin, or with no catechin to assess the effect of its removal from the system. These suspensions also contained 1% sodium pyrophosphate and were mixed vigorously by vortexing to aid in detaching cells from soil particles. Aliquots of each of these suspensions (100 μl) then were serially diluted into 900 μl of the same medium (but without pyrophosphate), with vigorous mixing after each dilution. After 7 d of incubation at room temperature with orbital shaking at 150 rev min^{-1} in the dark, each set of tubes was scored for bacterial growth based on visual examination for increased turbidity. Only tubes that exhibited good growth (increased turbidity clearly observable by the naked eye) were considered positive for these tests.

Population-Level Inhibition of Bacteria by Catechin To compare the degree to which catechin inhibited individual aerobic, heterotrophic bacterial populations, the three soils (native, invaded, and non-invaded) were sampled using serial dilution plating to obtain individual isolates from each site. To achieve this, 10 g of soil were placed into 90 ml sodium phosphate buffer (100 mM, pH 7.0), shaken vigorously by hand for 2 min, after which large particles were allowed to settle for 1 min. Decadal serial dilutions into phosphate buffer were performed to 10^{-8}, after which 100 μl of each dilution were spread onto R2A plates supplemented with cycloheximide. All plates were incubated at room temperature in the dark for ~14 d, after which 140 to 150 phenotypically distinct colonies (based on colony size, color, texture, and rate of growth) from appropriate dilutions (producing between 30–300 colonies per plate) for each soil type were sequentially replica-plated onto R2A agar containing: 500 μg ml^{-1} catechin; 1,000 μg ml^{-1} catechin; 3,000 μg ml^{-1} catechin; and, finally 0 μg ml^{-1} catechin to confirm growth of the transferred colony in the absence of catechin (each plate also contained 300 μg ml^{-1} cycloheximide). Colonies were transferred by touching the chosen colony with the blunt end of a sterile, plain wood applicator (Fisher Scientific Pittsburgh, PA, USA Cat# 01–340) and then touching each of the above four plates in succession in an ordered array—termed 'replica plating' in microbiology. All plates were incubated at room temperature in the dark, and colony growth at each position was recorded at 1, 2, 4, and 6 d to assess colony growth rate as a function of catechin concentration. Only colonies that grew successfully on the final control plate (i.e., no catechin added) were scored on the catechin-amended plates. Each bacterial population was categorized as either Not Affected (NA—colonies grew at same rate on catechin-containing plates as on the control plate), Completely Inhibited (CI—colonies only grew on the negative control plate, with no growth on the catechin-containing plates), or Semi-Inhibited (SI—colonies grew on catechin-containing plates, but perceptibly more slowly than on the control plate). Logistic mixed effects models with colonies taken as a random effect were fit by using the restricted maximum likelihood (REML) method to compare populations of microbes from the three sampling locations (Native, Invaded, Non-Invaded) in terms of their sensitivity to catechin at low, medium, and high concentrations (500, 1000, 3000 ppm, respectively).

Assessing Reversibility of Catechin Inhibition To determine whether catechin inhibition was bacteriostatic (and therefore reversible), or bactericidal, nine bacterial strains (representing 7 bacterial genera) that were inhibited by catechin on agar plates were tested for their ability to grow in liquid medium before and after removal of catechin from the medium. All strains were initially grown in MMO medium with 500 μg ml^{-1} glucose to mid-log phase. These cultures then were transferred (1:100 inoculum) into MMO medium containing 500 μg ml^{-1} glucose and the following amendments: 0 μg ml^{-1} catechin; 2000 μg ml^{-1} catechin; and 2000 μg ml^{-1} catechin that was removed after the corresponding no catechin control culture had reached stationary phase. The catechin concentration of 2000 μg ml^{-1} was selected as being intermediate in the previous inhibition experiments. Catechin was removed by collecting the inhibited cells by centrifugation, carefully pouring off the supernatant, resuspending and washing the cells once with sterile PB (100 mM phosphate buffer; pH 7), collecting by centrifugation, then resuspending the cells in MMO medium with 500 μg ml^{-1} glucose without catechin. All treatments were performed in triplicate and incubated at room temperature in the dark with rotary shaking at 150 rev min^{-1}.

Effect of Catechin on Bacterial Growth Kinetics *Burkholderia* strain G-5, a representative catechin-sensitive soil bacterial population, was used to examine in detail the kinetics of growth in the absence, presence, and following removal of catechin from the medium. Growth kinetic data for strain G-5 were obtained by 1:100 dilution of triplicate fresh overnight cultures in MMO medium with 500 μg ml^{-1} glucose into fresh MMO + glucose medium amended with: 0 μg ml^{-1} catechin; 2000 μg ml^{-1} catechin; and 2000 μg ml^{-1} catechin that was subsequently removed. For this last treatment, catechin was removed by collecting the inhibited cells by centrifugation after 36 h (when the parallel cultures of strain G-5 without catechin had reached stationary phase), carefully pouring off the supernatant, resuspending and washing the cells once with sterile PB, collecting by centrifugation, then resuspending the cells in

fresh MMO medium containing 500 μg ml^{-1} glucose but no catechin. All treatments were performed in triplicate and incubated at room temperature in the dark with rotary shaking at 150 rev min^{-1}. Cell growth was monitored based on optical density at 550 nm (i.e., OD_{550}) using a Spectronic 20D+ spectrophotometer (Milton Roy USA, Ivyland, PA, USA). As catechin exhibits limited auto-oxidation with resultant absorbance at 550 nm, two sets of blanks were used for this experiment. The blank for cultures grown without catechin was MMO medium with 500 μg ml^{-1} glucose, while the blank for cultures grown in the presence of catechin was MMO medium with 500 μg ml^{-1} glucose and 2000 μg ml^{-1} catechin. Both blanks were incubated under conditions identical to the cultures. To avoid adding methanol to these cultures, catechin was dissolved completely by gentle heating in 5 ml of sterile ddH_2O and immediate addition to the MMO+glucose medium, effectively diluting the catechin before it could precipitate.

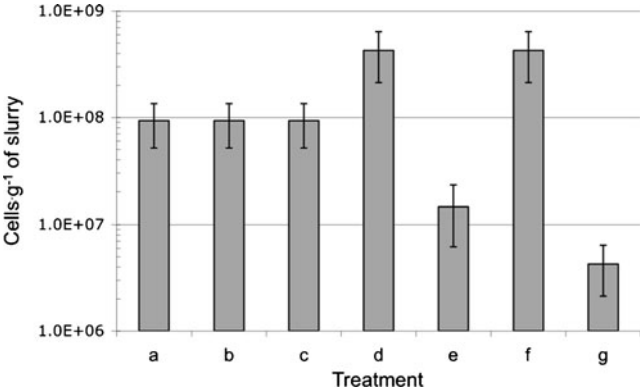

Fig. 1 Most-probable-number (MPN) analysis of non-invaded soil bacterial community grown in R2 broth + cycloheximide medium with and without catechin. Bars represent the average of triplicate determinations ±1 SE. Treatments were as follows: **a**) control (0 μg g^{-1} and 0 μg ml^{-1} catechin in soil and media, respectively); **b**) 500 μg g^{-1} catechin in soil, 0 μg ml^{-1} catechin in media; **c**) 500 μg g^{-1} and 500 μg ml^{-1} catechin in soil and media, respectively; **d**) 1000 μg g^{-1} catechin in soil, 0 μg ml^{-1} catechin in media; **e**) 1000 μg g^{-1} and 1000 μg ml^{-1} catechin in soil and media, respectively; **f**) 3000 μg g^{-1} catechin in soil, 0 μg ml^{-1} catechin in media; **g**) 3000 μg g^{-1} and 3000 μg ml^{-1} catechin in soil and media, respectively

Results

Inhibition of the Soil Bacterial Community by Catechin MPN enumeration using R2 broth was used to assess the general effect of catechin on the aerobic heterotrophic bacterial community of soils. This was accomplished by determining the fraction of the total bacterial community capable of growth in the presence of various concentrations of catechin. The number of culturable heterotrophs ranged from 4.27±2.14 (standard error, SE)×10^8 cells (g of soil)$^{-1}$ with no catechin to as low as 4.27±2.14 (SE)×10^6 cells (g of soil)$^{-1}$ when high levels of catechin were present (Fig. 1). Dose-dependent inhibition of growth with increasing catechin concentration was observed when catechin concentrations were maintained. Interestingly, samples treated with catechin but then released from its presence showed a complete reversal of catechin inhibition, and their MPN values were comparable to or exceeded those observed in the no-catechin control tubes.

Inhibition of Growth of Individual Bacterial Populations by Catechin Having shown that catechin had a general suppressive effect on the growth of the aerobic, heterotrophic bacterial community, the effect of catechin at the level of individual bacterial populations was investigated through ordered replication of colonies on media with various concentrations of catechin or no catechin via replica plating. Higher concentrations of catechin showed greater inhibition in terms of percent of populations capable of growth (Fig. 2). Further, when the growth of each individual bacterial population was classified as being not affected (NA), semi-inhibited (SI), or completely inhibited (CI) relative to no-catechin controls, there were significant differences between native soil populations and the invaded and non-invaded Montana populations based on the restricted maximum likelihood (REML) method ($P<10^{-7}$, $P<10^{-6}$, respectively). There were no significant differences in the normal growth percentages between the invaded and non-invaded Montana populations ($P=0.602$). Separate comparisons were also made within each catechin dose level (Table 2), which upheld the overall difference between the native and Montana populations at all catechin levels except for non-invaded populations at 1000 ppm.

Catechin Inhibition is Bacteriostatic To further investigate the seeming reversal of inhibition that was observed in the MPN analysis, a suite of soil bacterial isolates were tested for sensitivity or resistance to the inhibitory effects of catechin, and the sensitive isolates tested for their ability to resume growth after removal of catechin from the media (Table 3). Of the sixteen isolates tested, seven were unaffected by catechin and, interestingly, six of these were identified as *Pseudomonas* sp. representing five different taxa based on their 16S rRNA gene sequence, while the seventh was identified as *Rhodococcus* sp. (Table 3). Eight of the remaining nine strains tested were completely inhibited by catechin, while one, *Bacillus* strain C-5, was semi-inhibited. Growth of all nine of the inhibited strains (including C-5) was completely restored after removing catechin from the medium by washing the cells and placing

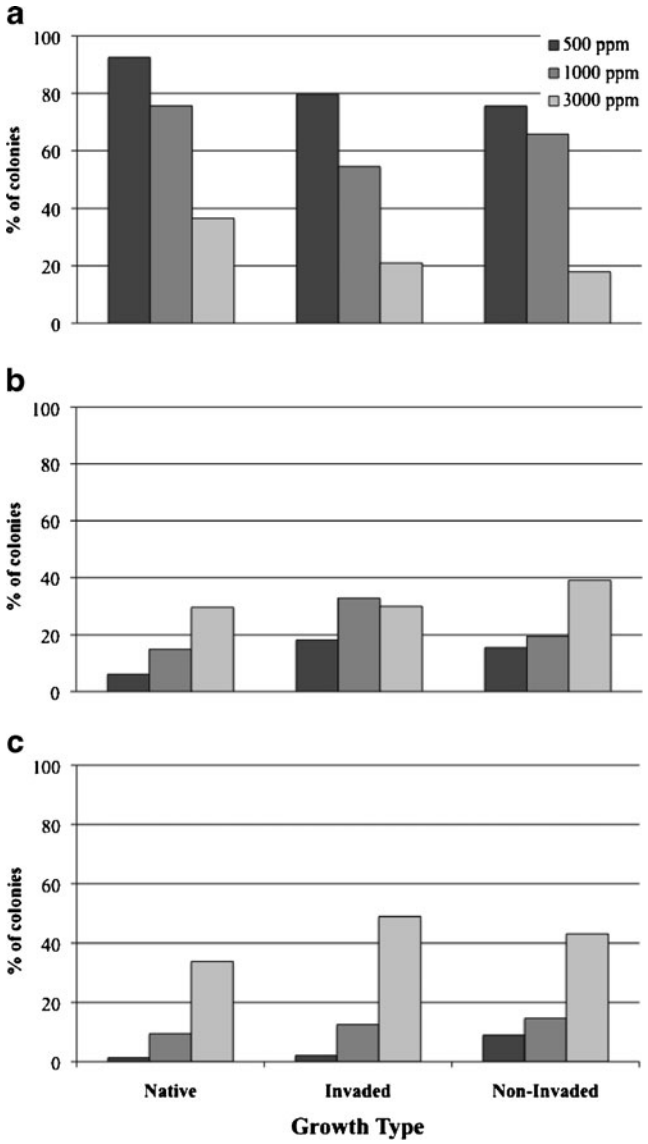

Fig. 2 Bacterial populations from native (148 isolates), invaded (143 isolates), and non-invaded (123 isolates) soils plated on R2A agar containing indicated concentrations of catechin. **a**: Percent of Not Affected colonies (NA); **b**: Percent of Semi-Inhibited colonies (SI); **c**: Percent of Completely Inhibited colonies (CI). Indicated growth of populations was as compared to its growth on the control plate with no catechin

them into fresh MMO plus glucose medium without catechin (Table 3). Seven different genera were represented in the group of nine sensitive—but recoverable—isolates, suggesting that catechin may be a fairly broad inhibitor of growth across bacterial populations, but clearly, not all are affected.

Catechin Effects on Bacterial Growth Kinetics To more closely examine the inhibitory effects of catechin on bacterial growth, *Burkholderia* strain G-5 was subjected to detailed growth kinetics assays in the absence, presence, and following removal of catechin in the medium (Fig. 3). When catechin was present, growth of strain G-5 was essentially completely inhibited relative to the no catechin control, even after prolonged (~200 h) incubation. When catechin was removed from the medium after 36 h of completely inhibited growth (by washing the cells and placing them into fresh MMO plus glucose medium), normal growth kinetics essentially indistinguishable from the no-catechin controls resumed following a substantial (≥80 h) lag period (Fig. 3).

Table 2 Between-soil comparison of catechin effect on soil bacterial populations

Catechin Concentration	Native vs. Invaded	Native vs. Non-Invaded	Invaded vs. Non-Invaded
500 ppm	0.0022[a]	0.0002	0.4216
1000 ppm	0.0002	0.0765	0.0615
3000 ppm	0.0025	0.0009	0.6212

[a] *P* values obtained by pair-wise restricted maximum likelihood (REML) analysis between soils at each catechin concentration.

Discussion

While the impact of catechin on indigenous plant species of North America has been extensively studied (Buta and Lusby, 1986; Iqbal et al., 2003; Inderjit et al., 2008), its effects on soil bacterial communities have not been thoroughly examined. The few reports to date on this topic have suggested that catechin is "antimicrobial" to certain laboratory strains relevant to soils (e.g., *Xanthomonas campestris*, *Agrobacterium radiobacter*, *Erwinia carotovora*, and *Erwinia amylovora*) (Veluri et al., 2004), but have not examined the nature of the inhibitory effect(s) or their generality against a broad array of soil microbial populations.

In the current study, we demonstrated a general dose-dependent suppressive effect of catechin on the aerobic, heterotrophic bacterial community of soils that reduced MPN enumeration values by up to two log units (a 99% decrease) at the highest concentration tested (Fig. 1). The inhibitory effect on total community numbers was fully relieved upon transfer to catechin-free medium, suggesting that its action is bacteriostatic rather than bactericidal. We note that the higher MPN numbers observed following relief from catechin inhibition in this MPN assay (Fig. 1) suggest the existence of some poorly understood rebound effect upon release from catechin suppression, since control treatments that never experienced catechin exposure and the 500 μg ml^{-1} treatment that was not significantly suppressed did not exhibit this same increase.

It is also interesting to note that a small proportion of the bacterial community in these soils (~1% based on the MPN assay) was capable of forming a soluble red compound in the presence of catechin (data not shown). This compound

[a] Strains in bold are inhibited by catechin but their growth is restored when catechin is removed from the medium

[b] NT stands for Not Tested

may represent some catechol-like intermediate of catechin breakdown by bacterial populations in the soil. While this interpretation is consistent with the observations, it is purely speculative in the absence of additional data and the basis for and significance of this phenomenon remain unknown at this time.

The data from the replica-plating assay with individual bacterial populations (refer to Fig. 2) are also indicative of dose dependent catechin inhibition in that, for each soil type, the number of NA populations decreased, while the number of SI or CI populations increased with catechin concentration. Figure 2 also demonstrates that the soil bacterial community from the native range is significantly more resistant to the inhibitory effects of catechin than either the invaded or non-invaded sites in Montana as evidenced by higher numbers of NA populations and lower numbers of SI or CI populations at each catechin concentration (Fig. 2 and Table 2). This phenomenon may reflect long-term selection for catechin-tolerant bacterial populations in the native range of *C. stoebe.*

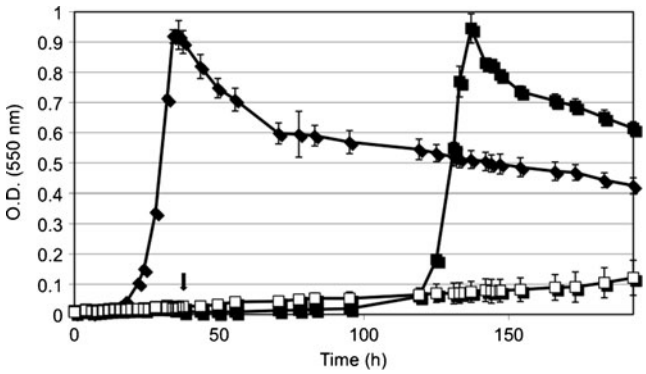

Fig. 3 Growth of *Burkholderia* strain G-5 in the presence, absence or following removal of catechin. Analyses were performed in triplicate and error bars indicate ±1 SE. ♦, MMO + glucose; □, MMO + glucose + catechin; and ■, MMO + glucose + catechin where catechin was removed at t=36 hr (indicated by arrow) and the cells placed into fresh MMO medium with glucose but no catechin. All glucose concentrations were 500 μg ml^{-1} and catechin concentrations were 2000 μg ml^{-1}

These results raise intriguing possibilities regarding soil bacterial population dynamics in the face of invasion by spotted knapweed. We previously have suggested that the soil microbial community from the home range of *Centaurea stoebe* LAM. has stronger inhibitory effects on its growth than soil microbes from where the weed has invaded in North America (Callaway et al., 2004a). The data presented herein suggest that some specific bacterial populations showing no sign of inhibition by catechin at any concentration (NA) have been selected for over time in the native soil such that the community has overall greater resistance or tolerance to the bacteriostatic effects of catechin. By contrast, NA populations in the non-invaded and invaded soils likely have some form of intrinsic resistance or tolerance for catechin and may represent potential successor populations in the presence of introduced catechin, possibly producing a shift in bacterial community composition to populations resistant or tolerant to catechin with prolonged exposure. This scenario could enhance the invasive success of spotted knapweed if those populations either facilitate its growth or suppress growth

of native plant populations. CI populations, on the other hand, represent catechin-sensitive taxa that might be supplanted by resistant or tolerant ones during knapweed invasion, although moderate numbers of CI populations also were detected in the native soil. Such population shifts could have dramatic effects on soil nutrient cycling or other important processes depending on the identities and functions of the inhibited populations (Thorpe and Callaway, 2011).

The SI populations also merit consideration. These were observed from all soils and there may be several reasons for their partial state of inhibition. Among these is the observed instability of catechin over time (Blair et al., 2005, 2006; Perry et al., 2007; Broeckling and Vivanco, 2008; Inderjit et al., 2008). Since catechin effects are dose-dependent, biotic or abiotic transformation of catechin into a biologically inert form might decrease its effective concentration below the inhibitory level for these populations over time, thereby restoring growth. Another possible explanation might be the ability of some microbial populations to mitigate the inhibitory effects of catechin. Since catechin is a known metal chelator (Gomah and Davies, 1974; McDonald et al., 1996; Lim et al., 2005; Pollock et al., 2009), delayed growth may represent a lag period prior to activation of pathways for sequestration of metals or other micronutrients required for growth. Indeed, earlier experiments that examined the effects of catechin and various related analogs (present as natural products in teas, wines, and certain other food products) on gastrointestinal microflora showed that various bacterial populations were differentially impacted by these compounds (Ishigami and Hara, 1993; Hara, 1997). Among those not affected were the Lactic Acid Bacteria, which, interestingly, are reported to have no metabolic requirement for iron (Archibald, 1983; Boyaval, 1989; Bruyneel et al., 1989; Pandey et al., 1994; Imbert and Blondeau, 1998). Finally, since catechin and similar compounds variously have been reported to damage cell membranes (Hoshino et al., 1999), block cellular transport systems (Shimizu et al., 2000; Song et al., 2002), and damage DNA (Hayakawa et al., 1999), bacterial populations with less extensive damage or more robust repair systems may be immune to (i.e., NA), or capable of overcoming with time (i.e., SI), inhibitory effects of catechin. Given the genetic, metabolic, and physiological diversity of soil bacteria, it is perhaps not surprising that a full spectrum of responses to catechin exposure was observed across these populations.

Sixteen soil bacterial populations isolated from the root zone of spotted knapweed and representing nine different genera were tested for their ability to grow in the presence of catechin (Table 3). Nine of these sixteen microbes exhibited either complete or partial inhibition of growth by catechin, which was shown to be restored after its removal. To better illustrate that catechin was capable of fully inhibiting growth and that growth could be fully restored by removing catechin, the kinetics of growth of *Burkholderia* strain G-5, were examined in detail. The results clearly demonstrated complete inhibition of growth of G-5 by catechin, and that normal growth was fully restored following catechin removal. We hypothesize that the lag phase observed after catechin removal (Fig. 3) represents catechin-induced cell damage that required repair before normal growth resumed. The possibility that differential sensitivity within the population could explain the observed lag, with some cells actually killed while others rapidly resume growth upon catechin removal, seems less likely given that no bacterial isolate tested was killed by catechin and every inhibited isolate was able to fully recover from its bacteriostatic effect.

The results presented herein collectively demonstrate that catechin is a bacteriostatic, not bactericidal, inhibitor of some, but not all, bacterial populations in soils. This is ecologically important in this invasive plant system because, if catechin were somehow removed (e.g., through knapweed suppression followed by biodegradation or abiotic transformation), inhibited bacterial populations could potentially rebound and resume normal growth. This scenario may be of significant relevance in attempts to mitigate knapweed invasion and restore the ecology of invaded systems.

In these experiments, we used a range of catechin concentrations ranging from 0–3,000 ppm (i.e., $\mu g\ ml^{-1}$). It is salient to note that reports in the literature have indicated catechin concentrations in soil harboring knapweed that range from 1.1 $\mu g\ g^{-1}$ soil to ~650 $\mu g\ g^{-1}$ soil (Blair et al., 2006; Perry et al., 2007). However, those prior studies measured catechin in bulk soil samples by using a procedure involving extraction and detection of chemically pure catechin by HPLC. We suggest that the concentrations of catechin a bacterium would encounter at the point of exudation into the soil (i.e., in the rhizoplane/rhizosphere/root zone) would be much higher and that the range of concentrations used in the current study are ecologically relevant for microbes living at the root—soil interface. We also suggest that a steep gradient of catechin concentration exists as a function of distance from knapweed roots, as is commonly found for other root exudates (Kuzyakov et al., 2003; Sauer et al., 2006), and that the inhibitory effects of catechin on soil microbial populations thus decrease with distance from the knapweed rhizoplane. We also note that catechin has been reported to be chemically unstable in media, sand, and soil (Blair et al., 2005, 2006; Perry et al., 2007; Inderjit et al., 2008; Pollock et al., 2009), presumably being transformed through biotic and/or abiotic processes into derivative compounds (e.g., the aforementioned soluble red compound), and that such compounds would not be

detected as catechin by the currently available HPLC-based methods. Finally, as we have shown recently, derivative compounds of pure catechin may have greater or less toxicity than chemically pure catechin (Pollock et al., 2009). In other words, it is difficult to determine precisely how much biologically active catechin is present in various compartments of soil ecosystems.

Catechin exuded by *C. stoebe* potentially disrupts a number of important plant:microbe interactions, both beneficial and antagonistic. Such disruptions may play an important role in the invasive success of spotted knapweed, as they impact both the plant and microbial components of the system (Callaway and Ridenour, 2004) by acting at the level of individual soil bacterial populations (this work). Thus, catechin may facilitate the invasion of spotted knapweed into non-invaded soils through a variety of potential mechanisms including suppression of pathogens of *C. stoebe*, facilitation of pathogens specific for native plants, suppression of microbes promoting growth of competitors, or facilitation of microbes promoting growth of *C. stoebe*.

Our results show that a diverse set of bacterial populations from soils native to spotted knapweed, invaded by spotted knapweed, and not invaded by spotted knapweed were differentially affected by catechin. More specifically, the data show that: 1) the inhibitory effect is dose-dependent at both the community and the population level; 2) individual microbial populations are differentially sensitive to catechin; 3) catechin is bacteriostatic to those populations that are affected; and, 4) removal of catechin from the system allows normal bacterial growth kinetics to resume. We hypothesize that, while native systems (including bacterial communities) have adapted to spotted knapweed and catechin over long time periods, the short-term response of an invaded community might be such that removal of catechin by degradation or transformation could allow the invaded bacterial community to recover its normal structure and function. This last suggestion may have profound ramifications for attempts to restore knapweed-infested ecosystems and warrants further investigation.

Acknowledgements Funding for this project was provided by United States Department of Agriculture – National Research Initiative USDA–CSREES Grant No. 2003-35320-13586. Funding for A.S.T. for soil collection in Romania was provided by NSF Grant No. 0331964. Special thanks to G. Thelen and R. Callaway for providing invaded soil samples, to M. Thompson for access to the non-invaded soils at the Clearwater Game Range, and to J. Graham for help in statistical analysis of the data.

Preliminary studies suggested that pea aphids, *Acyrthosiphon pisum* (Harris), elicit minimal plant volatile defense responses in broad bean plants. Herein, we asked whether failure of bean plants to respond to aphid feeding was due to an inability of plants to recognize and or respond to aphids, or alternatively, due to aphids' ability to suppress plant volatile emission. In several plant systems, when insects feed on plant tissue, the plant releases a blend of chemicals that is qualitatively and quantitatively different from control plants (see Felton and Tumlinson, 2008). However, in some cases (Turlings et al., 1998), when aphids feed on broad bean plants they do not induce a change in the emitted volatile blend or at best induce VOCs at a much lesser extent than caterpillar feeding. There are two possible explanations for why aphids do not cause changes in volatile emission. One is that aphids feed primarily intercellularly and thus cause relatively little damage to plant tissue compared to caterpillars and damage fewer plant cells, causing less induction of damage related volatiles. We feel that this is unlikely as aphids do cause considerable tissue degradation at high densities and cause punctures to epidermal, parenchyma, and vascular cells during stylet penetration and feeding (Tjallingii, 1995). Likewise, proteinaceous elicitors have been found within aphid saliva that trigger plant responses (de Vos and Jander, 2009). Therefore, aphids should provide ample cues for a rapid detection and a systemic plant response. The alternative hypothesis is that aphids are able to counteract plant defenses as they feed.

We designed experiments to measure the ability of pea aphids to suppress volatile emissions induced by beet armyworm caterpillars, *Spodoptera exigua*, which cause an increase in volatile emission when feeding on broad bean plants.

Methods and Materials

Plant and Insect Rearing Broad bean plants, *Vicia faba* L. (Var. Windsor) were used for all rearing of aphids and for volatile entrainments. *Vicia faba* seeds were purchased from Territorial Seed Co. (Cottage Grove, OR, USA) and planted singly in 10 cm round plastic pots and watered from the bottom as needed. Plants were grown in a greenhouse under controlled climatic conditions, (16:8 hr, L:D, 25°Celsius, 50% relative humidity) in autoclaved soil (MetroMix 200, Sun Gro Horticulture Canada Ltd, Bellevue, WA, USA).

Pea aphids used in volatile experiments were taken from an in-house colony originating from Lexington, KY, USA (Dr. Grayson Brown, University of Kentucky Department of Entomology). Beet armyworm (BAW) caterpillars, *Spodoptera exigua* were obtained as eggs from Benzon Research Inc. (Carlisle, PA, USA) and were reared on artificial diet until they reached the 3rd larval stage.

Aphid colonies were reared on one to 3-wk-old broad bean plants with the aerial portion of the plants enclosed within air-permeable (185×390 mm) cellophane bags (Armin Zeller, Nachf. Schütz & Co, Langenthal, Switzerland). Colonies were groomed weekly to maintain colony densities that were not crowded, i.e., they did not promote dispersal morph production.

Aphid Feeding The effect of aphid feeding on plant volatile production was tested on each of 8 plants over a 6-d period. Aphids feeding on plants was the sole treatment, and uninfested plants were used as controls. Fifty adult aphids were placed on each treatment plant 1 hr prior to the start of air entrainment. We chose this level of infestation because it did not result in the production of dispersal morphs and did not cause complete death of the plant after 6 d of air entrainment. For this experiment, volatiles were collected from the headspace of plants twice daily; one diurnal collection from 9:30 to 17:30, and one nocturnal collection from 21:30 to 5:30 the next morning.

Aphid and Beet Armyworm Feeding We tested for the effects of simultaneous feeding of aphid and caterpillar on plant volatile production. Treatments consisted of plants with: (1) aphids; (2) caterpillars; (3) aphids and caterpillars; or (4) control plants with no herbivory. We placed 50 adult aphids on plants used for volatile entrainment 24 hr before placing 3 third-instar caterpillars. This was done to establish sustained aphid feeding prior to caterpillar feeding. Aphids and caterpillars were placed on plants at 13:30 hr on their respective days. Caterpillar activity was monitored throughout the daytime collection periods, and new caterpillars were added to maintain even damage over all replicates. Six replicates were performed.

Air Entrainment Air was sampled from the headspace of 2-wk-old *V. faba* plants within individual volatile collection chambers (Fig. 1). The chambers consisted of 11 cm diam by 30 cm tall glass cylinders that were capped with Teflon® lids and placed over aluminum guillotines. Plants were inserted into the chambers so that the pot and soil were below the guillotine and the aerial portion of the plant was contained within the glass cylinder. Cotton wool was wrapped around the base of the stem to prevent aphids or caterpillars from escaping (Fig. 1).

Purified air originating from an in-house compressor was pumped into the chambers at a rate higher than the rate at which it was sampled (1.5 l per min in, 1.0 l per min sampled) to prevent contamination from outside the chamber. As air was removed from the chamber it passed over an adsorbent trap containing 30 mg of Super Q (80/100

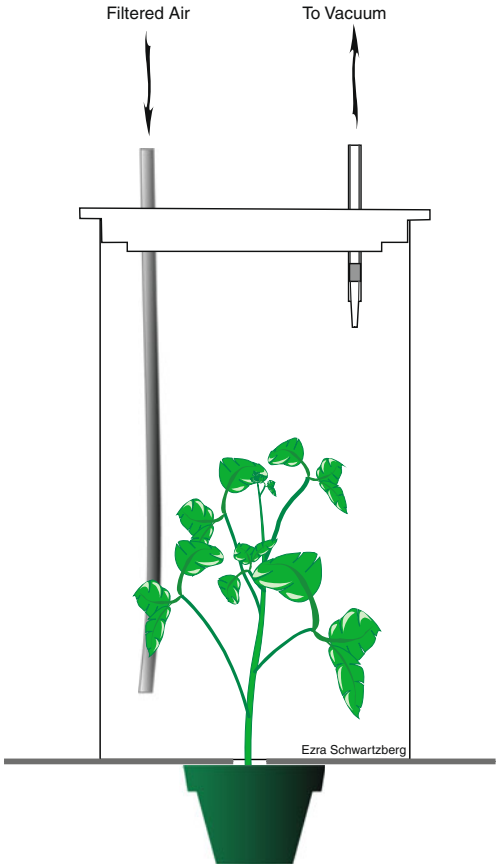

Fig. 1 Schematic of a volatile entrainment chamber. The aerial portion of the plant was isolated within glass chambers fitted with filtered air inlets and vacuum outlets. Headspace volatiles were collected on adsorbent filter cartridges over 8 hr collection periods. The chambers consisted of 11 cm diam by 30 cm tall glass cylinders that were capped with Teflon® lids and placed over aluminum guillotines

mesh, Alltech Inc, Nicholasville, KY, USA). Headspace volatiles were entrained for 8 hr per day during the photophase from 09:30 to 17:30. Volatile entrainments started at 9:30 hr, 4 hr prior to aphid placement on test plants allowing for an 8 hr collection period prior to the placement of caterpillars. Aphids were placed on plants within collection chambers at 8:30 on the morning of the first 8 hr collection period. Caterpillars were placed on plants at 17:30 following the first 8 hr collection period. Diurnal volatile entrainment of plants with aphid and caterpillar feeding continued until the end of the last collection period. At this point, leaves were photocopied to calculate total leaf area consumed between treatments.

Chemical Analysis Absorbent traps were removed within 24 hr of each collection period and eluted with 100 µl dichloromethane. Twenty µl of 8 ng/µl of nonyl-acetate in hexane were added as an internal standard to the elutant from each trap.

All samples were analyzed quantitatively by using a Hewlett-Packard 6890 GC equipped with a flame ionization detector (FID) and fitted with an Equity-1 bonded phase capillary column (0.25 mm×0.25 m×30 m, J&W Scientific, Folsom, CA, USA). The column temperature was programmed with an initial temperature of 40°C for 3 min, followed by an increase to 220°C at a rate of 5°C/min, with a 5 min hold at 220°C. The injector was set at 220°C. Samples were injected splitless, and the split valve was opened 0.75 min after injection. Helium was used as carrier gas at a linear flow rate of 36.3 cm/sec. Because 1/3 of all of the volatile compounds emitted from within the test chamber were lost to the outside environment, the resulting values for volatile emission were multiplied by 3/2 to obtain the total emission of compounds from the plant over each 8 hr collection period.

Selected samples were analyzed using an Agilent 6890N GC coupled with an Agilent 5973N Mass Selective Detector (GC-MS) in the electron impact mode (+70 eV) with an HP-1 bonded phase capillary column (30 m× 0.25 mm×0.25 um, J&W Scientific, Folsom, CA, USA) programmed as indicated above for compound identification. Kovats Indices (Kovats, 1988) were calculated for all peaks and compound mass spectra were compared to the NIST/EPA/NIH Mass Spectral Library (NIST02) for initial compound identification. Additionally, retention time and mass spectra were compared to those of synthetic standards.

Statistical Analysis For comparison of volatile emission, an analysis of variance was performed for each identified compound or the sum of all analyzed compounds per collection period using the statistical software package JMP 5.0 for Macintosh. When the sum of all emitted compounds was calculated, (*E*)-*ß*-farnesene was removed due to its perceived production source, i.e., because (*E*)-*ß*-farnesene is produced by aphids it only adds variation to the sum of plant-emitted compounds (see "Discussion"). All data were $\log_e(x+1)$-transformed to satisfy the assumptions of ANOVA and *post-hoc* comparisons were conducted by using Tukey's honestly significant difference (HSD) test.

Results

Aphid Feeding Aphid feeding had relatively minor effects on host plant volatile production. Over the six-day collection period, aphid colonies grew to the point where their host plant started to become desiccated. At the end of collection, aphid infested plants were noticeably smaller than controls, although there were no significant changes in volatile production. The exception to this was an increased emission of (*Z*)-3-hexenol by aphid-infested plants during the photophase of days three through six, and the increase of (*E*)-*ß*-farnesene after the fourth day of aphid infestation (Fig. 2).

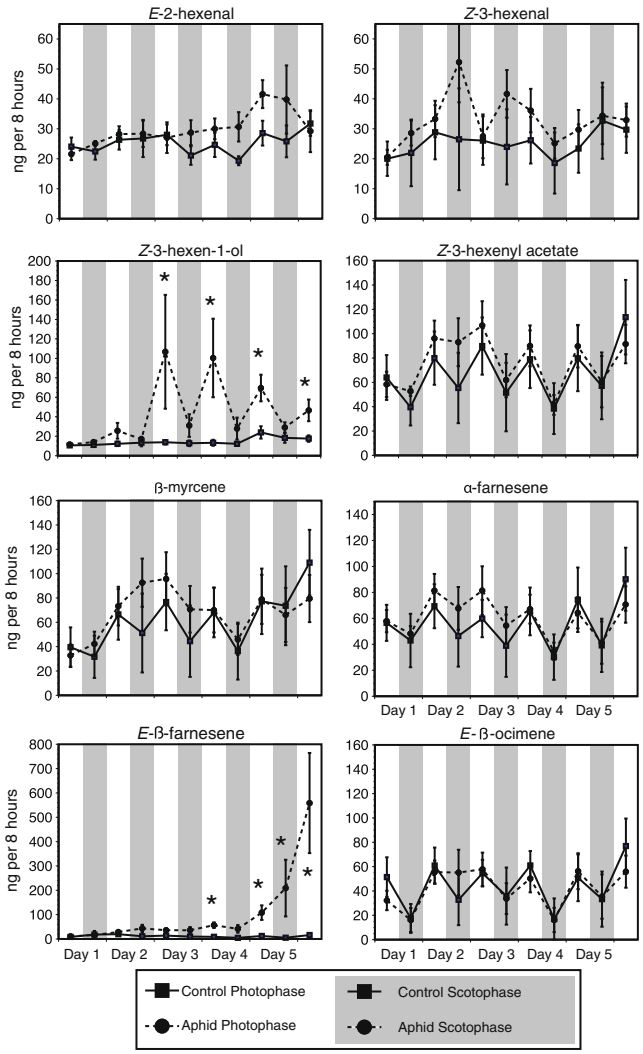

Fig. 2 Major compounds released by broad beans infested with 50 adult pea aphids during the photophase (*light area*) and scotophase (*shaded area*). Data show mean and SE of (*E*)-2-hexenal, (*Z*)-3-hexanal, (*Z*)-3-hexen-1-ol, *β*-myrcene, (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, (*E*)-β-farnesene, and *α*-farnesene. Data show values from eight replicates. An asterix indicates significant differences between treatments ($P<0.05$)

Combined Aphid and Beet Armyworm Feeding Beet armyworm caterpillars caused an induction of several volatile compounds within the first 8 hr collection period after the onset of feeding, with the greatest induction of most VOCs after 48 hr of feeding. Among the most abundant BAW-induced VOCs are the green leaf volatiles (GLVs) (Z)-3-hexenol and (*Z*)-3-hexenyl acetate, and the monoterpene (*E*)-*β*-ocimene, the sesquiterpene (*E*)-*β*-caryophyllene, and the homosesquiterpene (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) (Fig. 3) (Table 1). In this experiment, aphid feeding did not cause a significant increase in any plant-derived volatile compounds (Fig. 4), including the green leaf volatile (*Z*)-3-hexenol, which was not induced in aphid-infested plants. The lack of emission of this compound is contradictory to the previous experiment (Fig. 2), however, due to inherent variability between tests, this was not seen as abnormal.

Caterpillar-induced volatiles were altered significantly by the presence of aphids (Figs. 4 and 5), and moreover, there were differences in how each compound was affected. For example, *β*-caryophyllene and TMTT were suppressed by aphid feeding. In other words, lesser amounts of these compounds were released from plants when fed upon by the combination of aphids and caterpillars as compared to volatile release from plants in response to caterpillar feeding alone (Fig. 4). The GLV (*Z*)-3-hexenyl acetate and the sesquiterpene (*E*)-*β*-ocimene were reduced by aphid-feeding as compared to controls for at least one of the days sampled (Fig. 4). Moreover, aphid feeding had an affect on total volatile production in broad bean plants. This was seen by a significant reduction in emitted volatiles from plants with aphids as compared to controls on days one, two, and four, ($F=3.99$; $df=3, 23$; $P=0.022$) ($F=10.31$; $df=3, 23$; $P<0.001$) ($F=12.71$; $df=3, 22$; $P<0.001$), respectively, as well as compared to BAW feeding on day three ($F=4.54$; $df=3, 23$; $P=0.01$) (Fig. 5). Finally, we observed differences in (*E*)-*β*-farnesene emission among treatments, specifically, from aphids or the combination of aphids and caterpillars as compared to controls or caterpillars only (Fig. 4).

Leaf area measurements were made at the end of the two volatile collection experiments to assess total leaf area, leaf area consumed, and percent leaf area consumed. Aphid infested leaves were smaller than control plant leaves $t(10)$, $P=0.02$. There were no significant differences in total leaf area, leaf area consumed, or percent leaf area consumed between plants fed upon by beet armyworm caterpillars, or the combination of aphid-infestation and beet armyworm feeding.

Discussion

We observed different responses of broad bean plants to herbivory by two herbivores with differing feeding habits. While broad bean plants responded to herbivory by beet armyworm caterpillars (BAW), seen by an increase in the emission of several green leaf and terpenoid volatile compounds, broad bean did not respond similarly to herbivory by aphids. The volatile profile emission of broad bean plants infested with aphids remained similar to, or even lower than that of control plants. With the exception of the green leaf volatile (*Z*)-3-hexenol, there was no significant increase in emission of volatile compounds, suggesting that, unlike other plants, (Quiroz et al., 1997; Han and Chen, 2002a; James, 2003; Zhu and Park, 2005;

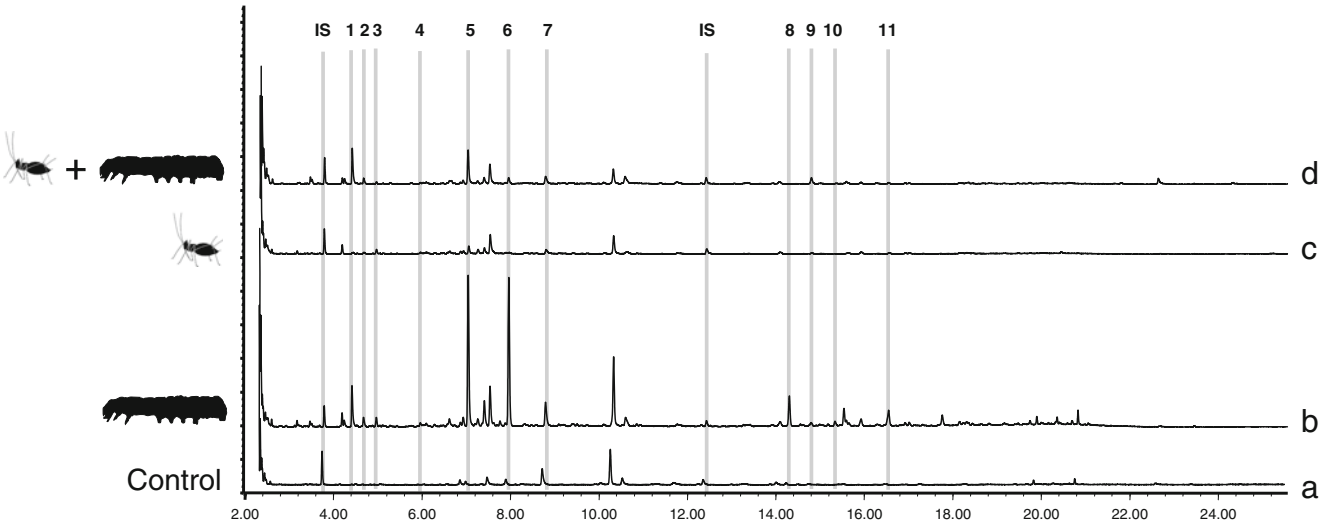

Fig. 3 Chromatograms of volatile compounds emitted on Day 3 from (*a*) control plants, (*b*) plants fed upon by 3 beet armyworm caterpillars (BAW), (*c*) plants colonized by 50 aphids, or (*d*) combination of aphids and BAW. Major compounds are labeled as in Table 1

Harmel et al., 2007), broad bean plants do not respond to herbivory by pea aphids. Our results also were inconsistent with previous studies that examined VOC emission from broad bean plants fed upon by pea aphids (Du et al., 1998). While Du et al. (1998) found that broad bean plants produced several compounds following aphid infestation, including 6-methyl-5-hepten-2-one, (Z)-3-hexenyl acetate, (*E*)-*ß*-ocimene, (*Z*)-3-hexenol, (*E*)-*ß*-farnesene, and geranic acid, we were unable to replicate this in our study. We speculate that these differences in plant behavior are the result of either differential responses inherent to plant variety, research conditions, or aphid strain. It has been demonstrated previously that plant VOC response is affected by both the variety of plant being tested (Loughrin et al., 1995; Gouinguene et al., 2001; Degen et al., 2004), herbivore species within the same feeding guild (De Moraes et al., 1998), and even herbivore life stage (Rodriguez-Saona et al., 2002) (Halloran, personal communication), although difference in induction by different strains of the same insect species has not been documented. We believe the difference is less likely due to aphid strain, as we have tested several strains of pea aphids, including both red and green morphotypes with no noticeable differences in plant VOC emission (unpublished data). A more likely reason for differences between our study and Du and others (1998) is aphid density. Our infestations were

Data show mean and SE of (*Z*)-3-hexen-1-ol, (*E*)-*β*-ocimene, (*E*)-*β*-caryophyllene, (*E*)-*β*-farnesene, TMTT, and (*Z*)-3-hexenyl acetate. Data show values from six replicates. Different letters indicate significance differences between treatments ($P<0.05$)

considerably lower than those of Du and others (1998), and this could explain the observed differences.

The presence of increased emission levels of (*Z*)-3-hexenol may not necessarily be a consistent indicator of aphid infestation. While we report an increase in this compound, we have not seen it consistently produced from broad bean fed upon by aphids (unpublished data).

Broad bean plants responded to caterpillar herbivory by emitting VOCs as compared to control plants or plants infested with aphids. Specifically, BAW caterpillars induced compounds previously shown to increase upon herbivore damage, including (*E*)-*β*-caryophyllene, and (*E, E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) (Colazza et al., 2004) as well others not previously reported to be induced by beet armyworm feeding on broad bean. We had expected that broad bean would respond to BAW feeding, and this is not the first study to show differential induction of VOCs from plants fed upon by both chewing and piercing-sucking insects (Rodriguez-Saona et al., 2003, 2005; Delphia et al., 2007). In fact, it is common to see a much greater induction of VOCs from chewing insects as compared to piercing-sucking insects (Turlings et al., 1998).

The ability of aphids to alter the response of broad bean plants to BAW feeding helps to explain a potential mechanism for the reduced VOC responses that are seen among plants fed upon by aphids and other piercing sucking insects as compared to plants fed upon by chewing insects such as caterpillars. While aphids feed on plant phloem, and reach the phloem intracellularly, they do cause considerable damage to plant tissue. As aphids guide their stylets to phloem tissue, they puncture almost every mesophyll cell along the stylet path (Prado and Tjallingii, 2007), and often they exhibit repetitive puncturing of the phloem sieve elements (Tjallingii and Gabrys, 1999). Therefore, we argue that it is unlikely that aphid stylet penetration simply goes un-noticed by plants. In our study, the ability of aphid feeding to suppress VOC emission in response to caterpillar feeding suggests that aphids actively suppress plant responses. Caterpillars fed equally when tested as the sole herbivore, or in combination with aphids, suggesting that the degree of damaged tissue is similar between treatments. Suppression of caterpillar-induced VOC emission eliminates the possibility that plants respond less to aphid feeding simply due to aphids' apparently stealthy feeding habits.

Beet armyworm induced compounds are quantitatively and qualitatively different from those emitted from control plants. For example, the sesquiterpene *β*-caryophyllene is produced only from broad bean plants fed upon by caterpillars and not from control plants, thus demonstrating a qualitative difference in emission. Additionally, the monoterpene

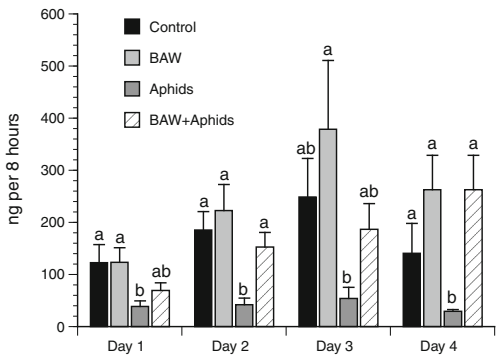

Fig. 5 Total volatiles released by broad beans infested with 3 beet armyworm caterpillars (BAW); *lightly shaded*, Aphids; *dark shaded*, combination of aphids and BAW; hatched, or control; *black bars*. Data show mean and SE of the sum of the 13 most abundant volatiles (with the exception of (E)-β-farnesene). The aphid alarm pheromone, ((E)-*β*-farnesene) was omitted from the calculation of total volatiles due to its suspected origin from aphids rather than the host plant. Data show values from six replicates. Different letters indicate significance differences between treatments ($P<0.05$)

(*E*)-*ß*-ocimene, which is consistently emitted from control plants, increases in emission in response to caterpillar feeding, demonstrating a quantitative difference in emission.

Aphid feeding also has varying affects on emission of different compounds. This is apparent when comparing total volatile emission (Fig. 5) to individual compounds (Fig. 4). In particular, it seems that BAW induced sesquiterpenes are affected more than beet armyworm induced GLVs. For example, the GLV (*E*)-2-hexenal is induced upon BAW feeding and is not affected by the presence of aphids, whereas emission of the terpenoid compounds *ß*-caryophyllene and (*E*)-*ß*-ocimene is greatly affected by the presence of aphids. Terpenes and GLVs are products of different metabolic pathways within plants; terpenes are produced via the mevalonate pathway while GLVs are produced via the oxylipin pathway (Creelman and Mullet, 1997). It is likely that the mechanism(s) responsible for the observed suppression of caterpillar-induced volatile production act differently, depending on what metabolic pathway they are affecting. This observed differential suppression also eliminates the possibility that suppression effects are due to changes in plant size or virus load that result from aphid infestation. Both of these also have been shown to decrease volatile production in a non-discriminatory manner, i.e., by decreasing all plant emitted compounds evenly (Jimenez-Martinez et al., 2004).

The differences in the propensity of various herbivore-induced compounds to be suppressed by aphid feeding also may shed light on the relative importance of individual compounds on parasitoid attraction. The pea aphid parasitoid, *Aphidius ervi*, is attracted to a blend of plant volatiles, including several of the ones emitted by our plants under caterpillar herbivory (Du et al., 1998). Interestingly, aphids effectively suppress some of these compounds, for example, the emission of the parasitoid-attracting compound (*E*)-*ß*-ocimene, thus suggesting that there may be a selective advantage for limiting a plant's production of this attractant. Suppression of spider mite-induced (*E*)-*ß*-ocimene by whiteflies inhibits the attraction of the predatory spider mite *Tetranychus urticae* (Zhang et al., 2009). Pea aphids also suppress the emission of (*E*)-*ß*-caryophyllene, a compound that, depending on its ratio to (*Z*)-3-hexenal, germacrene D, and TMTT, also attracts the parasitoid *Aphidius ervi* (Pareja et al., 2009).

Aphids may benefit from affecting VOC emission in other ways as well. Many aphids rely on the production and perception of the aphid alarm pheromone (*E*)-*ß*-farnesene. However, the response of pea aphids to this alarm pheromone can be affected by the ratio of (*E*)-*ß*-farnesene to sesquiterpenes and other compounds being produced from its host plant. For instance isothiocyanates act as synergists to alarm pheromone for the turnip aphid, *Lipaphis (Hyadaphis) erysimi* (Dawson et al., 1987), while (*E*)-*ß*-caryophyllene acts as an antagonist for the cabbage aphid, *Mysus persicae* (Dawson et al., 1984). The ability of pea aphids to affect the emission of these and other compounds may affect how they respond to natural enemies, and/or crowding, both of which are influenced by (*E*)-*ß*-farnesene perception (Kunert and Weisser, 2003).

In summary, our results show that feeding by multiple herbivores simultaneously affects the induction of VOCs compared to these same herbivores feeding independently. Furthermore, we demonstrate that aphid infestation inhibits the release of several VOCs normally induced upon feeding by the herbivore *S. exigua*, and that the level of suppression incurred by pea aphid infestation varies depending on the compound. While we speculate on why some compounds are suppressed and others are not, we have no definitive explanation why, or how, some compounds are affected differently from others. However, aphids may be actively suppressing inducible plant VOCs that alter aphid behavioral responses to their environment, or the response of aphid natural enemies to the aphid's host plant.

Acknowledgements We thank Mr. Bryan Banks of Volatile Assay Systems for equipment and technical assistance. Nathaniel McCartney assisted with maintenance and expertise in experimental and chemical procedures. Matthew Gordon, Chouc Vo, and John Mano provided essential procedural assistance as well as plant and aphid colony maintenance.

of the plant response, different populations of a single plant species may provide highly variable targets for prospective herbivores.

For insects that sequester defensive compounds produced by their host plants, variation in these compounds may have substantial consequences for these insects and their interactions with their natural enemies. For example, individual insects that feed on plants with higher levels of these compounds may suffer fitness consequences (Camara, 1997; Fordyce and Nice, 2008; Smilanich et al., 2009). Yet, at the same time, sequestered compounds may be important in protecting insects from their own enemies, and higher levels of these compounds may provide enhanced protection (Skelhorn and Rowe, 2006). While the efficacy of sequestered defensive compounds has been demonstrated for predators, less is known about how the compounds affect parasitoids.

There is little reason to assume that consumers at higher trophic levels are unable to evolve adaptations to dietary toxins, such as compounds sequestered by herbivores, yet relatively few studies have documented the transfer of sequestered compounds to higher trophic levels (e.g., McDougall et al., 1988; Rossini et al., 2000; Bowers, 2003; Reudler Talsma, 2007). Endoparasitoid larvae spend their entire larval development inside a single host where they often are exposed continuously to compounds sequestered by the host (Ode, 2006), and they are likely to ingest substantial amounts of these compounds. Because the mid- and hind-gut are not connected in hymenopteran endoparasitoids until emergence or pupation (Quicke, 1997), larvae of these species are incapable of egestion, and any ingested compounds not metabolized remain in their bodies. For instance, tomatidine, the aglycone of the alkaloid α-tomatine, was detected in larvae of the ichneumonid endoparasitoid, *Hyposoter exiguae,* that were developing within *Helicoverpa zea* caterpillars reared on alkaloid-spiked artificial diet (Campbell and Duffey, 1979). Several other studies have detected plant-produced or derived secondary metabolites in adult parasitoids, with concentrations magnified in adults of some species (McDougall et al., 1988; Campos et al., 1990; Reudler Talsma, 2007) and minute in others (Rossini et al., 2000; Bowers, 2003; Reudler Talsma, 2007).

In this study, we examined variation of catalpol and catalposide (a derivative of catalpol), two iridoid glycosides produced by Southern Catalpa trees, *Catalpa bignonioides* Walter (Bignoniaceae). We examined effects of these two defensive compounds on the primary herbivore of Catalpa, the Catalpa Sphinx, *Ceratomia catalpae* Boisduval (Lepidoptera: Sphingidae) and its primary endoparasitoid, *Cotesia congregata* Say (Hymenoptera: Braconidae). Iridoid glycosides (IGs) are monoterpene-derived secondary compounds that mediate interactions between plants, their herbivores and herbivore natural enemies (Bowers, 1993; Nishida, 2002 and references therein). Iridoid glycosides are sequestered by four orders of herbivores, including the Catalpa Sphinx (Bowers, 2003), and sequestered IGs can deter predators (e.g., Bowers, 1980; Bowers and Farley, 1990; Dyer and Bowers, 1996; Camara, 1997; Theodoratus and Bowers, 1999; Rayor and Munson, 2002). This study addressed three questions about variation in IGs in Catalpa trees, Catalpa Sphinx caterpillars, and *C. congregata* parasitoids: 1) Does IG content vary within and among populations of Catalpa trees, and is this variation associated with the presence of Catalpa Sphinx larvae? 2) Is the IG content of Catalpa Sphinx caterpillars correlated with the IG content of the trees on which they fed? 3) Are larvae of the parasitoid, *Cotesia congregata,* able to sequester IGs from their caterpillar hosts, and, if so, what is the relationship between IG concentrations in parasitoid larvae and caterpillar hosts?

Methods and Materials

Study System Catalpa bignonioides, the Southern Catalpa, is a widespread deciduous tree found throughout North America as an ornamental (Sibley, 2009). This species contains primarily two IGs, catalpol and catalposide, although a few others have been recorded (von Poser et al., 2000). The Catalpa Sphinx, *Ceratomia catalpae,* is a specialist on *Catalpa* spp. (Baerg, 1935; Nayar and Fraenkel, 1963; Bowers, 2003); larvae are gregarious and brightly colored, black, yellow and white, and sequester high concentrations of the IG catalpol from their host trees (Bowers, 2003). Adults are cryptically colored, grayish-brown; they do not contain IGs and are palatable to birds (Bowers and Farley, 1990).

A major natural enemy of Catalpa Sphinx larvae is the gregarious koinobiont parasitoid *Cotesia congregata*, which parasitizes larvae of a number of sphingid species, including Catalpa Sphinx (Harwood et al., 2002; Bowers, 2003). *Cotesia congregata* oviposit into 2nd-4th instar sphingid larvae and develop over ~2 wk, whereupon they emerge through the cuticle, spin silken cocoons, and pupate; adults emerge approximately 10 d later. Concentrations of catalpol in Catalpa Sphinx hemolymph, the sole source of nutrients for developing *C. congregata* larvae, can reach up to 50% dry weight (Bowers, 2003), and thus parasitoids developing in the hemocoel will be exposed to very high levels of IGs. Catalpol in the caterpillar host appears to have little negative impact on *C. congregata* fitness when reared from Catalpa Sphinx (Crocker, 2008; Lampert et al., 2010) despite evidence that catalpol is absorbed by developing parasitoid larvae (Bowers, 2003).

Leaf and Caterpillar Collections Leaves were collected 24–30 July 2008, from 14 separate *Catalpa bignonioides* stands at locations from New Jersey to Georgia (Table 1); trees in five of these stands were attacked by Catalpa Sphinx larvae. Trees in each population were sampled according to the same protocol. Approximately 10 leaves were removed from a single branch of caterpillar-free trees. To compare damaged and undamaged leaves in trees infested with Catalpa Sphinx larvae, approximately 10 leaves were collected from an undamaged branch and 10 from a damaged branch on each tree. At least 5 and up to 30 trees were sampled per site in this manner, depending on the number of trees in a stand. All leaves were dried for 2 d in an oven at 50°C, after which they were ground into fine powder using a coffee grinder.

In trees with larvae, all Catalpa Sphinx larvae within reach (~3.0 m) were removed. Larvae ranged from 2nd to 5th instar depending on the site. Larvae were stored alive in a plastic cooler until they could be processed in the laboratory in Boulder, CO, USA, where 5th instars (as determined by head capsule size) were immediately weighed to the nearest 0.1 mg and then frozen at −80°C for chemical analysis. Remaining larvae were used to collect parasitoids or to establish a laboratory colony.

Parasitoid Collections To determine the IG concentrations of parasitoid larvae and their caterpillar hosts, a separate set of Catalpa Sphinx larvae and larval *Cotesia congregata* were analyzed. Catalpol was measured in both caterpillar hemolymph and parasitoid larvae. For these data, Catalpa Sphinx larvae from a heavily parasitized population were collected in August 2008, from a mixture of catalpa trees at the USDA South Farm in Beltsville, MD, USA; the iridoid glycoside content of these trees was not measured. Tree species included *Catalpa ovata*, *C. x galleana* (a hybrid between *C. ovata* and *C. speciosa*), and *C. x erubescens* (hybrid of *C. ovata* x *C. bignonioides*). Twenty-four late 4th instars and 9 early 5th instars were included in chemical analyses. Larvae were anesthetized with CO_2, the abdominal horns were clipped, and 5 μl of hemolymph drained from these wounds were collected using microcapillary tubes and immediately placed in 5 ml methanol to extract catalpol. Caterpillars were dissected completely lengthwise and examined for *Cotesia congregata* larvae, which were removed, counted, washed with clean methanol, and dried with a paper towel. All members of a single *C. congregata* brood were pooled and weighed to the nearest 0.01 mg. *Cotesia congregata* larvae then were placed directly into methanol for catalpol extraction.

Tree Chemistry and Analyses A subsample of 25 mg of ground leaves was used for iridoid glycoside analysis. Sample preparation and analysis by gas chromatography (GC) followed previously described methods (Bowers and Stamp, 1993; Bowers, 2003). Briefly, samples were extracted overnight in methanol, filtered and evaporated to dryness, partitioned between water and ether to remove nonpolar compounds, and the water layer (containing the IGs) was evaporated. Phenyl-ß-D-glucopyranoside (PBG) was added as an internal standard. Standards composed of purified PBG, catalpol, and catalposide were used for instrument calibration. For GC analysis, iridoid glycosides were derivatized using Tri-sil Z™ (Pierce Chemical Company). GC analyses were performed on an Agilent 7890 system (Agilent Technologies) equipped with an Agilent DB-1 column (30 m, 0.320 mm, 0.25 μm particle size), and data were processed with Agilent ChemStations software (version B-03-01). Paired *t*-tests were used to compare catalpol and catalposide content between damaged and undamaged leaves of caterpillar-infested trees. A

random effects MANOVA was utilized to test for variation in catalpol and catalposide across populations, and profile analysis allowed for a comparison of variation of catapol vs. catalposide across populations. To examine the relationships between presence of caterpillars and leaf content of catalpol and catalposide in sampled trees, we utilized MANOVA and profile analysis, with population means of catalpol and catalposide as response variables and caterpillar presence as a fixed independent variable with three levels: trees from caterpillar-free populations, caterpillar-infested trees, and caterpillar-free trees from populations with caterpillars present. Residuals for both dependent variables were not significantly different from normal (Shapiro-Wilk test for normality, $P>0.3$ in either case). To avoid pseudoreplication, population means were utilized for these three levels of the independent variable. All linear contrasts between levels of independent variables were examined for the overall MANOVA model, and profile analysis tested the hypothesis that caterpillar presence affected catalpol differently from catalposide.

Caterpillar Chemical Analyses Fifth instar Catalpa Sphinx were removed from the freezer and immediately ground in methanol, with sand, to help macerate the insects. Iridoid glycoside extraction and analysis by GC were performed as described above. Fresh-dry weight conversions were obtained by weighing, drying, and re-weighing separate sets of larvae. The relationship between chemistry of leaves of individual trees and the catalpol sequestration by Catalpa Sphinx larvae was examined by using least-squares regression. Sequestration was compared among populations using ANOVA, with the percent dry mass of catalpol as the response variable. Because natural enemies such as vertebrate predators may consume an entire insect before finding it unpalatable, we also compared total catalpol amounts sequestered among populations by using analysis of covariance (ANCOVA), treating caterpillar dry weight as a continuous covariate and the quantity of catalpol (in milligrams) as the response variable. All statistical analyses were performed with SPSS and SAS 9.2.

Caterpillar Hemolymph and Parasitoid Chemical Analyses Capillary tubes of Catalpa Sphinx hemolymph were extracted for 72 h and *C. congregata* larvae were macerated with sand and extracted in 5 ml methanol for 48 h. Sample preparation and GC analysis were as described above. Because all *C. congregata* larvae from a single brood were ground and homogenized together, amounts of catalpol represented that absorbed by the entire parasitoid brood. Independent 2-tailed *t*-tests were performed to determine whether hemolymph catalpol content, parasitoid clutch size (number of larvae inside the host), parasitoid clutch dry mass, and parasitoid catalpol concentration (% dry mass) differed between 4th and 5th instar host larvae. Least-squares regression analyses were performed to determine if catalpol concentration in host hemolymph significantly influenced both the amount and concentration of catalpol in parasitoid larvae. Because all individuals from each brood were combined, we also performed multiple regressions to determine whether number and weight of parasitoid larvae and caterpillar catalpol sequestration influenced the amount and concentration of catalpol detected inside parasitoid larvae.

Results

Tree Chemistry Leaf iridoid glycoside content varied from <0.2 to 5.4% dry weight. There was no difference in the amount of catalpol ($t_{14}=1.44$, $P=0.17$), catalposide ($t_{14}=-0.33$, $P=0.74$), or total iridoid glycosides ($t_{14}=0.97$, $P=0.35$) between damaged and undamaged leaves within individual trees. Concentrations of both compounds were averaged for damaged and undamaged branches, and the mean was treated as the content of each tree for use in subsequent analyses. Catalpol and catalposide did, however, vary among populations (Wilk's $\lambda=0.5$, $F_{11,120}=10.10$, $P<0.001$), and profile analysis indicated that this variation was significantly greater for catalposide (Wilk's $\lambda=0.4$, $F_{11,120}=13.90$, $P<0.001$) (Fig. 1).

Leaf chemistry varied among trees in the three infestation categories (attacked trees, caterpillar-free trees from

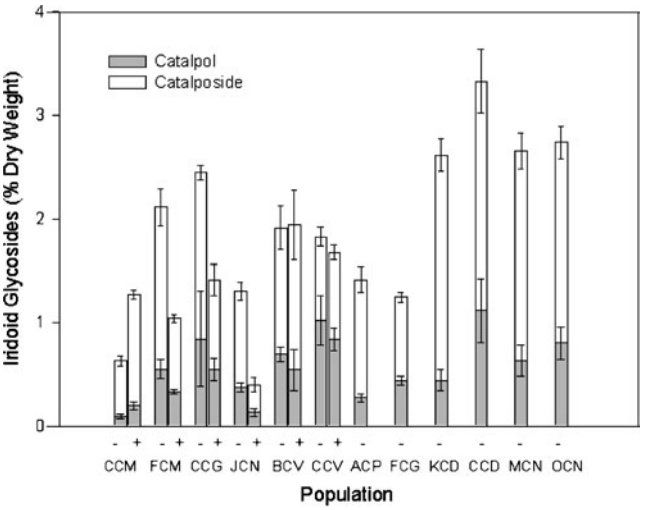

Fig. 1 Mean (± SEM) percent dry weight of catalpol and catalposide of all *Catalpa bignonioides* populations sampled. Plus signs (+) represent averages for trees attacked by Catalpa Sphinx caterpillars, while minus signs (−) represent averages for trees with no caterpillars. Abbreviations: **CCM** – Cecil Co., MD; **FCM** – Frederick Co., MD; **CCG** – Clarke Co., GA; **JCN** – Johnston Co., NC; **BCV** – Botetourt Co., VA; **CCV** – Cumberland Co., VA; **ACP** – Adams Co., PA; **FCG** – Franklin Co., GA; **KCD** – Kent Co., DE; **CCD** – Cumberland Co., NJ; **MCN** – Cape May Co., NJ; **OCN** – Ocean County, NJ

attacked populations, and trees from caterpillar-free populations) (Wilk's λ=0.7, $F_{2,15}$=3.60, P=0.05) (Fig. 2). Profile analysis showed that only catalposide concentration varied among the three infestation categories (Wilk's λ=0.6, $F_{2,15}$=4.60, P=0.03). According to pre-planned contrasts, leaves of trees from caterpillar-free populations had higher catalposide levels than trees with caterpillars (Tukey's P <0.05) (Fig. 2).

Caterpillar Chemistry As has been found in previous studies (Bowers, 2003; Lampert et al., 2010), only catalpol was detected in *C. catalpae* larvae. Percentage of catalpol sequestered by individual larvae ranged over an order of magnitude from 1.5-15.7% dry weight (Table 2), and was different among populations ($F_{4,73}$=13.45, P<0.001). After accounting for dry weight of larvae, the average mass of catalpol sequestered by individual larvae also varied significantly among populations ($F_{4,72}$=14.41, P<0.001) and many caterpillars contained over 15 mg of catalpol (Table 2). Furthermore, the percentage of catalpol in larvae was positively associated with the combined catalpol and catalposide concentrations in leaves upon which they fed ($F_{1,76}$=11.81, P<0.001) (Fig. 3). IGs sequestered by larvae increased with tree iridoid glycosides as expressed by the following equation: larva=1.61 * tree+5.22 (r^2=0.14).

Caterpillar Hemolymph and Parasitoid Chemistry Larvae from all *C. congregata* broods contained catalpol, although amounts varied substantially, ranging from 0.3-5.0% of their dry weight (mean=2.10±0.64). Neither the total mass of catalpol within parasitoids ($F_{1,29}$=0.003, P=0.95) nor percentage dry weight of catalpol ($F_{1,29\ =\ 0.31}$, P=0.58) inside parasitoid larvae was associated with hemolymph catalpol content of their host Catalpa Sphinx caterpillars.

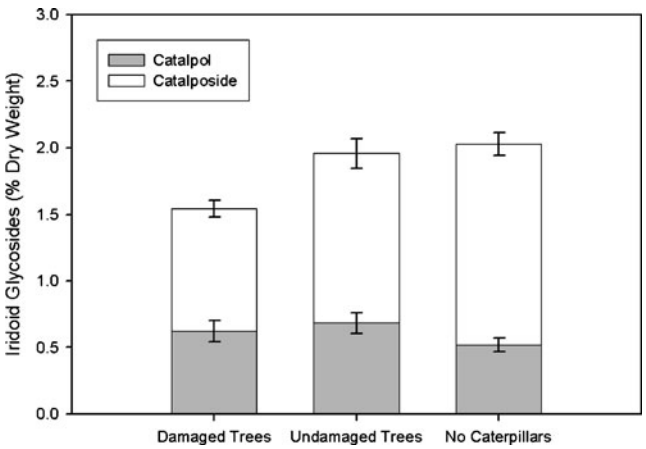

Fig. 2 Mean (± SEM) percent dry weight of catalpol and catalposide in *Catalpa bignonioides* trees attacked by Catalpa Sphinx caterpillars, caterpillar-free trees from attacked populations, and trees from caterpillar-free populations

Parasitoids dissected from 5th instars contained over twice as much catalpol (2.30% dry weight) as those dissected from 4th instars (1.18%) ($F_{1,28}$=7.48, P=0.01). According to the regression analysis, only total clutch size significantly (P=0.04) influenced parasitoid catalpol content. Larger clutches contained more catalpol (r^2=0.13, $F_{1,29}$=4.43, P=0.04).

Discussion

Variation in plant chemical defense is influenced by a combination of genetic and ecological factors, and the underlying genotypic and environmental influences on defensive chemistry can vary widely among plant populations. For *Catalpa bignonioides* leaves, there was considerable variation in IG content across the landscape in populations with and without caterpillars. This system is an attractive model study system due to this variation in defensive chemistry combined with the specialist feeding habits of associated caterpillars and parasitoids, and the variation in intensity of caterpillar and parasitoid attack among tree populations.

The presence of Catalpa Sphinx caterpillars was associated with quantitative differences in the IGs of *Catalpa bignonioides* leaves. In particular, catalposide concentration of trees with caterpillars was lower than that of trees with no caterpillars. However, caterpillar-damaged and undamaged leaves had similar catalpol and catalposide levels within individual trees, suggesting that there was no localized response to herbivory, or that sufficient time had elapsed to allow the response to become systemic or to attenuate. It may be that feeding by Catalpa Sphinx larvae suppresses IG production, as has been found for nicotine in wild tobacco in response to the specialist herbivore, *Manduca sexta* (Sphingidae) (Winz and Baldwin, 2001). If there is no effect of increasing levels of iridoid glycosides on this specialist caterpillar, then it may be more cost-effective for *Catalpa* trees to decrease production in response to herbivory to allow for greater allocation to other defenses; such a trade-off has been suggested for alkaloids vs. other defenses in *Senecio jacobaea* (Joshi and Vrieling, 2005). However, because we did not investigate female oviposition preferences, we have no way to determine whether the reduced IG concentration in trees with caterpillars was due to a direct effect of the caterpillar herbivory or whether females preferred trees that were lower in IGs. Whether or not feeding by Catalpa Sphinx larvae directly alters IG concentrations (induced resistance or induced susceptibility) requires further investigation.

Catalpa Sphinx larvae feeding on trees with leaves higher in IGs were themselves higher in IGs. This was found in a previous study (Lampert et al., 2010), but that

Lowercase letters within a column indicate significantly ($P<0.05$) different means according to Tukey's HSD test

study only considered six leaf samples. The present study examined IG content in over 160 individual trees and the caterpillars feeding on them. In this and previous studies, only catalpol was present in Catalpa Sphinx caterpillars (Bowers, 2003; Lampert et al., 2010). Although we have not done feeding trials where Catalpa Sphinx larvae are fed a diet with only catalposide, other studies with IG-sequestering species showed that esters of catalpol, such as catalposide, are hydrolyzed to catalpol and then sequestered (Gardner and Stermitz, 1988; L'Empereur and Stermitz, 1990). That is the most likely physiological process for Catalpa Sphinx larvae as well.

The positive correlation between caterpillar catalpol and iridoids of the leaves they were collected from has important ecological implications. No *Catalpa* tree species or cultivar has demonstrated resistance to Catalpa Sphinx (Olsen et al., 2006), regardless of secondary chemistry. Catalpol sequestration renders several caterpillar species unpalatable (Dyer and Bowers, 1996; Theodoratus and Bowers, 1999; Opitz et al., 2010), and Catalpa Sphinx larvae sequester high concentrations. Caterpillars that attack high-IG trees thus may be less palatable to their own natural enemies (with the exception of *Cotesia congregata*; Crocker, 2008; Lampert et al., 2010), and such trees may experience increased herbivory due to a combination of caterpillar phagostimulation and caterpillar escape from natural enemies.

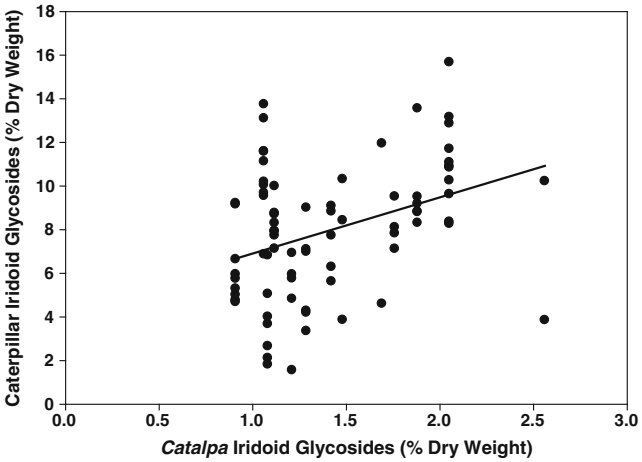

Fig. 3 Relationship between total iridoid glycoside content (catalpol plus catalposide) of leaves of individual *Catalpa* trees and the iridoid glycoside content (catalpol only) of the Catalpa Sphinx caterpillars collected from each tree

Parasitoid catalpol concentrations were much lower than concentrations in the hemolymph of host caterpillars. The fate of unsequestered catalpol absorbed by the parasitoid is unknown. Unaltered IGs, including catalpol, are water soluble and dissolved in caterpillar hemolymph (Bowers, 2003), the primary source of nutrition for *C. congregata*. Hymenopteran endoparasitoid larvae are unable to eliminate gut contents, and any ingested substance that is not metabolized by gut enzymes is expected to accumulate (Quicke, 1997). Indeed, in some systems, secondary compounds have been detected in higher concentrations in parasitoids than in the host (McDougall et al., 1988; Campos et al., 1990). However, our results suggest that relatively little catalpol is accumulated, while much is broken down. Also unknown is whether the detected catalpol is concentrated in the guts of the parasitoid larvae, or also is dissolved in their hemocoel. *Cotesia congregata* likely sequester some catapol in their hemocoel, as it has been detected in adults after meconium was eliminated (Bowers, 2003).

While parasitoids may sequester secondary compounds from their hosts (Benn et al., 1979; Fung, 1988; Rossini et al., 2000), it is still unknown whether parasitoid sequestration is an adaptive defense against natural enemies. Many parasitoids have a narrow host range, and those that attack sequestering hosts may be adapted to host chemistry. In this study, two hyperparasitoid genera, *Mesochorus* and *Hypopteromalus*, were reared from *C. congregata*, thus suggesting catalpol-rich *C. congregata* larvae are still susceptible to their own natural enemies. *Mesochorus* hyperparasitoids, which attack hosts in the larval stage (Baur and Yeargan, 1994), were reared from parasitoids collected in Beltsville, MD for the parasitoid chemistry analysis. A previous study (Lampert et al., 2010), as well as the present study, showed

no evidence that catalpol sequestration by either Catalpa Sphinx caterpillars or primary parasitoids deters *Mesochorus*. Reudler Talsma (2007) found that *Mesochorus* adults reared from *Cotesia melitaearum* [a specialist parasitoid of iridoid glycoside-sequestering *Melitaea* (Nymphalidae) caterpillars] also contained catalpol, presumably absorbed from their hosts. *Hypopteromalus* attack emerged *Cotesia* pupae (Gaines and Kok, 1999), and emerged from broods on the cuticle of caterpillars collected in Cecil Co., MD.

To our knowledge, no studies have directly examined the palatability of parasitoids that absorb secondary compounds from their hosts. *Cotesia congregata* reared from Catalpa Sphinx caterpillars appear to be palatable to predators, as ants have been observed carrying their pupae (Ness, 2003; Lampert, personal observation). Most likely these pupae contain catalpol concentrations too low to deter ants, although other studies have found catalpol to be highly deterrent to ants (e.g., Dyer and Bowers, 1996; Opitz et al., 2010).

Variation in chemical defense rarely has been described over multiple trophic levels. Secondary compound sequestration by herbivores is well known as an adaptive defense against natural enemies. However, predators and parasitoids often absorb and retain defensive compounds from herbivorous prey, and the ecological and adaptive consequences of defensive compounds present in the third trophic are unknown. Explicit tests of the palatability of carnivorous insects, particularly specialists like parasitoids, to their own natural enemies are required to determine if retention of defensive compounds is a physiological byproduct of predation or a potential adaptive response to natural enemies. Numerous multitrophic hypotheses assume that predators and parasitoids are less able to adapt to chemical defense than herbivores (e.g., Brower, 1958; Gauld et al., 1992), but this could be a misconception due to a dearth of studies that have examined various adaptations to chemical defense, such as catabolism or sequestration. More rigorous tests of multitrophic hypotheses about the ecology and evolution of plant-insect interactions will depend on a growing number of studies that have uncovered the effects of plant chemical defenses on predators and parasitoids.

Acknowledgements Several homeowners permitted collections on private property. Susan Bentz and Richard Olsen of the USDA National Arboretum collected and shipped Catalpa Sphinx larvae from the USDA farm in Beltsville, MD. N. Robinson, C. Quintero, and S. Whitehead provided useful comments on an earlier version of the manuscript. This study was funded by NSF grant DEB 0614883 awarded to M.D. Bowers and L.A. Dyer.

Introduction

In plants, research into the role of hybridization in the evolution of novel traits and new species is gaining momentum (Barton, 2001; Seehausen, 2004; Abbott et al., 2008). Hybrids have been used increasingly in experimental studies in ecology and evolution in part because interspecific hybrids (specifically segregating generations) often show greater variation in traits compared to parental species. Furthermore, segregating hybrids frequently show greater independence between different traits than the parental species (Hochwender et al., 2000; Lexer et al., 2003; Orians et al., 2010). Interspecific hybrids can have novel patterns of secondary chemical expression or accumulation compared to parental species, and sometimes can be more resistant or susceptible to herbivores than parental species (Rieseberg and Ellstrand, 1993; Fritz, 1999; Orians, 2000). This makes hybrids useful for studying the relationship between secondary metabolite variation and herbivores (Hallgren et al., 2003; Leiss et al., 2009).

Hybridization occurs frequently in the *Jacobaea* (syn. *Senecio*, Asteraceae) genus (Vincent, 1996). Members of this genus have been used extensively to study plant-herbivore interactions, which are largely mediated by a diverse group of pyrrolizidine alkaloids (PAs; see reviews by Hartmann, 1999; Macel, 2011). Twenty-six PAs have been reported from 24 *Jacobaea* species (Pelser et al., 2005). Pyrrolizidine alkaloids are ester alkaloids composed of a necine base (amino alcohol moiety) and an alkyl, or rarely aralkyl, necic acid (Hartmann, 1999). PAs can occur in two forms *in vivo*, the tertiary amine (free base) or the *N*-oxide form (Hartmann et al., 1989; Rizk, 1991; Wiedenfeld et al., 2008; Joosten et al., 2011). In *Jacobaea* species, all PAs except for senecivernine are derived from senecionine *N*-oxide, which is synthesized in the roots, transported to the shoots, and diversified into other PA structures (Hartmann and Toppel, 1987). Variation in PA structure and form can lead to variation in the performance of generalist insects and other plant enemies such as nematodes (van Dam et al., 1995; Macel et al., 2005; Dominguez et al., 2008; Thoden et al., 2009).

Jacobaea vulgaris (tansy ragwort or common ragwort, syn. *Senecio jacobaea*) is native to Europe and west Asia but invasive in North America, Australia and New Zealand. *Jacobaea aquatica* (marsh ragwort, syn. *Senecio aquaticus*) is closely related to, but not a sister species of, *J. vulgaris* (Pelser et al., 2003). Natural hybrids between these species occur in at least one location in The Netherlands (Kirk et al., 2004). The two parental species are attacked by different suites of specialist and generalist herbivores (personal observation). A previous study showed that artificial hybridization between these two species can be used to produce F_2 lines that are in some cases extremely susceptible, and in other cases extremely resistant, to generalist herbivores (Leiss et al., 2009).

Western flower thrips, *Frankliniella occidentalis* (hereafter WFT), is a key insect pest on a wide range of agricultural and horticultural crops globally (Kirk and Terry, 2003). Since this species is highly polyphagous and infests about 200 wild and cultivated host species (Yudin et al., 1986), *F. occidentalis* often is used as a representative generalist herbivore in studies of plant-insect interactions (e.g., Macel et al., 2005; Leiss et al., 2009). Previous studies have investigated the effects of PAs on WFT with experiments that used artificial diets (Macel et al., 2005), or demonstrated the relationship between PAs and WFT resistance in host plants (Macel, 2003; Leiss et al., 2009). These studies showed that PAs are toxic to WFT and play a role in the plant resistance against this insect. However, these authors incorporated only a limited number of PAs in their studies. Some PAs were not easily acquired for experiments. Only the major PAs were quantified in host plants, and PAs were measured without discrimination between the two forms due to technical limitations in analytical methods. The effects of PA variation in host plant on WFT resistance have not yet been tested.

The current study aimed to overcome the challenges associated with isolating many PA variants for diet studies by measuring WTF resistance in a segregating hybrid family, which is expected to demonstrate great variation in composition and concentration of secondary metabolites such as PAs. Additionally, technological advances now permit the detection of PAs that are present in extremely low concentrations or that demonstrate only slight structural variations compared to other PAs, thus allowing us to test the relationship between WFT resistance and PA composition using a comprehensive set of PAs *in vivo*.

We carried out WFT bioassays with an artificial hybrid family including one *J. vulgaris* genotype, one *J. aquatica* genotype, two F_1 offspring, and 94 different F_2 hybrid lines. We measured WFT feeding damage in the shoots of these genotypes, and investigated the relationship between PA variation and susceptibility to attack by WFT in the segregating F_2 generation. We addressed the following questions: 1) Is there variation in WFT resistance among segregating *Jacobaea* hybrids? 2) Is WFT resistance explained by PA concentration and composition? and if so, 3) Do different structural PA variants affect WFT resistance differently? 4) Are there any interactions between the effects of different PAs on WFT resistance?

Methods and Material

Study System and Plant Growth Jacobaea vulgaris seeds (collected at Meijendel Nature Reserve, 52° 7' 54" N, 4° 19'

46" E, The Netherlands) and *J. aquatica* seeds (collected at the Zwanenwater Reserve, 52° 48' 38" N, 4° 41' 7" E, The Netherlands) were germinated in glass vials. Clones were produced from tissue cultured seedlings, and several clones were subsequently grown in pots in climate rooms under standard conditions of 20°C, 70% relative humidity, light: dark 16 h: 8 h (Cheng et al., 2011). Potted plants were vernalized at 4°C with the standard light and humidity conditions for approximately 10 weeks to facilitate flowering. Both species are self-incompatible and crosses were performed by rubbing flower heads together (Kirk et al., 2005). Two rayed F_1 offspring were selected from this initial cross, and were reciprocally crossed with each other to produce two sets of F_2 offspring. One F_2 set consisted of 56 individuals and the other consisted of 46 individuals. The parental, F_1 and F_2 individuals were maintained in tissue culture and were cloned to perform experiments using replicate genotypes.

We grew about 6 cloned replicates per F_2 genotype and about 12 cloned replicates per parental and F_1 genotype for the WFT bioassay. In addition we grew the same number of replicates of the genotypes for PA analysis. The PA data for these genotypes were used both to study WFT resistance as described in this paper and for an analysis of patterns of PA profiles in *Jacobaea* hybrid plants that was published elsewhere (Cheng et al., 2011). The clones were individually potted in 1.3 l pots filled with 95% sandy soil (collected from Meijendel), 5% potting soil (Slingerland Potgrond company, Zoeterwoude, The Netherlands) and 1.5 g/l Osmocote slow release fertilizer (N:P:K=15:9:11, Scott®, Scotts Miracle-Gro, Marysville, OH, USA). Plants were kept in a climate room under standard conditions described above for 6 wk before the bioassay was initiated.

WFT Bioassay We used 12 replicates of each parental and F_1 genotype, and 3–6 replicates of each of 94 F_2 hybrid genotypes (6 replicates were used for most genotypes, though less than 6 were used in cases where plants died or were too small compared to other plants of the same genotype). A total of 587 plants were placed randomly in a climate room and grown under standard conditions. About 5870 adult WFT, previously reared on chrysanthemum (*Dendranthema grandiflora*), were released at evenly spaced points in the climate room. During the 3 wk feeding period, plants were watered every 2 d without wetting or disturbing the leaves. After 3 wk, silver damage caused by feeding from WFT on both upper and lower leaf surfaces was visually scored in mm^2 for each leaf, according to the methods developed by Leiss et al. (2009). Above ground plant parts (shoots) were harvested just above the root crown and dried for 3 d in an oven at 50°C before establishing the dry masses of the shoots.

PA Data Acquisition A Waters Acquity ultra performance liquid chromatographic system coupled to a Waters Quattro Premier XE tandem mass spectrometer (LC-MS/MS) (Waters, Milford, MA, USA) was used for PA analysis. Analysis was performed using a different set of the same tissue culture-derived clonal plants consisting of the same genotypes and number of clones as those used in the WFT bioassay, and grown under identical conditions. The plant shoots were harvested, stored at −80°C, and freeze-dried for 1 wk under vacuum with a collector temperature of −55°C. Dried plant material was ground to a fine powder and about 10 mg were extracted with 2% formic acid in a mass to volume ratio of 1:100. Heliotrine (Latoxan, Valence, France) was added as an internal standard to the extraction solvent at a concentration of 1 μg/ml. The extract was filtered through a 0.2 μm nylon membrane filter (Acrodisc, Pall Life Sciences, Ann Arbor, MI, USA). An aliquot (25 μl) of the filtered PA extract was diluted with water (975 μl) and injected into the LC-MS/MS system.

Seventeen individual PA standards were available for this study, representing the major PAs present in the plant extracts (Table 1). Senecionine, seneciphylline, retrorsine, and their corresponding *N*-oxides were obtained from Phytolab, Vestenbergsgreuth, Germany; senkirkine was obtained from Phytoplan, Heidelberg, Germany. Riddelliine and its *N*-oxide were obtained as authentic standards from Dr M. Chou (NCTR, Jefferson, AR, USA), and integerrimine was a gift of Dr. J. Trigo (UNICAMP, Campinas, Brasil). Jacobine and erucifoline were isolated from *J. vulgaris* plant material (PRISNA, Leiden, The Netherlands). The identity of the isolated standards was confirmed by ^{1}H-NMR and LC-MS analysis and by comparison with literature data (Logie et al., 1994). Acetylseneciphylline was obtained by acetylation of seneciphylline with acetic anhydride and pyridine, according to the procedure described by He et al. (2010). Integerrimine *N*-oxide, jacobine *N*-oxide, erucifoline *N*-oxide, and acetylseneciphylline *N*-oxide were prepared by *N*-oxidation of the corresponding tertiary amine PAs according to the procedure described by Christie et al. (1949) and adapted by Chou et al. (2003). The purity of the obtained standards was checked by LC-MS analysis and was at least 90%.

The other PAs listed in Table 1 were tentatively identified on the basis of their retention time, molecular mass and fragmentation pattern, and on comparison with PA standards and literature data. The presence of PA *N*-oxides was confirmed by selective reduction to the corresponding tertiary amines according to the method of Joosten et al. (2010). All PAs included in this study have been reported before as constituents of *J vulgaris* and/or *J aquatica* (Hartmann and Witte, 1995; Joosten et al., 2011; Langel et al., 2011) and no new PAs were identified.

Table 1 Pyrrolizidine alkaloids (PAs) detected in *Jacobaea aquatica*, *Jacobaea vulgaris* and hybrids

Group	PA	Retention time (min)	Precursor mass (m/z)	Fragment mass 1; 2 (m/z)	Collision energy 1; 2 (eV)	Standard PA used for quantification
Senecionine-like PAs (simple senecionine-related derivatives)	senecionine	9.93	336.2	94.0; 120.0	40; 30	senecionine
	senecionine *N*-oxide	6.97	352.2	94.0; 120.0	40; 30	senecionine *N*-oxide
	integerrimine	9.72	336.2	94.0; 120.0	40; 30	integerrimine
	integerrimine *N*-oxide	6.83	352.2	94.0; 120.0	40; 30	integerrimine *N*-oxide
	retrorsine	8.49	352.2	94.0; 120.0	40; 30	retrorsine
	retrorsine *N*-oxide	6.01	368.2	94.0; 120.0	40; 30	retrorsine *N*-oxide
	usaramine	8.29	352.2	94.0; 120.0	40; 30	retrorsine
	usaramine *N*-oxide	5.89	368.2	94.0; 120.0	40; 30	retrorsine *N*-oxide
	riddelliine	7.91	350.2	94.0; 138.0	40; 30	riddelliine
	riddelliine *N*-oxide	5.48	366.2	94.0; 118.0	40; 30	riddelliine *N*-oxide
	seneciphylline	9.16	334.2	94.0; 120.0	40; 30	seneciphylline
	seneciphylline *N*-oxide	6.36	350.2	94.0; 138.0	40; 30	seneciphylline *N*-oxide
	spartioidine	8.96	334.2	120.0; 138.0	30; 30	seneciphylline
	spartioidine *N*-oxide	6.36	350.2	94.0; 138.0	40; 30	seneciphylline *N*-oxide
	acetylseneciphylline	11.80	376.2	120.0; 138.0	30; 30	acetylseneciphylline
	acetylseneciphylline *N*-oxide	8.86	392.2	94.0; 118.0	40; 30	acetylseneciphylline *N*-oxide
	senecivernine	10.09	336.2	94.0; 120.0	40; 30	integerrimine
Jacobine-like PAs (jacobine-related derivatives)	jacobine	7.89	352.2	120.0; 155.0	30; 30	jacobine
	jacobine *N*-oxide	5.49	368.2	120.0; 296.0	30; 25	jacobine *N*-oxide
	jacoline	6.13	370.2	94.0; 138.0	40; 30	jacobine
	jacoline *N*-oxide	4.39	386.2	94.0; 120.0	40; 30	jacobine *N*-oxide

	floridanine	6.79	442.2	122.0; 168.0	30; 30	senkirkine
	doronine	9.01	460.2	122.0; 168.0	30; 30	senkirkine

Data were recorded in multiple monitoring mode (MRM) using two selected precursor ions to product ion transitions per compound. The MS settings are shown in Table 1. For quantification, the sum of the two peak areas obtained for each compound was normalized against the peak area of the internal standard. Quantification was performed against a standard solution (100 μg/l) of the PAs in an extraction of tansy (*Tanacetum vulgare*), a plant known to be free of PAs. The use of a PA standard solution in blank plant extract was considered to be a more reliable approach than quantification against a PA solution in solvent only. This PA standard extraction was injected into every 30 samples and the averaged response was used for quantification. For those PAs without standards available, a semi quantitative (indicative) value was obtained by comparison with the most closely related analogue (e.g., an isomer) as indicated in Table 1. Data processing was conducted with Masslynx 4.1 software (Waters, Milford, MA, USA).

PA expression is genetically controlled under standard growth conditions, and PA production is not induced in shoots by aboveground herbivory in *Jacobaea* plants (Vrieling and Bruin, 1987; van Dam et al., 1993; Vrieling et al., 1993). Therefore, we averaged the concentration of

each PA across all clones of each genotype and used the genotypic mean concentrations in the analyses presented here. The 37 PAs identified from the *Jacobaea* hybrids could be classified into four types, according to their structural characteristics, biosynthetic pathways, and expression pattern: senecionine-like PAs, jacobine-like PAs, erucifoline-like Pas, and otonecine-like PAs (Pelser et al., 2005; Cheng et al, 2011). We followed this classification in this study (Tables 1–2). The total PA concentration as well as the amount for each structural group was calculated by summing the concentrations of the individual PAs.

Data Analysis We used general linear models to determine whether WFT resistance differed according to plant genotype. Feeding damage (dependent variable) was log-transformed to achieve normality, and plant genotype was defined as the independent variable with plant dry mass as covariate. Normal distributions and homogenous variances were confirmed by testing the residuals of the models using Shapiro tests and Bartlett tests respectively. Two models were set up: in the first, *J. vulgaris* was used as a reference, and in the second, *J. aquatica* was used. All other genotypes were compared to the reference in the model.

Table 2 Pearson / Spearman correlation tests between western flower thrips (WFT) feeding damage and the concentrations of individual pyrrolizidine alkaloids (PAs) in the 94 F_2 hybrid genotypes from *Jacobaea aquatica* and *Jacobaea vulgaris*

Differences between the hybrid and parental genotypes were evaluated by using the regression coefficient matrices of the two models. In each matrix, the estimated coefficient of a hybrid indicated whether it had suffered more or less damage than the reference genotype, and the *P* value showed whether the difference was significant (Crawley, 2005). This is similar to a *post-hoc* test of an ANOVA model, however, such a *post-hoc* test includes all pair-wise comparisons between groups, and we were interested only in testing for differences between hybrid and parental genotypes. The difference between the two parental genotypes was also tested by using the same regression coefficient matrices. WFT resistance of each hybrid genotype was categorized according to these definitions: ND—no difference, leaf damage area of the hybrid was not different from that of both parents; A—additive, damage was intermediate between that of the parents; Ds—susceptible-dominant, damage was similar to that of the susceptible parent; Dr—resistant-dominant, damage was similar to that of the resistant parent, S—susceptible, damage was greater than that of the susceptible parent; R—resistant, damage was less than that of the resistant parent (Supplementary Table 1).

For correlation tests and principal components analysis, we included only data from F_2 genotypes, since we were interested in using the variation from this segregating generation to search for underlying relationships between WTF resistance and PA expression. We were not able to test for differences in these relationships between the different generations described in this study because only a limited number of genotypes were included from the parental and F_1 generations. However, the parental and F_1 plants provided reference points for WFT resistance comparison. We used log-transformed genotypic mean values of feeding damage and PA concentrations to carry out correlation analyses. Either Spearman (for six minor PAs that did not have normally distributed concentrations) or Pearson correlation tests were carried out to test the relationship between feeding damage and the concentrations of individual PAs, pooled concentrations of each of the four PA groups and total PA (see details in Table 2 and Fig. 3).

Pyrrolizidine alkaloids from within structural groups were closely correlated with each other, and it was not possible, therefore, to investigate the interactions between them. The PAs from different structural groups, however, were generally expressed independently. The sum concentrations of the PAs from the four groups were not correlated with one another (Cheng et al., 2011). We used a multiple-regression model to test for interactions between the effects of different PA structural classes on feeding damage. In this model, feeding damage (represented by log-transformed genotypic mean values) was defined as the dependent variable, and the sum concentrations of each of the four PA structural groups (log-transformed and centered genotypic mean concentrations) were defined as independent variables.

The principal component analysis (PCA) was carried out by using log-transformed genotypic mean concentrations of all individual PAs except the six minor PAs that did not have normally distributed concentrations. Compared to the major PAs, these six PAs were present at very low concentrations (on average less than 1% of total PA concentration). Pearson correlation tests were carried out between the first six principle components (PCs) from the PCA and feeding damage. In order to evaluate the contribution of each PA to each PC (in other words the loading), Pearson correlation tests were carried out between individual PAs and the first 3 PCs, since PCs four to six

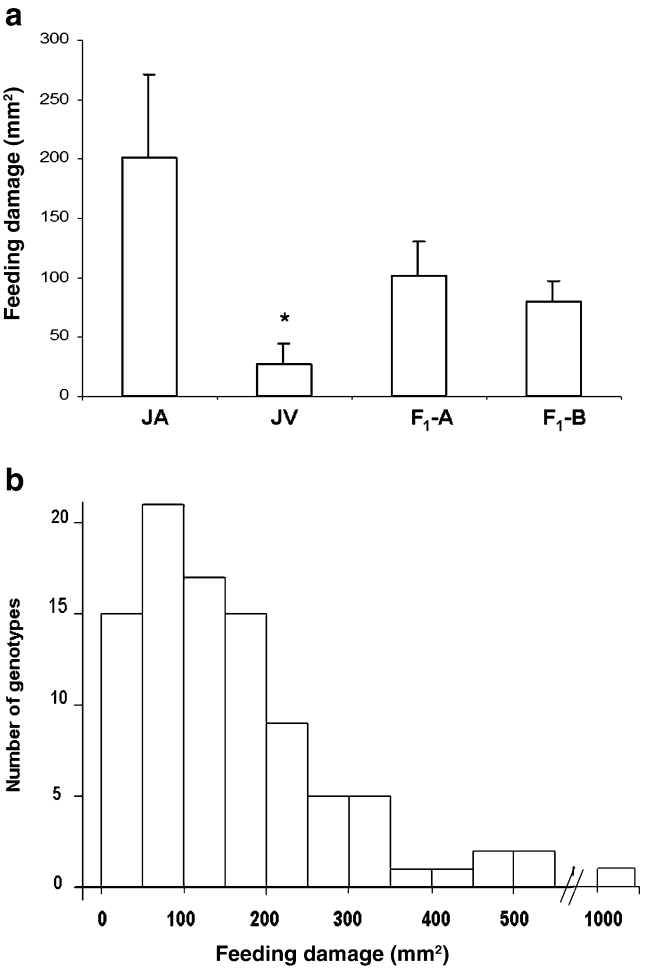

Fig. 1 Variation in western flower thrips (WFT) feeding damage (mm^2) on *Jacobaea aquatica, Jacobaea vulgaris*, 2 F_1 and 94 F_2 hybrids. **a** Mean feeding damage for one *J. aquatica* genotype (JA), one *J. vulgaris* genotype (JV), and 2 F_1 (F_1-A and F_1 -B) genotypes. Error bars are standard errors, $N=12$. *J. vulgaris* was significantly different from the other genotypes at * $P<0.05$. **b** Distribution frequency for genotypic mean WFT feeding damage of 94 F_2 hybrids. $N=3$–6 for each genotype. In total, 587 plants were used in WFT bioassay

accounted for a low proportion of the total variation and were not correlated with WFT feeding damage. The *P*-values were adjusted using the sequential Bonferroni method when multiple tests were carried out.

All analyses were conducted in R version 2.10.0 (R Development Core Team, 2009)

Results

Variation in Feeding Damage Feeding damage was genotype-dependent (*d.f.*=97,488; F=5.30; P<0.001). Plant mass also had effect on feeding damage (*d.f.*=1,488; F=18.44; P<0.001). Among the two parental genotypes, *J. aquatica* suffered more feeding damage than *J. vulgaris* (*d.f.*=1, 22; t=6.18; P<0.001). Both of the F_1 lines were as susceptible as *J. aquatica*. Among the 94 F_2 hybrids, 69 were as susceptible as *J. aquatica*, 10 were more susceptible than *J. aquatica*, 15 showed intermediate resistance, 9 were as resistant as *J. vulgaris*, and none were more resistant than *J. vulgaris* (Fig. 1, see statistical details in Supplementary Table 1).

Relationship Between Feeding Damage and PA Concentration Correlation tests between feeding damage and individual PAs showed that feeding damage was negatively correlated with the concentrations of the *N*-oxides of two jacobine-like PAs (jaconine and jacoline). Jacobine *N*-oxide concentration was marginally correlated with feeding damage, and the correlations between the free bases of jacobine-like PAs and feeding damage were not significant after correction for multiple testing. No other individual PAs were correlated with feeding damage (Table 2). Total PA concentration also was correlated with feeding damage (Fig. 2a). Of the four structural groups of PAs, only the sum concentration of jacobine-like PAs was significantly correlated with feeding damage by WFT (Fig. 2c). The sum concentrations of the other three groups were not correlated with feeding damage (see the statistical results for senecionine-and erucifoline-like PAs in Fig. 2b,d; for otosenine-like PAs: *d.f.*=92, r=0.35, P=0.77).

The multiple regression models showed that among the four PA groups only jacobine-like PAs had significant negative effects on feeding. There were no two-way interactions between the groups. A three-way interaction between senecionine-like, jacobine-like and erucifoline-like PAs and an interaction between the four PA groups were present. However, these were only marginally significant (0.05<P< 0.1, Table 3).

Relationships Between Feeding Damage and PA Composition We used principal component analysis (PCA) to reduce the PA data set to a smaller number of uncorrelated axes. PC1 explained 44%, PC2 explained 19% and PC3 explained 12% of the variation in the data. More than 90% of the total variation was accounted for by the first 6 PCs. Among first 6 PCs, PC1 was negative correlated (*d.f.*=92, r=−0.32, P=0.002) and PC3 was positively correlated with feeding damage (*d.f.*=92, r=−0.23, P=0.04). No other PCs

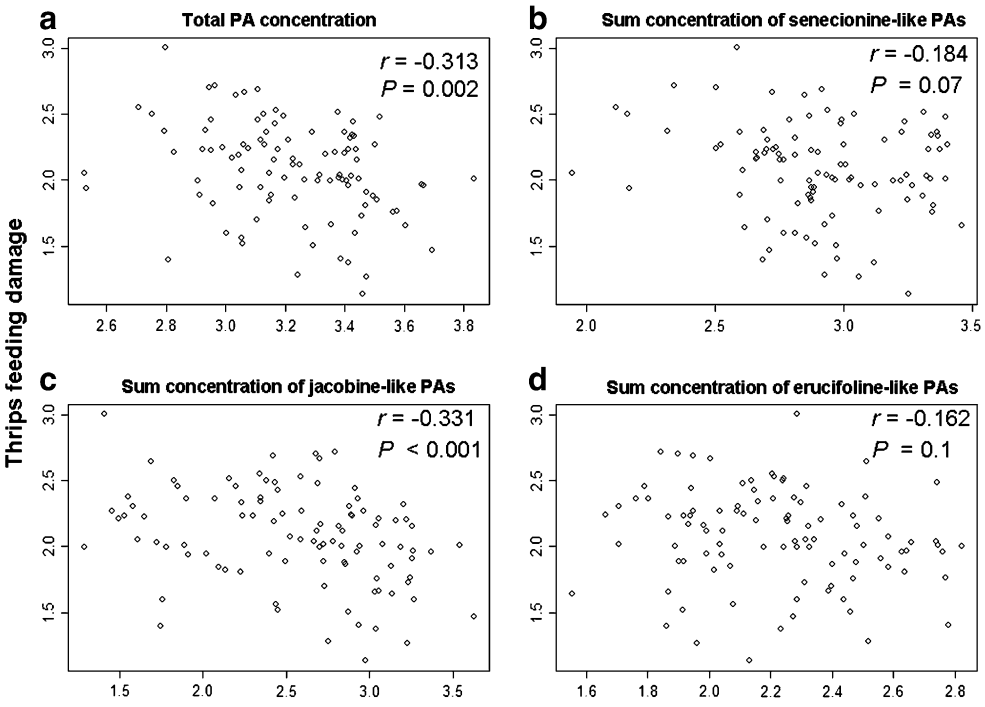

Fig. 2 Relationship between feeding damage by western flower thrips (WFT) (mm^2) and the concentration of total pyrrolizidine alkaloid (PA), senecionine-like, jacobine-like, and erucifoline-like PAs (μg/g dw) of F_2 hybrids of *Jacobaea aquatica* and *Jacobaea vulgaris*. The data for WFT feeding damage and concentrations are the log-transformed genotypic mean values. In each panel, the results of the Pearson correlation tests between feeding damage and the PA concentrations are provided; in all cases, *d.f.*=92

Table 3 Results of multiple regression of western flower thrips (WFT) feeding damage (mm^2) against the sum concentration of four structural groups of pyrrolizidine alkaloids (PAs, μg/g dw) in the 94 F_2 hybrid genotypes from *Jacobaea aquatica* and *Jacobaea vulgaris* (For the regression model: adjusted R^2=0.1655; *d.f.*=15, 78; F=2.23; P=0.012)

Significance codes: + P<0.1, * P <0.05, ** P<0.01

were correlated with feeding damage (data not shown). Correlation tests between each PC and individual PAs' concentrations allowed us to identify which PAs were associated with each PC. Jacobine-like PAs (except jacozine and its *N*-oxide) were strongly correlated with PC1, such that individuals with high PC1 scores had high concentrations of jacobine-like PAs. Variation in some senecionine-like, erucifoline-like PAs and otosenine-like PAs contributed strongly to PC3 (individuals with high PC3 scores had low/high concentrations of these PAs; Supplementary Table 2). A plot of PC1 vs. PC2 shows that F_2 hybrids can be divided roughly into different groups. Feeding damage, indicated by the size of the dots, is not clearly clustered either on the plot of PC1 vs. PC2 or the plot of PC_1 vs. PC_3 (Fig. 3).

Discussion

Segregating hybrids are sometimes used to study correlations and trade-offs between different ecologically important traits in plants, because they exhibit greater variation than parental species, and greater independence between traits (e.g., Orians et al., 2010). We showed that there is high variation in the WFT susceptibility among F_2 hybrids of *J. vulgaris* and *J. aquatica*. Although most F_2 hybrids were as susceptible as or even more susceptible than *J. aquatica* (73% and 11% among all F_2 hybrids respectively), there were still some hybrids with resistance similar to *J. vulgaris* (10%) or intermediate to the two parents (6%). The expression of PAs among the F_2 hybrid generation was highly variable (Cheng et al., 2011, but also see Fig. 2 and Fig. 3), and this variation provided an opportunity to investigate the *in vivo* effects of PA composition on plant resistance to a generalist herbivore.

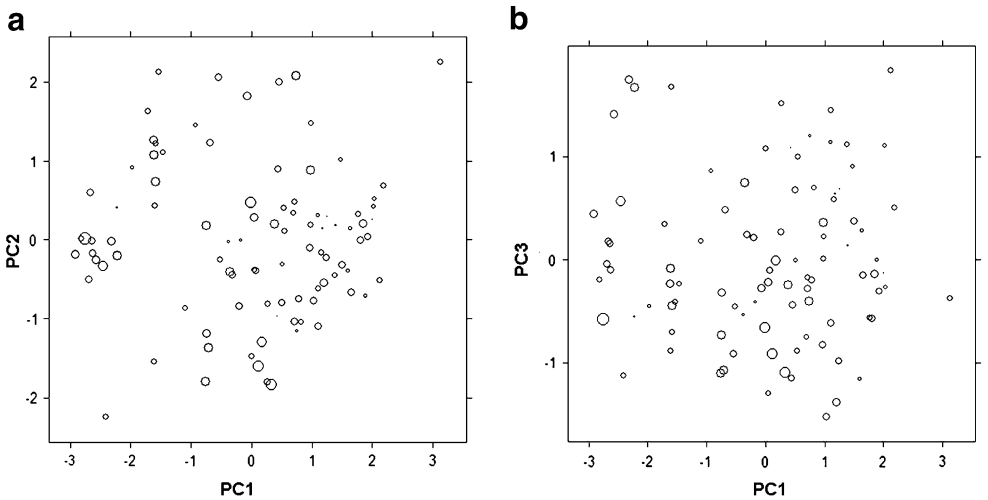

Fig. 3 Principal component analysis (PCA) of the pyrrolizidine alkaloid (PA) profiles of F_2 hybrids of *Jacobaea aquatica* and *Jacobaea vulgaris*. PCA was performed on the log-transformed genotypic mean concentrations of all individual PAs excluding six minor PAs that did not have normally distributed concentrations (see Table 2). One dot represents one of 94 F_2 hybrid genotypes. Size of each dot represents mean WFT feeding damage for that genotype. The genotypic mean concentrations are the average value of the three to six replicates from the same genotype

We demonstrated that concentrations of total PA and jacobine-like PAs were negatively correlated with feeding damage by using correlation tests. The multiple regression and PCA also indicated that concentrations of jacobine-like PAs were more closely related to WFT resistance than concentrations of the other PAs. The important role of jacobine-like PAs in WFT resistance of *Jacobaea* plants also has been supported by previous studies. Macel (2003) found that WFT feeding damage was negatively correlated with total PA concentration and with jacobine (both *N*-oxide and free base) concentration in *J. vulgaris* plants. Leiss et al. (2009) found that resistant *Jacobaea* hybrids had higher concentrations of jacobine *N*-oxide and jaconine *N*-oxide than susceptible hybrids. To develop a better understanding of the deterrent effects of different PAs on WFT, bioassays should be conducted using pure samples of different PAs.

Macel et al. (2005) tested WFT larval survival on artificial diets containing six individual PAs including senecionine, seneciphylline, retrorsine, senkirkine, heliotrine, and monocrotaline, or mixtures of senecionine, seneciphylline, and retrorsine. The experiment indicated that toxic effects of PAs on WFT larva differed among the individual PAs. Furthermore, higher PA concentrations had more potent toxic effects, and no synergistic effects resulted from PA mixtures. These findings support the results of our study, with the caveat that our analysis revealed a potential weak interaction between the different kinds of PAs. However, the interactions were slight ($0.05<P<0.1$, Table 3), and it is difficult to interpret interactions between more than two predictors.

PA variation accounted for a relatively low proportion of the variation in feeding damage ($R^2=0.17$, Table 3). Therefore, other factors likely play roles in plant susceptibility to WFT. These factors may include plant physical characteristics such as plant size, which was found to be a significant covariate in this study. Total PA concentration and plant size together explained a slightly higher proportion of the total variation ($R^2=0.20$). Other secondary metabolites have been reported from these species and their hybrids, including flavonoids, kaempferol glucoside, and chlorogenic acid (Leiss et al., 2009; Kirk et al., 2011), and other phytochemicals such as sesquiterpene lactones may be present but remain unreported. These metabolites may also play a role in resistance to herbivores, individually or in interaction with PAs.

Acknowledgements Dandan Cheng thanks the China Scholarship Council (CSC) of the Ministry of Education for financial support. We thank Cilke Hermans, Karin van der Veen-van Wijk and Henk Nell for technical assistance in plants growth and WFT bioassay; Lotte Joosten for help in PA extraction, measurements, and analysis; Kirsten Leiss, Mohammed Mirnezhad, Kelly Stolk and Anniek de Vreede for help in feeding damage scoring. We also thank two anonymous reviewers for suggestions on manuscript writing.

studies, early stages (typically L1 or L2) of the host were attacked, whereby the hosts were a fraction of the size of the ovipositing female parasitoid. This means that the host had to grow considerably during the parasitism phase to achieve a size capable of supporting the minimal nutritional requirements of the parasitoid progeny. A commonly reported trend is that both hosts and parasitoids perform equally well (or poorly) on plants of a given quality, suggesting that the effects of plant-related traits on parasitoid performance are similar up the food chain (Barbosa et al., 1986; Gunasena et al., 1990; Ode et al., 2004; Harvey et al., 2005; Gols et al., 2008a,b; Morse, 2009; Lampert and Bowers 2010).

The effects of plant quality on the development of herbivores (and, by association their parasitoids), often has been invoked on the basis of *extrinsic* threats to survival. The 'slow-growth-high-mortality' hypothesis posits that the growth of hosts feeding on nutritionally poor diets will be prolonged, thus extending their 'window of susceptibility' to a suite of natural enemies such as predators and parasitoids as well as to abiotic stresses (Benrey and Dennor, 1997; Fordyce and Shapiro, 2003). Because the mortality of the parasitoid is proportional to that of the host during the interaction, parasitoids also will die in hosts that suffer precocious mortality as a result of pathogens of predators (Fritz, 1982). However, less attention has been paid to exploring the effects of plant quality on *intrinsic* (host-related) threats to the survival of parasitoids and to how these are temporally correlated. For instance, if the effects of ingested plant toxins are gradual and cumulative on the host, we might expect that parasitoids that terminate their relationship with the host earlier would survive better than parasitoids that emerge from older hosts. This would be especially true if host and parasitoid mortality are proportional on specific herbivore diets.

An important aspect of parasitoid biology that may be linked to differences in host plant quality is how the wasp regulates host growth relative to that of healthy hosts. This parameter is intimately correlated with the size of the adult parasitoid relative to the maximum potential size of its herbivore host. In many associations that involve macrolepidopteran hosts and their solitary koinobiont endoparasitoids, host growth is reduced by 90% or more, compared with healthy hosts (Jones and Lewis, 1971; Vinson, 1972; Smilowitz and Iwantsch, 1975; Harvey et al., 1999, 2004, 2010a). In other host-parasitoid associations, however, regulation of host growth is more subtle or absent entirely, at least in examples where the maximum size of healthy hosts and adult parasitoid size are not markedly different (Harvey et al., 1994; Gols and Harvey, 2009b). In situations where hosts pass through fewer instars and/or growth is arrested earlier in development, we might expect the development of solitary parasitoids to be less constrained by differences in plant quality than in situations where hosts must grow larger to satisfy the nutritional requirements of the parasitoid offspring. However, as far as we know, this assumption remains untested.

Here, we compared development of the cabbage moth, *Mamestra brassicae* L. (Lepidoptera: Noctuidae) and its solitary koinobiont endoparasitoid, *Microplitis mediator* Haliday (Hymenoptera: Braconidae) on wild cabbage plants originating from three populations growing naturally along the Dorset coast of Great Britain, as well as on two cultivars. Like other members of the large family Brassicaceae, cabbage plants produce inducible glucosinolates (hereafter GS) (Fahey et al., 2001). Glucosinolates and their breakdown products negatively affect the growth and/or development of herbivores (Li et al., 2000; Buskov et al., 2002; Agrawal and Kurashige, 2003; Hopkins et al., 2009). Previous work has shown that wild cabbages exhibit strong inter- and intrapopulation variation in heritable aliphatic GS (Giamoustaris and Mithen, 1995; Moyes et al., 2000; Gols et al., 2008a; Newton et al., 2009a,b). Cultivated cabbage is an important global crop. Due to the effects of artificial selection via domestication, plant breeders have often sought to reduce levels of foliar GS and to eliminate variation in various other plant traits (Gols and Harvey, 2009a). Despite this, cultivated strains of cabbage have been used extensively in ecological and behavioral studies (reviewed by Hopkins et al., 2009).

Here, survival, body mass and larval development time of *M. brassicae* and *Mi. mediator* were examined on three wild strains and two cultivars of *B. oleracea* that were either undamaged or induced by herbivore feeding. The three main aims of the current study were: (1) to compare the performance of an herbivore and its parasitoid on the various cabbage strains and to see if effects of plant quality on insect performance are similar in both organisms; (2) to determine if the effects of plant quality on development of male and female parasitoids are similar; and (3) to measure differences in GS concentrations in the three wild populations and two cultivars of *B. oleracea*, and by using these data, to determine if insect performance is correlated with qualitative or quantitative aspects of plant allelochemistry. We hypothesized: (1) that there would be a strong link between plant quality and both herbivore and parasitoid performance; (2) that this parameter would be correlated with total amounts of GS present in leaf tissues of *B. oleracea*; and (3) that previous herbivore damage would lead to increased levels of plant defense and that this also would be reflected in insect performance.

Methods and Materials

Plants Seeds of wild *B. oleracea* plants were collected from three populations growing in meadows adjacent to chalk cliffs along the south coast of Great Britain to the

west and north of Swanage, Dorset. The populations are located at sites known as 'Old Harry' (50°38′N, 1°55′E), 'Winspit' (50°35′N, 2°02′E), and 'Kimmeridge' (50°36′N, 2°07′E). In addition, two cultivated strains of *B. oleracea*: Brussels sprouts (var. gemmifera) cv. 'Cyrus', on which the lab culture of *M. brassicae* had been reared for many generations, and white cabbage (var. alba) cv. "Stonehead" were used. For simplicity, we also refer to the cultivars as 'populations'. Hereafter, the populations are abbreviated as OH (Old Harry), WIN (Winspit), KIM (Kimmeredge), CYR (Cyrus cultivar), and STH (Stonehead cultivar).

Seeds from the various populations were germinated in moist soil, and the seedlings were transferred to 2.1-l pots that had been filled with potting soil ('Lentse potgrond' no. 4, Lent, The Netherlands). Plants were grown in facilities operated by Unifarm at Wageningen University (WU), The Netherlands, in a greenhouse compartment at 18–25°C, 50–70% r.h. with a photoperiod of at least 16 hr. If the light intensity dropped below a level of 500 μmol photons m^2/s during the 16 hr photoperiod, supplementary illumination was supplied by high pressure mercury lamps. All plants were uniformly watered on a daily basis. When plants were 4 wk-old, they were fertilized once a week with Kristallon Blauw (16 N:6 P:20 K:3 Mg) at a concentration of 2.5 mg/l. Plants were 7 wk-old at the start of the experiments. Watering and fertilization continued during the experiments.

Insects Larvae of *M. brassicae* were collected originally from cabbage fields grown in the vicinity of Wageningen University, and had been reared for many years in the laboratory on Brussels sprout (*B. oleracea* var. gemmifera cv. Cyrus) plants. *Mamestra brassicae* is native to the Palearctic, considered to be a generalist herbivore, and is frequently a pest in cabbages and other crops. Newly emerged moths were placed in groups of 20 into plastic containers (35 by 20 cm) with 10% sugar solution absorbed into cotton wool in small plastic vials. Filter paper was placed into the containers as a cover, and the moths laid their eggs onto this substrate. Every day the filter paper was removed and stored at 7°C pending hatching. New filter paper was placed inside and over the containers. *Microplitis mediator* was collected from young *M. brassicae* caterpillars on potted cabbage plants that had been placed for a week into a flowering meadow adjacent to the Laboratory of Entomology at Wageningen University. This parasitoid also is native to Eurasia and develops in first (L1) to third (L3) instars of its hosts. It is a specialist of species of moths in the family Noctuidae. In Europe, *M. brassicae* is considered to be its most important host. Like other members of the higher Microgastrinae, larvae of *Mi. mediator* feed exclusively on host hemolymph, and thus consume only a small proportion of available host tissues. At maturity, the parasitoid larva perforates a hole in the side of the host and emerges to spin a brown, papery cocoon. The host dies within a few days.

Several hundred newly hatched L1 caterpillars were placed onto cabbage plants in a rearing cage (40×40×60 cm) and allowed to feed. After 24 hr, 60 wasps >5 d-old (about half of each sex) were released into the cage and allowed to parasitize the larvae for several days. Sugar solution was provided constantly, and new plants were supplied as necessary for the larval development. Larvae were allowed to develop until parasitoid egression and pupation. Cocoons of *Mi. mediator* were collected from cages and placed into large Petri dishes (15 cm dia.) until parasitoid eclosion.

Insects were reared in climate rooms at 23±2°C with a 16:8 hr L:D photoperiod.

Development of Mamestra brassicae and Microplitis mediator on Induced and Non-induced Brassica oleracea Leaves Healthy hosts: Egg batches of *M. brassicae* were allowed to hatch on the filter paper. Neonate larvae then were randomly allocated to 9.5-cm Petri dishes (7 larvae per dish) with excised middle-aged leaves from each of the 10 following plant treatments: induced or non-induced plants from the cultivars (CYR, STH) or from the wild populations (OH, KIM, WIN), with 10 dishes used per treatment. To induce *B. oleracea* plants, 10 L1 *Pieris rapae* larvae (distributed over 3 leaves) were allowed to move freely around and feed on the plants for 7 d after which time they were removed. Sections of leaf tissue from the herbivore-damaged or undamaged plants were provided as food for the caterpillars in the Petri dishes. Induced plants were prepared every 2 d.

A disc of moistened filter paper was inside each dish to prevent leaf tissues from desiccating. Every 2 d, leaf materials as well as the filter papers were replaced, and mortality of the larvae was recorded. Healthy larvae grow much larger than parasitized larvae. Therefore, healthy larvae from each Petri dish were transferred to larger plastic containers (15×10×10 cm) when they were L4. Mature larvae normally burrow into the soil in order to pupate; here, mature L5 larvae were provided with a layer of vermiculite approximately 3 cm deep in plastic boxes for this purpose. Pre-pupae that had stopped feeding and were in the vermiculite were carefully checked every day in order to determine when they had pupated. Fresh pupae were removed and weighed on an analytic balance (accuracy ± 0.1 mg). Larval development time was determined as the number of days between hatching and pupation.

Parasitized hosts: Newly molted L2 caterpillars that had been feeding on either non-induced or induced excised leaf tissues from the various cabbage populations were presented individually to mated female *Mi. mediator* wasps on

the end of a brush in small plastic vials. Parasitism was verified by a single insertion and removal of the ovipositor. Parasitized caterpillars then were placed into 9.5-cm Petri dishes (7 caterpillars per dish, 12 dishes per treatment) lined with moistened filter paper and provided with excised leaves from the same treatment group as they had been feeding on previously. Every 2 d, leaf materials as well as filter papers were replaced, and mortality of the larvae was recorded. Parasitoid larvae typically egress from the host and pupate after 8–9 d. Cocoons were transferred to and maintained individually in labeled glass vials. Newly emerged adult wasps were sexed, narcotized using $C0_2$, and weighed on a microbalance (accuracy 1 μg). Parasitoid eclosion was checked several times over the course of 24 hr. Development time (in hours) was determined as the duration between parasitism and adult emergence. All experiments were conducted in climate rooms at 23±2°C with a 16:8 hr L:D photoperiod.

Glucosinolate Analysis GS concentrations were measured in leaf tissues sampled from 8 to 10 plants from each treatment × population combination. Plants induced by *P. rapae* feeding were prepared similarly as in the developmental experiments. Non-induced and herbivore-induced plants were of the same age, and all plants were sampled at the same day. Two discs, 17-mm diam, were punched per leaf, one from each central part of a leaf half, and 6 fully unfolded leaves were sampled per plant. Leaf discs were pooled per plant and frozen in liquid nitrogen immediately after sampling and then stored at −80°C. Samples were later freeze-dried and pulverized. Glucosinolates were extracted using a methanol extraction, identified and quantified as described by van Dam et al. (2004). Briefly, GS were extracted with boiling 70% methanol solution, desulphatased with arylsulphatase on a DEAE-Sephadex A 25 column, and separated on a reversed phase C-18 column on HPLC with an acetonitril-water gradient. Detection was performed with a single wavelength detector set to 226 nm, with sinigrin used as an external standard.

Glucosinolates were classified based on their amino-acid origin into indole GS (derived from tryptophan), aromatic GS (derived from phenylanaline), and alipathic GS (derived from methionine). The latter group was further divided according to GS modification steps into sulfinyl, alkenyl, and hydroxylated GS (Halkier and Gershenzon, 2006).

Statistics To compare the effect of plant population and induction on the fitness correlates, development time, and body mass of both the herbivore and the parasitoid, we used an analysis of variance model with fixed (population and induction) and one random variable (Petri dish = replicate). In the analysis of the *Mi. mediatior* data, we also included sex as a fixed factor. The estimation of the effects in the model was based on restricted likelihood maximization (REML). The Satterthwaite method was used for approximating the denominator degrees of freedom for the *F*-tests of the fixed effects (Littell et al., 2002). To compare GS concentrations, we used a general linear model ANOVA with population and induction as factors. Development times were log transformed, and GS concentrations were log(x+1) transformed to meet assumptions of normality and equal variances. Data on the survival were analyzed by using non-parametric Kaplan-Meier survival analyses. The log-rank test was used to compare survival curves. Data were analyzed separately for the herbivore and the parasitoid. Parasitized hosts that did not produce a parasitoid were excluded from the analyses. All analyses were carried out using the statistical package SAS 9.1.

Multivariate statistics (PLS = Projection to Latent Structures) was used to reveal whether the variation in GS chemistry could explain the variation in the performance of the herbivore and the parasitoid. We used the PLS extension of the SIMCA P+ 12.0 software program (Umetrics AB, Umeå, Sweden) The program's cross validation procedure evaluates the significance of each additional component (starting with none) by comparing the goodness of fit (R^2) and the predictive value (Q^2) of the extended model with that of the reduced model. First, we ran the PLS analysis with all variables, and then we eliminated those GS variables from the model that contributed little to explaining the variation based on the variable importance on projection values (VIP values). Variables with VIP values >1 are most influential to the model (Eriksson et al., 2006). Per leaf sample, concentrations of the individual GS compounds, pooled levels for each of the GS classes as described in GS analysis section, served as variables in the model. Data were log transformed, mean-centered, and scaled to unit variance before they were subjected to analysis. Insect performance data, which represented the Y-matrix variables, included for the herbivore development time, pupal mass, and survival; and for the parasitoid for both sexes separately, development time, adult body size, and survival to cocoon formation (male and females combined).

Results

Development of Mamestra brassicae and Microplitis mediator on Induced and Non-induced Brassica oleracea Leaves Both development time ($F_{4,\ 73.7}$=270, P<0.001) and pupal mass ($F_{4,\ 92.3}$=100, P<0.001) of the herbivore *M. brassicae* were affected by the plant population on which the caterpillars had been feeding previously (Fig. 1a and b). Development time ($F_{1,\ 64.4}$=158, P<0.001) was longer and pupal mass ($F_{1,\ 75.3}$=52.1, P<0.001) was lower

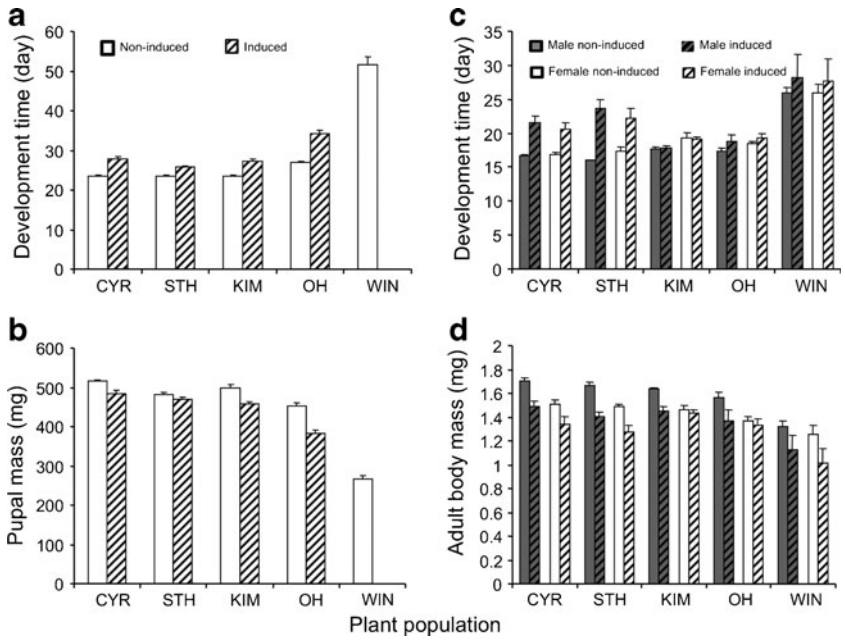

Fig. 1 Fitness correlates (development time and mass) of the herbivore *Mamestra brassicae* (**a**, **b**) and its parasitoid *Microplitis mediator* (**c**, **d**) when they were reared on cultivated (CYR or STH) or wild (KIM, OH, WIN) cabbage (*Brassica oleracea*). Hosts (healthy or parasitized) were reared in Petri dishes and provided with leaf tissues collected from non-induced plants (*open bars*) or from plants that had been exposed to *Pieris rapae* feeding for 7 d (*hatched bars*). Leaf tissues were replaced every other day. Parasitoids data are given for males (*grey* or *hatched grey bars*) and females (*white* or *hatched white bars*) separately. Bars are the mean values (+SE) based on pooled data per dish

on induced compared to non-induced plants (Fig. 1a and b). Induction differentially affected development time and pupal mass depending on the population on which the caterpillars had previously been feeding (population–induction interaction for development time $F_{3,\ 64.4}=5.68$, $P=0.002$, and for pupal mass $F_{3,\ 75.3}=5.12$, $P=0.003$). The effect of induction was strongest for WIN plants, as none of the larvae developed into pupae when they had been feeding on induced WIN plant tissues. Larval survival to pupation was high; more than 90% of the larvae successfully developed into pupae on all plant populations with the exception of the WIN population (Fig. 2a). Survival curves of larvae feeding on induced and non-induced leaf tissues were significantly different for the WIN population only (log-rank test, $P<0.001$).

Development time and biomass of the parasitoid on the various populations, exposed to previous feeding or not, reflected that of healthy hosts (Fig. 1). Plant population had an effect on development time of the wasps ($F_{4,\ 99.7}=39.4$, $P<0.001$); development time was longest on WIN leaf tissues. Moreover, the development time of the wasps was longer on induced than on non-induced plants ($F_{1,\ 110}=40.4$, $P<0.001$), and induction affected development differently depending on the plant population (population–induction interaction, $F_{4,\ 109}=8.80$, $P<0.001$). Previous herbivory tended to prolong development more on cultivated than on wild cabbage. The plant–sex interaction term also was significant ($F_{4,\ 331}=3.96$, $P=0.004$); females tended to develop slower than males on OH and KIM plants, while on the other populations this pattern was less clear. Plant population ($F_{4,\ 114}=19.9$, $P<0.001$), induction ($F_{1,\ 130}=38.9$, $P<0.001$) and sex ($F_{1,\ 478}=33.9$, $P<0.001$), all affected biomass of the adult wasps, with wasps being smaller on induced than on non-induced plants, and males being larger than females. Induction affected adult biomass of the males more strongly than that of the females (induction–sex interaction $F_{1,\ 478}=4.49$, $P=0.03$). Compared to healthy hosts, survival to pupation was more idiosyncratic for the parasitoid (Fig. 2b). Survival was higher on non-induced than on induced plant tissues for all populations except for the KIM populations (log rank tests: WIN, $P<0.001$; STH, $P<0.001$, OH, $P=0.003$, CYR, $P=0.02$, KIM, $P=0.95$). When survival curves on non-induced plant tissues were compared, it was similar on KIM, OH, and STH (log rank test was no longer significant after successive omission of CYR and WIN data). Using a similar approach, survival on induced plant tissues was not significantly different for OH, KIM and CYR plants.

Glucosinolate Analysis GS profiles differed profoundly for the different plant populations (Fig. 3). In CYR plants, the profile was dominated by sulfinyl GS (primarily 3-methylsulfinylpropyl GS), whereas in STH plants, it was dominated by alkenyl GS (primarily 2-propenyl GS). In the wild populations, there was both quantitative and qualitative variation in GS profiles. WIN plants produced high levels of alkenyl GS (especially 3-butenyl GS), and most

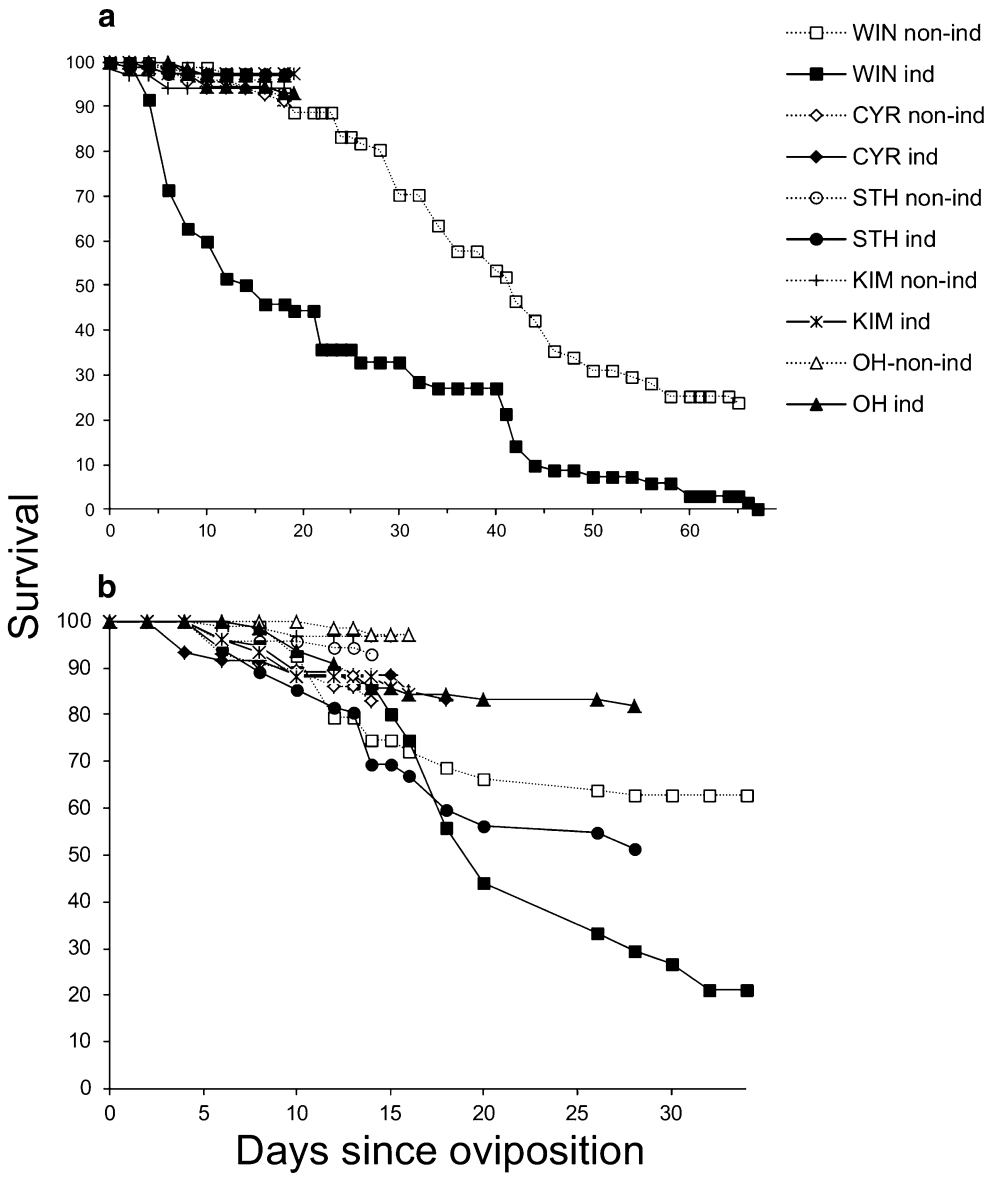

Fig. 2 Survival curves of healthy unparasitized *Mamestra brassicae* caterpillars (**a**) and caterpillars parasitized by *Microplitis mediator* (**b**). Survival was measured from hatching to pupation for healthy *M. brassicae* and for *Mi. mediator* from oviposition until cocoon formation. A few parasitized caterpillars developed into healthy caterpillars. These caterpillars were either not parasitized or the eggs were encapsulated and these were excluded from the data set

plants of this population contained small amounts of the aromatic GS 2-phenylethyl GS, whereas in the other two wild populations, all aliphatic GS classes were represented. Feeding by *P. rapae* increased levels of the indole GS and total GS concentration (indole GS, $F_{1,81}=59.0$, $P<0.001$; total GS, $F_{1,81}=10.0$, $P=0.001$). For the indole GS, the degree of induction depended also on the population (population–induction interaction $F_{4,81}=9.96$, $P<0.001$). The increase of indole GS was significant only for the wild populations (all P-values <0.001, Tukey-Kramer).

The final PLS analysis, from which the variables had been omitted that contributed little in explaining the variation, resulted in a model with two significant principal components explaining 46 and 25% (=R^2X), respectively, of the variance among the GS variables and 63 and 4% (=R^2Y), respectively, among the performance variables. The predictive value of this model was 65% (=Q^2). Each of the three performance parameters measured in healthy hosts, male wasps, and female wasps, respectively, were grouped together. Development time correlated negatively with both survival and biomass. Levels of 3-butenyl GS and 2-phenylethyl GS had a strong negative impact on insect performance, whereas levels of 3-methylsulfinylpropyl GS and 2-hydroxy-3-butenyl GS positively correlated with insect performance. Indole GS had little effect on insect performance based on PLS analysis and only separated the wild populations from the cultivars.

Discussion

The results of this study show that the development of *M. brassicae* and *Mi. mediator* was similar on the two cultivars

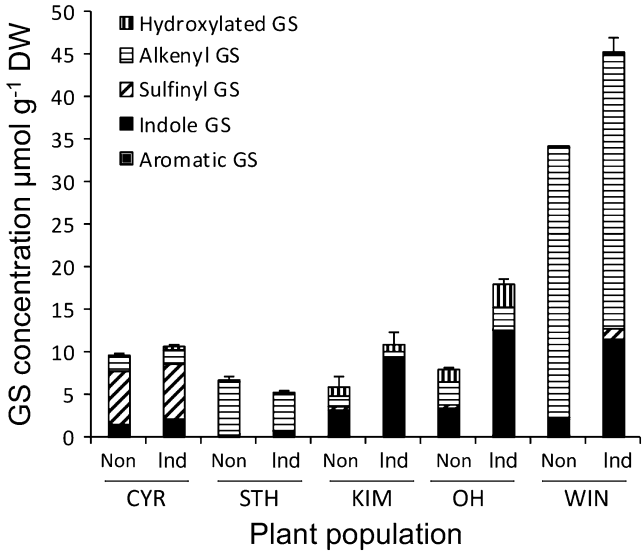

Fig. 3 Glucosinolate (GS) concentrations measured in samples taken from cultivated (CYR or STH) or wild cabbage (*Brassica oleracea*) plants originating from England (KIM, OH, WIN population). Samples were taken from non-induced plants (Non) and from plants that had been exposed to *Pieris rapae* feeding for 7 d (Ind). Concentrations of the detected 11 GS compounds were pooled for the three different GS classes: aromatic, indole, and aliphatic GS. Aliphatic GS were further subdivided into sulfinyl, alkenyl and hydroxylated GS. Bars give the mean values (+SE) for total GS concentrations. The number of samples varied between 8 and 10 per plant line and treatment

(CYR and STH) and the wild cabbage population KIM. Food plant quality of the wild populations ranked KIM>OH>WIN based on visual inspection of the data. There also was a general decline in fitness correlates of the host and parasitoid when developing on plants that had been previously induced by *P. rapae*. However, survival to pupation of healthy *M. brassicae* caterpillars was high on all but the WIN population, irrespective of whether the plants had been induced or not. When the caterpillars developed on WIN plants, survival decreased dramatically. Moreover, on induced tissues of the WIN population, all caterpillars died. Surprisingly, aside from the WIN population, the effects of induction on survival were more pronounced on the parasitoid, *M. mediator* than on the herbivore, *M. brassicae*. In contrast, on WIN plants, parasitoid survival was higher than survival of unparasitized caterpillars on both non-induced and induced plants.

In many plant–herbivore associations, early instars are more susceptible to plant allelochemicals and other plant quality characteristics than later instars. In this case, mortality spikes during the first instar and then levels off as the larvae grow and become better able to detoxify and/or excrete the plant's toxins (Zalucki et al., 2002). However, in our study, the effects of plant quality in WIN plants on the survival of *M. brassicae* and *Mi. mediator* were gradual on non-induced and induced plants. *Microplitis mediator* terminates its relationship with the host at an earlier stage of development (typically L3 or early L4), a point when the host is only approximately 5% of the mass of a fully grown healthy caterpillar (Fig. 4). We also noted that some caterpillars of *M. brassicae* feeding on WIN plants successfully molted to the 5th instar, but were quite small (<500 mg) and refused to eat after molting, generally perishing within a week or so. Furthermore, whereas the larval development of a healthy *M. brassicae* caterpillar can last up to 3 weeks or even longer, that of a parasitized caterpillar is less than half of this duration. This means that parasitized caterpillars are under fewer host-growth-related constraints than healthy caterpillars, and this may explain the discrepancy in survival of the host and parasitoid on induced and undamaged WIN leaf tissues, compared with the other strains/populations (Fig. 4). We have provided a conceptual graph (Fig. 4) showing that koinobiont parasitoids, such as *Mi. mediator*, which terminate their relationship with the host at a very early stage of development (e.g., when it is very small), may be less susceptible to plants of low quality than parastioids that either require the host to grow to a large final size or healthy hosts. This is because the effects of plant toxins may be cumulative over the course of herbivore/parasitoid development, or else because the insects are forced to interact with the plant for a longer period of time.

A previous study (Gols et al., 2008a) found that the performance of a specialist herbivore, *Pieris rapae*, and its solitary endoparasitoid *Cotesia rubecula* (a close relative of *Mi. mediator*) on the same wild populations of *B. oleracea* was less variable than found for the host and parasitoid used in this study. Moreover, whereas *M. brassicae* develops poorly on diets where concentrations of aliphatic and total GS are high, the specialist appears to be more sensitive to higher levels of indole GS (Gols et al., 2008a). This probably reflects adaptive differences in the two associations that relate to specialization via frequency-dependent selection. Using *Arabidopsis thaliana* plants with mutations that greatly reduced levels of aliphatic GS, indole GS, or both, Müller et al. (2010) demonstrated that the growth of *Trichoplusia ni*, *Manduca sexta*, and *Spodoptera exigua* caterpillars, three lepidopteran species, were all negatively affected by the presence of aliphatic GS. Only the growth of *S. exigua* was negatively affected also by the presence of indole GS (Müller et al., 2010). The effects of plant quality on development and survival of both generalist and specialist herbivores often are proportional up the food chain (Gunasena et al., 1990; Ode, 2006; Gols et al., 2008a,b; Harvey et al., 2011), or else less well-adapted parasitoids perform worse than their hosts as levels of direct plant defenses increase (Harvey et al., 2003, 2005; Ode, 2006; Gols et al., 2008b). By contrast, high concentrations of plant toxins sometimes impair the development

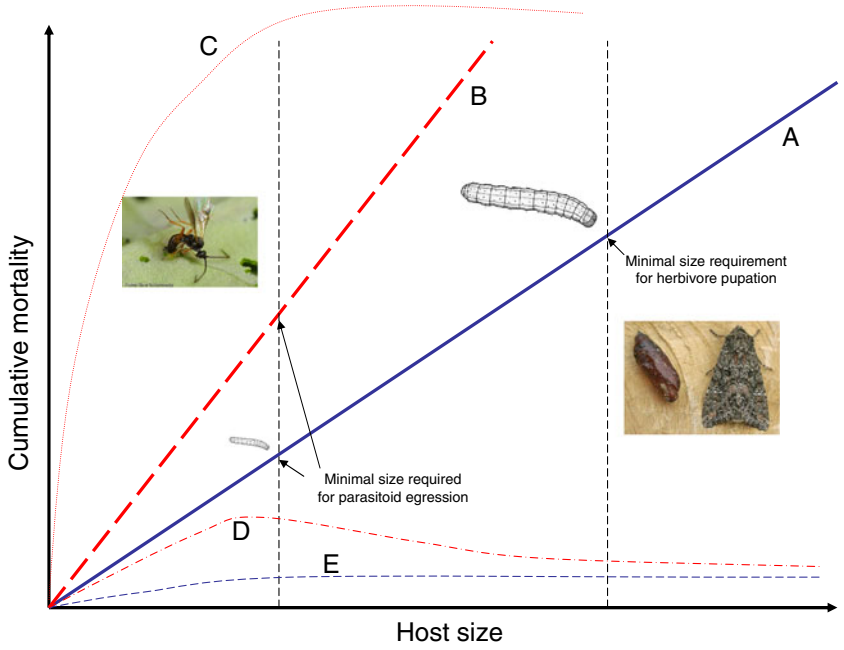

Fig. 4 Conceptual diagram showing the relationship between herbivore (healthy or parasitized) growth curves and cumulative mortality on food plants that differ in their quality. *Solid line* **a** and short *dashed line* **e** represent herbivore growth curves on non-induced plants; *long dashed line* **b**, *dotted line* **c** and *alternating dot-dashed line* **d** lines represent herbivore growth curves on induced plants. In this example, the parasitoid is solitary and the host caterpillar must reach a much smaller critical size to support parasitoid development (*left dashed black vertical line*) than to successfully pupate (*right vertical black dashed line*). In this study, induction steepens the mortality curve (lines **a**, **b**) reducing survival of both the parasitoid and the herbivore; the latter does not survive at all on induced plants because it cannot grow large enough to reach a minimum viable size for pupation. If the plant is even more toxic, then the parasitized host does not even reach a critical size and all parasitoids die before egression form the host (line **c**). In some instances, perhaps due to stress caused by parasitism, parasitoids may experience higher mortality on induced plants than their hosts (line **d**), or else herbivore and parasitoid mortality on non-induced plants does not differ (line **e**). Many different combinations are possible, depending on the effects of the plant on the herbivore and parasitoid, the parasitoid on the herbivore, and quantitative differences in the required growth of healthy and parasitized hosts

of the host more than that of the parasitoid (Devine et al., 2000; this study). In these examples, the outcome of the interaction may hinge on the effects that plant allelochemicals have on the physiology of the insects through processes associated with host-parasitoid nutritional ecology and/or on host immunity (Bukovinszky et al., 2009; Smilanich et al., 2009).

Analysis of allelochemicals in plant tissues revealed qualitative and quantitative variation among the populations. Furthermore, induction by *P. rapae* feeding mainly affected levels of indole GS, and these increased more in wild than in cultivated cabbage (see also Harvey et al., 2011). However, PLS analysis did not reveal a significant relationship between levels of indole GS and performance of the herbivore or the parasitoid. We only found a negative correlation between insect performance and levels of 3-butenyl GS and 2-phenylethyl GS. However, van Leur et al. (2008) demonstrated that the performance of *M. brassicae* was little affected when feeding on *Barbarea vulgaris* genotypes that produce 2-phenylethyl GS at much higher concentrations than the WIN plants used in this study. The effect of plant induction on survival was more pronounced in the parasitoid than in healthy hosts. This suggests that something other than GS, with perhaps the exception of 3-butenyl GS, is responsible for the decline in insect performance, especially for the parasitoid. Primary metabolites, such as nitrogen, phosphorous, and carbon, were not measured in the current study, but previous research with crucifers suggests that nitrogen, often a limiting nutrient for insect development, is always present in high concentrations in *Brassica* species (Soler et al., 2005). It is more likely that some unidentified secondary plant metabolite(s), that is/are present in leaf tissues of cabbage plants is induced after herbivore damage. For example, highly toxic cardenolides have been found in addition to GS in leaf tissues of the crucifer, *Erysimum cheiranthoides* (Renwick, 2002). Cipollini and Gruner (2007) have isolated cyanide from leaves of the garlic mustard, *Alliaria petiolata*. The invasive crucifer, *Bunias orientalis*, is highly toxic to specialist herbivores although its main allelochemical, the aromatic GS sinalbin, is also present in other crucifers that are suitable food plants for these herbivores (Harvey et al., 2010b).

In summary, this study has reported that differences in the quality of cultivated and wild cabbage plants affected the development and survival of a generalist herbivore and its solitary endoparasitoid. Differences in plant quality on insect performance were linearly correlated with concentrations of the aliphatic 3-butenyl GS, which in WIN plants exceeded some quantitative threshold for successful development. The poor quality of WIN plants also had a more serious affect on survival of the host, *M. brassicae*, than of its parasitoid, *Mi. mediator*, which probably reveals different temporal and physiological constraints imposed by the plant on both organisms. Thus far, more intimate aspects of life-history and development strategies in herbivores and their natural enemies in response to differences in plant quality have been largely ignored. Instead, researchers have tended to lump the insects according to their trophic status. By incorporating biological and physiological characteristics of the insects, such as their feeding strategies, growth patterns, and other relevant criteria, a better understanding of three (and higher) trophic level interactions will be attained.

Acknowledgments The authors thank Leon Westerd, Frans van Aggelen, and André Gidding for rearing *Mamestra brassicae*. and Puterka, 2004). In addition to acyl sugars, nicotine, caffeoylputrescine, and several derivatives of the flavonoid, quercetin, are produced in trichomes and contribute to the leaf surface chemistry of *N. attenuata* (Roda et al., 2003). Many important steps in the biosynthesis of nicotine-related compounds take place in the trichomes. For example, nornicotine in *Nicotiana stocktonii* is converted in trichomes to *N*-hydroxyacylnornicotine, which subsequently is rapidly excreted onto the leaf surface (Zador and Jones, 1986). Such *N*-acylnornicotines (NacNN) have been shown to be a much more potent defense against the specialist herbivore *Manduca sexta* than nicotine itself (Jones et al., 1985). In *Nicotiana repanda,* the production of NacNN from nornicotine and its exudation to the leaf surface is rapidly elicited by methyl jasmonate (Laue et al., 2000). All these studies make inferences about trichome chemistry and function not by directly examining trichomes but rather by washing the leaf surface or even extracting complete leaf tissue.

In recent years, advances in non-destructive techniques such as NMR-spectroscopy have improved our ability to study intact tissues and plant organs. Hence NMR is the method of choice to gain a better understanding of the role of trichomes in the wild tobacco, *Nicotiana attenuata.* We examined wild type plants and a line of plants transformed with an RNAi construct harboring a fragment of the subunit of a SnRK1 (SNF1-related kinase) protein kinase (Schwachtje et al., 2006). This particular transformed line produced large trichomes with large basal cells (Supplemental Fig. S1E). Since only one of more than 20 transformed lines produced this phenotype, we infer that the trichome phenotype results from a t-DNA insertional mutagenesis event, rather than the RNAi of the SnRK1. These enlarged trichomes allowed us to harvest sufficient trichome mass to conduct NMR experiments and HPLC analysis to profile the secondary metabolites in the different cell types of type C trichomes and in the trichome heads of type D trichomes.

NMR spectroscopy and LC-TOF-MS analysis revealed for the first time the presence of phaseoloidin in the trichomes of a Solanaceous plant. This homogentisic glucoside was described previously from the seeds of *Entada phaseoloides* (Fabaceae) (Barua et al., 1988). Additionally, we showed in bioassays with artificial diets that phaseoloidin reduces larval growth of the specialist larvae *Manduca sexta* and the generalist larvae *Spodoptera littoralis,* suggesting a strong defensive function comparable to that of nicotine.

Methods and Materials

Plant Growth We used an isogenic line, obtained after 30 generations of inbreeding, of *Nicotiana attenuata* Torr. *ex* Watson originally derived from field-collected seeds. For trichome collection, a transformed line, (irGAL83; transformation construct described in Schwachtje et al. (2006)) containing a tDNA insertion mutation that resulted in the production of large trichomes. Seed germination was performed as described by Krügel et al. (2002). All plants were grown individually in 1 L pots in the glasshouse at 26–28°C under 16 hr of light supplied by Philips Sun-T Agro 400- or 600-W sodium lights.

Trichome Collection For the NMR studies, the two distal cells with the glandular vesicle of 20 trichomes (C tip, as indicated in Supplemental Fig. S1, panel A) or the following three to four cells (C middle) of flowering plants containing the insertional mutation were collected with tweezers. Approximately 150 heads of type D trichomes of flowering plants were collected with a glass capillary (D head). All samples were dissolved in 600 µl deuterated methanol directly after collection. Cells were sonicated before ^{1}H NMR measurements at 500 MHz using a cryogenic probe.

To estimate the amount of phaseoloidin and nicotine present in trichomes (Fig. 1), we harvested 60 type C trichomes from the midvein of rosette stage wild type *N. attenuata* leaves. Trichomes were excised with a razor blade and rinsed from the blade by dipping into a 4-ml vial containing 2 ml of methanol; a process that was repeated three times. Afterwards the samples were sonicated and the solvent was removed under a constant flow of nitrogen. The residue was then dissolved in 70 µl deuterated methanol, and 7.5 µg phloroglucinol (Fluka) were added as internal standard (ISTD) for quantification. Total amounts of phaseoloidin and nicotine were calculated according to formula 1–2, described in Fig. 1.

Isolation of Phaseoloidin Seeds of *Entada phaseoloides* (90 g) were obtained from Urban Jungle (Munich, Germany). The seeds were ground and defatted with *n*-hexane (200 ml each) × 3 and extracted with 80% aqueous ethanol (300 ml) × 3. The alcoholic extract was concentrated, and subsequently fractionated with *n*-hexane, ethyl acetate, *n*-butanol/water. The ethyl acetate fraction (5.0 g) was subjected to two silica gel 60 (40–63 µm, *Merck*, Darmstadt, Germany) column chromatographic separations and eluted with *n*-hexane/ethyl acetate (9:1, 8:2, 7:3, 6:4). The fractions were monitored by TLC on silica gel 60 F_{254} plates (*Merck*), using a mixture of n-hexane/ethyl acetate 13:7, and visualized under a UV lamp (254 nm) after heating and spraying with phosphomolybdic acid in ethanol. The similar fractions were combined. Ten fractions (200.0 mg) contained crude phaseoloidin and were subjected to a second column chromatography separation to produce 150.0 mg semi-pure phaseoloidin, which was

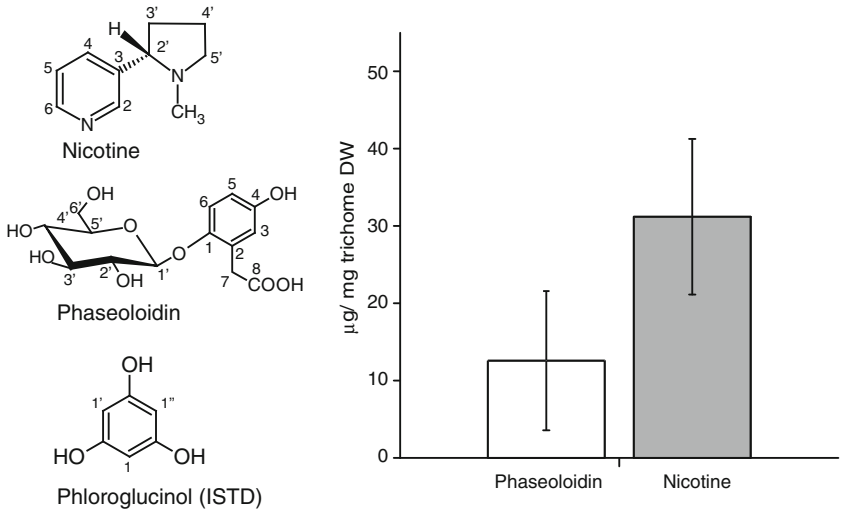

Fig. 1 Quantification of phaseoloidin and nicotine content in *Nicotiana attenuata* wild type trichomes was achieved by ^{1}H NMR. Total amounts of both metabolites were calculated relatively to phloroglucinol (ISTD) according to Formulae 1–2 (below). The integrals of the following proton signals were summed: phaseoloidin: No. of nuclei 3; H-6, H-3, H-5; nicotine: No. of nuclei 4; H-2, H-6, H-4, H-5; phloroglucinol: No. of nuclei 3; H-1, H-1′, H-1″. Error bars indicate standard errors (N=3)

Formula 1: Calculation of the absolute phaseoloidin content

$$m_{phaseoloidin} = \frac{\text{No. of nuclei}_{ISTD} \times n_{ISTD} \times \text{Area}_{phaseoloidin}}{\text{No. of nuclei}_{phaseoloidin} \times \text{Area}_{ISTD}} \times M_{phaseoloidin}$$

Formula 2: Calculation of the absolute nicotine content

$$m_{nicotine} = \frac{\text{No. of nuclei}_{ISTD} \times n_{ISTD} \times \text{Area}_{nicotine}}{\text{No. of nuclei}_{nicotine} \times \text{Area}_{ISTD}} \times M_{nicotine}$$

Abbreviations: m—mass; M—molar mass; n—amount of substance; Area—Integrated area of the NMR peak; ISTD—internal standard (Phloroglucinol)

further purified by preparative HPLC (LiChrospher RP18, 5 µm, 250×10 mm, respectively, *Merck*, Darmstadt, Germany) with the following solvents A (0.1% trifluoroacetic acid in H_2O) and B (100% MeOH) and a linear gradient from 3% B to 30% B in 15 min. The flow rate was 5 ml min^{-1} and a total of 50.0 mg pure phaseoloidin were isolated.

NMR—Experiments ^{1}H NMR, ^{13}C NMR, APT, ^{1}H,^{1}H-COSY, ROESY, HMBC, and HSQC spectra were recorded on a Bruker AVANCE 500 spectrometer (Bruker, Rheinstetten Germany) operating at a ^{1}H frequency of 500.13 MHz and a ^{13}C frequency of 125.76 MHz at 300 K using a TCI Cryoprobe™ (5 mm). Presaturation was used for suppression of the HDO signal in the 1D ^{1}H NMR spectra. Chemical shifts were referenced to internal tetramethylsilane (TMS) for ^{1}H and ^{13}C resonances.

LC-TOF-MS Analysis Prior to NMR measurements, the samples were separated using an Agilent HPLC 1100 Series system, with a Gemini NX C18 column (150×2 mm) and the following binary gradient: 0 to 6 min, isocratic 70% A (deionized water, 0.1% [v/v] acetonitrile [Baker HPLC grade] and 0.05% formic acid), 30% B (acetonitrile and 0.05% formic acid); 6 to 13 min, isocratic 20% A, 80% B; and 70% A, 30% B; 13 to 18 min, isocratic 70% A, 30% B. The flow rate was 200 μl min^{-1}. Eluted compounds were detected by a Bruker MicroToF mass spectrometer (Bruker Daltonics, Bremen, Germany) equipped with an ion spray source operated in negative ion mode. The instrument was operated with parameters described in (Heiling et al., 2010). Electrospray ionization conditions: TOF 2100 V, capillary voltage 4500 V, capillary exit −130 V, dry temperature 200°C, dry gas flow of 8 Lmin^{-1}. Mass calibration was performed using sodium formiate (50 ml isopropanol, 200 ml formic acid, and 1 ml 1 M NaOH in water).

Phaseoloidin ^{1}H NMR (MeOH-d_4), 500.13 MHz, internal standard TMS): δ 7.03 (1H, *d*, *J*=8.8 Hz, H-6), 6.70 (1H, *d*, *J*=3.0 Hz, H-3), 6.58 (1H, *dd*, *J*=8.8, 3.0 Hz, H-5), 4.68 (1H, *d*, *J*=7.5 Hz, H-1′), 3.87 (1H, *dd*, *J*=12.1, 5.4 Hz, H-6′a), 3.68 (1H, *dd*, *J*=12.1, 2.2 Hz, H-6′b), 3.56 (1H, *d*, *J*=14.4 Hz, H-7a), 3.46 (1H, *d*, *J*=14.4 Hz, H-7b), 3.45 (1H, *m*, H-2′), 3.44 (1H, *m*, H-3′), 3.42 (1H, *m*, H-4′), 3.33 (1H, *m*, H-5′); ^{13}C NMR (MeOH-d_4, 125.13 MHz, internal standard TMS): δ 179.4 (C-8), 153.7 (C-4), 150.1 (C-1), 130.0 (C-2), 119.0 (C-6), 118.7(C-3), 114.9 (C-5), 104.8 (C-1′), 78.1 (C-5′), 78.0 (C-2′), 75.1 (C-3′), 70.0 (C-4′), 62.7 (C-6′), 39.7 (C-7); HREIMS: *m/z* 331.101 $[M + H]^+$, 329.089 $[M–H]^-$.

Nicotine ^{1}H NMR (MeOH-d_4, 500.13 MHz, internal standard TMS): δ 8.51 (1H, *dd*, *J*=2.2, 0.9 Hz, H-2), 8.44 (1H, *dd*, *J*=5.0, 1.6 Hz, H-6), 7.86 (1H, *ddd*, *J*=7.9, 2.2, 1.6 Hz, H-4), 7.43 (1H, *ddd*, *J*=7.9, 5.0, 0.9 Hz, H-5), 3.24 (1H, *ddd*, *J*=9.6, 7.9, 2.3 Hz, H-5′a), 3.20 (1H, *dd*, *J*=9.1, 8.0 Hz, H-2′), 2.37 (1H, *ddd*, *J*=9.6, 9.3, 8.6 Hz, H-5′b), 2.26 (1H, *m*, H-3′a), 2.17 (3H, *s*, N-CH_3), 1.97 (1H, *m*, H-4′a), 1.89 (1H, *m*, H-4′b), 1.77 (1H, *m*, H-3′b); ^{13}C NMR (MeOH-d_4, 125.13 MHz, internal standard TMS): 149.82

(C-2), 149.15 (C-6), 140.14 (C-3), 137.41 (C-4), 125.40 (C-5), 70.13 (C-2′), 57.90 (C-5′), 40.58 (N-CH_3), 35.73 (C-3′), 23.28 (C-4′).

Caterpillar Bioassays Larvae of *Manduca sexta* (Lepidoptera) were derived from an in-house colony. Larvae of *Spodoptera littoralis* were from Bayer CropScience (Monheim, Germany). *Spodoptera littoralis* larvae were fed prior to the experiments on an artificial diet consisting of 300 g L^{-1} agar, 250 gL^{-1} bean flour, 4.5 g ascorbic acid, 4.5 g ethyl *p*-hydroxybenzoate, 2.5 g vitamin E (all supplied by Sigma, Milan, Italy) dissolved in 17 ml of seed oil and 2 ml formaldehyde.

Artificial diet for feeding experiments was prepared according to (Waldbauer et al., 1964). While the diet was still liquid and cooling, phaseoloidin, homogentisic acid, and nicotine were dissolved in 5 ml MeOH and added to achieve a final concentration of 0.16 μg mg^{-1} diet. As a control, 5 ml of pure MeOH were added. The diet was sealed with plastic wrap and aluminum foil and kept at 5°C until use. Freshly hatched *M. sexta* larvae were transferred to plastic containers containing pieces of artificial diet. Ten caterpillars were placed in one box. Larval mass was measured every 3 day, and the diet was refreshed on these days as well.

Spodoptera littoralis were fed for 5 day on bean flour-containing diet and then transferred to artificial diet amended with either phaseoloidin or nicotine. Because *Spodoptera* larvae are cannibalistic, larvae were kept in single plastic cups with small cubes of diet and wet tissue paper to maintain humid conditions. Caterpillars were weighed and the diet was changed every 3 day.

Results

Trichome Profiling Extracts of the two types of glandular trichomes (long stalked type C and short stalked type D) present on the leaves on *N. attenuata* (Supplemental Figs. S1A, B) were analyzed by NMR. We chose to analyze both trichomes types because of their difference in cell number and distributions on the leaf surface. An insertional mutant with enlarged trichomes allowed for the efficient harvests of type D trichome heads and the middle and tip part of type C trichomes (Supplemental Fig. S1). NMR analysis of the trichome extracts from the transformed plants showed the presence of nicotine, glucose (α, β), fatty acids, and phaseoloidin. The fatty acid and sugar signals most likely result from the well-described *O*-acyl sugars present within trichomes and their exudates (Arrendale et al., 1990). A small amount of phaseoloidin, a β-glucoside of homogentisic acid, was isolated by HPLC from *N. attenuata* trichomes and the structure was unambiguously identified by 1D- and 2D NMR spectroscopy and LC-TOF-MS. ^{1}H and ^{13}C-NMR data are identical with those reported in the literature (Barua et al., 1988). We could not detect phaseoloidin in MeOH/H_2O extracts of entire leaves in our studies using NMR in positive nor negative mode LC-MS-TOF analysis. ^{1}H NMR of trichomes revealed a variable distribution of the metabolites within the trichomes. The nicotine: phaseoloidin ratio across all trichome types and segments within wild type plants of *N. attenuata* is approximately 2: 1 (Fig. 1). There was a clear difference in the amount of nicotine between the different type of trichomes as well as the different trichome tissues dissected (Fig. 2b). Nicotine was distributed in C Tip: C Middle: D Head in an approximate 4: 1: 1 ratio, as calculated by assuming the same water content for all cells and using the water signal for normalization. While the exact ratio varied across different measurements, the overall trend of higher nicotine contents in the tip and middle of type C trichomes remained constant across all measurements. In contrast to the pattern observed for nicotine, the concentration of phaseoloidin was equivalent in the middle and the tip of type C trichomes, where it was three times less than in the head of type D trichomes. The analysis of trichome extracts by LC-TOF-MS showed a slightly different pattern because the amount of phaseoloidin is, in contrast to the NMR- results, higher in the middle part of type C trichomes. Nevertheless the overall finding of lower amounts in type D trichomes was confirmed (Fig. 3a). The ratio of nicotine: phaseoloidin in typical samples was 3: 1 in the trichome heads of type D, 1: 1 in the middle and in 4: 1 tip segments (including heads) of type C trichomes. Additional experiments were conducted on wild type *N. attenuata* plants that revealed no difference in phaseoloidin content compared to the insertional mutant, irGAL83 (Supplemental Fig. S2). Interestingly there was as well a difference in the *O*-acyl sugar distribution between both types of trichomes. The aliphatic part of the NMR- spectra showed much more intense signals corresponding to sugars and fatty acids for type D heads than for type C middle and tip (Supplemental Fig. S3).

Isolation and Identification of Phaseoloidin Due to the fact that the amount of phaseoloidin extractable from the trichomes of *N. attenuata* was insufficient for a bioassay, preparative isolation was performed from the seeds of *Entada phaseolides*. The defatted ground seeds were extracted with aqueous ethanol. The alcoholic extract was partitioned against water, *n*-hexane, ethyl acetate, and *n*-butanol. The ethyl acetate was subjected to two successive column chromatography separations using silica gel followed by semi-preparative HPLC to yield pure phaseoloidin. The structure was identified by 1D- and 2D NMR spectroscopy and HR-TOFMS at *m/z* 329.087 [M-H],

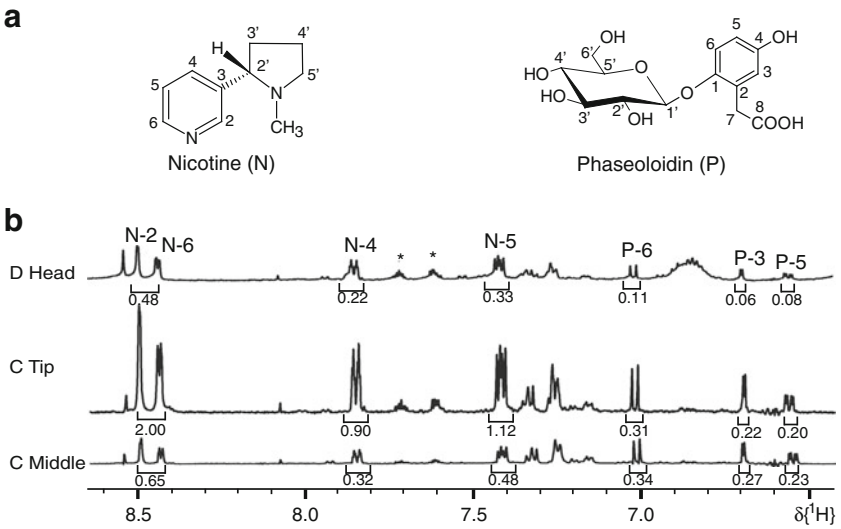

Fig. 2 **a** Structures of nicotine and phaseoloidin found in the two different trichome types of *Nicotiana attenuata*. The identity of phaseoloidin was verified by NMR and LC-ToFMS [M-H 329.0878] with a standard isolated from the seeds of *Entada phaseoloides*. **b** ^{1}H NMR spectra (500 MHz, MeOH-d_4) of head (type D), tip, and middle sections of extracts of tall trichomes (type C). Assuming the same water content of all trichome cells, the integral of the water signal (not shown) was used to determine the relative levels of phaseoloidin and nicotine in the middle and the tip (including the head) sections of type C trichomes and the head of type D trichomes. Typically the ratio of nicotine in sections C Tip: C Middle: D Head was approximately 4: 1: 1 The phaseoloidin concentrations are equivalent in the middle of type C and the head of type D trichomes, which, in turn, are three times less than in the tip of type C. Additional signals in the range of 7.4–7.1 marked with an *asterisk* (*) are from a contamination (phthalate)

corresponding to the molecular formula of $C_{14}H_{18}O_9$ (Fig. 3b, c). The ^{1}H and ^{13}C-NMR data are identical with those reported in the literature (Barua et al., 1988). The MS fragmentation pattern verified the previous results (Fig. 3b, c).

Phaseoloidin Decreases Caterpillar Growth We tested the effects of phaseoloidin and nicotine against the larvae of a generalist herbivore, *Spodoptera littoralis.* Because this insect is known be strongly affected by nicotine, we conducted an assay with this neurotoxin as a comparison. As trichomes are one of the first feeding choices of freshly hatched larvae (Weinhold and Baldwin, 2011), it is likely that trichome-derived compounds are ingested by the caterpillars. Both substances were added to an artificial diet at a final concentration of 0.16 μg mg^{-1}, a concentration approximately 100 times less than that found within the trichomes (Fig. 1). As expected, caterpillars showed decreases in growth of about 45% when fed a nicotine-containing diet. Interestingly they showed a similar decrease in growth when fed on phaseoloidin-containing diets. This response was marginally more pronounced (55% decrease) than the response to nicotine, although the differences were not statistically significant (Fig. 4).

The most damaging insect herbivore on *N. attenuata* frequently is the tobacco hornworm *M. sexta*, and we conducted the same bioassay with this insect species. In addition, we tested the aglycone of phaseoloidin, homogentisic acid. To examine possible synergistic effects of both trichome-derived compounds, we tested the combinations of nicotine and phaseoloidin and nicotine in combination with homogentisic acid. Similar to the response of the generalist, *M. sexta* larvae grew significantly less on diets with either phaseoloidin or nicotine (50 and 37% decreases in growth). Furthermore we observed the same decrease in caterpillar mass for the aglycone as well as for both combinations of phaseoloidin and the aglycone with nicotine (Fig. 4).

Discussion

Trichomes and especially trichome-derived compounds are defensive traits that protect plants from attacking herbivores or pathogens, and recent reports have shown that trichome cells are highly specialized in their ability to synthesize metabolites (Dai et al., 2010). Here, we showed that metabolites contributing to defense occur in *N. attenuata* trichomes in fairly high concentrations (1% of dry mass) and report the presence of a homogentisic acid glucoside, phaseoloidin, in two different trichome types of a Solanaceous plant. Phaseoloidin was found previously within the seeds of *Entada phaseoloides*, a putative function of this substance remained elusive even though Barua et al. (1988) showed a toxicity against fish at fairly high concentrations (125 mg ml^{-1}). Since phaseoloidin was not detectable in complete leaf extracts, we infer that this metabolite occurs primarily in the trichomes, at relatively high concentrations

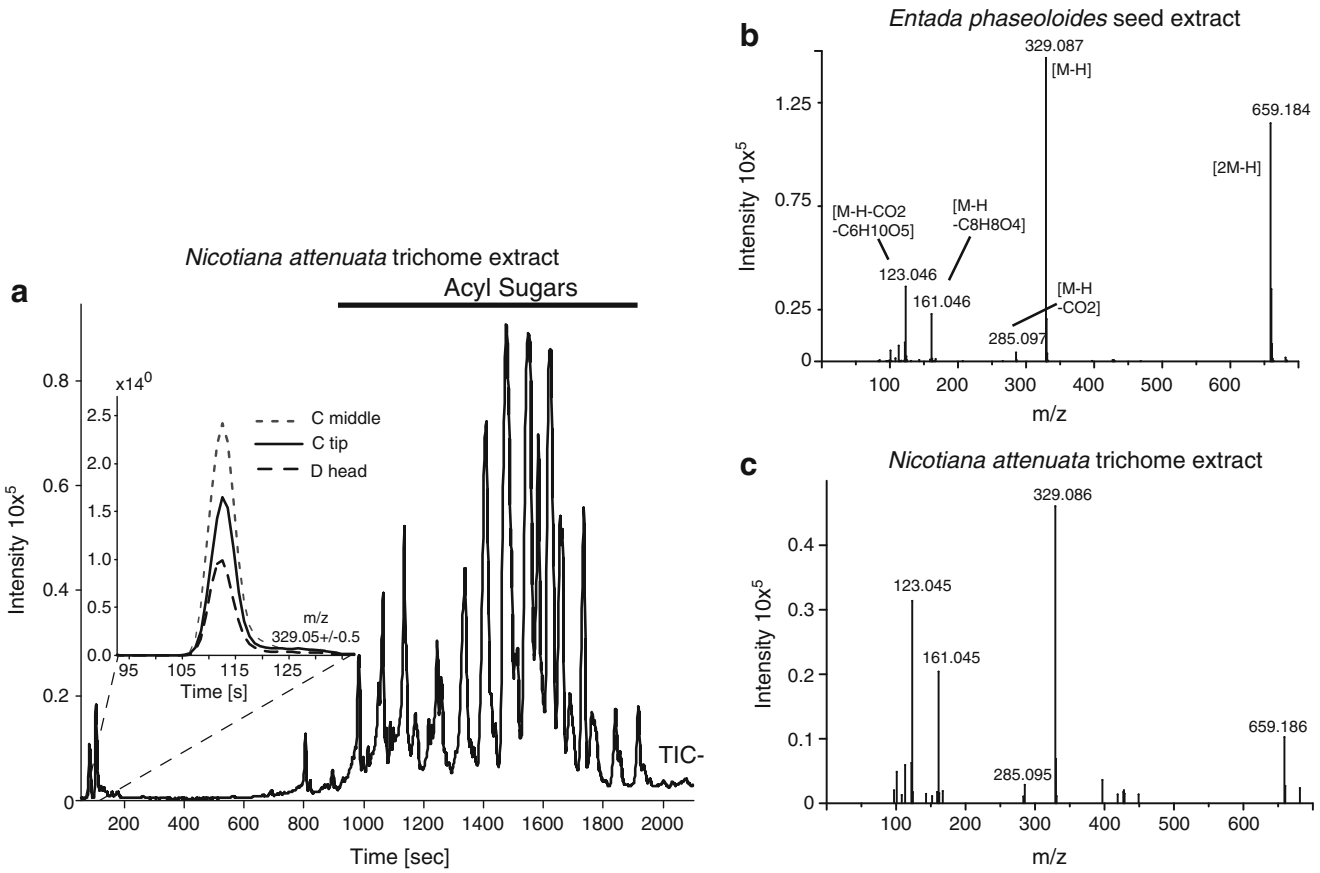

Fig. 3 **a** TIC- (negative total ion current) of a methanolic extract of excised type C and D trichomes from *Nicotiana attenuata*. The TIC is dominated by *O*-acyl sugars (MS spectra not shown) but the phaseoloidin and the differences in the amount between the different tissues can be clearly observed in the ion trace of 329.087 (Inset). **b** Negative ionization mass spectra of phaseoloidin from *Entada phaseoloides* seeds. [M-H] peak is clearly visible (*m/z* 329.087) as well as the loss of CO_2 from the carboxy group of the aglycone (*m/z* 285.097). The fragments at *m/z* 123.045 and *m/z* 161.045 originate from the cleavage of the glycosidic bond. **c** Negative ionization mass spectra of *N. attenuata* trichome extracts confirm the presence of phaseoloidin in this tissue

of approximately 10 μg mg^{-1} dry mass (Fig. 1). These findings suggest that phaseoloidin and nicotine occur in both trichome types present on *N. attenuata's* leaf surface.

The variation in the amounts of metabolites between both types of trichomes as well as among the different trichome parts may be due to variable cell numbers and size but could as well be a consequence of a different biosynthetic site for both metabolites. It is known that nicotine is produced within the roots (Shoji et al., 2000) of *Nicotiana* species upon attack (Baldwin, 1989) and then transported via xylem to leaves, flowers, and trichomes. This transport is mediated by a multidrug and toxic compound extrusion (MATE) transporter as shown for *Nicotiana tabacum* (Morita et al., 2009). In contrast, the biosynthetic site of the phaseoloidin remains unknown. Phaseoloidin is a glucoside of homogentisic acid, which is derived from phenylalanine or tyrosine via 4-hydroxyphenylpyruvate dioxygenase. This enzyme has been described for many plant systems, and so far has not been shown to be present in trichomes (Moran, 2005).

Since phaseoloidin could not be detected in leaf tissue, it most likely is synthesized in the trichomes. Thus, the presence of nicotine and phaseoloidin is an interesting case in which two metabolites differing in their origin are found in trichomes. This tissue type is considered to be highly specific, and there are reports of secondary metabolites specifically synthesized in the trichomes. Examples are the production of artemisinin within trichomes of *Artemisia annua* (Duke et al., 2000), cannabinoids in *Cannabis sativa* (Sirikantaramas et al., 2005), and as well the specific terpenoids in trichomes of *Solanum lycopersicon* (van Schie et al., 2007). Since recent reports show that MATE transporter might be involved in the transport of nicotine, the silencing of the transport of nicotine into the trichomes may show how phaseoloidin acts in the absence of nicotine.

Many trichome-derived compounds have been reported to play a defensive role against herbivores. Our artificial diet bioassays showed that this also holds true for phaseoloidin. This compound decreased caterpillar performance as much as the known defensive compound,

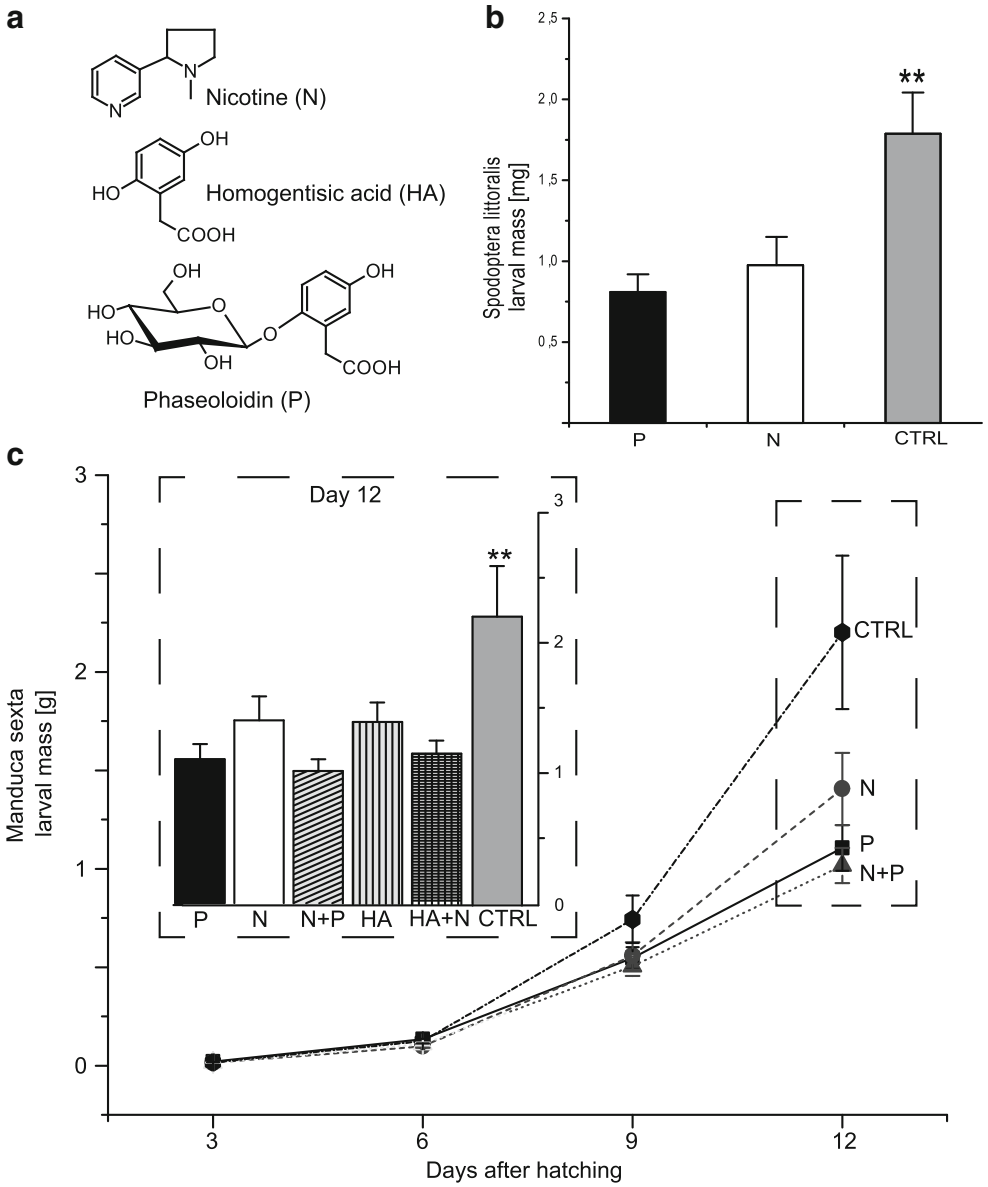

Fig. 4 **a** Structure of compounds used in the bioassay were nicotine (N), phaseoloidin (P) and its aglycone, homogentisic acid (HA). Compounds were dissolved in 5 ml methanol and mixed with freshly prepared artificial diet. As a control (CTRL) diet mixed with 5 ml pure methanol was used. Caterpillars of two different lepidopteran species were fed the amended artificial diet (Waldbauer et al., 1964) to which either nicotine or phaseoloidin in concentrations of 0.16 μg mg^{-1} were added. Larval mass was measured after 8 day for *Spodoptera littoralis* **b** and after 12 day for *Manduca sexta*. Insert shows the larval mass of *M. sexta* after 12 day feeding on artificial diet **c**. Error bars indicate standard errors. *Asterisks* indicate significance levels according to a *Fischer PLSD* * <0.05 ** <0.01 *** <0.001

nicotine. We are aware that artificial diet assays do not reflect the true nature of a plant-herbivore interaction and that silencing the biosynthesis of the target compound would be a more elegant way to examine our hypothesis. Nevertheless, this experimental set-up allows us to study the influence of a single, highly abundant, metabolite without interference from other plant metabolites or proteins. The outcome of these assays shows clearly that phaseoloidin is active against Lepidopteran insects, and ingestion of this homogentisic acid glucoside significantly compromises the performance of generalist and specialist herbivores. Since the effect of phaseoloidin feeding was as pronounced as for the well-known defense metabolite, nicotine, we propose that phaseoloidin functions as a direct defense. From this finding, we hypothesize that diverse functionality of the two trichome types could additionally be responsible for the different ratios of nicotine and phaseoloidin. As has been shown previously, trichomes contribute to plant defense by exuding acyl sugars. These exudates are known to play a major part in plant defense against herbivores, e.g., tagging caterpillars with a distinct body odor that attracts predatory ants (Weinhold and Baldwin, 2011). Hence, it is not surprising that the phaseoloidin concentration is lowest in type D trichomes where the most acyl sugars are exuded (Supplemental Fig. S3). As a consequence, caterpillars may be not deterred by either phaseoloidin or nicotine and can thus feed more intensively on acyl sugars, which leads finally to their predation. In the case of the type C trichomes, the opposite situation occurs; the tips exude less acyl sugars than type D trichomes, but have 3–4 fold higher nicotine and phaseoloidin concentrations. We propose that in type C trichomes,

these metabolites act synergistically as deterrents and toxins for attacking herbivores. In addition to their role in plant defenses, trichomes are known to play a role in the sequestration of phytotoxins (Sirikantaramas et al., 2008). Therefore, we cannot exclude the hypothesis that phaseoloidin might be a detoxification catabolite.

Glandular hairs or trichomes frequently function as physical obstacles and entrap insects by the exudation of glue-like substances, such as *O*-acyl sugars. We propose that caterpillars experience the deterrent effects of phaseoloidin when they navigate around these physical barriers on the leaf surface and become coated with trichome exudates or directly ingest trichome contents. Since phaseoloidin and its aglycone, homogentisic acid, had similar effects, it is possible that the aglycone, or a metabolic product, is itself the active substance. Further experiments with a bioassay-guided fractionation approach may highlight the important defensive function of this new metabolite in the Solanaceae.

Acknowledgments We thank three anonymous reviewers for their comments and the Max Planck Society for funding.

larvae of an Apiaceae-feeding swallowtail species, *Papilio polyxenes* (*ajax*). Despite this early finding, the chemical basis of feeding responses to host chemicals by papilionid larvae remains largely unknown.

Many swallowtail species in the genus *Papilio* utilize host plants in the family Rutaceae. Larvae of *P. xuthus* L. feed on various *Citrus* species and plants in other rutaceous genera such as *Poncirus*, *Zanthoxylum*, *Fagara*, and *Phellodendron* (Honda and Hayashi, 1995). While the oviposition stimulants of *P. xuthus* are composed of a complex mixture of flavonoids, alkaloids, and polar compounds acting synergistically (Nishida et al., 1987; Ohsugi et al., 1991), the specific composition of the larval feeding stimulants remains unknown. The relationship between oviposition preference and offspring performance is a central issue in the evolution of host adaptation in swallowtail butterflies (Wiklund, 1975; Berenbaum and Feeny, 2008). In this connection, a comparison of the chemosensory bases of responses to host-plant cues for adult oviposition and larval feeding in the same swallowtail species could provide insight into divergent selective pressures that act on the adult and larval stages. This report describes the chemical elucidation of the complex larval feeding stimulant system for *P. xuthus* contained in the leaves of one of its favorite hosts, *C. unshiu*.

Methods and Materials

Insects Eggs of *P. xuthus* were obtained from gravid females captured in the city of Kyoto, Japan. Larvae were raised on leaves of *C. unshiu* and other *Citrus* plants at 24± 2°C under a 16:8 hr, L:D photoperiod.

Bioassay Feeding stimulants were bioassayed after application to strips of two-ply toilet paper (Nepia premium soft roll double, Oji Nepia Co., Ltd., Tokyo, Japan, 20× 10 mm). Fifth instars of *P. xuthus* readily bit into and chewed the edges of the strips when these were treated with a crude extract of *C. unshiu*, sometimes biting off much of the edge material. They did not, however, consume significant areas of the strips, comparable to those eaten when feeding on a host-plant leaf. Our bioassay, therefore, was designed to isolate and identify attractants and stimulants responsible for the initiation of feeding. Other components, such as the "swallowing factors" identified by Hamamura and Naito (1961); Hamamura et al. 1962 as stimulants for larval feeding by silkworm larvae, *Bombyx mori*, on mulberry diets, may be required for continued food ingestion by *P. xuthus* larvae.

Each test extract, fraction or mixture of test compounds was applied at a given concentration to the test strip with a micro syringe. A similar volume of control solution (typically a solvent blank or a sugar blend) was added to a separate, control, strip. Doses were expressed as gram-leaf equivalents (g.l.e.) per test strip (200 mm^2). A last-instar larva of *P. xuthus* (12~48 hr after molting) was introduced into a Petri dish (20×90 mm i.d.) containing the test strip and a corresponding control strip (solvent blank). Dishes were kept for 24 hr (24±2°C, 16:8 hr, D:L photoperiod), after which feeding damage was measured. Since the larvae initiated feeding at the margins of the strips, the activity of a particular test sample could be estimated as the area of edge bitten off. Edge was considered to be a 1 mm wide band around the strip, 56 mm in length. There were thus 56 edge sections, each 1 mm^2 in area per ply, and a total of 112 sections per two-ply strip. Feeding was measured as number of sections losing more than half their area (0.5 mm^2) to insect biting and chewing activity. Differences in responses (counts) between the test and control strips were compared by a Wilcoxon rank sum test.

Instruments for Chemical Analysis Preparative HPLC was carried out at 40°C and monitored either with an SPD-20A UV/VIS detector (Shimadzu Corporation, Kyoto, Japan) or an RI-96 refractive index detector (Labo System, Tokyo, Japan). Negative and positive electrospray ionization-mass spectral (ESI-MS) measurements were carried out with an LCMS-2010EV instrument combined with an HPLC system (Shimadzu Corporation), using a reversed-phase column (Mightysil RP-18 GP 75–3.0, 3 μm; Kanto Chemical Co. Inc., Tokyo, Japan) eluted (0.2 ml/min) with a solvent gradient of 20–95% acetonitrile in water over 15 min at a column oven temperature of 40°C. High resolution-electron ionization (HR-EI)-MS data were obtained on a JEOL JMS700 mass spectrometer (Tokyo, Japan). Proton and carbon-13 nuclear magnetic resonance (^{1}H-NMR and ^{13}C-NMR) spectra were measured with a Bruker Avance 400 FT-NMR (Yokohama, Japan) and JEOL JNM-ECP 500 (Tokyo, Japan) using TMS as an internal standard (*J*-values given in Hz).

Extraction and Fractionation Fresh leaves of *C. unshiu* (Miyagawa-wase) were collected in Wakayama Prefecture in August 2005 and extracted with ethanol. The ethanolic extract (2.5 kg.l.e.) was dissolved in water and washed sequentially with ether and ethyl acetate (Fig. 1). The water layer (30.0 g, 500 g.l.e.) was chromatographed on a reverse-phase column (Cosmosil 140C18-OPN, 140 μm, Nacalai tesque, Inc., Kyoto, Japan), eluted with water (Fr. 1A, yield 17.9 g), 10% methanol (Fr. 1B, 771 mg), 20% methanol (Fr. 1C, 1.02 g), 40% methanol (Fr. 1D, 1.84 g), 60% methanol (Fr. 1E, 563 mg), 80% methanol (Fr. 1F, 87 mg), and methanol (Fr. 1G, 363 mg). Fr. 1E was rechromatographed on a reverse-phase column (Cosmosil

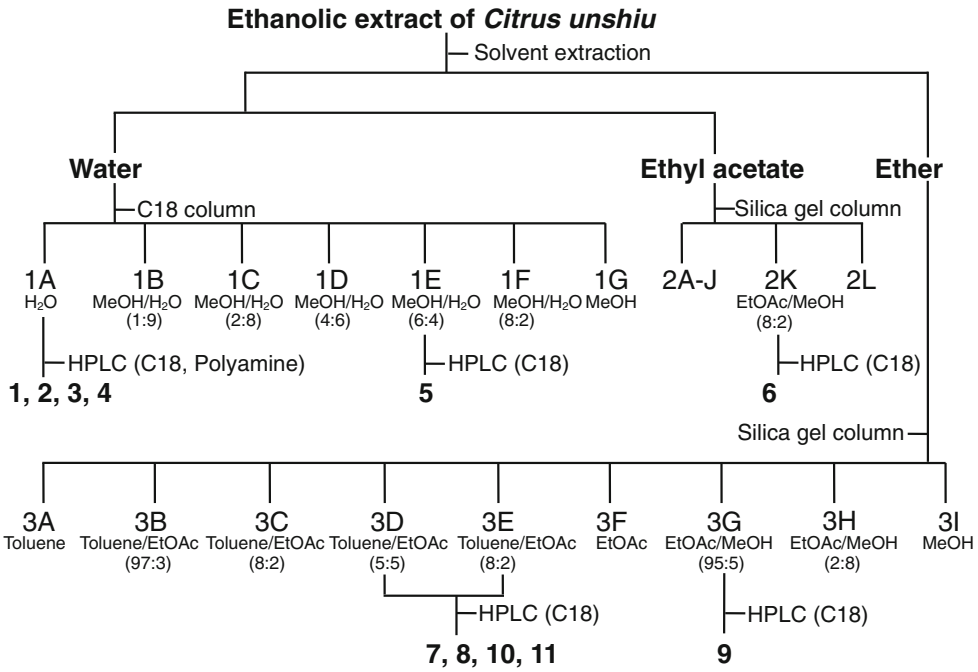

Fig. 1 Procedure for separating feeding stimulants (**1**–**11**) for *Papilio xuthus* larvae from an ethanolic extract of *Citrus unshiu* leaves

140C18-OPN, 140 μm), to separate it into 13 fractions, eluted with a solvent gradient of 40–60% methanol in water.

The ethyl acetate layer (1.76 g, 1 kg.l.e.) was chromatographed on a normal-phase silica gel column (Wakogel C-200, 75–150 μm, Wako Pure Chemical Industries, Ltd., Osaka, Japan), eluted successively with toluene (Fr. 2A, 24 mg), 2% ethyl acetate/toluene (Fr. 2B, 21 mg), 5% ethyl acetate/toluene (Fr. 2C, 17 mg), 15% ethyl acetate/toluene (Fr. 2D, 37 mg; Fr. 2E, 45 mg), 40% ethyl acetate/toluene (Fr. 2F, 96 mg; Fr. 2G, 42 mg), 75% ethyl acetate/toluene (Fr. 2H, 115 mg), ethyl acetate (Fr. 2I, 132 mg; Fr. 2J, 98 mg), 20% methanol/ethyl acetate (Fr. 2K, 209 mg), and methanol (Fr. 2L, 511 mg).

A portion of the ether layer (9.1 g, 500 g.l.e.) was chromatographed on a silica gel column (Wakogel C-200, 75–150 μm), eluted with toluene (Fr. 3A, 4.05 g), 3% ethyl acetate/toluene (Fr. 3B 143 mg), 20% ethyl acetate/toluene (Fr. 3C, 1.30 g), 50% ethyl acetate/toluene (Fr. 3D, 696 mg), 80% ethyl acetate/toluene (Fr. 3E, 269 mg), ethyl acetate (Fr. 3F, 129 mg), 5% methanol/ethyl acetate (Fr. 3G, 135 mg), 20% methanol/ethyl acetate (Fr. 3H, 1.28 g), and methanol (Fr. 3I, 375 mg).

HPLC Separation of Compounds **1**–**11** Fraction 1A was chromatographed on a reverse phase HPLC column (YMC-Pack ODS-AQ, 250×10 mm i.d., YMC Ltd., Kyoto, Japan) eluted with water at a flow rate of 2.0 ml/min, and separated into two fractions: *R*t (retention time)=0–6.5 min; *R*t=6.5–8.0 min. These were chromatographed further on a YMC-Pack Polyamine II column (250×10 mm i.d., YMC Ltd.) with 75% acetonitrile at a flow rate of 2.0 ml/min. Compound **1** was isolated at *R*t=37.0 min (2.8 mg/g.l.e.); **2** at *R*t=30.0 min (1.0 mg/g.l.e.); **3** at *R*t=54.5 min (2.1 mg/g.l.e.); **4** at *R*t=20.5 min (0.79 mg/g.l.e.). Fr. 1E (60% methanol eluate, 26 mg) was chromatographed on a reverse phase HPLC column (YMC-Pack ODS-AM, 300×10 mm i.d., YMC Ltd.) eluted with 70% methanol in water at a flow rate of 2.0 ml/min, and **5** was isolated at *R*t=17.4 min (10 μg/g.l.e.).

Fraction 2 K was chromatographed on a reverse-phase Prep Pak Cartridge 25×100 mm column (Prep Nova-Pak HR C18, 6 μm, 60Å, Waters, Milford, MA, USA) eluted with 60% methanol in water at a flow rate of 3.0 ml/min, and **6** was isolated at *Rt*=38.0 min (3.8 μg/g.l.e.) (Fig. 1).

A series of lipidic components in Fr. 3D and Fr. 3E were recovered from the ether soluble fractions. They were fractionated by a reverse phase HPLC column (Cosmosil MS-II, 250×20 mm i.d., Nacalai tesque Inc.), eluted with 90% methanol in water at a flow rate of 2.0 ml/min. Compounds **7**, **8**, and **11** were isolated at *R*t=63.0 min (96.0 μg/g.l.e.), *R*t=79.0 min (13.2 μg/g.l.e.) and *R*t=105 min (2.8 μg/g.l.e.), respectively. Compound **10** was obtained mainly from Fr. 3D employing a preparative HPLC column (YMC-Pack Pro C18, 250×10 mm i.d., YMC Ltd.) eluted with 90% methanol in water at a flow rate of 2.0 ml/min [isolated at *R*t=32.5 min (11.8 μg/g.l.e.)]. Fraction 3G was chromatographed on a reverse-phase Prep Pak Cartridge 25×100 mm column (Prep Nova-Pak HR C18, 6 μm, 60Å, Waters) using methanol at a flow rate of 3.0 ml/min, and a fraction in a range of *R*t=28–36 min was isolated. This was further chromatographed on a reverse phase HPLC column (YMC-Pack Pro C18, 250×10 mm i.d., YMC Ltd.), eluted with methanol at a flow rate of

2.0 ml/min. Compound **9** was isolated at *R*t=19.1 min (63.4 μg/g.l.e.).

Authentic Samples for Bioassays Compounds **1**, **2**, and **3** (D-glucose, D-fructose, and D-sucrose) were purchased from Wako Pure Chemical Industries, Ltd. Compound **8** (1-linoleoyl-rac-glycerol, approx. 99%) from Sigma Aldrich Japan (Tokyo, Japan). Compounds **10** (glycerol α-monooleate) and **11** (monostearin) were purchased from Kanto Chemical Co. Inc. (Tokyo, Japan), and they were used after purification by HPLC. Other compounds (**4**, **5**, **6**, **7**, and **9**) used for bioassay were obtained from *C. unshiu* leaves (as described above, purity>98%). Standard samples of 1,3-dioleoylglycerol, linolenic acid, and glycerol were purchased from Wako Pure Chemical Industries, Ltd. and trioleoylglycerol (triolein) was purchased from Kanto Chemical Co. Inc.

Results

Larval Feeding Stimulant Activity of Fractions An ethanolic extract of *C. unshiu* was fractionated systematically, and the feeding-stimulant activity of fractions monitored with the paper-strip bioassay, as shown in Fig. 1. The feeding-stimulant activities of the ethanolic extract, ether layer, ethyl acetate layer, and individual chromatographic fractions are shown in Fig. 2. The ethanolic extract showed the highest activity, whereas individual fractions were much less active. Only Fr. 1A and Fr. 1E induced significant feeding responses among the column chromatography fractions (Fr. 1A-1G, Fig. 2). A series of sugars (**1**, **2**, and **3**), amino acids, organic acids (e.g., quinic acid), a basic compound (synephrine), glycerol and an amphoteric compound (**4**) were isolated from Fr. 1A. Sugars **1**, **2**, and **3**, found to be essential ingredients for stimulating larval feeding, were identified as D-glucose, D-fructose, and D-sucrose, respectively (Fig. 3), from their diagnostic ^{1}H-NMR, ^{13}C-NMR spectra and by comparison of these with authentic samples. The activity of the sugar blend (**1**+**2**+**3**) was significantly enhanced by **4** (Fig. 4). Compound **4** was identified as stachydrine by comparison of ^{1}H- and ^{13}C-NMR spectral data (Ohsugi et al., 1991) (Fig. 3). The activity of the sugar blend (**1**+**2**+**3**) was also synergized by compound **5**, isolated from Fr. 1E (Fig. 4), which was identified as a cyclic peptide, citrusin I (Fig. 3).

Citrusin I (**5**): A colorless amorphous powder. ESI-MS *m/z* $[M + H]^+$ 704, ^{1}H-NMR (500 MHz, CD_3OD): δ 0.94 (3H, t, *J*=6.5 Hz), 0.96 (3H, d, *J*=7 Hz), 0.98 (3H, d, *J*=7 Hz), 1.08 (3H, d, *J*=6.5 Hz), 1.16 (3H, d, *J*=6.5 Hz), 1.27 (m), 1.53 (d, *J*=7 Hz), 1.55–1.69 (4H, m), 1.87 (1H, m), 3.01 (1H, dd, *J*=14, 6 Hz), 3.24 (1H, dd, *J*=14, 6 Hz), 3.47 (1H, d, *J*=16.5 Hz), 3.89 (1H, d, *J*=7.5 Hz), 3.99 (1H, m), 4.00 (1H, d, *J*=7 Hz), 4.14 (1H, d, *J*=16.5 Hz), 4.36 (1H, d, *J*=3 Hz), 4.49 (1H, m), 4.53 (2H, d, *J*=3 Hz), 4.81 (1H, d, *J*=6 Hz), 7.26 (5H, m); ^{13}C-NMR (125 MHz, CD_3OD): δ 176.1, 174.8, 174.0, 173.6, 173.6, 173.0, 172.0, 138.6, 131.1, 129.9, 128.1, 70.3, 68.0, 61.1, 60.7, 60.7, 56.2, 53.1, 52.5, 44.4, 41.8, 38.0, 37.4, 27.3, 26.4, 23.9, 21.7, 20.6, 20.4, 16.8, 16.0, 11.6. ^{1}H- and ^{13}C-NMR data are consistent with reports from Matsubara et al. (1991).

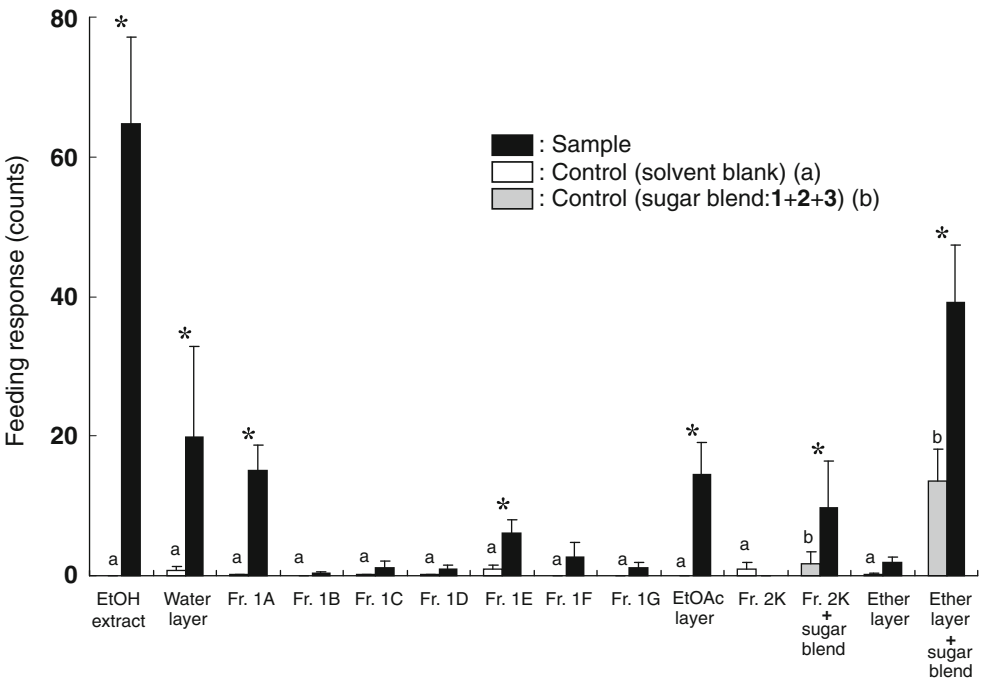

Fig. 2 Feeding stimulant activities of fractions from a *Citrus unshiu* extract in bichoice tests with paper strips a: control (solvent blank), b: control (**1**+**2**+**3**) [Sample dose: 0.05 g leaf equivalent/strip] *: Wilcoxon rank sum test: $P<0.05$, $N=9$ for each paired test, mean ± SE

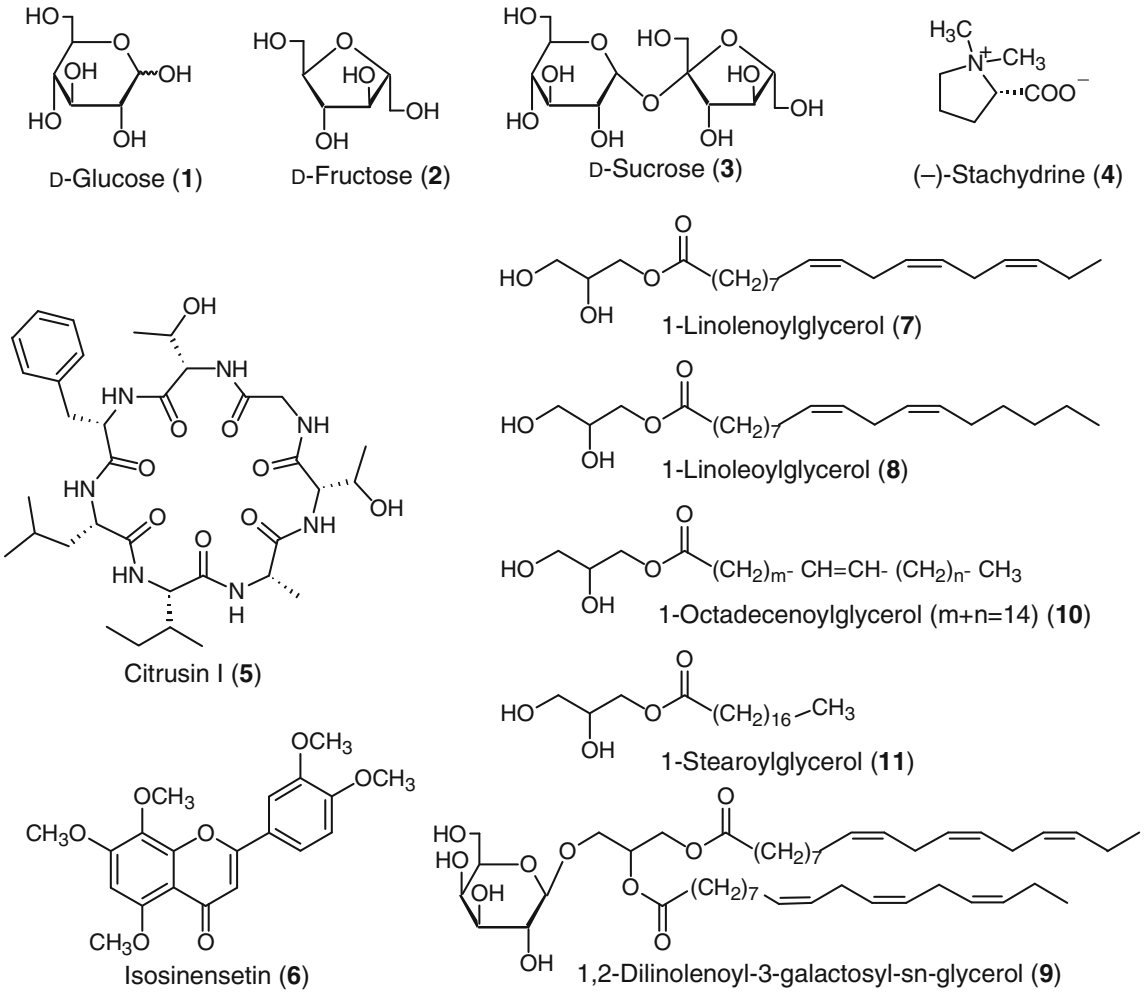

Fig. 3 Structures of larval feeding stimulants (**1**–**11**) of *Papilio xuthus* isolated from leaves of *Citrus unshiu*

Although the ethyl acetate layer showed moderate activity, there were no active fractions among Frs. 2A-2L. When each fraction was tested in combination with the sugar blend, only fraction 2K enhanced activity (Fig. 2). A polymethoxyflavone, isosinensetin (**6**) (Fig. 3), was characterized from fraction 2K and synergized the activity of the sugar blend (**1**+**2**+**3**) significantly (Fig. 4).

Isosinensetin (**6**): A light brown amorphous powder. ESI-MS *m/z* $[M + H]^+$ 373, ^{1}H-NMR (400 MHz, CD_3OD): δ 7.59 (1H, dd, *J*=8.5, 2 Hz), 7.42 (1H, d, *J*=2 Hz), 7.28 (1H, s), 6.99 (1H, d, *J*=8.5 Hz), 4.02 (3H, s), 3.99 (3H, s), 3.98 (3H, s), 3.96 (6H, s). ^{13}C-NMR (100 MHz, CD_3OD): δ 177.8, 160.5, 156.4, 156.2, 151.8, 151.7, 149.1, 130.5, 123.8, 119.4, 111.0, 108.7, 108.3, 106.9, 92.3, 61.3, 56.4, 56.1, 55.9, 55.8. ^{1}H- and ^{13}C-NMR data were consistent with reports by Machida and Osawa (1989).

The activity of a mixture of the six compounds (**1**+**2**+**3**+**4**+**5**+**6**) was appreciably lower than that of the crude ethanolic extract, indicating the presence of one or more additional components in other fractions (Fig. 4). The ether layer, which exhibited marginal activity alone, strongly enhanced activity of the sugar blend (**1**+**2**+**3**) (Fig. 2). After separation on a silica gel column into nine fractions (3A-3I, Fig. 1), the strongest synergistic activity was found in fractions 3D, 3E, and 3 G (Fig. 5). Compounds **7** and **8** were isolated as the two major constituents in fractions 3D and 3E. Compound **9** was characterized from fraction 3G. These compounds, entirely inactive alone, each showed significant activity when mixed with the sugar blend (Fig. 4). Compounds **7**, **8**, and **9** were identified as 1-linolenoylglycerol, 1-linoleoylglycerol, and 1,2-dilinolenoyl-3-galactosyl-sn-glycerol, respectively, by their mass spectra and ^{1}H- and ^{13}C-NMR spectra, as shown below (Fig. 3). In addition, compounds **10** and **11,** relatively minor constituents of fractions 3D and 3E, were identified as a 1-octadecenoylglycerol (tentatively identified as 1-oleoylglycerol without confirmation of the position of unsaturation) and 1-stearoylglycerol by comparison of the spectral data with those of authentic samples of 1-monoolein and 1-monostearine, respectively (Fig. 6).

1-Linolenoylglycerol (**7**): A colorless viscous oil. HR-EI-MS *m/z* [M^+] 352.2615 (calcd. for 354.2615). ^{1}H-NMR (400 MHz, $CDCl_3$): δ 5.34 (6H, m), 4.15 (1H, dd, 12, J= 6.5 Hz), 4.12 (1H, dd, J=12, 6.5 Hz), 3.90 (1H, m), 3.66 (1H, dd, J=11.5, 3.5 Hz), 3.57 (1H, dd, J=11.5, 6 Hz), 2.78 (4H, m), 2.32 (2H, t, J=8 Hz), 2.04 (4H, m), 1.60 (2H, m), 1.20–1.35 (8H, m), 0.95 (3H, t, J=7.5 Hz); ^{13}C-NMR (100 MHz, $CDCl_3$):δ 174.5, 132.0, 130.3, 128.4, 128.3, 127.8, 127.2, 70.3, 65.2, 63.4, 34.2, 29.6, 29.2, 29.2, 29.2, 27.3, 25.7, 25.6, 24.9, 20.6, 14.4. ^{1}H- and ^{13}C-NMR data are consistent with reports by Fraser et al. (2007).

1-Linoleoylglycerol (**8**): A colorless viscous oil. HR-EI-MS *m/z* [M^+] 354.2768 (calcd. for 354.2771). ^{1}H-NMR (400 MHz, $CDCl_3$): δ 5.36 (4H, m), 4.20 (1H, dd, J=11.5, 4.5 Hz), 4.16 (1H, dd, J=11.5, 6 Hz), 3.93 (1H, m), 3.70 (1H, dd, J=11, 5 Hz), 3.60 (1H, dd, J=11, 5 Hz), 2.77 (2H, t, J=6.5 Hz), 2.35 (2H, t, J=7.5 Hz), 2.05 (4H, m), 1.64 (2H, m), 1.25–1.40 (14H, m), 0.89 (3H, t, J=6.5 Hz); ^{13}C-NMR (100 MHz, $CDCl_3$): δ 174.3, 130.2, 130.0, 128.1, 127.9, 70.3, 65.2, 63.3, 34.1, 31.5, 29.6, 29.3, 29.1, 29.1, 29.1, 27.2, 27.2, 25.6, 24.9, 22.6, 14.1. ^{1}H- and ^{13}C-NMR data are consistent with reports from Kim et al. (2003).

1,2-Dilinolenoyl-3-galactosyl-sn-glycerol (**9**): A colorless viscous oil. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 5.36 (12H, m), 4.39 (1H, dd, J=12, 3 Hz), 4.26 (1H, d, J=7.5 Hz), 4.20 (1H, dd, J=12, 6.5 Hz), 4.02 (1H, m), 3.91 (1H, dd, J=11, 5 Hz), 3.85 (2H, m), 3.71 (1H, dd, J=11, 6.5 Hz), 3.66 (1H, d, J=7.5 Hz), 3.60 (1H, m), 3.54 (1H, t, J=5.5 Hz), 2.80 (8H, m), 2.31 (4H, m), 2.06 (8H, m), 1.60 (4H, m), 1.30 (16H, m), 0.97 (6H, t, J=7.5 Hz). ^{13}C-NMR (100 MHz, $CDCl_3$): δ 173.9, 173.5, 131.9, 130.2, 128.3, 128.2, 127.8, 127.1, 104.0, 74.6, 73.5, 71.3, 70.2, 69.1, 68.1, 62.9, 62.0, 34.3, 34.1, 29.6, 29.6, 29.2, 29.2, 29.1, 29.1, 27.2, 25.6, 25.5, 24.9, 24.8, 20.5, 14.3. ^{1}H- and ^{13}C-NMR data are consistent with reports by Sachdev-Gupta et al. (1993) and Jassbi (2003).

Larval Feeding Stimulant Activity of Constituents The nine major feeding stimulants (**1**–**9**) (Fig. 3), characterized by the systematic bioassay of fractions from *C. unshiu* leaf extracts, were tested in various combinations to assess their

activity to *P. xuthus* larvae (Fig. 4). No individual component stimulated feeding by itself when assayed at the concentration found in the crude ethanolic extract of *C. unshiu* (data for **1**, **2**, **3**, **7**, and **9** not shown in Fig. 4). A mixture of the three sugars (**1**+**2**+**3**) had little activity alone but was strongly synergized by any of the non-sugar compounds (**4**, **5**, **6**, **7**, **8**, and **9**) (Fig. 4). A mixture of **4**, **5**, and **6** was inactive alone but showed moderate activity when combined with the sugar blend (**1**+**2**+**3**+**4**+**5**+**6**). A blend of the three lipids (**7**+**8**+**9**) showed low activity but this was significantly enhanced by addition of the sugar blend (**1**+**2**+**3**) (Fig. 4). The two sugarless mixtures **4**+**5**+**6**+**7**+**8** and **4**+**5**+**6**+**7**+**8**+**9** were both significantly more active than the sugar blend (Fig. 4). A mixture with sugar **1**+**2**+**3**+**4**+**5**+**6**+**7**+**8** showed much higher activity than that of the sugarless mixture (**4**+**5**+**6**+**7**+**8**), (Welch's *t*-test, $P<0.05$). A mixture of all the components (**1**–**9**) showed the highest activity, comparable to that of the crude ethanolic extract (Fig. 4).

In a separate pairwise bioassay, activity of the whole mixture (**1**+**2**+**3**+**4**+**5**+**6**+**7**+**8**+**9**) was compared again with that of the crude ethanolic extract. The activity of the mixture [biting counts (mean ± SD): 37.8±9.0] did not differ significantly from that of the ethanolic extract [biting counts: 38.8±9.9] (Wilcoxon rank sum test $P>0.05$, $N=10$, dose: 0.5 g.l.e./strip) (not shown in Fig. 4).

To examine the synergistic effect of the secondary substances (**4**+**5**+**6**) on the primary sugars (**1**+**2**+**3**) and lipids (**7**+**8**+**9**), feeding responses to the mixture of primary compounds (**1**+**2**+**3**+**7**+**8**+**9**) in the presence and absence of the secondary substances (**4**+**5**+**6**) were compared in a pairwise test. Biting counts were significantly higher in the presence of the secondary substances [mean ± SE: 29.4±5.2] than in their absence [13.5±4.1] (Wilcoxon rank sum test $P<0.05$, $N=12$, dose: 0.5 g.l.e./strip) (not shown in Fig. 4).

Larval Feeding Stimulant Activity of Lipids In addition to compounds **7**, **8**, and **9**, several other lipid constituents of the ether soluble fraction of *C. unshiu* leaves were tested for feeding-stimulant activity with the pairwise paper-strip bioassay. These included the two additional minor monoacylglycerols, **10** and **11** (together accounting for approximately 12% of total 1-monoacylglycerol content), authentic diacylglycerol, triacylglycerol, a free fatty acid, and glycerol, as shown in Fig. 6. Only the monoacylglycerols (**10** and **11**) exhibited significant activity in the presence of sugars (**1**+**2**+**3**) (Fig. 6).

Discussion

In this study, we characterized 11 larval feeding-stimulant components for *P. xuthus* from its major host, *C. unshiu*. These were three sugars (**1**–**3**), a betaine (**4**), a cyclic peptide (**5**), a polymethoxyflavone (**6**), and five lipids (**7**–**11**) (Fig. 3). No individual component alone elicited a feeding response but typical feeding activity was stimulated in varying degrees by the synergistic actions of some of the individual components on the other components of the mixture (Figs. 4 and 6). Sugars (**1**+**2**+**3**) seem to provide a basic taste stimulus, while the rest of the components (**4**–**11**) effectively "seasoned" the sugar taste to varying extents. It also was noted that a mixture of lipids (**7**+**8**+**9**) alone exhibited significant stimulant activity, further enhanced by a mixture of secondary substances (**4**, **5**, and **6**), even in the absence of sugars (Fig. 4).

(−)-Stachydrine (**4**), an effective synergist on sugars (**1**+**2**+**3**), is an amphoteric compound found in quantities as high as 800 μg/g.l.e. in *C. unshiu* leaves. This compound is known to occur especially in *Citrus*, alfalfa, *Chrysanthemum*, and *Stachys* species, and was characterized earlier as one of the oviposition stimulants of *P. xuthus* from *C. unshiu* (Ohsugi et al., 1991, and refs therein).

Citrusin I (**5**) is a unique cyclic peptide composed of seven amino acids that contain a hydrophobic amino acid sequence, phenylalanine-isoleucine-leucine-alanine. Similar cyclic peptides are known as constituents of various *Citrus* species, although their biological function in plants is unknown (Matsubara et al., 1991; Matsumoto et al., 2001, 2002; Morita et al., 2007). Cyclic oligopeptides are known also from other plant taxa (Annonaceae, Caryophyllaceae, Lamiaceae, Linaceae, Rubiaceae, etc.), but their overall distribution in plants is still poorly known.

Isosinensetin (**6**) (3′,4′,5,7,8-pentamethoxyflavone) is one of polymethoxyflavones widely distributed in *Citrus* plants (Machida and Osawa, 1989; Mizuno et al., 1991; Sugiyama et al., 1993; Hirata et al., 2009). Although *C. unshiu* leaves contained several additional polymethoxyflavones, two positional isomers of **6** isolated during fractionation in the present study, namely tangeritin (4′,5,6,7,8-pentamethoxyflavone) and sinensetine (3′,4′,5,6,7,-pentamethoxyflavone), were inactive when compared at the same dose (5 μg/strip) in the presence of sugars (**1**+**2**+**3**). This indicates fairly narrow specificity in the structural requirement for polymethoxyflavone stimulation in *P. xuthus* larvae (T. Murata and R. Nishida, unpublished).

It was surprising that 1-monoacylglycerols (**7**, **8**, **10**, and **11**) and monogalactosyldiacylglycerol (MGDG, **9**) played a central role as potent synergists. 1-Monoacylglycerols are known to coexist with triglycerides as minor components in plants (Dayrit et al., 2008). We have identified lipids **7** and **8** in leaves of another favorite larval host of *P. xuthus*, *Zanthoxylum piperitum* (Rutaceae), in a non-host *Orixa japonica* (Rutaceae), and in carrot *Daucus carota* (Apiaceae) in substantial quantities (unpublished data), suggesting that 1-monoacylglycerols may be present universally among

larval host plants of several *Papilio* species. As shown in Fig. 6, diacyl and triacylglycerols, and corresponding free carboxylic acids, were entirely inactive in combination with sugars, demonstrating the high specificity of the monoacylglycerol structure. The number of double bonds on the fatty acid moiety did not affect the activity (Figs. 4 and 6). MGDG (**9**) is present ubiquitously in the chloroplast as a major membrane lipid consisting of diacylglycerol with a galactosyl moiety (Roughan and Batt, 1969; Joyard et al., 1998; Ohta et al., 2000). Although the molecular structure of **9** has no direct similarity to that of the monoacylglycerols, the compounds may share surfactant properties (Selmair and Koehler, 2008). MGDG was reported as an oviposition stimulant component for a pipevine swallowtail butterfly, *Battus philenor*, together with aristolochic acids (Sachdev-Gupta et al., 1993). Insects are capable of synthesizing many fatty acids and these may not be required as fundamental dietary ingredients, but polyunsaturated fatty acids are essential to many insects as a dietary source (Nation, 2002). The responses to such compounds, as well as to mono- and disaccharides, as feeding stimulants may provide *P. xuthus* larvae with the ability to assess the quality and/or quantity of essential dietary nutrients in plant tissues.

The strong affinity toward essential nutrients can be observed universally throughout the animal kingdom; sugars and amino acids in particular are known as general feeding stimulants in herbivorous insects, where the larvae develop specific receptors tuned for these primary substances (Bernays and Simpson, 1982; Schoonhoven et al., 2005). However, we could not detect any prominent activity in amino acid fractions by using our paper-strip bioassay method. *Citrus unshiu* leaves contain an extraordinarily high quantity of L-proline (0.64 mg/g.l.e.) along with its *N*,*N*-dimethyl analog, stachydrine (**4**), but L-proline exhibited no synergistic activity on the sugar mixture (**1**+**2**+**3**) [biting counts: control (**1**+**2**+**3**) 0.67±0.47, sample (**1**+**2**+**3**+ L-proline 0.89±0.67]. Interestingly, another Rutaceae-feeding swallowtail, *P. protenor*, uses both stachydrine (**4**) and proline as oviposition stimulants in *C. unshiu* (Honda, 1990).

Coincidence of chemical profiles between larval feeding stimulants and oviposition stimulants has been shown in several butterfly taxa. Examples are glucosinolates as stimulants for cabbage butterflies, *Pieris* spp. (Pieridae, host Brassicaceae), iridoid glycosides for the buckeye, *Junonia coenia* (Nymphalidae, host Scrophulariaceae etc.), and aristolochic acids for a pipevine swallowtail, *Atrophaneura alcinous* (Papilionidae, host Aristolochiaceae) (Verschaffelt, 1910; David and Gardiner, 1962; Renwick and Lopez, 1999; Renwick, 2002; Bowers, 1984; Pereyra and Bowers, 1988; Nishida and Fukami, 1989a, b). These patterns suggest a possible congruency of chemosensory mechanism developed in both the gustatory receptors on the mouthparts of larvae and the tarsal receptors of adult females that perceive specific host chemicals. In the case of *P. xuthus*, ten oviposition stimulants identified from *C. unshiu* include flavonoid glycosides (vicenin-2, hesperidin, narirutin, rutin), a nucleoside (adenosine), protoalkaloids (5-hydroxy-*N*ω-methyl-tryptamine, bufotenine, synephrine), a cyclitol (*chiro*-inositol), and a betaine (stachydrine). Only stachydrine (**4**) has been identified as both a larval feeding and an oviposition stimulant. Unlike polymethoxyflavone **6**, flavonoid glycosides with oviposition stimulant activity did not seem to stimulate larval feeding, since the corresponding fractions (i.e., 1C, and 1D in Fig. 1) were totally inactive in the paper strip assay (Fig. 2). We also have tested other major oviposition stimulant components, such as synephrine and *chiro*-inositol, for feeding-stimulant activity but the results appeared negative when tested in combination with sugars (**1**+**2**+**3**) at the given dose (0.5 g.l.e./strip) (unpublished). These findings suggest that adults and larvae of *P. xuthus* may differ in their chemosensory mechanisms for host recognition, although the chemical bases of neither oviposition stimulants nor larval feeding stimulants in the *P. xuthus*—*C. unshiu* association have been fully elucidated (Nishida, 2005). As hypothesized by Wiklund (1975), the difference in host preferences between the egg-laying female and feeding larvae of the Apiaceae-feeding swallowtail, *P. machaon*, may be determined by separate gene complexes. By contrast, however, a congruent chemosensory mechanism in *P. xuthus* has been suggested by the rejection of allomonal chemicals contained in a non-host rutaceous plant, *O. japonica*, where two specific hydroxybenzoic acid derivatives commonly act as potent deterrents on both female tarsal chemoreceptors and larval maxillary taste receptors (Ono et al., 2004; Nishida, 2005).

Although both oviposition and larval feeding are controlled by multiple chemical factors in *P. xuthus*, all of the ten oviposition stimulants are regarded as secondary metabolites. By contrast, of the 11 larval feeding stimulants identified in the present study, only three (**4**, **5,** and **6**) can be considered as secondary while the other eight (**1**, **2**, **3**, **7**, **8**, **9**, **10,** and **11**) are primary metabolites. This contrast in the patterns of chemosensory cues used by larvae and adults presumably reflects divergent selective pressures acting on the two different life-history stages. Reliance by adult females on unique chemical profiles of secondary compounds is likely to facilitate the location and recognition of individual host plants within diverse plant communities. Responses to ubiquitous primary metabolites presumably would be less useful for the females, except perhaps as supplementary cues for leaf choice and egg placement on the host plant. Once the *P. xuthus* female lays an egg on a *Citrus* plant, the hatched larva usually stays on

the same shrub or tree throughout all the larval stages and typically does not seek another food plant. Unique secondary compounds thus may be less critical for larval feeding than are primary compounds such as sugars and lipids that may facilitate the choice of foliage more favorable for larval growth and survival within the host shrub or tree. This contrast in host-recognition profiles for adults and larvae may differ for herbaceous feeders, such as the pipevine swallowtail, *A. alcinous*, whose larvae must seek new host-plant patches after the original plant is entirely consumed. For both larvae and ovipositing females of this species, aristolochic acids function as a major host-finding cue (Nishida and Fukami, 1989a).

The complexities of host recognition and feeding stimulation in lepidopteran larvae initially were demonstrated for the silkworm moth, *Bombyx mori*. Larval feeding behavior in this species is controlled by three distinct factors: attractants (e.g., citral, linalool, 3-hexenol), biting factors (e.g., isoquercitrin, β-sitosterol), and swallowing factor (cellulose) in addition to co-factors (e.g., sucrose, *myo*-inositol, inorganic phosphate) (Hamamura and Naito, 1961, Hamamura et al., 1962). A recent study revealed an olfactory receptor protein responsible for detection of a key mulberry leaf volatile, jasmone (Tanaka et al., 2009). Although our paper-strip bioassay did not provide any indications of an involvement of olfactory cues in feeding by *P. xuthus* larvae, the importance of specific host-plant volatiles prior to feeding has been demonstrated in the lemon butterfly, *P. demoleus* (Saxena and Prabha, 1975). Dethier (1941) found that larvae of the black swallowtail, *P. polyxenes*, were attracted by certain volatiles in plants of the Apiaceae and Rutaceae and speculated that these volatiles may have facilitated host shifts by some *Papilio* species from the Rutaceae to the Apiaceae. Similarly, a resemblance of underlying phytochemical cues appears to have facilitated host shifts from the Apiaceae to the Asteraceae in species of the *Papilio machaon* group (Murphy and Feeny, 2006). Elucidation of olfactory and gustatory chemical cues and their chemosensory mechanisms of host recognition both at egg-laying and larval feeding will contribute to understanding the evolution of host selection in these closely related oligophagous *Papilio* species.

Acknowledgements The authors thank Mr. S. Sato and Mr. T. Matsuki of Tohoku Pharmaceutical University for HR-EI-MS measurements, and Mr. Fumio Kodama for the supply of *Citrus unshiu* leaves. We also thank Prof. P. P. Feeny of Cornell University for useful comments and reviewing the manuscript. This work was partially supported by the Grant-in-Aid for Scientific Research from JSPS (No. 19310142) and a Grant-in-Aid for the 21st Century COE Program for Innovative Food and Environmental Studies Pioneered by Entomomimetic Sciences, from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

them (Chen and Dorn, 2009). Despite these similarities, infestation by the highly invasive pest *G. molesta* has not been reported on Juglandaceae or other plants that contain naphthoquinones, in contrast to the codling moth, which thrives on walnut (Phillips and Barnes, 1975; Piskorski and Dorn, 2011). Juglone contents in walnut fluctuate over the season (Radix et al., 1998; Colaric et al., 2005; Solar et al., 2006; Stampar et al., 2006), and survival rates of the codling moth were high at the lower juglone level and moderate at the higher level reported for this plant species. Concentrations of juglone that were double the maximum juglone content in walnut were lethal to the codling moth larvae (Piskorski and Dorn, 2011), indicating that detoxification is limited even in a herbivorous species adapted to walnut (Barnes, 1991) and its naphthoquinones. We hypothesized that the oriental fruit moth may be unable to detoxify juglone, thus limiting its potential to use walnut as a host. However, by using performance bioassays we showed that *G. molesta* can survive on a diet containing juglone, and chemical analysis of larval frass suggests the ability of this species to reduce this compound in its digestive tract.

Methods and Materials

Insects Larvae of the oriental fruit moth were collected from a peach orchard in Trentino, Italy, in 2007 and reared in the laboratory under controlled conditions [16 : 8 hL:D cycle at 26/24°C and 60% relative humidity (r.h.)]. Upon emergence, the adults were transferred to a paper cylinder with moist cotton (Hern and Dorn, 1999). Neonate larvae were transferred to Petri dishes and allowed to feed on an artificial diet as specified below. Corrugated cardboard strips were offered for pupation. Unfed first-instars (24± 12 h-old) were used for bioassays.

Artificial Diet The diet offered to larvae was a soya flour-based artificial diet devoid of any fruit material, used in mass rearing of the oriental fruit moth in our laboratory (Torriani et al., 2010). Juglone was added at the end of diet preparation; the diet was homogenized and distributed into plastic Petri dishes of 55-mm diam to yield a 4-mm thick layer (Piskorski and Dorn, 2011). Juglone (purity≥97%; Sigma-Aldrich, Buchs, Switzerland) was added to the diet at concentrations of 5, 25, and 50 mg/g dry weight (d.w.), with the first two concentrations corresponding to the minimum and maximum of the seasonally fluctuating juglone content in walnut husks (Radix et al., 1998; Stampar et al., 2006; Piskorski and Dorn, 2011). The diet was prepared directly prior to conducting the bioassay. Juglone was stable throughout the diet preparation and bioassay (Piskorski and Dorn, 2011).

Effect of Juglone on G. molesta Performance First-instar larvae of *G. molesta* (N=30–34 per juglone concentration) were placed individually with a fine brush into Petri dishes with artificial diet containing juglone or with juglone-free diet (Piskorski and Dorn, 2011). Insects were allowed to develop under controlled conditions with a 16 : 8 hL:D cycle at 26/24°C and 60% r.h. Corrugated cardboard strips were attached to the inner wall of each Petri dish lid after 7 d of feeding to allow for pupation.

Development was monitored daily from day 7 onwards, i.e., before the larvae were expected to terminate feeding prior to pupation. Larval developmental time was recorded as the number of days from introduction of the larva onto the diet until its entry into the cardboard strip for pupation. Pupal developmental time was recorded as the period between larval entry into the cardboard strip and adult emergence, thus including any non-feeding prepupal stage the larva may have undergone (Notter-Hausmann and Dorn, 2010; Piskorski and Dorn, 2011). Larval survival was assessed as the proportion of individuals that entered the cardboard strip in relation to those that had been introduced as first-instar larvae. Pupal survival was assessed as the proportion of emerged adults in relation to the number of individuals that had entered the strip (Notter-Hausmann and Dorn, 2010; Piskorski and Dorn, 2011).

To track sublethal effects, the weight of adults was recorded upon emergence (Velten et al., 2007; Piskorski and Dorn, 2011); within 24 h of emergence the adults were killed by freezing, dried for 24 h in a 60°C oven, and weighed. To determine the larval weight gain, fresh weights of larvae were recorded on the 9th day of feeding (Piskorski and Dorn, 2011), i.e., when all larvae were still feeding and none had yet entered the non-feeding prepupal stage.

Fate of Juglone To follow the fate of juglone in insects feeding on the diet that contained juglone at 25 mg/g d.w. the following samples were analyzed: (1) frass, which was collected only from larvae (N=8), which successfully entered the pupal stage; (2) larval regurgitant (N=12), collected by gently touching the head with a micropipette and collecting the fluid; (3) larval hemolymph (up to 1 µl from each larva; N=12), collected with a micropipette directly from each insect after cutting its cuticle from head to abdomen on the ventral side; (4) fed late-instars, i.e., larvae containing filled guts (N=12); (5) starved late-instars (N=6), which were placed for 17 h in Petri dishes, devoid of any food, on humid filter paper to empty their gut prior to analysis; (6) pupae (5–7 d-old; N=8); (7) newly emerged adults (N=12) (Piskorski and Dorn, 2011). Samples (2)–(5) were collected after a 9-d-feeding period. Samples (1), (2), and (7) (frass, regurgitant, and adults) were taken from insects subjected to the performance trial, whereas samples (3)–(6) (body tissues) were prepared in a separate trial.

Insects were killed by freezing, freeze-dried, and ground before extraction. Samples of each type were pooled. All samples were extracted twice with a $CHCl_3$:MeOH (2:1) mixture (5 ml, or 0.5 ml for regurgitant and hemolymph, 10 min sonication) (Piskorski and Dorn, 2011), the two extracts were combined, and analyzed with gas chromatography–mass spectrometry (GC-MS).

Chemical Analysis GC-MS analysis was performed with a 6890 GC-5973 MS instrument (Hewlett-Packard, Palo Alto, CA, USA) equipped with a 30 m × 0.25 mm i.d., 0.25 μm, DB-5 ms column (J&W Scientific Inc., Folsom, CA, USA). Helium was used as carrier gas at a constant flow (1.0 ml/min); an aliquot of each sample (1 μl) was injected. The oven temperature was kept at 50°C for 2 min, then increased to 320°C at a rate of 10°C/min, and kept at that temperature for an additional 10 min. Electron ionization (70 eV) mass spectra were recorded with ion source temperature of 230°C, and quadrupole temperature of 150°C. Identification of juglone and 1,4,5-trihydroxynaphthalene was based on chromatographic and mass spectrometric characteristics and confirmed with synthetic standards; 1,4,5-trihydroxynaphthalene was synthesized previously in our laboratory (Piskorski and Dorn, 2011). Linear retention indices (RI) were calculated using *n*-alkanes as standards and argon as an unretained compound (Piskorski et al., 2007). If juglone or related compounds were not detected in a given extract, the extract was concentrated and re-analyzed.

Statistical Analysis Developmental times and larval and adult weights were analyzed across treatments using analysis of variance (ANOVA) followed by Tukey's *post hoc* test. The χ^2-test was used to test for differences in the number of surviving individuals between treatments; survival on the control diet served as baseline value. The statistical analyses were performed with the JMP 8.0 software (SAS Institute Inc., Cary, NC, USA).

Results

Effect of Juglone in the Artificial Diet on G. molesta Performance Juglone concentrations reflecting the minimum of the seasonally fluctuating level in walnuts (5 mg/g d.w.) did not have any direct effect on survival rate of *G. molesta,* whereas concentrations reflecting the maximum level (25 mg/g d.w.) significantly affected larval and pupal survival, reducing the number of individuals that reached adulthood by one third compared to the control (Table 1). Amending the diet with a juglone concentration (50 mg/g d.w.) that reflected twice the maximal level reported from the field completely prevented larval development, and all larvae on that diet died within a few days.

A similar effect was observed for larval developmental time (Table 2). Mean developmental time of larvae feeding on diet supplemented with juglone at a concentration representing the lowest natural levels was not affected. Significantly prolonged development time of larvae fed on diets containing the highest juglone level reported from the field was observed. It lasted nearly twice as long as in the control. Pupal developmental time

[b] No development at the larval stage

remained unaffected at both of these juglone concentrations (Table 2).

Sublethal effects of juglone on insect weight were noted. After 9 days, larvae feeding on diets containing juglone had significantly lower weights compared to larvae feeding on the control diet (Table 3). Larval weight was reduced only about 10% by the low juglone diet, but was reduced 95% by levels of juglone similar to the highest levels reported in walnut. Adult weights were reduced approximately 25% for larvae fed diets containing the high level of juglone reported from walnut husks (Table 3).

Fate of Juglone To understand the successful development of *G. molesta* feeding on diet containing juglone, chemical analysis of larval exudates, hemolymph, and insect bodies was performed in search of juglone or its likely metabolites. In larval frass, the reduced form of juglone, 1,4,5-trihydroxynaphthalene, was detected in relatively high concentrations compared to juglone, with a ratio of 1.22 : 1.00 (1,4,5-trihydroxynaphthalene : juglone). In fed larvae, the guts contain food and digesta, and traces of both juglone and its reduced form were detected. In starved larvae, the gut is empty and neither juglone nor its reduced form were present. Furthermore, neither these nor related phenolic or quinone derivatives were detected in larval regurgitant, in larval hemolymph, in pupae, or in adults. Other likely derivatives of juglone were not detected in any of the samples.

Discussion

The oriental fruit moth *G. molesta*, which has not been reported to use plants containing naphthoquinones as hosts, successfully achieved adulthood on diets supplemented with juglone at levels reflecting those found in walnut husks. At juglone concentrations reflecting the minimum and maximum of the seasonally fluctuating levels (Radix et al., 1998; Stampar et al., 2006), survival rates to adulthood were 90% and more than 50%, respectively, of the control survival rate. Survival rates observed in an analogous experiment with the codling moth *C. pomonella*, which readily accepts walnut as a host, were similar at the low juglone concentration, and only approximately 20% higher at the high juglone concentration (Piskorski and Dorn, 2011).

Sublethal effects observed in juglone-fed *G. molesta* consisted of slightly reduced larval weight gain at the low juglone concentration, and prolonged developmental time as well as reduced larval and adult weight at the high juglone concentration as compared to the control. These effects qualitatively resemble those found recently for *C. pomonella* (Piskorski and Dorn, 2011), but they are quantitatively more pronounced in *G molesta*. Development was completely prevented in *G. molesta* at the juglone level reflecting twice the maximum reported from the field, suggesting that the adverse effects were dose dependent. Similarly, none of the *C. pomonella* larvae exposed to this excessively high level of juglone survived (Piskorski and Dorn, 2011), indicating that even in a herbivorous species that includes naphthoquinone-containing plant material in its diet, the capability to cope with these defensive metabolites is limited.

It is surprising that an herbivorous species can tolerate a defensive compound that is not a constituent of its reported hosts. In fact, physiological constraints of plant-feeding insects are thought to be particularly serious limitations to host plant expansion (Praz et al., 2008; Sedivy et al., 2011). Similar to the oriental fruit moth, the fall armyworm *Spodoptera frugiperda* (Lepidoptera: Noctuidae) and the gypsy moth *Lymantria dispar* (Lepidoptera: Lymantriidae) have not been observed to feed on plants that contain naphthoquinones. Juglone is lethal for these two lepidopteran larvae at doses as low as 2.0 mg/g (Yu, 1987; Lindroth et al., 1990), which is lower than the lower limit reported for walnut (Radix et al., 1998; Stampar et al., 2006;

Table 3 Larval fresh weight after 9 days of feeding and adult dry weight of *Grapholita molesta* reared on artificial diet containing juglone

	Larva (mg)[a]	Adult (mg)[a]
Juglone 5 mg/g	14.6±2.1 (25) b	3.9±0.2 (31) a
Juglone 25 mg/g	0.9±0.3 (17) c	3.1±0.3 (18) b
Juglone 50 mg/g[b]	–	–
Control	16.1±1.3 (20) a	4.1±0.2 (26) a

[a] Mean values±SEM of the number of individuals given in brackets. Different letters after the mean indicate significant differences between treatments in a column at $P<0.05$ (comparison between treatments with ANOVA and Tukey's *post hoc* test)

[b] No development at the larval stage

Piskorski and Dorn, 2011), and lower than the concentrations tolerated by the oriental fruit moth.

The mechanism of tolerance to juglone by the oriental fruit moth needs further investigation. In other lepidopteran species, redox cycling (Thiboldeaux et al., 1994) or conjugation with glutathione (Thiboldeaux et al., 1998) could not satisfactorily explain the observed effects of 1,4-naphthoquinones. However, enzymatic reduction of the conjugated cyclic 1,4-dione moiety to the corresponding diol offered a good explanation for different susceptibilities of various lepidopteran species. Quinone reductase, which catalyses reduction of juglone, is active in the intestinal system of some lepidopterans (Yu, 1987; Lindroth, 1989). Low levels of quinone reductase activity (maximum 50 nmol/min/mg protein) were found in the fall armyworm and the gypsy moth, which perform poorly on juglone-containing diet (Yu, 1987; Lindroth et al., 1990). In contrast, a high level of quinone reductase activity (174 to 288 nmol/min/mg protein) was measured in the luna moth, which performs well on juglone-containing diets (Lindroth, 1989).

We suggest that juglone is reduced in the intestinal system of *G. molesta*. Larval frass of *G. molesta* contained relatively high amounts of the trihydroxynaphthalene, but also some juglone, that may represent the compound derived directly from the diet. However, it is more likely that juglone is the product of a spontaneous reoxidation of 1,4,5-trihydroxynaphthalene in air (Hedin et al., 1980; Piskorski and Dorn, 2011). Various plant phenolic compounds are oxidized in the insect's gut (Summers and Felton, 1994; Barbehenn et al., 2003), but such reoxidation of trihydroxynaphthalene seems to be negligible, as indicated by the current work and two previous studies on juglone-tolerant lepidopterans (Lindroth, 1989; Piskorski and Dorn, 2011). Moreover, the absence of juglone in hemolymph and in larvae with emptied guts indicates that this compound is not sequestered by the insect. Hence, the mechanism of overcoming naphthoquinone-based plant defense in *G. molesta* may resemble that recently described for *C. pomonella* (Piskorski and Dorn, 2011).

Lack of infestation of Juglandaceae by the invasive *G. molesta* may have various reasons. First, the volatile profile of walnut (Bezemer and Mills, 2001; Witzgall et al., 2005; Casado et al., 2008) differs from that of peach, this herbivore's primary host (Natale et al., 2003) and from that of apple, its secondary host (Vallat and Dorn, 2005). Hence, the volatile blend emitted from walnut may fail to attract oriental fruit moth females during flight. Second, deterrent properties of naphthoquinones may prevent host acceptance, as shown for other insect species (Ferkovich and Norris, 1971; Faccoli et al., 2005). Third, the skin of walnut husks may pose a harder physical barrier than that of peach and other rosacean fruits, thus preventing penetration by neonate larvae. Finally, we cannot exclude that some infestations may have gone unnoticed, as has similarly been discussed for related internal fruit feeders (Chen and Dorn, 2009).

We do not know whether juglone influences other life-history traits in this herbivore, such as fertility, mating success, longevity, or flight capacity (Cisneros and Barnes, 1974; Keil et al., 2001; Moreau et al., 2006; Torriani et al., 2010). Lifetime fecundity may suffer in cases with reduced adult weight (Bezemer and Mills, 2001) as noted for the high, but not for the low juglone level reported from walnut husks. However, naphthoquinones can be antimicrobial (Clark et al., 1990; Inbaraj and Chignell, 2004) and can act as dietary antioxidants (Johnson and Felton, 2001; Rodríguez et al., 2007), so that by feeding on nutritional sources containing naphthoquinones, insect herbivores may compensate for some fitness losses, or even gain fitness benefits by being better protected against infections and strong oxidants.

It is commonly accepted that many herbivores can widen not only their geographic but also their host range (Dambroski et al., 2005; Myers et al., 2006; Erbout et al., 2009; Chen and Dorn, 2010; Piskorski et al., 2010). The European corn borer *Ostrinia nubilalis* (Lepidoptera: Pyralidae) successfully added maize to its original host range in spite of the toxic properties of hydroxamic acids from this plant, in particular 2,4-dihydroxy-7-methoxy-l,4-benzoxazin-3-one (DIMBOA) (Campos et al., 1988; Martel et al., 2003). Likewise, apple was initially reported only as a secondary, relatively unimportant host plant of the oriental fruit moth (Rothschild and Vickers, 1991), but its significance as a host is continuously increasing (Natale et al., 2004; Myers et al., 2006), indicating the potential of this insect to rapidly adapt to new hosts. Our results suggest that in future, *G. molesta* could include juglandacean plants into its host range, provided other factors are favorable.

Key Words Aggregated nesting · Aggressive behavior · Nestmate recognition · Gas-chromatography mass-spectrometry · Microsatellite analysis · Stingless bees

Introduction

In social insects, large aggregations of colonies from the same species occasionally occur where aggression among members from different colonies is absent. Such large colonies were most intensively studied in ants (supercolonies: Holway et al., 1998; Tsutsui et al., 2000; Drescher et al., 2007; supercolonies: Steiner et al., 2007; Helanterä, 2009). They are characterized by an absence of aggression of workers from different nests within supercolonies (Holway et al., 1998; Tsutsui et al., 2000; Giraud et al., 2002; Drescher et al., 2007) and frequent exchange of workers between nests (Pedersen et al., 2006). Supercolony formation may result from reduced genetic variation i.e. due to a population bottleneck (Tsutsui et al., 2000). It may also result from a reduced self-nonself recognition, i.e. due to a uniform composition of chemical compounds on their body surface (hitherto called "chemical profiles") (Giraud et al., 2002; Errard et al., 2005), or to low benefits in comparison to the costs of aggressive interactions (Steiner et al., 2007). In general, social insects distinguish between related and unrelated individuals based on interspecific and intercolonial differences in the number and amount of hydrocarbons (HCs) in their chemical profiles (Crozier and Dix, 1979; Getz and Chapman, 1987; Howard, 1993; Howard and Blomquist, 2005): Related individuals are chemically similar and hence tolerated, whereas unrelated individuals are chemically different and therefore aggressively attacked (Lacy and Sherman, 1983; Martin and Drijfhout, 2009).

Whereas the relationship between aggression, chemical profiles and relatedness has been frequently investigated in ants, nest aggregations of bee colonies have received comparatively little attention, although nest aggregations are common in solitary, semi-social and social bees (Wcislo, 1993; Kukuk et al., 2005; Thiele and Inouye, 2007; Gonzalez and Ospina, 2008; Haeseler, 2008; Timmermann and Kuhlmann, 2008). These nest aggregations frequently comprise unrelated individuals or colonies (Ward and Kukuk, 1998; Cameron et al., 2004).

There are multiple hypotheses on the causes of such nest aggregations (reviewed by Ward and Kukuk, 1998). One possibility may be a lack of suitable nest sites (Michener, 1974; Eltz et al., 2001) or that bees assess nest site quality by the presence of other colonies (Eltz et al., 2001). Aggregated nesting may also decrease the risk of individual nests to be subject to predators due to a 'selfish herd' effect, as has been shown in birds (Clark and Robertson, 1979) and in stenogastrine wasps (Landi et al., 2002). Alternatively, in bees, aggregated nests of unrelated colonies could facilitate mating between females and unrelated males, thereby significantly decreasing the risk of inbreeding (Cameron et al., 2004; Kukuk et al., 2005) which may be particularly costly in hymenoptera due to their sex determination mechanism (Cook and Crozier, 1995; Zayed and Packer, 2005).

In some tropical stingless bee species (Apidae, Meliponini), nests of several colonies can be heavily aggregated with up to eight colonies at the base of a single tree (Eltz et al., 2001; Cameron et al., 2004; Leonhardt et al., 2010b). In Southeast Asia, aggregated nests of unrelated colonies are most prominent in the stingless bee *Tetragonilla collina* (Roubik, 1996; Eltz et al., 2001; Cameron et al., 2004; Leonhardt et al., 2010b). Moreover, this species shows very low levels of aggression towards both conspecific and heterospecific individuals (Leonhardt and Blüthgen, 2009; Leonhardt et al., 2010b), although aggressive encounters between stingless bees can be commonly observed at floral resources and baits (Hubbell and Johnson, 1977; Nagamitsu and Inoue, 1997; Leonhardt and Blüthgen, 2009).

To better understand the mechanisms behind aggregated nesting in *T. collina*, we investigated whether behavioral responses of *T. collina* individuals can be predicted by variation in relatedness and/or chemical profiles. We tested for differences in behavioral responses in *T. collina* bees from (1) the same colony, (2) different colonies of the same aggregation and (3) distant aggregations. To examine whether behavioral responses correlated with genetic relatedness and/or chemical profiles, we analyzed and compared differences in both genetic relatedness and the composition of cuticular compounds (1) within colonies, (2) within aggregations and (3) between aggregations.

Methods

Study Sites, Aggregations and Bees

Sampling of specimens for genetical and chemical analyses as well as behavioral experiments were performed at two different field sites in Borneo (Malaysia), in August–November of 2007 and 2008. (1) The Danum Valley Conservation Area (DVC: Sabah, 4°55′ N 117°40′ E, 100 m asl) comprises one of the major remaining patches of Sabah's primary lowland dipterocarp rainforest (43 800 ha) (Marsh and Greer, 1992). (2) The Kabili Sepilok Reserve (KSR: Sabah, 5°54′ N, 118°04′ E, 20–120 m asl) covers an area of 4294 ha of coastal dipterocarp and mangrove forest (Fox, 1973) surrounded by oil palm plantations. Attached to KSR is the Rainforest discovery centre (RDC), a small (148.6 ha) education centre with secondary and planted vegetation. Both field sites have a

typical equatorial rainforest climate with a mean annual temperature of 26–30°C and a yearly rainfall of 2600–3000 mm (Fox, 1973; Sakai et al., 1997). Fifteen stingless bee species (species and genus names as in Moure, 1961) were recorded for DVC (Eltz, 2004), whereas 15 to 20 species can be found in KSR and RDC according to collections of specimens held by the Forestry Research Centre in Sepilok and our own studies (Leonhardt and Blüthgen, 2009).

Overall, we sampled 19 colonies from four nest aggregations (between 2 and 7 nests per aggregation) and two single, non-aggregated colonies (stcrf1 and sltc8) of *Tetragonilla collina* for genetical analyses. Note that stcrf1 nested in aggregation with another, morphologically similar species that was excluded from analyses due to strong differences in its chemistry and alleles for the genotyped loci, suggesting that it may represent a different species (Fig S1 and S2).

All colonies' nests were situated in or beneath tree trunks (14 nests) or in cavities in walls (seven nests). Aggregations were characterized by a high nest density with all nests having at least one neighboring nest less than 50 cm away and a maximum distance of ≤3 m from the most distant nest. Eight of these colonies (representing three different aggregations and one single colony) were tested for differences in behavioral responses towards colonies from the same or a distant aggregation (Table 1). Detailed chemical analyses were performed for overall twelve colonies from all four aggregations and one single colony (Table 1).

Bee Sampling and Behavioral Testing

Individual bees were caught at their nest entrances by putting a clean transparent plastic bag or container above the nest entrance tube. Behavioral experiments followed the protocols successfully applied to Bornean stingless bee species in Leonhardt et al. (2009) and Dworschak and Blüthgen (2010): A focal bee was directly transferred from the plastic bag or container to a clean arena (a plastic Petri dish inversely placed on a gauze that was tightened to a large plastic box) and left undisturbed for habituation. After 1 min, a dead bee (that was killed by freezing prior to the experiment) was inserted into the arena. We observed the behavioral responses of the focal living bee towards the dead bee ('alive against dead experiment') for a period of

Within-colony relatedness [± SE] (r), chemical variation (equivalent to mean Bray-Curtis distances [± SD]) for all compounds (C), only resin-derived compounds (Cr) and only non-resin derived compounds (Cg) as well as the number of individuals used for the microsatellite analysis (N1), tested in behavioral experiments (N2: numbers in brackets give the number of bees tested in control/intra-aggregation/inter-aggregation trials) and used for chemical analyses (N3) are given

3 min, assigning all behavioral responses observed towards the dead bee to one of the following three response levels: '1' neutral response (investigation of dead bee with antennae, mandibles closed), '2' slight aggression (open mandibles), and '3' high aggression (biting in extremities, biting off body parts, dragging dead bee around arena). We calculated the aggression level (A_i) for each focal bee individual i as described in Leonhardt et al. (2010b): $A_i = (L2 + L3)/(L1 + L2 + L3)$, where L1, L2, and L3 are the number of behavioral responses of each aggression level. We tested for differences in aggression as well as the overall number of responses between control trials, inter-colonial trials with associated colonies and inter-colonial trials with non-associated colonies using Kruskal Wallis tests.

Both focal and dead bees were tested only once. Ten replicates were performed per inter-colonial trial and ten per intra-colonial trial (control trials). Overall, 180 bees (eight colonies) were tested (four bees that died during the test trial were excluded from the analysis, Table 1).

Microsatellite Analysis

Individual bees were collected from nest entrances of each of 21 colonies, killed in a freezer and directly transferred into 99% ethanol. In total 273 bees were analyzed. Between 4 and 19 individuals were analyzed per colony (mean ± SD 12.9±3.33 bees per colony). Genomic DNA was extracted from abdomen tissue of individual workers using Puregene ® DNA Purification Kit (Gentra Systems) according to the manufacturer's recommendations. DNA pellets were resuspended in 50 µl low TE and stored at −20°C.

Initially five microsatellite loci were used, that were developed for *Tetragonula carbonaria* (Green et al., 2001): Tc1.20, Tc3.155, Tc3.56, Tc7.13 and Tc4.287. The locus Tc1.20 gave poor amplification results and was later omitted from the analysis. PCR amplification was performed in an Eppendorf Mastercycler® or Biometra T1 Thermocycler®, in a total reaction volume of 12.5 µl containing approximately 10 ng of template DNA, 1x PCR-buffer, 1.1 mM $MgCl_2$, 160 µM dNTPs, 2.5 µM of each primer (forward primer labeled with fluorescent IR-700 or IR-800dye) and 0.5U of *Taq* DNA polymerase (*MolTaq*®, Molzym GmbH). Cycle parameters were as follows: 3 min at 94°C, followed by 30 cycles of 94°C for 30 sec, annealing step 30 sec, 72°C for 30 sec, and a final extension of 8 min at 72°C. Annealing temperatures were as follows: Tc3.155: 67°C; Tc3.56: 64.5°C; Tc4.287: 52°C; and Tc7.13: 58°C. PCR-products were diluted between 1:5 and 1:30 and analyzed on a LICOR® 4300 DNA Analyzer.

To test for deviation from Hardy-Weinberg-Equilibrium (HWE) and genotypic linkage disequilibrium (LD) we generated four datasets with one randomly chosen worker from each colony. HWE and LD were tested using Genepop On The Web (Raymond and Rousset, 1995: http://genepop.curtin.edu.au/). Relatedness within and between colonies and aggregations was calculated using Relatedness 5.0.8 (Queller and Goodnight, 1989), including all individuals as reference population and colonies weighted equally. Standard errors were obtained by jack-knifing over loci.

The partitioning of genetic variance within the population was determined by a hierarchical AMOVA based on F_{ST} as implemented in ARLEQUIN 3.1 (Excoffier et al., 2006). We performed a three-level hierarchical AMOVA with the nested levels: whole population variance, within-aggregation variance and within-nest variance.

Chemical Analysis

Between 3 and 11 individuals were sampled from overall 12 colonies and separately extracted in hexane for 2 min, resulting in 75 individual *T. collina* extracts. We analyzed these extracts using a Hewlett Packard HP 6890 Series Gas Chromatographic System coupled to a Hewlett Packard HP 5973 Mass Selective Detector (Agilent Technologies, Böblingen, Germany). The GC was equipped with a J & W, DB-5 fused silica capillary column (30 m×0.25 mm ID; df=0.25 µm; J & W, Folsom, CA, USA). Temperature was programmed from 60°C to 300°C with a 5°C/min heating rate and was held for 10 min at 300°C. Helium was used as carrier gas (constant flow of 1 ml/min). Injection was carried out at 250°C in the splitless mode for 1 min. Electron impact mass spectra (EI-MS) were recorded at an ionization voltage of 70 eV and a source temperature of 230°C. We used the Windows version of the ChemStation software package (Agilent Technologies, Böblingen, Germany) for data acquisition. Compounds were characterized as described in Leonhardt et al (2009), by comparing their mass spectra and retention indices with mass spectra and retention indices from three commercially available libraries (Wiley 275, NIST 98 and Adams EO library 2205), and by comparing them to synthetic standards (Sigma-Aldrich, Munich, Germany) if standards were available.

To test for differences in the cuticular chemical profiles between individual *T. collina* bees from (1) different colonies, (2) different aggregations, and (3) different regions, we performed permutation tests (adonis, R-package vegan 1.15, 10000 runs) based on relative peak areas. Relative peak areas were calculated by dividing each peak's integrated area by the total integrated peak area. To account for potential differences between non-resin-derived CHCs and resin-derived compounds, we performed separate Adonis tests confined to these two groups of compounds. Graphs for visual presentation were produced by two-dimensional NMDS (non-metric dimensional scaling). Bray-Curtis dissimilarities based on the proportions of all compounds that accounted for more than 0.5% of the

total peak area in at least one sample (start configuration: PCoA, 1000 iterations) were used for NMDS and Adonis tests. Overall, 82 compounds were used for the analysis, 47 of which were most likely derived from plant resins (environmentally derived). A detailed list of compounds is given in Table S2.

To test whether related individuals had more similar chemical profiles than unrelated individuals, we performed a Mantel test based on Pearson's product moment correlation using relatedness and chemical distances among colonies.

Results

Behavioral Tests

Only 21 out of 176 *T. collina* bees tested showed little aggression (open mandibles) towards dead bees from either their own colony (13% of bees tested in control trials were slightly aggressive), their own aggregation (15%) or a distant aggregation (5%). The large majority of bees tested responded non-aggressively towards dead bees no matter whether they were taken from their own or a foreign colony. Hence the number of aggressive responses towards dead bees did not differ for bees of the same colony (control trials: mean aggression [± SD] A_i=0.10±0.28), bees of different colonies but the same aggregation (mean A_i=0.12± 0.30), or bees of distant aggregations (mean A_i=0.04±0.18; Kruskal Wallis test: H=2.07, p=0.35). They also showed no differences in the overall number of responses (aggressive and non-aggressive ones) towards dead bees (Kruskal Wallis test: H=1.95, p=0.38).

Relatedness Within and Between T. collina Colonies

The 271 bees analyzed were all successfully genotyped for at least three of the four loci with good amplification results. Locus Tc7.13 showed the highest number of failed amplifications with only 194 individuals being successfully genotyped. For the other three loci, at least 235 individuals were successfully genotyped. Failed amplifications were not concentrated on particular colonies but scattered among colonies. Number of alleles per locus ranged from 3 (Tc7.13) to 5 (loci Tc3.155 and Tc3.56) (for details see Table 2). The four loci showed no significant linkage disequilibrium.

Out of the 16 tests performed (4 loci x 4 datasets containing a single individual per colony), 3 showed significant deviation from HWE (heterozygote deficiency). In two out of the four datasets, the locus Tc4.287 deviated significantly from HWE and Tc7.13 in one (Fisher's exact test; p<0.05).

Table 2 Characteristics of microsatellite loci for *T. collina* workers

Locus	N	A	H_O	H_E
Tc3.155	235	5	0.581	0.489
Tc3.56	247	5	0.488	0.612
Tc4.287	249	3	0.487	0.541
Tc7.13	194	4	0.443	0.560

N number of individuals genotyped; *A* number of alleles; H_O observed heterozygosity and H_E expected heterozygosity, based on a dataset containing four randomly chosen workers per colony

(a) Relatedness within colonies:

Within-colony regression relatedness of the 21 colonies sampled ranged from 0.133 to 0.888 (mean ± SD: 0.61±0.24) and was on average significantly lower than 0.75, the expected relatedness among full sisters in monogynous colonies (one-sample t-test against 0.75, p=0.015, T=−2.65, df=20). Five of the 21 colonies showed within-colony relatedness values lower than 0.353 (Table 1), thus deviating from the expected within-colony relatedness of 0.75 where all workers are full sisters and derived of a single monandrous queen.

(b) Relatedness within aggregations:

Aggregations comprised both related and unrelated colonies (Table S1). Within-aggregation relatedness was highest in aggregation D1 in DVC with the two colonies being closely related (r=0.71±0.11), whereas all aggregations in KSR and RDC (S1 to S3) showed variable within aggregation relatedness (average relatedness of colonies in S1: r=0.16±0.42 comprising 3 nests; S2: r=0.07±0.06 comprising 7 nests; S3: r=0.14±0.07 comprising 7 nests).

(c) AMOVA results: partitioning of genetic variance:

The AMOVA revealed that a significant proportion of the genetic variance was explained by within-nest variation (67.7%; p<0.0001) as well as by variation among nests within aggregations (32.6%; p<0.0001). In contrast, variance between aggregations (within-population variance) did not contribute significantly to the total genetic variance (−0.2%; p=0.48 n.s.).

Chemical Profiles

The twelve *T. collina* colonies analyzed generally varied in their chemical profiles (Fig. 1, Adonis: R^2=0.50, p<0.001) with chemical differences being more pronounced between (mean Bray-Curtis distance [± SD]: 0.45±0.16, number of distance pairs N=5414) than within (0.31±0.15, N=1726) colonies. The three aggregations also had different chemical profiles (Fig. 1, R^2=0.36, p<0.001). However, when colonies were directly compared to one another, only 26

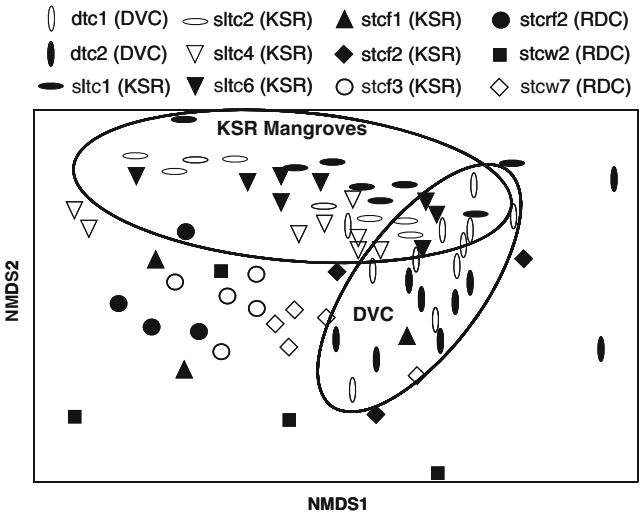

Fig. 1 Similarity in chemical profiles of surface compounds from 12 *Tetragonilla collina* colonies of five nest aggregations in Borneo (ordination figure based on Bray-Curtis dissimilarities, stress value= 13.87). Different symbols represent different colonies (each symbol represents one individual bee): *Circled* colonies mark two colonies from an aggregation in DVC (black and white upright ellipses) and four colonies from an aggregation found close to the coast in KSR (black and white ellipses, *black and white triangles* upside down). The remaining colonies stem from one aggregation in the interior forest of KSR (*black diamond*, *black triangle* and *white circle*), and one aggregation (*white diamond* and *black square*) as well as one single colony (*black circle*) at the RDC

out of 66 colony pairs could be distinguished (with *p*-values<0.001, which was the required significance level according to Bonferroni correction for multiple testing).

As expected, non-resin derived compounds more clearly separated both colonies and aggregations (colonies: R^2=0.54, p<0.001; aggregations: R^2=0.40, p<0.001) than did resin-derived compounds (colonies: R^2=0.44, p<0.001; aggregations: R^2=0.31, p<0.001). Resin-derived compounds further showed an on average higher chemical variation within colonies (mean Bray Curtis distance: 0.35±0.08) than did non-resin derived compounds (mean Bray Curtis distance: 0.27±0.07; Table 1).

Chemical similarity among *T. collina* colonies did not correlate with degrees of relatedness, neither for all compounds (Mantel test: r=−0.13, p=0.84), nor for resin-derived (r=−0.17, p=0.88) or non-resin derived compounds (r=−0.10, p=0.72).

Discussion

Colonies of the stingless bee *Tetragonilla collina* frequently nest in aggregation with up to seven other conspecific colonies in our study area, but did not show any aggressive behavior among each other. Likewise, aggression was absent between colonies of different aggregations. This atypically peaceful behavior contrasts with other studies on stingless bees that found relatively strong aggression between con- or heterospecific non-nestmate individuals (Johnson and Hubbell, 1974; Hubbell and Johnson, 1977, 1978; Howard, 1985; Inoue et al., 1999; Kirchner and Friebe, 1999; Nunes et al., 2008; Leonhardt and Blüthgen, 2009).

In contrast to honeybees where new colonies are established by old queens while young queens remain in their mother nests, new stingless bee colonies are founded by young queens (Inoue et al., 1984; Roubik, 1989). These young queens frequently build their nests in close proximity to their mother colony and the two nests exchange workers and resources until the new colony finally becomes independent (Inoue et al., 1984). *Tetragonilla collina* nest aggregations can therefore contain a mother and several daughter colonies which may explain why five colony pairs within the aggregations investigated in our study were more closely related (> 0.40) than colonies of distant aggregations and why chemical profiles were more similar within than among aggregations. However, 39 out of 52 aggregated colony pairs were only little related (< 0.25). Likewise, Cameron and colleagues (Cameron et al., 2004) found no or only little relatedness among aggregated *T. collina* colonies in Thailand, indicating that aggregations may include both related and unrelated colonies. Hence, relatedness among colonies may account for the lack of aggression in some behavioral assays, such as in the pairing of colony stcf1 and stcf3 (with relatedness being 0.23±0.29), but not in assays conducted with bees from unrelated colonies (see Table S1).

Whether the *T. collina* population sampled in this study generally shows only little genetic variability in the markers used or whether this low level of variability is due to high population viscosity can currently not be fully resolved. Nonetheless, different degrees of relatedness did not translate into different degrees of aggressiveness in this species of stingless bee. Within colony relatedness did further not correlate with chemical similarity, neither for environmentally derived nor for genetically determined compounds: Two out of five colonies with low within-colony relatedness showed very little chemical variation (colonies stcw7 and sltc2), but one colony (stcw2) with high within-colony relatedness had a strongly diverging chemical profile (Table 1). Chemical variation among individuals of the same colony was comparatively large in five of our 12 colonies (Fig. 1). However, overall, all colonies, and particularly those within aggregations, had qualitatively and quantitatively similar chemical profiles, and 40 out of 66 colony pairs could chemically not be distinguished.

Lack of statistical discrimination between chemical profiles does however not imply a lack of recognition. It is unknown whether stingless bees use the entire bouquet of

chemical compounds on their body surface to recognize colony members or whether they rely on a subset of compounds, as suggested for other social insects. For instance, ants also have a variety of hydrocarbons on their body surfaces, including saturated- and unsaturated ones linear ones as well as methyl-branched ones (reviewed by Martin and Drijfhout, 2009). However, in two *Formic*a ant species, unsaturated (n-alkenes) or branched hydrocarbons were found to be more important for the recognition of colony members (nestmates) than linear n-alkanes (Akino et al., 2004; Martin et al., 2008). Likewise, in the honeybee *Apis mellifera*, n-alkenes and fatty acids seemed to be most important for nestmate recognition (Châline et al., 2005; Dani et al., 2005). The neotropical stingless bee *Trigona fulviventris* also used fatty acids to differentiate between nestmates and non-nestmates, but n-alkanes and floral oils further affected their recognition ability (Buchwald and Breed, 2005). To our knowledge, there are no other studies that have investigated nestmate recognition cues in stingless bees (let alone in any paleotropical stingless bee species). It is thus possible, yet remains to be shown, that stingless bees can obtain sufficient information about another bee's colony identity from only a subset of surface compounds or from compounds not detected by the GC-MS (e.g. proteinaceous compounds), which is likely to be overlooked by our chemometrical analysis. More studies on compounds or compound groups used as recognition cues by stingless bees are therefore needed.

Besides cuticular hydrocarbons (CHCs), the chemical profile of *T. collina* comprises large amounts of terpenoid compounds (Leonhardt et al., 2009, 2010a). By comparing the bees' profiles with compounds of plant resins, we found that these terpenoids were derived from resins (Leonhardt et al., 2011) which the bees collect for nest construction, maintenance and defense (Leonhardt and Blüthgen, 2009; Leonhardt et al., 2009). The composition of resin-derived terpenoids is highly species-specific, rendering mere contamination of the bees' surfaces by resin unlikely (Leonhardt et al., 2009). Moreover, we found that resin-derived terpenoids show a species-specific distribution even on the bees' wings (Leonhardt et al., 2009) – the insect body part considered least prone to contamination (McDaniel et al., 1984). The terpenes may (at least) partly account for the lack of correlation between genetic relatedness and chemical similarity. They may further increase the chemical overlap between different *T. collina* colonies, because chemical distinction was less pronounced (R^2=0.44) and chemical variation was larger (mean Bray-Curtis distance [± SD]: 0.35±0.08) for terpenes than for non-resin-derived CHCs (R^2=0.54, mean Bray-Curtis distance: 0.27±0.07). Moreover, the addition of environmentally derived compounds increases the diversity of chemical compounds in the bees' surface profiles and thus potentially also cue diversity. It was suggested that increased cue diversity can cause cue overlap amongst colonies and thus a decrease in the accuracy or even a total lack of nestmate recognition (Peeters, 1988; Satoh and Hirota, 2005; Martin et al., 2009). Whether terpenes do actually play a role in the nestmate recognition system of stingless bees is as yet unknown. Sesquiterpenes – a group of terpenes that makes up for the majority of terpenes on the body surface of *T. collina* – were found to reduce aggression in another stingless bee species that lacks sesquiterpenes itself (Leonhardt et al., 2010b). Consequently, environmentally derived terpenes in the chemical profiles of stingless bees may or may not be directly involved in nestmate recognition. If not directly involved, some terpenes may still impair the bees' ability to distinguish between related and unrelated individuals and thus (at least partly, albeit not exclusively) explain the lack of aggression in *T. collina*.

One would expect that a lack of aggression in an insect colony as well as aggregated nesting of multiple colonies should favor social parasitism by either foreign queens or foreign workers ("floaters" or "drifters": Lopez-Vaamonde et al., 2004; Sumner et al., 2007). Unless they are hindered by resident bees, foreign queens may take over nests and produce own offspring, while foreign workers may produce males (brood parasitism', reviewed by Beekman and Oldroyd, 2008) or simply steal food reserves (cleptoparasitism: Cardinal et al., 2010) which frequently occurs in stingless bees (Roubik, 1989, 2006). Social parasitism by egg-laying workers entering unrelated colonies has been found in the stingless bee *Melipona scutellaris* (Alves et al., 2009). Alternatively, queen supersedure within colonies may explain the reduced within-colony relatedness that we observed in some colonies. Queen supersedure was also found quite frequently in stingless bees (Paxton et al., 2003; Alves et al., 2009). However, only five out of our 19 colonies had within-colony relatedness values below 0.4 (indicating the presence of unrelated individuals), whereas eight colonies even had relatedness values above 0.7, matching predictions for full sisters in colonies with a single-mated queen. Hence, foreign individuals may occur in *T. collina* colonies but do not appear to be common.

We cannot exclude that aggression towards foreign individuals occurred in the inner nest parts of *T. collina* colonies, as we observed bees only outside their nests and in a relatively artificial arena environment. However, our aggression assays were successfully applied to several Bornean stingless bee species (testing encounters between both two alive bees and one alive and one dead bee) and revealed strong aggression for inter-colonial as well as inter-specific encounters (Dworschak and Blüthgen, 2010; Leonhardt et al., 2010b). Notably, *T. collina* did not show any aggression towards other stingless bee species neither

when tested in behavioral assays (Leonhardt et al., 2010b) nor when observed in the field (Leonhardt and Blüthgen, 2009). *T. collina* can thus clearly be considered less aggressive than other Bornean stingless bee species. The causes for its unusual 'peacefulness' remain unclear.

Reduced aggression or even a lack of aggression does however not necessarily correlate with reduced or lack of recognition (Chapuisat et al., 2005; Steiner et al., 2007; Martin et al., 2009). It can also stem from high costs of erroneously rejecting related individuals, i.e. in situations of reduced between-colony competition (Reeve, 1989; Downs and Ratnieks, 2000), low costs of accepting foreign workers or to save resources better used for colony growth and reproduction (Holway et al., 1998), because aggression is costly (Reeve, 1989). Thus, *T. collin*a may still be able to distinguish between individuals of its own and a foreign colony, as has, for instance, be shown in *Formica paralugubris*: these ants successfully discriminated between nestmates and non-nestmates (as indicated by significantly higher rates of trophallaxis exchanged with nestmates than with non-nestmates), but showed little to no aggression towards unrelated individuals (Chapuisat et al., 2005). *Lasius austriacus* ants were equally non-aggressive towards unrelated individuals, but performed significantly longer antennation bouts with unrelated than with related ants (Steiner et al., 2007). In contrast to these authors, we did however not find a difference in the overall number of behavioral responses (including aggressive and non-aggressive ones).

Conclusions

Relatedness did not generally explain the lack of aggression between *Tetragonilla collina* nests within aggregations, as colonies found in aggregation could be either closely or distantly related. Moreover, the composition of compounds on the cuticle of *T. collina* bees was no more similar for related than for unrelated individuals, nor did low within-colony relatedness correlate with a larger chemical variation. The observed chemical divergence was mainly due to environmentally derived resin-compounds which are found in the chemical profile of *T. collina* in addition to genetical determined cuticular hydrocarbons. The presence of these compounds may partly explain the lack of aggression in *T. collina*, as it may result in decreased recognition acuity due to either higher cue diversity or to impairing of recognition.

It remains unclear why most of the aggregated *T. collina* colonies studied showed relatively high within-colony relatedness (partly even matching predictions for colonies with a single-mated queen), although both lack of aggression and aggregated nesting should favor social parasitism by unrelated workers or queens.

Acknowledgements We thank the Economic Planning Unit (EPU) for giving us permission to perform research in Malaysia, and the Royal Society for their help with planning and conducting field work in Borneo. This project was further kindly supported by Dr. Chey Vun Khen, Dr. Arthur Chung and Dr. Robert Ong (Forestry Research Centre, Sandakan). Ben Oldroyd and Emilie Cameron provided additional data for comparison and validation of our results and Linda-Maria Jung helped with data collection. The comments of two anonymous reviewers greatly improved the manuscript. SDL was supported by a grant of the German *Excellence Initiative* to the Graduate School of Life Science, University of Würzburg, NB, HF and TS by the Sonderforschungsbereich SFB 554 (Mechanisms and Evolution of Arthropod Behaviour) of the Deutsche Forschungsgemeinschaft (DFG).

males from approaching. These studies suggest that inhibition of the approach of males to females by use of pheromones may function as: a) a pre-mating mechanism, preventing the approach of suitors during a courtship encounter; and b) a post-mating mechanism, preventing subsequent mating by the female, thereby benefiting sperm precedence of the last male that copulated (the most recent male to mate prior to oviposition is the one most likely to fertilize the most eggs; Andersson et al., 2003).

Most studies on the volatiles released by male Lepidoptera during courtship, however, have shown that such compounds attract females or cause females to become quiescent, thus facilitating copulation (Birch et al., 1989). In many species, HP volatiles have a clear effect on female behavior and influence the overall mating success of a courting male (Fitzpatrick and McNeil, 1988; Hillier and Vickers, 2004). In *G. molesta*, males 'flash' abdominal HPs directly in front of females that initiates short-range attraction (Baker and Cardé, 1979; Baker et al., 1981; Baker 1983). HP volatiles more frequently function as arrestants of female behavior, subduing activity and thereby increasing the probability of male mating success (Birch et al., 1990).

HP ablation studies (effectively, volatile removal) have shown the necessity of HP volatiles during courtship in several species. In *Pseudaletia unipuncta* Haworth, HP ablation caused a decrease in female acceptance of courting males (Fitzpatrick and McNeil, 1988). Female antennectomy or male HP ablation also significantly lowered mating success in courtship by the European corn borer, *Ostrinia nubilalis* Hübner (Lepidoptera: Pyralidae; Royer and McNeil, 1992). In *H. virescens*, proper HP display by males is critical for successful mating (Cibrian-Tovar and Mitchell, 1991).

The involvement of HP pheromones in courtship has been hypothesized as a mechanism of intersexual selection through female mate choice (Baker and Cardé, 1979). The elaboration of male-specific structures, and the diversity of male courtship volatiles observed across taxa, suggest that HP volatile composition may communicate information that is species-specific (Hillier and Vickers, 2004). Male pheromones in courtship behavior are thought to be especially important between congeneric, sympatric species, particularly if the female sex pheromone composition is similar (Birch et al., 1990). Under such circumstances, there should be greater selective pressure to prevent interspecific mating.

Previous research has demonstrated that male *H. virescens* and *H. subflexa* display HPs during courtship with conspecific females (Laster, 1972; Teal and Tumlinson, 1997). These species can hybridize under laboratory conditions, though this has a direct fitness cost, producing sterile F_1 males (Laster, 1972; Proshold and LaChance, 1974). Several studies have described the courtship behavior of *H. virescens* and *H. subflexa*, along with F_1 hybrids and backcrosses to each species (Laster, 1972; Cibrian-Tovar and Mitchell, 1991). In one of the first studies to examine hybridization in these species, Laster (1972) found *H. virescens* males and *H. subflexa* females readily mated, but *H. subflexa* males and *H. virescens* females did not. Teal and Tumlinson (1997) hybridized males and females in both directions, using synthetic female sex pheromone to increase male courtship activity to females of the other species. HP display appears important for males of either species to mate successfully with *H. virescens* females, but not for *H. subflexa* females (Cibrian-Tovar and Mitchell, 1991). Furthermore, *H. subflexa* males have smaller HP structures relative to other heliothine species [such as *H. virescens* or *Helicoverpa zea* Boddie (Lepidoptera: Noctuidae)], and produce smaller quantities of pheromone (Teal and Oostendorp, 1993, 1995).

In *H. virescens*, HP volatiles facilitate mating with females capable of discriminating between HP mixtures of closely related species (Hillier and Vickers, 2004). HP composition in both *H. virescens* and *H. subflexa* is primarily a blend of saturated 14–18 carbon-chain alcohols, acetate esters, and carboxylic acids (Teal and Tumlinson 1989, 1997; Teal and Oostendorp 1995). Antennectomized *H. virescens* females and HP-ablated *H. virescens* males mate less frequently than sham-operated counterparts. Interestingly, female acceptance of HP-ablated males may be restored in the presence of *H. virescens* HP extract, but not with extracts from the congeneric *H. subflexa* or *H. zea*. This suggests that HP volatiles function as a means of pre-zygotic reproductive isolation in this species.

Heliothis virescens and *H. subflexa* occur sympatrically, although there is little evidence that hybridization occurs naturally (Heath et al. 1990; Teal and Oostendorp 1995). This has largely been attributed to differential attraction and repulsion by males to components of the respective female sex pheromones. Groot et al. (2006) found in field trials that cross-attraction between these species is low (i.e., a very small percentage of males were attracted to females of the other species). During incidences in which individuals of the two species come into contact by chance, or through response to an inappropriate blend, it is possible that secondary characteristics such as HPs play a role for specific discrimination. The role of HP volatiles in preventing interspecific mating in sympatric species is not well understood.

Preliminary observations of *H. subflexa* mating indicated that courtship occurs more quickly than in *H. virescens* (personal observation). The reduced prominence of *H. subflexa* HPs, along with observations that *H. subflexa* females might not require HP display for mate acceptance, suggested that these structures are of diminished importance in *H. subflexa* courtship.

There were two major objectives of this study. The first was to determine the importance of HP volatiles in mating of *H. subflexa*, and the second was to assess the effects of male HP extracts on interspecific mating attempts by *H. virescens* and *H. subflexa*.

Methods and Materials

Insects

Virgin female and male moths from the *H. virescens* and *H. subflexa* colonies at the University of Utah were used for behavioral assays and HP extraction. *Heliothis virescens* larvae were reared on a pinto bean diet, while *H. subflexa* larvae were reared on a corn-soy diet, until pupation (Shorey and Hale, 1965). Pupae were separated by sex and placed in an environmental chamber (25°C, 60% relative humidity, on a reversed 14L:10D light cycle). Male and female pupae of each species were placed in separate 250-ml paper cups filled with moistened vermiculite, in different chambers, in order to prevent pre-mating exposure of either sex to the conspecific pheromones. Upon eclosion, moths were provided with sugar water (1:5 *w*/*v*) in a 30 ml cup with a paper towel wick. Males and females of each species (3–5 d-old) were selected for use in behavioral assays. Moths were placed in a darkened experimental room to acclimate for 1 hr before experimentation. Before and during experiments, containers with each sex were kept separated under a ventilated airflow (0.40 m.sec^{-1}, generated via a laboratory vacuum line) to minimize pheromone pre-exposure. Assays were conducted between the 3rd and 5th hours of the scotophase.

Volatiles

Preliminary observations showed that the number of mating attempts by males to a female of the other species was low. To facilitate male courtship, and to increase the number of copulation attempts, an artificial lure resembling the conspecific female sex pheromone was presented during interspecific mating trials (Teal and Tumlinson, 1997). Female sex pheromone sources used in interspecific mating trials were prepared by using stock solutions of synthetic female sex pheromone compounds from Bedoukian Research Inc. (Danbury, CT, USA). These solutions were diluted as a decade series in hexane (10 ng/μl–100 μg/μl) and stored at −20°C until used. Samples of stock solutions were confirmed as >95% purity by analysis with a Shimadzu GC 17A gas chromatograph, equipped with a 30 m×0.25 mm ID DB-5 capillary column. For the *H. virescens* female odor source, a mixture of (*Z*)-11-hexadecenal (*Z*11-16:Ald; 50 μg) and (*Z*)-9-tetradecenal (*Z*9-14:Ald; 2.5 μg) on a red rubber septum was used (Tumlinson et al., 1975; Tingle et al., 1978; Klun et al., 1980; Pope et al., 1982; Vetter and Baker, 1983; Teal et al., 1986). The *H. subflexa* female odor source consisted of *Z*11-16:Ald (50 μg), (*Z*)-9-hexadecenal (*Z*9-16:Ald; 25 μg) and (*Z*)-11-hexadecenol (*Z*11-16:OH; 5 μg) in a ratio of 10:5:1, respectively. This blend elicits upwind flight by *H. subflexa* males (Klun et al., 1982; Vickers, 2002).

HP extracts from male *H. virescens* and *H. subflexa* were produced by excising the HPs of 20 males into 1.0 ml hexane. For behavioral assays, one male equivalent (1ME; 50 μl of extract) was applied to a 1 cm diam. filter paper disc, held by an alligator clip attached to a 23 cm wire post. Hexane was allowed to evaporate from the filter paper prior to behavioral testing, and the post was rinsed with acetone between trials to prevent cross-contamination.

Behavioral Assays

Observations of moth mating behavior were conducted as previously described (Hillier and Vickers, 2004). Briefly, experiments were conducted in a dark room, illuminated by a single red incandescent bulb dimmed by a rheostat. Room temperature was 20.2–24.0°C. Mating assays were conducted in a circular chamber, consisting of two 17.5 cm diam Plexiglas plates, above and below a 6 cm tall wire mesh wall (Hillier and Vickers, 2004). The chamber could be rotated around a screw at the center of the base plate, and was mounted to the laboratory bench. An intake duct, positioned 2 cm from the chamber, maintained a suction airflow of 0.20–0.40 m.sec^{-1}. Moth behavior was recorded with a video camera (Panasonic© WV-BP330 CCTV) set up on the opposite side from the intake duct. Rotation of the chamber ensured that female moths were upwind from male moths at the commencement of courtship, and that the moths could be kept within the plane of focus of the camera.

Individual female moths were observed prior to all assays for calling behavior. Only those females that exhibited a stable calling posture (stationary, wings vibrating with ovipositor exposed) were used. The chamber was turned to position females at the most upwind portion; single males were placed in the downwind portion. Behavior was observed for 5 min. If moths engaged in behavioral interactions during this 5 min. period, the trial continued for an additional 5 min. If no interaction occurred, the moths were removed. Female behaviors were recorded in response to specific male courtship bouts, along with the number of mating attempts and copulation success or failure. A successful mating was defined as a clasp by a male suitor lasting for at least 1 min. during the 5 min period of interaction. Behaviors observed were: moving away (female moved more than 40 mm away from source

or suitor), flying away (also part of the 'move away' behavior, but more vigorous movement, involving flight to the opposite side of the chamber), wing fanning, ovipositor extension, abdominal extension, abdominal curling, clasping and false clasping (for a more complete description of these behaviors see Hillier and Vickers, 2004). Abdominal extension, abdominal curling, clasping, and false clasping are associated with successful mating attempts.

HPs were ablated by applying gentle pressure to the abdomen, and then trimming the hairs with iridectomy scissors. Sham-operated males were squeezed to expose HPs, but no hairs were removed. All sham-operations and ablations were conducted before the onset of the scotophase on the same day as the insects were tested. One hour before experimentation, the moths were placed in the experimental room for acclimation to light conditions. Two experiments were conducted:

Experiment 1: Effect of HP Ablation and Replacement on *H. subflexa* Mating

To determine whether or not HP volatiles are important in courtship and mate acceptance in *H. subflexa*, females were paired with either HP-ablated males, with or without *H. subflexa* HP extract, or with sham-operated male *H. subflexa*. The odor source was presented only in behavioral assays when an active courtship bout was exhibited by the male (i.e., only during the period when the HP-ablated male would normally be releasing HP volatiles). During these situations, the odor source was held 1–2 cm upwind from the female. The control for this experiment was a filter paper disc with hexane applied to it, and presented similarly.

Experiments 2 (a and b): HP Volatiles and Interspecific Mating

To determine whether HP volatiles influence the success of interspecific mating or not, two experiments were conducted: (a) with *H. subflexa* males and *H. virescens* females, and (b) with *H. virescens* males and *H. subflexa* females. In each experiment, female behavior and mating success were recorded in response to the following: a sham-operated interspecific male, a sham-operated interspecific male with conspecific HP extract, an HP-ablated interspecific male with conspecific HP extract, and an HP-ablated interspecific male with a hexane source. Pairs of male and female *H. virescens* and male and female *H. subflexa* also were tested as a reference for behavioral and mating frequency in each experiment.

Data Analysis

Frequencies of mating attempts, moving away, flying away, wing fanning, ovipositor extension, abdominal extension, abdominal curling, clasping, and false clasping were calculated for each experiment, with a *chi-square* test of independence and Yates correction ($P>0.05$) being used to determine differences in the frequencies of the behaviors. Differences in the mean number of mating attempts were analyzed using a one-way analysis of variance. All analyses were conducted with STATISTICA© 6.0 (Statsoft, Tulsa, OK, USA; Statsoft Inc., 2007).

Results

Experiment 1: Do HP Volatiles Increase Mating Success for *H. subflexa* Males?

Frequency of successful mating by male *H. subflexa* with conspecific females was affected by HP ablation. Mating by HP-ablated male *H. subflexa* was reduced ($P<0.001$) relative to that of sham-operated males, either with or without a hexane blank source (Table 1). When a filter paper loaded with 1ME of *H. subflexa* HP extract was presented along with HP-ablated males, the frequency of successful mating increased, and was greater than that of HP-ablated males in the presence of a hexane source. This suggests a key role for male-produced volatile signals in *H. subflexa* courtship.

Consistent differences were found in the behavioral responses of females among treatments (Fig. 1). Successful clasping was reduced in the HP-ablated male treatments compared to all other treatments. The frequency of false clasping was increased in both sham-operated male + hexane and HP-ablated male + hexane treatments. No differences ($P>0.05$; data not shown) were found in the number of mating attempts among males from any of the treatments.

Experiment 2: Do HP Volatiles Increase Interspecific Mating Success?

H. subflexa Males and H. virescens Females

For trials between male *H. subflexa* and female *H. virescens*, several differences were observed among HP treatments (Table 1). Control (intraspecific) pairs mated successfully 88.0% and 100.0% of the time, for *H. virescens* and *H. subflexa*, respectively. The frequency of mate acceptance between sham-operated male *H. subflexa* and female *H. virescens* was lower ($P<0.001$) than that of *H. subflexa* pairs (Table 1). Presentation of a hexane-loaded filter paper disc during the observations did not affect mating acceptances for the intraspecific pair compared to the sham-operated or HP-ablated male treatments (Table 1). Presentation of *H. virescens* HP extract (1ME) during courtship resulted in an increase in mate acceptance only in

Table 1 Frequency of mate acceptance for: (a) Female *Heliothis subflexa* and conspecific males with sham-operated or ablated hair pencils (HPs), and a source loaded with either *H. subflexa* HP extract or hexane; (b) Female *H. virescens* and *H. subflexa* males with sham-operated or ablated HPs, and a source loaded with either *H. virescens* HP extract or hexane; and (c) Female *H. subflexa* and *H. virescens* males with sham-operated or ablated HPs, and a source loaded with either *H. subflexa* HP extract or hexane

[a] Means with no letters in common are different (*P*<0.05) from others for mating frequency within each experiment

HP-ablated male *H. subflexa*–female *H. virescens* treatments (relative to treatments with HP-ablated males alone or HP-ablated males plus a hexane blank).

Frequency of abdominal extension and abdominal curling increased for treatments with sham-operated or HP-ablated *H. subflexa* males in the presence of *H. virescens* HP extract, relative to treatments without *H. virescens* HP extract (sham operated and HP-ablated males alone or with addition of hexane; Table 2), indicating that the presence of conspecific male HP extract caused increased occurrences of behaviors associated with successful mating. Frequency of clasping was increased in HP-ablated *H. subflexa* males in the presence of *H. virescens* HP extract relative to the addition of hexane. Pairings in the presence of *H. virescens* HP extract also showed a higher number of false clasps. Mean number of mating attempts by male *H. subflexa* was not different between treatments with or without *H. virescens* HP extract (Fig. 2a).

H. virescens Males and H. subflexa Females

Conspecific pairs of both species mated in high frequencies (Table 1). Mating frequencies between *H. virescens* males and *H. subflexa* females was low for sham-operated and HP-ablated males, with or without hexane. The presence of 1ME of *H. subflexa* HP extract with sham-operated or HP-ablated males resulted in increased mating acceptances, to levels similar to that of control *H. virescens* matings.

The presentation of *H. subflexa* HP extract along with a sham-operated *H. virescens* male resulted in changes in the frequencies of female behaviors linked with mate acceptance, compared to when *H. subflexa* HP extract was absent. This included reductions in flying and moving away, and increases in abdominal extension (Table 3). Abdominal curling increased in both HP-ablated and sham-operated treatments when *H. subflexa* HP extract was present (compared to when it was absent), and was not different

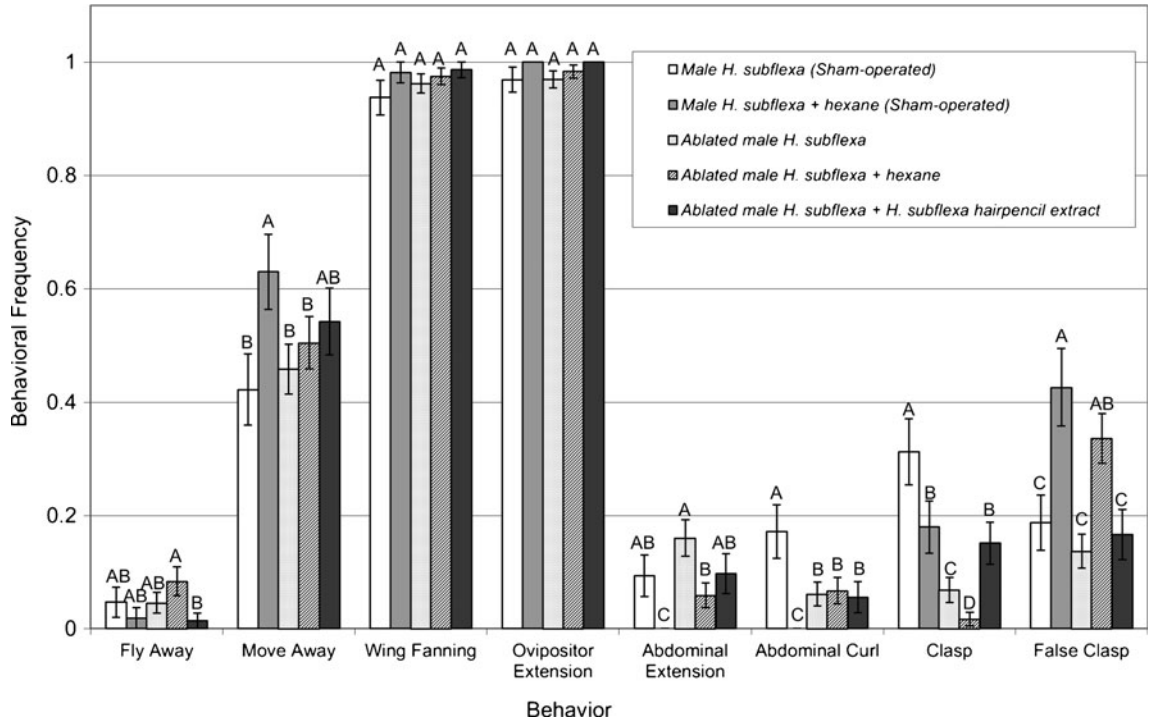

Fig. 1 Behavioral responses of female *Heliothis subflexa* to conspecific males with various treatments: sham-operated hair pencils (HPs), sham-operated HPs plus a hexane source, ablated HPs, ablated HPs with a hexane source, or ablated males with a one male equivalent of *H. subflexa* HP extract source. Means with the same letter are not different (at $P<0.05$). Behavioral differences among treatments: Fly away, $X^2=6.29$, $P=0.18$; Move away, $X^2=12.5$, $P<0.01$; Wing fanning, $X^2=3.36$, $P=0.50$; Ovipositor extension, $X^2=4.08$, $P=0.40$; Abdominal extension, $X^2=14.2$, $P<0.001$; Abdominal curl, $X^2=14.6$, $P<0.01$; Clasp, $X^2=41.2$, $P<0.001$; False Clasp, $X^2=27.0$, $P<0.001$ (4° of freedom in each case)

Table 2 Behavioral responses of female *Heliothis virescens* to male *H. subflexa* with various treatments involving sham operation or ablation of hair pencils (HPs), and additional sources of hexane or HP extract (one male equivalent = 1ME) of male *H. virescens*. Pairs of male and female *H. virescens*/*H. virescens* and *H. subflexa*/*H. subflexa* were used for comparison of mating frequencies. *Means with the same letter are not different (at $P<0.05$)

Control female *H. subflexa* + male *H. subflexa*	23	0.05 (0.022)A	0.43 (0.053)AB	0.15 (0.038)A	0.09 (0.031)B	0.26 (0.047)A	0.13 (0.036)C

from the frequency observed in male and female *H. virescens* pairings. The mean number of mating attempts was greater for treatments with sham-operated and HP-ablated male *H. subflexa* compared to that in the control *H. subflexa*/*H. subflexa* pairing (Fig. 2b). Overall, the presence of *H. subflexa* HP extract resulted in reduced numbers of mating attempts by both HP-ablated and sham-operated males.

Discussion

Hairpencils and *H. subflexa*

Male HP volatiles are important in courtship and mate acceptance in *H. subflexa*; surgical removal of male *H. subflexa* HPs reduced the frequencies of clasping and corresponding mating acceptance relative to those of controls. In the presence of *H. subflexa* HP extract, the frequency of mating in operated males was restored to a level comparable to that of control pairs. Therefore, HP volatiles influence *H. subflexa* courtship and should not be considered purely vestigial. It is unclear what specific behavioral effect HP volatiles elicit in female *H. subflexa*, as there was no distinct qualitative difference in behavioral response when HP extract was present or absent. In *H. virescens*, HP volatiles caused a decrease in the frequency of moving away and an increase in abdominal extension and curling in females (Hillier and Vickers, 2004). In *H. subflexa*, abdominal extension and curling were rarely observed, even in control treatments, and HP volatiles did

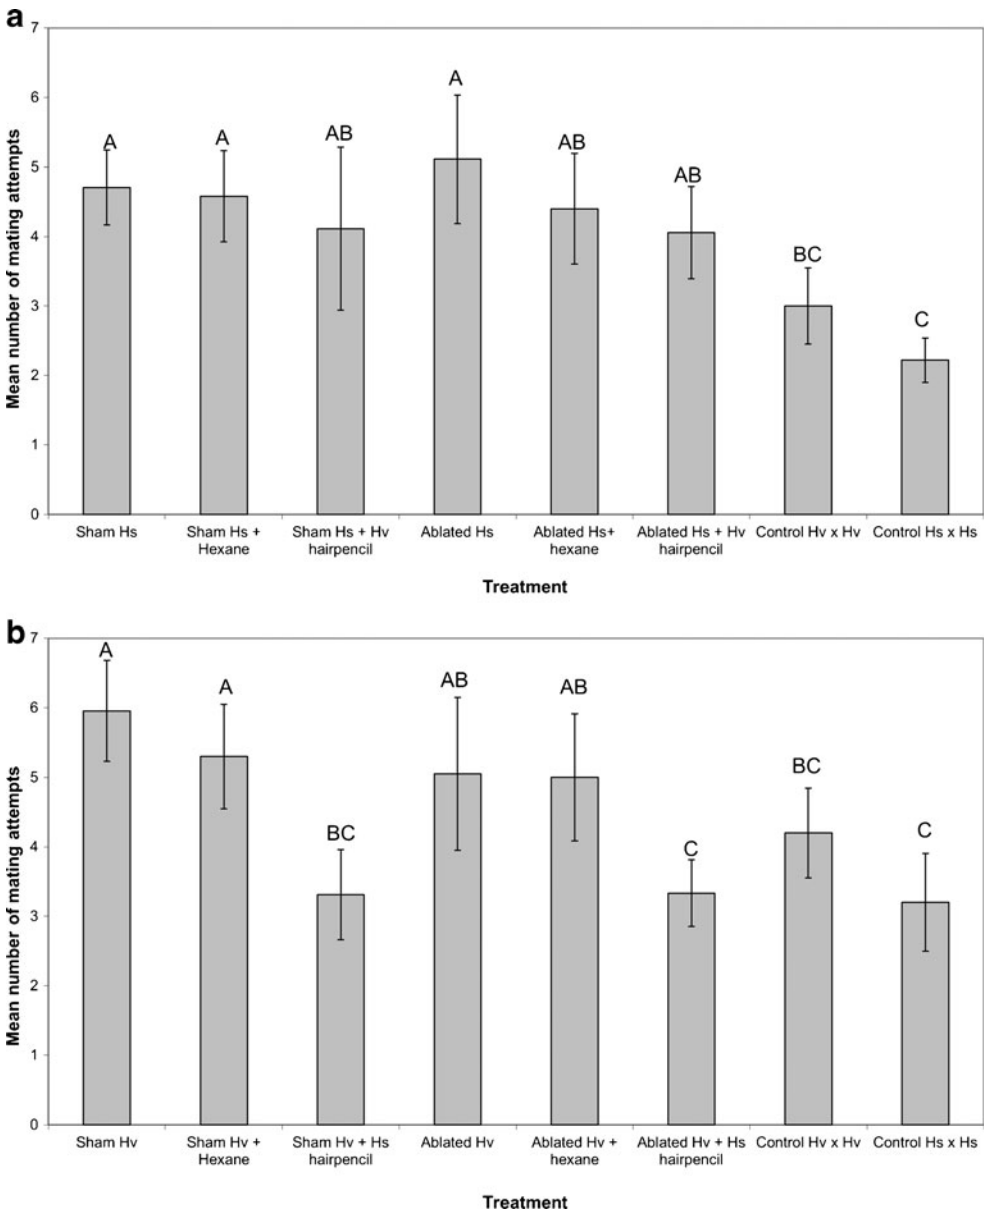

Fig. 2 **a** Mean number of mating attempts between female *Heliothis virescens* (Hv) and male *H. subflexa* (Hs) with various treatments: sham-operated hair pencils (HPs), sham-operated HPs plus a hexane source, sham-operated HPs plus one male equivalent of *H. virescens* HP extract, ablated HPs, ablated HPs plus a hexane source, ablated HPs plus one male equivalent of *H. virescens* HP extract. Pairs of male and female *H. virescens*/*H. virescens* and *H. subflexa*/*H. subflexa* were for comparison of mating frequency. **b** Mean number of mating attempts between female *H. subflexa* and male *H. virescens* with various treatments: sham-operated HPs, sham-operated HPs with a hexane source, sham-operated HPs plus a source of one male equivalent of *H. subflexa* HP extract, ablated HPs, ablated HPs plus a hexane source, ablated HPs plus one male equivalent of *H. subflexa* HP extract. Pairs of male and female *H. virescens*/*H. virescens* and *H. subflexa*/*H. subflexa* (N=20) were for comparison of mating frequency. For each experiment (**a** and **b**), means with the same letter are not different (at P<0.05)

not appear to inhibit females from moving away from courting males.

In spite of this, 38% of HP-ablated male *H. subflexa* mated successfully, indicating that while HP volatiles influence mating success, their absence does not preclude successful mating. In *H. virescens*, HP volatiles appear to have a greater influence on mating success, with <5% of females mating with HP-ablated males (Hillier and Vickers, 2004). The effect on mating by HP-ablated *H. subflexa* males is similar to that of other species, such as *E. elutella* and *Mamestra brassicae* L. (Lepidoptera: Noctuidae), in which HP volatiles improve mating success but are not essential for mating (Phelan et al., 1986; Birch et al., 1989). Possibly, other stimuli not recorded in this study, including visual and acoustic cues, might play a role in female mate acceptance in the absence of olfactory signals.

H. subflexa Males and *H. virescens* Females

The frequency of successful matings between *H. subflexa males* and *H. virescens females* was lower than that for the intraspecific mating of *H. subflexa*/*H. subflexa*. Since ablation of HPs of *H. subflexa* males further decreased the proportion of successful matings, and mating success of *H. subflexa* males courting *H. virescens* females increased in the presence of *H. virescens* HP extract, it suggests a role for these chemicals in prezygotic reproductive isolation between these species. The presence of conspecific HP volatiles during courtship caused an increase in the frequency of abdominal extension and curling by female *H. virescens*; both of these behaviors have been shown previously to correlate with mate acceptance in this species (Hillier and Vickers, 2004).

H. virescens Males and *H. subflexa* Females

Addition of *H. subflexa* HP extract caused an increase in the mating acceptance in both sham-operated and HP-ablated *H. virescens* males. HP extract caused reduced moving and flying away by females, and increased abdominal extension, compared to when extract was not present. The frequency of abdominal curling, a behavior rarely observed in *H. subflexa* mating, also increased in treatments in which HP extract was present, compared to those in which it was not present. The greater frequency of this behavior in the interspecific trials may be due to it being more difficult to observe with *H. subflexa* males because of their rapid, 'aggressive' courtship.

Hairpencils and Reproductive Isolation

Although these two species differ in (larval) host range, the overlap of the highly mobile adults likely increases the possibility of interspecific mating. Differences in the phenologies of adults also can help preclude interspecific matings, but both species are multi-generational, increasing

Table 3 Behavioral responses of female *Heliothis subflexa* to male *H. virescens* with various treatments involving sham operation or ablation of hair pencils (HPs), and additional sources of hexane or HP extract (one male equivalent = 1ME) of male *H. subflexa*. Pairs of male and female *H. virescens*/*H. virescens* and *H. subflexa*/*H. subflexa* were used for comparison of mating frequencies. *Means with the same letter are not different (at $P<0.05$)

the likelihood of temporally overlapping cohorts (Stadelbacker and Martin, 1981). Thus, HP volatiles during courtship are likely a further barrier, in addition to differential attraction to the respective female-produced sex pheromones, to avoid interspecific mating. Redundancy in pre-mating species isolating mechanisms provides a means for reduced risk for mating mistakes in sympatry (Birch et al., 1990).

Recent studies have documented the inheritance, genetic architecture, neurophysiology, and behavioral phenotype of female sex pheromone preferences in male *H. virescens* and *H. subflexa*, along with associated hybrid and backcross progenies (Baker et al., 2006; Vickers, 2006a,b; Gould et al. 2010). These studies suggest strong linkages between specific genes coding putative olfactory receptor proteins, olfactory receptor neuron specificity, antennal lobe activity, and behavioral output of male moths relative to specific female sex pheromone components of each species. We previously identified an olfactory receptor neuron in *H. virescens* males and females that is sensitive to the male HP components hexadecyl acetate, octadecyl acetate, and to (*Z*)-11-hexadecenyl acetate (*Z*11-16:OAc; Hillier et al., 2006, 2007). In *H. virescens*, chemicals detected by this olfactory receptor neuron inhibit male upwind flight and thus function to repel competing males during courtship. The presence of *H. virescens* HP extract also causes a decrease in the overall number of mating attempts by *H. virescens* males (Hillier and Vickers, 2004). In this study, however, there were no differences in mating attempts by *H. subflexa* males, regardless of whether HP extract (of either species) was present or not (data not shown). This is curious, and is perhaps related to the presence of *Z*11-16:OAc in the *H. subflexa* female sex pheromone. Given the similarity in HP composition of the two species, future neurophysiological experiments should examine how such chemicals are detected by *H. subflexa*, to determine whether there are differences in how HP chemicals are processed between these closely related species.

Results of the current study may indicate a circumstance in which evolution of quiescent behavioral responses to both male and female sex pheromone components overlap in these species. Given their recent divergence, a mechanism of mate recognition and selection by females could be implicated in speciation between *H. virescens* and *H. subflexa*. Work by Lassance and Löfstedt (2009) suggests that analogies exist between male and female courtship signals in *Ostrinia nubilalis* Hübner (Lepidoptera: Crambidae), wherein pleiotropy could influence coincident evolution of signals involved in mate selection. Other characters, including host plant choice, female sex pheromone composition, and male pheromone preference might have greater importance in such speciation, though selection for HP composition and female preference would be reinforced through assortative mating (Lassance and Löfstedt, 2009; Gould et al., 2010). Furthermore, the interaction of these traits may be supported by the fact that in many other insect species, male pheromone composition is dictated by sequestration of host plant volatiles (Birch et al., 1990).

In summary, this study provides evidence that HP volatiles are important in reproductive isolation and mate acceptance in *H. subflexa*. We previously demonstrated that *H. virescens* females discriminate between HP extracts of males of the two species (Hillier and Vickers, 2004). Our observations suggest that HP volatiles have similar effects on *H. subflexa* females as they do on *H. virescens* females: quiescence and arrestment (along with abdominal extension and curling).

MS) using a Shimadzu GC17A − GCMS-QP5050A. The GC was equipped with a 30 m×0.25 mm CP-Sil 8CB fused silica capillary column (Varian Inc., Lake Forest, CA, USA). Helium was used as carrier gas, and the GC was programmed from 80°C for 5 min, then 8°C/min to 270°C. The injector temperature was set to 200°C. Mass spectra were acquired at 70 eV. Gas chromatographic analyses were carried out on a Shimadzu GC2014AFSC equipped with a flame ionization detector, and a 30 m× 0.25 mm RTX®-5 fused silica capillary column (Restek U.S., Bellefonte, PA, USA). Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker AMX-400 spectrometer (400 MHz for ^{1}H, 100.6 MHz for ^{13}C) with TMS as internal standard.

Syntheses of Compounds All solvents and chemicals were purchased either from Sigma Aldrich (St. Louis, MO, USA) or Merck (Darmstadt, Germany). Silica gel for column chromatography was from Merck (silica gel 60, 63–200 μm; silica gel 60, 32–63 μm for flash chromatography). Dodecyl acetate (12:Ac) was obtained by acetylation (Ac_2O, DMAP, pyridine) of dodecan-1-ol, (*Z*)-5-tetradecenyl acetate (Z5-14:Ac), and (*E*)-5,13-tetradecadienyl acetate (E5,13-14:Ac) were prepared as described previously (Bergmann et al., 2007), and (*Z*)-5,13-tetradecadienyl acetate (Z5,13-14:Ac, **1**) was prepared as described below.

*8-(Tetrahydro-2H-pyran-2-yloxy)octan-1-ol (**2**)* PPTS (0.35 g, 1.4 mmol) was added to a solution of octane-1,8-diol (7.0 g, 47.9 mmol) and 4.55 ml 3,4-dihydro-2*H*-pyran (4.19 g, 49.8 mmol) in dry dichloromethane (30 ml), and the mixture was stirred at room temperature. After 5 hr of stirring, hexane (60 ml) and sat. $NaHCO_3$ solution (20 ml) were added to the mixture. After 10 min stirring, the phases were separated, and the aqueous phase was extracted with Et_2O. The combined organic phases were dried (Na_2SO_4), and the solvent was removed under vacuum. The residue was purified by chromatography on silica gel (hexane-ethyl acetate 1:1), yielding 7.25 g (65%) of **2** as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 4.57 (t, 1H, J=3.5 Hz), 3.91-3.83 (m, 1H), 3.72 (dt, 1H, J=9.7, 6.9 Hz), 3.63 (t, 2H, J=6.6 Hz), 3.53-3.46 (m, 1H), 3.38 (dt, 1H, J=9.7, 6.9 Hz), 1.87-1.77 (m, 1H), 1.75-1.67 (m, 1H), 1.65-1.48 (m, 8H), 1.40-1.27 (m, 8H). ^{13}C NMR ($CDCl_3$): δ 98.9, 67.7, 63.1, 62.4, 32.8, 30.8, 29.7, 29.4, 29.3, 26.2, 25.7, 25.5, 19.7. MS (EI, 70 eV): *m/z* 39 (37), 41 (88), 42 (26), 43 (31), 53 (12), 54 (28), 55 (100), 56 (37), 57 (28), 67 (29), 68 (14), 69 (26), 85 (37), 101 (5), 230 (M^+, <1).

*8-(Tetrahydro-2H-pyran-2-yloxy)octanal (**3**)* To a stirred solution of 8.30 ml oxalyl chloride (12.5 g, 98.0 mmol) in dry dichloromethane (50 ml) at −78°C, 18.0 ml DMSO (19.8 g, 254 mmol) in dichloromethane (50 ml) were slowly added under nitrogen atmosphere. After 30 min of stirring, a solution of **2** (7.20 g, 31.3 mmol) in dichloromethane (20 ml) was added dropwise. After further 40 min stirring, 52.0 ml Et_3N (38.0 g, 376 mmol) were added, the mixture was left stirring at room temperature for 1 hr, treated with H_2O, and extracted with Et_2O. The organic phase was dried (Na_2SO_4), and the solvent was removed under vacuum. The residue was purified by chromatography on silica gel (hexane-ethyl acetate 5:1), giving compound **3** as a colorless oil (6.67 g, 93%). ^{1}H NMR ($CDCl_3$): δ 9.74 (t, 1H, J=2.0 Hz), 4.56-4.52 (m, 1H), 3.88-3.80 (m, 1H), 3.70 (dt, 1H, J=9.3, 6.8 Hz), 3.51-3.44 (m, 1H), 3.35 (dt, 1H, J=9.3, 6.3 Hz), 2.40 (dt, 2H, J=7.3, 1.5 Hz), 1.84-1.75 (m, 1H), 1.72-1.65 (m, 1H), 1.65-1.46 (m, 8H), 1.40-1.28 (m, 10H). ^{13}C NMR ($CDCl_3$): δ 202.8, 98.8, 67.5, 62.3, 43.8, 30.7, 29.6, 29.1, 29.0, 26.0, 25.4, 21.9, 19.6. MS (EI, 70 eV): *m/z* 39 (12), 41 (69), 42 (11), 43 (29), 55(47), 56 (36), 57 (28), 67 (43), 84 (14), 85 (100), 98 (3), 101 (24), 109 (17), 127 (1), 228 (M^+, <1).

*Tetrahydro-2-(non-8-enyloxy)-2H-pyran (**4**)* Under an inert atmosphere, a solution of $NaN[Si(Me)_3]_2$ in THF (1 M, 30.0 ml, 30.0 mmol) was added to a suspension of methyl triphenyl phosphonium bromide (10.6 g, 29.7 mmol) in dry THF (100 ml). The mixture was stirred at −20°C for 30 min. The solution then was cooled to −78°C, and **3** (6.65 g, 29.3 mmol) was slowly added. The mixture was allowed to warm to room temperature, stirred for 30 min, then poured into ice-water and extracted with Et_2O. The organic phase was washed with brine, dried (Na_2SO_4), evaporated to near dryness, and chilled to precipitate most of the Ph_3PO. After filtration and washing of the precipitate with hexane, the filtrate was concentrated under vacuum. The residue was purified by chromatography on silica gel (hexane- ethyl acetate 5:1) to yield 4.01 g (61%) of **4** as colorless oil. ^{1}H NMR ($CDCl_3$): δ 5.82 (ddt, 1H, J=17.1, 10.3, 6.9 Hz), 4.98 (d, 1H, J=17.0 Hz), 4.92 (d, 1H, J= 10.3 Hz), 4.57 (m, 1H), 3.91-3.84 (m, 1H), 3.73 (dt, 1H, J= 9.6, 6.6 Hz), 3.54-3.47 (m, 1H), 3.39 (dt, 1H, J=9.6, 6.6 Hz), 2.08-2.00 (m, 2H), 1.88-1.80 (m, 1H), 1.76-1.70 (m, 1H), 1.69-1.47 (m, 6H), 1.42-1.28 (m, 8H). ^{13}C NMR ($CDCl_3$): δ 139.2, 114.1, 98.9, 67.7, 62.4, 33.8, 30.7, 29.7, 29.3, 29.0, 28.8, 26.1, 25.5, 19.6. MS (EI, 70 eV): *m/z* 39 (11), 41 (57), 43 (19), 55 (33), 56 (27), 57 (14), 67 (18), 69 (27), 83 (15), 85 (100), 101 (17), 226 (M^+, <1).

*Non-8-en-1-ol (**5**)* Compound **4** (4.00 g, 17.7 mmol) was added to a solution of *p*-toluenesulfonic acid in MeOH (50 ml), and the reaction mixture was stirred at room temperature for 4 hr. The solvent was evaporated, and the resulting residue was dissolved in CH_2Cl_2 (25 ml). The organic phase was washed with brine, dried (Na_2SO_4), concentrated, and the residue was chromatographed on

silica gel (hexane:ethyl acetate 4:1) to yield **5** (1.69 g, 67%). ^{1}H-NMR ($CDCl_3$): δ 5.81 (ddt, 1H, J=17.0, 10.3, 7.2 Hz), 4.99 (dd, 1H, J=17.0, 1.9 Hz), 4.93 (dd, 1H, J=10.3, 1.9 Hz), 3.64 (t, 2H, J=6.6 Hz), 2.04 (overlapped dt, 2H, J~7.4 Hz), 1.62-1.52 (m, 2H), 1.42-1.28 (m, 9H). ^{13}C NMR ($CDCl_3$): δ 139.1, 114.2, 63.1, 33.8, 32.8, 29.3, 29.1, 28.8, 25.7. MS (EI, 70 eV): *m/z* 39 (35), 41 (100), 42 (19), 43 (20), 54 (49), 55 (77), 57 (13), 67 (46), 68 (32), 81 (29), 82 (20), 95 (11), 96 (5), 109 (1), 124 (1), 142 (M^+, <1).

*Non-8-enal (**6**)* In a procedure essentially similar to the synthesis of **3**, 3.58 ml (5.37 g, 41.0 mmol) oxalyl chloride, 6.3 ml DMSO (6.93 g, 89.5 mmol), 5.74 g of **5** (37.3 mmol), and 26.0 ml (18.87 g, 186.5 mmol) Et_3N were reacted to give 4.25 g **6** as slightly yellow oil (75%) The crude product was used in the next step without purification. ^{1}H NMR ($CDCl_3$): δ 9.77 (t, 1H, J=2.0 Hz), 5.80 (ddt, 1H, J=17.0, 10.3, 7.0 Hz), 5.00 (dd, 1H, J=17.0, 1.8 Hz), 4.94 (dd, 1H, J=10.3, 1.8 Hz), 2.42 (dt, 2H, J=7.3, 2.0 Hz), 2.04 (overlapped dt, 2H, J~7.3 Hz), 1.68-1.59 (m, 2H), 1.42-1.28 (m, 6H). ^{13}C NMR ($CDCl_3$): δ 202.9, 138.9, 114.3, 43.9, 40.8, 33.6, 29.0, 28.8, 22.0. MS (EI, 70 eV): *m/z* 41 (85), 43 (33), 54 (54), 55 (100), 56 (20), 57 (23), 67 (25), 68 (22), 69 (11), 70 (12), 79 (15), 80 (14), 81 (24), 93 (10), 98 (12), 111 (3), 140 (M^+, <1).

*5-Acetoxypentyl Triphenyl Phosphonium Bromide (**8**)* A solution of 5-bromopentyl acetate (4.0 g, 19.2 mmol) and triphenylphosphine (5.0 g, 19.2 mmol) in dry acetonitrile (30 ml) was stirred under reflux for 24 hr. After cooling to room temperature, the solvent was evaporated under vacuum. Flash chromatography of the resulting residue on a silica gel column using (CH_2Cl_2 — MeOH 8:1) yielded 7.5 g (84%) of **8** as a viscous yellow oil. To assure solubility of the sample, the NMR spectrum was acquired in methanol-D4. The signals appeared broadened and are reported as multiplets, as coupling constants could not be determined. ^{1}H NMR (CD_3OD): δ 7.95-7.62 (m, 15H), 4.08-4.00 (m, 2H), 3.50-3.36 (m, 2H), 2.00 (s, 3H), 1.78-1.56 (m, 6H).

*(Z)-Tetradeca-5,13-dienyl Acetate (**1**)* A solution of NaN[$Si(Me)_3$]$_2$ in THF (1 M, 2.6 ml, 2.6 mmol) was added to **8** (1.20 g, 2.55 mmol) in dry THF (50 ml) at −20°C in N_2 atmosphere. The mixture was stirred for 30 min. The solution then was cooled to −78°C, and **6** (0.35 g, 2.55 mmol) was added dropwise. The reaction mixture was stirred for additional 2 hr at −78°C, and 1 hr at room temperature. The reaction mixture was poured into ice-water and extracted with Et_2O. The organic phase was washed with brine, dried (Na_2SO_4), and evaporated to dryness to yield a residue that was purified by chromatography on silica gel (hexane-ethyl acetate 20:1), giving **1** as colorless oil (227 mg, 36%). Chemical purity (GC) >98%, isomeric purity (GC): 94% Z, 6% E. Traces of the geometric isomer were removed by argentation chromatography as follows. To a solution of 5 g $AgNO_3$ in 15 ml CH_3CN, 15 g silica gel were added, the mixture was ground for 5 min, and the beaker was covered completely with aluminum foil, and held at 70°C overnight resulting in the evaporation of the solvent. The slightly grayish silica was used for chromatography as usual, covering the column with aluminum foil (Li et al., 1995). ^{1}H NMR ($CDCl_3$): δ 5.81 (ddt, 1H, J=17.0, 10.4, 7.4 Hz), 5.42-5.29 (m, 2H), 4.99 (dd, 1H, J=17.0, 1.9 Hz), 4.93 (dd, 1H, J=10.4, 1.9 Hz), 4.06 (t, 2H, J=7.0 Hz), 2.09-1.98 (m, 6H), 2.05 (s, 3H), 1.68-1.59 (m, 2H), 1.44-1.24 (m, 10 H). ^{13}C NMR ($CDCl_3$): δ 171.2, 139.2, 130.5, 129.1, 114.1, 64.5, 33.8, 29.6, 29.1, 29.0, 28.9, 28.2, 27.2, 26.7, 26.0, 20.9. The NMR data were in general agreement to those reported earlier in CCl_4 as solvent (Cahiez et al., 1980). MS (EI, 70 eV): *m/z* 41 (67), 43 (100), 54 (56), 55 (62), 67 (68), 68 (31), 79 (26), 80 (32), 81 (44), 82 (23), 93 (14), 94 (15), 95 (28), 96 (13), 107 (8), 110 (8), 121 (11), 135 (7), 149 (3), 163 (1), 192 (1), 252 (M^+, <1).

Laboratory Bioassays Larvae of the last instar (Olivares and Angulo, 1992) were removed from the plastic cups, and held individually under bioassay conditions (20°C) 1 hr prior to assay. Behavioral assays used a glass Y-tube olfactometer (3.5 cm i.d., 20 cm arms) coupled via Teflon tubing (4 mm i.d., 70 cm in length) to two 1 l glass containers. The Y-tube was placed horizontally, and the inside bottom was provided with screen in appropriate dimensions to facilitate movement of larvae. Charcoal-filtered air was supplied at a rate of 1.5 $lmin^{-1}$, prior optimization using NH_3/HCl to visualize the air flow (Baker and Linn, 1984). One of the glass containers contained the stimulus and the other either air only (first experiment) or solvent-treated filter paper (second and third experiment) as control. A single larva was placed at the base of the main olfactometer tube, its behavior was observed for 7 min and its choice recorded. Larvae that did not make a choice were excluded from statistical analysis. The stimulus source was rotated randomly to avoid positional bias. The olfactory responses of larvae to the following stimuli were assayed:

1. *Live conspecific larvae* Either 10 or 1 larvae of the last stage were separated and placed into the glass odor container 60 min before starting the assays.
2. *Hexane extract of larvae* A 5×5 cm piece of filter paper was loaded with either 510, 51, or 5.1 mg extract, corresponding to 10, 1, or 0.1 larval extract equivalent (LEE), respectively, 1 LEE being the amount of extract obtained when extracting 1 larva in hexane. After evaporation of the solvent, the paper was placed in the

glass container. Each treated filter paper was used in 5 experiments.

3. *Synthetic compounds* Synthetic compounds were assayed individually in amounts equivalent to their proportion in 1 LEE. Filter paper pieces were loaded with 22 mg Z5,13-14:Ac, 19 mg of 12:Ac, and 7 mg of Z5-14:Ac, respectively.

Data were analyzed by *Chi-square* test using Statistica 7.0 software.

Results

Synthesis of (Z)-5,13-tetradecadienyl acetate The individual reactions used to obtain **1** are summarized in Fig. 1. Swern oxidation of monoTHP-protected (Nishiguchi et al., 2000) octane-1,8-diol (**2**) yielded aldehyde **3,** which was chain-elongated by Wittig reaction using methyl triphenylphosphonium bromide (28% over three steps). Deprotection (67%) of resulting THP-protected 8-nonen-1-ol (**4**) followed by another Swern oxidation gave access to 8-nonenal (**6**), which was used in the next step without further purification. In parallel, 5-bromopentyl acetate was transformed into Wittig salt **8** by treatment with triphenylphosphine in MeCN (84%). Wittig reaction between **6** and **8** under salt-free conditions (Bestmann et al., 1976) yielded target compound **1** with about 6% of the geometrical isomer which was effectively removed by argentation chromatography.

Identification of Compounds Z5,13-14:Ac and E5,13-14:Ac were separated by GC, with the *E* isomer eluting later on a non-polar column (Retention indices 1786 and 1790, respectively, on RTX-5). The retention time of the main compound in hexane extracts of larvae matched that of the *Z* isomer (Fig. 2). Matching of mass spectra for the natural and synthetic materials was confirmed earlier (Bergmann et al., 2007).

Laboratory Bioassays The olfactory responses of larvae to different stimuli in a Y-tube olfactometer are summarized in Table 1. Larvae were attracted to 10 (χ^2=6.545, *df*=1, *P*=0.011) or 1 (χ^2=5.000, *df*=1, *P*=0.025) conspecifics. Hexane extracts of larvae in doses of 10 LEE (χ^2=10.714, *df*=1, *P*=0.001) and 1 LEE (χ^2=7.200, *df*=1, *P*=0.007) were attractive as well, but a dose of 0.1 LEE (χ^2=0.200, *df*=1, *P*>0.05) showed no attractiveness. Of the three major compounds identified in the hexane extract and tested at a 1 LEE dose, only Z5,13-14:Ac was attractive (χ^2=8.048, *df*=1, *P*=0.005), while 12:Ac (χ^2=0.297, *df*=1, *P*>0.05) and Z5-14:Ac (χ^2=0.200, *df*=1, *P*>0.05) were not attractive.

Discussion

Last-instars of *Ch. valdiviana* produce and are attracted to (*Z*)-5,13-tetradecadienyl acetate. The identification of the compounds present in hexane extracts of larvae of *Ch. valdiviana* has been described earlier (Bergmann et al., 2007); however, the identification of the main compound Z5,13-14:Ac was based on the mass spectrum and retention time of minor amounts of this compound in a sample of the geometric isomer E5,13-14:Ac. With the pure synthetic material in hand, we now confirm the identification.

Similar compounds have been found in other cossid species. Although the exact composition of the secretions vary, Z5,13-14:Ac, together with other compounds, also is produced by larvae of *Cossus cossus* (Trave et al., 1966), *Zeuzera pyrina* (Marchesini et al., 1969), and *Chilecomadia moorei* (Garbarino and Gambado, 1988). Apart from the chemical composition of these secretions, the respective

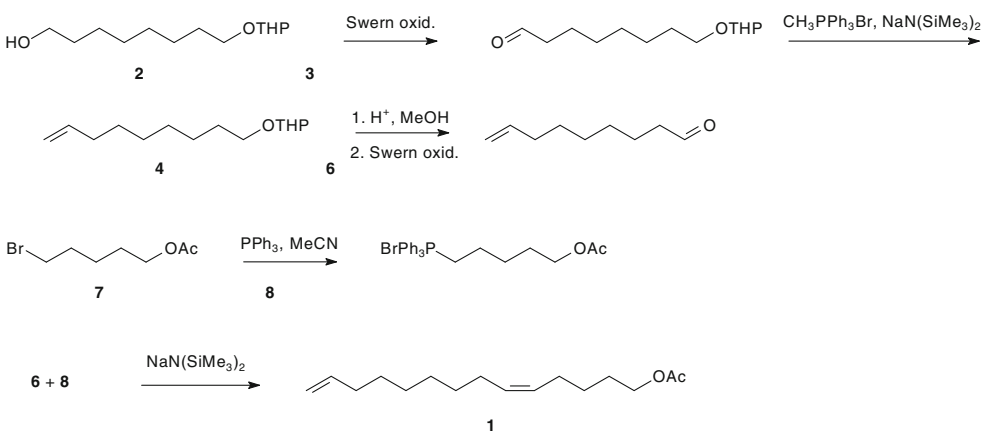

Fig. 1 Synthesis of (*Z*)-5,13-tetradecadienyl acetate

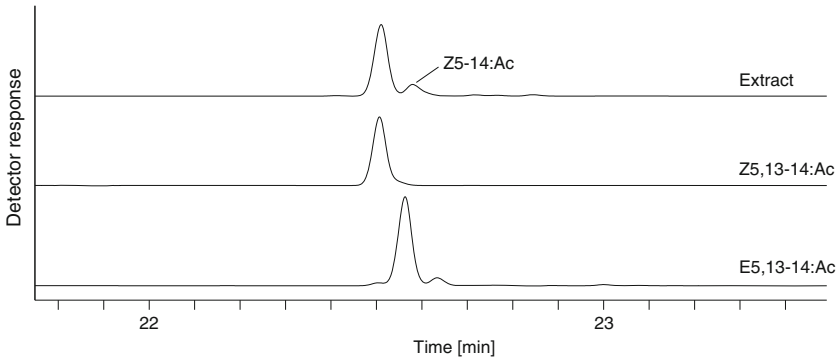

Fig. 2 Gas chromatograms of a hexane extract of *Chilecomadia valdiviana* larvae (*top*), synthetic samples of (*Z*)- (*middle*), and (*E*)-5,13-tetradecadienyl acetate (*bottom*)

reports contain no information about function. To give conclusive answers as to the role of the larval secretion in *Ch. valdiviana*, knowledge of the biology of the insect is needed, but little information is available in the literature. One report presents preliminary conclusions drawn from observations made during the 1992/1993 season (Cerda and Lewis, 1994) indicating, for example, that the life cycle is possibly completed in 2 or 3 years, with adults emerging from November — January. The same report highlights the gregarious habit of larvae, which translates into a magnification of the damage in host trees, due to the concentration of galleries in the affected zone. The present study links this behavior to the chemicals previously identified.

The adaptive role of this communication under natural conditions, however, still needs to be clarified. Taking into consideration available reports, it seems possible that mass attack may facilitate overcoming the defenses of a host tree. During the study, we observed that larvae have a strong tendency to wander when not inside galleries or covered by sawdust, which would facilitate aggregation (and also explain the high number of responders in the laboratory bioassays). The possibility of higher reproductive success when larvae pupate in aggregations, as suggested for *Cydia pomonella* (Duthie et al., 2003), cannot be excluded, but seems less likely as there is no evidence in *Ch. valdiviana* of inter-stage communication (e.g., larva-adult or pupa-adult). In particular, no adult moths were caught in traps baited with varying doses of larval extract during a preliminary field trial (unpublished results). It is also noteworthy that the sex pheromones produced by adult females of *C. cossus* and *Z. pyrina* consist of compounds different from those found in the respective larvae (Capizzi et al., 1983; Castellari, 1986).

This is the second example of a larval aggregation pheromone in Lepidoptera. A volatile aggregation pheromone was identified previously in *Cydia pomonella*, where a blend of compounds produced by cocoon-spinning larva containing (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, geranylacetone, 3-carene, octanal, nonanal, and decanal, attracts conspecific larvae (Jumean et al., 2005a), while a similar blend (heptanal, octanal, nonanal, decanal, (*E*)-2-octenal, 3-carene, sulcatone, and geranylacetone) was attractive to a larval parasitoid (Jumean et al., 2005b). Another example of chemical communication in lepidopteran larvae is the pheromone-mediated trail following and group foraging behavior exhibited by some social caterpillars (see, for example, Fitzgerald, 2003). In some species, the compound eliciting this behavior has been identified as 5β-cholestan-3-one (Fitzgerald, 1993; Ruf et al., 2001).

Synthesis of Z5,13-14:Ac has been described before, for example by taking advantage of the stereospecific addition of lithium alkyl cuprates to acetylene, followed by alkylation of the *Z*-configured vinylic cuprate (Cahiez et al., 1980). Our approach uses well-known reactions and avoids the use of acetylene and the carcinogenic solvent HMPT in the alkylation step, by employing Wittig reactions.

In summary, we showed that (*Z*)-5,13-tetradecadienyl acetate is the compound responsible for the aggregation of the larval stage of *Chilecomadia valdiviana*.

Table 1 Behavioral response of larvae of *Chilecomadia valdiviana* to conspecific larvae, hexane extract of conspecific larvae, and single synthetic compounds in a Y-tube olfactometer

	Stimulus	N	No. of larvae responding to	
			Stimulus[a]	Control
Exp. 1	10 larvae	25	17*	5
	1 larva	22	15*	5
Exp. 2	Extract (10 LEE)	25	18*	3
	Extract (1 LEE)	24	16*	4
	Extract (0.1 LEE)	25	9	11
Exp. 3	Z5,13-14:Ac (1 LEE)	24	17*	4
	12:Ac (1 LEE)	31	9	14
	Z5-14:Ac (1 LEE)	20	9	11

[a] Statistically significant differences in responses ($P<0.05$ according to *chi-square* test) are marked with *

additional compounds that give prolonged activity. However, no additional active compounds have been identified.

Z9-16:Ald is known also as a component of some moth sex pheromones (Nesbitt et al., 1975; El-Sayed, 2011), and is commercially available. The use of trail pheromone to reduce or eliminate foraging, based on the moth mating disruption paradigm (Bartell, 1982; Witzgall et al., 2010), has been examined for control of Argentine ants (Tatsuki et al., 2005; Suckling et al., 2008; Tanaka et al., 2009; Nishisue et al., 2010; Sunamura et al., 2011). According to studies that use a single point source, and that are confirmed with a dispersed formulation in small plots outdoors, trail disruption acts by changing the walking track angle of ants within a treated area (Suckling et al., 2008). At close range to a point source, disruption results in a significant drop in trail integrity of individual ants, defined by the linear regression statistic, r^2, which is very high (0.9–1.0) on straight trails. High amounts of pheromone presented near a trail led to a build up of ants in the area; as ants entered the disrupted area, they lost the trail they were following and had difficulty leaving the area because they could not find the other end of the trail back to the food or nest. When pheromone was applied over a wide area, using dispensers or widely dispersed micro-encapsulated sources, ant foraging was reduced (Suckling et al., 2010; Sunamura et al., 2011). To be a successful control tactic, trail pheromone disruption must reduce foraging efficiency and suppress ant populations.

Several substrates for controlled release of trail pheromone have been tested for Argentine ants. Tanaka et al. (2009) used polyethylene tubing dispensers and, like Nishisue et al. (2010), found that small plots were reinvaded readily when the dispensers were removed. Disruption of trails lasted as long as pheromone was released in the small plots, but the practicality of hand applying polyethylene tubing dispensers 40 cm above ground may be limited. Suckling et al. (2008) used a short-lived formulation of sand plus trail pheromone in 1 and 4 m^2 plots to demonstrate another control approach: disruption of the boundary layer where ants are active. Suckling et al. (2010) used micro-encapsulated, widely dispersed, point sources and extended the longevity of the disruptant effect to 2 weeks. These methods could offer different approaches for intervention against invading ants, (Sunamura et al., 2011). However, more information is needed on the mechanisms, concentrations, and active components required for success of trail pheromone disruption for ant control.

Ant trail pheromone concentration likely is to be linked to the density of ants trailing, and the quality or enduring nature of the food resource (Deneubourg et al., 1990; Jackson and Châline, 2007), as successful foraging individuals reinforce the trail back to the nest (Van Vorhis Key and Baker, 1986). Here, we hypothesized that trail pheromone disruption should be related to initial trail pheromone concentration, in the same way that moth pheromone disruption is more successful at lower insect density (Witzgall et al., 2010). We also were interested in observing switching of trails to higher concentration ones, and the capacity for recovery at specific concentrations, because this might provide insight into the phenomenon, by indicating any effect of adaptation or sensory overload, a mechanism relevant to moth disruption, especially with off-ratio blends (Minks and Cardé, 1988).

Methods and Materials

Insects Five queen-right Argentine ant colonies were used and maintained by methods adapted from that described for the red imported fire ant, *Solenopsis invicta* (Banks et al., 1981). Colonies were field collected from Hoon Hay, Christchurch 43°34S 172°35E in December 2009, April and November 2010. Colonies were starved of protein and carbohydrates 2–3 d prior to the start of experiments, but allowed access to water, to encourage foraging.

Chemicals Z9-16:Ald (94.5% chemical purity) was purchased from Bedoukian Research (Danbury, CT, USA), and diluted in ethanol for use.

Experimental Set-up We hypothesized that concentrations required for disruption should depend on the strength of the base foraging trail (Trail 1), and that disruption of foraging by a second upwind stimulus trail (Trail 2) at the same concentration, should occur independent of trail strength. We used the approach reported by Suckling et al. (2008), based on the parallel trails used by Morgan et al. (2006), of a suspended horizontal glass plate (400×200×5 mm) as the substrate. This was connected by a single wire at one diagonal end to channel and regulate the foraging of an ant between nest and food source. The rectangular plate was positioned so as to allow airflow from Trail 2 across Trail 1 (Supplemental Fig. A, Fig. 1). A white background, with faint pencil lines drawn on paper under the glass, was used to maximize contrast. Trails were filmed diagonally overhead (i.e., at 45°) with a webcam (Logitech Pro 9000 webcam, Freemont, CA, USA; screen size 80% of actual, 960×720 pixels at 15 frames per second). This allowed viewing of the maximum length of the trail on the glass and the determination of trail integrity (defined as a significant value of r^2) of the base trail. The base trail (Trial 1, 30 cm length) of Z9-16:Ald was applied at two rates (1 and 100 pg/cm), by streaking 3 μl of pheromone in ethanol, from a glass capillary tube, in a straight line. Following application of the base trail, Trail 2 (10 cm length) was

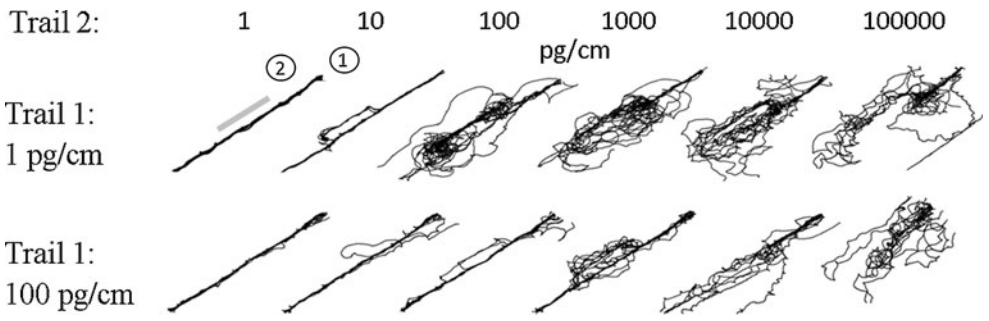

Fig. 1 Combined tracks of Argentine ants (N=10), *Linepithema humile*, at low and high (1 or 100 pg/cm) base-trail (Trail 1, 30 cm long) pheromone concentrations, disrupted by an upwind trail (Trail 2, shown as grey, wide line in top left image) of various concentrations (1–100,000 pg/cm) of (*Z*)-9-hexadecenal

drawn parallel, 1.5 cm upwind of the base trail, at six rates (1, 10, 100, 1,000, 10,000, and 100,000 pg/cm). Low speed directional air movement (~0.05 m.sec^{-1}) was generated by conducting the experiment 1.5 m from a fume hood. This airflow occurred at a ~60° angle to increase the angle of incidence (from 90° to >120°) for ants affected by Trail 2 (from the top down in Supplemental Fig. A). Experiments were conducted for a maximum of 30 min., or until 10 individuals were recorded on an outward journey from one colony. This was repeated five times for two base-trail concentrations, at six disruption rates, using 5 different colonies (N=50 ants per treatment). A dental roll with 10% sugar water was placed at the end of the trail downwind to provide a reward and to assess the success of forager ants in discovering this food source, as well as reducing the incidence of ants walking back onto the glass sheet. Only ants leaving the nest were recorded. This was done to reduce the influence of any additional cues to the trail pheromone that returning ants may have used to return to the nest (e.g., Cavill et al., 1979).

Walking of an individual ant was analyzed with MaxTraq v1.9 (Innovision Systems, Lapeer, MI, USA), using a minimum of 30 and a maximum of 600 recorded frames. A general linear model was conducted on the effect of base trail (Trail 1), stimulus trail (Trail 2), and their interaction, on disruption, measured as residual error sums of squares obtained by using the least squares regression method. Stimulus trail (Trail 2) concentrations of 100, 1,000, 10,000, and 100,000 pg/cm were analyzed, with the lower concentrations excluded, as there was no effect observed. The residual error sums of squares values were used instead of the r^2 trail integrity statistic (bounded by 0 and 1), due to the unsuitability of r^2 values to meet the assumptions of normal distribution and homogeneity of variance of the general linear model. The residual error sums of squares values are, in effect, a distance measure in one dimension, as they are calculated from the vertical distance from the line to the point and not the perpendicular distance. A square root transformation of the residual error sums of squares was used to meet the assumptions of normal distribution and homogeneity of variance of the general linear model. A second analysis was conducted, with colony added as a repeated factor, to examine any effect on disruption measures. Ant arrival success was recorded in binary form (success or failure), and a binary logistic regression was conducted with ant arrival success rate as the response, and base trail (Trail 1), stimulus trail (Trail 2), and their interaction as factors. The low concentration tests of Trail 2 were discarded, as for the general linear model. The percentages of ants that stayed on the base trail (Trail 1), switched to the disrupting trail (Trail 2), or were fully disrupted (never followed any trail), were recorded and compared.

Results

Preliminary tests indicated that the trail-inducing range of Z9-16:Ald on glass was substantially higher than that reported by Van Vorhis Key and Baker (1982b) using paper. They reported activity above the solvent control at approximately 0.2 pg/cm, and optimal trail following (mimicking the natural product) between 2,000 and 20,000 pg/cm, using a trail pheromone purity of >98%. Our results, however, indicated optimal trail-following integrity between 1 and 100 pg/cm and a loss in trail-following integrity outside of this range.

Individual ants tracked the 1 pg/cm and 100 pg/cm base trails consistently (Fig. 1). When the second trail was added upwind, ants showed a range of tracks, depending on the concentration of both the base (Trail 1) and stimulus (Trail 2) trails. When Trail 2 was 100-fold higher in concentration than Trail 1, tracks had erratic direction and changes in track angle (Fig. 1). The general linear model on residual error sums of squares showed that Trail 1 and Trail 2 both had an effect on trail integrity (Trail 1, $F_{(1,3,3)}$=55.88, P<0.001, Trail 2$F_{(1,3,3)}$=30.89, P<0.001), with no interaction between Trails 1 and 2 ($F_{(1,3,3)}$=0.44, P=0.726).

Adding colony as a repeated factor made little difference to the result ($F_{(4)}$=1.83, P=0.151). A similar result was obtained from the binary logistic regression conducted on ant success data, with Trail 1 and Trail 2 both having an effect on bait discovery success (Trail 1, P<0.001, Trail 2, P=0.002); there was no interaction (P=0.091) between the two trail effects.

At 1 pg/cm base trail, there was no evidence of ants switching to the parallel trail at the same concentration. Switching did not occur until the disruption trail (Trail 2) was 10–100 times greater in concentration than the base trail. At 100 pg/cm base trail, switching occurred when the disruption trails was also 100 pg/cm, and occurred more frequently when the disruption trail was 10–100 times more concentrated. Of the relatively few ants that switched between trails, when Trail 2 was not inducing full disruption, several returned successfully to the base trail before they reached the end of the disruption trail (Fig. 1).

Plotting the trail integrity statistic (r^2) against Trail 2 concentration (Fig. 2), showed the concentration difference between the two trails that was required for disruption of trail following on the base trail. At 1 pg/cm, no change in trail integrity on the base trail occurred at the two lowest concentrations of the disruption trail. However, once the disruption trail concentration reached 100 pg/cm, trail integrity on the base trail decreased. Similarly, at 100 pg/cm base-trail concentration, disruption was evident when the disruption trail was 10,000 pg/cm. Therefore, disruption of trail following on the base trail required a 100-fold greater concentration of the disruption trail.

Similar results were obtained for the arrival success of workers at the other end of a trail, after passing through the treated area (Fig. 2); i.e., a reduction in arrival was apparent only when the disruption trail concentration was roughly 100 times that of the base trail. There was a logarithmic relationship ($y=1.1076e^{4.513x}$ r^2=0.97) between arrival success and trail integrity (r^2), and general agreement in results for the two base-trail concentrations (Fig. 3). Changes in arrival success were more greatly affected by disruption than changes in trail integrity (e.g., when r^2 was ~0.6 the arrival success of workers at food sources was only ~15%).

Disruption and trail switching (from Trail 1 to Trail 2) of ants, at some point during trailing, occurred more frequently as the disruption trail concentration increased, as shown in Fig. 4. At a base-trail concentration of 1 pg/cm, the percentage of ants that switched to the disruption trail (Trail 2; black bar) peaked when the disruption trail's concentration was 100-fold greater greater than Trail 1. Above this concentration, trails were disrupted, with few ants following either trail (grey bar). At a base-trail concentration of 100 pg/cm, the percentage of ants on the disruption trail peaked when the trail's concentration was 10-fold greater; above this, trail following was reduced substantially. The two trails appeared to merge (confounding our analysis) with greater differences between concentrations of the two trails (Fig. 1).

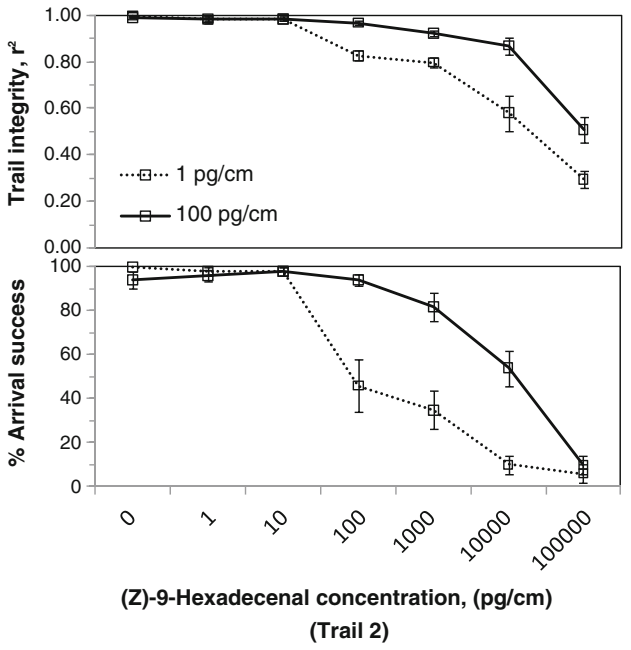

Fig. 2 Loss of Argentine ant, *Linepithema humile*, trail integrity (r^2) (*upper*) and arrival success (*lower*) over a 30 cm distance following a 1 or 100 pg/cm base trail, disrupted by an upwind trail (Trail 2) of various concentrations of synthetic (*Z*)-9-hexadecenal

Discussion

Trail following by worker ants was readily established using the trail pheromone component, *Z*9-16:Ald, over a wide range of concentrations on glass. Optimal following was in the range 1–100 pg/cm; above this, we observed a

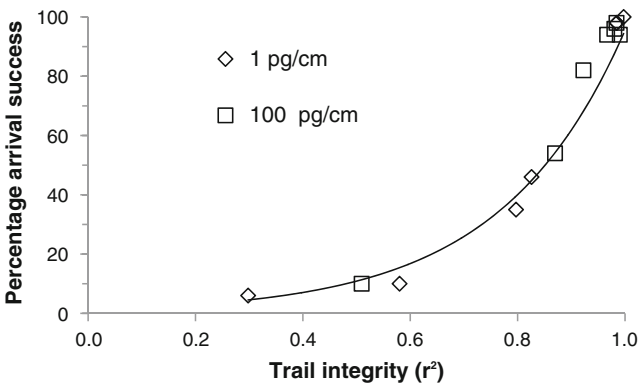

Fig. 3 Relationship between arrival success at food source and trail integrity (r^2), along base trail disrupted by an upwind trail of various concentrations of synthetic (*Z*)-9-hexadecenal, for Argentine ants, *Linepithema humile*

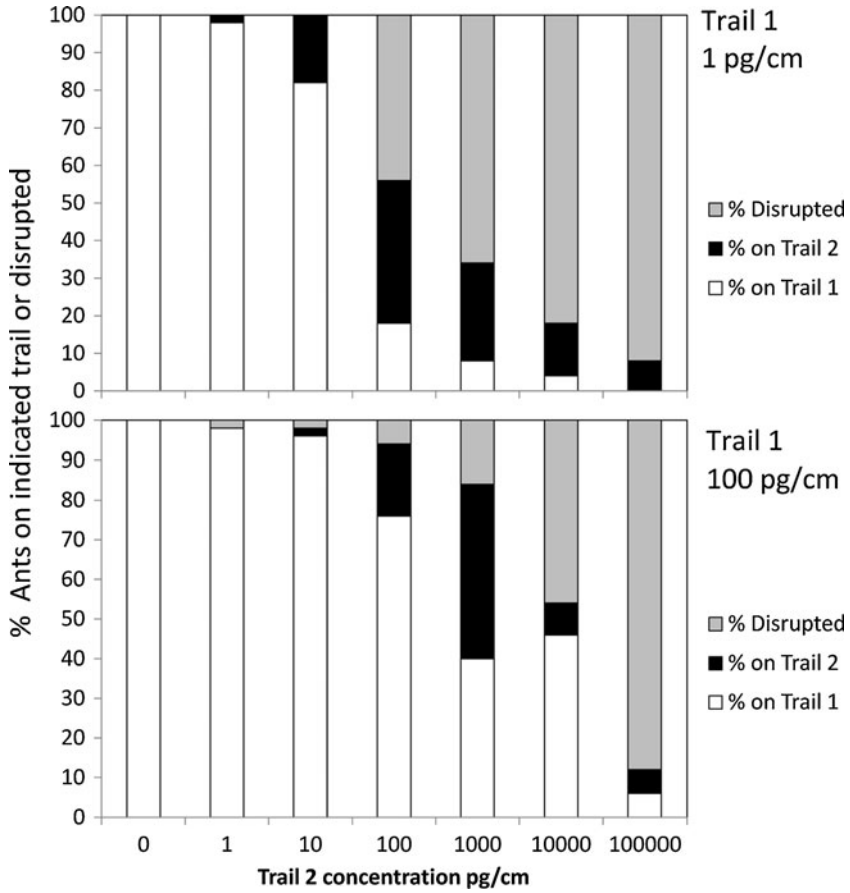

Fig. 4 Percentage of Argentine ants, *Linepithema humile*, that stayed on the base trail (Trail 1), switched to the disrupting trail (Trail 2), or were fully disrupted (not following any trail), in trials testing two concentrations of Trial 1 and various concentrations of Trial 2

decrease in trail following. This compares with the optimum amount of pheromone for trails of *Atta sexdens sexdens* (15–150 pg/cm; Morgan et al., 2006), and *Myrmica rubra* (3–300 pg/cm; Evershed et al., 1982). One pg/cm and one hundred pg/cm trails were chosen for tests of disruption, because these represented the concentration limits (i.e., weak and strong stimuli) for effective trail-following, likely reflecting low and high densities of worker ants. We demonstrated that it was possible to disrupt both trail concentrations, but only if greater pheromone concentrations were applied to the secondary (disrupting) trail. Not surprisingly, our results showed that weaker trails were more readily disrupted than stronger trails at lower concentration disrupting trails. Our trail integrity value, r^2, appeared to under-estimate trail disruption success, with a trail integrity value of 0.8 showing some impact on successful trail following, while a r^2 value of 0.6 had an arrival success of only 15%.

Hangartner (1967) manipulated trailing worker ants (*Lasius fuliginosus*) and noted that "it was observed that by asymmetric placing of the antenna tips in the scent path the animals could detect a concentration difference between left and right." Argentine ants follow trails by comparing inputs between their antennae, and move obliquely across a trail into clean air, before turning and repeating the process in a zigzag fashion. Communication disruption of trail-following ants, by excess trail pheromone in the air, could operate in several ways including, masking of the trail, sensory overload, or "false trail following". If a trail is too wide, ants can become disrupted (Morgan et al., 2006). Thus, it is possible that disruption could work by effectively widening a trail so that its boundaries with clean air are not encountered. Alternatively, sensory overload by prolonged adaptation to pheromone has been put forward as an explanation for the mechanism of disruption in a number of species of moths, including, *Epiphyas postvittana* (Bartell and Lawrence, 1973) and Oriental fruit moth, *Cydia* (=*Grapholitha molesta*) (Rumbo and Vickers, 1997), and thus, it is possible that the increased concentration of trail pheromone in the air could cause sensory adaption in the trail-pheromone ants. False-trail following, in which search effort is expended unsuccessfully, is another mechanism proposed for mating disruption in moths (Bartell, 1982). It is possible that disrupted ants lose control of their turning angles (Suckling et al., 2008) in response to instantaneous concentration peaks, and follow new trails, rather than the initial trail they were following.

Detection and response to overlapping pheromone plumes in the pea moth, *Cydia nigricana,* were studied by

Wall and Perry (1981). They found that male pea moths moved past lower dose sources for higher dose sources upwind. Later, Schofield et al. (2003) showed how almond moth *Caudra cautella* detected and responded to overlapping plumes in a wind tunnel. Morgan et al. (2006) found that workers of the ant *A. sexdens sexdens*, when given a choice of concentrations at a trail branch, always chose the more concentrated one. We observed that overstrength trails had increasing recruitment success at the expense of weaker trails. Moreover, these higher concentration trails may be reinforced by attracting more ants, and hence obtaining greater amounts of trail pheromone (Van vorhis Key and Baker, 1982b). We speculate that a similar kind of false-trail following, in response to local variation in instantaneous concentration, could cause ants to move with the tortuous and random tracks observed in this work. However, unlike the majority of moths investigated, we observed that once clean air was presented to an ant walking out of a disrupting cloud, it was able to relocate the initial trail to the food or nest. If true, such a lack of prolonged orientation disruption would mean that behavioral control of walking ants through trail pheromone disruption will be more difficult to achieve than mating disruption of flying moths.

Our results suggest greater amounts of pheromone would be needed to disrupt higher density trails, as might occur near nests and rich food sources. However, this problem may be less important if very large areas are treated over relatively long periods of time, as the disruption of new foraging trails would reduce the discovery of additional resources. Over time, this could result in a significant reduction in the flow of food back to the nest, thus reducing nest and range expansion (Aron et al., 2001).

Although these laboratory tests show promise for using this approach as a pest management system, more developmental work on suitable formulations for use in the field is needed. Moreover, we used only a single compound for trail disruption. There is some evidence for additional active compounds in the natural pheromone (Van Vorhis Key and Baker, 1982a), and identification of these could prove important for more effective trail disruption. Once a suitable formulation has been developed (e.g., Nishisue et al., 2010), larger spatial scale trials can be run for the effects of trail disruption on food foraging, and population growth in Argentine ant colonies.

(Wyatt, 2010), which provides final assurance before allowing lambs at the udder (Lindsay, 1988). When ewes are not in parturition and not lactating, olfactory cues play an inhibitory role in maternal responsiveness, resulting in ewes displaying indifferent or hostile behavior toward neonatal lambs (Dwyer, 2008). However, for a short period, around the time of parturition, ewes become highly interested in neonatal lambs and may even steal lambs from other ewes. During parturition, odor produced by or associated with a lamb is a powerful stimulus, and neural structures such as the olfactory bulb undergo extensive changes when exposed to such odors (Kendrick et al., 1992). The bond between ewe and lamb is established through contact within 4–6 h after birth. If this fails to happen, maternal interest wanes and the ewe will not accept the lamb. However, once the bond is formed, ewe and lamb can be separated for relatively long periods without disruption of bond integrity (Lindsay, 1988).

The common factor that characterizes most post-partum deaths of lambs is impediment or disturbance of bond formation between ewes and offspring (Lindsay, 1988). In order to curtail financial losses that result from rejection of newborn lambs, a well-known phenomenon in all sheep races, farmers and scientists have examined methods of facilitating adoption of rejected lambs by ewes with ample milk. In addition to the Aristotelian method, other methods of odor transfer are practiced, albeit with limited success, by sheep farmers and have been subjected to scientific scrutiny including, for example, the transfer of the odor of a foster mother's own lamb to a rejected or orphaned lamb (Price et al., 1984, 2003; Alexander et al., 1987, 1989a, b).

Although sheep have been domesticated for about 11,000–12,000 years, and are regarded as one of the most studied animal species (Adams and McKinley, 1995), the olfactory cue that mediates ewe-lamb bonding has not yet been characterized. There are several sources from where the volatile organic compounds (VOCs) constituting a lamb's unique olfactory cue could be released. One possibility is a maternal label originating from amniotic fluid, milk, saliva, or some other secretion/excretion of the ewe. Rietdorf (2002) investigated three possible sources of sheep maternal odor: colostrum, amniotic fluid, and inguinal gland secretion. Because ewes are strongly attracted to amniotic fluid for a few hours after parturition (Lévy et al., 1983; Vince et al., 1985), farmers often smear a newborn lamb with a ewe's amniotic fluid so as to strengthen the bond (Lévy et al., 2004). However, the amniotic fluid has no effect on maternal acceptance, indicating that the fluid contains cues for general attractiveness rather than individual recognition (Lévy et al., 2004).

Alternatively, a lamb could be born with its own individual odor, with amniotic fluid having a supporting role in recognition by inducing a ewe to lick and groom a lamb, thus enabling the ewe to become acquainted with the lamb's olfactory profile. The interest that ewes display in the hindquarters, head, and neck areas of their lambs is well documented (Alexander et al., 1983; Price et al., 1984; Lynch et al., 1992; Houpt, 2005). However, from our observations, it is apparent that, in general, a ewe has no preference for a specific area on a lamb's body during the initial identification process; she simply inspects the closest part of the lamb. The lamb is finally accepted at the udder with its head turned away from the head of the ewe, at which stage the ewe, perhaps for practical reasons, shows increased interest in the lamb's hindquarters. These observations are in accord with other findings that indicate that the discrimination by ewes between their own and alien lambs is mediated primarily by olfactory cues from the lamb's wool and skin, and not from a specific area on the lamb's body or amniotic fluid (Alexander and Stevens, 1981; Lynch et al., 1992; Brennan and Kendrick, 2006). Furthermore, Kendrick et al. (1992) found that lamb odors had no influence on the activity of olfactory bulb neurons of ewes during the period before birth, but when tested after birth these odors were potent; the smell of a lamb's wool being almost as effective a stimulus as the smell of the whole lamb. Subsequently, Lévy et al. (2004) showed that ewes could recognize lambs solely through VOCs, without direct contact. Cues responsible for the individual olfactory signature of a lamb are not effective at distances greater than 250 mm (Alexander and Shillito, 1977; Alexander, 1978; Poindron et al., 2003), suggesting that the cues are either not very volatile or are present at very low concentrations.

Poindron et al. (2006) and Romeyer et al. (1993) showed that ewes use phenotype matching to recognize lambs. A ewe implanted with monozygotic twin embryos, and allowed to learn the odor of one of the twins after birth, recognized the second monozygotic lamb without being previously exposed to it. However, when this experiment was repeated with dizygotics, the ewe did not identify the twin after first being exposed to the other dizygotic (non-identical) twin. This experiment also shows that at least some features of the lamb's odor are genetically based (Wyatt, 2003).

Here, we report the results of qualitative and quantitative analyses of VOCs present in the cranial wool of Döhne Merino lambs, as well as results of preliminary field tests with synthetic mixtures of the identified VOCs.

Material and Methods

General All (borosilicate) glassware used for the collection of samples was washed thoroughly with distilled water,

heated (400°C) for at least 30 min. to remove all traces of adsorbed organics, and then cooled immediately prior to use. Samples (1 ml) of solvents dichloromethane (DCM) (Romil, Super Purity, Cambridge, UK or Pestanal Grade, Riedel de-Haën, Seelze, Germany) and *tert*-butyl methyl ether (TBME) (Sigma-Aldrich, anhydrous, 99.8%, St Louis, MO, USA) were concentrated to 10 μl in a nitrogen atmosphere (Reiter et al., 2003) and analyzed for impurities. These solvents were sufficiently pure for the extraction of semiochemicals. Syringes were cleaned by flushing barrels and rinsing plungers with DCM.

Sample Collection and Preparation A ewe flock of Döhne Merinos at Mariendahl, an experimental farm of Stellenbosch University located 14 km outside Stellenbosch, was available for study. The Döhne Merino sheep race produces a high percentage of twins. Singleton- and twin-bearing ewes were housed in separate paddocks. After birth, the singleton-bearing ewes plus lambs were moved to another paddock, while the twin-bearing ewes with lambs were moved to lambing pens for 2–3 d, after which they were housed in their own paddock. Sixteen (9.69%) of a flock of 165 twin-bearing ewes were used as a sample group. Using a pair of scissors, wool samples (*ca* 200–400 mg) were collected from the foreheads of 32 lambs on the morning after birth. Cranial wool was used because the head of a lamb should be less contaminated with foreign matter than the rest of the body. The samples were stored in glass vials (25 ml) with Teflon-faced septa at −20°C until analyzed. The wool harvested from one lamb was sufficient for several analyses (Supplementary material, Fig. S1).

The procedures that were followed in our research were approved by the Stellenbosch University Ethics Committee: Animal Care and Use (Ethics number 11NC_BU01).

Analytical Methods Gas chromatographic (GC) analyses were carried out with a Carlo Erba HRGC gas chromatograph (Milan, Italy) with a Grob split/splitless sample inlet and flame ionization detector operated at 220°C and 280°C, respectively. Gas chromatographic data were acquired with a DELTA Chromatography Data System, Version 5.0 (Digital Solutions, Brisbane, Australia). The capillary columns were manufactured by the Laboratory for Ecological Chemistry (LECUS, Stellenbosch University) and were provided with integrated retention gaps of 1–2 m. The following columns were used: column A [glass, 40 m× 0.25 mm i.d., coated with 0.25 μm of apolar PS-089-OH (DB-5 equivalent)], column B [glass, 40 m×0.25 mm i.d., coated with 0.25 μm of polar AT-1000 (FFAP equivalent)], enantioselective column C [glass, 30 m×0.3 mm i.d., coated with 0.25 μm of OV-1701-OH containing 10% heptakis(2,3-di-O-methyl-6-O-tert-butyldimethylsilyl)-β-cyclodextrin], and enantioselective column D [glass, 30 m×0.3 mm i.d., coated with 0.25 μm of OV-1701-OH containing 10% heptakis(2,3-di-O-acetyl-6-O-tert-butyldimethylsilyl)-β-cyclodextrin)]. Hydrogen was the carrier gas at a linear flow velocity of 50 $cm.sec^{-1}$ (column temperature 40°C). Samples were injected in the split mode, at a column temperature below 30°C. The column temperature was increased ballistically to 40°C, after which columns A and B were temperature programmed at 2°C.min^{-1} to 280°C and 250°C, respectively. The final temperature was held for 20 min. The enantioselective columns were programmed at 1°C.min^{-1} from 40 to 220°C.

Gas chromatographic-low resolution electron impact mass spectrometric analysis (GC-LRMS) of material from wool samples was carried out on a Carlo Erba QMD 1000 instrument (Milan, Italy), using the columns and GC parameters specified above. Electron impact (EI) mass spectral data were acquired at 70 eV from *m/z* 25–350. Helium was the carrier gas at a linear flow velocity of 28.6 $cm.sec^{-1}$ (column temperature 40°C). Inlet and interface temperatures were 220°C and 250°C, respectively. The ion source temperature was set at 180°C, and the pressure in the source housing was *ca*. 2×10^{-5} mm Hg at a column temperature of 40°C, decreasing to *ca*. 1×10^{-5} mm Hg towards the end of the temperature program. A scan rate of 0.9 $sec.scan^{-1}$ and an interscan delay of 0.1 sec were used. This instrumentation also was used for retention time comparisons of the volatiles in the wool samples (wool volatiles) with authentic synthetic reference compounds. Gas chromatography-mass spectrometry (GC-MS) was used to monitor the syntheses of reference compounds, and to confirm the identification of the wool volatiles by retention time comparison with commercially available synthetic compounds (Sigma-Aldrich, Cape Town) available from previous research projects, or compounds synthesized during the present study (Supplementary material). High resolution mass spectrometric data were acquired on a gas chromatograph coupled to a time-of-flight mass spectrometer (GC-TOF-HRMS), employing a Waters GCT Premier GC-MS instrument (Waters, Milford, MA, USA) fitted with capillary column E (30 m×0.25 mm i.d., 0.25 μm film, DB-5 ms, Agilent JW Scientific, Folsom, CA, USA). Helium was the carrier gas at 1 $ml.min^{-1}$. An inlet temperature of 260°C was used, and samples were introduced in the split mode (split ratio 1:5) at a column temperature below 30°C. The column temperature was then increased ballistically to 40°C, after which the oven was programmed at 2°C.min^{-1} from 40 to 280°C (isothermal 5 min.), followed by a 2°C.min^{-1} ramp to 300°C (isothermal for 20 min). EI-MS data were acquired at 70 eV, scanning the range *m/z* 35–600 at a rate of 0.2 sec/scan, with an inter-scan delay of 0.05 sec. The source temperature was 180°C and perfluoro-tri-*n*-butylamine was used as mass reference.

The identification of the compounds associated with the cranial wool of the experimental lambs also was substantiated by the determination of retention indices (Kovats, 1958).

^{1}H and ^{13}C NMR spectra of synthesized reference compounds were recorded in $CDCl_3$ on Varian VNMRS 300, Unity INOVA 400 and UNITY INOVA 600 NMR instruments (Varian, Palo Alto, CA, USA).

Sampling Methods

Conventional Sample Extraction Dichloromethane (DCM) and *tert*-butyl methyl ether (TBME) were tested for the extraction of wool volatiles. TBME (1 ml) was found to be more effective for extracting wool samples (300–500 mg). Methyl hexanoate (14.8 μg/ml) was added as an internal standard. Synthetic analogs of all the compounds identified also were used as external standards. Extracts were concentrated in a nitrogen atmosphere by placing a vial into a 100-ml beaker, covering the beaker with aluminum foil, and purging the solvent vapor from the beaker without directing the nitrogen flow into the vial (Reiter et al., 2003). During evaporation, the extracts were transferred to smaller Reacti-Vials. The concentration process took about 15 h to yield a final volume of *ca* 10 μl. Aliquots (1 μl) of extracts were subjected to GC-MS analysis by using split and septum purge flows of 10 and 1 $ml.min^{-1}$, respectively.

Headspace Sampling by Solid Phase Microextraction (SPME) Headspace volatiles of a sample of wool (70 mg) in a bottle (8 ml) were sampled by SPME for 15 h at 50°C in a conventional laboratory oven with air circulation.

Headspace Sampling by Sample Enrichment Probe (SEP) A second generation SEP50 sample enrichment probe (MasChrom Analisetegniek, Stellenbosch, South Africa), consisting of a fused silica stalk, or shaft, carrying a 50 mm sleeve (47 mg) of polydimethylsiloxane (PDMS) tubing (Burger et al., 2006, 2011), was used to trap VOCs from wool samples for GC and GC-MS analyses. The Teflon face of a septum was pierced centrally with the sharpened back end of the SEP, and the septum positioned on the stalk so as to enable headspace sampling from an 8-ml vial. The wool sample (70 mg) was placed in the vial, the SEP50 installed with its lower tip clearing the sample, and, after tightening the vial cap, the SEP was exposed to the headspace at 70°C for 1 h. The volatile compounds retained in the PDMS were desorbed at 220°C in the GC-MS. The SEP was left in the injector until completion of an analysis (Burger et al., 2006).

Dimethyl Disulfide Derivatization

The double bond positions of unsaturated VOCs of wool were determined by dimethyl disulfide (DMDS) derivatization and GC-MS analysis of the resulting adducts, similar to the method of Vincenti et al. (1987). An aliquot of a TBME extract of wool volatiles was concentrated to 5 μl in a Reacti-Vial, using a slow stream of purified nitrogen. The concentrate was re-dissolved in carbon disulfide (50 μl), and treated with an excess of iodine solution (5 μl of 60 mg of I_2 in 1 ml of TBME) and DMDS (50 μl). The Reacti-Vial was sealed, and the reaction mixture was heated at 60°C for 40 h. The reaction was quenched with 5% aqueous sodium thiosulfate, and the aqueous layer separated from the organic layer by centrifuging the mixture at 3,000 rpm. The organic layer was transferred to another Reacti-Vial and washed with water (2×20 μl), utilizing centrifugation to facilitate phase separation. The extract was concentrated and used for GC-MS analysis.

Determination of Absolute Configuration of Chiral Compounds

Enantioselective columns C and D were used to separate enantiomers of the chiral constituents present in wool samples.

Statistical Analysis of VOCs

Of the 133 constituents identified, only those present in 20% or more of the wool samples were considered as variables for statistical analysis, reducing the number of constituents included in the analysis to 88. The chromatographic data used for multivariate analyses still contained a large number of variables (peak areas for these identified constituents, $N \leq 88$) relative to the number of sample units (wool samples, $N \leq 32$). Peak areas were normalized across all samples to produce comparable variables with zero means and unit standard deviation (Kowalski and Bender, 1972). Permutation tests were carried out to determine whether the wool of twin lambs could be grouped according to the qualitative and quantitative composition of VOCs present in their wool. The following null-hypothesis was tested: twin lambs cannot be grouped according to the qualitative and quantitative composition of their wool volatiles. Thus, the calculated *P*-value provided an indication of whether the similarities found between twin lambs could be attributed to the fact that they are twins or to random variation in the data. Using this principle, the similarity in the odor profile of the wool of a pair of twin lambs was assessed by executing 10,000 permutation tests.

The 88 constituents and their quantities in the wool of day-old lambs born during the lambing season of 2007 were used to construct a principal component analysis (PCA) biplot. Biplots can be considered as multivariate scatterplots that simultaneously give a graphical presentation of samples (lambs) and variables (identified constituents). Lambs are displayed as points on the graph while the identified constituents are displayed as linear axes. The significance of an axis of a biplot is similar to that of an ordinary scatterplot: if a line is drawn from any point in a biplot perpendicular to a biplot axis, the value of the variable at that point can be read on the axis. In addition, the angle between any two axes approximates the correlation between two relevant variables. Constituents displayed as axes that are 90 degrees in relation to one another have no correlation with each other, and those constituents lying on axes close to one another have a high level of correlation with one another. An axis is labeled at the positive value of its calibration.

PCA biplots, permutation tests, and investigations into predictivity, were performed using R (Vienna, Austria), as described in Aldrich et al. (2004) and Gardner-Lubbe et al. (2008).

Bioassays

Bioassays were performed with singleton- and twin-bearing Döhne Merino ewes during the lambing season at Mariendahl from March to April 2009 and 2010. Singleton-bearing ewes, with their lambs, were placed in a 0.2-ha paddock within 12 h after parturition, while twin-bearing ewes, with lambs, were isolated in lambing pens (1.2× 1.6 m) inside a naturally illuminated and ventilated shed. All bioassays were conducted in these pens, outside in an enclosed concrete-surface arena (12× 8 m), or in paddocks (ca. 10,000 m^2) with natural vegetation.

Exploratory bioassays were carried out during 2009 and 2010 by dressing lambs in treated cotton fleece jackets (which served as an odor-disseminating medium), and presenting alien lambs to ewes. In order to prevent, or at least curtail, odor diffusion through the jackets during the 5 min of the bioassay, alien lambs were fitted first with disposable diapers (Huggies, New Born, Kimberly-Clark SA, South Africa). In addition, the bodies and legs of experimental lambs were wrapped in several layers of low-density polyethylene-based film (Clorox, Rockdale, Australia). Jackets were made from new, white or pale grey, fleece cloth that had been repeatedly washed in hot water and sodium dodecyl hydrogen sulfate in a domestic washing machine and air-dried on a washing line. Pieces of the cloth were subjected to SEP-headspace analysis to ensure that the material was free from contaminants that could otherwise interfere with the bioassays. Openings were made in the jackets for the legs, ears, eyes, and snouts of lambs, before placing the jackets on lambs. The jackets were fastened ventrally and under the chins of lambs by safety pins. The tail ends of some of these jackets were folded together so as to form artificial tails, and these were kept in shape with rubber bands (Fig. S2). Hoodless jackets were made with openings for the legs. These covered the body of a lamb from the buttocks to the shoulders. Some of the bioassays carried out during April 2010 were done with experimental ewes that had been conditioned to their own lambs wearing jackets. For these and other experiments requiring lambs to wear jackets for periods of up to 72 h, excess cloth was cut away from the hind legs of male lambs to prevent them from wetting jackets.

In control experiments, one of the lambs of a twin-bearing ewe was removed from the lambing pen for the duration of the experiment. The other lamb was presented to a ewe from a non-adjacent pen (so as to preclude the possibility that she could have been in occasional semi-ochemical contact with the experimental lamb). The lamb was then diapered, wrapped and presented to its own mother and then to the other ewe, after which a new cotton jacket was added, and the lamb presented again to its mother and the other ewe. Finally, it was undressed and presented to its own mother. Drastic measures were not used to facilitate acceptance of an alien lamb. An alien lamb was considered accepted if it was allowed at the udder and if the ewe directed no butts (Supplementary material, videos available at http://scholar.sun.ac.za/handle/10019.1/3980) or butt attempts toward it over a period of 5 min after first contact. If a ewe rejected an alien lamb and displayed aggressive behavior toward it, the experiment was terminated immediately and the lamb removed from the pen or experimental arena. In order to allow experimental lambs to drink, the snouts and area around the eyes were not completely covered, and thus lambs were dressed mostly in hoodless jackets. In these experiments, the lamb (N=5) was presented sideways to the ewe so that the ewe could first sniff at the jacket. After completion of the experiments, the animals were kept under observation until it was clear each lamb was not permanently rejected by its mother.

Wool extracts also were tested. Approximately 8 g of wool were sheared from the bodies of day-old lambs and Soxhlet-extracted with either pentane (N=15), diethyl ether (N=4), DCM (N=4) or ethyl acetate (N=1) for 2 h. The extracts were sprayed uniformly on new, washed fleece cloth jackets. The respective solvents were allowed to evaporate before the bioassays were carried out, always within 24 h after the wool had been harvested. In a further experiment, approximately 16 g of wool, collected from both twins of a ewe, were extracted in pentane (N=2) or DCM (N=4). To restrict co-evaporation of VOCs from the jackets, extracts were added to a freshly cleaned, new jacket in a flange flask. The flask with its contents was cooled to

−30°C, after which most of the solvent was removed under reduced pressure at the lowest temperature possible (between −30°C and −50°C), in order to restrict co-evaporation of VOCs from the treated jackets. The residual solvent traces were allowed to evaporate before the alien lambs were dressed in the jackets.

Finally, in exploratory experiments, the responses of twin-bearing ewes to alien lambs dressed in jackets sprayed with synthetic mixtures of identified wool VOCs were investigated. The synthetic mixtures were dissolved in pentane to match the composition of the wool VOCs of an experimental ewe's own lambs (analyzed as above). The bioassays were carried out within 24 h after the wool had been harvested. With the exception of a few unidentified constituents, authentic synthetic samples of all the VOCs identified in the cranial wool of the experimental lambs were available.

The interpretation of the results of the behavioral experiments was based on the consensus opinion of two or three observers.

Results and Discussion

As a working hypothesis, we presumed that the odor profiles of twin lambs were identical, or at least similar, and quantitatively different from those of other lambs. Based on the assumption that the odor of a lamb is directly related to the VOC composition in the headspace of a wool sample (i.e., to the relative percentages in which all of the compounds are present in the sample's headspace, and thus in the effluvium of the lamb), it should be possible to identify and quantify the chemicals constituting the ewe–lamb recognition cue by intra- and inter-twin comparisons of the effluvia of a representative sample of lambs. The results of GC-MS analyses, as exemplified in Fig. 1, showed that the odors in twins were indeed remarkably similar, in contrast to the differences found between the odors of lambs born to different ewes (e.g., Fig. 2).

Exploratory experiments showed that the wool of day-old lambs contained only trace quantities of VOCs, and about 5–10% of high-boiling point organics (lanolin). The minute quantities of VOCs precluded the use of solvent extraction; Soxhlet extraction and the removal of solvent from extracts was expected to result in unacceptable quantitative reproducibility and, also, the injection of large quantities of organic compounds with high boiling points could have a deleterious effect on the performance of capillary GC columns. Thus, headspace analysis was used. SPME was found to be too insensitive (results not shown). An adapted version of closed-loop stripping (Grob, 1973) also was evaluated. Although reasonable results were obtained (data not shown), this technique was rejected because the air-circulating pump became contaminated by semi-volatile compounds that could not be removed by circulating water, methanol, acetone, methanol and DCM (in that order) through the pump and purging solvent vapors from the pump by overnight pumping of purified air. Because of its high sensitivity and simplicity, the SEP technique (Burger et al., 2006, 2011) eventually was used for sample enrichment of the wool VOCs. The recently introduced term "enrichment" has gained wide acceptance, and is now preferred for sampling techniques in which the constituents of a gas sample, or the headspace of solids or liquids, are concentrated in the sample preparation step prior to introduction of the sample into the injector of the analytical instrument. A typical total ion trace (TIC) of the cranial wool volatiles of a day-old lamb is depicted in Fig. 3.

Nevertheless, several wool samples also were extracted with DCM for determination of the total composition of the collected wool and for physical data required for the

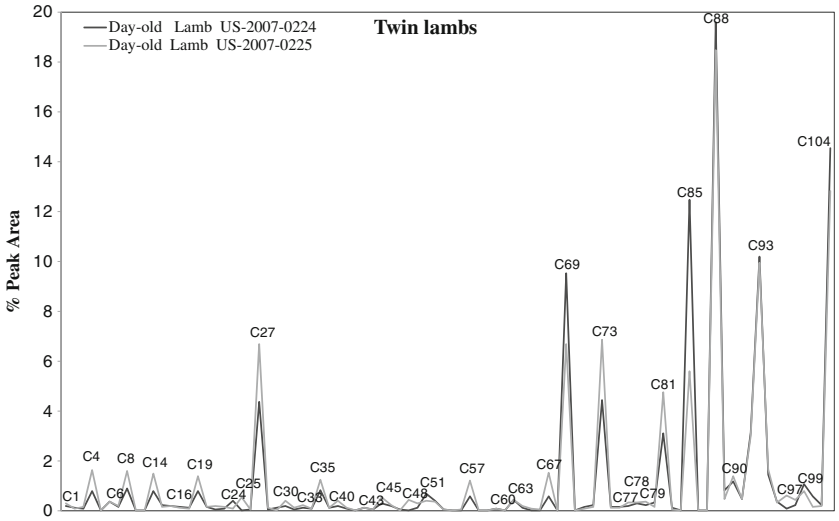

Fig. 1 Comparison of the percentage peak areas derived from mass chromatograms of the sample-enrichment-probe-enriched wool volatiles of day-old twin lambs US-2007-0224 (*black*) and US-2007-0225 (*grey*) analyzed on apolar column A. The peaks are numbered according to the information in Table 1. The minor VOCs P1–P10 were not visible in these chromatograms. Note that the concentrations of compounds 87 to 96 are so similar that the black chromatogram of lamb US-2007-0224 is only visible at the apexes of the peaks

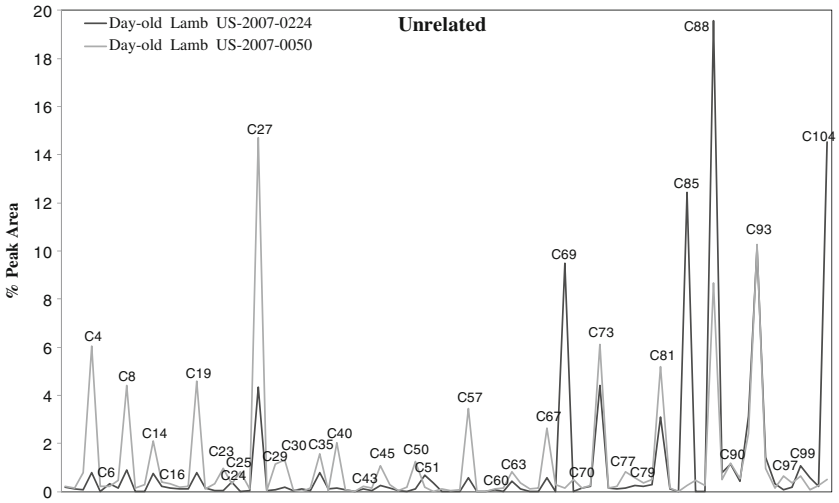

Fig. 2 Comparison of the percentage peak areas derived from mass chromatograms of the sample-enrichment-probe-enriched wool volatiles of the unrelated lambs US-2007-0224 (*black*) and US-2007-0050 (*grey*). The peaks are numbered according to Table 1

calculation of the composition of the concentration of the volatiles and semi-volatiles in the wool from the headspace data. The wool of day-old lambs typically contained 5–10% moisture, 1–4% inorganic particles, and 4–8% extractable organic material (commonly known as lanolin). The lanolin contained traces of volatile and semi-volatile organic compounds that eluted from an apolar capillary column at temperatures up to 280°C.

A total of 133 constituents (Table 1), comprising saturated and unsaturated alkanes, branched and unbranched primary alcohols, branched and unbranched aldehydes, unsaturated aldehydes, aromatic aldehydes, branched and unbranched methyl ketones, ethyl ketones, branched and unbranched carboxylic acids, unsaturated carboxylic acids, benzoic acid, esters, γ-lactones, terpenoids, 3-octanol, 2-pentylfuran, dimethyl sulfone, 3-ethyl-4-methyl-1H-pyrrole-2,5-dione, 3-ethyl-3-methyl-pyrrolidine-2,5-dione, 3-methyl-4-vinyl-1H-pyrrole-2,5-dione, and 2-ethyl-3-methylpyrrolidine-2,5-dione, were unambiguously identified by GC-LRMS and GC-HRMS analyses, Kovats retention index (RI) determination, and GC-MS comparison with authentic synthetic standards (Table 1). These compounds had masses from 60.05 to 410.39, and boiling points from 119°C to 360°C. The enantiomeric compositions of the chiral constituents [3-methyl-2-undecanone, a series of γ-substituted γ-lactones (alkan-4-olides), 3-methylpentanal and 2-ethyl-3-methylpyrrolidine-2,5-dione; Table 2] of wool were determined by GC-MS comparison with the corresponding synthetic compounds, using enantioselective columns C and D, and data published by Maas et al. (1994) and Burger et al. (2008). The terpenoids eluted as single peaks and were presumably present in the wool as pure isomers. However, since the individual enantiomers or racemates were not available for retention time comparison, it could not be established whether this assumption was correct or not. A large number of the carboxylic acids, hydrocarbons, and alcohols identified in this study have been identified previously in lanolin (Motiuk, 1979a,b, 1980; Schlossman

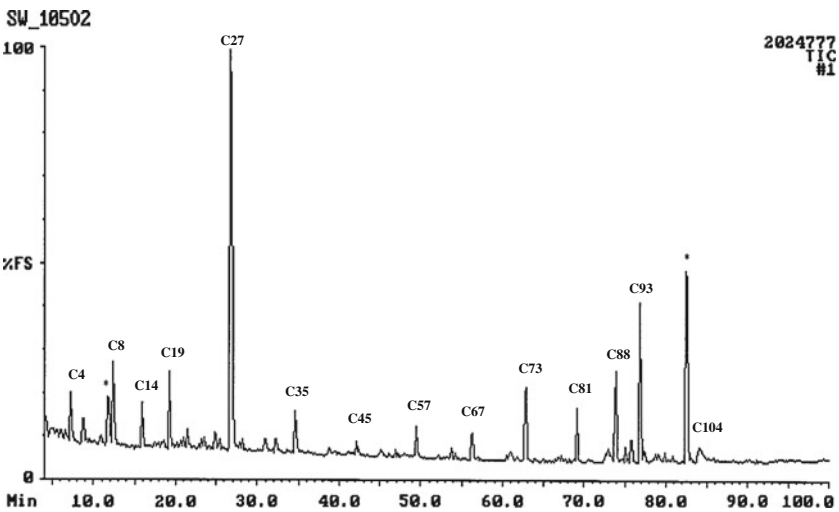

Fig. 3 Total ion chromatogram (TIC) of the headspace of the wool of Döhne Merino lamb US-2007-0105 analyzed on apolar column A. The peaks are numbered according to Table 1. Two impurities, present in all samples, are indicated by an asterisk

o: Compounds identified in cotton fleece jacket left on lamb for 3 days

and McCarthy, 1979). In the present investigation, these compounds were not considered as potential components of the recognition cue because of their high boiling points. The constituents of such a cue must be reasonably volatile because bond formation does not require direct physical contact between the ewe and lamb (Lévy et al., 2004).

The 133 compounds identified in this study were all present in at least 10% of the samples collected during 2007. The number and varying concentrations of these compounds are consistent with the constraints on the design of chemical communication systems used in kin recognition which, according to Alberts (1992), requires a wide variety of compounds present in different concentrations. Approximately 50% of the total average peak area of the VOCs present in the headspace of the wool of the day-old Döhne Merino lambs consisted of only five compounds: ethyl tetradecanoate (20%), nonanal (12%), 6,10,14-trimethyl-2-pentadecanone (9%), tetradecanal (4%), and pentadecanal (4%).

The use of statistical analysis to elucidate active compounds in complex semiochemical mixtures is limited

Table 2 Enantiomeric composition of chiral constituents of wool determined by gas chromatography using columns C and D[a]

Compounds		Enantiomeric ratio (*R*:*S*)
C38	3-Ethyl-4-methylpyrrolidine-2, 5-dione[b]	54:46 (*N*=1, C[c])
C47	3-Methyl-2-undecanone	91:9 to 100:0 (*N*=4, C)
C48	Nonan-4-olide	69:31 to 78:22 (*N*=5, C)
C61	Decan-4-olide	58:42 to 74:26 (*N*=3, C)
C76	Undecan-4-olide	66:34 (*N*=1, C)
C109	Hexadecan-4-olide	54:46 (*N*=1, D[d])

[a] The ratios were determined by integration of single ion plots of the base peaks of the individual enantiomers. The quantitative data are given in the order of elution of the enantiomers from column C or D. In some samples, one or both of the enantiomers co-eluted with other constituents and could thus not be quantified, which accounts for the difference in the number of listed samples (*N*)

[b] Order of elution unknown

[c] Enantioselective column C

[d] Enantioselective column D

by the possibility that constituents identified as principal components in multivariate analyses might not necessarily be key components of an olfactory cue. In order to determine whether any basis existed for using twins in this study, an attempt was made to quantify intra-twin similarities and inter-twin differences in the odors of neonatal lambs by multivariate analysis of the data obtained from a randomly selected 9.69% sample of the ewe flock.

The permutation tests of the analytical data calculated a *P*-value<0.001, indicating that the pairing of twin lambs, according to the qualitative and quantitative composition of the wool, did not occur by chance, and was significant. Assuming that the odor of a lamb is related directly to the composition of the VOCs in the headspace of a wool sample, our GC-MS analyses (Figs. 2 and 3) showed that the odors of twins are remarkably similar, but there are differences between odors of lambs born to different ewes. Twin lambs thus possess odor profiles that are unique, with odor profiles more similar to each other than to those of other randomly selected non-twin lambs (See also Supplementary material, Fig. S3).

The PCA biplot depicted in Fig. 4a provides the optimal two-dimensional presentation of the data matrix. Not all 32 samples and 88 variables are equally well represented in the biplot and axis predictivity (Gardner-Lubbe et al., 2008). The quality of a biplot is an overall measure of the accuracy of the two-dimensional approximation of the data matrix and hence also of the reliability of the analytical data. Furthermore, sample predictivities and axis predictivities provide detailed information about how accurately each datum point is represented in the biplot and the degree of accuracy in the predictions made from the biplot axes. Predictivity values range from 0 to 1, with a value of 1 representing the best predictivity. In Fig. 4a, b, only the 21 axes with predictivities >0.800 are displayed. The quality of display for the PCA biplots in Fig. 4a, b is 54%, which reflects the proportion of variation in the data accounted for

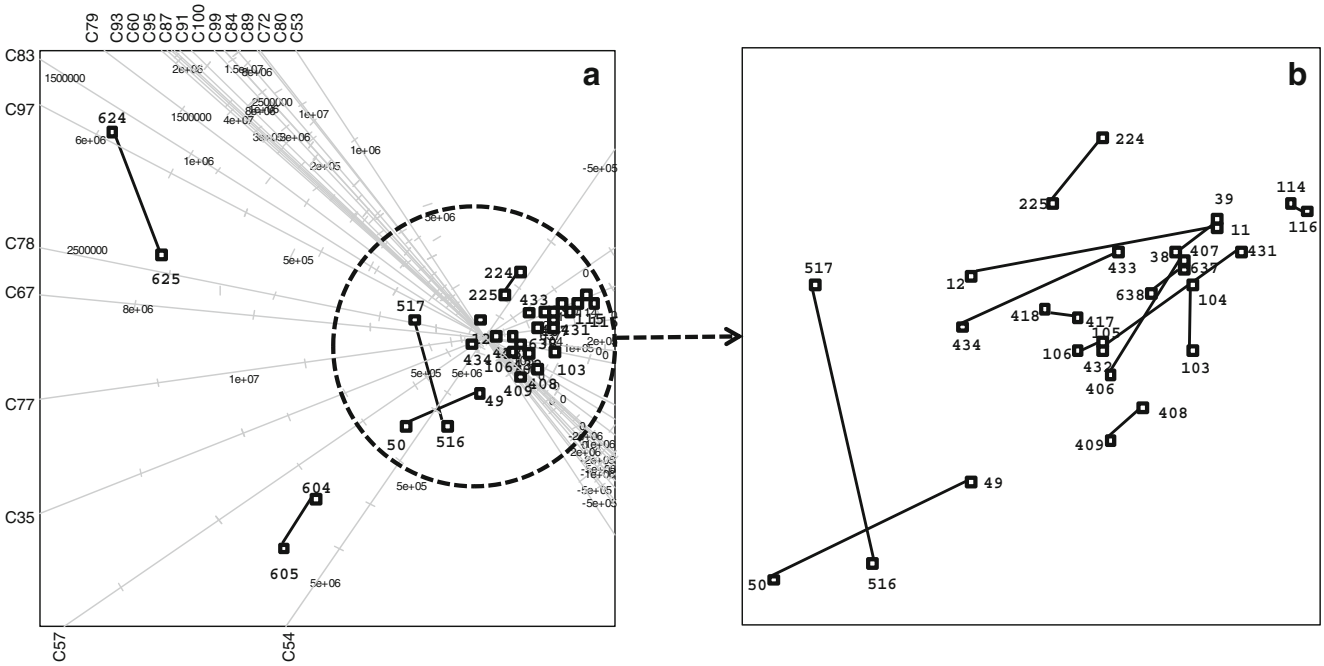

Fig. 4 **a** Principal component analysis biplot for the wool volatiles collected from day-old lambs during the lambing season of 2007; **b** PCA biplot displaying a magnified view of the crowded area in Fig. 4a. Lambs possessing similar odor profiles are circled. For identities of chemical codes refer to Table 1

in the first two dimensions of the two-dimensional display (Gower and Hand, 1996). The other 46% is explained in the remaining 30 dimensions. In Fig. 4b, the axes are not displayed in order so as to draw attention to the positions of the twin lambs. Each square represents a sample of wool collected from a day-old lamb, and the last three digits of the lamb's number are indicated in the biplot. Data pertaining to the lambs of each of the 16 twins are connected with black lines in Fig. 5a, b. The group of lambs concentrated in the encircled area indicates that these lambs possess odor profiles that are generally similar. The fact that non-twins (e.g., lambs 12 and 434) are closer in Fig. 4a, b than some twins can perhaps be explained in terms of possible variables that were not chosen in this experiment.

The 21 constituents with predictivities>0.800 in order of decreasing predictivity are 2,6,10,14-tetramethylhexadecane (**C91**), 2-pentadecanone (**C79**), octadecane (**C89**), 1-pentadecanol (**C87**), (5*E*)-6,10-dimethyl-5,9-undecadien-2-one (**C60**), 15-methylhexadecanal (**C97**), unidentified constituent **C84**, (*E*)-2-tetradecenal (**C78**), 2-dodecanone (**C54**), tridecanal (**C67**), decanoic acid (**C53**), decanal (**C35**), 6,10,14-trimethyl-2-pentadecanol (**C95**), 13-methyltetradecanal (**C77**), hexadecane (**C72**), heptadecane (**C80**), nonadecane (**C100**), 2-heptadecanone (**C99**), unidentified constituent **C83**, 6,10,14-trimethyl-2-pentadecanone (**C93**) and dodecanal (**C57**). Interestingly, all the aldehydes have maxima on the left-hand side of the plot. All the methyl ketones, except 2-dodecanone, and all the hydrocarbons and decanoic acid are highly correlated with each other.

In 2009, eight, day-old twins from five of the ewes that belonged to the sample group in 2007, were available for further investigation. These twins and those used in 2007 were sired by different rams. As for the wool volatiles collected in 2007, in 2009 only the volatiles present in 20% or more of the samples collected were considered as variables for statistical analysis, which reduced the number of variables to 84 constituents. The similarity in the odor profiles of the wool of a pair of twin lambs was again assessed by executing 10,000 permutation tests. A *P*-value of 0.006 was calculated, indicating that the null hypothesis was rejected, and that the twin lambs born in 2009 possessed odor profiles that were unique and more similar than those of randomly selected non-twins. A higher *P*-value was obtained for lambs investigated in 2009 than for those investigated in 2007, but this could be attributed to the smaller number of wool samples available in 2009.

The flock of ewes used in this project is being used for a long-term sheep breeding study at the Faculty of AgriSciences, and thus we could not carry out an experiment examining whether wool volatiles of offspring produced by the same parents are quantitatively and qualitatively similar from one lambing season to the next. A comparison of wool volatiles from lambs born in 2007 and 2009 from the same ewes, but with different fathers, showed that odor profiles of the 2 years were not different, with nearly all the constituents identified in wool in 2007 also present in 2009. However, the PCA biplot (Fig. 5) shows a definite separation between wool volatiles from lambs born in 2007 and those born in 2009, indicating substantial quantitative differences. This provides evidence that the odor profiles of lambs born of the same ewe, but sired by different rams, are not identical. We are studying this aspect in more detail.

The quality of display of the PCA biplot (only the 20 constituents with predictivities >0.800 are displayed) in Fig. 5 is 56%. The constituents, in order of decreasing predictivity, are tridecane (**C46**), 13-methyltetradecanal (**C77**), 3-octanone (**C16**), 1-heptanol (**C15**), hexanal (**C4**), unidentified constituent **C64**, tridecanal (**C67**), (*E*)-2-tetradecenal (**C78**), octanal (**C19**), (*E*)-2-nonenal (**C30**), 2-pentadecanone (**C79**), tetradecanal (**C73**), dodecanal (**C57**), hexadecane (**C72**), 6-methyl-2-heptanone (**C14**), (*E*)-2-octenal (**C23**), heptanal (**C8**), *N*-methyl-2-piperidinone (**C29**), hexadecanal (**C90**) and 2,5-dimethylpyrimidine (**C11**). It is clear from Fig. 5 that lambs born in 2007 have larger quantities of all these compounds. The figure suggests that the two nitrogen containing constituents, *N*-methyl-2-piperidinone (**C29**) and 2,5-dimethylpyrimidine (**C11**), are highly correlated. All the hydrocarbons, ketones

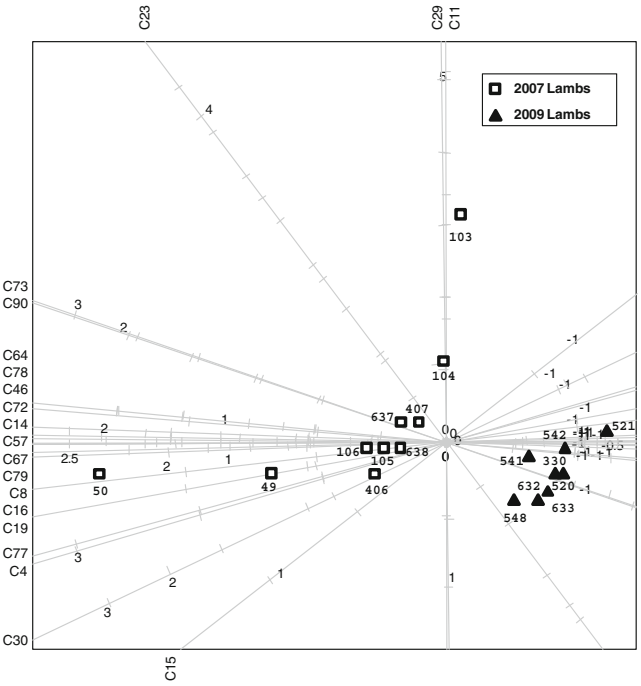

Fig. 5 Principal component analysis biplot for the wool volatiles collected from day-old lambs during the lambing seasons of 2007 and 2009. For identities of chemical codes refer to Table 1

and aldehydes, except (*E*)-2-octenal (**C23**), also correlate reasonably well with each other.

Price et al. (1984), placed nylon stockinettes worn by lambs for 72 h on alien lambs, which were then presented to ewes. Initially, 38% of alien lambs were accepted immediately and another 50% accepted over a further 36 h. More drastic measures have been used in other studies to force ewes to accept alien lambs treated with various odors or synthetic materials. For example, ewes were tethered to prevent them from displaying their typical udder denial behavior in experiments that continued over periods of up to 72 h (Alexander et al., 1987, 1989b).

We carried out similar experiments. However, the experimental lambs were diapered and wrapped in polyethylene film to impede the diffusion of odor of the lambs into the treated jackets. In our control experiments, carried out to test the effect of diapers and polyethylene film, the majority of ewes rejected the wrapped and dressed alien lambs (Table 3). A smaller majority of ewes rejected their own wrapped and dressed lambs. Although the lambs did not bleat much, it is possible that these ewes could have recognized their own lambs by auditory or visual cues. It was apparent, nevertheless, that the diapers plus polyethylene film were sufficiently impermeable to restrict diffusion of wool volatiles into the cotton jackets during the short bioassays (ca 5 min).

The results in Table 3 draw attention to the problems involved in the interpretation of various behavioral responses of ewes when approached by an alien lamb. The mothering instinct of ewes varies: some tolerate the presence of an alien lamb as long as it keeps its distance, while others react aggressively, butting the lamb. The behavior of ewes also varies depending on the number of lambs they have mothered. Young ewes are normally more suspicious and more aggressive than more experienced ewes, perhaps because older ewes have become accustomed to the presence of observers. In bioassays, typical behavioral patterns of ewes were observed, ranging from total rejection to enthusiastic acceptance, including, immediate and repeated aggressive butting of the lamb, one or more less aggressive buts, moving in circles to prevent the lamb from getting at the udder, stamping of a hind foot on the side of the approaching lamb, stepping gently aside, allowing the lamb to approach, allowing the lamb to drink for a few moments before moving away or butting it, allowing the lamb to drink for longer periods before moving away or, finally, accepting the lamb and uttering low grunts of acceptance and/or encouragement. The reaction of the ewe also depended on how thirsty the lamb was, or on or how persistent it was at getting to the udder. It was clear that some lambs smelled or in some other way realized that an experimental ewe was not its mother. In some cases, the ewe and alien lamb simply avoided each

Table 3 Efficacy of diapering and wrapping experimental lambs in polyethylene foil in order to curtail the release of the recognition cue during bioassays[a]

	Alien lamb Naked	Own lamb Diapered and wrapped	Alien lamb	Own lamb Diapered, wrapped and jacketed	Alien lamb	Own lamb Naked afterwards
Ewe 79 Lamb 298	Rejected[b]	Rejected	Rejected without being sniffed at	Rejected	Rejected	No sign of rejection; lamb did not attempt to drink[c]
Ewe 298 Lamb 79	Avoided by ewe	Rejected; did not attempt to drink	Rejected	Rejected	Rejected	Accepted immediately[d]
Ewe 204 Lamb 96	Avoided by ewe	Accepted at the udder, then rejected	Did not attempt to drink; ewe showed no aggression	Ewe avoided lamb; no aggression	Did not attempt to drink	No sign of rejection; lamb did not attempt to drink
Ewe 188 Lamb 78	Rejected	Accepted at the udder	Rejected	Accepted at the udder	Rejected	Accepted immediately
Ewe 78 Lamb 188	Avoided by ewe	Accepted at the udder	Avoided ewe; did not attempt to drink	Avoided by ewe; did not attempt to drink	Ewe avioded lamb	Accepted immediately
Totals[e]	Rejected 100%	Rejected 60%	Rejected 80%	Rejected 80%	Rejected 80%	Accepted 100%

[a] The experiments were carried out in the absence of the other twin of the twin-bearing ewes. The wrapping and dressing procedure is described in the text

[b] Based on butting of the lamb and/or various ways of avoiding contact with the lamb

[c] Probably due to the lamb being awkwardly dressed

[d] Immediately accepted at the udder; in some cases accompanied by ewe's typical low grunts encouraging the lamb to drink

[e] Based on consensus of opinion of two observers

other, a situation that made it difficult to decide whether the ewe rejected the lamb or *vice versa*. A small minority of ewes did not accept any lamb. In another set of control experiments, we observed a ewe aggressively butting a jacketed alien lamb without having sniffed at it and afterwards even rejecting her own twin lambs for more than an hour.

In further experiments carried out in 10,000-m^2 paddocks, lambs of singleton-bearing ewes wore hoodless cotton fleece jackets for 72 h. Alien lambs, dressed in these jackets and presented to the respective ewes, were all accepted by ewes, without any of the typical signs of rejection (acceptance rate 100%; N=6). The experimental lambs then were undressed and returned to their mothers and were all immediately accepted. One of these jackets was stored in a glass jar and the VOCs in the headspace analyzed by GC-MS. Not all the previously identified VOCs were detected (Table 1), probably because of partial evaporation of the more volatile constituents during the bioassay. On the other hand, no compounds other than those listed in Table 1 were detected.

Because our qualitative chemical analyses were carried out on lambs born to twin-bearing ewes, we conducted similar bioassays with the twin-bearing ewes. An acceptance rate of lambs of only 62% (N=13) was obtained. The difference in acceptance rates between singleton- and twin-bearing ewes could possibly be ascribed to increased stress on the twin-bearing ewes due to the experiments being carried out in a concrete arena or in small lambing pens in a shed housing about 40 other ewes with twins (as opposed to the paddocks for the singleton-ewe trial). Alternatively, the absence of the second twin during the experiment may also have contributed to the stress of these ewes.

Similar experiments, spraying extracts of 8 g of lamb wool on new washed fleece cloth jackets were carried out. In five (20%; pentane, N=4; dichloromethane, N=1) of the experiments, the alien lambs were accepted by ewes. Although the small sample size precluded meaningful statistical analysis, we suspect that selective co-evaporation of some of the more volatile compounds with the solvent could have contributed to the low acceptance rate. Headspace analyses of jackets treated with these wool extracts, or with mixtures of synthetic VOCs, revealed that VOCs are not released from the treated jackets in the same ratios in which they are present in the wool or in the synthetic mixtures. These results showed that the volatile, apolar compounds, in particular, are prone to co-evaporation with the solvent. It is also possible that the dissemination of VOCs from cotton cloth differed from that of lamb's wool, or that some constituents were converted to other products during Soxhlet extraction.

A more concentrated extract of 16 g (collected from both twins of the ewes) of wool was applied to the jackets, with solvent evaporated at low temperature so as to minimize the co-evaporation of VOCs. Ewes (N=6) rejected all the treated alien lambs, although they did sniff at the jackets for longer than in previous bioassays before rejecting the aliens.

Finally, twin-bearing ewes rejected all (N=4) the alien lambs dressed in jackets sprayed with mixtures of synthetic VOCs. With the exception of a few unidentified constituents, authentic synthetic samples of all the VOCs identified in the cranial wool of lambs were available. Therefore, for these experiments we did not have to select only the 21 constituents with predictivities >0.800, as in the statistical analyses of our analytical results.

Our observations in these experiments suggested that cues other than lamb odor might be used by ewes when confronted with a decision of whether to accept or reject a lamb. In the experiments we could not preclude alien lambs from bleating, nor could we cover the heads and snouts of the lambs in such a way that they could still see and drink while preventing ewes from finding unprotected parts of the lambs to sniff at. The jackets appeared to hamper the normal persistence of lambs to get at the udder, and the awkward gait of lambs dressed in this manner could have triggered their rejection.

Future work will focus on finding a more reliable bioassay, and on devising methods for dissemination of the VOCs in natural concentrations and ratios.

Acknowledgements Financial support by the NRF and Stellenbosch University is gratefully acknowledged. We thank the experimental farm of Stellenbosch University, Mariendahl, for making experimental sheep available for this research and for invaluable advice and assistance.

2006). This predator is known to aggregate on trees infested by bark beetles, especially during the earliest stages of colonization (Dixon and Payne, 1979). Adult *T. dubius* locate trees under colonization by bark beetles by using bark beetle pheromone components such as frontalin (*D. frontalis*), ipsenol (*I. grandicollis*), and ipsdienol [*I. pini, Ips calligraphus* (Germar), and *Ips avulsus* (Eichhoff)] that act as kairomones to guide them to their prey. Each kairomonal signal can be perceived alone (Payne et al., 1984; Herms et al., 1991; Raffa, 2001) or associated with tree-produced monoterpenes such as α- and β-pinene (Billings and Cameron, 1984; Erbilgin et al., 2003; Seybold et al., 2006; Reeve et al., 2009). This predator also responds to sulcatol in the field (Costa and Reeve, unpublished data), a pheromone component emitted by the ambrosia beetle *P. flavicornis* (Renwick et al., 1977).

Although *T. dubius* can respond to a broad range of volatiles, including kairomonal signals, little is known about the olfactory behavior of individuals. Previous studies have concentrated on field trapping (Billings and Cameron, 1984; Strom et al., 1999; Erbilgin and Raffa, 2001; Erbilgin et al., 2003; Reeve et al., 2009) or wind tunnels with groups of predators (Mizell et al., 1984), whereas individuals have only been investigated with electroantennography (e.g., Payne et al., 1984). Understanding predator preference at the individual level is important for understanding the mechanisms that underlie responses of *T. dubius* populations in the field. For example, is each individual predator a generalist able to respond toward a broad range of semiochemicals (e.g., kairomones), or do predator populations consist of groups of individuals with fixed prey preferences and the capacity only to respond to specific semiochemicals? When differences among populations in kairomone preference are observed (Reeve et al., 2009), is this generated by changes in individual behavior or by the relative abundance of various specialists (chemomorphs)? To date, these questions have not been addressed, but could be examined by using wind tunnel observations (Costa and Reeve, 2011). In particular, *T. dubius* displays a typical antennal behavior prior to upwind flight in response to prey pheromones, to tree volatiles, or to a mixture of both (Costa and Reeve, 2011). This methodology could be used to test for the occurrence of chemomorphs in *T. dubius* populations.

Because bark beetle populations can greatly fluctuate in both abundance and species diversity (Turchin et al., 1991; Reeve and Turchin, 2002), generalist predators like *T. dubius* may have evolved a number of strategies to survive despite unpredictable prey resources. The prolonged developmental time and diapause plasticity of *T. dubius* (Reeve, 2000) might limit the detrimental effects caused by extreme prey fluctuations on their survival. These generalist predators also may benefit from altering their preference for different prey species through switching behaviors (Murdoch, 1969; Křivan, 1996). Field-trapping studies suggest that *T. dubius* populations became more responsive to *Ips* pheromones when *D. frontalis* is absent or endemic, in a pattern that could be generated by switching behavior (Reeve et al., 2009). If switching does occur, it may imply that an individual can learn cues associated with the most abundant prey, thereby increasing its foraging efficiency (Murdoch, 1969; Mizell et al., 1984; Turlings et al., 1993). Optimal foraging theory predicts that learning should increase fitness by maximizing a forager's ability to exploit unpredictably distributed resources (Stephens and Krebs, 1986; Křivan, 1996).

Learning can be defined as a modification of behavior through experience (Papaj and Prokopy, 1989). In many studies that have investigated the effect of olfactory experience among insects, associative learning (*sensu* Pavlov, 1941) has been demonstrated to increase the response to an initially low or non-attractive stimulus after a paired exposure of this stimulus with a reward (Vet et al., 1995; Cunningham et al., 2004; Chaffiol et al., 2005). Finally, simple exposure to a stimulus also could enhance the response by sensitization (*sensu* Smith, 1993). The effect of olfactory experience on the chemo-orientated response of true predators is largely unexplored in arthropods (De Boer and Dicke, 2006; Dukas, 2008), with limited evidence from anthocorid bugs (Drukker et al., 2000a), and predatory mites (Drukker et al., 2000b). *Thanasimus dubius* could be a good candidate to learn cues from its environment (Mizell et al., 1984; Reeve et al., 2009) because of its broad potential diet, the unpredictable distribution of its prey resources in both space and time, and its long-lived adult stage. Although *T. dubius* might learn to recognize tree volatiles as well, prey pheromones would seem a more reliable indicator of the presence of a particular prey (Vet and Dicke, 1992).

We conducted three experiments to investigate the ability of individual *T. dubius* to respond to different prey olfactory signals (bark beetle pheromone components) and to assess this predator's potential for learning. Although there is substantial literature on the responses of *T. dubius* to prey pheromone components, these studies evaluated the response of predator populations and could mask variation among individual responses. Our study combines field data and wind tunnel responses of individual *T. dubius* in order to understand how these predators can cope with fluctuations of prey resources. To our knowledge, this is the first evidence that the behavior of a bark beetle predator could be influenced by previous olfactory experience.

Methods and Materials

Collection and Handling of Adult Thanasimus dubius (Wild Individuals) Wild adult *T. dubius* used in Experiment 2 (see

below) were captured in central Wisconsin at Black River Falls State Forest (Millston, WI, USA) with 12-unit funnel traps (Lindgren, 1983) (Contech Enterprises Inc., Delta, BC, Canada) baited with frontalin and turpentine. Racemic frontalin was released from two 0.4 ml polyethylene vials, each loaded with 0.3 ml (297 mg) of frontalin to achieve a release rate of 5.2 mg/d at 20°C (Contech Enterprises). A 40 ml volume of turpentine (EZ Gum Turpentine, E. E. Zimmerman Co., Pittsburgh, PA, USA) was released from a 30 cm long piece of polyethylene tubing sealed at both ends, which produced a release rate of 1 g/d at 20°C (Reeve et al., 2009). Field-captured *T. dubius* were brought to the laboratory in plastic bags (17 cm × 24 cm) inside a cooler and stored for<10 d at 8°C with most insects being kept< 7 d. Four days before use, they were placed by groups of 40–50 individuals in cylindrical plastic containers (21 cm high × 21 cm diam) and held (no longer than 14 d) in an incubator at 23.0±0.5°C and a photoperiod of 16 L/8D until testing in the wind tunnel. All individual *T. dubius* were fed with adults of the cowpea weevil, *Callosobruchus maculatus* Fabricius (Coleoptera: Bruchidae), a factitious prey (Nebeker et al., 1980; Reeve et al., 2003). Water was provided with a wet piece of sponge. On the day before the test, wild *T. dubius* were placed individually in labeled plastic Petri dishes (9 cm diam) where they were provided with a wet sponge and fed *C. maculatus* (6–8 prey/individual).

Rearing of Adult Thanasimus dubius (Naive Individuals) All predators used in Experiment 3 (see below) were produced by this rearing method. The laboratory culture was initiated with wild *T. dubius* collected in Louisiana in 2004 by using 12-unit funnel traps baited with frontalin and turpentine with the same baits and release rates as mentioned above. Insects were reared through at least two generations in the laboratory. Adults were held, fed, and watered as described above. Eggs of *T. dubius* were collected on folded paper towels. Larvae were fed a meridic diet that is a mixture of foodstuffs and other ingredients that have been used to rear *T. dubius* (Reeve et al., 2003). This diet was presented in Parafilm® capsules, with each capsule containing approximately 0.3 ml of diet. To avoid cannibalism, newly hatched larvae were kept individually in 50 mm Gelman Petri dishes (Pall Life Sciences, Port Washington, NY, USA) covered with a Kimwipe® tissue. Each larva was provided with one or two Parafilm® capsules of diet and a moistened sponge every 2–3 d. When the larvae turned purple, indicating a readiness to pupate, they were provided with a piece of sterilized pine bark. After the larvae entered the bark, the bark pieces were placed together in 17 × 12 × 6 cm plastic containers. Emergence was examined every 2 d so that adult *T. dubius* could be separated into groups of similar age.

All adult *T. dubius* used in Experiment 3 were thus considered semiochemically naive because (1) larvae were reared on artificial diet; (2) adults were fed factitious prey; and (3) adults were not exposed to any semiochemical before testing them in the wind tunnel.

Wind Tunnel Flight Bioassays Our wind tunnel, similar to that of Visser (1976), consisted of a 140 × 70 × 70 cm Plexiglas flight chamber. Air flow was created by using a box fan. Between the chamber and the fan, a 2 cm thick activated charcoal filter was set to purify incoming air, followed by four layers of cheesecloth mounted on a wooden frame to make the airflow laminar. The flight chamber was illuminated by six 120 cm long 58 W fluorescent tubes placed on top of the chamber. To limit phototaxis created by intense light, a Plexiglas light diffuser and a white cotton sheet were interposed between the lights and the top of the chamber. A platform, made of a clear plastic cylinder (14 cm high × 14 cm diam), was used to release insects and was placed 80 cm downwind from the source. Airspeed at the release point was 0.1 m/s. Low-speed designs have been used previously with success for other Coleoptera (Salom and McLean, 1990; Wyatt et al., 1993; Heath et al., 2001); stronger winds can inhibit upwind flight of some insects (Mizell et al., 1984; Marchand and McNeil, 2000). Air exited the tunnel into a fume hood and was exhausted from the building. Temperature, humidity, and barometric pressure were recorded in the room during testing. Air in the tunnel was humidified to ensure that it remained above 50%. As the humidifier tended to cool the air, a small space heater was used to match temperature in the chamber with the room. Room temperature was always 23±1°C. To reduce any potential bias created because of observer presence or other visual stimuli, the tunnel was covered with a white sheet during the test. Behavior of *T. dubius* was observed through two small apertures in the sheet.

Tests were always conducted between 1300 and 1800 h. This time remained constant throughout the entire experiment to limit any potential effect of time on beetle response. Each insect was tested individually. For each test, the odor source was first introduced into the wind tunnel for 1 min; then the insect was released on a 3 × 3 cm section of paper towel on the platform center. Behavior was monitored for 5 min or until the insect left the platform either by flying or walking, although walking seldom occurred in preliminary tests. In all experiments, the platform was located 80 cm downwind from the odor source. We used the same methods as in Costa and Reeve (2011).

We have shown previously that adult *T. dubius* display a typical "stand up" antennal behavior (where the insect makes a complete stop, erects its antennae, and while

elevating the thorax lifts one of its front legs) before flying upwind, and that significantly more stand up antennal behaviors are performed when exposed to an attractive source (Costa and Reeve, 2011). We further designated as "upwind flights" those flights in which the insect landed upwind *and* displayed at least one stand up antennal behavior, because this appears to indicate a genuine olfactory response to the chemical source.

The total number of stand up antennal behaviors was recorded, and their mean rate (number of behaviors/individual/min) was calculated for each treatment. Time until takeoff and the landing position also were recorded. Lines drawn every 10 cm on the tunnel floor were used to indicate the landing position as a distance from the odor source. In both Experiments 2 and 3, we used the number of insects flying upwind to compare the attractiveness of each treatment. In Experiment 3, we also present for each treatment the mean rate of stand up antennal behaviors (number of behaviors/individual/min).

Experiment 1: Mark-Release-Recapture and Field Choice Test with Wild Thanasimus dubius In 2006 and 2007, we examined the responses of individual *T. dubius* adults to three prey pheromone components (frontalin, ipsenol, and ipsdienol), by using a combined mark-release-recapture experiment and field choice test. At each site, 12-unit funnel traps were arranged in an 86 m diam ring consisting of nine traps, set 30 m apart. Rings of traps were all located in red pine, *Pinus resinosa* Ait., plantations that had similar densities (trees were 6–8 m apart from each other), and the traps were intermingled among the trees. Within the same ring, traps were baited with the three prey pheromones (racemic ipsenol, ipsdienol, and frontalin, Table 1), providing three replicates for each semiochemical (Fig. 1). The sequence of prey pheromones was determined randomly for each ring. We set up a total of five rings at two sites: two at Black River Falls State Forest (Millston, WI, USA) and three at Dell Creek Wildlife area (Reedsburg, WI, USA). Because two of the rings at Dell Creek Wildlife area were both used twice, in 2006 and 2007, we obtained a total of seven blocks for the whole experiment. Insects that responded to one compound (i.e., captured in a trap baited with that prey pheromone) were stored at 8°C (less than 10 d), and then released from a piece of burlap attached to a tree located in the center of a ring. Predators captured with a particular pheromone were color-coded (Fig. 1) by applying enamel paint to the pronotum (Cronin et al., 2000). We then recorded the subsequent prey pheromone choices of the marked individuals within the trap ring.

Experiment 2: Breadth of Kairomonal Range in Wild Thanasimus dubius Our field experiment (Experiment 1) suggested that individual *T. dubius* were attracted to the three prey pheromone components. We then used a wind tunnel to investigate the extent to which this behavior may occur for a wider range of semiochemicals.

All predators used in this experiment were wild predators, collected in Wisconsin (see above). Each predator was tested twice in the wind tunnel described above (see *Wind Tunnel Flight Bioassays*), with two of the following stimulus sources: frontalin, ipsenol, ipsdienol, sulcatol, and α-pinene. The two sources were presented the same day, within a 2 h interval. Although some predators were tested with the same source twice (e.g., frontalin-frontalin), others were tested with two different sources (e.g., ipsenol-sulcatol). We also compared all semiochemical treatments to a control group, where all individuals were tested during both trials with no chemical (blank). A total of N=220 individual *T. dubius* were tested. We tested N=40 insects for each semiochemical treatment during the first trial (thus, a total of N=40 x 5=200) and N=20 were used for the control. In the second trial, each group of 40 insects tested toward a semiochemical was then divided equally into 5 groups. The 20 individuals tested to the blank during the first trial were all retested with a blank so that each trial could be compared to a "no chemical source" situation with the same level of testing in the wind tunnel. Frontalin, ipsenol, and ipsdienol (all racemic) were released at 1–2 mg/d (20°C), whereas

Table 1 Background data on semiochemicals used in flight experiments with *Thanasimus dubius*, 2006–2007

Semiochemical[a]	Elution device	Chem. Purity	Release rate	Vendor	Used in
Frontalin[b]	Polyethylene vials (0.25 ml)	99%	0.5–1.0 mg/d	Contech	Experiments 1, 2, & 3
Ipsenol[b,c]	Bubble caps	98%	0.5–1.0 mg/d	Contech	Experiments 1, 2, & 3
Ipsdienol[b,c]	Bubble caps	98%	0.5–1.0 mg/d	Contech	Experiments 1, 2, & 3
Sulcatol[c]	Bubble caps	98%	2.2 mg/d	Contech	Experiment 2
α-Pinene	Polyethylene transfer pipette Samco # 252	98%	100 mg/d	Sigma Aldrich	Experiment 2

[a] All semiochemicals used were racemic

[b] Two bubble caps or vials were used in Experiment 2 to achieve a 1.0–2.0 mg/d release rate

[c] Semiochemicals formulated in bubble caps were diluted in the inert solvent acetyl tributyl citrate to prevent polymerization

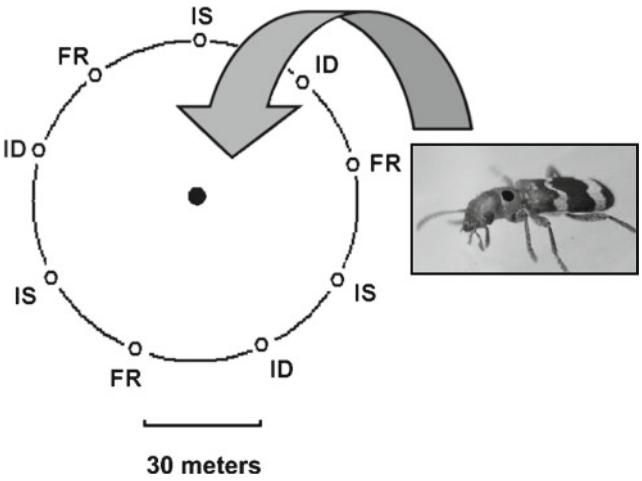

Fig. 1 Experimental design used for the mark-release-recapture experiment: marked *Thanasimus dubius* were released at the center of a ring of multiple-funnel traps baited alternately with prey pheromones: FR = frontalin, IS = ipsenol, and ID = ipsdienol (*T. dubius* photo: M. Venarsky and A. Costa)

sulcatol was released at 2.2 mg/d (20°C) (Contech Enterprises). Racemic α-pinene (98% chemical purity, Sigma-Aldrich Chemical Company Inc., St. Louis, MO, USA) was released at 100 mg/d (20°C) from a Samco #252 clear pipette (Samco Scientific, San Fernando, CA, USA). We used these release rates because: (1) they are known to be active in field experiments (Erbilgin and Raffa, 2001; Reeve et al., 2009) and previous wind tunnel studies (Costa and Reeve, 2011); and (2) we were primarily interested in examining the effect of experience rather than different concentrations on attraction.

Experiment 3: Effect of Experience on Thanasimus dubius Response Because individual *T. dubius* showed an ability to respond to different semiochemicals in Experiments 1 and 2, suggesting that they are true generalist predators, we also studied the ability of *T. dubius* adults to learn cues from their environment. All *T. dubius* used in this experiment were initially naive (see *Rearing of Adult Thanasimus dubius*).

We examined two forms of experience: sensitization and associative learning. Some treatments *exposed* adult *T. dubius* twice to one prey pheromone component, whereas other treatments *conditioned* them to a prey pheromone component by exposing the individual to the component when the beetle was consuming a food reward. As a reward, we used adult *C. maculatus*, which is a prey that is not likely associated with any bark beetle pheromone components. We also included naive groups of predators that were *well-fed* (*ad libitum*) to ensure that starvation would not modify predator responsiveness to a particular prey pheromone component. We recorded flight responses toward two major prey pheromone components, frontalin and ipsenol, presented alone or associated with the reward. Thus, we compared the percentages of upwind flights and the mean rate of stand up antennal behavior between predators, initially naive, that either received some type of olfactory experience (*exposed* or *conditioned*), or stayed naive (*control* groups).

Prior to testing, naive adult *T. dubius* were isolated in Petri dishes as in the first wind tunnel experiment and starved for 10 d. This starvation period ensured that the predators would readily attack a prey item. Just prior to exposure, all insects were placed into conditioning dishes made of a 9 cm diam Petri dish with fine mesh nylon attached to a 1 × 5 cm opening on the side. For predators that were *conditioned* (Table 2), the dish was set on the platform of the wind tunnel as soon as they attacked a weevil, with the open side of the dish facing the semiochemical source (frontalin or ipsenol), which was located less than 5 cm upwind. Each exposure lasted 1 min and was repeated three times, with a 3 min interval between each exposure. Other individual *T. dubius* were identically *exposed* to the pheromone component, but were not provided any weevil prey during the exposure period; they

Table 2 Summary of all treatments used in the wind tunnel experiment testing the effect of olfactory experience on *Thanasimus dubius* response toward three bark beetle pheromone components

Group	N[a]	Treatment[b]	Feeding status	Exposure	Test
1	19	Conditioned	2 weevils	Ipsenol	Ipsenol
2	18	Conditioned	2 weevils	Frontalin	Frontalin
3	18	Exposed	2 weevils	Ipsenol	Ipsenol
4	18	Exposed	2 weevils	Frontalin	Frontalin
5	17	Control starved	2 weevils	None	Ipsenol
6	18	Control starved	2 weevils	None	Frontalin
7	19	Control well-fed	5–10 weevils	None	Ipsenol
8	19	Control well-fed	5–10 weevils	None	Frontalin

[a] N=sample size for each group; a total of N=146 beetles were tested

[b] Each exposure was performed twice, the day before and 1 h before the test

were fed two weevils at least 2 h after the exposure to a prey pheromone component. Other individual *T. dubius* ("*control starved*") were fed with two weevils after having been starved but had never experienced an exposure to a prey pheromone component. Finally, we needed to ensure that starvation would not modify predator responsiveness to a particular prey pheromone; thus, we included naive groups of predators that were *well-fed* (*ad libitum*). All treatment groups (*control starved, control well-fed, exposed*, and *conditioned*) were tested for responses to ipsenol or frontalin, i.e., eight groups (Table 2).

Statistical Analyses The number of predators that were captured twice in Experiment 1 were analyzed by using an exact *G* test of independence as implemented in PROC FREQ (SAS Institute Inc., 2003), with the rows representing the pheromone component on which a predator was first captured and the columns the pheromone component for which the second capture occurred. The numbers of recaptured insects were low; thus, we pooled them across the two sites (Black River Falls and Dell Creek). The exact *G* test analyzed whether first and second choices to pheromone components were independent. If predators were specialists with a particular pheromone preference, then one would expect more captures on the diagonal and more likely a significant test result. Generalists, on the other hand, should show a more even pattern of recapture along all cells and a non-significant test result. Additionally, the mean number of predators caught the first time for each prey pheromone was analyzed by using a three-way ANOVA with site and pheromone treatment as fixed effects and block as a random effect (PROC MIXED, SAS Institute Inc., 2003).

For Experiment 2, we first compared the numbers of upwind flights (defined as individuals landing upwind *and* displaying at least one stand up antennal behavior) among different semiochemical treatments for each trial with an exact *G* test of independence that analyzed whether flying upwind was independent of the nature of the odor source. We also performed pairwise comparisons among treatments with exact *G* tests and applied a sequential Bonferroni correction to judge significance (α=0.05, Sokal and Rohlf, 1995; PROC FREQ and PROC MULTTEST, SAS Institute Inc., 2003). Then, numbers of predators that flew upwind twice were compared with an exact *G* test of independence to determine whether upwind flight during the first trial was independent from upwind flight during the second trial.

In Experiment 3, we tested 146 individual *T. dubius* during 6 d. Each day represents a block for the analysis. For each group shown in Table 3, N=17 to 19 predators were tested. We first used logistic regression to test whether the likelihood of flying upwind was influenced by the semiochemical or by experience. Our model used a binomial dependent variable Y that could take the values Y=0 or Y=1 (landing upwind or not). The two independent variables, the semiochemical and experience treatments, were both categorical. We also incorporated a block effect in this model by using PROC GLIMMIX (SAS Institute Inc., 2003). For each pheromone component, we also ran pairwise comparisons among experience treatments by using exact *G* tests and applied a sequential Bonferroni correction to judge significance (α=0.05, Sokal and Rohlf, 1995; PROC FREQ and PROC MULTTEST, SAS Institute Inc., 2003). We used this exact *G* test because the logistic regression analysis could not provide pairwise comparisons among the four experience treatments (*control starved, control well-fed, exposed*, and *conditioned*). These pairwise comparisons are still useful to rank the effect of a particular experience treatment relative to the attractiveness of the semiochemical. The mean rate of antennal behaviors/individual/min was square-root transformed and analyzed by using a three-way ANOVA with experience and semiochemical treatment as fixed effects and block as a random effect (PROC MIXED, SAS Institute Inc., 2003). To compare the effects of the experience treatment for each pheromone, we performed separately a two-way ANOVA with experience treatment as a fixed and block as a random effect (SAS Institute Inc., 2003, PROC MIXED). We also performed pairwise comparisons with the Tukey-Kramer multiple comparison procedure to judge significance (α=0.05, Sokal and Rohlf, 1995).

Results

Experiment 1: Mark-Release-Recapture and Field Choice Test A total of 327 *T. dubius* was caught in 2006 and 2007, and 9.2% of these were recaptured. There was an effect of site ($F_{1,5}$=8.97; P=0.03) on beetle catch, but the semiochemical treatment × site interaction was not significant ($F_{2,10}$=0.95; P=0.42), indicating there was no difference in

preference between Dell Creek and Black River Falls. Overall, there was no difference in preference for prey pheromone components during first capture (Fig. 2, $F_{2,10}$= 3.45; P=0.07). The results (Table 3) show that the first and second choices were independent (exact G test, G=0.11, P=0.999), indicating that each individual *T. dubius* acted as generalist in its response to these prey pheromone components.

Experiment 2: Breadth of Kairomonal Range in Wild Thanasimus dubius We tested N=220 *T. dubius* adults (wild individuals from Wisconsin) in the wind tunnel (Fig. 3). During the first trial (Fig. 3**a**), the highest percentage of upwind flights was obtained when predators were exposed to sulcatol (73%), which was significantly higher compared to frontalin (35%) (exact G test, G=11.60; P=0.017 after Bonferroni correction). In the second trial (Fig. 3**b**), ipsenol, ipsdienol, and α-pinene were all more attractive than frontalin (exact G test, after Bonferroni correction, respectively: G=10.12; P=0.029; G=18.81; P<0.001; G= 13.20; P=0.007). The test of independence for insects responding twice was not significant (Table 4), suggesting that the response to a particular semiochemical during the first trial was independent from response on the second trial (exact G=5.09; P=0.997). As in Experiment 1, this result suggests that individual *T. dubius* act as generalists. In both the first and second trials, predators flew upwind more often when exposed to a semiochemical treatment relative to the no stimulus control (exact G test, first trial G=34.79; P<0.001 and second trial G=47.02; P<0.001); few insects (5%) responded to the no stimulus control.

Experiment 3: Effect of Experience on Thanasimus dubius Response: Upwind Flights Overall, experience greatly influenced the probability of upwind flight (logistic regression, χ^2=12.83; df=3; P=0.005; Fig. 4). The semiochemical treatment had no significant effect on upwind flight (logistic regression, χ^2=2.31; df=1; P=0.128), and the semiochemical × experience interaction was not significant (logistic regression, χ^2=1.93; df=3; P= 0.587). However, pairwise comparisons of the treatments within each semiochemical treatment suggested an effect of experience on the response to ipsenol (exact G test= 14.51; df=3; P=0.003), whereas the effect was not significant for frontalin (exact G test=4.52; df=3; P= 0.248). In particular, 63% of *T. dubius* that were *conditioned* flew upwind to ipsenol and this difference was significantly higher than either the control group *well-fed* or the control group *starved* (Fig. 4). Simple exposure also produced a moderate increase of upwind flights toward ipsenol (39%), but was not significantly different from the *control well-fed* or the *conditioned* groups.

Experiment 3: Effect of Experience on Thanasimus dubius Response: Antennal Behaviors The mean number of stand up antennal behaviors/individual/min to ipsenol was affected by experience (Fig. 5), similar to the trend observed for upwind flight (mixed model ANOVA; $F_{3,138}$=3.29; P= 0.023). *Conditioned* individuals were overall more responsive than *well-fed* ones (Tukey-Kramer, P=0.029). There

also was a highly significant effect of semiochemical on antennal response (mixed model ANOVA; $F_{3,138}$=14.84; P< 0.001), meaning that predators were more responsive to ipsenol than frontalin. The experience × semiochemical interaction was not significant (mixed model ANOVA; $F_{3,138}$=2.33; P=0.077). For ipsenol, the number of antennal behaviors was almost four times higher in *T. dubius conditioned* to ipsenol relative to those *starved* (Tukey-Kramer, P=0.001) (Fig. 5). For frontalin, there was no significant difference in the mean number of stand up antennal behaviors/individual/min (mixed model ANOVA; $F_{3,65.4}$=0.86; P=0.466) (Fig. 5).

Discussion

Our results suggest that *T. dubius* populations from Wisconsin consist of generalists in terms of response to kairomonal signals. Indeed, mark-release-recapture experiments showed that individual *T. dubius* are able to respond to all three major prey pheromone components that we deployed (frontalin, ipsenol, and ipsdienol). The wind tunnel experiment with adults collected in Wisconsin confirmed the breadth of *T. dubius* responses toward various semiochemicals, including another kairomone, sulcatol, and the tree volatile α-pinene. The individuals in the wind tunnel experiments initially were captured by using frontalin and turpentine, and, hypothetically, could represent a subset of the population that has a preference for these semiochemicals. However, it seems unlikely that these adults represented a subset of the population with a particular semiochemical preference because in the subsequent studies they responded to all semiochemicals (Table 2, Fig. 3). Furthermore, the mark-release-recapture results suggest that *T. dubius* initially captured on any pheromone were attracted to all others. Similar results were also obtained from individuals collected in Louisiana and southern Illinois (Costa and Reeve, unpublished data), suggesting that the present results are not restricted to *T. dubius* populations from Wisconsin.

The ability of adult *T. dubius* to respond to a variety of bark beetle semiochemicals is also a feature of other clerid predators that are distributed in the western U.S., such as *Enoclerus lecontei* (Wolcott) and *Enoclerus sphegeus* (Fabricius) (Seybold et al., 1992). This strategy may have evolved to enable *T. dubius* to locate sufficient prey resources despite drastic fluctuations in abundance (Turchin et al., 1991; Reeve and Turchin, 2002). One disadvantage of this strategy could be reduced efficiency in locating and utilizing any particular prey species, but it might be optimal when switching costs (e.g., longer prey handling time) are minimal (Stilmant et al., 2008).

The results of the present study also demonstrate that semiochemically naive predators became more attracted toward ipsenol after having experienced conditioning with this kairomone and a reward. Predator responses rose from 12% of upwind flights toward ipsenol for naive individuals to 63% for those conditioned. Trained *T. dubius* also performed significantly more stand up antennal behaviors than naive

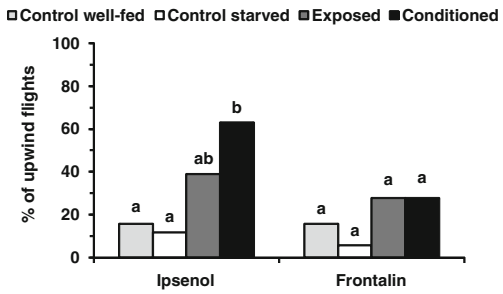

Fig. 4 Effect of previous olfactory experience on *Thanasimus dubius* response. Percentages of adult *T. dubius* flying upwind toward ipsenol or frontalin (N=146). For each prey pheromone component (ipsenol or frontalin), bars capped with different letters indicate a significant difference (P<0.05)

For each prey component (ipsenol or frontalin), bars capped with different letters indicate a significant difference (P<0.05)

ones. Control individuals that experienced a 10-d period of starvation were as responsive toward prey pheromones as were those that were well fed, thus showing that the increase of attraction toward ipsenol seen in experienced predators was not due to starvation. Combining our results with previous work on the carabid beetle, *Pterostichus melanarius* (Illiger) (Plotkin, 1979), or on coccinellids (e.g., De Jean et al., 2003) suggests that olfactory experience can influence the behavior of individuals in several groups of predatory beetles.

We showed here an effect of experience on predator response toward ipsenol because conditioned predators were more responsive than naive ones. However, we cannot exclude that a sensitization component may have acted as well in the significant increase of attractiveness shown in conditioned *T. dubius* (63%), because it was not significantly different from the exposed ones (39%). Thus, the present results do not allow us to distinguish whether sensitization, associative learning, or both are involved in this pattern. Yet our results provide a possible explanation for the pattern observed by Reeve et al. (2009) where the relative response to ipsenol increased in areas where *I. grandicollis* (an ipsenol emitter) was present, but *D. frontalis* (a frontalin-emitter) was absent or at a low population density.

Attraction toward frontalin was slightly increased in exposed and conditioned predators (28%), especially in comparison to ipsenol. Training for a response to frontalin may possibly require more exposure to significantly increase the preference. At this release rate (0.5–1 mg/d), naive predators were more responsive to ipsenol than to frontalin in the wind tunnel, and possibly a higher release rate for frontalin would elicit a stronger response. Additionally, these results suggest that *T. dubius* response to this kairomone could be a fixed trait because the sensitization and learning treatments had no effect on the response. This is in agreement with field-trapping studies showing that this predator invariably displays a strong response to frontalin, even in areas where frontalin-emitting prey appear to be at low population densities (Billings and Cameron, 1984; Aukema and Raffa, 2005; Reeve et al., 2009). The relatively low response of adult *T. dubius* to frontalin in the wind tunnel was somewhat surprising and, at first, seems to disagree with the results of the mark-release-recapture experiment. However, we did not include any visual silhouettes in the wind tunnel while testing the semiochemicals. This was not the case in field experiments where the black silhouette could enhance the response to frontalin. Indeed, adult *T. dubius* have been shown to use visual cues in concert with frontalin in the field (Strom et al., 1999; Reeve et al., 2009).

How *T. dubius* populations cope with unpredictable and patchily distributed prey resources in the field has not been fully elucidated. Individual predators in this study seem to act as generalists based on odor preference for prey. The ability of individuals to respond to various kairomones is likely to help *T. dubius* populations to cope with drastic changes in bark beetle abundance. Our results also suggest that previous olfactory experience plays a role in the response of *T. dubius* to certain prey pheromones (ipsenol) but not others (frontalin). Further research on learning could use naive *T. dubius* conditioned with an artificial flavor such as vanilla (Lewis and Tumlinson, 1988), which is not innately attractive (Costa and Reeve, 2011), to determine whether associate learning, sensitization, or both are involved.

Finally, we hope that future studies will investigate whether experience generally affects olfactory behavior in other clerid species (e.g., *Enoclerus* spp.) that attack bark beetles and are generalists in terms of diet. Additional studies could focus on clerids that also are predatory but whose prey inhabit herbaceous plants (such as *Phyllobaenus* or *Trichodes* spp.) and, thus, deal with different resources (Foster, 1973; Opitz, 2002). Given that many of these predators also experience large changes in their prey communities, the learning of prey kairomones may be a common strategy within this taxonomic group.

Acknowledgments This research was supported by a cooperative agreement with the Southern Research Station, USDA Forest Service and by NSF LTREB 0515781 to Kenneth F. Raffa and John D. Reeve. We thank Celia Boone for assistance in the field, Robert Murphy, Jack Helprider, and Jennifer Boice for helpful site information, and Kenneth F. Raffa for logistical support. We thank land managers Bryan Woodbury, Paul Zajackowski (Dell Creek Wildlife area) and Peter Bakken (Black River Falls) for permission to access the study sites and their friendly collaboration. We thank two anonymous reviewers for their valuable comments on an earlier draft of this manuscript.

(southwestern USA), *P. ponderosa* exhibits substantial polymorphism in the constitutive monoterpene composition of its oleoresin (Smith et al., 1969; Latta et al., 2003; Davis and Hofstetter, 2011). This polymorphism can occur at highly localized scales, and multiple chemical variants of *P. ponderosa* often are interspersed geographically (Latta et al., 2003). In addition to inter-tree polymorphism, the monoterpene composition of conifer oleoresin can vary within an individual (Nerg et al., 1994; Barnola et al., 1997). For example, the monoterpene composition of *P. ponderosa* needles often is different from the monoterpene composition of phloem or xylem oleoresins, which may also differ (Latta et al., 2000). In other conifer systems, enantiomeric compositions and relative amounts of monoterpenes also can vary within individual trees (Persson et al., 1996). However, relative monoterpene composition of conifer phloem oleoresin is a quantitative trait and under moderate to strong genetic control (Hanover, 1971, 1992).

It has been long believed that the chemical composition of tree resin can mediate bark beetle population dynamics (Hopkins, 1916; Raffa et al., 2005). There are few experimental demonstrations that oviposition behavior or fecundity of *Dendroctonus* spp. bark beetles is regulated by intraspecific variation in the monoterpene composition of host conifers (Sturgeon, 1979; Wallin and Raffa, 2004). Our objective was to assess the effect of two common monoterpene compositions (henceforth, 'chemotypes') of *P. ponderosa* in northern Arizona in combination with the chemical history of *D. brevicomis* on the rate of host acceptance, egg gallery construction behavior, and fecundity. We tested two hypotheses: (1) beetle performance (i.e., host acceptance, egg gallery construction, and fecundity) varies between host tree chemotypes, and (2) beetle performance is mediated by insect chemical history. We addressed these hypotheses by using a series of rearing assays in which we controlled for the chemotype of host material in which the beetles developed. By evaluating the F_1 generation, we were able to compare beetle performance across chemotypes, and between natal and non-natal chemotypes. Experimental evidence suggests that both oviposition behavior and fecundity were mediated by beetle chemical history, but performances were equivalent between tree chemotypes.

Methods and Materials

Oleoresin Collection and Compound Identification To collect resin from *Pinus ponderosa* var *scopulorum* trees, a No. 16 resin collection punch (C.S. Osborne Co., Harrison, NJ, USA) was used, and a 25 ml glass collection vial was inserted into the resulting hole. Holes for oleoresin collection were punched through the outer bark at a height of 1.47 m, and approximately 3 mm into the phloem layer. This sampling height and depth is relevant to *D. brevicomis*, as the beetle primarily attacks stems at a height range of 0.5–10 m, and generally only colonizes the phloem layer (Wood, 1982). Since we only wished to analyze oleoresin collected from the phloem, we were careful to ensure that oleoresin collection holes did not puncture the xylem. After 24 h (Latta et al., 2000), vials were collected, and this typically yielded 10–25 g of resin for each vial. This time period reflects a collection of constitutive (vs. induced) resin (e.g., Wallin et al., 2003), and previous studies have shown that mechanical stem wounding has little effect on monoterpene cyclase activity in phloem tissues of *P. ponderosa* (Lewisohn et al., 1991). Oleoresin samples from tree populations in northern Arizona were collected between 15 May and 15 July 2008, and stored at −20°C until used in gas chromatography. A sample of constitutive phloem oleoresin was collected from every ponderosa pine (N=194) over a 2 ha area, at an elevational range of 2100–2200 m (Davis and Hofstetter, 2011).

To prepare oleoresin samples for analysis, 1 g of sample from each tree was dissolved in hexane (GC grade, > 99.0%) to a total volume of 2.0 ml. Fifty μl of this solution were further diluted to 5 ml with GC grade hexane, and 50 μl of 9.48 mg/ml L-fenchone (>98.0% chemical purity, 99.5% isomeric purity, Aldrich, Milwaukee, WI, USA) were added as an internal standard. The same concentration of fenchone was added to calibration standards. Six calibration standards, each with increasing concentrations of monoterpenes, were prepared along with two check standards. All standards were created from a stock solution. The stock solution contained high purity monoterpenes (Table 1) dissolved in GC grade hexane. The monoterpenes α-pinene, β-pinene, myrcene, Δ-3-carene, limonene, and terpinolene were tested. All samples and standards were transferred to 2 ml glass vials with ivory PTFE/red rubber septa. Vials were stored in a freezer at −20°C until analysis.

A Hewlett-Packard 5890 Series II Gas Chromatograph (GC) (Agilent, Santa Clara, CA, USA) with a 6890 Series auto-sampler injector and a 100 vial tray were used for the analysis of the oleoresin samples. The system used on-column injection and a flame ionization detector (FID), and a J&W Scientific (Agilent, Santa Clara, CA USA) capillary GC DB-1 column (30 m×0.25 mm i.d.; film thickness of 0.25 μm). The column was heated to 300°C for 1 h prior to the start of analysis to condition the column and remove any residual compounds from previous analyses. Carrier gas (He) flow rate was 20 ml/min; makeup gas (N_2) flow rate was 10 ml/min; and detector gas (H_2 and compressed air) flow rates were 30 ml/min and 370 ml/min, respectively. Injector temperature was 275°C, and the detector temperature was 300°C. Injection mode was manual, and the temperature program

Table 1 The mean concentrations of six monoterpenes (± s.e.) collected from phloem oleoresins in two chemotypes of ponderosa pine, *Pinus ponderosa* var *scopulorum*, found in northern Arizona (southwestern USA.)[a,b,c]

Chemotype	Monoterpene concentration (mg/g resin)					
	α-Pinene	β-Pinene	Myrcene	Δ-3-Carene	Limonene	Terpinolene
α-Pinene	169.75±35.76	8.05±2.98	14.06±1.74	5.78±2.78	32.08±3.83	0.78±0.23
Δ-3-Carene	71.48±1.76	5.19±1.35	10.38±0.75	113.57±0.57	13.14±1.50	7.31±0.17

[a] From the oleoresin samples of 194 ponderosa pines, 24.7% were the α-pinene chemotype (N=48) and 37.1% were the Δ-3-carene (N=72) chemotype. These chemotypes are geographically intermixed. All samples were collected in Coconino County, Arizona

[b] Chemical purities, (enantiomeric purities), and commercial sources of calibration standards used in GC analysis are as follows: (1*R*)-(+)-α-pinene 99.0% (96.5%), Sigma-Aldrich, St. Louis, MO, USA; (1*S*)-(−)-β-pinene 99% (98.5%), Aldrich Chemical Company, Milwaukee, WI, USA; myrcene (technical) >75% (achiral), Aldrich Chemical Company, Milwaukee, WI, USA; Δ-3-carene 95.7% (95%), Aldrich Chemical Company, Milwaukee, WI, USA; (*R*)-(+)-limonene 97% (97.5%), Aldrich Chemical Company, Milwaukee, WI, USA; terpinolene 85% (achiral), TCI America, Portland, OR, USA

[c] Chemotype data modified from Davis and Hofstetter, 2011

was as follows: Start 45°C, hold 0.1 min; ramp 25°C/min to 70°C, hold 0.1 min; ramp 2°C/min to 96°C, hold 0.5 min, ramp 40°C/min to 300°C, hold 1 min.

A SRI Instruments Peak Simple Model 202 data system and software were used to acquire the FID signal from the GC and draw chromatograms. Monoterpenes were identified by retention time. This software identifies each peak within a defined window of expected retention time. Calibration curves were created for each monoterpene by plotting the corrected peak area (area of the monoterpene peak divided by the area of the fenchone peak for that sample) vs. the known monoterpene concentration for each calibration standard. Calibration curves were used to determine the monoterpene concentration in each diluted sample. A duplicate and a check standard were analyzed every 10 samples, and all results were found to be repeatable. Results were reported as mg of each monoterpene per g of oleoresin sample.

Bark Beetle Collection *Dendroctonus brevicomis* were collected from Lindgren funnel traps [Lindgren, 1983; PheroTech Inc. (now Contech Enterprises, Inc.), Delta, BC, Canada] baited with *D. brevicomis* enhanced pheromone lures consisting of *exo*-brevicomin, frontalin, and α-pinene (Synergy Semiochemicals Corp, Burnaby, BC, Canada, P130 Lot No. WPP10416). The enantiomeric composition, chemical purity, and release rate of each compound in the trap baits were as follows: *exo*-brevicomin 50%-(−), 99%, 1.5 mg ±0.2 mg/d; frontalin 50%-(−), 99%, 1.5 mg±0.2 mg/d; and α-pinene 80%-(+), 99%, 2.5 mg±0.3 mg/d. Traps were placed in forested areas predominated by *P. ponderosa* in northern Arizona at elevations of 2100–2200 m. Beetles were collected live and placed individually into clear, size 0 gelatin capsules (Torpac, Fairfield, NJ, USA, Lot No. 1100049271). Beetles were stored in the lab in dark environmental chambers at 5°C until introduced into host material. Beetles were held in chambers no longer than 24 h prior to use. Beetles were collected from 1 May 2009 to 1 October 2009 and from 1 May 2010 to 1 October 2010.

Rearing Experiments Four chemotypes were identified based on our surveys of monoterpene composition (consistent with Latta et al., 2003; result described in Davis and Hofstetter, 2011). For the purposes of the present study, only two host chemotypes were used: 1) Constitutive oleoresin composed primarily of α-pinene; or 2) Constitutive oleoresin composed primarily of Δ-3-carene. The α-pinene chemotype is characterized by high concentrations of α-pinene and limonene, and very low concentrations of Δ-3-carene and terpinolene. Conversely, the Δ-3-carene chemotype exhibits high concentrations of Δ-3-carene and terpinolene, low concentrations of limonene, and a 58% reduction in α-pinene relative to the previous chemotype (Table 1). The suitability of trees for use in rearing experiments was determined by chemotype and size [diameter at breast height (1.47 m) range 25–35 cm, height range 10–17 m]. Trees were felled and then cut into logs that were 30 cm in length. The ends of all logs were sealed with melted paraffin wax to prevent desiccation. For each series of rearing assays, host material of each chemotype was collected from the same location and on the same day. In 2009, six trees of each chemotype (N=12 total) were felled and used, and in 2010, seven trees of each chemotype (N=14 total) were felled and used. Each tree typically resulted in approximately 25 logs, and the use of log material in rearing experiments was randomized.

The replication of experimental units was performed at the log level, as described previously (Davis and Hofstetter, 2009). Beetles were introduced into logs at a density of 1 pair/dm^2. This resulted in a mean introduction rate of approximately 20 (mean = 19.78) females per log. Holes were drilled with a bore diameter of 3 mm into logs, to the

phloem layer. A gelatin capsule containing a female *D. brevicomis* was placed inside the resulting hole. All introductions were performed simultaneously for each log. After 48 h, each log was examined to ensure that females had successfully initiated tunneling. Females that did not begin tunneling after 48 h were removed from logs and discarded. For each successful female, a male was introduced into the hole, as described above. Each log was placed into a metal rearing canister. In 2009, 1,694 trap-caught beetles were introduced into 46 logs (23 α-pinene chemotype; 23 Δ-3-carene chemotype), and in 2010, 2,666 trap-caught beetles were introduced into 62 logs (32 α-pinene chemotype; 30 Δ-3-carene chemotype).

As adults from the F_1 generation emerged (42–50 d following initial introductions), they were placed into gelatin capsules and stored in the lab in dark environmental chambers at 5°C until used. We discerned re-emerging adults from offspring based on the length of time it took for beetles to appear in rearing canisters following introduction. Re-emerging adults typically appeared in rearing canisters after approximately 10–20 d, whereas, as noted above, F_1 offspring typically appeared 42–50 d following introductions. F_1 beetles were held for 48–72 h prior to use in experiments (Paine and Birch, 1983). In 2009, 1,755 F_1 beetles were collected, and in 2010 2,903 F_1 beetles were collected. The chemotype of the host material that each beetle was collected from was recorded. F_1 offspring beetles were introduced into host material that was the same chemotype as the log they developed in (natal) or the opposing chemotype (non-natal), and female acceptance rate was assessed at 48 h. In 2009, 1,610 F_1 beetles were introduced into 35 logs (13 α-pinene chemotype; 22 Δ-3-carene chemotype), and in 2010, 1,316 F_1 beetles were introduced into 34 logs (18 α-pinene chemotype; 16 Δ-3-carene chemotype).

Adults from the F_2 generation were collected and tallied but not used further in experiments. In 2009, 2,143 F_2 beetles were collected, and in 2010, 1,750 F_2 beetles were collected. Following complete emergence of all beetles from each log, the outer bark was removed and the length of each egg gallery was measured. Thus, for each log, the proportion (%) of females that entered the log, the mean egg gallery length (cm), and the mean number of offspring that were produced by each female were determined.

Statistical Analyses All statistical tests incorporated a type I error rate of $\alpha=0.05$, and all statistics were computed by using the software JMP 8.0 (SAS Institute). The rearing experiment was analyzed as a two-way ANOVA. Our model accounted for chemotype of host material ($N=2$ α-pinene chemotype, Δ-3-carene chemotype) and chemical history ($N=3$: unknown/trap-caught, natal, non-natal) of beetles. These were treated as fixed effects on the response variables of proportion (%) female acceptance, mean egg gallery length, and mean number of offspring per female. The interaction of chemotype X chemical history also was evaluated. When significant differences were detected in the model, Tukey's HSD test was used to separate means. In addition, the correlation between mean egg gallery length and mean number of offspring per female was analyzed by using least-squares linear regression.

Results

The proportion of female beetles that accepted host material did not vary with chemotype ($F_{1,\ 175}=1.29$; $P=0.256$), beetle chemical history ($F_{2,\ 175}=1.03$; $P=0.357$), or the chemotype X chemical history interaction ($F_{2,\ 175}=2.21$; $P=0.112$). The mean rate of host acceptance was 74.3% for female beetles that developed in the α-pinene chemotype and 79.4% for female beetles that developed in the Δ-3-carene chemotype. The mean rate of host acceptance was 73.2% for trap-caught female beetles; 79.6% for female beetles that were introduced to natal host material; and 77.7% for female beetles that were introduced to non-natal host material.

Mean egg gallery lengths did not vary between host chemotypes ($F_{1,\ 175}=0.00$; $P=0.962$), but mean egg gallery lengths varied with beetle chemical history ($F_{2,\ 175}=9.22$; $P<0.001$). Mean egg gallery length was 25.11 cm (± 0.70 s.e.) for trap-caught beetles; 23.75 cm (± 1.25 s.e.) for beetles in natal host material; and 18.70 cm (± 1.30 s.e.) for beetles in non-natal host material. Parent beetles produced oviposition galleries that were 24.3% longer on average when reared in host material that was chemically similar to their natal host (Fig. 1). Mean egg gallery length and the mean number of offspring produced per female were weakly correlated ($r^2=0.03$; $F_{1,\ 175}=5.67$; $P=0.018$; equation: [Offspring per female] = 0.829+0.077 * [mean gallery length (cm)]). Mean egg gallery lengths did not vary by the chemotype X chemical history interaction ($F_{2,\ 175}=0.26$; $P=0.769$).

Mean number of offspring produced per female did not vary between host chemotypes ($F_{1,\ 171}=0.05$; $P=0.807$), although in non-natal hosts beetles reared in α-pinene host material produced more offspring than beetles reared in Δ-3-carene host material. Mean offspring production per female varied by beetle chemical history ($F_{2,\ 171}=3.58$; $P=0.029$). Trap-caught female beetles produced 3.10 (± 0.31 s.e.) offspring on average; beetles that developed in natal host material produced 2.52 (± 0.56 s.e.) offspring on average; and beetles that developed in non-natal host material produced 1.33 (± 0.57 s.e.) offspring on average. Beetles that developed in natal host material produced 52.8% more offspring, on average (Fig. 2), than those that developed in non-natal host

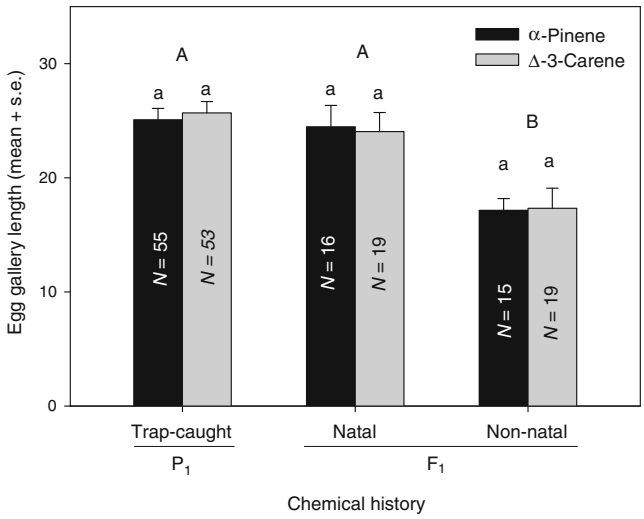

Fig. 1 The effect of host chemotype (black bars: α-pinene; grey bars: Δ-3-carene) and beetle chemical history on mean egg gallery length of *Dendroctonus brevicomis*. Error bars represent one standard error of the mean. The number of experimental units used to calculate each mean is shown for each bar. Lower case letters denote a separation of means test by chemotypes, and upper case letters denote a separation of means by beetle chemical history. P_1 indicates the parent generation, and F_1 indicates the reared generation

material. The chemotype X chemical history interaction was marginally non-significant ($F_{2,\ 171}$=2.45; P=0.088) on the response variable of mean offspring production.

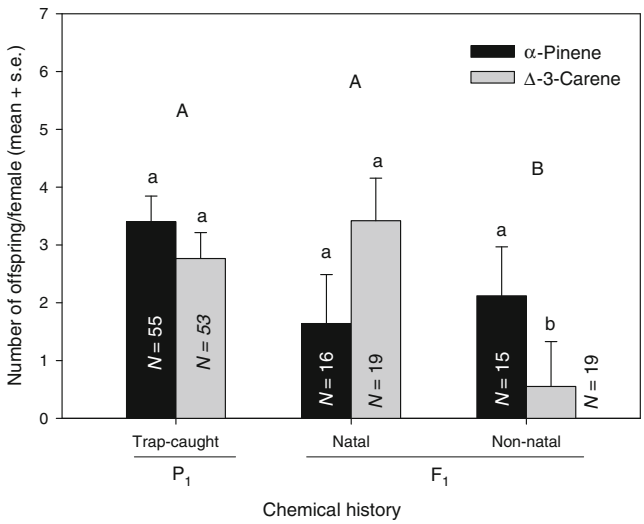

Fig. 2 The effect of host chemotype (black bars: α-pinene; grey bars: Δ-3-carene) and beetle chemical history on mean offspring production from *Dendroctonus brevicomis* pairs. Error bars represent one standard error of the mean. The numbers of experimental units used to calculate each mean are shown for each bar. Lower case letters denote a separation of means test by chemotypes, and upper case letters denote a separation of means by beetle chemical history. P_1 indicates the parent generation, and F_1 indicates the reared generation

Discussion

Our experiments support the hypothesis that *D. brevicomis* performance is mediated by chemical history, but we did not find evidence to support the hypothesis that performance varies between two host *P. ponderosa* chemotypes in Arizona. We show that egg gallery construction behavior and fecundity were both influenced by insect chemical history. In both cases, F_1 beetle performance was superior when beetles developed in host material that was chemically similar to their natal host. Interestingly, rates of host acceptance did not appear to vary across host chemotype or by beetle chemical history. Thus, although we do not show evidence that host acceptance, egg gallery construction, or fecundity are related to a particular chemotype, we did find evidence to suggest that some aspects of *D. brevicomis* performance are mediated by the monoterpene composition of its previous host. Our results are consistent with the findings of Davis and Hofstetter (2011), which showed that chemical legacy impact the growth of nutritional fungal symbionts associated with *D. brevicomis*.

The results of our experiment warrant discussion of Hopkins' host selection principle (HHSP). Hopkins (1916, 1917) postulated that "insects become conditioned to the host on which they develop, and this will influence the adult female to deposit her eggs on the same species of host and might restrict her progeny to that host" (Walsh, 1864; Barron, 2001)." We assessed the effects of beetle chemical history both from a behavioral (i.e., host acceptance, egg gallery construction) and ecological (i.e., reproductive rate) perspective. Under the proposal that any mechanism causing larval host plant experience to affect oviposition decisions satisfies HHSP (Janz et al., 2009), our experiments provide evidence that both refutes and supports Hopkins' theory. Consistent with the results of Janz et al. (2009), we found no evidence that *D. brevicomis* was more likely to accept host material that was chemically similar to their natal hosts, which implies that restriction to a single chemotype in nature is improbable. However, we did find that *D. brevicomis* produced longer egg galleries in natal chemotypes, which suggests that some behavioral differences may exist among beetles that develop in differing chemotypes. Also, we showed that fecundity was higher on natal chemotypes. This implies that host plant chemistry may act rapidly as an agent of natural selection on *D. brevicomis* to produce lineages within endemic beetle populations that are adapted to a diversity of tree chemotypes. So, although we refute the notion of beetles becoming 'conditioned' to a particular chemotype (Corbet, 1985), we do find that there are likely to be consequences to beetle reproductive rates that result from the interaction between *D. brevicomis* and pine chemotypes (Futuyma and Peterson, 1985). Natural selection to this end is consistent with a genetic mechanism for HHSP, as

described by Barron (2001); and indicates that HHSP could perhaps benefit from further examination of oviposition behaviors within individual host plant species.

Several limitations of the experimental design should be noted. One shortcoming of our experiment is that a no-choice assay of host acceptance does not reflect a true estimation of host selection. In a natural setting, host selection trends may depart from the trends in acceptance that we observed due to fluctuations in temperature and precipitation, the presence of natural enemies, and stand or site conditions. Furthermore, we altered the influences of pheromonal communication and aggregation among beetles by deliberately introducing F_1 beetles to host material, and our experiment restricted F_1 beetles from flight. This could dramatically affect the likelihood that beetles will accept a host (Byers and Wood, 1981; Byers et al., 1984). Additionally, our trapping method for parent beetles may have selected for a portion of the beetle population that responded to the specific semiochemicals that we used for trapping (*exo*-brevicomin, frontalin, and α-pinene). Thus, it is possible that another portion of the population may have responded to other enantiomers of bicyclic acetals and to other monoterpene co-attractants, and that these insects may have produced offspring that performed differently.

Primary chemistry (e.g., nitrogen, carbohydrates, phosphorous) and other secondary chemicals (e.g., phenols, calcium oxalate) present in host material may have affected the responses tested in this experiment. However, we attempted to control for these factors by randomizing our use of host material across 26 trees. In addition, initial chemotyping was performed on standing trees, rather than logs. Monoterpenes rapidly volatilize, and sectioning trees into logs may have elicited an induced response from host material, so it is possible that monoterpene compositions differed over time in log material. Thus, in the context of this experiment the only factor that we can attribute differences in *D. brevicomis* oviposition behavior and fecundity to is the initial chemical factor that we controlled for: i.e., constitutive monoterpene composition of phloem oleoresins of living trees. However, it should be recognized that other chemical factors could have contributed to the treatment effects observed here.

Despite these limitations, our introduction technique achieved an average acceptance rate of 76.8%, so a majority of beetles entered host material despite the absence of conspecific pheromones, alterations to tree material, and the restriction of flight. We noted that fecundity is reduced when *D. brevicomis* are reared in a laboratory setting (approximately 3 offspring/female), compared to approximately 10 offspring per female in study trees in the field (Davis and Hofstetter, 2009). Collectively, a disturbance to pheromonal communication, restriction of flight, our trapping method, and the reduction of fecundity may contribute to different behaviors between laboratory-reared and natural populations of *D. brevicomis*. These factors should be taken into consideration when comparing the results of our experiment to beetle behaviors in Nature.

In summary, we found support for the hypothesis that insect chemical history can mediate egg gallery construction and fecundity of *D. brevicomis*. This result may be consistent with a genetic mechanism for HHSP (Barron, 2001). We showed here that the monoterpene composition of natal hosts is likely to influence beetle performance on subsequent hosts. However, we did not find any support for the hypothesis that beetle oviposition behavior or fecundity varies fundamentally between chemotypes of *P. ponderosa*. Rather, our experiment suggests that monoterpene composition of *P. ponderosa* may act rapidly as an agent of selection on *D. brevicomis* populations, and that multiple lineages adapted to a variety of pine chemotypes may exist in natural populations. This could indicate that *D. brevicomis* population dynamics are regulated by the chemical diversity present in populations of their host pine. For example, high-density beetle populations (outbreaks) are rarely observed in northern Arizona (USDA Forest Service, 2010), where pine chemical diversity is high (Latta et al., 2003). In contrast, outbreaks occur at relatively frequent intervals in northern California, where host pine chemical diversity is comparatively low (Sturgeon, 1979). We detected substantial chemical diversity in *P. ponderosa* at a scale of 2 ha, and found that beetle oviposition behaviors and fecundity vary across the chemotypic diversity at this scale. Future work in this system should focus on assaying host selection by beetles with controlled chemical histories in a field setting.

Acknowledgments We thank N. Foote and E. Jensen for assistance in the field and lab. Chemical analysis (GC) of monoterpenes was performed by B. Moan at the Colorado Plateau Analytical Laboratory, Northern Arizona University. Partial funding for this work was provided by the A.R.C.S. Foundation, Inc., and the N.S.F. IGERT Program at Northern Arizona University to T.S.D., and USDA. Forest Service Joint Venture Agreement 08-JV-11221633-250 to R.W.H. We also extend our gratitude to the USDA Forest Service Rocky Mountain Research Station for providing laboratory space. Finally, we thank the anonymous referees for their review of this work and for commentary that greatly improved the quality of this manuscript.

and Tueller, 2001; Santoro et al., 2001; McHugh et al., 2003; Sullivan et al., 2003; Wallin et al., 2003; Elkin and Reid, 2004; Hood and Bentz, 2007; Six and Skov, 2009). Lombardero et al. (2006) found *Ips pini* (Say) and *Ips grandicollis* (Eichhoff) preferred fire-injured *Pinus resinosa* Aiton, suggesting such behavioral adaptations may underlie a significant ecological relationship between some bark beetles and their hosts. From a population dynamics perspective, fire-injury may provide a refuge for some bark beetles during their endemic phase, but not by itself necessarily lead to outbreaks (Powell et al., 2012).

This high variability poses substantial challenges to natural resource managers, who must make important and often contentious policy decisions involving fire and insect suppression, controlled burns, fuel accumulation to restore more natural conditions, and protection of human habitations. Understanding more about the mechanisms by which fire injury affects tree susceptibility to bark beetles could potentially address this problem.

Conifers are defended against bark beetle attack through several integrated mechanisms. Constitutive defenses act as a first line of defense and include physical barriers such as thick bark and lignin (Franceschi et al., 2005) and chemical barriers such as terpenoids and phenolics (Martin et al., 2003). Inducible defenses are triggered by insect or pathogen invasion and include formation of necrotic tissue that confines the invader (Paine and Stephen, 1988) and increased terpene and phenolic production, which deters establishment (Cook and Hain, 1988; Raffa and Smalley, 1995; Franceschi et al., 2005). In particular, increased monoterpene concentrations, and sometimes changes in their relative proportions, have deterrent, adulticidal, and ovicidal activities against bark beetles, and inhibit growth and germination of their fungal symbionts (Coyne and Lott, 1976; Raffa et al., 2005; Keeling and Bohlmann, 2006; Seybold et al., 2006; Bonello et al., 2006; Erbilgin et al., 2007; Bohlmann and Gershenzon, 2009; Zulak and Bohlmann, 2010). The ability to undergo induced total monoterpene accumulation appears particularly well correlated with tree survival in the field (Raffa and Berryman, 1982; Boone et al., 2011).

Stressors, such as severe drought, defoliation, lightning, and root disease, can reduce tree defenses against bark beetles (Christiansen et al., 1987; Flamm et al., 1993; Klepzig et al., 1996; Lombardero et al., 2006; Wallin and Raffa, 2001; Lewis and Lindgren, 2002; Turtola et al., 2003; Raffa et al., 2005). The effects of stress caused by fire injury on tree defenses, and its subsequent effect on bark beetle colonization and reproductive success, however, are less well known. Defensive resin flow has been shown to increase with fire injury in some conifers, but only several months post-fire (Wallin et al., 2003; Lombardero et al., 2006; Knebel and Wentworth, 2007). Our knowledge of how fire affects host chemical concentration and composition is even more limited. In one study, dead, fire-injured lodgepole pine (*Pinus contorta* var. *latifolia* Douglas) (Jakubas et al., 1994) had lower total volatiles than live uninjured trees. In another, total monoterpenes decreased 1 month post-fire in red juniper (*Juniperus virginiana* Lawson) (Campbell and Taylor, 2007). The defenses of fire-injured lodgepole pines that remain alive and hence potentially, susceptible to bark beetle attack, have not been examined, nor have the inducible chemical defenses that follow fire injury in any system.

The mountain pine beetle (*Dendroctonus ponderosae* Hopkins) is of major concern throughout the western United States and Canada. It recently has caused extensive mortality in both pine forests where it historically has undergone intermittent outbreaks and at higher latitudes and elevations than were previously common or recorded, an expansion attributable to changing climate (Kurz et al., 2008; Raffa et al., 2008; Safranyik et al., 2010). The primary host of the mountain pine beetle is lodgepole pine. During colonization attempts, it appears to benefit from its fungal symbiont, *Grosmannia clavigera*, in degrading lodgepole pine defenses (DiGuistini et al., 2011). The mountain pine beetle also exploits some host monoterpenes as precursors, stimulants, and synergists of the aggregation pheromones that it uses to coordinate the mass attacks need to overwhelm tree resistance (Wood, 1982; Blomquist et al., 2010).

We examined the effects of fire injury on lodgepole pine chemical defenses. Specifically, we tested whether fire affects the constitutive and induced total volatile concentrations, and their composition, in lodgepole pine phloem. We also tested whether mountain pine beetles caged onto trees with varying levels of fire injury would enter at similar frequencies.

Methods and Materials

Plot Description and Classification of Fire Injury Category The LeHardy fire began on July 30, 2008, and burned 3,777 ha of lodgepole pine and mixed lodgepole pine and spruce forest in Yellowstone National Park, U.S. A. Sampling took place 1 year post fire, in July of 2009. Trees in nine, 1 ha plots separated by at least 100 m within the burn were classified for degree of fire injury using the methods of Ryan (1982) and Powell et al., (2012). Measurements of percent basal, bole, and canopy injury, and cambium kill rating (ckr) were used to designate the injury to each tree as unburned, low, moderate, and high as follows: Unburned trees were healthy, and without fire injury. Low-injured trees had 0–10% injury on the tree base and bole, and a ckr of zero or one. Moderately-injured trees

had 11–49% injury on the tree base and bole, 0–10% injury of the canopy, and a ckr of two or three. Highly-injured trees had 50–100% injury on the tree base and bole, 10–100% injury of the canopy, and a ckr of three or four. Trees were at least 15 cm diam at 1.3 m.

Measurements were taken for additional variables that potentially could affect tree defenses. Tree-level variables included diameter at 1.3 m, tree height, presence and rating of dwarf mistletoe (*Arceuthobium americanum* Nuttall Ex. Engelmann) by using the method of Hawksworth (1979), and presence of *Cronartium* spp. stem rust by using the method of Geils and Jacobi (1984). We deliberately selected healthy trees without attacks by stem-boring insects; in a few cases, we found evidence of old attacks or new attempts between initial designation and final sampling, so this was also built into our model. Stand level variables included aspect, slope, and elevation.

Effects of Fire Injury on Constitutive and Induced Volatile Compounds Two pieces of phloem (approximately 5 cm long by 2 cm wide) were removed with a razor blade from 50 lodgepole pines from each fire injury category, sealed in plastic tubes, transported from the field in dry ice-cooled Styrofoam coolers, and frozen at −20°C until analysis. One phloem piece each was removed from the north and south aspects of the tree, or if the tree was moderately- or highly-fire-injured, they were removed from the burned or unburned portions of the tree. These served as the constitutive samples.

We elicited induced responses on the same trees by challenge inoculations that mimicked the combined entry of the mountain pine beetle and its major fungal symbiont, *Grosmannia clavigera*. We isolated *G. clavigera* by rolling live beetle larvae from lodgepole pine phloem onto malt extract agar, isolating and culturing at 25°C for 7 d by using the method of Wallin and Raffa (1999). A pure culture of *G. clavigera* was isolated and identified by its morphology by using microscopy and descriptions from Upadhyay (1981). Simulated attacks of 1 cm agar-fungi plugs were administered at the xylem/phloem interface by using sterile techniques. The 2 cm bark-phloem plug was replaced immediately to the site of introduction. Two inoculations were administered per tree, on the north and south aspects, or the burned or unburned portions for moderately- and highly-injured trees. We simulated attack at the same time when constitutive phloem was sampled. We sampled the reaction zone 7 d after simulated attack and stored the samples as above.

Compounds were extracted from finely chopped constitutive and induced phloem samples after 24 hr of agitation in 1 ml of hexane as described in Raffa and Smalley (1995). This solution was filtered with glass wool. The sample vials were rinsed twice with 250 μl of hexane, which resulted in a final volume of 1.5 ml volatile-hexane solution. One μl of 0.1% isobutylbenzene was added to each sample as an internal standard. This internal standard has been commonly used in previous, including recent, analyses of these compounds (Robert et al., 2010; Boone et al., 2011), thereby facilitating between-study comparisons. However, some variation could arise from different response factors to any common internal standard (Raffa and Steffeck, 1988), and likely increases when non-monoterpene hydrocarbons are included. The remaining phloem was dried at 25°C for 1 wk and weighed.

Samples were analyzed with a Shimadzu 17 gas chromatograph with an Agilent Technologies cyclodex chiral column: 30 m long, 0.25 mm internal diam, and 0.20 μm film thickness with Helium as the carrier gas. Each analysis began at an initial temperature of 60°C for 10 min, followed by an increase in 5°C per min until 160°C. The total run for each sample lasted 69 min. Thirty pure volatile standards from Sigma-Aldrich for those commonly found in pines also were run using the above described method. We compared the retention times of these standards with the peaks on the chromatogram produced after the run of each sample. Milligrams of each compound were calculated by integrating its area under the curve and the internal standard, and we multiplied this value by the density of the internal standard.

Effects of Fire Injury on Mountain Pine Beetle Entry Ten separate trees from each of the four fire injury categories were selected for a beetle entry bioassay that was conducted under no-choice conditions. Beetles were captured using ten 12-funnel flight traps (Lindgren, 1983) that were baited with *trans*-verbenol, myrcene, and *exo*-brevicomin from Contech Enterprises Inc. Captured beetles were kept in a refrigerator for no longer than 1 wk prior to bioassay. Only vigorous, active female beetles were used. A 13 cm^2 square of aluminum screening was secured to the north or unburned portion of the tree bole at 1.3 m high. Five females were introduced into each cage. Needles and lichen from lodgepole pine branches were provided to give the beetles traction on a natural surface. Beetle entry and mortality were tabulated after 24 hr. For each tree, we noted diameter at 1.3 m, height, and potential sources of stress to incorporate conditions other than fire injury category that may affect beetle entry in our analysis, as described previously. The trees included in this experiment were of similar size and condition as those analyzed for chemical content.

Statistical Analyses Concentrations of volatiles were calculated on a per dry weight of phloem basis. Concentrations from the north and south, or burned and unburned, aspects of the bole were averaged. We did not observe any

difference between burned or unburned bole portions for either treatment, and we only observed differences between the north and south aspects of the bole for constitutive, unburned samples, and induced low injury samples (Supplementary Materials: Table 1). Concentrations were square root transformed to achieve normality. Normality and homogeneous variance were tested using quantile-quantile plots and Bartlett tests, respectively. We performed a two-way ANOVA using the statistical program R v2.7.2 (R Core Development Team, 2008) to identify potential differences of total volatile amounts among fire injury categories, constitutive or induced treatment, and the interaction between category and treatment. We used ANOVA to test for differences across fire injury categories within constitutive and induced phloem, and then performed *t*-tests with a Bonferroni correction to test for pairwise differences. Separate two-way ANOVAs tested for potential differences of total concentrations between fire injury category and bole aspect, and between constitutive or induced treatment and bole aspect. We constructed a single generalized linear model with a square-root transformation to evaluate other potentially important pathogenic and environmental variables on total concentrations. We used a backward elimination procedure with Akaike's information criteria (AIC) (Akaike, 1973), and selection of variables with $\alpha \leq 0.05$, to identify the best model for analyzing total volatile concentrations.

Individual volatile percentages in each sample were calculated and compared among fire-injury categories and constitutive and induced treatments. Normality was not achieved after an arcsin square-root transformation, so tests were performed using the non-parametric Kruskal-Wallis rank-sum test.

Beetle entry into trees of various fire-injury categories was analyzed using a *Chi-square* analysis. We constructed a single generalized linear model with a logit transformation to evaluate variables other than fire injury on no-choice, beetle entry. We used a backward eliminated procedure with AIC (Akaike, 1973), and selection of variables with $\alpha \leq 0.05$, to identify the best model for no-choice, beetle entry analysis.

Results

Effects of Fire Injury on Constitutive and Induced Volatiles We detected 13 monoterpene hydrocarbons in the tissue of the constitutive samples, 12 monoterpene hydrocarbons in the induced samples, 4 allylic monoterpene alcohols, 1 ester and 1 phenyl propanoid, of which the monoterpene hydrocarbons comprised at least 96% in all induction and fire injury categories (Tables 1 and 2). Hereafter, our use of 'total volatiles' refers to these compounds. Total volatile concentrations (mg/g dry phloem)

were affected by fire injury category, induction treatment, and the interaction between category and treatment (category: $F_{(3,\ 391)}$=8.65, P<0.001, treatment: $F_{(1,391)}$=67.9, P<0.001, interaction: $F_{(3,391)}$=4.73, P=0.003). Total concentrations of volatiles within constitutive phloem tissue did not vary with fire injury ($F_{(3,196)}$=1.04, P=0.376). In contrast, the concentrations of induced volatiles decreased by nearly half with the occurrence of any fire injury, regardless of severity (Fig. 1, $F_{(3,195)}$=18.1, P<0.001). This pattern did not vary among the various measurements of fire injury.

The linear regression model incorporating all tree- and stand-level factors that yielded the best fit was R^2=0.263, $F_{(11,387)}$=12.6, P<0.001, and included fire injury category, induction treatment, the interaction between category and treatment, tree height, hillside slope steepness, and UTM-easting and UTM-northing plot position (Table 3). In addition to the effects of fire injury and induction, total volatile concentrations decreased with tree height, slope steepness, and more eastern and northern plot positions (Supplementary Material: Table 2).

Effects of Fire Injury on Constitutive and Induced Volatile Composition Fire injury influenced the proportions of several volatiles in constitutive phloem tissue (Table 1). Concentrations (mg/g dry phloem) are listed in Supplementary Material: Tables 3 and 4. Proportions of (−) α-pinene, (+) α-pinene, (−) β-pinene, (+) limonene, and α-terpineol increased with fire injury by 3%, 1%, 7%, 0.6%, and 0.3%, respectively. Proportions of myrcene, β-phellandrene, terpinolene, 4-allylanisole, and (−) *trans*-caryophyllene decreased with fire injury, by 2%, 7%, 1%, 0.8%, and 2%, respectively. Two monoterpenes showed a non-linear response to fire injury: (+) 3-Carene was detected only in the low fire injury category, and (+) β-pinene was

Multiple Linear Regression Model Was Selected Based on Best Fit: $\mathbf{y} = \beta_0 + \beta_1\mathbf{x_1} + \ldots + \beta_k\mathbf{x_k}$. $R^2 = 0.263$, $F_{(11,387)} = 12.6$, $P < 0.001$

highest in the unburned category and lowest in the low fire injury category. (−) Camphene, (+) camphene, α-terpinene, linalool, borneol, geraniol, and bornyl acetate showed no change in percentage with fire injury.

Fire injury also affected the percentages of individual compounds within induced phloem tissue (Table 2). Proportions of the monoterpenes (−) α-pinene, (−) β-pinene, and (+) limonene increased with fire injury, by 2%, 9%, and 0.6%, respectively. Proportions of myrcene, β-phellandrene, 4-allylanisole, and (−) *trans*-caryophyllene decreased with fire injury by 1%, 11%, 0.4%, and 0.6%, respectively. (+) Camphene was highest in the low injury category but not detected in the high injury category. (−) Camphene likewise was not detected in the high injury category. (+) β-Pinene was highest in the unburned category and lowest in the moderate category. Linalool was detected only in the low and moderate injury categories. Terpinolene was highest in the high fire injury category and lowest in the moderate category. Borneol was not detected in uninjured trees, and geraniol was not detected in the highly-injured trees. Percentages of (+) α-pinene, α-terpineol, bornyl acetate, and *trans*-β-ocimene in induced tissue were not affected by fire injury.

Effects of Fire Injury on Mountain Pine Beetle Entry There was no statistical difference among fire injury categories in the percentage of trees entered by caged female mountain pine beetles (Fig. 2a, χ^2=3.51, *df*=3, *P*= 0.320), nor in the percentage of beetles that entered these trees (Fig. 2b, χ^2= 4.58, *df*=3, *P*>0.250). The overall trend, however, was of a parabolic relationship, with highest entry into lightly injured trees. Incorporating other variables did not yield statistically significant explanatory variables of mountain pine beetle entry (Table 4, R^2=0.012, $F_{(3,36)}$=1.15, *P*=0.341).

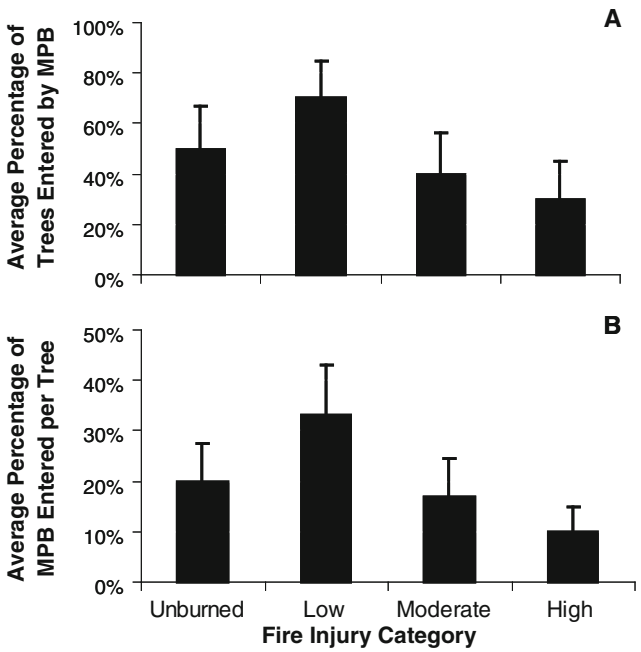

Fig. 2 Entry of caged female mountain pine beetles (MPB) into lodgepole pines that had experienced varying degrees of wildfire injury. **a**. Average percentage of lodgepole pines entered by mountain pine beetles (χ^2=3.51, *df*=3, *P*=0.320). **b**. Average percentage of mountain pine beetles entered per tree (χ^2=4.58, *df*=3, *P*>0.250)

Table 4 Linear regression model, with logit transformation, relating incidence of mountain pine beetle entry to fire injury category

Variable	Estimate (**x**)	Std. Error	*P*
β_o (intercept; unburned category)	0.500	0.159	0.003
β_1 (low category)	0.200	0.225	0.380
β_2 (moderate category)	−0.100	0.225	0.659
β_3 (high category)	−0.200	0.225	0.380

Model Was Selected Based on Best Fit by R^2. These Results Are Fitted to Equation, $\ln(\mu/1-\mu) = \beta_0 + \beta_1 \mathbf{x_1} + \ldots + \beta_k \mathbf{x_k}$. $R^2 = 0.012$, $F_{(3,36)} = 1.15$, $P = 0.341$

Discussion

These results indicate that fire injury reduced the induced, but not constitutive quantities of total monoterpenes and other less abundant volatiles available to defend against attack by mountain pine beetles and its associated micro-organisms. Further, only a small amount of injury was needed to exert this effect. This reduction in the ability to undergo induced accumulation of monoterpenes and additional volatiles at an attack site corresponds with increased likelihood of successful attack by mountain pine beetle in lodgepole pines injured by wildfire in this same region (Powell et al., 2012). Induced accumulation of monoterpenes likewise has been shown to be compromised by a broad range of biotic and abiotic stress agents in multiple conifer-bark beetle systems (Reviewed in Raffa et al., 2005). Similarly, a recent study by Boone et al. (2011) identified induced monoterpene accumulation as the best overall predictor of lodgepole pine defense against mountain pine beetle.

Fire injury also affected the proportions of individual compounds within trees. Among the volatiles affected in constitutive, induced, or both phloem tissues, (−) α-pinene, (+) limonene, myrcene, 4-allylanisole, and terpinolene, are known to affect several aspects of bark beetle colonization, such as entry (Coyne and Lott, 1976), survival (Raffa and Berryman, 1983), and pheromone communication (Wood, 1982; Hayes and Strom, 1994; Erbilgin et al., 2007; Borden et al., 2008; Blomquist et al., 2010). 4-Allylanisole inhibits mountain pine beetle aggregation (Hayes and Strom, 1994), so its reduction in both constitutive and induced phloem tissue with fire injury potentially could create an environment more conducive for mountain pine beetle success. Likewise, the increase in (−) α-pinene with fire injury could benefit the beetle, as this compound is a precursor of mountain pine beetle aggregation pheromone during biosynthesis (Wood, 1982). However, the relative reductions in myrcene and terpinolene with fire injury could have the opposite effect, as both of these compounds synergize the attractiveness of the mountain pine beetle's aggregation pheromone (Borden et al., 2008). Overall, the compositional changes in individual volatiles caused by fire injury appeared potentially more important in constitutive, rather than induced phloem tissue. We currently lack sufficient information with which to characterize these proportionate changes as programmed tree reactions to specific agents that predispose them to bark beetle attack, generalized stress reactions, beetle adaptations to chemical changes that accompany stress, idiosyncratic events, or various combinations thereof. For example, Boone et al. (2011) saw some of these same changes, such as increased α-pinene and reduced β-phellandrene, in lodgepole pine following infestation by lower stem beetles, but other reactions differed.

Our caged beetle entry results showed no significant difference among fire injury categories, but identified a slight trend of more entry in the low injury category. This pattern is interesting because several studies have shown the incidence of bark beetle attack is often higher in moderately burned than in either unburned or severely burned trees (Elkin and Reid, 2004; Powell et al., 2012). We cannot discount the possibility that larger sample sizes would have generated a statistically significant relationship, and so additional research is necessary. Additionally, future research should evaluate the relative ability of entered beetles in healthy vs. fire-injured trees to elicit attraction in the field.

Acknowledgements This study was funded by the National Science Foundation DEB-0816541, McIntire Stennis WIS0469, Joint Fire Sciences Program 06-2-1-20, and the University of Wisconsin College of Agricultural and Life Sciences. Permission to conduct research within Yellowstone National Park was kindly provided by the National Park Service, especially Cindy Hendrix. Lodging and support during the field season was provided by the University of Wyoming and the University of Wyoming, National Park Service Research Center. Field and laboratory assistance was provided by Christopher Pennings, Andrew Long, and Hillary Thompson. We thank Joerg Bohlmann, Univ. British Columbia and Celia Boone, Univ. Northern British Columbia for analytical chemistry guidance. Helpful reviews by two anonymous referees improved this manuscript and are much appreciated.

borer than evolutionarily naïve North American ash species (Rebek et al., 2008).

Relatively little is known about traits that underlie resistance of woody angiosperms to wood-boring insects. Proposed physical mechanisms of resistance include high rates of sap flow (Morewood et al., 2004) and specialized water-containing vesicles (Hanks et al., 1991, 1999), which can inhibit larval establishment. Additionally, induction of wound periderms (callus tissues) in response to larval feeding is hypothesized to function defensively by encapsulating larvae (Anderson, 1944; Dunn et al., 1990; Fierke and Stephen, 2008). Putative chemical mechanisms of resistance include constitutive and induced secondary metabolites present in bark and phloem tissues (Morewood et al., 2004). For example, differences in phenolic profiles in stem phloem tissues of resistant and susceptible ash species were implicated as resistance mechanisms to emerald ash borer (Eyles et al., 2007).

The secondary chemistry of *Betula* is dominated by phenolic compounds, including low molecular weight phenolics, tannins, and lignin (Julkunen-Tiitto et al., 1996; Ossipov et al., 1996; Mämmelä, 2001; Laitinen et al., 2004; Mattson et al., 2005), but how these chemicals vary in the phloem of mature paper birch and European white birch is not known. Therefore, as a follow-up to the common-garden study of Nielsen et al. (2011) that documented greater resistance to BBB in paper birch relative to European white birch, we initiated a study at the same site with the goal of elucidating potential mechanisms underlying variation in resistance. Specifically, we compared qualitative and quantitative differences in phenolic profiles of the stem phloem tissues of these two species. The first objective was to compare interspecific variation of constitutively expressed low molecular weight phenolics present in phloem tissues of paper birch and European white birch and to assess how this variation corresponds with reported patterns of resistance to BBB. The second objective was to analyze intraspecific variation in constitutively expressed phenolics among clones and/or half-siblings within each species.

Methods and Materials

Plant Material and Experimental Design Paper birch and European white birch were grown in a common garden for 12 years at the Ohio Agricultural Research and Development Center in Wooster, OH, USA. Trees were planted at a 3×3 m spacing. In total, there were 56 paper birch and 54 European white birch. Paper birch and European white birch had mean stem heights of 35.3±1.3 (SE) and 46.5±1.2 m, and mean stem diameters of 9.1±0.3 and 10.4±0.3 cm, respectively. All trees were reproductively mature and had similar phenology, with bud burst of all individuals varying by less than 2 weeks (V.L. Muilenburg, personal observations).

Intraspecific variation of paper birch was assessed by using two clones (231 and M2) and two half-sibling families (M1 and 12). M1, M2, and 12 were collected from Midland County Michigan, and 231 were collected from Pennsylvania. Intraspecific variation of European white birch was assessed by using four clones (5818, 5832, 5938 and 50076) selected by the Finnish Forest Research Institute. These European white birch clones are used in birch cultivation by the Finnish forest industry and have been evaluated previously for their resistance to mammalian and insect herbivores (Rousi et al., 1997; Ylioja et al., 2002).

Trees were planted in a randomized complete block design with 8 trees of each species per block, two replicates per clone or half-sibling in each block. One tree of each of the clones or half-siblings per species was randomly sampled in each of the 8 blocks (N=64 trees). Clone/half-sibling was treated as a factor nested within species.

Phloem Samples and Extraction One phloem sample 10 mm diam was excised from each tree stem approximately 1.3 m above ground level with an arch punch. Samples were taken 26 June 2007 to correspond with the natural timing of feeding by BBB larvae (Akers and Nielsen, 1984). The arch punch was inserted into the tree to the depth of the phloem-xylem interface in order to excise the phloem and outer bark. Upon excision, the outer bark was removed, and the phloem samples were flash frozen immediately in liquid nitrogen. The phloem was ground to a powder in liquid nitrogen, and 100 mg (fresh weight) were extracted twice in 500 µl of HPLC-grade methanol (Fisher, Pittsburgh, PA, USA) for 24 h at 4°C (Bonello and Blodgett, 2003). The supernatants were combined and stored in 1.5 ml microcentrifuge tubes at −20°C until analysis by high-performance liquid chromatography (HPLC).

Qualitative Phenolic Analysis Constitutively expressed phenolics were characterized with HPLC-MS analysis by using a Varian 212-LC chromatography pump, Varian Polaris™ RP18, 5 µm, 4.6×150 mm column, ProStar 410 HPLC Autosampler, and Varian 500-MS ion trap mass spectrometer with the ESI source operated in the negative ion mode. The MS detector had a capillary voltage of 80 V and a cone voltage of 5000 V, with a scan range of m/z 100–1400. MS/MS scans were completed on-the-fly by the instrument when the threshold of the pseudomolecular ion reached 20,000 counts. Ions generated by MS^2 and MS^3 underwent further fragmentation at 4,000 counts. The binary mobile phase consisted of 0.1% glacial acetic acid

in HPLC-grade water (solvent A) and 0.1% glacial acetic acid in HPLC-grade methanol (solvent B). The flow rate was 300 μl/min with a linear gradient of B from 0 to 10% in 10 min, then to 25% by 20 min, to 35% by 40 min, to 45% by 56 min, to 65% by 64 min, and finally to 100% by 70 min, with a 20 min hold. The injection volume for each sample was 5 μl.

Quantitative Phenolic Analysis Phenolics were quantified with a Waters 2690 separations module (Milford, MA, USA) equipped with a Waters Xterra™ RP18, 5 μm, 4.6× 150 mm column, a Waters Xterra™ RP18, 3.9 μm, 3.0× 20 mm guard column, and a Waters 996 photodiode array detector. The binary mobile phase consisted of 2% glacial acetic acid in HPLC-grade water (solvent A) and 2% glacial acetic acid in HPLC-grade methanol (solvent B). The flow rate was 1 ml/min, with a linear gradient of B: 0% (0–2 min), 0–10% (2–4 min), 10–48% (4–20 min), 48–100% (20–38 min), and then held for 1 min. The injection volume for each sample was 10 μl.

Phenolics were quantified at 280 nm against the following standards: catechin (Alexis Biochemicals, San Diego, CA, USA), chlorogenic acid (MP Biomedicals, Solon, OH, USA), and salicin (Sigma Aldrich, Milwaukee, WI, USA). The glycosides catechin pentoside, betuloside, betuloside pentosides, and diarylheptanoids were expressed as salicin equivalents. Catechin and procyanidins were expressed as catechin equivalents. Coumaroylquinic acid, platyphylloside, and unknown peaks 9–12 were expressed as chlorogenic acid equivalents.

To align the UV and MS chromatograms, which required different solvent programs, a subset of samples was re-analyzed on an in-line HPLC/UV/MS instrument: a Waters 2695 HPLC (Milford, MA, USA) with a 2.6 μm× 3.00 mm×150 mm Kinetex™ RP18 column and Krud-Katcher™ Ultra filter (Phenomenex, Torrance, CA, USA), a Waters 996 photodiode array detector, and a Micromass ZQ 2000 quadrupole mass detector operated in the negative ion ESI mode. UV absorbance was determined from 237 nm to 400 nm. The MS detector had a capillary voltage of 3.2 kV, a cone voltage of 60 V, and a source temperature of 80°C, with a scan range of m/z 100–1200. The autosampler and column temperatures were set at 30°C. Samples were run using the solvent parameters for the UV quantitation above, with the flow split 2:1 to reduce the rate of mobile phase entering the ZQ detector. When appropriate, the additional fragmentation from the quadrupole spectra were used to help with compound identification.

*Statistical Analyses*The relative concentrations of phenolic compounds were analyzed by univariate analysis of variance (ANOVA) using SAS 9.1 (SAS Institute 1999). All factors (block, species, clone/half-sibling) were considered fixed. Data that did not have equal variances were log-transformed. Fisher's LSD was used to separate means of clones and half-siblings (α=0.05). Intraspecific and interspecific variation of phenolic profiles was analyzed by using principal component analysis (PCA) with Minitab 15 (Minitab Inc. 2007).

Results

Characterization of Phenolics Seventeen compounds, which appeared in at least half of the samples for either species, were quantified (Fig. 1). Characterization of these chemicals was based on comparison of UV spectra, mass fragmentation, and relative retention time with published data and standards, when available (Table 1).

Monomeric/Oligomeric Flavanols Peak 1 fragmentation patterns $[M\text{-}H\text{-}152\text{-}18]^-$ are indicative of retro-Diels-Alder fission (RDA-F) of heterocylic rings with the loss of water (Friedrich et al., 2000; Shui and Leong, 2004). These spectral characteristics are consistent with those reported for procyanidin dimers (Tsang et al., 2005). Similarly, peak 4 fragmentation patterns $[M\text{-}H\text{-}170]^-$ are indicative of RDA-F with the loss of water as well as interflavan bond cleavage $[M\text{-}H\text{-}288]^-$ (Friedrich et al., 2000; Shui and Leong, 2004). These spectral characteristics are consistent with those reported for a procyanidin trimer (Tsang et al., 2005). Regio- and stereochemistry of the interflavan bonds were not determined for peaks 1 and 4. Peak 2 fragment ions (*m/z* 421.2, 289.1, and 245) correspond with those reported for catechin pentoside previously found in European white birch wood (Mämmelä, 2001), and after the loss of pentose, with fragmentation patterns of a catechin standard. Peak 3 was identified as catechin by comparison with a standard.

Phenolic Acid Peak 5 had a pseudomolecular ion of *m/z* 337.1 and a λ_{max} of 311 nm, which are consistent with coumaroylquinic acid (Ossipov et al., 1996; Poon, 1998).

Phenolic Arylbutanoids Peaks 6 and 8 ($[M\text{-}H]^-$=459.3) had the same fragmentation patterns in the quadrupole mass spectrometer, suggesting that they are enantiomers. Fragmentation patterns $[M\text{-}H\text{-}132]^-$ indicate a loss of pentose, and the remaining aglycone (*m/z* 327.2) is consistent with betuloside (Mämmelä, 2001). Therefore, compounds 6 and 8 were tentatively identified as betuloside pentoside A and betuloside pentoside B, respectively. Peak 7, with $[M\text{-}H]^-$= 327.2, is consistent with betuloside (Mämmelä, 2001).

Phenolic Diarylheptanoids MS^n of peak 13 ($[M\text{-}H]^-$=475) did not generate any daughter ions; however, the quadrupole mass spectrometer generated a base ion at *m/z* 295,

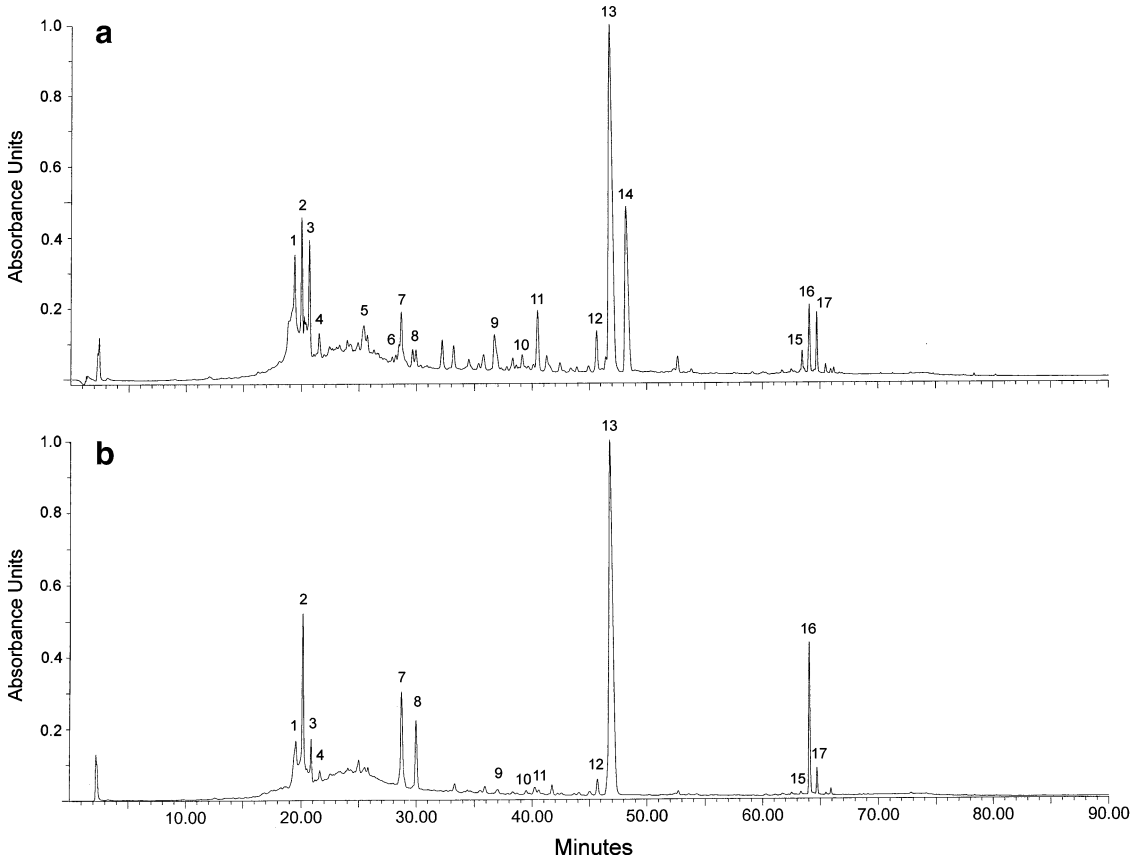

Fig. 1 Comparison of constitutive phenolic profiles from stem phloem tissues of (**a**) paper birch, *Betula papyrifera* and (**b**) European white birch, *Betula pendula*. Chromatograms were generated from the HPLC-PDA at 280 nm. For characterization of numbered peaks, see Table 1

indicating loss of hexose and water, consistent with platyphylloside (Vainiotalo et al., 1991; Smite et al., 1993) (Fig. 2a). Major fragments of peak 14 (*m/z* 149.1 and 121.0) and the aglycone (*m/z* 315.3) are consistent with a diarylheptanoid hexoside (Fig. 2b) related to platyphylloside (Jiang et al., 2006). The MS of peaks 15, 16, and 17 suggest the same aglycone, but with different sugar moieties (Fig. 2c). *M/z* 299.3 and its daughter *m/z* 121 are consistent with an ethyl *p*-hydroxybenzoyl moiety (Jiang et al., 2006) and the diarylheptanoid centrolobol (Smite et al., 1993). Peak 15 fragmentation $[M\text{-}H\text{-}132\text{-}132\text{-}162]^-$ suggests the presence of a hexose and two pentose sugars, while peak 16 fragmentation $[M\text{-}H\text{-}132\text{-}162]^-$ is consistent with a hexose and a pentose sugar, and peak 17 fragmentation $[M\text{-}H\text{-}162]^-$ indicates a hexoside. The aglycone of centrolobol has been detected previously in European white birch phloem, conjugated with a monosaccharide, disaccharide, and trisaccharide comprised of glucose and apiose (Smite et al., 1993).

Unknowns Four of the 17 selected compounds (peaks 9–12) were not given tentative identifications due to lack of correspondence of diagnostic mass and UV spectra to that of known chemical species.

*Interspecific Variation*There was both qualitative and quantitative variation in phenolics between species (Table 2). Paper birch phloem contained several compounds not detected in European white birch phloem including coumaroylquinic acid (5), betuloside pentoside A (6), and diarylheptanoid hexoside (14). Paper birch phloem also had higher concentrations of six phenolics than European white birch phloem, including betuloside pentoside B (8) ($F_{1,\ 48}$= 20.86), centrolobol glycoside (15) ($F_{1,\ 48}$=20.72), and four unknown compounds [(9, 10, 11, 12) ($F_{1,\ 48}$= 38.87, 68.97, 32.44, and 8.74, respectively)]. European white birch phloem contained higher concentrations of three phenolics than paper birch phloem, including catechin pentoside (2) ($F_{1,\ 48}$= 62.97), platyphylloside (13) ($F_{1,\ 48}$=12.26), and centrolobol glycoside (16) ($F_{1,\ 48}$=31.99).

The phenolic profiles of paper birch and European white birch were different (Fig. 3), as indicated by principal component analysis. Separation between species occurred largely along the first PC axis, which explained 29.6% of

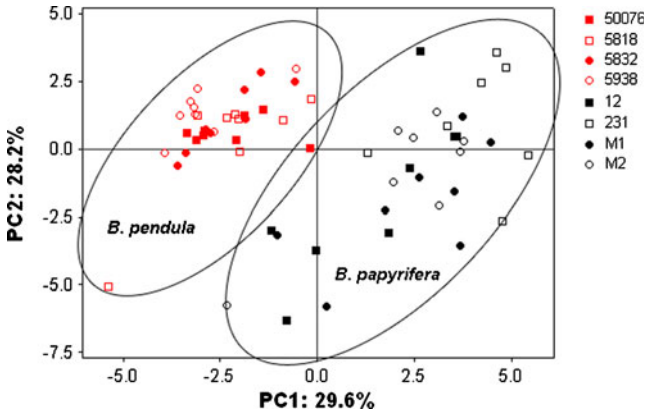

Fig. 3 Inter- and intraspecific variation in phenolic chemistry from stem phloem tissues of European white birch, *Betula pendula*, and paper birch, *Betula papyrifera*, as indicated by principal component analysis (PCA). 50076, 5818, 5832, and 5938 are clones of European white birch. 231 and M2 are clones and 12 and M1 are half-siblings of paper birch. Percentage of total variability explained by first two principal components shown

the total variation. Location along the first PC axis was primarily determined by coumaroylquinic acid (5) (eigenvector (EV): 0.388), diarylheptanoid hexoside (14) (EV: 0.391), and compound 10 (EV: 0.376), which were all associated with paper birch, and catechin pentoside (2) (EV: −0.291) and centrolobol glycoside (16) (EV: −0.214), which were associated with European white birch.

Intraspecific Variation Within each species, there were quantitative differences among clones and/or half-siblings (Table 3). Among clones and half-siblings of paper birch, there was variation in concentrations of four out of 17 compounds: catechin pentoside (2) ($F_{6,\ 48}$=5.26), procyanidin trimer (4) ($F_{6,\ 48}$=16.60), coumaroylquinic acid (5) ($F_{6,\ 48}$=4.49), and betuloside (7) ($F_{6,\ 48}$=9.14). Among clones of European white birch there was variation in concentrations of five out of 14 compounds: catechin (3) ($F_{6,\ 48}$=3.42), procyanidin trimer (4) ($F_{6,\ 48}$=4.33), compound 12 ($F_{6,\ 48}$=3.29), and two centrolobol glycosides (15, 16) ($F_{6,\ 48}$=13.81, 5.18, respectively).

Discussion

We found important qualitative and quantitative differences between constitutive phenolics in stem phloem of paper birch, which is resistant to BBB, and European white birch, which is much more susceptible (Table 2, Fig. 3). Phloem tissues of paper birch contained coumaroylquinic acid, betuloside pentoside A, and a diarylheptanoid related to platyphylloside, which were not detected in European white birch and, therefore, may contribute to greater resistance of paper birch. Six compounds (betuloside pentoside B, a centrolobol glycoside, and four unknown compounds) found in higher concentrations in paper birch than in European white birch may also contribute to variation in resistance between species. Further research is needed to determine if any of these compounds contribute to interspecific variation in resistance to BBB by acting as toxins or antifeedents. Additionally, three compounds (catechin pentoside, platyphylloside, and a centrolobol glycoside) were found in higher concentrations in European white birch and might play a role as feeding or ovipostional stimulants, although we do not have any evidence that these chemicals modulate BBB behavior. Overall, paper birch and European white birch had similar phenolic profiles (Fig. 1), with 14 of 17 phenolics analyzed in this study present in both species (Table 1). This phytochemical similarity likely reflects their close phylogenetic relationship within the subgenus *Betula* (Schenk et al., 2008).

Concentrations of 24% and 36% of phenolics varied among clones and/or half-siblings of paper birch and European white birch, respectively (Table 3). However, there was no separation among clones and half-siblings within either species based on multivariate profiles of their phenolic composition (Fig. 3). In birch leaves and seedlings, intraspecific genetic variation in birch secondary metabolites is well documented (Keinanen et al., 1999; Laitinen et al., 2000, 2004; Ossipov et al., 2008) and is hypothesized to slow herbivore adaptation to a single chemical profile (Keinanen et al., 1999). In our study, the relative resistance of clones and half-siblings of paper birch and European white birch to BBB is not known. Therefore, it is difficult to make inferences on the potential role the variation (or lack thereof) in phenolic composition we observed has on BBB resistance. However a 12-year common garden study in Michigan, USA documented large intraspecific variation in resistance among half-siblings of paper birch, ranging from no colonization to high levels of colonization by BBB larvae (Miller et al., 1991). In contrast, there was little variation in resistance among half-siblings of European white birch, as all were highly susceptible to BBB colonzation (Miller et al., 1991).

Of the compounds for which some structural information could be established, four were monomeric/oligomeric flavanols (1–4), three were phenolic arylbutanoids (6–8), and five were phenolic diarylheptanoids (13–17) (Fig. 2). The monomeric flavanol catechin (3) and its stereoisomers are the building blocks of oligomeric procyanidins (condensed tannins) (1,4) (Hagerman and Butler, 1991), which we detected in birch phloem tissues. Diarylheptanoids (13–17), which possess anti-inflammatory, anti-hepatotoxic, and free radical scavenging activity, have been isolated from many plant genera including *Acer*, *Alnus*, *Betula*, *Curcuma*, *Juglans*, and *Zingiber* (Claeson et al., 1994; Akazawa et al., 2006). Platyphylloside (13) and centrolobol (15–17), which are glycosidic diarylheptanoids, also have been previously isolated from birch phloem (Smite et al., 1993; Julkunen-Tiitto et al., 1996). Both compounds have an inhibitory effect on ruminant digestion *in vitro* and are considered to be part of the chemical defense against mammalian herbivores (Sunnerheim et al., 1988; Sunnerheim and Bratt, 2004). Coumaroylquinic acids (5) are common intermediates in the phenylpropanoid biosynthetic pathway (Steck, 1968). All of these phenolic compounds have been detected previously either from stems or leaves of *Betula* spp. (Kolodziej, 1990; Smite et al., 1993; Julkunen-Tiitto et al., 1996; Mämmelä, 2001; Laitinen et al., 2004; Haviola et al., 2006; Karonen et al., 2006).

Previous research has suggested that birch species such as river birch (*B. nigra* L.), that lack rhododendrol (an arylbutanoid), are resistant to BBB (Santamour, 1990; Santamour and Lundgren, 1997; Nielsen et al., 2011). Moreover, Santamour (1990) found a short-range attraction of mated BBB females to this compound. Rhododendrol is generated by the hydrolysis of the glycosides containing this aglycone, including betuloside (also known as rhododendrin) and betuloside pentoside (Smite et al., 1993; Julkunen-Tiitto et al., 1996; Santamour and Lundgren, 1997). We found no difference among species in the levels of betuloside, and the highly resistant paper birch actually contained significantly higher levels of two betuloside pentosides than susceptible European white birch (Table 2). Therefore, although rhododendrol and/or its glycosides may mediate BBB oviposition behavior, their presence does not appear to contribute or relate to susceptibility.

The low molecular weight phenolics measured in this experiment are only one class of compounds that are present in birch phloem that could affect BBB larval performance. High molecular weight phenolics (tannins and lignins) (Wainhouse et al., 1990; Moilanen and Salminen, 2008), defensive proteins (Poyla, 2003; Dafoe et al., 2009), and nutritive components (amino acids, proteins, sugars, sterols, etc.) (Haack and Slansky, 1987; Slansky, 1992) are important mediators of other plant-insect interactions and could also impact growth and survival of wood-boring insects. Furthermore, while the goal of this study was to characterize constitutively expressed phe-

nolics, induced responses of birch to BBB are also likely important components of resistance and merit investigation.

In summary, we documented qualitative and quantitative differences in phenolic composition of stem phloem tissue between paper birch, which is resistant to bronze birch borer, and European white birch, which is more susceptible. Specifically, we found three compounds that were present only in paper birch and six other phenolics that were higher in concentration in paper birch compared to European white birch, which could contribute to the much higher resistance of paper birch. Developmental and behavioral bioassays are needed to determine if these differences contribute to the high resistance of paper birch to BBB. We also found genetic-based intraspecific variation in phenolic composition within both species, but clones and half-siblings within each species could not be distinguished by their phenolic profiles by using multivariate analysis.

Acknowledgements We thank Priyadarshani Loess and Loren Rivera for assistance with fieldwork and preparation of samples, Justin Whitehill, Christopher Wallis, and Terry Graham for technical assistance with the HPLC, and Bert Bishop for statistical consultation. We thank Matti Rousi, The Finnish Forest Research Institute, for providing European white birch trees and Daniel Struve, The Ohio State University, for providing paper birch trees. This research was funded by a Cooperative Agreement with the USDA Forest Service Northern Research Station, Rhinelander, WI and state and federal funds appropriated to the Ohio Agricultural Research and Development Center and The Ohio State University.

about the ecology of the Southern pouched lamprey, *Geotria australis*, which is endemic to New Zealand. Once an important traditional fishery, anecdotal evidence suggests that populations have declined steadily over time (James, 2008). Recent research has focused on enhancing knowledge of the distribution and abundance of *G. australis* populations within New Zealand, and developing methods for monitoring populations via pheromones released by stream resident larvae (Baker et al., 2009).

Within the laboratory, the larvae of *G. australis* produce large quantities of PS, with markedly lower amounts of PADS, and with PSDS undetected (Stewart and Baker, in press). Thus, population monitoring of *G. australis* is more likely to be successful by concentrating on detection of PS in river water. However, as a generally applicable method, it would be desirable to include PADS and PSDS in the methodology.

For monitoring of fish populations (using pheromone detection), a robust, rapid, and accurate measurement of these chemicals is essential. Liquid chromatography coupled to triple quadrupole mass spectrometry (LC/MS/MS) is ideally suited to this application, as it is highly sensitive and selective in the analysis of environmental concentrations of organic water soluble chemicals. As such, we explored the suitability of a pre-concentration step followed by LC/MS/MS analysis in quantifying PS, PADS, and PSDS in a river water matrix. Here, we describe the method process and validation.

Methods

Standards PS was purchased from Toronto Research Chemicals (P293526), while PADS and PSDS were kindly supplied by Professor Peter Sorensen, from the University of Minnesota.

Pre-concentration Lamprey pheromones were concentrated from the water matrix by Oasis HLB solid phase extraction (SPE) cartridges (Waters Corporation). SPE cartridges (60 mg) were conditioned with methanol (2 ml) and H_2O (2 ml), prior to sampling. Water samples (20 ml) were eluted through the SPE, using positive pressure. The water sample was eluted fully through the SPE cartridge and all eluent discarded. The cartridge then was removed of excess H_2O by several passes of air through with positive pressure. The material retained by the SPE cartridge was immediately eluted into a 2 ml amber glass vial with methanol (2 ml). All methanol was removed under a stream of N_2 gas. The sample was re-dissolved in 1:1 methanol:H_2O (100 μl), sonicated briefly, and transferred to a low volume 150 μl glass insert, inside the 2 ml amber glass vial. The sample was sealed with a lid and septum for LC/MS/MS analysis. All analyses were carried out in triplicate.

Spike Recovery PS, PADS, and PSDS were spiked into blank stream water at concentrations equivalent to 0.01 μg/l and 0.001 μg/l. Water from a stream with no known lamprey larvae (Donny Park Stream, a tributary of the Waikato River) was used for spiking and procedural blanks. Samples of stream water (100 ml) were spiked with each standard (100 μl at 1000-fold desired concentration), to keep methanol concentration negligible (0.1% v/v), and avoid compromising the performance of SPE.

Procedural Blanks Procedural blanks were used for stream water samples and were processed as above.

Post SPE Spikes To assess matrix interference procedural blank samples were spiked with standards (9.1 ng/ml) and analyzed by LC/MS/MS.

LC/MS/MS Analysis Quantitation of PS, PADS, and PSDS was achieved on an Agilent 6460 Triple Quadrupole mass spectrometer with an electrospray ionization (ESI) source coupled to an Agilent binary pump HPLC system (1200 Series Binary Pump SL, HiP-ALS SL+ autosampler and 1200 series degasser). Samples were analysed on an Agilent Zorbax 1.8 μm, 2.1×50 mm SB-C18LC column, using a gradient of mobile phase A (0.01 M ammonium acetate in Type 1 water) and mobile phase B (acetonitrile). Flow was 0.3 ml/min with an initial proportion of 20% B holding for 0.5 min, a linear gradient to 30% over 0.5 min, 60% over 2.5 min, 100% over 0.5 min, holding for 0.5 min, and back to 20% B over 0.5 min and holding for 1 min, a column temperature of 50°C was maintained. PS and PADS were analysed in positive ion mode, while PSDS was analysed in negative ion mode. PS was observed as the ammonium adduct at *m/z* 492.4 ($[M+H+NH_4]^+$) with specific transitions to *m/z* 359.3 for the quantifier ion (Quant) and *m/z* 412.4 for the qualifier ion (Qual). PADS was observed as the trihydrogen adduct ($[M+3H]^+$) at *m/z* 705.4, with the Quant ion at *m/z* 509.3 and the Qual ion at *m/z* 607.4. PSDS was observed as the doubly charged anion ($[M]^{2-}$) at *m/z* 294.3, with the Quant ion at *m/z* 491.3 and the Qual ion at *m/z* 97 ($[SO_4H]^-$).

Results

Quantification of Pheromones Spike recoveries for PS were 79.2 (2.5)% and 76.4 (8.1)% [(% Relative Standard Deviation (RSD)] for concentrations of 0.01 μg/l and

0.001 μg/l, respectively. Spike recoveries for PADS were 67.1 (5.5)% and 65.5 (3.0)% (% RSD) for concentrations of 0.01 μg/l and 0.001 μg/l, respectively. Due to poor fragmentation of PSDS in spike recoveries, it could only be quantified for the 0.01 μg/l spike experiments, with an average recovery of 141 (10)% (% RSD).

Post-spiking of procedural blanks showed a 92–95% response of the signal expected for all three pheromones, suggesting that a typical river matrix did not result in significant suppression or enhancement when using this method, at the higher 0.01 μg/l spike concentration.

The triple quadrupole analysis afforded instrument practical quantitation limits (PQL) of 0.05 μg/l for PS and PADS and 0.5 μg/l for PSDS.

Discussion

Previous methods for quantitation of lamprey migratory pheromones have been restricted to PS and allocholic acid (ACA) by using methods based around induced fluorescence by enzymatic oxidation of the 3α-hydroxy functional group (Polkinghorne et al., 2001), or direct infusion mass spectrometry by using selected ion monitoring (SIM) (Fine and Sorensen, 2005). The method of Polkinghorne et al. (2001) is time consuming (160 min), reasonably insensitive (detection threshold >0.01 μg in a clean background), requires a custom made column, is not selective to specific chemicals of interest (will detect any 3α-hydroxy bile acid), and will not detect PADS or PSDS. The method of Fine and Sorensen (2005) uses an ion trap mass spectrometer, which

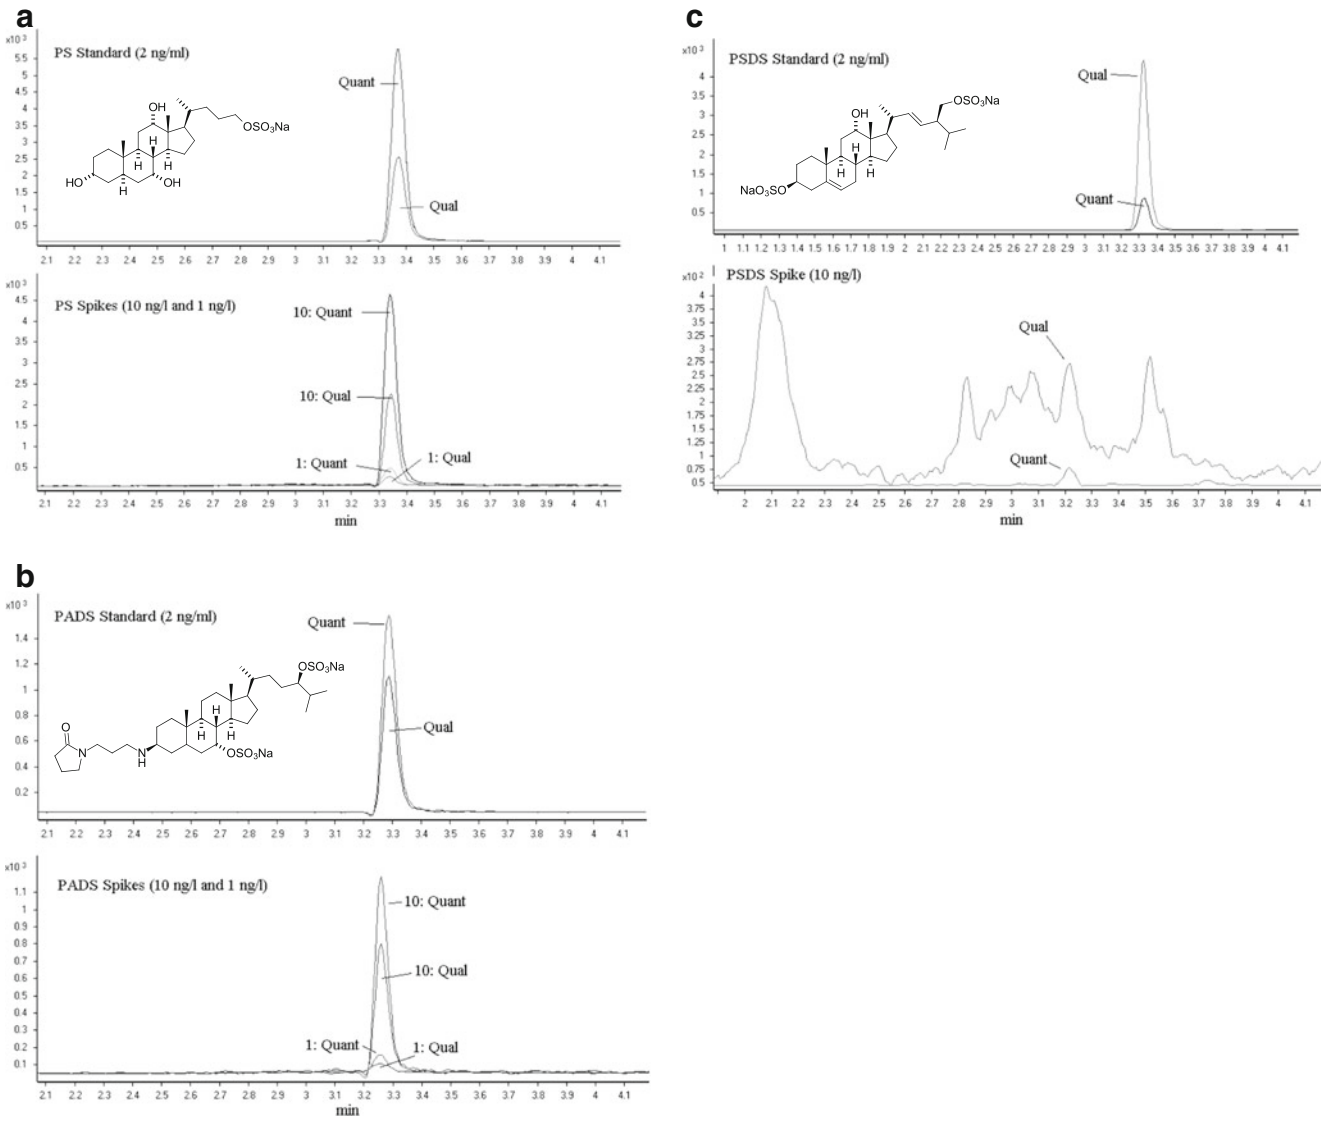

Fig. 1 LC/MS/MS chromatograms of PS, PADS and PSDS. **a** PS standard at 2 ng/ml (top trace) and spikes at 10 ng/l and 1 ng/l (bottom trace); **b** PADS standard at 2 ng/ml (top trace) and spikes at 10 ng/l and 1 ng/l (bottom trace); **c** PSDS standard at 2 ng/ml (top trace) and spike at 10 ng/l (bottom trace): Note different time scales for PSDS

is incapable of fragmenting PS and so relies on a narrow SIM window to detect and quantify this compound. Furthermore, with no chromatographic fractionation, matrix effects can be large and there is no retention time confirmation.

The LC/MS/MS method presented here has many benefits over existing methods for quantifying lamprey migratory pheromones. It uses a short highly efficient HPLC column to provide retention time confirmation of the compound of interest, and as such is extremely rapid, with a total run time of 7 min. It uses defined concurrent fragmentation of each compound of interest to form ions for quantitation (Quant) and ions to qualify (Qual) the existence of that compound (see Fig. 1). The method is further validated by analysis of Quant/Qual ion ratios and is extremely sensitive, with instrumental practical quantitation limits (PQL) of 0.05 mg/l for PS and PADS and 0.5 mg/l for PSDS. The PQL is defined as the minimum concentration of which quantification can be achieved with known level of accuracy and precision. A pre-concentration factor of 200 equates to "in water" PQL of 0.25 ng/l for PS and PADS and 2.5 ng/l for PSDS, corresponding to molar concentrations of 5×10^{-13} M, 7.5×10^{-13} M and 6.25×10^{-12} M for PS, PADS and PSDS, respectively. However, greater pre-concentration steps also are applicable, and a 4000-fold pre-concentration—as has been used in water sampling of streams (Stewart and Baker, 2011)—equates to "in water" molar PQLs of 2.5×10^{-14} M, 3.75×10^{-14} M, and 3.125×10^{-13} M for PS, PADS, and PSDS, respectively. The analysis is fully automated, is not labor intensive, and can process many samples in a short period of time. Furthermore, the suite of chemicals of interest can be expanded manifold without significantly increasing the method run time or impacting on other chemicals currently being analysed.

The analysis of PSDS by this method was not as robust as that of PS and PADS, with observed sensitivity reduced by 90%. This was largely a function of the poor fragmentation yield from the parent ion (*m/z* 294.3) to the quantifier ion (*m/z* 491.3) and low specificity of the relatively low molecular weight qualifier ion (*m/z* 97), leading to significant background noise from the matrix (Fig. 1c). Further avenues could be investigated to improve the detection limit of PSDS. However, this is the first described method for quantitation of PSDS and with suitable pre-concentration (4000×), sub picomolar quantitation can still be achieved.

A similar method for quantitation of the male sea lamprey sex pheromone, 3-keto-PS has been described recently (Xi et al., 2011). Like the current method, the method of Xi et al. uses triple quadrupole mass spectrometry for analysis. However, the authors noted that a mixed mode ion exchange cartridge was necessary to minimize matrix interference. Fragmentation of 3-keto-PS was not selective, with a daughter ion observed at *m/z* 97, as was observed for PSDS in the current method. Such a non-selective ion fragment likely accounts for the high matrix interference observed in both our method for PSDS and that of Xi et al. The method of Xi et al. uses negative ion mass spectrometry to quantify 3-keto-PS. We found that positive ion mass spectrometry—facilitated by ammonium acetate in the mobile phase—gave more useful fragmentation ions for PS and PADS than negative ion, leading to reduced matrix interference and associated lower PQL.

The methodology described in this paper is suitable for quantifying environmental concentrations of migratory lamprey pheromones. In addition, the methodology can be modified easily to measure other organic chemicals present in natural waters, such as hormones, pheromones, and metabolic by-products excreted by fish, provided suitable standards are available to achieve accurate quantitation. This method (or related methodologies) hopefully will provide a useful tool in species monitoring and management, and we aim to use this technique to develop an assay for assessing lamprey populations within New Zealand streams.

Acknowledgments The authors thank Professor Peter Sorensen from University of Minnesota for PADS and PSDS standards.

Recently, we (Foster, 2009; Foster and Johnson, 2010) discovered that sugar feeding by adult female *Heliothis virescens* (Fabricius) (Lepidoptera: Noctuidae) increases pheromone and precursor titers, probably through increased glycolysis. This suggested an approach for quantifying pheromone biosynthesis at natural precursor levels by using ^{13}C-labeled sugar and MIDA. This system seemed suitable for MIDA because labeled sugar is rapidly absorbed into hemolymph (Foster, 2009) and then utilized at a steady rate for pheromone production (Wolfe and Chinkes, 2005).

In this report, we show, for the first time, application of MIDA to calculate synthetic rates of an insect-produced semiochemical.

Methods and Materials

Insects Insect rearing has been described elsewhere (Foster, 2009). Adult females (16:8 L:D), were collected daily and allowed to feed on water until used at 2 day. A 25 µl drop of glucose (either 99% U-$^{13}C_6$-glucose, Cambridge Isotope Laboratories, Andover MA, USA, or unlabeled) solution (10% w/w) was placed on a clean watch glass, and a virgin female allowed to feed. Only females that finished the drop (typically within 2 min) were analyzed. Timing started after completion of feeding. For the scotophase experiment (*Scot*), females fed during a window of 1 hr before to 3 hr into the scotophase. For the photophase experiment, females fed during the 2nd–5th photophase hours (*Phot*), and were sampled before the 9th photophase hour. These sampling times correspond to periods of high and low pheromone titers (see Results).

Pheromone Analyses Pheromone was analyzed by gas chromatography–mass spectrometry, as reported (Foster, 2009; see also, Supplementary). Only the major component, (*Z*)-11-hexadecenal (Z11-16:Ald), was subjected to titer analysis and MIDA, with *m/z* 220 (M-H_2O, a characteristic ion of unlabeled Z11-16:Ald, with carbon skeleton intact), and its two isotopomers (*m/z* 222 and 224, respectively), corresponding to incorporation of one or two $^{13}C_{1,2}$- acetyl CoA, recorded.

Results and Discussion

For *Scot* females, MIs of singly (*m/z* 222) and doubly labeled (*m/z* 224) Z11-16:Ald were detectable shortly after feeding, and rose over the first 4 hr (Fig. 1a). The tracer: tracee ratios of singly [TTR(M+1)] and doubly [TTR(M+2)] labeled Z11-16:Ald were calculated (Eqns 1 and 2, Supplementary), after correcting for abundance of naturally occurring isotopes and contribution of isotopic abundances of

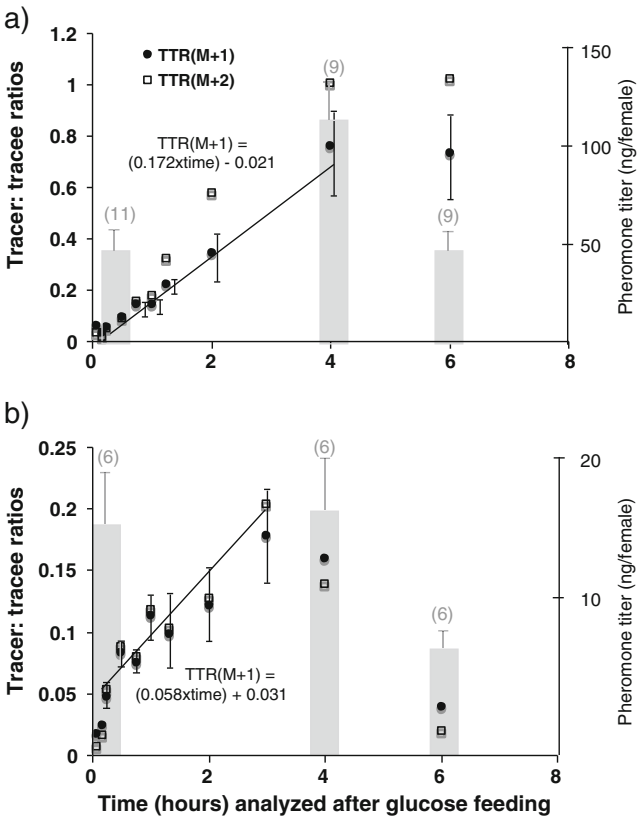

Fig. 1 Tracer to tracee ratios (TTRs) of corrected singly [TTR(M+1)] and doubly [TTR(M+2)] labeled (*Z*)-11-hexadecenal mass isotopomers, at various times after feeding on 25 µl of a 10% solution of U-$^{13}C_6$-glucose, for female *Heliothis virescens*. (**a**) Fed and analyzed during the scotophase; (**b**) fed and analyzed during the early photophase (3rd–9th hour). Mean pheromone titers (light grey bars) at various hours of the scotophase scotophase (0, 4 and 6 hr) and photophase (3, 7, and 9 hr) times are given in 1(**a**) and 1(**b**), respectively. SEMs are given for TTR(M+1)s and pheromone titers. Regression lines (and equations) for the rate of change of singly labeled (*Z*)-11-hexadecenal enrichment are shown. Sample sizes for determination of mean titers are given atop error bars. Each TTR point is the mean of 5–9 females

singly to doubly labeled MIs (Fig. 1). Acetate p (Eqn 3, Supplementary) was calculated as 0.315, and converted to units of singly labeled Z11-16:Ald enrichment (Ep) (Eqn 4, Supplementary), yielding a value of 0.178. The rate of increase of singly labeled Z11-16:Ald enrichment before isotopic steady state (i.e., the plateau) was calculated by regression as 0.172/h (Fig. 1a). Dividing this by Ep (Eqn 5) yielded a fractional synthetic rate (FSR) of 0.965; i.e., 95.5% of the net Z11-16:Ald pool per hour is synthesized from acetate derived from glucose. Crudely averaging (using three times; Fig. 1a) Z11-16:Ald titer over the scotophase gave a value of 66.1 ng, yielding an average absolute synthetic rate (ASR) of 63.1 ng/h.

The *Phot* TTRs of Z11-16:Ald MIs showed a steady increase until roughly 2–4 hr after feeding, and then declined (Fig. 1b). This decline later in the photophase

suggests that at this time pheromone was increasingly biosynthesized from pools of acetate other than those generated from the ingested sugar (i.e., in hemolymph trehalose), most likely from recycled (unlabeled) fatty acids (Foster, 2005). Decreased biosynthesis of pheromone from hemolymph trehalose at this later part of the photophase was supported by the lower mean titer at the 9th hour of the scotophase compared to the two earlier times. Using similar calculations to that for the *Scot* data, photophase values of 0.237 and 0.285 of p and Ep, respectively, were calculated. Singly labeled Z11-16:Ald enrichment increased at 0.058/h (Fig. 1b), allowing calculation of the FSR during the first half of the photophase of 0.204 (i.e., 20.4% of the Z11-16:Ald pool per hour is synthesized from glucose). Crudely averaging (using the two times; Fig. 1b) the Z11-16:Ald pool during this period gave a mean of 15.8 ng, which gives an ASR of 3.2 ng/h.

These data show very large differences in synthetic rates of pheromone derived from hemolymph sugar between the two photoperiodic times. During the peak period of synthesis (*Scot*), when pheromone is released, ASR is nearly 20 times that during the photophase when pheromone is not being released. This difference presumably is due to the presence/absence of PBAN in the hemolymph, as it is consistent with differences in amounts of *de novo*-synthesized pheromone during *in vitro* assays using the presence and absence of PBAN (Jurenka et al., 1991; Rafaeli and Jurenka, 2003).

The high synthetic rate of pheromone throughout the scotophase means that roughly 430 ng (8×53.9; 1.8 nmoles) of pheromone is produced in this period. Assuming a total hemolymph volume of 50 µl (Raina et al., 1994), at a trehalose concentration of roughly 75 mM (Foster and Johnson, 2010), then there is roughly 3.75 µmoles of trehalose (= 7.5 µmoles glucose = 15 µmoles acetyl CoA) potentially available. Since eight molecules of acetyl CoA make one pheromone molecule, then the amount of pheromone produced during a single scotophase represents roughly 0.1% of potential precursor from hemolymph trehalose. In reality, more precursor will be expended, since large amounts of fatty acids are also synthesized (Foster, 2005). The high FSR (95.5%), along with the fairly constant titer throughout this period, indicates that not only is pheromone being turned over very rapidly in the gland, but that pheromone production is roughly in steady state with pheromone release and degradation.

Typically, it can be problematic in MIDA experiments obtaining values of TTR(M+2) large enough to be accurately measured (Wolfe and Chinkes, 2005). However, we obtained relatively large TTR(M+2) values, even shortly after feeding. This indicates that ingestion and absorption of labeled glucose occur rapidly and at a high level, giving high precursor enrichment in trehalose and pheromone gland acetate precursor pools, in female moths. Thus, this system seems especially suited to MIDA.

The application of MIDA to determine pheromone biosynthetic rates in *H. virescens* should facilitate determination of more quantitative measures of pheromone production, under different physiological and environmental conditions, in this and other moths. Moreover, this approach has wider applicability to studying synthetic rates of semiochemicals derived from glycolysis in other sugar-feeding insects.

Acknowledgments This work was funded by a North Dakota State University Agricultural Experiment Station Hatch grant.

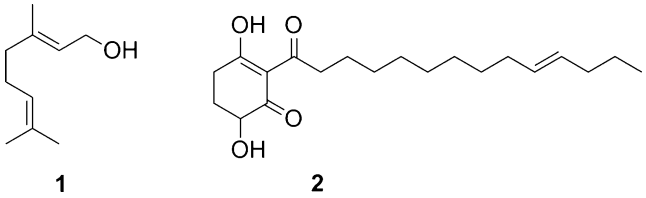

Fig. 1 Chemical structures of geraniol (1) and 3,6-dihydroxy-2-[1-oxo-10(*E*)-tetradecenyl]-cyclohex-2-en-1-one (2)

Although an alarm pheromone response has been described in *C. ciliata* (Kearns and Yamamoto, 1981), there has been no further exploration of the chemical compounds involved, hence the initiation of this alarm pheromone study.

Methods and Materials

Study Species Sycamore lace bugs, *Corythucha ciliata* (Say), were collected from the London Plane, *Platanus* x *hispanica,* at Kyoto Gakuen University in 2009, and were used for all chemical and behavioral studies in the laboratory without any preliminary conditioning.

Chemical Analysis Gas chromatography-mass spectrometry (GC-MS) analysis was conducted using a Network GC System (6890 N; Agilent Technologies Inc.) coupled with a mass selective detector (5975 Inert XL; Agilent Technologies Inc.) operated at 70 eV, using an HP-5MS capillary column (0.25 mm i.d. × 30 m, 0.25 μm film thickness; Agilent Technologies Inc.). Helium was used as carrier gas at a flow rate of 1.00 ml/min, with a split-less mode at a temperature programmed to change from 60°C (2 min) to 290°C at a rate of 10°C/min. This 290°C temperature was then maintained for 5 min. GC and GC-MS data were obtained by Chemstation (Hewlett Packard Co.), with reference to an MS database (Wiley275 library; Hewlett Packard Co.).

Mass Extraction Nymphs (ca. 1 ml volume) of all developmental stages were collected from leaves by brushing. They were dipped subsequently in hexane (3 ml) for 3 min, and the resulting extracts were obtained by decantation. The residue was washed twice with hexane (3 ml), and the combined extracts, after concentration *in vacuo*, were subjected to a SiO_2 column chromatography to purify the alarm pheromone.

Individual Extraction Individual adults and nymphs at specific developmental stages were each placed separately into a glass tube (0.1 ml volume with a conical bottom, glass vial insert, Agilent Technologies Inc.). Potential alarm pheromones were extracted with hexane (4 μl). After 3 min, the extract was collected with a 10 μl micro-syringe, and subjected to GC–MS analysis or bioassay for alarm pheromone activity. For quantitative analyses, we extracted groups of five individuals at each developmental stage with hexane (4 μl, five replications per stage). Extracts then were subjected to GC–MS analysis.

Bioassay Method Escape behavior was observed at 25°C with ambient humidity, using a leaf bearing a colony (ca. 1 cm diam) with ca. 100 nymphs (3 rd-5th instars) on its underside. The leaf was held upside down, and a piece of filter paper (1×2 mm), with a known impregnated amount (ng/μl) of test compound or volume of extract, was placed at the center of the aggregation with minimum disturbances.

We defined a filter paper sample to be active or inactive according to the strength of avoidance behavior exhibited by nymphs moving away from the filter paper. Avoidance behavior was measured (N=5 trials) as the time in seconds for all nymphs to reach more than 1 cm from the test paper. When all nymphs took less than 2 min to reach more than 1 cm distance, the dose and compound were defined as active. Doses and compounds that resulted in avoidance behavior slower than 2 min were defined as inactive. Time data were analyzed using ANOVA; *post hoc* comparisons were made with Tukey's test.

Determination of Geraniol Content Authentic geraniol (**1**, reagent grade, Wako Pure Chemical Industries, Ltd.) was diluted with hexane. The following concentrations were prepared: 0.1, 0.5, and 1 ppm. A dose–response curve was obtained by correlating GC–MS response data with each volume (1 μl=1 ng) of three standard solutions (N=4 trials).

Results and Discussion

All developmental stages of *C. ciliata* are found on the underside of London Plane *P.* x *hispanica* leaves, and nymphs aggregate to form colonies varying in sizes from 0.5 cm to ca. 3 cm diam. When a crushed nymph is introduced into the center of a colony, nearby nymphs show evasive behavior (Kearns and Yamamoto 1981). In our study, all nymphs within 1 cm dispersed within 2 min. This phenomenon was reproduced when a filter paper impregnated with one nymph-equivalent of extract was introduced to a colony. In comparison, nymph avoidance behavior was not observed in response to adult extracts. The active component occurred only in nymphs, and functions as an alarm pheromone for other conspecific nymphs.

Hexane extracts from a 5th-stage nymph and an adult were compared by GC–MS analyses (Fig. 2). A small but distinctive compound (**1**) at t_R 10.013 min was detected

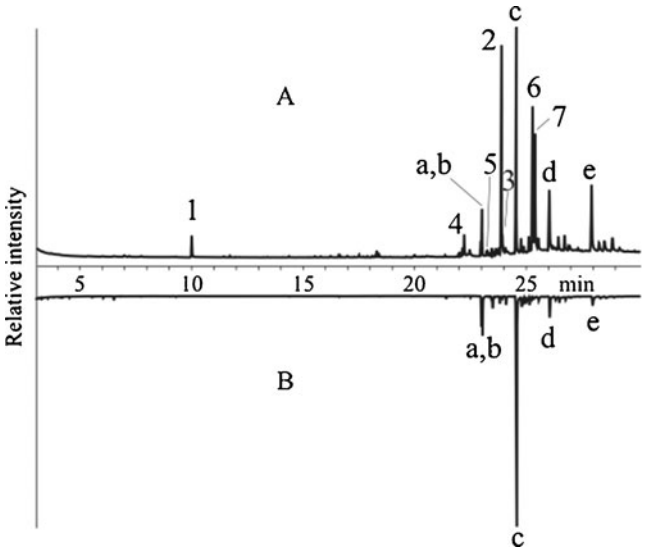

Fig. 2 Gas chromatographic comparison of hexane extracts from a nymph and an adult. A, Fifth nymphal stage; B, adult. **1**, geraniol; **2**, 3,6-dihydroxy-2-[1-oxo-10(*E*)-tetradecenyl]-cyclohex-2-en-1-one; **3**, 3,6-dihydroxy-2-[1-oxo-tetradecyl]-cyclohex-2-en-1-one; **4**, 3,6-dihydroxy-2-[1-oxo-dodecyl]-cyclohex-2-en-1-one; **5**, 3-hydroxy-2-[1-oxo-tetradecenyl]-cyclohex-2-en-1-one; **6**, 3,6-dihydroxy-2-[1-oxo-hexadecadienyl]-cyclohex-2-en-1-one; and **7**, the structure unknown with M^+ ion at *m/z* 364 and the base ion at *m/z* 139. **a**, *n*-docosanol; **b**, *n*-pentacosane; **c**, *n*-heptacosane; **d**, *n*-nonacosane; and **e**, *n*-hentriacontane

from extracts of the nymph, as well as those of other stages (data described below). In contrast, no trace of the corresponding peak was found in extracts of adult. Compound **1** indicated M^+ ion at *m/z* 154(2%) and the base ion at *m/z* 69(100%) with the diagnostic fragment ions *m/z* 139(4%), 136(4%), 123(13%), 121(8%), 111(7%), 93 (29%), 84(8%), 55(8), 53(9%), and 41(53%), suggesting an open chain monoterpene. The authentic compound **1** showed its GC peak at t_R 10.008 min, and gave an identical mass spectrum to those obtained from nymphal extracts. Hence, the structure of compound **1** was identified as *E*-3,7-dimethyl-2,6-octadien-1-ol, geraniol (**1**) (Fig. 1).

After evaporation of the solvent *in vacuo*, hexane extracts were applied to a SiO_2 (200 mg, Wako-gel C200; Wako Pure Chemical Industries, Ltd.) column and eluted stepwise with a 2-ml mixture of hexane, then 5, 10, and 50% ethyl acetate in hexane. Activity was found in the fraction eluted with 50% ethyl acetate in hexane. The active fraction was purified further on a SiO_2 (1 g) column eluted with a mixture of 50% ethyl acetate in hexane. Then, the eluate was collected into five fractions (each 1 ml), and the alarm pheromone activity was detected in the third fraction. Active fractions in each column chromatography contained **1** commonly as their major component. Except for compound **1**, no other compounds such as (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, linalool, or nerolidol aldehyde were detected in *C. ciliata*, as reported by Kearns and Yamamoto (1981). We, therefore, concluded the alarm pheromone to be compound **1**.

Nymphs were separated into five groups (designated as 1st, 2nd, 3rd, 4th, and 5th developmental stages, respectively) by their body sizes. The content of compound **1** in each respective developmental stage was 0.29±0.04 ng, 0.54±0.07 ng, 1.16±0.48 ng, 2.30±0.55 ng, and 4.20±1.50 ng (N=5 for each developmental stage) (Fig. 3). Compound **1** showed the following activity: 162.2±35.7 s (N=5) at 0.5 ng, 90.6±26.3 s (N=5) at 1 ng, and 42.4±11.9 s (N=5) at 3 ng (Fig. 4). Compound **1** was concluded to be active at a dose of 1 ng. Under the same conditions, one individual 5th-instar nymph took 45.7±13.1 s (N=5) to move 1 cm from filter paper impregnated with compound **1** (Fig. 4). Since compound **1** elicited activity at a dose of more than 1 ng, and a nymph older than the 3rd stage contained more than 1 ng of the compound, the alarm pheromone of *C. ciliata* was identified as compound **1**.

Kearns and Yamamoto (1981) first reported the presence of alarm pheromones in *C. cydoniae*, *C. marmorata, C. ciliata*, and *G. solani* by observing each of their alarm behaviors in response, not only to conspecific nymphs, but also to the other tingid species. Aldrich et al. (1991) identified acetaldehyde, *E*-2-hexenal, *E*-4-oxo-2-hexenal, **1**, and nerolidol aldehyde from anterior and posterior dorsal abdominal glands of *G. solani,* and a similar set of compounds (acetaldehyde, *E*-2-hexenal, **1**, linalool, and nerolidol aldehyde) from *C. cydoniae.* They proposed that the five compounds listed above, excluding nerolidol aldehyde, are involved in their alarm messages, although the alarm pheromone of *C. marmorata* and *C. ciliata* remains inconclusive.

In our study, the alarm pheromone of *C. ciliata* was identified as **1**; none of the other components described above (except acetaldehyde, not detectable by the present GC-MS condition) was recognized in the active SiO_2 fraction, and the dose–response of **1** alone was confirmed as comparable to that of nymph extracts. Cross activity

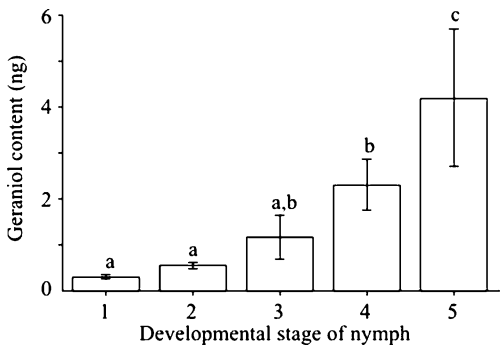

Fig. 3 Geraniol content in nymphal stages. Means capped with the same letter are not significantly different by Tukey's HSD test (P<0.05). Bars represent the mean±S.D. (N=5)

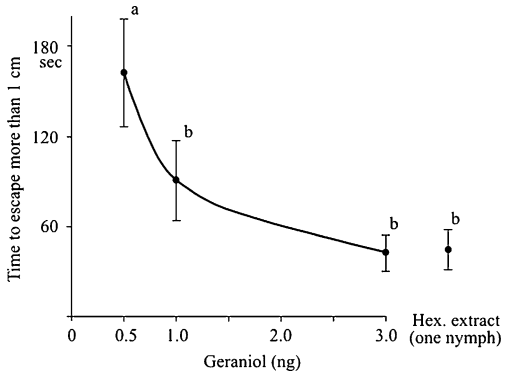

Fig. 4 Alarm pheromone activity of geraniol (**1**), and of hexane extract from a fifth-instar nymph. Means capped with the same letter are not significantly different by Tukey's HSD test ($P<0.05$). Bars represent the mean±S.D. ($N=5$)

among lace bugs may be explained by the presence of **1**, which is a compound common to all lace bugs analyzed (Kearns and Yamamoto 1981).

The natural chemical, 3,6-dihydroxy-2-[1-oxo-10(*E*)-tetradecenyl]-cyclohex-2-en-1-one [**2**, Figs. 1 and 2, M^+ ion at *m/z* 336(72%), the base ion at *m/z* 55(100%) and characteristic third-high-intensity ion $(C_9H_{11}O_4)^+$ at *m/z* 183(43%)] were reported from nymph stages of sycamore lace bug along with other related five minor compounds whose M^+ ions are only mentioned as *m/z* 338, 336, 362, 346, and 362, respectively (Lusby et al., 1987), however their structures remain obscure. In the present study, compound **2** (Fig. 1) was detected as peak **2** at t_R 23.776 min with M^+ and the base ion at *m/z* 336(100%) and the second highest intensity ion at *m/z* 183(50%).

In addition to peak **2,** five other compounds [peaks **3**–**7**, among which M^+ ions of peaks **5**–**7** corresponded to those reported (Lusby et al., 1987)] also were observed in the GC chromatogram as specific nymphal components. The MS libraries, analyses of mass spectra and co-chromatography to those of *Plodia interpunctella* larva (modified from Kuwahara et al., 1983, and extracted from a larva by dipping in hexane for 3 min.) were combined to elucidate the structure of these compounds.

Compound **3** was concluded to be 3,6-dihydroxy-2-[1-oxo-tetradecyl]-cyclohex−2-en-1-one, because it appeared as a shoulder peak at t_R 23.839 min with M^+ ion at *m/z* 338 (M^+ ion, 79%, two mass unit larger than that of compound **2**) and its base ion at *m/z* 183 (100%), indicative of saturated 2-(1-oxo-alkyl) analogue of compound **2**. The spectrum also was identical to MS libraries. Compound **4** [t_R 22.166 min with M^+ ion at *m/z* 310(57%) and the base ion at *m/z* 183(100%)] was concluded to be 3,6-dihydroxy−2-[1-oxo-dodecyl]-cyclohex-2-en-1-one, based on the fact that the same mass spectrum was demonstrated in *P. interpunctella* extract at t_R 22.155 min, in addition to MS libraries. The structure of compound **5** [t_R 23.145 min with M^+ ion at *m/z* 320(5%) and the base ion at *m/z* 167(100%)] was elucidated to be 3-hydroxy-2-[1-oxo-tetradecenyl]-cyclohex-2-en-1-one, comparing the mass spectrum of an homologue, 3-hydroxy-2-[1-oxo-hexadecyl]-cyclohex-2-en-1-one [the same fragmentation pattern with the same base ion (*m/z* 167, 100%), but different M^+ ion (*m/z* 350=*m/z* 320+28 +2, 10%)] present in *P. interpunctella* (Kuwahara et al., 1983) at t_R 24.808 min by co-chromatography. Mass spectrum of compound **6** at t_R 25.168 min with M^+ ion at *m/z* 362(32%) and the base ion at *m/z* 183 (100%) was similar to those of compounds **2** and **5**, and the structure of compounds **6** was elucidated as 2-(1-oxo-alkadienyl) homologue, 3,6-dihydroxy-2-[1-oxo-hexadecadienyl]-cyclohex-2-en-1-one. The MS libraries were not available. Peak **7** at t_R 25.290 min, seems to correspond to *m/z* 346 with one exchangeable hydrogen (Lusby et al., 1987), but its structure still remains obscure with the following mass spectrum [*m/z*(% rel.int.)]; 364(M^+, 0.9), 346(0.8), 328 (61), 300(2.6), 261(5.3), 243(12), 229(18), 221(37), 203 (36), 189(69), 177(17), 167(61), 154(63), 139(100), 126 (17), 111(20), 95(19), 79(34), 67(55), 55(40) and 41(22). These compounds (peaks **1**–**7**) were not detected in extracts of adults. Sexual dimorphism of components also was not observed using GC–MS in hexane extracts (data not indicated).

Other compounds (**a** - **e**) were equally distributed between nymph (A) and adults (B) in Fig. 2. Compound **a** at t_R 22.918 min was identified as *n*-docosanol. Its mass spectrum [*m/z*(% rel.int.)] was as follows; 308 (M^+-H_2O) (3.5), 280(3.9), 264(0.4), 252(0.8), 238(1.2), 222(1.4), 208 (1.6), 196(2.0), 182(2.8), 167(4.3), 153(4.7), 139(6.2), 125 (29), 111(75), 97(99), 83(100), 69(81), 57(83) and 43(64), and was identical to that of the authentic *n*-docosanol at t_R 22.927 min. The other compounds (**b** - **e**) were each identified as *n*-pentacosane (M^+ ion at *m/z* 352, peak **b**), *n*-heptacosane (M^+ ion at *m/z* 380, peak **c**), *n*-nonacosane (M^+ ion at *m/z* 408, peak **d**) and *n*-hentriacontane (M^+ ion at *m/z* 436, peak **e**), based on their characteristic sigmoid decreases of fragment ion intensities from *m/z* 57 to each *m/z* (M^+-29) fragments, respectively.

2-Acylcyclohexan-1,3-diones [3-hydroxy-2-(1-oxo-alkyl)-cyclohex-2-en-1-one] and 4-hydroxy-2-acylcyclohexan-1,3-diones [3,6-dihydroxy-2-(1-oxo-alkyl)-cyclohex-2-en-1-one], whose saturated-, monoene-, and diene-acyl moieties are composed mainly of C_{16}, C_{18}, and C_{20} carbon chains, are known as epideictic pheromones in larvae of four phycitid moths (the almond moth *Cadra cautella*, the Indian meal moth *P. interpunctella*, the Mediterranean flour moth *Anagasta kuehniella*, and the tobacco moth *Ephestia elutella* (Corbet, 1971)), and as an oviposition pheromone (Corbet, 1973). These compounds additionally exploited as a kairomone of the parasitic wasp *Venturia canescens*

(Corbet, 1971; Mudd and Corbet, 1973). The epideictic pheromones present in each phycitid appear to be species-specific, although compositions of 2-acylcyclohexan-1,3-diones are comparable among the four species (Kuwahara et al., 1983; Nemoto et al., 1987a, b). Although biological functions of these compounds remain unknown in the sycamore lace bug, it is nevertheless interesting to note that two taxonomically independent insect species share the same groups of compounds.

Compound **1**, distributed widely among plants as a minor component of their essential oils, also is found in astigmatid mites as a biosynthetic precursor of geranial and possibly of neral, and functions either as an alarm, aggregation, or sex pheromone (Kuwahara, 2004). Its geraniol dehydrogenase has been purified and characterized phylogenetically as a new class of enzyme (Noge et al., 2008). The honeybee *Apis mellifera* contains this compound as a component of the Nasanov gland pheromone (Free et al., 1981), and in the pepper weevil *Anthonomus eugenii* it functions as an aggregation pheromone (Eller et al., 1994).

Compound **1** is a stable monoterpene with agreeable flavor so it may be useful as a in conjunction with insecticide for lace bug control. As well as functioning as an alarm pheromone, compound **1** may irritate and force *C. ciliata* individuals to move around such that they more frequently come into contact with applied insecticides. This may improve the effectiveness of insecticides for lace bug control, and reduce environmental hazards caused by insecticide toxins.

Acknowledgments We wish to thank Miss Maiko Ueno, Kyoto Gakuen University, for helping to collect the sycamore lace bugs and for technical assistance.

Methods and Materials

Insects Larvae of *S. salinella* were collected from glasswort at Gimje (35.4°N, 126.4°E), Korea in early May 2010. Larvae were reared on glasswort in screen cages (30×30×30 cm), and maintained at 25°C under an L14:D10 photoperiod. Pupae were separated by sex and kept individually in plastic bottles (7 cm high and 2.5 cm diam). After eclosion, moths were provided with a cotton pad soaked with a 10% sucrose solution as food.

Chemicals Synthetic *E*3-12:OAc, *Z*3-12:OAc, *E*5-12:OAc, *Z*5-12:OAc, *E*5-14:OAc, and *Z*5-14:OAc were purchased from Pherobank (Wageningen, The Netherlands). Isomeric purity of these compounds exceeded 99%. Dimethyldisulfide, iodine, and sodium thiosulfate were obtained from Sigma-Aldrich (St. Louis, MO, USA).

Pheromone Extraction Preliminary observations revealed that female *S. salinella* exhibited calling behavior during the second half of the scotophase. Therefore, the abdominal tips with pheromone gland of 1- to 2-d-old females were removed 7.0-7.5 hr into scotophase, and placed in 10 μl of hexane in a 0.3-ml conical glass vial (Wheaton, Millville, NJ, USA) for 30 min. The supernatant was transferred into another vial and stored at −20°C until gas chromatographic-mass spectrometry (GC-MS) analysis.

Dimethyldisulfide Derivatizations Double bond positions in unsaturated compounds were determined from dimethyl-disulfide (DMDS) adducts of the female-produced compounds (Buser et al., 1983). DMDS derivatization of a 47-female gland extract was performed as previously described by Yang et al. (2008).

Collection of Female Emissions Solid phase microextraction (SPME) was used to collect pheromone compounds emitted by calling *S. salinella* females. A SPME fiber (100 μm polydimethylsiloxane coating, Supelco, Bellefonte, PA, USA) was conditioned before use at 250°C for 30 min in a GC injector. Three virgin females were placed overnight at room temperature into a 10 ml glass vial containing a SPME fiber. Then the SPME fiber was desorbed for 30 sec in the injection port to start the GC-MS analysis.

Chemical Analysis Gland extracts and SPME-collected volatiles were analyzed on an Agilent 6890N GC interfaced to an Agilent 5975C mass-selective detector. Samples were run on DB-Wax and DB-23 columns (30 m×0.25 mm ID, 0.25 μm film thickness, J&W Scientific, Folsom, CA, USA). Helium was the carrier gas (1 ml/min), and the injections were splitless. Injector temperature was 250°C, and the GC oven temperature was programmed from 80°C (1-min hold) to 200°C at 5°C/min and held for 10 min. The ionization voltage was 70 eV, and the ion source temperature was 230°C. Compounds were identified by comparison of Kováts retention indices (KIs; Marques et al., 2000), and mass spectra with those of authentic standards on two different columns. DMDS-derivatized gland extract was analyzed with a DB-23 column, using a temperature program of 100°C to 240°C at 10°C/min with other GC conditions as those described above.

Field Experiments Field trials were conducted in June of 2010 in heavily infested glasswort fields at Gimje, Korea. Sticky delta traps (Green Agro Tech, Gyeongsan, Korea) were hung from sticks at a height of 50 cm. Traps were baited with white rubber septa (8 mm OD; Aldrich Chemical, Milwaukee, WI, USA) loaded with test compounds in hexane. Two 1- to 2-d-old virgin females in small mesh cages were used as positive controls. All field tests employed a complete randomized block design with four replicate blocks. The distance between traps within a block was 10 m, and the distance between blocks was approximately 150 m.

Experiment 1 investigated the attraction of *S. salinella* males to *Z*3-12:OAc, *E*3-12:OAc, *Z*5-12:OAc, and *Z*5-14:OAc singly and in binary blends. Experiment 2 tested *Z*3-12:OAc in binary, ternary, and quaternary combinations with *E*3-12:OAc, *Z*5-12:OAc, and *Z*5-14:OAc. Finally, experiment 3 was conducted to determine the effects of addition of *Z*5-12:OAc at different doses to 100 μg of *Z*3-12:OAc. Trap catch data (x) were transformed to log (x + 1) to normalize the variance before analysis. Means were compared by one-way analysis of variance (ANOVA) followed by Tukey's test at α=0.05 (SAS Institute Inc., 2008).

Results

Chemical Analysis GC-MS analysis of pheromone gland extracts of *S. salinella* females revealed one major component and three minor components along with minor unknown compounds (Fig. 1). The mass spectrum of compounds 1, 2, and 3 were similar and had diagnostic fragment ions *m/z* 166 (M^+-CH_3COOH), 138, 124, and 61 ($CH_3COOH_2^+$), suggesting dodecenyl acetates. The DMDS adduct of compounds 1 and 2 showed a molecular ion *m/z* 320 and diagnostic ions *m/z* 173 ($C_9H_{18}SCH_3^+$) and 147 ($O_2C_5H_8SCH_3^+$), proving the addition of DMDS to a double bond at position 3 of dodecenyl acetates (Buser et al., 1983). Comparison of KIs of the natural compounds with *E*3-12:OAc and *Z*3-12:OAc standards on the DB-Wax

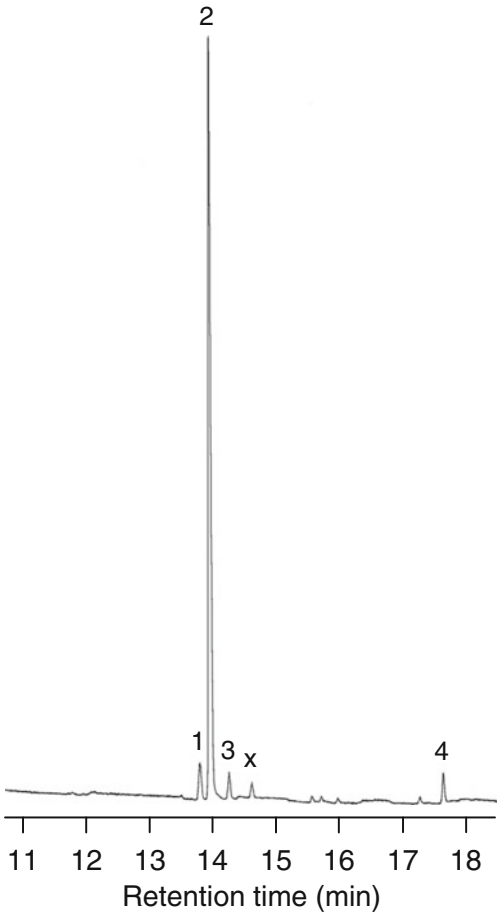

Fig. 1 Total ion chromatogram (TIC) of GC-MS analysis of pheromone gland extract from female *Scrobipalpa salinella* on a DB-23 column. Compound identities as follows: 1) *E*3-12:OAc, 2) *Z*3-12:OAc, 3) *Z*5-12:OAc, x) unknown, 4) *Z*5-14:OAc

and DB-23 columns confirmed that compounds 1 and 2 were *E*3-12:OAc (KIs of 1913 and 1917, respectively) and *Z*3-12:OAc (KIs of 1917 and 1927, respectively). The mass spectrum of the DMDS adduct of compound 3 gave diagnostic fragments at *m/z* 320 (M^+), 145 ($C_7H_{14}SCH_3^+$), and 175 ($O_2C_7H_{12}SCH_3^+$), indicating the original double bond at position 5 of the monounsaturated acetate. Although *E*5-12:OAc and *Z*5-12:OAc standards were not separated on the DB-Wax column, we confirmed compound 3 as *Z*5-12:OAc by matching KI to that of standard on the DB-23 column (KI=1944; KI of *E*5-12:OAc was 1934).

Compound 4 showed diagnostic ions *m/z* 194 (M^+-CH_3COOH), 166, 138, 124, and 61 suggestive of a tetradecenyl acetate. The mass spectrum of a DMDS adduct with M^+ at *m/z* 348, derived from the tetradecenyl acetate in gland extract, showed 173 ($C_9H_{18}SCH_3^+$) and 175 ($O_2C_7H_{12}SCH_3^+$), placing the double bond at position 5. KIs of compound 4 on the DB-Wax and DB-23 columns were identical to those of the *Z*5-14:OAc (KIs of 2125 and 2155, respectively) standard rather than *E*5-14:OAc (KIs of 2128 and 2146, respectively). The amount (±SE) of the major component *Z*3-12:OAc present in the gland extract was estimated as 1.2± 0.2 ng per female (*N*=12), the relative ratio of *E*3-12:OAc, *Z*3-12:OAc, *Z*5-12:OAc, and *Z*5-14:OAc was 8:100:5:7.

GC-MS analysis of the SPME samples from live females revealed the presence of *Z*3-12:OAc and *Z*5-12:OAc by their GC retention times and mass spectra in comparison with those of authentic standards (Fig. 2). Although there was considerable variability among samples, the mean ratio (±SE) of *Z*3-12:OAc and *Z*5-12:OAc was estimated to be 100:54±31 (*N*=3). In contrast, *E*3-12:OAc and *Z*5-14:OAc identified from gland extracts were not found in emissions of females.

Field Experiments A total of 2,755 *S. salinella* male moths were caught in field experiment 1. Traps with *Z*3-12:OAc, *E*3-12:OAc, *Z*5-12:OAc, or *Z*5-14:OAc as single components or blend containing *Z*3-12:OAc plus *Z*5-14:OAc caught few moths (Fig. 3). In contrast, traps baited with *Z*3-12:OAc together with either *E*3-12:OAc or *Z*5-12:OAc caught significantly more males than did traps baited with a hexane control. The binary blend of *Z*3-12:OAc and *Z*5-12:OAc captured approximately five times more males than caged females, while the blend containing *Z*3-12:OAc and *E*3-12:OAc caught similar numbers of moths as the virgin females. In field experiment 2, a total of 5,370 moths were

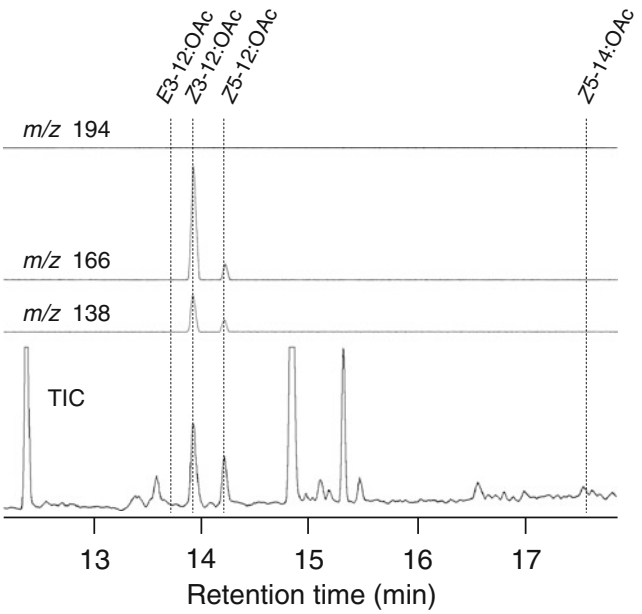

Fig. 2 TIC and the selected ion chromatogram of SPME samples from female *Scrobipalpa salinella*. Selected ions were monitored at *m/z* 194, 166, and 138 for tetradecenyl acetates, and *m/z* 166 and 138 for dodecenyl acetates

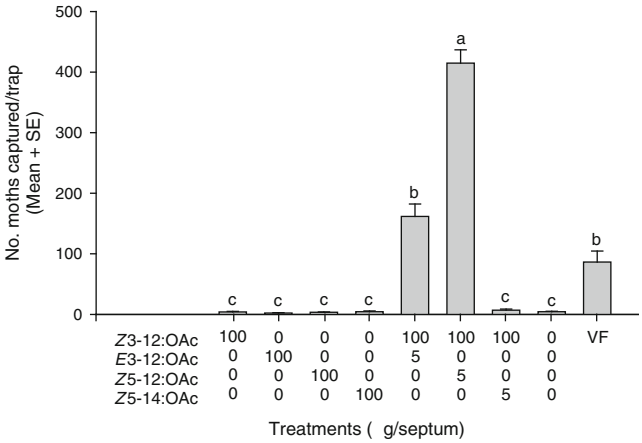

Fig. 3 Catches of male *Scrobipalpa salinella* in traps baited with *Z*3-12:OAc, *E*3-12:OAc, *Z*5-12:OAc, and *Z*5-14:OAc singly and in binary blends in glasswort fields in Gimje, Korea, 14–16 June 2010. Bars with the same letter are not significantly different (Tukey's test: $P>0.05$). VF = two virgin females

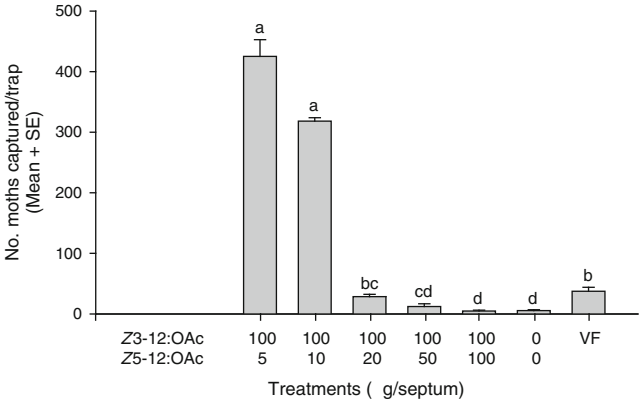

Fig. 5 Effect of addition of *Z*5-12:OAc at different doses to 100 μg of *Z*3-12:OAc on captures of male *Scrobipalpa salinella* in glasswort fields in Gimje, Korea, 18–20 June 2010. Bars with the same letter are not significantly different (Tukey's test: $P>0.05$). VF = two virgin females

caught during two nights. This experiment again showed the blend containing *Z*3-12:OAc plus *Z*5-12:OAc caught significantly more males than virgin females (Fig. 4). Moreover, trap catches of males to this blend were unaffected by the addition of the *E*3-12:OAc and/or *Z*5-14:OAc. Conversely, removal of *Z*5-12:OAc from the synthetic blends resulted in a significant decrease in attraction. In the final experiment, testing different blends of *Z*3-12:OAc and *Z*5-12:OAc, totals of 3,328 moths were caught. Increasing the amount of *Z*5-12:OAc from 5% to 100% relative to *Z*3-12:OAc showed a maximum catch at 5%, but 20% and greater amounts dramatically reduced trap catches (Fig. 5).

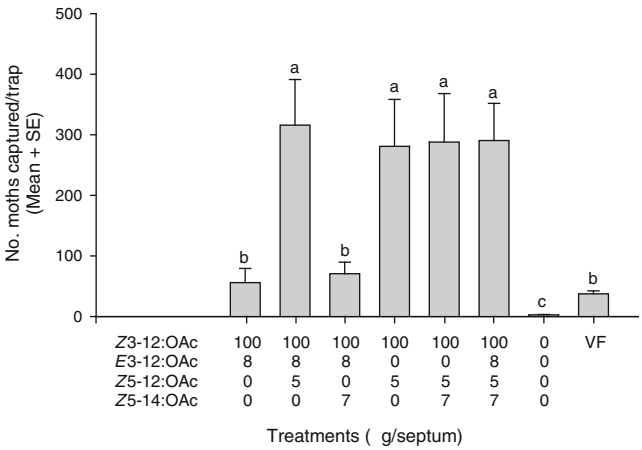

Fig. 4 Catches of male *Scrobipalpa salinella* in traps baited with *Z*3-12:OAc in binary, ternary, and quaternary combinations with *E*3-12:OAc, *Z*5-12:OAc, and *Z*5-14:OAc in glasswort fields in Gimje, Korea, 16–18 June 2010. Bars with the same letter are not significantly different (Tukey's test: $P>0.05$). VF = two virgin females

Discussion

This study demonstrates that *S. salinella* uses 100:5 blend of *Z*3-12:OAc and *Z*5-12:OAc as its sex pheromone. These two components have been identified in SPME collections and solvent extracts, but their relative ratios are markedly different from each other. Differences in pheromone composition between gland extracts and female volatiles have been reported from other moths, including *Sesia apiformis* (Francke et al., 2004), *Marmara gulosa* (McElfresh et al., 2009), and *Spodoptera exigua* (Acín et al., 2010), showing that this discrepancy is usual in the Lepidoptera. The considerable variability in relative ratio and small amount of *Z*3-12:OAc and *Z*5-12:OAc recovered from SPME samples may be attributable to the degradation and/or adsorption of acetate components by the moth bodies, the loose scales, and adsorption to the walls of the container during overnight collections, as observed in other moths (Baker et al., 1980; Millar and Rice, 1992). In field testing different blend ratios of *Z*3-12:OAc and *Z*5-12:OAc, the 100:5 blend, respectively, found in gland extracts caught ca. 35 times more *S. salinella* males than a 100:50 ratio similar to that found in SPME samples. This finding supports our previous observations that male moths are preferentially attracted to synthetic blends that mimic the ratios found in pheromone gland extracts of their conspecific females (Yang et al., 2008, 2011a, b).

*E*3-12:OAc was recovered in gland extracts of *S. salinella* females, but not in volatiles emitted by females. In field trials, the binary blend of *Z*3-12:OAc and *E*3-12:OAc was as attractive as virgin female moths, although it was significantly less attractive than the binary blend of *Z*3-12:OAc and *Z*5-12:OAc. This indicates that *E*3-12:OAc cross activated the peripheral pheromone receptor for *Z*5-12:OAc, the critical secondary pheromone com-

ponent (Priesner, 1986). There is some evidence for substitution of minor components by structural analogs of pheromone components (Inomata et al., 2005; Naka et al., 2007). In contrast, addition of *E*3-12:OAc at the level found in the glands of females did not affect captures of male moths to the primary binary blend of *Z*3-12:OAc and *Z*5-12:OAc, suggesting that *E*3-12:OAc is not part of a sex pheromone blend of this species. Similarly, *Z*5-14:OAc was detected in gland extracts, but its biological activity was not confirmed in field trials. Therefore, *E*3-12:OAc and *Z*5-14:OAc found in *S. salinella* pheromone glands may be present as by-products from the pheromone biosynthetic pathway that produces the major component, *Z*3-12:OAc.

Sex pheromones in the genus *Scrobipalpa* have been elucidated for only two species. The sex pheromone of *S. ocellatella* was reported to consist of *E*3-12:OAc as a single component (Renou et al., 1980). In another congeneric species, *S. heliopa,* females produce *E*3-13:OAc as the main pheromone component, which is highly attractive to conspecific males in the field (Baker et al., 1985). Thus, to date, *S. salinella* is the only *Scrobipalpa* species for which two components are essential for attraction of male moths.

*Z*3-12:OAc, the major component of the sex pheromone of *S. salinella*, has been discovered to be an attractant for two gelechiids, *Aproaerema anthyllidella* (Priesner, 1987) and *Aproaerema anthyllidella* (Reed and Chisholm, 1985), in field tests, but had not been identified from conspecific females. Conversely, Nesbitt et al. (1985) identified *Z*3-12:OAc in *Tecia* (formerly *Scrobipalpopsis*) *solanivora* as a minor component, and found an antagonistic effect of this compound on male attraction when it was mixed with the major component, *E*3-12:OAc. Our study with *S. salinella* is the first case in which *Z*3-12:OAc identified from females was attractive to males of the same species. Similarly, *Z*5-12:OAc, the critical component for attraction of male *S. salinella,* has been reported as an attractant in several gelechiid species, including *Caryocolum marmoreum*, *Chionodes fuscomaculella*, and *Gelechia sororculella* (El-Sayed, 2011). However, *Z*5-12:OAc has not been identified previously from pheromone glands of females in any gelechiid species. Thus, this is the first report of this compound as a sex pheromone component in the Gelechiidae.

In another field trial conducted during July and October of 2010 in glasswort fields at Gimje and Shinan, Korea, we captured only a few individuals of other insects in traps baited with a 100:5 blend of *Z*3-12:OAc and *Z*5-12:OAc, indicating that this mixture is a sensitive and selective attractant for monitoring *S. salinella*. Studies are underway to evaluate the effect of pheromone-based mating disruption against this species under field conditions.

Acknowledgements The authors thank Prof. Kyu Tek Park for identification of *Scrobipalpa salinella*. We also acknowledge the assistance of Si Hyuk Choi and Jae Seong Han with field trials. The manuscript was improved by constructive comments from Jeffrey Aldrich and two anonymous reviewers.

useful mating disruptant for integrated pest management (IPM) of the moth in pear orchards. In Gracillariidae, sex pheromones have been identified from two *Caloptilia*, one *Conopomorpha*, and one *Marmara* species (Gracillariinae); one *Cameraria* and 11 *Phyllonoryctor* species (Lithocolletinae) and one *Phyllocnistis* species (Phyllocnistinae) (Ando, 2011; El-Sayed, 2011).

The components are mono-, di-, and trienyl compounds with a functional group at the terminus of a C_{12}–C_{16} straight chain. The positions of the double bonds vary, and several compounds with a characteristic polyenyl system have been reported as follows: a C_{14} 4,10-diene in *Phyllonorycter ringoniella* (Sugie et al., 1986; Ujiye et al., 1986), C_{14} 8,10-dienes in *Cameraria ohridella* (Svatoš et al., 1999) and *Phyllonorycter emberizaepenella* (Mozûraitis et al., 2002), a C_{14} 10,12-diene in *Phyllonorycter crataegella* (Ferrao et al., 1998), C_{16} 4,6,10-trienes in *Conopomorpha cramerella* (Beevor et al., 1986), and a C_{16} 7,11-diene and a C_{16} 7,11,13-triene in *Phyllocnistis citrella* (Mafi et al., 2005; Leal et al., 2006; Moreira et al., 2006; Lapointe et al., 2006). Pheromones secreted by the *Spulerina* species, however, have never been investigated. We became interested in the pheromone structure of *S. astaurota*, and then found 9,11-dienes from the female moths. Results of field evaluation of synthetic pheromone components appear likely to lead to a reliable monitoring method.

Methods and Materials

Insects and Pheromone Extract Larvae of *S. astaurota* overwinter and pupate in May. Pupae were collected from Asian-pear orchards in Tottori Prefecture (Japan) from late May to early June 2009, and were reared in plastic boxes in the laboratory (25±1°C, 16L-8D). After emergence, male and female moths were sexed and individually placed into 5-ml vials. Abdominal tips of fifty 2- to 4-d-old female moths were cut and extracted with hexane for 1 hr, filtrated, and kept in a freezer at −30°C until use. A portion of the female extract was used for bioassays and chemical analysis without purification. Column chromatography of an aliquot of the extract (30 female equivalents, FE) was conducted on Florisil (500 mg) using 5, 10, 20, and 30% ether in hexane (3 ml each) as an eluant.

Derivatization of Pheromone Components A 25-FE aliquot of crude extract was dissolved in CH_2Cl_2 (10 μl), and treated with a CH_2Cl_2 solution of 4-methyl-1,2,4-triazoline-3,5-dione (MTAD, 10 mg/ml, 40 μl) for 30 min at room temperature (Young et al., 1990). After changing the solvent to hexane, the MTAD adducts were analyzed by gas chromatography coupled with mass spectrometry (GC-MS). To confirm the structure determination of the natural pheromone components, a mixture of authentic 9,11-tetradecadienyl compounds (250 ng each) was treated with the MTAD solution in the same manner as for the natural pheromone, and the products were analyzed by GC-MS.

Analytical Instruments The extracts of females and synthetic compounds were analyzed by GC with an electroantennographic (EAG) detector (GC-EAD). The GC was equipped with a DB-23 capillary column (0.25 mm×30 m, 0.25 μm, J & W Scientific, Folsom, CA, USA), and the effluent from the column was split into two lines, which led to a flame ionization detector (FID) and EAD at a ratio of 1:1 (Inomata et al., 2005). The oven temperature was maintained at 80°C for 1 min, programmed at 8°C/min to 210°C, and held for 10 min. Electron ionization (EI, 70 eV) GC-MS was conducted with an HP5975 mass spectrometer system (quadrupole type, Hewlett Packard) equipped with a split/splitless injector, and the same DB-23 column as the GC-EAD analysis or an HP-5 column (0.25 mm×30 m, 0.25 μm, Hewlett-Packard, Wilmington, DE, USA). The flow rate of the carrier gas (He) was 1.0 ml/min for all GC analyses, and the temperature of GC-inlet was 220°C. The oven temperature for all GC-MS analyses was the same as that for GC-EAD except for the MTAD derivatization experiment, for which the oven temperature of adducts was maintained at 100°C for 2 min, programmed at 15°C/min to 280°C, and held for 15 min. ^{1}H and ^{13}C NMR spectra were recorded by a Jeol Delta 2 Fourier transform spectrometer (JEOL Ltd., Tokyo, Japan) at 399.8 and 100.5 MHz, respectively, in $CDCl_3$ solutions containing TMS as an internal standard.

Synthesis of 9,11-Tetradecadienyl Compounds Four geometrical isomers of C_{14} 9,11-dienes were synthesized starting from 1,8-octanediol (**1**) or 1,9-nonanediol (**5**) as shown in Fig. 1. Experimental details are shown in supplements.

(9*Z*,11*Z*)-Isomers (Scheme A): After one hydroxyl group of the commercially available diol **1** was protected with 3,4-dihydro-2*H*-pyran, another hydroxyl group was iodized by a treatment with a mixture of I_2, triphenylphosphine (PPh_3), and imidazole to yield a THP ether of 8-iodooctan-1-ol (**2**). A coupling reaction of **2** with lithium trimethylsilylacetylide in a mixed solvent of THF and HMPA and desilylation of the product with potassium carbonate in methanol produced a THP ether of 9-decyn-1-ol (**3**). Sonogashira-Hagihara coupling (Sonogashira et al., 1975) between **3** and (*Z*)-1-bromo-1-butene, which was prepared from (*E*)-2-pentenoic acid (Mori and Brevet, 1991; Mori, 2009), furnished a THP ether of (*Z*)-11-tetradecen-9-yn-1-ol (**4**). ^{1}H NMR analysis of **4** confirmed the *Z* configuration of the double bond at the 11-position; i.e., olefinic proton

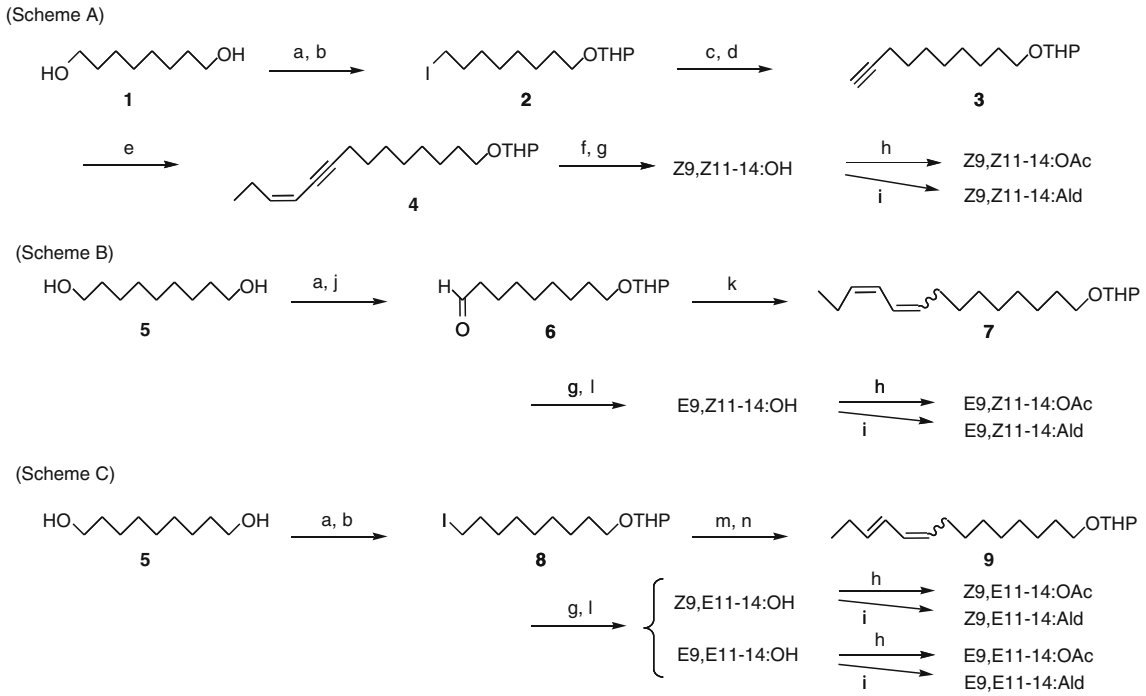

Fig. 1 Synthetic schemes for 9,11-tetradecadienyl compounds (alcohols, acetates, and aldehydes); (9*Z*,11*Z*)-isomer (Scheme A), (9*E*,11*Z*)-isomer (Scheme B), and (9*Z*,11*E*)- and (9*E*,11*E*)-isomers (Scheme C). Reagents: a, 3,4-dihydro-2*H*-pyran/*p*-TsOH/CH_2Cl_2; b, I_2-PPh_3/imidazole/THF; c, TMSC≡CH/BuLi/THF-HMPA; d, K_2CO_3/MeOH; e, (*Z*)-1-bromobutene/$Pd(PPh_3)_4$/CuI/$PrNH_2$/benzene; f, (1) $BH(C_6H_{11})_2$/THF, (2) AcOH, (3) $NaOH/H_2O_2$ (30%); g, *p*-TsOH/EtOH; h, Ac_2O/pyridine; i, PCC/CH_2Cl_2; j, $(COCl)_2$/DMSO/Et_3N/CH_2Cl_2; k, (*Z*)-2-pentenylenetriphenylphosphorane/THF; l, column chromatography with SiO_2-$AgNO_3$; m, Ph_3P/Δ; n, (1) BuLi/THF, (2) (*E*)-2-pentenal

resonating at δ 5.40 and 5.80 ppm showed a similar coupling constant (J=10.5 Hz) as that usually detected for (*Z*)-isomers of disubstituted alkenes. The triple bond of **4** was selectively reduced to a (*Z*)-double bond by hydroboration-protonolysis using dicyclohexylborane, and deprotection of the produced THP ether yielded (9*Z*,11*Z*)-9,11-tetradecadien-1-ol (Z9,Z11-14:OH). ^{1}H NMR δ ppm: 0.99 (3H, t, J=7.5 Hz, CH_3CH$_2$), ~1.3 (10H, m), 1.55 (2H, m, CH_2CH$_2$OH), 2.17 (4H, m, CH_2CH=CHCH=CHCH_2), 3.61 (2H, t, J=6.5 Hz, CH_2OH), 5.44 (2H, m, C*H*=CHCH=C*H*), 6.23 (2H, m, CH=C*H*C*H*=CH), ^{13}C NMR δ ppm: 14.2, 20.8, 25.8, 27.5, 29.2, 29.4, 29.5, 29.6, 32.8, 62.9, 123.0, 123.5, 132.1, 133.6. The acetate (Z9,Z11-14:OAc) and aldehyde derivative (Z9,Z11-14:Ald) were synthesized from Z9,Z11-14:OH by treatment with acetic anhydride in pyridine and with pyridinium chlorochromate (PCC) in CH_2Cl_2, respectively.

(9*E*,11*Z*)-Isomers (Scheme B): Half protection of diol (**5**) with 3,4-dihydro-2*H*-pyran and Swern oxidation of the remaining hydroxyl group produced a THP ether of 9-hydroxynonanal (**6**). A bromide derived from (*Z*)-2-penten-1-ol was converted to (*Z*)-2-pentenyltriphenylphosphorium bromide by heating with PPh_3. The aldehyde **6** was coupled with the ylide, which was prepared from the phosphonium salt by the treatment with butyllithium (BuLi), to yield a THP ether of 9,11-tetradecadien-1-ol (**7**). NMR analysis revealed that **7** was a mixture of (9*E*,11*Z*)- and (9*Z*,11*Z*)-isomers in a ratio of about 1:1. After deprotection, Z9,Z11-14:OH and the (9*E*,11*Z*)-isomer (E9,Z11-14:OH) were separated by column chromatography utilizing silica gel impregnated with $AgNO_3$. NMR data of E9,Z11-14:OH; ^{1}H NMR δ ppm: 0.99 (3H, t, J=7.5 Hz, CH_3CH$_2$), ~1.3 (10H, m), 1.56 (2H, m, CH_2CH$_2$OH), 2.08 (2H, m, CH_2CH=CH), 2.18 (2H, m, CH_2CH=CH), 3.63 (2H, t, J=6.5 Hz, CH_2OH), 5.30 (1H, dt, J=11, 7.5 Hz, C*H*=CHCH=CH), 5.65 (1H, dt, J=15, 7 Hz, CH=CHCH=C*H*), 5.91 (1H, dd, J=11, 11 Hz, CH=C*H*CH=CH), 6.30 (1H, dd, J=15, 11 Hz, CH=CHC*H*=CH); ^{13}C NMR δ ppm: 14.3, 21.0, 25.7, 29.2, 29.4 (×2), 29.5, 32.8, 32.9, 63.1, 125.5, 128.0, 131.7, 134.7. The acetate (E9,Z11-14:OAc) and aldehyde derivative (E9,Z11-14:Ald) were synthesized from E9,Z11-14:OH.

(9*Z*,11*E*)- and (9*E*,11*E*)-Isomers (Scheme C): In a similar synthetic procedure from C_8 diol **1** to **2**, C_9 diol **5** was converted to a THP ether of 9-iodononan-1-ol (**8**). The iodide **8** was heated with PPh_3, and a produced phosphonium salt was treated with BuLi to make an ylide, which was coupled with (*E*)-2-pentenal to yield a THP ether of 9,11-tetradecadien-1-ol (**9**). NMR analysis revealed that **9** was a mixture of (9*Z*,11*E*)- and (9*E*,11*E*)-isomers in a ratio of about 7:3. After deprotection, two alcohols, Z9,E11-14:OH and E9,E11-14:OH, were separated by column chro-

matography utilizing silica gel impregnated with $AgNO_3$. NMR data of Z9,E11-14:OH; ^{1}H NMR δ ppm: 1.01 (3H, t, J=7.5 Hz, CH_3CH$_2$), ~1.3 (10H, m), 1.54 (2H, m, CH_2CH$_2$OH), 2.12 (4H, m, CH_2CH=CHCH=CHCH_2), 3.58 (2H, t, J=6.5 Hz, CH_2OH), 5.28 (1H, dt, J=11, 7.5 Hz, CH=CHCH=CH), 5.68 (1H, dt, J=15, 7 Hz, CH=CHCH=CH), 5.93 (1H, dd, J=11, 11 Hz, CH=CHCH=CH), 6.29 (1H, dd, J=15, 11 Hz, CH=CHCH=CH); ^{13}C NMR δ ppm; 13.7, 25.8, 25.9, 27.7, 29.3, 29.5, 29.6, 29.8, 32.7, 62.7, 124.8, 128.7, 130.0, 136.1. NMR data of E9, E11-14:OH; ^{1}H NMR δ ppm: 0.99 (3H, t, J=7.5 Hz, CH_3CH$_2$), ~1.3 (10H, m), 1.56 (2H, m, CH_2CH$_2$OH), 2.06 (4H, m, CH_2CH=CHCH=CHCH_2), 3.62 (2H, t, J=6.5 Hz, CH_2OH), 5.59 (2H, m, CH=CHCH=CH), 6.00 (2H, m, CH=CHCH=CH); ^{13}C NMR δ ppm: 13.7, 25.6, 25.7, 29.1, 29.39, 29.43, 29.5, 32.6, 32.8, 63.0, 129.4, 130.4, 132.4, 133.9. The acetates (Z9,E11-14:OAc and E9,E11-14:OAc) and aldehyde derivatives (Z9,E11-14:Ald and E9,E11-14:Ald) were synthesized from the corresponding alcohols.

Field Trapping of Male Moths The synthetic pheromone constituents dissolved in hexane (100 µl) were incorporated into rubber septa (white rubber, O.D. 8 mm; Sigma-Aldrich, USA) used as dispensers. Each lure was placed at the center of a sticky board trap (SE-trap®, 30×27 cm bottom plate with a roof; Sankei Chemical Co., Ltd., Kagoshima, Japan), and hung separately in Asian-pear orchards at intervals of 10 and 1.5 m height. Four experiments (A–D) were conducted in Tottori Prefecture in 2010 and 2011, and the number of captured males was counted weekly. In each field test, the replicated data were log-transformed before analysis by Tukey-Kramer's HSD test (Sokal and Rohlf, 1995). The level of significance in all tests was set at 5%.

Results

Structure Elucidation of Pheromone Components GC–EAD analyses of a crude pheromone extract of *S. astaurota* females showed three EAG-active components (Fig. 2). Of the three, the male antenna responded most to **III**. Compounds **I** and **II** were detected in the 10% ether fraction of the crude extract on a Florisil column, indicating an aldehyde and acetate, and **III** eluted in the 30% ether fraction as would an alcohol. Next, the crude extract was analyzed by GC-MS. The total ion chromatogram (TIC) and mass spectra of **II** and **III** (Fig. 3), exhibited M^+ ions at *m/z* 252 and 210 consistent with tetradecadienyl acetate and the parent alcohol, respectively. The chromatographic behavior with relatively long retention times on a polar GC column suggested conjugated dienyl structures, and characteristic fragment ions at *m/z* 82 and 95 in both spectra indicated two double bonds located at the same 9- and 11-positions (Ando et al., 1988; Ando and Yamakawa, 2011). Since **I** and an unknown substance were eluted together on the GC-MS analysis, no clear mass spectrum of **I** was recorded. However, mass chromatograms monitoring some characteristic ions for 9,11-tetradecadienal confirmed the occurrence of this compound in the crude pheromone extract. The chromatogram at *m/z* 67 suggested that females produce **I**–**III** in a ratio of about 1:2:20, respectively. The double bond positions were confirmed by GC-MS analysis

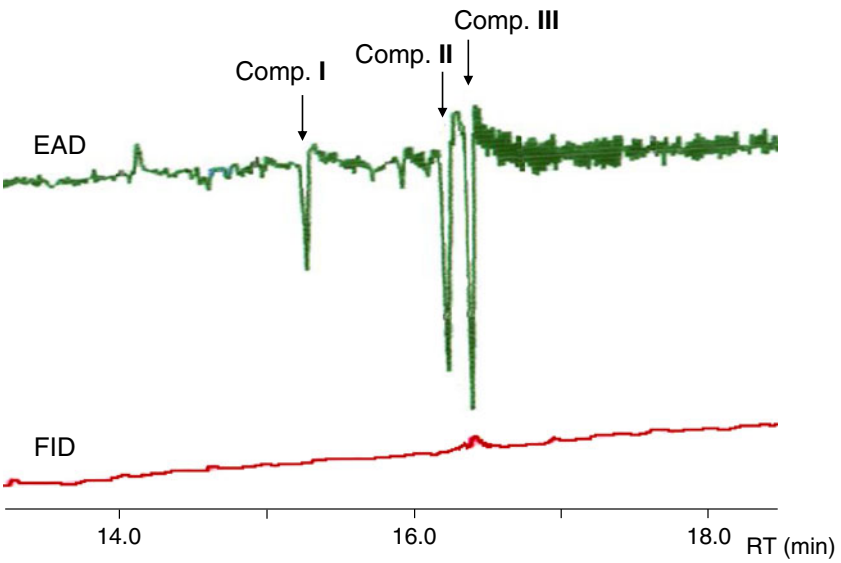

Fig. 2 GC-EAD analysis of the sex pheromone components of *Spulerina astaurota* females. Analysis of a crude pheromone extract from the female (0.5 FE), indicating three EAG-active components (**I**, RT 15.2 min; **II**, RT 16.2 min; and **III**, RT 16.4 min)

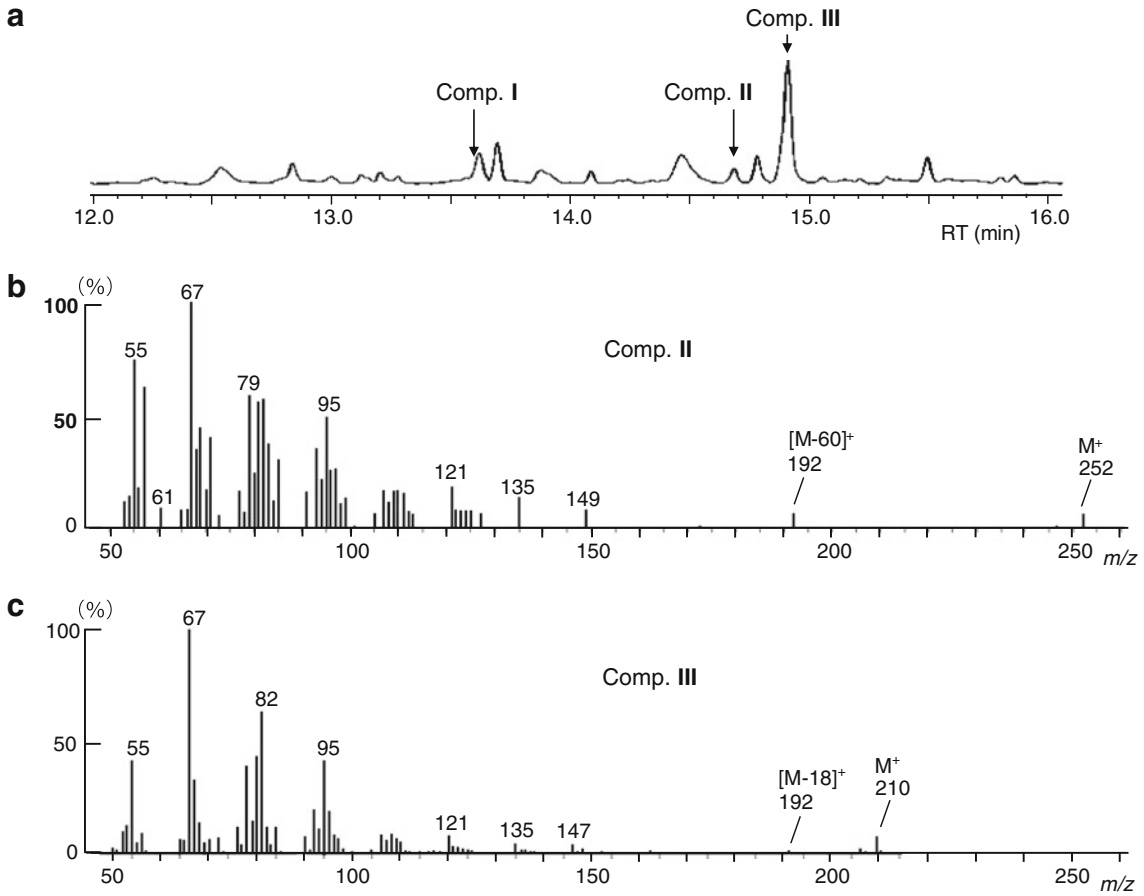

Fig. 3 GC-MS analysis of a crude pheromone extract from *Spulerina astaurota* females (3.5 FE). **a**, Total ion chromatogram (TIC); **b**, mass spectrum of **II** (Z9,Z11-14:OAc, RT 14.68 min); and **c**, mass spectrum of **III** (Z9,Z11-14:OH, RT 14.91 min). Mass chromatograms of M^+ at *m*/*z* 208 and some characteristic fragment ions of tetradecadienal (ions at *m*/*z* 67, 82, and 95) indicated an occurrence of **I** (Z9,Z11-14:Ald, RT 13.63 min) in the extract

of the crude pheromone extract (25 FE) after a treatment with MTAD. This analysis showed the formation of an MTAD adduct (RT 15.48 min) derived from **III**, the major pheromone component in the gland extract. The mass spectrum exhibited an M^+ ion at *m*/*z* 323, and fragment ions at *m*/*z* 294 and 194, characteristic for the adduct of 9,11-tetradecadien-1-ol.

Identification with Authentic Compounds All geometrical isomers of 9,11-tetradecadienyl compounds were synthesized by three different schemes, as shown in Fig. 1. (9*Z*,11*Z*)-Isomers were stereoselectively synthesized via a (*Z*)-9-en-11-ynyl intermediate (**4**), which was partially reduced to the conjugated diene by hydroboration (Scheme A). A mixture of (9*E*,11*Z*)- and (9*Z*,11*Z*)-isomers was prepared utilizing an ylide derived from (*Z*)-1-bromo-2-pentene (Scheme B). Another mixture of (9*Z*,11*E*)- and (9*E*,11*E*)-isomers was synthesized via Wittig coupling with (*E*)-2-pentenal as a key reaction (Scheme C). The two isomers in each mixture were separable, and their chemical structures were confirmed by NMR analyses. The (9*E*,11*Z*)- and (9*Z*,11*E*)-isomers showed four olefinic protons with a different chemical shift. Configuration of the double bonds was revealed by a coupling constant; i.e., 11 Hz for the *Z* configuration and 15 Hz for the *E* configuration. Although the coupling constant was not clear in the (9*Z*,11*Z*)- and (9*E*,11*E*)-isomers, allylic carbons resonated with crucially different chemical shifts reflecting the configuration; i.e., 20.8 and 27.5 ppm for Z9,Z11-14:OH and 25.6 and 32.6 ppm for E9,E11-14:OH.

Table 1 shows the RT of each isomer of 9,11-tetradecadienyl compounds (aldehyde, acetate, and alcohol) analyzed by GC-MS on two different columns, a strongly polar column (DB-23) and a weakly polar column (HP-5). While the RT of the aldehyde was the shortest among the three compounds in either column, the elution order of the acetate and alcohol changed according to the polarity of the column. Four geometrical isomers of each compound separately eluted from both columns in the same order of (9*Z*,11*E*)-, (9*E*,11*Z*)-, (9*Z*,11*Z*)-, and (9*E*,11*E*)-isomers. RTs

of three natural pheromone components coincided well with those of the (9*Z*,11*Z*)-isomers, indicating **I**, **II,** and **III** to be Z9,Z11-14:Ald, Z9,Z11-14:OAc, and Z9,Z11-14:OH, respectively. The GC-MS analysis of the crude pheromone extract indicated that one female possessed about 2 ng of Z9,Z11-14:OH.

Field Evaluation of the Synthetic Pheromone Since the *S. astaurota* females produce Z9,Z11-14:OH (**III**) as the major pheromone component, the activities of synthetic pheromone lures including Z9,Z11-14:OH alone and mixed with Z9,Z11-14:OAc (**II**) in different ratios (totally 0.5 mg for each septum) were examined first (Experiment A). The results from the 2010 tests are shown in Table 2. While Z9, Z11-14:OH without Z9,Z11-14:OAc attracted some males, the activities of the 7:3 and 5:5 mixtures were significantly greater than the single component lure. No males were attracted by the lure baited solely with Z9,Z11-14:OAc, indicating that the acetate occurring as a minor pheromone component is an effective synergist. Next, activities of four geometrical isomers were compared in order to confirm the configuration of the natural pheromone components (Experiment B). The 7:3 mixture of Z9,Z11-14:OH and Z9, Z11-14:OAc more effectively attracted male moths than did 7:3 mixtures of the dienyl alcohol and acetate with other configurations, as shown in Table 3.

Based on results of the field tests in 2010, the effect of Z9,Z11-14:Ald (**I**) on the activity of the 7:3 mixture of Z9, Z11-14:OH (0.35 mg/septum) and Z9,Z11-14:OAc (0.15 mg/septum) was examined in 2011 (Experiment C). Male attraction by the three-component lures including the aldehyde (0.05–0.5 mg/septum) was not significantly different from that by the two-component lures (Table 4). The number of captured males/trap/night decreased extraordinary in 2011, indicating a lower population density than that in 2010.

Although no geometrical isomers of Z9,Z11-14:OH were found in the gland extract, their contamination in the synthetic pheromone might easily have happened. To apply the synthetic lure as a monitoring tool, it is important to understand their effects on male attraction. Each isomer of Z9,Z11-14:OH was added to the 7:3 mixture of Z9,Z11-14: OH and Z9,Z11-14:OAc, and the lures were evaluated in the field (Experiment D). Significant differences were not observed between the lure unmixed and mixed with one geometrical isomer as a third component even at a ratio of 7:3:4 (Table 5).

Discussion

GC-EAD and GC-MS analyses of the pheromone gland extract of *Spulerina astaurota* females revealed three EAG-active components; 9,11-tetradecadien-1-ol, its acetate, and an aldehyde derivative (Figs. 2 and 3). Comparing their chromatographic behaviors to those of the synthetic standards of all geometrical isomers confirmed the 9*Z*,11*Z* configuration of the natural components (Table 1). Therefore, we concluded Z9,Z11-14:OH, Z9,Z11-14:OAc, and Z9,Z11-14:Ald as candidates of the *S. astaurota* pheromone components. Their biological activities were evaluated in a series of field-trap experiments using synthetic compounds (Tables 2, 3 and 4). The male moths were attracted to a lure baited with Z9,Z11-14:OH alone, and Z9,Z11-14:OAc strongly synergized attraction. Among the lures tested, the

[a] Tested using three traps for each lure from June 22 to July 13, 2010 in an Asian-pear orchard of Tottori city and Hokuei town in Tottori Prefecture

[b] Z9,Z11-14:OH (Comp. **III**), Z9,Z11-14:OAc (Comp. **II**)

[c] Mean±SE. Values within each test followed by a different letter are significantly different at $P<0.05$ by Tukey-Kramer test

mixture of Z9,Z11-14:OH and Z9,Z11-14:OAc in a ratio of 7:3 exhibited the strongest attraction. On the other hand, the addition of Z9,Z11-14:Ald to the mixture did not significantly increase the number of males attracted. The role of Z9,Z11-14:Ald in this communication system is unclear.

Some other dienyl pheromones are known for the species in Gracillariidae, but the 9,11-dienes have not been identified from species in this family (Ando, 2011; El-Sayed, 2011). More than 200 Gracillariidae species occur in Japan, including several species in the *Spulerina* that mine into specific host plants, such as *S. corticicola* that attacks pine trees. 9,11-Tetradecadienyl compounds, however, are not novel pheromone components of lepidopteran insects. Interestingly, females of the currant shoot borer, *Lampronia capitella* (Incurvarioiidae), also produced the same three components, Z9,Z11-14:OH, Z9,Z11-14:OAc, and Z9,Z11-14:Ald, and the mixture in a ratio of 100:26:13 attracted the males (Löfstedt et al., 2004). The two micro-lepidopteran species are classified in different groups even at a superfamily; i.e., *S. astaurota* in Gracillarioidea and *L. capitella* in Incurvarioidea. In addition to these two species, Z9,Z11-14:OAc has been identified from *Idaea aversata* and *I. straminata* (Geometridae) as a main pheromone component (Zhu et al., 1996).

Several lepidopteran sex pheromones including geometrical isomers of (9*Z*,11*Z*)-9,11-tetradecadienyl compounds also have been reported (Ando, 2011; El-Sayed, 2011). Z9, E11-14:OAc is a well-known pheromone component of Noctuidae species (*Spodoptera eridania*, *S. littoralis*, and *S. litura*), and this compound has been identified from a Pyralidae species, *Dioryctria abietella*. The aldehyde derivative with 9*Z*,11*E* configuration was produced by another Pyralidae species (*Ectomyelois ceratoniae*), and an Elachistidae species (*Stenoma cecropia*). Furthermore, E9, E11-14:OAc is secreted by a Tortricidae species, *Epiphyas postvittana*. Thus, taxonomically unrelated species have evolved to produce the same conjugated dienyl compounds in the Lepidoptera.

Biosynthesis of the pheromone components have been studied in *S. littoralis* and *E. postvittana*. In the former species, Z9,E11-14:OAc was biosynthesized by Δ9-desaturation of (*E*)-11-tetradecenyl intermediate (Dunkelblum and Kehat 1987; Martinez et al., 1990). In contrast, E9,E11-14:OAc was biosynthesized by Δ11-desaturation of (*E*)-9-tetradecenyl intermediate, which was produced by β-oxidation of (*E*)-11-hexadecenoate, in the latter species (Foster and Roelofs, 1990). Two different pathways were proposed for 9,11-dienes with a different configuration. To date, no biosynthetic studies have focused on lepidopteran pheromones with *Z*,*Z* configured conjugated dienyl compounds; therefore, (9*Z*,11*Z*)-9,11-dienes of the *S. astaurota* females might be interesting in this regard.

The *S. astaurota* adults appear twice a year; from June through July and in September. In our 2010 field tests, we caught approximately 4,000 male moths, indicating that the synthetic pheromone is powerfully attractive and potentially useful for accurately detecting mating activity of this pest. In field experiment D, the activity of the synthetic pheromone was not decreased by admixture of geometrical isomers of Z9,Z11-14:OH (Table 5). This result indicates that high purity of the synthetic dienyl compound is not necessary to make a lure for monitoring. Regrettably, some data in Tables 3, 4 and 5 vary with a large standard error. Each of Experiments B through D was carried out in one village, but the traps baited with the same lure were placed in different orchards located at some distance apart. It is possible that the population densities in the orchards used for the field tests were different, resulting in the variable attraction. These results also suggest that the flight area for each male moth was not extensive. The number of captured males in 2011 was extraordinary small, as shown in Tables 4 and 5, indicating the possibility of a lower population density in 2011 than in 2010. Future work utilizing the synthetic pheromone of *S. astaurota* should clarify the ecology of this species, including the extent to which the number of trapped males correlates with larval damage.

Acknowledgements We thank the Asian-pear growers, especially T. Ikuhashi, Y. Kaigo, Y. Nakahara, H. Ohta, S. Okabe, K. Takeuchi, and I. Tokuyama, who participated in this research and contributed their farms and time to the effort. We are grateful to T. Ishiko and S. Toita of the Tottori Prefectural Agriculture and Forest Research Institute. We also thank Drs. F. Tamura, A. Itai and M. Azuma for offering important information, and Ms. A. Oda and students of the Laboratory of Applied Entomology in Faculty of Agriculture at Tottori University for their help with field experiments and rearing insects.

high sugar resource, with cascading impacts on the ecosystem (Blüthgen and Fiedler, 2004; Blüthgen et al., 2004). Honeydew also has facilitated the establishment and spread of some invasive species such as yellow crazy ants (*Anoplolepis gracilipes*) on Christmas Island (O'Dowd et al., 2003) and *Vespula* wasps in New Zealand (Harris et al., 1991). Other nutrient-rich food resources, such as extra floral nectaries (EFNs) and nectar, influence ant preferences via sugar and amino acid composition (González-Teuber and Heil, 2009a, b). The first step towards understanding the ecological processes influenced by honeydew is to describe its chemical composition.

In New Zealand, there are two endemic genera of coelostomidiid scale insects that produce droplets of honeydew at the end of a long waxy anal filament (Morales, 1991). These scale insects form the basis for at least three honeydew-influenced native forest communities: *Ultracoelostoma* spp.–southern beech (*Nothofagus*) forest; *Coelostomidia zealandica*–coastal forest; *C. wairoensis*–kānuka (*Kunzea*) scrub (Table 1). The dominant above-ground animal honeydew consumers differ among these forest types, with birds and insects utilizing *Ultracoelostoma* spp. honeydew in southern beech forests (Gaze and Clout, 1983; Beggs and Wardle, 2006), geckos and insects utilizing

Table 1 Summary of three honeydew-influenced forest communities in New Zealand

			
	Beech forest	Kānuka scrub	Coastal forest
Main host species:	Beech (*Nothofagus* spp.)	Kānuka (*Kunzea ericoides*)	Ngaio (*Myoporum laetum*) & Karo (*Pittosporum crassifolium*)
Main scale insect species:	*Ultracoelostoma* spp.	*Coelostomidia wairoensis*	*Coelostomidia zealandica*
Scale insect distribution:	Widespread	Widespread	Widespread
Scale insect infestation pattern:	Heavy infestation common	Heavy infestation common	Heavy infestation rare
Main native animal honeydew consumers:	Birds & insects	Moths & other insects	Reptiles & insects
Threats:	*Vespula* invasion	*Vespula* invasion	Habitat fragmentation

Kānuka scrub: photograph shows a moth feeding on honeydew (photo: RGG)

Coastal forest: photograph shows a gecko feeding on honeydew (photo RGG)

Coelostomidia zealandica honeydew in coastal forest (Towns, 2002), and only insects utilising *C. wairoensis* honeydew regularly in kānuka scrub (Gardner-Gee and Beggs, 2009, 2010).

From a global perspective, these communities are unusual, because ants, which often dominate honeydew resources elsewhere, play minor ecological roles in these forests (Gardner-Gee, R, unpublished data). Ants are found in all three forest communities (Ward, 2009). Some ant species such as *Prolasius advena*, *Monomorium* spp., and *Huberia* spp. feed on honeydew, but they do not seem to monopolize the resource, and the same species are wide spread in the absence of honeydew (pers. comm. Ward D.).

Despite the fact that New Zealand honeydew communities are distinctive and relatively well studied, the chemical composition of honeydew from these forests is poorly characterized. The sugar composition of honeydew from two *Ultracoelostoma* species (Coelostomidiidae: Homoptera) has been analyzed, showing a small proportion of glucose and larger but more variable proportions of fructose, sucrose, and unidentified oligosaccharides (Grant and Beggs, 1989; Beggs et al., 2005). There have been no analyses of *Coelostomidia* honeydew.

In this study, we analyzed the composition of honeydews from both genera of coelostomidiid scale insects that occur in New Zealand, collecting samples in three New Zealand honeydew consumer communities. We collected honeydew from *Coelostomidia zealandica, C. wairoensis*, *and Ultracoelostoma* sp. We used recently developed TMS- and MCF- derivatization methods (Villas-Bôas et al., 2006; Smart et al., 2010) followed by highly sensitive GC-MS detection technique to provide the first detailed account of these ecologically important honeydews.

We asked three questions: 1. Do the honeydews contain distinctive compounds that distinguish them from previously known honeydews, especially the ant-dominated honeydews? 2. Are the honeydews from the three New Zealand communities chemically distinct from each other? 3. Are there important site or host tree influences on honeydew composition?

Methods and Materials

Collection Methods and Sites The standing crop of honeydew was collected in 2008 from five sites in New Zealand, namely Karamatura Valley (−37.004051°, 174.556554°), Korapuki Island (−36.657787°, 175.849492°), Pelorus Bridge (−41.162914°, 172.819921°), Rotoiti (−41.832856°, 172.818879°), and Rotoroa (−41.909007°, 172.654177°), with the scale insect-host-site combinations described in Table 2. The standing crop represents the honeydew droplets hanging from the anal filaments and exposed to the environment. Since honeydew is constantly excreted by scale insects and removed by consumers, different droplets are exposed to the environment for different time periods and thus have undergone different amounts of chemical conversions induced by bacteria and yeasts associated with the sugar-rich environment. To obtain homogeneity and reduce variability due to droplet exposure time, each sample comprised numerous pooled droplets of honeydew from several scale insects on one tree. *Ultracoelostoma* spp. includes *Ultracoelostoma assimile* and *U. brittini*, which are morphologically indistinguishable in the field, exhibit no differences in host usage, and have been reported previously at the collection sites (Ball and Armstrong, 2007). At each site, at least six trees were sampled and 50 μl of honeydew were collected from each tree into microcapillary tubes. Samples were transported on ice at 4°C and were stored at −80°C until analysis.

Chemicals The methanol, sodium hydroxide, chloroform, and sodium sulfate were analytical grade and purchased from different suppliers (Smart et al., 2010). The derivatization reagents methylchloroformate (MCF), N-methyl-N-(trimethylsilyl) trifluoroacetamide (MSTFA), methoxylamine hydrochloride, and pyridine as well as the isotope-labeled internal standard L-alanine-2,3,3,3-d_4 and D-ribitol were obtained from Sigma-Aldrich (St. Louis, MO, USA).

Sample Preparation Samples for analysis of sugars and derivatives were diluted 50-fold before mixing 10 μl of the diluted sample with 10 μl of the internal standard D-ribitol

Table 2 Sampling overview

	Ultracoelostoma spp.		*Coelostomidia wairoensis*		*Coelostomidia Zealandica*	
Host Number of trees sampled/site	Black beech *N*=6	Hard beech *N*=6	Red beech *N*=6	Kānuka *N*=6	Ngaio *N*=6	Karo *N*=1
Collection date	29–31 Jan 2008			11 Feb 2008	25 Feb 2008	25 Feb 2008
Collection site/s	Rotoiti (*N*=12) and Rotoroa (Nelson Lakes), Pelorus Bridge, (Marlborough)	Rotoroa (Nelson Lakes)	Rotoiti (Nelson Lakes)	Karamatura Valley (Auckland)	Korapuki Island (Coromandel)	Korapuki Island (Coromandel)

(10 μM). Samples were freeze-dried before derivitization, because drying with a speed vacuum apparatus caramelized them. Samples for analysis of amino and non-amino organic acids were prepared by combining 10 μl of undiluted honeydew sample with 10 μl of the internal standard D_4-alanine (10 mM) and 180 μl of 1 M NaOH. The alkalinized samples then were derivatized.

Sample Derivatizations The trimethylsilyl (TMS) derivatization for analysis of sugars and derivatives was based on the optimized protocol described by Villas-Bôas et al. (2006). In summary, the dried samples were resuspended in 80 μl of methoxyamine hydrochloride solution in pyridine (2 g/100 ml) and incubated in a domestic microwave oven for 2.8 min, with multimode irradiation set to 400 W and 30% of exit power. MSTFA (80 μl) then was added to each sample followed by 3.0 min incubation in a microwave oven as described above.

The MCF derivatization for analysis of amino and non-amino organic acids was performed according to Villas-Bôas et al. (2003). In summary, alkaline samples were mixed with 34 μl of pyridine and 167 μl of methanol before adding 20 μl of MCF and vigorously mixing for 30 s. An additional 20 μl of MCF were added to the reaction mixture followed by vigorous mixing for 30 s. To separate MCF derivatives from the reactive mixture, 400 μl of chloroform were added with vigorous mixing for 10 s, followed by the addition of 400 μl of sodium bicarbonate (50 mM) and vigorous mixing for 10 s. The upper aqueous layer was discarded, and the chloroform phase was analyzed with GC-MS.

GC-MS Analysis and Compound Identification GC-MS analysis was performed with as Agilent GC-MS system 6,890 gas chromatograph coupled to an Agilent 5,975 quadrupole mass selective detector on electron impact (EI) mode operated at 70 eV. The column used for all analyses was a ZB1701 (Zebron, Phenomenex), 30 m×250 μm i.d.× 0.15 μm film thickness. The MS was operated in scan mode (start after 4.5 min, mass range 40–650 a.m.u. at 0.15 s/scan). The parameters for separation and analysis of TMS and MCF derivatives are described in Villas-Bôas et al. (2006) and Smart et al. (2010), respectively. For compounds forming more than one major derivative, the most intense peak was selected for quantification. We used the Automated Mass Spectral Deconvolution and Identification System (AMDIS) to identify compounds present in each sample based on mass spectra and retention times against our in-house MS library of spectra. AMDIS is software freely distributed by the National Institute of Standards and Technology (http://www.amdis.net/) and has been widely applied to metabolite analysis. For more details on our library see Smart et al. (2010).

Data Analysis The TMS (sugars and derivatives) and MCF (amino and non-amino organic acids) data were treated separately throughout the analysis as they are two independent subsets, comprising relative abundance values of each compound detected in relation to the concentration of an internal standard added to the samples (D-ribitol or d_4-alanine). Each data set was standardized to binary presence-absence data for compositional analysis. Multi-dimensional scaling (MDS) was used on a binary distance matrix for comparing each dataset to variables such as scale insect species, host tree (within *Ultracoelostoma* spp.) at Rotoiti, and site (within *Ultracoelostoma* spp.) for black beech (*N. solandri*) host. Multiple sample sets of black beech were available from Rotoiti, allowing us to examine environmental differences by testing variability between two sets of samples collected from the same location. A non-parametric test of variance, Adonis, was used on the binary distance matrices for difference comparisons. Host differences at single sites and site differences of single hosts were compared across the chemical profiles of *Ultracoelostoma* spp. honeydew. All analyses were carried out in R (version 2.11.1) with additional packages Vegan and MASS, downloaded from CRAN servers (www.cran.r-project.org).

Results

Composition Seventy seven distinct compounds were detected in honeydew, comprised of 36 TMS derivatives (carbohydrates) and 41 MCF derivatives (amino- and non-amino organic acids). We identified 71% of the compounds, but the rest remained unidentified. Of those identified, 38% have not been reported previously associated with phloem-based honeydews.

Honeydews produced by *Ultracoelostoma* and *Coelostomidia* species contained a complex array of sugars and sugar-related compounds. The disaccharide sucrose was present in all honeydews sampled, as was the monosaccharide D-fructose and an unknown compound suspected to be 1-monooctadecanoylglycerol. D-glucose, maltose, meso-inositol, and sorbitol also were found in most samples. An additional 19 sugars and 9 other carbohydrate compounds were detected in some samples (Table 3).

Seven amino acids were detected, along with 34 other organic acids (Table 4). Among the amino acids, valine, leucine, isoleucine, proline, phenylalanine, glutamate, and tyrosine were detected in some samples. Of these, proline was most consistently present in honeydews from each species, but was not found in those produced by *C. zealandica* on karo (*Pittosporum crassifolium*). Several fatty acids including stearic (C18:0), oleic (C18:1n-9), palmitic (C16:0), levulinic (C5 keto acid), behenic (C22:0), and arachidic (C20:0) acid also were detected.

Table 3 Low molecular weight sugars and other metabolites detected in honeydew samples using trimethylsilyl (TMS) derivatization and GC-MS analysis. Significant *P*-values computed among the honeydews of the different species are indicated

variability in the data was captured within the first two dimensions [TMS: Eigen values (Eig.) 0.6860109 0.3205074; MCF: Eig. 0.6747290 0.3029696; plots a, d Fig. 1]. Host also did not have a discernible effect on honeydew composition, since honeydew from *Ultracoelostoma* spp. collected from red (*N. fusca*) and black (*N. solandri*) beech (both at Rotoiti) did not show any clear patterns in the MDS plots, and the first two dimensions captured most of the variability (TMS: Eig. 0.5404770 0.2291629; MCF: Eig 0.6402101 0.2265920, see plots e, f Fig. 1). In order to compare the three scale insect species, we pooled the 36 *Ultracoelostoma* samples and compared the composition to that of the honeydews of *C. wairoensis* and *C. zealandica*. This analysis of the MCF and TMS derivatives revealed significant differences among the three species, and indicated that each scale insect species had a distinctive honeydew composition (MCF: Eig 3.425742 1.050942; TMS: Eig 3.971345 1.881466, see plots a, b Fig. 1).

Multiple sample sets of honeydew from black beech collected at a single site at Rotoiti were tested bi-directionally (with pooled host variances and site variances) using non-parametric test ADONIS, and no significant differences were found in the TMS or MCF composition, suggesting minimal variation due to collection effects (see Table 5 for *P*-values). This also suggests that environmental variability due to differential environmental influence on each individual drop is diminished as the samples are pooled. Red beech and black beech from Rotoiti had a small significant difference in the TMS residues (P=0.004), while no difference was observed for the MCF residues. Neither TMS nor MCF residues showed any significant compositional differences between hard beech (*N. truncata*) and black beech samples from Rotoiti. TMS residues from black beech samples from Pelorus, Rotoiti and Rotoroa showed a small but significant difference (P=0.001), while the MCF residues had smaller differences (P=0.041).

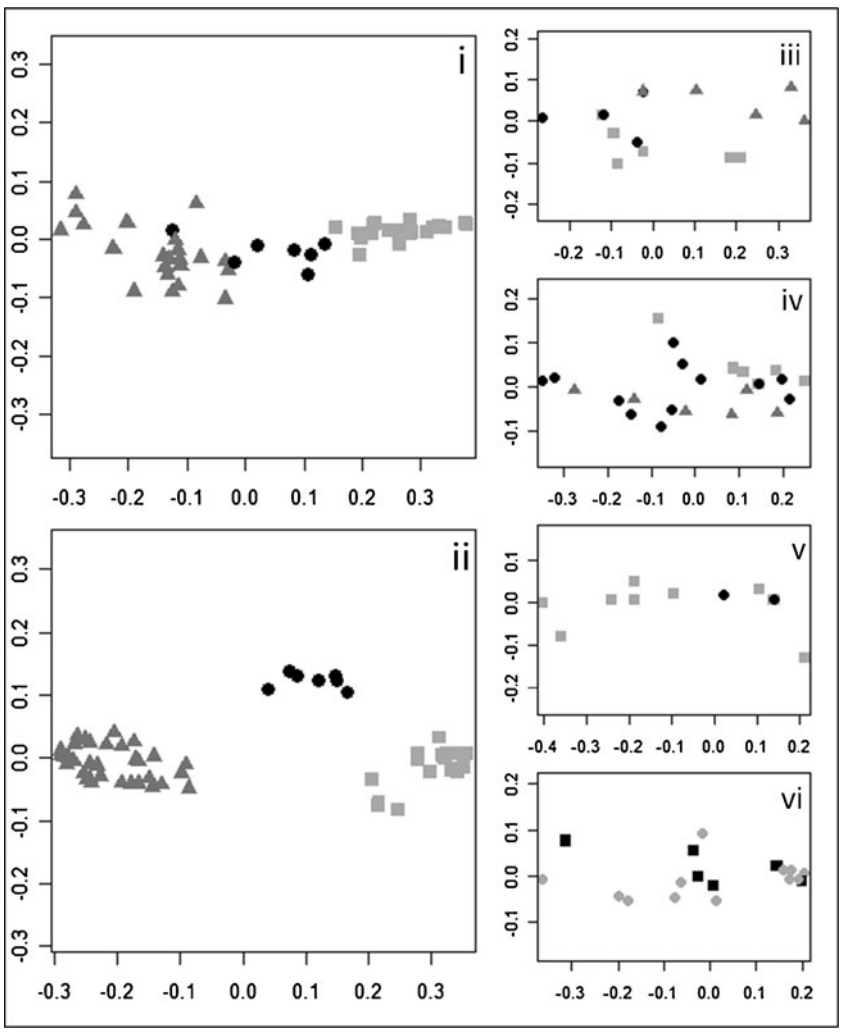

Fig. 1 Multidimensional scaling plots comparing honeydew composition. **i**, amino and non-amino organic acid composition (MCF derivatives) and, **ii**, carbohydrate composition (TMS derivatives) between the three scale insect species, namely *Ultracoelostoma* spp. (*triangle*), *Coelostomidia zealandica* (*circles*) and *C. wairoensis* (squares); amino and non-amino organic acid composition between sites (**iii**) and hosts (**v**) and carbohydrate composition between the sites (**iv**) and hosts (**vi**). Hosts of *Ultracoelostoma* spp. were black beech (*squares*) and red beech (*circles*) at site Rotoiti; and the three sites of *Ultracoelostoma* spp. were Rotoiti (*circles*), Pelorus Bridge (*triangles*) and Rotoroa (*squares*) with host black beech

Table 5 Summary of Adonis results to test variance within hosts (BB: Black beech, RB: Red beech and HB: Hard beech) at one site, within sites (Pel: Pelorus, Roi: Rotoiti and Roa: Rotoroa) with single host and within multiple sample sets at single site (BB, BB) or with single host (Roi, Roi). * = $P<0.005$, ** = $P<0.001$

Discussion

Over 75 distinct compounds were detected from honeydew, of which more than a third have not been reported previously associated with phloem-based honeydew from any insect (Tables 3 and 4). Blüthgen's work on honeydews of ant-attended homopteran insects reported only 25 compounds by using high-performance liquid chromatography (HPLC) (Blüthgen et al., 2004). Chemical analysis of honeydew is not an easy task due to the high sugar content of the samples, which severely interferes with the analysis of other, non-sugar components. However, by using a relatively novel derivatization method designed for metabolome analysis, MCF, we identified 16 non-sugar metabolites by using only 10 μl of sample (Villas-Bôas et al., 2011). This could be accomplished because the MCF derivatization minimizes the interference of sugars by extracting the derivatized analytes with chloroform, and because the GC-MS system is highly sensitive (Villas-Bôas et al., 2011). MCF cannot be used to derivatize sugars and related compounds. However, the TMS method described in Villas-Bôas et al. (2006) is optimized to simultaneously analyze over 53 different sugars and derivatives (monosaccharides, disaccharides, trisaccharides, sugar alcohols, and amino sugars). This method has been employed here for honeydew analyses for the first time. This pushes the boundaries of honeydew compositional analyses by reporting many additional compounds such as glycerols, sugar alcohols, fatty acids, dienes, alkaloids, and other organic acids along with the well described sugars and amino acids.

The reported carbohydrate composition of honeydew usually is limited to a dozen or so well-known sugars (Hendrix et al., 1992), some of which were detected in our analysis (Table 6). Honeydew carbohydrate composition varies among homopteran species and among host species (Hendrix et al., 1992; Fischer and Shingleton, 2001), but usually consists of the disaccharide sucrose, its component monosaccharide sugars (fructose and glucose), and one or more oligosaccharides (Byrne et al., 2003) (Table 6). In our study, we detected sucrose in all honeydew samples, suggesting that scale insects are not completely utilizing all of the plant sugars. They are instead venting some of it directly to the outside, by-passing most of the midgut (Foldi, 1990) where sucrase activity is maximal

Table 6 List of known honeydew amino acids and carbohydrates. Data from this study and published papers (Blüthgen et al., 2004; Byrne et al., 2003; Douglas, 1998; Fischer and Shingleton, 2001; Grant and Beggs, 1989; Gray, 1952; Hendrix et al., 1992; Lamb, 1959; Völkl et al., 1999; Yao and Akimoto, 2001). Essential and non-essential amino acid status notation based on Douglas, 1998 and Chapman, 1998. Compounds in bold were reported in the present study

Essential amino acids	Non-essential amino acids	Carbohydrates
Arginine	α-aminoapidic acid	Xylose
Histidine	Alanine	Fructose
Iso-leucine	Asparagine	Galactose
Leucine	Aspartic acid	Glucose
Lysine	β-amino butyric acid	Maltose
Methionine	Citrulline	Melibiose
Phenylalanine	Cystine	Sucrose
Threonine	Glutamate	Trehalose
Typtophan	Glutamine	Trehalulose
Valine	Glutathione	Turanose
	Glycine	Bismisiose
	o-phosphoethanolaminne	Erlose
	Proline	Raffinose
	Serine	Melezitose
	Tyrosine	Maltotriose
		Stigmatriose
		Stigmapentose
		Stachyose
		Stigmatetrose

(Karley et al., 2005). We also detected the trisaccharide raffinose, which is one of the three main types of sugars translocated in the phloem and has been detected occasionally in honeydews (Byrne et al., 2003). Components of sucrose and raffinose (galactose, fructose, and glucose) commonly occurred in our samples, along with maltose (a disaccharide composed of two glucose units). A few other unknown disaccharides were present in many of the samples.

Polyols such as meso-inositol, sorbitol, mannitol, and galactinol were detected in our samples. Mannitol, which was present only in *C. zealandica* honeydew, and sorbitol , are thought to provide thermo- and osmoprotection in aphids and whiteflies, respectively (Hendrix and Salvucci, 1998). 1-Monooctadecanoylglycerol is a lipid precursor that has been detected previously in sugarcane plants (Glassop et al., 2007) but not in honeydews, and it may be plant-derived.

The remaining sugars and compounds that we detected in the honeydews could be scale insect, host plant, or microbially derived, from the microbes that colonize the insects or the droplets of honeydew. For example, it is thought that phloem-feeding insects reduce the sucrose content of ingested phloem sap by polymerization processes that yield oligosaccharides, thus regulating gut osmotic pressure (Hendrix et al., 1992; Byrne et al., 2003; Douglas, 2006). Nine other trisaccharides were present, but we were unable to confirm their identities.

Insects depend on external sources to acquire essential amino acids (Chapman, 1998), but the requirements vary among species and are not known for scale insects. We found seven amino acids in scale insect honeydew (Table 6). Since scale insects are unable to synthesize amino acids, these were either derived from the host plant, or synthesized from plant precursors with the aid of bacterial inhabitants (Douglas, 1998). For example, the sharpshooter *Homalodisca coagulata* contains the bacterial symbiont *Sulcia muelleri*, which can synthesize proline (McCutcheon and Moran, 2007). Bacterial symbionts closely related to *S. muelleri* have been found previously in *C. wairoensis* (Dhami MK, unpublished data). Chemical analysis of phloem composition would allow us to determine whether phloem is the source of these amino acids.

A number of organic acids including citric, malic, succinic, lactic, and fumaric acids also were detected in our samples and have been reported previously from honeydew of aphids and mealybugs (Gray, 1952; Lamb, 1959; Hussain et al., 1974). These compounds may play a role in altering the pH of honeydew, which may result in some consumers being deterred or attracted to honeydew.

The honeydews reported here contained many compounds not detected in earlier research. Technological advances are primarily responsible for these differences, as our methods were able to detect and identify many more compounds than previously possible. Even so, despite the high resolution of the technique, 27% of detected compounds were categorized as unknown, due to a lack of corresponding advances in compound identification.

The main influence on honeydew composition is likely to be the species of scale insect, consistent with honeydew from aphids (Völkl et al., 1999). Site and host did influence amino- and non-amino organic acid composition. Closer sites (Rotoiti and Rotoroa, map1) had more similar compositions, compared to the more distant site (Pelorus Bridge), probably because environmental factors such as local climate influence the biochemistry of the forest ecosystem. Two species of host also had a small significant difference on the amino acid composition of *Ultracoelostoma* spp. honeydew. However, both site and host influences were minor compared to the influence of scale insect species (Fig. 1). Each of the three New Zealand honeydew communities may, therefore, be based upon chemically distinct honeydew because it is produced by a different scale insect species in each system. Some components of honeydew potentially could attract or deter different consumers. For example, melezitose is proposed as an ant attractant in some studies (Völkl et al., 1999; Fischer and Shingleton, 2001; Yao and Akimoto, 2001), although it does not act as an ant attractant in all honeydews (Romeis and Wäckers, 2000; Blüthgen and Fiedler, 2004). We found melezitose in all *C. wairoensis* honeydew collected from kanuka (*Kunzea ericoides*) (Table 3), however, only a few ants were observed feeding on *C. wairoensis* honeydew in a recent survey (Gardner-Gee, unpublished thesis), which suggests that melezitose may not have an ant-attraction role in this system. Nevertheless, a wide range of new compounds were detected in this study, and some of these compounds may have an influence on chemo-sensitive consumers, such as wasps and other parasitoids (Wäckers, 2001). Further testing of specific honeydew compounds paired with consumer groups, as has been done for EFNs and nectar (González-Teuber and Heil, 2009a, b), is needed to fully unravel these relationships.

Honeydew is composed of a complex variety of compounds, some of which have been reported here for the first time. Our study highlights the incomplete nature of our knowledge of honeydew composition and the unexplored potential of honeydew as a source of novel and rare compounds. Many of the detected compounds potentially could influence consumer communities, but at this stage it is difficult to hypothesize their roles. Comparison of scale insect species has shown that they have a significant influence on the chemical composition of their respective honeydews, which may explain the characteristic consumer communities associated with them.

Acknowledgements The authors thank Rhyl Beggs for assistance with collecting honeydew and Shane Baylis, Jo Smith, Nico Blüthgen, Darren Ward, Andrew Veale, Mike Taylor, Julien Granger, Peter Deines, and Raphael Aggio for valuable contributions to the manuscript and statistical analysis performed. Two anonymous referees improved the manuscript. This research was funded by the University of Auckland, and MKD is supported by University of Auckland international doctoral scholarship.

At the same time, reproductive queens must produce signals that regulate reproductive development and behavior of other colony members (Keller and Nonacs, 1993). Elucidation of the mechanisms that underlie the communication of individual reproductive potential and status is critical for understanding the organization of ant societies.

A key question regarding these mechanisms is what compounds are used to mediate the interactions between queens and workers? Studies suggest that cuticular hydrocarbons play a central role in nestmate discrimination, queen attraction, and regulation of reproduction in many ants, bees, wasps, and termites (Monnin, 2006; Le Conte and Hefetz, 2008; Liebig et al., 2009; Peeters and Liebig, 2009; Weil et al., 2009; van Zweden and D'Ettorre, 2010). The hydrocarbon characteristic of reproductive queens in the ant *Pachycondyla inversa*, for example, elicits a strong antennal response in electro-antennograms of workers, thus suggesting a sensory bias to this compound (D'Ettorre et al., 2004). In the ant *Aphaenogaster cockerelli*, workers with highly active ovaries produce cuticular hydrocarbons identical to those of reproductive queens (Smith et al., 2008); such workers are attacked by nestmates, presumably preventing them from reproducing. These attacks can be triggered in laboratory assays by the alkane *n*-pentacosane, the main component of the hydrocarbon profile of reproductive queens (Smith et al., 2008). Other direct evidence for an important role for hydrocarbon profiles in the regulation of ant reproduction comes from egg discrimination experiments in *Camponotus floridanus*. Reproductive queens produce a hydrocarbon profile that contains roughly twice the number of components as the profiles of non-reproductive queens (Endler et al., 2006). These reproductive queen hydrocarbon profiles also are present on queen-laid eggs, but not on worker-laid eggs, allowing workers to recognize and eliminate the latter (Endler et al., 2004). Finally, a primer effect of a major hydrocarbon compound produced by fertile queens of the ant *Lasius niger* has been demonstrated through reduced ovarian development of workers exposed to this compound compared to controls (Holman et al., 2010).

Given the widespread association between cuticular hydrocarbon profiles and reproductive status in eusocial insects, and the direct evidence for these compounds as fertility signals, it is especially interesting to find and explain possible exceptions to this pattern. In the red imported fire ant, *Solenopsis invicta*, the role of cuticular hydrocarbons has been studied only in the context of nestmate discrimination, with experimental transfer of hydrocarbons having no effect, thus suggesting that these compounds are not involved in this behavior (Anderson and Vander-Meer, 2001). Because cuticular hydrocarbons are involved in nestmate discrimination in many other social insect species (van Zweden and D'Ettorre, 2010), their lack of use in nestmate discrimination for *S. invicta* suggests that they also may not be involved in fertility signaling. In fact, hydrocarbon patterns for the postpharyngeal glands of queens did not change over the course of 10 days following mating and initiation of oogenesis (Vander Meer et al., 1982), a period during which such signaling to potential reproductive rivals or worker nestmates should be important.

Previous studies have shown that fully reproductive *S. invicta* queens produce a pheromone that inhibits winged, virgin queens from shedding wings (dealating) and developing ovaries (Fletcher and Blum, 1981; Vargo, 1998); workers are not affected in this way, because they have rudimentary ovaries and cannot lay eggs. The inhibitory pheromone(s) apparently originates from the venom sac and the postpharyngeal glands (Vargo and Hulsey, 2000), but the components are yet to be identified. The venom sac also has been shown to be the source of large amounts of venom alkaloids (Brand et al., 1972, 1973) and of pyranones. The latter are attractive to workers (Rocca et al., 1983a,b) but do not inhibit the reproductive development of winged queens (Glancey et al., 1984). In workers, the most abundant components of the alkaloids are *trans*-2-methyl-6-(*cis*-4′-*n*-tridecenyl) piperidine (*trans*-$C_{13:1}$), *trans*-2-methyl-6-*n*-tridecylpiperidine (*trans*-C_{13}), *trans*-2-methyl-6-(*cis*-6′-*n*-pentadecenyl) piperidine (*trans*-$C_{15:1}$), and *trans*-2-methyl-6-*n*-pentadecylpiperidine (C_{15}). In alate queens, the venom constituents are different, with the most abundant component being *cis*-2-methyl-6-*n*-undecylpiperidine (*cis*-C_{11}) (Brand et al., 1973). While workers inject venom directly into other animals for defense and predation, or spray it throughout the nest environment, presumably for protection against microbial pathogens, queens apply it over eggs as they are laid. It has been suggested that this behavior protects eggs from entomopathogenic fungi (Vander-Meer and Morel, 1995; Tschinkel, 2006). However, this behavior also raises the possibility that venom alkaloids on the surface of eggs may play a role in advertising the presence and fertility status of queens, as do hydrocarbons in other social insects.

An added element of complexity in the pheromonal regulation of reproduction and social organization in *S. invicta* comes from the occurrence of two social forms: monogyne, in which colonies contain a single queen, and polygyne, in which colonies contain multiple queens. The two social forms differ in several ways. For example, monogyne colonies are initiated by a single queen who raises her first brood by using body reserves, while polygyne colonies are initiated by budding, a process in which queens and workers leave the colony to initiate a new colony nearby (see Ross and Keller, 1995). Polymorphism in social organization is associated with allelic variation at the gene *Gp-9*; in the USA, monogyne colonies contain only inhabitants bearing the *B* allele, while polygyne colonies also include inhabitants bearing the *b*

allele (Gotzek and Ross, 2007). Monogyne workers (all of which are *BB* homozygotes) accept a single *BB* replacement reproductive queen if their colony has been queenless for several days, but they do not tolerate queens bearing the *b* allele. Alternatively, polygyne workers (a mix of individuals with and without the *b* allele) accept multiple reproductive queens bearing the *b* allele, but do not tolerate *BB* queens (Ross and Keller, 1998, 2002). This genotype-specific pattern of aggression or tolerance of queens by workers extends to nestmate non-reproductive queens in polygyne colonies; worker aggression toward young *BB* queens escalates as these queens approach two weeks of adult age, coincident with attainment of sexual maturity and reproductive competence (Keller and Ross, 1993a, 1999; Brent and Vargo, 2003). Ultimately, all sexually mature *BB* queens in polygyne colonies are executed or leave the nest on mating flights (Keller and Ross, 1999). Importantly, worker aggression toward *BB* queens in polygyne colonies is induced by a transferable queen signal on the cuticle (Keller and Ross, 1998). While production of this signal is related to weight and tendency to initiate egg-laying in non-reproductive queens, it is not related to fecundity in reproductive queens (Keller and Ross, 1993a, 1999; Ross and Keller, 1998). This has led to the suggestion that at least two distinct queen-produced pheromones are involved in regulation of colony queen number and identity in *S. invicta*: one communicating *Gp-9* genotype and the other communicating actual or potential reproductive status (Keller and Ross, 1999, Gotzek and Ross, 2007).

Here, we compared venom alkaloid and cuticular hydrocarbon profiles of queens of different stages of sexual maturity, reproductive status, and *Gp-9* genotype, as well as workers, originating from monogyne and polygyne *S. invicta* colonies. If cuticular hydrocarbons do not encode any of the above-mentioned types of information, then the abundant piperidines, unique to the venom of this group of ants, may fill this role instead. Our goal was to detect associations between chemical profiles and reproductive state/genotype of different classes of colony members. Such associations may indicate a role for specific compounds as releaser or primer pheromones involved in communicating *Gp-9* genotype and/or fertility status to workers, roles essential to the regulation of colony social organization in fire ants.

Methods and Materials

Insects Large colonies of each social form of *Solenopsis invicta* were collected and reared in the laboratory under standard conditions (Ross, 1988). A total of 25 polygyne and 23 monogyne colonies were collected from Athens-Clarke Co. and Oglethorpe Co., Georgia, USA, respectively. Social organization of the polygyne colonies was determined by finding multiple reproductive (wingless, egg-laying) queens in each. Social organization of the monogyne colonies was determined by finding only a single reproductive queen in each. Social organization was subsequently confirmed for all colonies by genotyping several reproductive queens (polygyne colonies) or 20 adult workers (monogyne colonies) at the gene *Gp-9*, using horizontal starch gel electrophoresis coupled with amido black staining (DeHeer et al., 1999); all polygyne reproductive queens possessed the *Bb* genotype, while all monogyne workers possessed the *BB* genotype, as expected (Gotzek and Ross, 2007). Colonies were fed daily by alternating a high-protein diet (tuna/dog food/peanut butter mix) with a high-carbohydrate diet (assorted vegetables/granulated sugar mix). These diets were supplemented with crickets and/or mealworms on a twice-weekly basis.

Several hundred adult workers from individual laboratory colonies were collected by placing a glass vial upright in the foraging area of each rearing unit for several minutes, and allowing workers to fall into the vial; vials were placed briefly on dry ice, then stored at −80°C until extraction. Thirteen colonies of each social form were sampled in this way for determination of piperidine alkaloid profiles, while ten colonies of each form were sampled for determination of hydrocarbon profiles (see Table 1 for sample size information).

We collected queens at three different key stages of sexual and reproductive development. First, we collected 2d-old, sexually immature and non-reproductive, queens from polygyne colonies. These were obtained by transferring 1–6 newly emerged (callow) adult queens to small rearing units with several hundred worker brood and adults from the natal colony (see Table 1 for sample sizes). Forty-eight hours after transfer, queens were collected for chemical analysis. Second, we collected 14d-old queens from polygyne colonies. By this age, queens have undergone extensive weight gain and accumulation of energy reserves (fat and glycogen), characteristic of completion of maturation in *S. invicta* (Keller and Ross, 1993a, 1999; Brent and Vargo, 2003). Such queens are sexually mature, but typically embark on a mating flight and are inseminated before becoming reproductively active. Two to six newly emerged queens from each polygyne source colony were held individually in small rearing units, with worker brood and adults from the natal colony, for 14 d before being collected for analysis (see Table 1 for sample sizes). These queens were held individually, rather than in groups, because workers execute queens with a *Gp*-9 *BB* genotype when they attain sexual maturity in colonies that also contain queens with a *Bb* genotype (see Keller and Ross, 1998, 1999). This procedure also ensured that the reproductive development of young queens was not inhibited by the presence of other queens in the same unit. In the rearing

units, some of the 14d-old queens dealated, a behavior associated with onset of oogenesis (Fletcher and Blum, 1981; Brent and Vargo, 2003); the identities of these queens were recorded. No 2d-old queens dealated. The third category of queens was reproductive. We collected one or two of these queens from polygyne laboratory colonies and the sole queen heading monogyne colonies (see Table 1). The mating status of the polygyne reproductive queens was unknown [approximately one-third of such queens remain unmated in invasive populations in the USA (Ross and Keller, 1995)], whereas all monogyne reproductive queens were assumed to have mated. All reproductive queens were collected after the colonies had been maintained in the laboratory for 1 month.

All collected queens were held in glass vials at −80°C, for several days to several weeks, pending chemical extraction. The *Gp-9* genotypes of all 14d-old queens were determined by starch gel electrophoresis following chemical extraction; 14d-old queens of both genotypes (*BB*, *Bb*) were included in the study (Table 1). Previous work has shown that reproductive queens from established polygyne colonies always possess genotype *Bb*, while reproductive queens heading monogyne colonies invariably possess genotype *BB* (Ross and Keller, 1998; Gotzek and Ross, 2007).

Chemical Extraction For piperidine analyses, queens were extracted individually in 80 μl of hexane (Fluka, Buchs, Switzerland) for 2 min., and then extracted in 80 μl dichloromethane (Riedel-deHaen, Seelze, Germany) for 11 min. Adult workers were extracted as groups of 200–500 individuals in 1 ml hexane for 2 min., and then in 1 ml dichloromethane for 11 min. Solvent from the extracts was evaporated under N_2, and the residue reconstituted with a known amount of hexane or dichloromethane.

We extracted individual queens and groups of workers from a second set of samples for hydrocarbon analysis. Queens were extracted in 80 μl hexane for 8 min. The solvent was evaporated under N_2, and the solute was re-dissolved in 2 μl hexane. Residual solvent on 14d-old queens was allowed to evaporate for 10 min., after which queens were stored at −80°C until determination of *Gp-9* genotype.

For hydrocarbon extraction of workers, subsets of 40 individuals were taken randomly from frozen colony samples and extracted in 100 μl hexane for 8 min. Solvent was removed from the extract by a N_2 stream, and the residue re-dissolved in 20 μl of hexane.

Chemical Analysis For piperidine analyses, extracts were first analyzed qualitatively on an Agilent (Santa Clara, CA, USA) 6890 gas chromatograph (GC), coupled with an Agilent 5975 mass selective (MS) detector operated in electron impact ionization mode. Peaks in extracts then were quantified by flame ionization detection (FID). GCs were operated in splitless injection mode, and were fitted with a DB-1MS column (30 m×0.25 mm×0.25 μm; Agilent). Column ovens were programmed from 60°–200°C at 40°C min^{-1}, after an initial delay of 2 min, then to 320°C at 5°C min^{-1}, and held at 320°C for 5 min. The injector was set at 260°C, the MS quad at 150°C, MS source at 230°C, and transfer line at 300°C. FID temperature was set at 320°C.

For hydrocarbon analysis, the MS was used exclusively, in order to identify some alkenes that differed with queen *Gp-9* genotype.

Chemical Identification Venom alkaloids and hydrocarbons were identified based on retention indices, mass spectra, and fragmentation patterns, with these data compared with previously published data (Brand et al., 1972, 1973; Nelson et al., 1980; Chen and Fadamiro, 2009; Dall'Aglio-Holvorcem et al., 2009). Double bond positions in unsaturated alkyl chains were determined by GC-MS fragmentation patterns of dimethyl disulfide adducts, as described in Liebig et al. (2009). See Table 1 for details of diagnostic ions.

Quantitative Analysis Peaks (Table 1) were aligned across samples, with only piperidines and unsaturated hydrocarbons used in the quantitative and statistical analyses. FID peak areas from both hexane and dichloromethane extracts were added, and the percentage of each peak out of total peak area calculated.

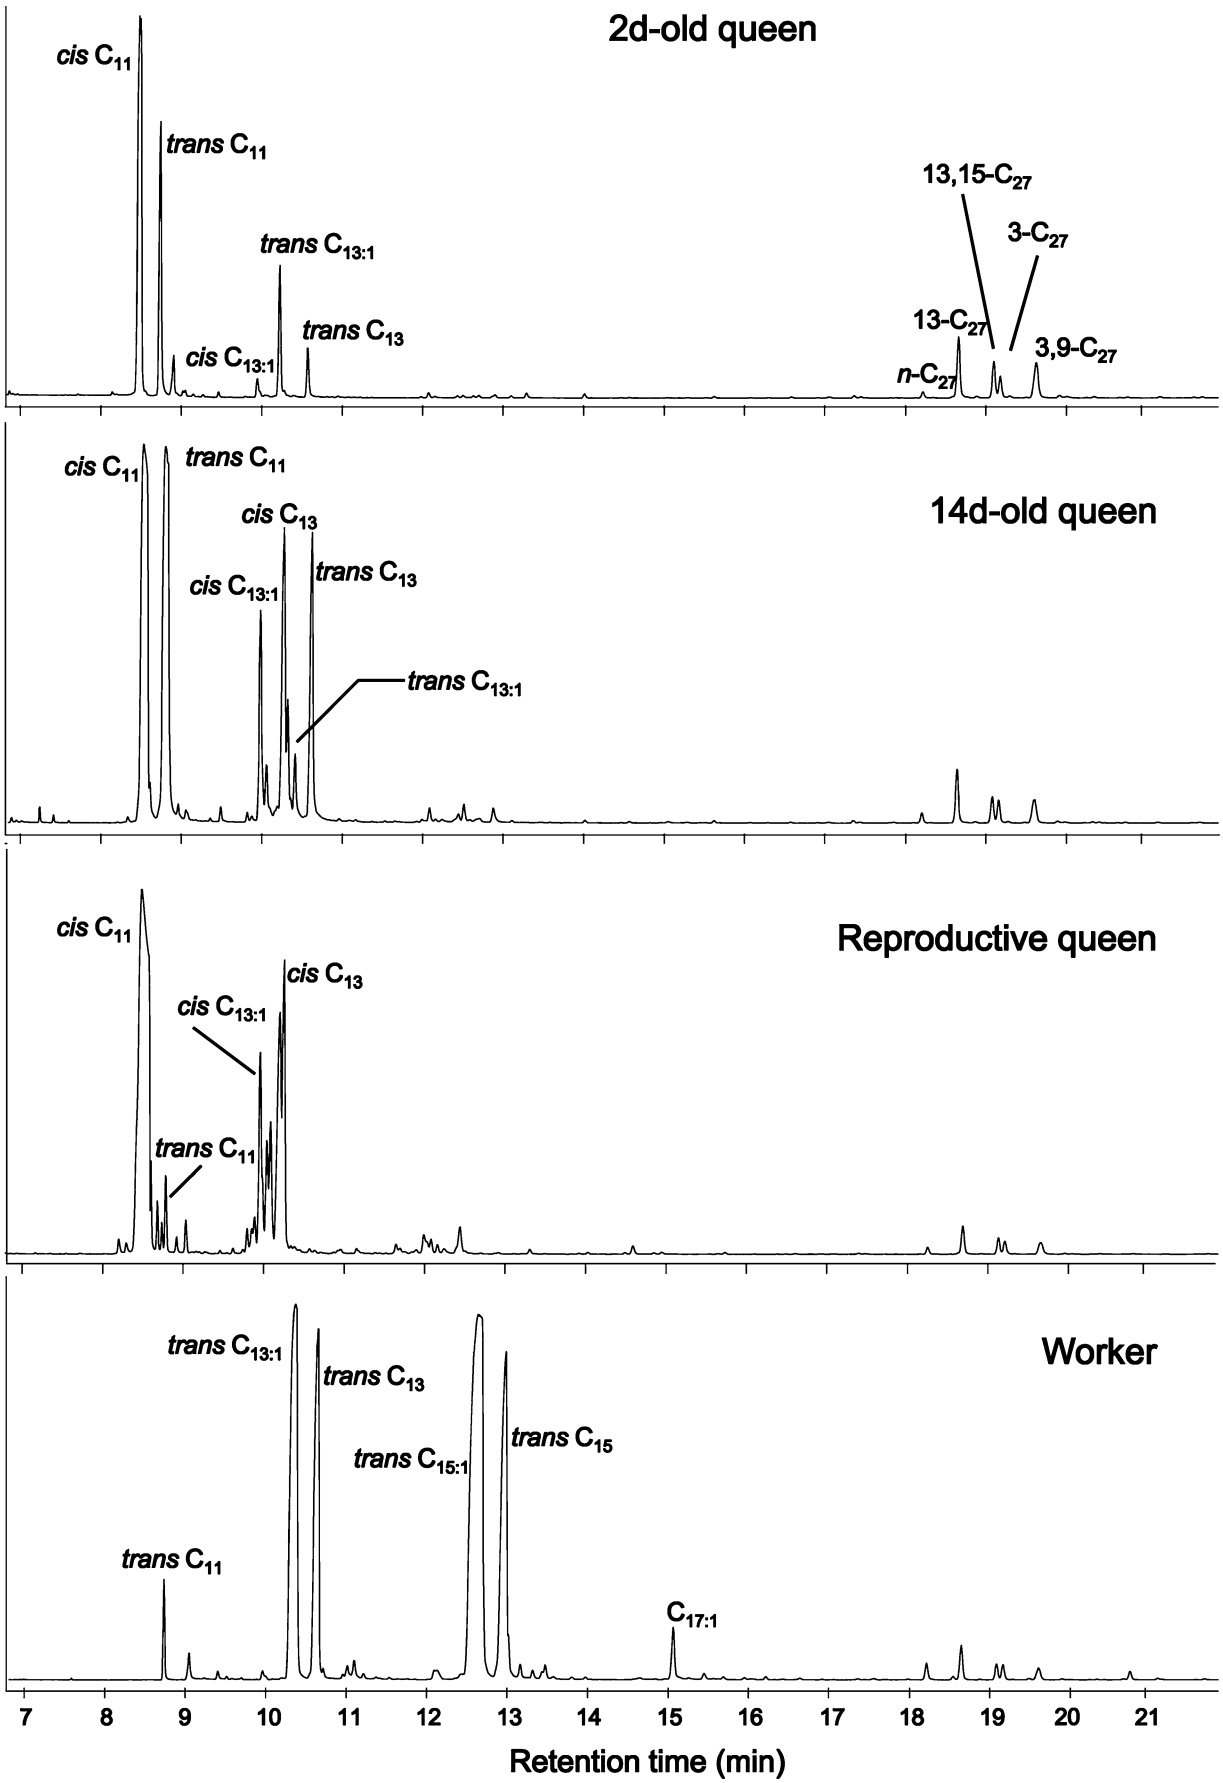
In the second set of samples, only hydrocarbon peaks were analyzed. We detected 49 compounds that were presumed to be hydrocarbons; this number was reduced to 26 for subsequent analysis. The peak area of all 49 presumptive hydrocarbons was summed and the relative proportion of each compound calculated. Then, the mean relative peak area of each compound was calculated for all queen and worker classes. For further analysis, we selected only compounds that had a mean of at least 1% of total peak area across all classes. The total amount of these 26 most abundant compounds was used as a reference for calculation of the relative proportions of each major unsaturated alkane. Peak areas of both data sets were calculated using MSD ChemStation D.02.00.275 data analysis software (Agilent Technologies).

Statistical Analysis For piperidines, Euclidean distances were used in non-metric multi-dimensional scaling (NMDS) analyses (Kruskal, 1964), using the program PRIMER 6.0. The first two dimensions of the model always resulted in stress values below 0.05, which is considered an excellent representation of data structure (Clarke and Warwick, 2001). The program STATISTICA 7.1 (StatSoft) was used to test for differences between monogyne and polygyne workers, and between monogyne and polygyne reproductive queens, in selected constituents

of the chemical profiles, using the *t*-test for independent samples (these data are normally distributed; Kolmogorov-Smirnov test, $P>0.2$).

Data for ratios of *cis*-C_{11}/(*cis*+*trans*)-C_{11} piperidines and peak areas of alkenes/alkadienes in queens were analyzed by means of resampling procedures coupled with binomial tests; resampling procedures were necessary because the use of multiple non-reproductive and reproductive queens from many of the polygyne source colonies meant that all replicates were not independent, violating a basic assumption of most standard statistical tests. Each class of queen was compared pairwise, with respect to ratios/peak areas, to each of the other classes, in the following way. For each iteration, a single replicate of each paired queen class was randomly selected and the difference in ratios/areas recorded; only paired replicates from different colonies were accepted. A third replicate of either of the two focal classes then was randomly selected from a different source colony than used for the first two replicates, and the difference between the two same-class replicate ratios/peak areas recorded. This procedure was repeated 1000 times (with replacement), and the paired between-class and within-class differences analyzed with binomial tests. The sample sizes, used for calculating the binomial probabilities following such resampling procedures, potentially range from the number of independent source colonies (most conservative) to the number of replicates (most liberal) used in the comparison; we chose to use the number of colonies in our calculations.

Results



Differences in Venom Alkaloid Composition Among Females of Different Classes Qualitative differences were apparent in the venom alkaloid profiles of the different classes of *S. invicta* females (Fig. 1, Table 1). The 2d-old (sexually immature, non-reproductive) queens contained the lowest amounts of alkaloids relative to hydrocarbons, with the most abundant alkaloids being the two forms of C_{11} piperidine and, to a lesser extent, the *trans* configuration of C_{13} piperidines. The 14d-old (sexually mature, non-reproductive) queens also contained mostly C_{11} piperidines, but had greater proportions of both *cis* and *trans* C_{13} piperidines than younger queens. Reproductive queens lacked many of the *trans* piperidines. In contrast to queens, workers contained almost no C_{11} piperidines, but they had large amounts of longer-chain piperidines, especially C_{13} and C_{15} *trans* forms.

NMDS analysis confirmed these differences by showing clustering of piperidine profiles of the different classes (Fig. 2). Workers were separated completely from all types of queens, and workers originating from monogyne colonies were separated from those from polygyne colonies without overlap (2D stress value: 0.02). With the exception of a single individual (highlighted as an outlier in Fig. 3), reproductive queens also were completely separated from all types of non-reproductive queens. There was, however, no consistent difference between the reproductive *BB* (monogyne) queens and reproductive *Bb* (polygyne) queens. Similarly, there were no evident differences in piperidine profiles of the young non-reproductive queens of the different maturation stages and *Gp-9* genotypes.

Differences in Venom Alkaloid Composition Associated with Reproductive Status of Queens The proportion of *cis* piperidines (*cis*-C_{11}/totalC_{11}) was not different between 2-d- and 14d-old non-reproductive queens (Figs. 1, 3A). However, reproductive queens had higher proportions of *cis* piperidines than did either 2d- or 14d-old queens (Fig. 3A). There also was an effect of *Gp-9* genotype on proportion of *cis* piperidines in 14d-old queens, with *BB* queens having a higher proportion of *cis*-C_{11} than *Bb* queens (Fig. 3b). In this age class, the proportion of *cis* piperidines also was different between queens that had dealated and those that had not (Fig. 3b), in agreement with previous observations showing that *Gp-9 BB* queens dealate more readily than those with genotype *Bb* (Keller and Ross, 1999). Indeed, in the present study, there was also an association between *Gp-9* genotype and dealation, with 92.9% (26/28) of *BB* queens having dealated, while only 15.7% (8/51) of *Bb* queens dealated (*Fisher's exact test*, $P<0.001$).

Differences in Venom Alkaloid Composition Between Workers from Monogyne and Polygyne Colonies Adult workers from monogyne colonies had a higher proportion of saturated piperidines than workers from polygyne colonies (Fig. 4). This difference stemmed mainly from differences in saturated/total C_{13} piperidine ratios.

Differences in Cuticular Hydrocarbon Composition Associated with Gp-9 Genotype and Reproductive Status of Queens All castes possessed the typical hydrocarbons found in previous studies (e.g., Cabrera et al. 2004). However, we also found additional unsaturated compounds not previously reported (Fig. 5; Table 1). The following compounds met our criterion for detailed analysis: heptacosene, nonacosene, nonacosadiene, hentriacontene, and hentriacosadiene. As for the piperidine profiles, these compounds gave profiles of reproductive queens that were distinct from those of other classes of females. In particular, these compounds were completely lacking in workers (Table 1); worker hydrocarbon profiles differed from those of all queen classes (resampling procedures coupled with binomial tests, all $P<0.05$). Importantly, the total relative amounts of the

Retention time (min)

◀ **Fig. 1** Representative total ion chromatograms of cuticular extracts of different classes of queens and of a worker of *Solenopsis invicta*. Venom alkaloids have retention times <17 min, whereas cuticular hydrocarbons have retention times >17 min. The 2d-old and 14d-old queens originated from polygyne colonies (*Gp-9* genotypes undetermined). The reproductive queen and worker profiles depicted are from individuals of the monogyne social form (*Gp-9* genotype *BB*). See Table 1 for definitions of the chemical acronyms

focal unsaturated hydrocarbons in queens varied according to *Gp-9* genotype and reproductive status, most dramatically between reproductive queens of the alternate (social forms) genotypes (Fig. 6). Reproductive *Bb* queens from polygyne colonies had a median of 17.7% of unsaturated hydrocarbons in their profile, while reproductive *BB* queens from monogyne colonies had a median of only 0.8% of unsaturated hydrocarbons, with one of the latter queens having no detectable amounts of unsaturated hydrocarbons.

While most (19/21) of 2d-old queens lacked any detectable amounts of unsaturated alkanes, the genotype-specific pattern of alkenes and alkadienes observed in reproductive queens had already begun to develop in queens over a 14-d period of maturation following eclosion (Fig. 6). Significantly, most 14d-old-*Bb* queens showed pronounced peaks of unsaturated hydrocarbons (median peak amount of 1.7%), while 14d-old-*BB* queens either lacked detectable amounts or had peak amounts of <0.1%. Thus, this difference in amount of unsaturated hydrocarbons, characteristic of reproductive queens of alternate genotypes, is paralleled by smaller differences in young, non-reproductive queens of alternate genotypes.

Discussion

This study shows that both venom alkaloid and hydrocarbon profiles in the fire ant *S. invicta* are associated with caste, queen reproductive status, queen *Gp-9* genotype, and colony social organization (Electronic supplementary material Fig. 7). Venom alkaloid composition changes dramatically, both qualitatively and quantitatively, as queens become reproductively active, and also differs between workers from monogyne and polygyne colonies. Cuticular hydrocarbon profiles also show pronounced differences among different classes of queens, with the qualitative and quantitative differences observed based mainly on the amount of alkenes and alkadienes. Differences in amounts of these unsaturated hydrocarbons are related not only to queen reproductive status, but also to *Gp-9* genotype of queens, with this latter difference already noticeable at 14 days post-eclosion, when queens are sexually mature but not yet reproducing.

Previous studies showed that the venom sac of reproductive fire ant queens contains mostly C_{11} alkaloids, which are barely present in the sac of workers (Brand et al., 1973). We found that the proportion of *cis* piperidines (the less abundant geometric configuration in workers), gradually increases in the venom of queens as they become fully reproductive. Moreover, in 14d-old (mature, but non-reproductive) queens, the proportion is higher in individuals of the *Gp-9 BB* genotype than in those of the *Bb* genotype. Similarly, alkenes/alkadienes are found in significant amounts only in the queen caste, and only polygyne reproductive queens contain copious amounts. It is important to note that the difference in amounts in 14d-old queens that we detected between *Bb* and *BB* queens is attributable to variation at the *Gp-9* gene (or variation at

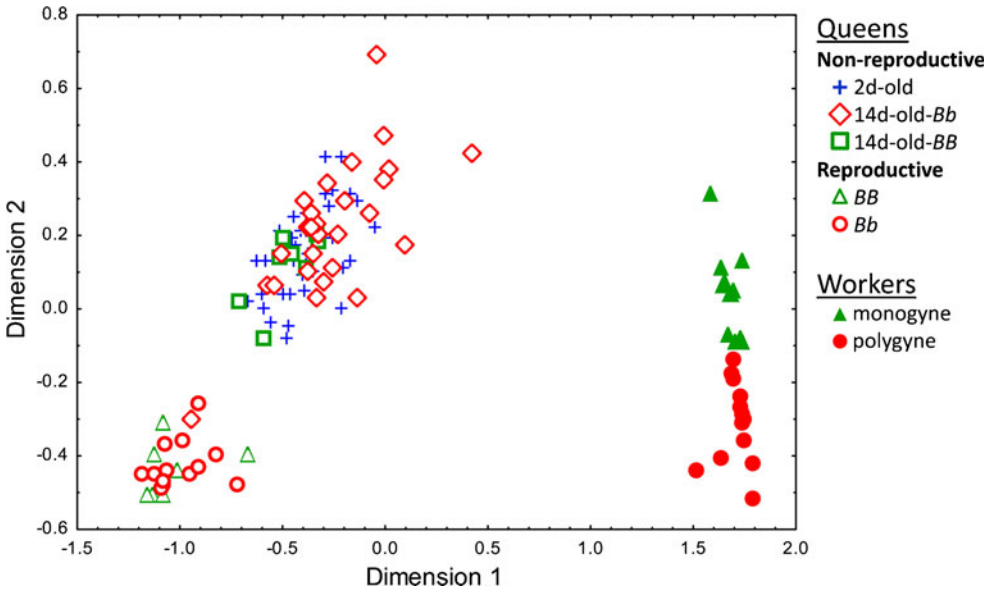

Fig. 2 Results of non-metric multi-dimensional scaling analyses of piperidine venom alkaloids of different classes of *Solenopsis invicta* females

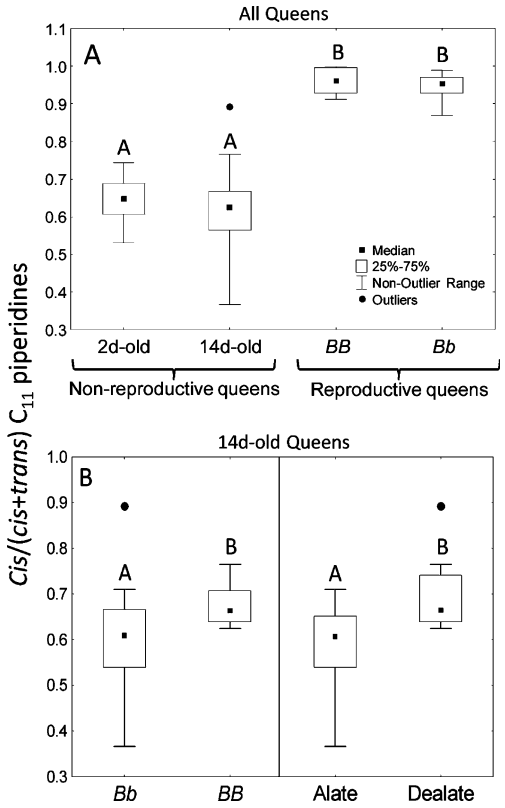

Fig. 3 Ratios of *cis*-C_{11}/(*cis*+*trans*)-C_{11} piperidines in different classes of *Solenopsis invicta* queens. Different letters within panels denote statistically significant differences. The outlier represents a dealate queen (included in the statistical analyses) evident in Fig. 2. **A** Patterns based on queen sexual maturity/reproductive status and on *Gp-9* genotype/social form of origin (resampling procedures coupled with binomial tests: 2d-old queens vs. *BB* or *Bb* reproductive queens, both $P<0.001$; 14d-old queens vs. *BB* or *Bb* reproductive queens, both $P<0.001$; 2d-old vs. 14d-old queens, $P=0.17$; *t*-test for independent samples: *BB* vs. *Bb* reproductive queens, $P=0.42$). **B** Patterns based on *Gp-9* genotype and dealation status of 14d-old queens (resampling procedures coupled with binomial tests: genotype *Bb* vs. *BB*, $P<0.001$; alates vs. dealates, $P<0.001$). *Cis*-C_{11}=*cis*-2-methyl-6-*n*-undecylpiperidine; *trans*-C_{11}=*trans*-2-methyl-6-*n*-undecylpiperidine

linked genes), rather than to effects of social environment, because all 14d-old queens in our study originated from polygyne source colonies. This initial difference, attributable to genotype, becomes more pronounced as queens age, accelerate oogenesis, and become fully competent reproductives.

That profiles of *cis* piperidines and unsaturated hydrocarbons differ between sexually mature *BB* and *Bb* queens suggests that these suites of chemicals constitute signals that workers use to recognize and discriminate between queens of the two genotypes. Importantly, such behavioral discrimination by workers only becomes apparent once queens become sexually mature (Ross and Keller, 1998; Gotzek and Ross, 2007), suggesting an association between ontogeny of these presumptive queen chemical signals and discrimination behavior directed toward them.

Previous studies showed that 14d-old-*BB* queens accumulate greater energy reserves, dealate more readily, and lay more eggs immediately upon dealation than 14d-old-*Bb* queens; i.e., sexually mature *BB* queens are at a more advanced state of reproductive development (Keller and Ross, 1993b; Ross and Keller, 1998; DeHeer, 2002). Thus, changes in alkaloid and hydrocarbon compositions are closely tied to physiological changes that accompany sexual maturation and the onset of reproduction that, in turn, are related to *Gp-9* genotype. Specifically, proportions of *cis*-C_{11} piperidines increase more rapidly during maturation in *BB* than *Bb* queens before attaining high proportions in reproductives of both genotypes, while amounts of alkenes/alkadienes increase more rapidly in maturing *Bb* than *BB* queens before reaching extremely high levels in *Bb* reproductives only. In line with this, 14d-old queens that dealated (i.e., those in a more advanced reproductive state, most of which lacked allele *b*) also had a higher proportion of *cis* piperidines than queens of the same age that had not dealated (most of which possessed allele *b*). Our results support tenets of the model of regulation of queen number proposed by Gotzek and Ross (2007), which invokes two distinct signaling components, one (piperidines) communicating actual or potential fertility status, and the other (alkenes/alkadienes) communicating *Gp-9* genotype. We note, however, that our data are not fully congruent with the model, which predicts that workers bearing the *b* allele should display the same chemical profile as queens bearing this allele; workers lacked the unsaturated hydrocarbons that were differentially abundant in queens of alternate *Gp-9* genotypes. There are several possible explanations for this incongruence, including the two classes of chemicals acting synergistically, rather than as distinct components, hydrocar-

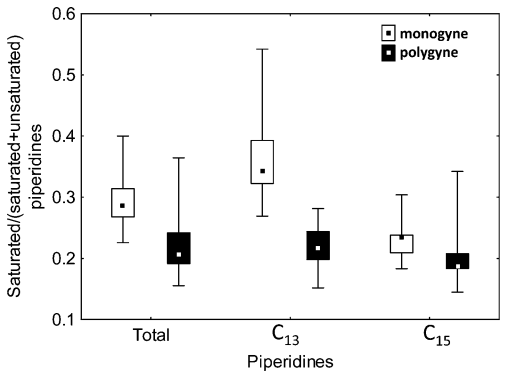

Fig. 4 Ratios of saturated to total piperidines in *Solenopsis invicta* workers from monogyne (*Gp-9* genotype *BB* only) and polygyne (mixed *Gp-9* genotypes) colonies. Comparisons of total piperidines, C_{13} piperidines, and C_{15} piperidines, respectively, are shown. Only total and C_{13} piperidines are different in ratios (*t*-test for independent samples: total, $t=3.46$, $P<0.003$; C_{13}, $t=6.05$, $P<0.001$; C_{15}, $t=1.72$, $P=0.098$)

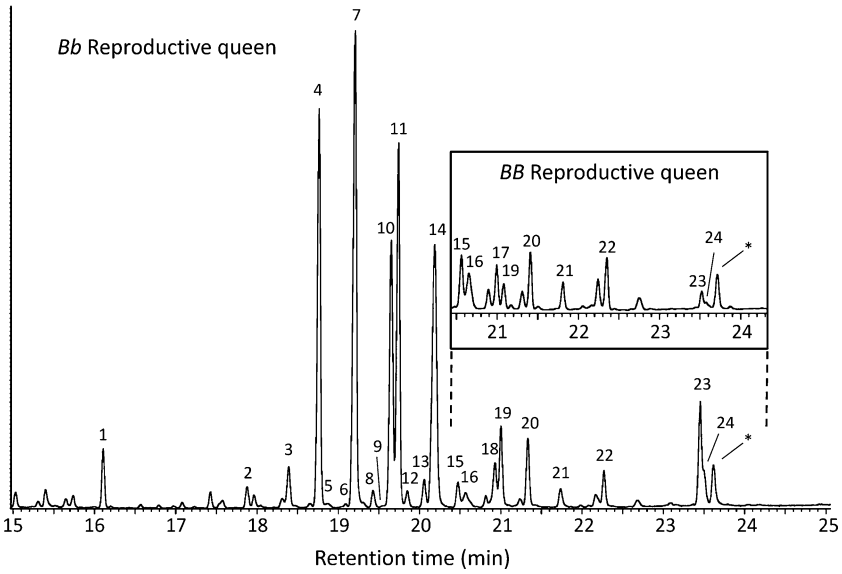

Fig. 5 Representative cuticular hydrocarbon profiles of *Solenopsis invicta* reproductive queens of *Gp-9 Bb* (polygyne queen) and *BB* (monogyne queen) genotypes. The highlighted partial profile of the *BB* queen is at the same scale as the profile of the *Bb* queen. *Numbers* correspond to compounds listed in Table 1. Any hydrocarbons eluting before 15 min are not shown. *Asterisk* indicates a contaminant

bon expression depending jointly on genotype and fertility status, or other classes of chemicals on the cuticle surface, including perhaps the GP-9 protein itself (unpublished data), being involved in signaling *Gp-9* genotype in *S. invicta*.

To date, fertility signaling has been assigned to cuticular and egg surface hydrocarbons in most social insects in which this effect has been investigated (Monnin, 2006; Le Conte and Hefetz, 2008; Peeters and Liebig, 2009; Liebig, 2010). In *S. invicta*, it appears that both hydrocarbons and piperidines may play roles in providing information relevant to regulation of colony queen number, as described above. Like hydrocarbons, piperidines are derived from acetate (Leclercq et al., 1996), raising the possibility that similar metabolic processes regulate the synthesis of hydrocarbon chains and piperidines.

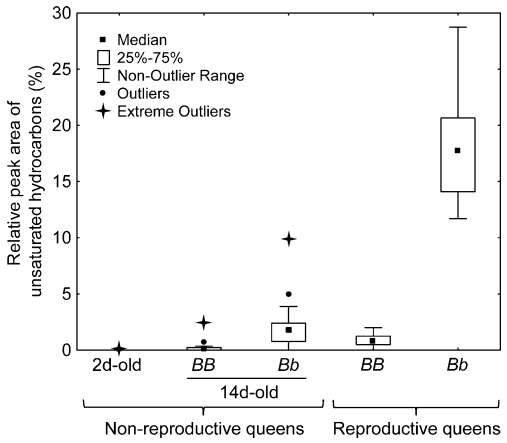

Fig. 6 Alkene and alkadiene relative amounts in different classes of *Solenopsis invicta* queens. All pairwise differences are significant (resampling procedures coupled with binomial tests: 2d-old queens vs. 14d-old-*BB* queens, and 14d-old-*Bb* queens vs. *BB* reproductive queens, both $P<0.05$; 14d-old-*Bb* queens vs. 2d-old and 14d-old-*BB* queens, both $P<0.01$; all other combinations, $P<0.001$)

Previously, piperidines were found not to be attractive in *S. invicta* (Vander Meer et al., 1980). The attractiveness of the queen poison gland secretion is attributed to two pyranones identified by Rocca et al. (1983a,b). Nevertheless, these pyranones do not delay the onset of reproduction in young queens, a primer effect that the poison sac was found to produce (Fletcher and Blum, 1981; Glancey et al., 1984; Vargo, 1998). Piperidines, with their large amounts dominating poison sac content, could be potential players in this phenomenon.

The ratio of saturated piperidines in adult worker cuticular extracts was higher in *S. invicta* workers from monogyne colonies than in workers from polygyne colonies (Fig. 4). This is in agreement with previous findings of differences in alkaloid composition between workers of the two social forms (Lai et al., 2008; Lin et al., 2010). Quantitative differences in piperidine composition have also been found between minor and major workers, as well as among workers of different ages (Deslippe and Guo, 2000), suggesting that piperidines also may be used for caste and possibly nestmate recognition.

Many ants use secretions from the metapleural gland as antiseptics for their nest and body surface. Fire ants have fatty acids with antimicrobial properties in the metapleural glands that may be used for that purpose (Cabrera et al., 2004), although venom alkaloids also may take part in defense against microbial pathogens. Workers of *S. invicta* display gaster-flagging behavior, whereby they spray the contents of the poison gland onto the nest and their body (Obin and Vander-Meer, 1985). Indeed, venom alkaloids dominate in solid phase microextraction (SPME) extracts of *Solenopsis xyloni*, even when the gaster cuticle is excluded

from extraction (unpublished data). As high molecular weight compounds, these alkaloids are nonvolatile (MacConnell et al., 1971) and potentially can remain on the cuticle for long periods. Considering the above, it is not surprising that piperidines also are found in abundance throughout the nest (Chen, 2007). The large quantities of venom alkaloids produced for a possible role in protecting ants from microbial pathogens may have facilitated their co-option to serve as fertility signals within colonies, especially if a queen's venom becomes distributed on her cuticle. Thus, the present study suggests that venom alkaloids of fire ants may have secondarily evolved roles in communication that typically are assigned to cuticular hydrocarbons in many other social insects (Monnin, 2006; Le Conte and Hefetz, 2008; Peeters and Liebig, 2009; Liebig, 2010). Despite the large amounts of alkaloids, hydrocarbons still may play a role in regulating social structure by signaling queen *Gp-9* genotype. Future manipulative behavioral studies should directly examine whether, and if so how, these and other compounds found on the queen cuticle, including GP-9 protein, function in maintaining the structure of fire ant societies.

consequently, a young queen will take off for nuptial flight (Engels and Engels, 1984, 1988; Engels, 1987; Roubik, 1990; Sommeijer and De Bruijn, 2004).

Pheromones of virgin queens are believed to trigger DCA formation (Sommeijer and de Bruijn, 1995; Imperatriz-Fonseca et al., 1998; Veen Van and Sommeijer, 2000a), although definitive experimental proof has yet to demonstrate this. *Tetragonisca angustula* DCAs have been observed near nests (Sakagami, 1982; Engels and Engels, 1988; Veen Van and Sommeijer, 2000a; Galindo-López and Bernhard-Kraus, 2009), but rarely elsewhere in the field. Consequently, little is known about how mating occurs (Imperatriz-Fonseca et al., 1998; Veen Van and Sommeijer, 2000b). In order to learn more about *T. angustula* mating behavior, we established meliponaries with virgin queens in different habitats during the main male-production period (Velthuis et al., 2005). Curiously, after establishing these meliponaries, and while preparing new colonies to raise additional virgin queens, drones from a DCA located about 7 m away were attracted to a single physogastric (i.e., fertilized) queen previously removed from a queen-right colony (unpublished data). This led us to wonder whether queen volatiles were responsible for drone attraction.

Until now, there have been only two reports on drone attraction in stingless bees. The first was with *Scaptotrigona postica* (Engels et al., 1990), in which an artificial mixture of secondary alcohols (present in cephalic volatiles found in virgin queens) was shown to attract drones in an aggregation in the field. The second, with *S. mexicana* (Verdugo-Dardon et al., 2011), used both field and laboratory experiments, and showed that drones differentiated between virgin and physogastric queen volatiles originating from the head. Virgin queen cephalic extract elicited strong drone antennal and behavioral responses.

In this study, we observed *T. angustula* drone assembling behavior, and examined drone behavioral and electrophysiological responses to natural and synthetic volatiles of virgin and physogastric queens. We also recorded the relative abundances of volatiles in regard to queen reproductive status, and located the source of volatiles in the queen body.

Methods and Materials

Study Site and Meliponaries Experiments were carried out in the Soconusco region, Chiapas, Mexico, from Dec. 2009 to March 2011. Four *T. angustula* meliponaries were established in two sites, eight km apart. Site 1) agroforestry cacao plantation, with two meliponaries, Izapa (14°54′N and 92°11′W) and Medio Monte (14°53′ N and 92°11′ W), with seven colonies in each site, 2.8 km apart; Site 2) Urban area with two meliponaries, Downtown (14° 54″ N and 92° 16″ W) and ECOSUR (14°53′ N and 92°17′ W), with five and seven colonies, respectively, 2 km apart. Each colony contained at least one recently emerged virgin queen. Meliponaries were established by Dec 2009, with the exception of ECOSUR, which was established in Dec 2010 at the El Colegio de la Frontera Sur (ECOSUR) facility. Most of the work reported here used colonies at the urban ECOSUR site.

Bee Colonies and Recording All colonies in the meliponaries were removed from feral nests and established in wooden boxes (30×20×10 cm) from which the queen was removed. The queenless colonies contained 500–1,000 workers, few drones, several combs with emerging broods, at least one mature queen cell, and sufficient food stores. The meliponaries were observed daily for drone congregations. After the first DCA was formed, we checked every 2 h between 08:00 and 18:00 h, and recorded the number of drones. Ten bait hives in each site, located to attract swarms of *T. angustula*, were hung 1–15 m from the occupied hive. These bait hives were checked daily to determine whether new colonies had settled in them (Engels and Imperatriz-Fonseca, 1990).

Collection of Volatiles and Sample Preparation Individual virgin (1–5 d-old; $N=6$) and physogastric ($N=17$) queens (both types taken directly from the nest and assayed immediately), as well as individual heads, thoraces, and abdomens from queens ($N=3$), were placed in 20 ml Erlenmeyer flasks with an aluminum foil lid. Queen bees were left in flasks for 30 min before volatile collection. Volatiles were collected from the flasks for 30 min. at ambient temperature using a Solid Phase Micro-Extraction method (SPME) fiber (65 mm polydimethylsiloxane divinylbenzene; Supelco, Bellefonte, PA, USA). For extracts, an individual intact queen (virgin or physogastric), or dissected body parts (head, abdomen, and thorax), was crushed in 400 µl of dichloromethane. Extracts were concentrated to 100 µ1 (queens and abdomen) or 50 µl (head and thorax) per queen equivalent by a nitrogen stream, and stored at −20°C until used for analysis or bioassays.

Electrophysiology Gas chromatography-electroantennographic detection (GC-EAD) analyses were performed using SPME volatile collections of living queens and queen body parts, as well as 2 µl of synthetic isopropyl hexanoate (IPH; 2 mg/ml). Antennae from drones caught from a DCA, or workers (nurse and forager) from established colonies, were carefully removed, and the base was inserted into a reference glass capillary electrode, previously filled with saline solution (Malo et al., 2004). The distal end of an antenna was inserted into the tip of the glass recording capillary electrode. The signal generated by

an antenna was passed through a high-impedance amplifier (Syntech NL 1200, Hilversum, The Netherlands) and displayed on a monitor using Syntech software for processing GC-EAD signals. One drone or worker antenna constituted one sample (N=10).

Chemical Analyses To identify EAD-active compounds, volatiles and extracts were analyzed on a Varian Star model 3400 CX GC (Palo Alto, CA, USA). A DB-5 column (30 m×0.25 mm ID) was temperature programmed from 50°C (held for 2 min) to 250°C at 15°C min^{-1}. The injection port temperature was held at 200°C. The GC was coupled to a Varian Saturn 4D mass spectrometer and integrated data system. Ionization was carried out by electron impact at 70 eV, 230°C. Mass spectral identifications of the compounds were confirmed by comparison of retention times and mass spectra with those of synthetic standards. The relative amount of each compound was calculated from peak area, while the relative percentage of a component was calculated relative to the sum of all peak areas.

Preparation of Esters Esters were prepared by heating the corresponding alcohol (10 μl), carboxylic acid (5 μl), and acetic acid (2 μl) together with a drop of concentrated sulfuric acid in a Keele microreactor (Attygalle and Morgan, 1986) for 12 h at 100°C. The reaction was neutralized with $NaHCO_3$, and esters extracted with hexane (200 μl). IPH was synthesized from isopropyl alcohol (Merck, Mexico, S.A., chemical purity 99.7%) and hexanoic acid (Sigma-Aldrich, Toluca, Mexico, chemical purity 99%); butyl hexanoate (BH) from butanol (Productos Quimicos, Monterrey, Mexico, chemical purity 99.4%) and hexanoic acid; hexyl hexanoate (HH) from hexanol (Sigma-Aldrich, Toluca, Mexico, chemical purity 98%) and hexanoic acid.

Behavioral Bioassays To test the attractiveness of samples from both virgin and physogastric queens, bioassays were conducted in the ECOSUR bee yard. Live physogastric queens (N=5), in a wire cage on a 1.5-m-high tripod, and a 5 mm diam. cotton ball in another wire cage (used as positive and negative controls, respectively) were exposed three times, each 1 min., daily around noon, with breaks of 30 min between exposures. These tests were conducted over 5 d at a distance of 1, 3, 5, 7, 10, 15, and 20 m from DCA 3 (containing ~2,000 drones, estimated by counting the number of males that visited the cages). Virgin queens (N=3), 3–7 d-old were exposed on 3 different days, as described above, to DCAs 3 and 6 (each with ~2,000 males).

A short distance, two-choice bioassay was carried out to test the attractiveness of parts of the queen body (head, thorax, and abdomen; N=3), as well as queen extract, and IPH alone or combined with BH and HH. A queen, a part of the queen body, a cotton ball impregnated with one queen equivalent, IPH (0.4 mg) alone, or a blend of IPH (0.4 mg), BH (0.2 mg) and HH (0.2 mg), was presented on a stand (0.5 m from DCA 7 with ~150 drones), along with a blank cotton ball (control), around noon for 5 min. A drone's response was classified as "attract" when it flew upwind toward and within 5 cm of a sample; "touch" when it had brief contact with a cotton ball or a wire cage; and "mount" when it attempted to copulate. To avoid habituation, cotton balls and wire cages were changed after each test. Each queen was used only once per day.

Statistical Analysis The significance of drone attractiveness to both queen statuses at different distances, as well as the drone responses to the queen body parts and synthetic blend or alone, were calculated using the Wilcoxon T test with continuity correction. This method is contained in the software *R* Development Core Team (2010). A significance level of 5% was used.

Results

Drone Congregation Areas A total of eight *T. angustula* DCAs were observed during the experiment. Two established in the "Downtown" site and six in the "ECOSUR" site, both in urban areas. Three DCAs had more than 2,000 males during the days of highest assemblage. DCAs remained in place for up to 35 d (Table 1). The DCAs formed on different substrates, such as a clay tile, a wooden planter with some bees on overhanging vegetation, or a hive, but always close to (~0.5 m) or beside colonies or bait hives with a recently established swarm containing a virgin queen. The mean number of drones arriving the first day was 190 (±147). Males arrived daily at the congregation site from 08:00 to 18:00 h, with peak arrival time between 11:00 and 14:00 h. No DCA was observed at any of the two (Izapa and Medio Monte) meliponaries in the agroforest location.

Electrophysiology Queen volatiles, collected by SPME from either virgin or physogastric queens, elicited strong signals from *T. angustula* drone antennae (Fig. 1a and b, respectively), but not from females (nurses and foraging workers, data not shown). At least one EAD-active compound was apparent (retention time, 6.7 min) from both types of queens. This compound was present in the abdomen of queens. Antennal responses to extracts of intact queen or dissected abdomens elicited a weaker signal than the SPME collections. Although traces of the active

compound were found in the thorax and head, no EAD responses to volatiles collected from these parts were obtained. Synthetic IPH elicited a discernible EAD response from drone (Fig. 1c), but not female, antennae (data not shown).

Chemical Analyses Typical gas chromatograms of SPME volatile collections from live virgin and physogastric *T. angustula* queens are presented in Fig. 1a and b, respectively. Three major peaks were identified: IPH [retention time: 6.7 min., major *m/z* (relative abundance,%): 43(100), 56(47), 84(41), 99(44), 117(50)]; BH [retention time: 8.3 min., *m/z* 43(60), 56(100), 71(29), 99(78), 117(57)], and HH [retention time: 10.3 min., *m/z* 43(100), 60(40), 71 (20), 99(46), 117(22)]. Chemical analyses of the two types of queens were similar qualitatively, but differed quantitatively, with virgin queens characterized by an abundance of IPH, a small amount of BH, and a trace of HH, while physogastric queens had relatively large amounts of IPH and HH, and a small amount of BH (Table 2). Interestingly, young, recently mated queens (2–4 wk-old) had relative amounts of HH in between the other two types (Table 2). The composition in the abdomen of virgin queens was similar to that for live queens, whereas the thorax and head had only traces of IPH and HH, as well as several compounds not found in the abdomen (Table 2).

Drone Behavioral Bioassay with Living Queens and Synthetic Compounds Drones were attracted to live virgin and physogastric queens over various distances. Both virgin and physogastric queens were detected by drones when slowly brought closer to the DCA (~2,000 males), with attraction increasing the closer the queens were exposed to the DCA (Fig. 2). At 20 m from the DCA, no males were attracted to queens.

Of the three body parts tested in the bioassay, the greatest number of responses occurred to the abdomen of a virgin queen, with fewer males responding to the thorax and none to the head (Table 3). The attract, touch, and mount responses to the abdomen and thorax were greater than the corresponding responses to the control. Only a few seconds after exposing the cage containing a queen's abdomen, drones flew upwind and touched or attempted to mount it, with fairly consistent responses recorded over each of the 5 min of the bioassay (Table 3). One equivalent of virgin queen extract attracted a significant number of males (relative to the control), of which only two (not different from that to the control) touched the cotton ball containing the extract. Relatively high numbers of drones were attracted to synthetic IPH, but few (three, not different from the control) of these actually touched the cotton ball. Similar responses were obtained to the mixture of IPH, BH and HH. The blank (control) did not attract any drones (Table 3).

Discussion

Tetragonisca angustula male aggregations are common, usually establishing during the reproductive stage of colonies. However, it is rare to find wild *T. angustula* DCAs, and consequently, not much is known about how mating occurs (Imperatriz-Fonseca et al., 1998; Veen Van and Sommeijer, 2000b). In our study, we found two *T. angustula* DCAs established in the "Downtown" meliponary and six DCAs in the "ECOSUR" meliponary, both urban areas. All DCAs were established during the main drone production period, as observed in other stingless bee species (Velthuis et al., 2005). The DCAs were found close to nests containing a virgin queen and located on a variety of substrates, as known for several stingless bee species (Sakagami, 1982; Engels and Engels, 1988; Veen Van and Sommeijer, 2000a; Sommeijer and De Bruijn, 2004; Galindo-López and Bernhard-Kraus, 2009). These results suggest that the presence of at least one virgin queen is a primary element that triggers the onset of DCA formation (Sommeijer and de Bruijn, 1995; Imperatriz-Fonseca et al., 1998; Veen Van and Sommeijer, 2000a). However, it seems that it is not the only factor, as males still aggregated at the same site even after the queen was fertilized. We speculate that *T. angustula* drones may leave "markings" that are used in the orientation of other drones toward a given site, as observed in *S. mexicana*. In this species, once a site is selected, the aggregation remains in the same place regardless of the queen's status (virgin, physogastric, or even queenless) (Galindo-López and Bernhard-Kraus, 2009).

We observed no DCAs formed in the agroforest meliponaries, suggesting that the density of feral nests, as well as spatial distribution, plays a crucial role in the formation of aggregations. *Tetragonisca angustula* uses a broad diversity of substrates for nesting, and is thus well suited to urban environments (Noll et al., 1993; Sousa et al., 2002). In our study areas, *T. angustula* was three times more abundant in urban areas, and was distributed relatively homogenously, than in the agroforest areas, where it has a more random spatial distribution (Fierro et al., in press).

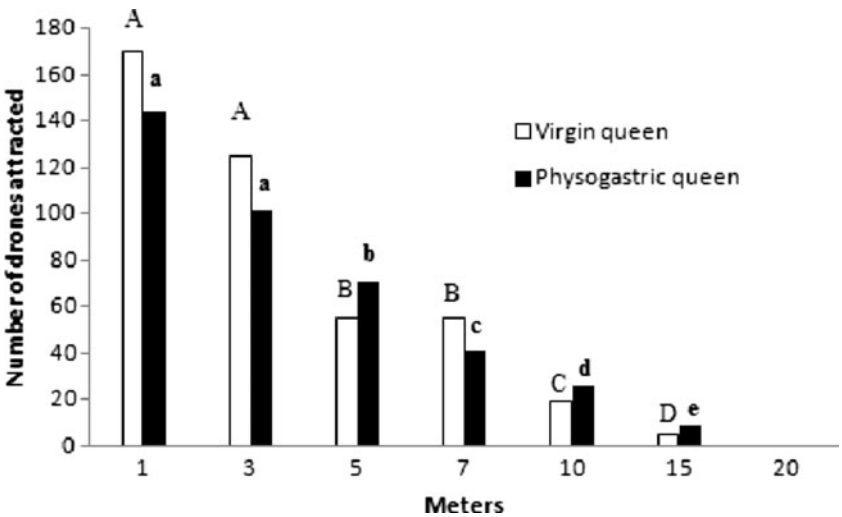

Fig. 2 Numbers of drones, from large congregations of ~2,000 males, attracted to virgin (N=9) (*light bars*), and physogastric (N=15) (*dark bars*) *Tetragonisca angustula* queens. Queens were exposed for 1 min at different distances from the drone congregations. *Same letter* of the same case, among drone responses at different distances, indicate no statistical difference (P>0.05; Wilcoxon T test with continuity correction)

IPH=isopropyl hexanoate (IPH); synthetic blend = IPH + butyl hexanoate + hexyl hexanoate(HH)

* Response different ($P<0.05$) from that to the control

** No drones responded (attract, touch, or mount) to the control

With the exception of DCA 8, all our drone aggregations were formed by greater than several hundred males. Such large numbers of drones should ensure that queens mate with an almost panmictic sample and therefore avoid inbreeding (Baudry et al., 1998). The stay of drones at a DCA generally lasts only a few days, with males disappearing after the queen has been fertilized (Veen Van and Sommeijer, 2000a). However, three of the six DCAs we found (Table 1), and remained in the same place for 19–35 d. This behavior is similar in DCAs observed in meliponaries of *S. mexicana*, in which DCAs remained in the same place for 24 d (Galindo-López and Bernhard-Kraus, 2009). This long stay may occur because of the intensive handling of bee colonies within a meliponary (preparing new colonies to raise new virgin queens).

The range of attraction (1–20 m) of drones we observed in our bioassay is consistent with that of other stingless bee species (Engels and Engels, 1988; Sommeijer and De Bruijn, 2004) and congruent with the successful formation of DCAs seen in urban areas. The efficiency of queen-male chemical communication is amplified by male-male communication, and the uniform spatial distribution of nests in urban areas favors DCA formation (Fierro et al., in press). Curiously, when we were preparing colonies to raise new virgin queens, drones from a DCA (>2,000 males) were attracted to a single physogastric queen removed from a queenright colony and placed in a wire cage (unpublished data). This attraction was similar to that observed to virgin queens, and may indicate that polyandry occurs in this species, as reported for several other species of solitary and social Hymenoptera (Page and Metcalf, 1982; Page, 1986). Queens of highly eusocial bees mate only during a short period at the beginning of their reproductive lives. For example, queens of *Apis* species copulate with an average of 23 drones, during one or more mating flights, and then start oviposition (Adams et al., 1977). In contrast, stingless bee queens have long been thought to mate only once, e.g., *M. quadrifasciata* (Kerr, 1969; Silva et al., 1972; Peters et al., 1999). However, mating in stingless bees has been studied in only a small number of species (Lopes et al., 2003), and evidence of attraction to physogastric queen volatiles (Engels and Engels, 1988; Campos and Melo, 1990) may indicate that queens of some species do mate more than once.

Both virgin and physogastric queens released the same three esters, but in different relative amounts. Engels et al. (1990) and Verdugo-Dardon et al. (2011) found a similar result in cephalic chemistry between virgin and physogastric queens in both *S. postica* and *S. mexicana*. In our study, the most obvious difference between virgin and physogastric queens was the relative amount of HH. This compound had elevated levels in recently mated queens. In *S. mexicana* queens, HH became the most abundant com-

pound once a queen was fertilized and began egg laying (Grajales-Conesa et al., 2007). Thus HH levels may be a marker for a queen's reproductive state, and perhaps may be involved in regulating colony organization and worker behavior. Further work is needed to test this.

While HH has previously been found in *S. mexicana*, the other two compounds have not been found in other stingless bees. Butyl hexanoate is used as a sex pheromone in *Megalotomus quinquespinosus* (Heroptera, Alydidae, Alydinae), and as a kairomone in *Cydia pomonella* and *Grapholita molesta* (Lepidoptera, Tortricidae), (El-Sayed, 2011). Isopropyl hexanoate has been found in extracts of sexually mature *Drosophila putrida* (Diptera, Drosophilidae) males, while in *D. recens* it is a sex pheromone (Jaenike et al., 1992). Isopropyl hexanoate is widely distributed in flower essences where its evolutionary function is to attract pollinators (Dobson and Bergström, 2000).

Although *T. angustula* males showed strong attraction to IPH, either alone or in combination with BH and HH, males exhibited little touching. Since isolated abdomens both attracted and elicited males to mount, this suggests that there may be other close-range olfactory stimuli involved in eliciting more complete behavior. Similar results have been found in Apidae. For example, with the bumblebee, *Bombus terrestris*, a blend of synthetic virgin queen pheromone elicited male attraction but did not provoke "mounting" (Krieger et al., 2006). In honey bee queen pheromone studies, 9-ODA (a queen sex pheromone component) attracted males (Butler and Fairey, 1964), but this compound alone was less attractive than an intact queen (Slessor et al., 1988). In *S. postica*, a mixture of four synthetic secondary alcohols, placed on a dummy, elicited only occasional "touching" when presented to a drone congregation (Engels et al., 1990). The presence of additional behaviorally active compounds produced by queens should be investigated.

We have shown that volatiles from both virgin and physogastric *T. angustula* queens attract and influence the behavior of drones. This attraction is caused, at least in part, by IPH released from the abdomen of a queen. However, further research is needed to elucidate any biological function of the presence of this compound in *T. angustula* physogastric queens, as well as its possible effect as a queen pheromone in the reproduction of the highly eusocial Meliponini.

Acknowledgments We thank Dr. Edi Malo for advice on GC-EAD, Antonio Santiesteban and Bernardino Diaz for technical assistance, and Dr. Gerald Loper for assistance in the English translation. This work was made possible through a doctoral scholarship (57515) granted by El Consejo Nacional de Ciencia y Tecnología (CONACYT). Finally, we thank the Research and Postgraduate Division of the Universidad Autónoma de Chiapas (UNACH) for permission and support.

mediators of two of the hallmarks of sociality: the queen-worker reproductive division of labor, and worker task specialization (Wilson, 1971). Furthermore, sociality and the accompanying pheromone-communication systems have evolved independently multiple times in the order Hymenoptera (bees, ants, and wasps), allowing comparative approaches for understanding the evolution of these systems (Wilson, 1971; Ross and Matthews, 1991; Brady et al., 2006; Hines et al., 2007). It is likely that these complex communication systems evolved from systems that regulate more basal pheromone-mediated behaviors, such as mating and defense, which are found even in solitary lineages of wasps (Blum, 1969). Thus, chemical cues associated with physiological status, particularly reproductive state, may have been co-opted as signals that regulate social status (reviewed in Wyatt, 2003).

In the last 10–15 years, a great deal of progress has been made in identifying pheromones and characterizing pheromone responses, particularly at the molecular level. Here, we build on previous reviews of pheromones in ants and honey bees (Monnin, 2006; Le Conte and Hefetz, 2008; Heinze and d'Ettorre, 2009; Holman, 2010; van Zweden, 2010), and provide an overview of recent advances in our understanding of pheromone systems that regulate queen-worker interactions in multiple social insect species, including honey bees, bumble bees, wasps, ants and termites. We further discuss how this information impacts our understanding of the ultimate mechanisms that underlie pheromone communication. Finally, we discuss how recent advances in genomics have contributed to our understanding of the mechanisms that regulate pheromone communication, and how these tools may be used in the future to elucidate further the evolution of these sophisticated chemical communication systems.

The Role of Pheromones in Regulating Reproductive Division of Labor The reproductive division of labor found in social insects leads to conflicts between individuals over reproductive status (reviewed in Ratnieks et al., 2005). Kin selection theory (Hamilton, 1964) proposes that these conflicts are resolved in part because sterile workers increase their inclusive fitness by rearing related, reproductive nestmates to offset the loss of direct fitness. However, conflict can still exist, especially in the case of male production. In smaller colonies, where individuals can interact directly with each other, physical dominance interactions may have evolved as a means to resolve these conflicts through social hierarchies, and, in some cases, these appear to have been reinforced by pheromones (West-Eberhard, 1967; Wilson, 1971; Keller and Nonacs, 1993). In many primitively eusocial wasps and bees, there are no morphological differences between castes, and reproductive dominance tends to be established by one or a few individuals through behavioral dominance or food restriction, which prevent full reproductive development (West-Eberhard, 1967). In *Polistes* wasps and permanently queenless ants, aggression by the dominant reproductive individual limits both mating opportunities and reproduction of subordinates (Reeve, 1991; Roeseler, 1991; Peeters, 1993; Monnin and Peeters, 1998). However, after reproductive dominance is established, a reduction in aggression levels often is observed, which may be mediated by chemical cues, at least in *Polistes dominulus* (Sledge and Boscaro 2001) and *Bombus terrestris* (Sramkova et al., 2008; Röseler and Van Honk 1990; Amsalem and Hefetz, 2010). In bumble bees, *Bombus terrestris*, direct contact with the queen is necessary for the inhibition of worker reproduction. However, these interactions do not appear to be aggressive in nature (Alaux et al., 2004; Lopez-Vaamonde et al., 2007), suggesting that a contact pheromone that inhibits worker reproduction may be present. In the sympatric, primitively eusocial paper wasp species, *Ropalidia marginata* and *Ropalidia cyathiformis*, it appears that *R. cyathiformis* queens rely primarily on physical aggression to establish reproductive dominance, while *R. marginata* queens appear to use chemicals produced in the Dufour's gland to mediate reproductive dominance, and are not physically aggressive (Kardile and Gadagkar, 2002; Bhadra et al., 2010).

In larger, more derived societies, such as honey bees, vespine wasps, and several species of ants, queen pheromones are used in combination with other types of pheromones (Pettis et al., 1997) and worker policing (Ratnieks and Visscher, 1989) to maintain the reproductive division of labor. As a result, few aggressive interactions are observed among queens and workers (Fletcher and Ross, 1985; although see Smith et al., 2009 for reproductive inhibition by aggression in a highly-eusocial ant). However, detailed studies of these pheromones are rare, and have focused primarily on two species: the fire ant, *Solenopsis invicta* (reviewed in Vargo, 1998), and the honey bee, *Apis mellifera* (reviewed in Le Conte and Hefetz, 2008). Recently, queen pheromones also have been identified in a termite (Matsuura et al., 2010) and in the ant *Lasius niger* (Holman et al., 2010a, b).

Queen Pheromones Cuticular hydrocarbons (CHCs) appear to be associated with reproductive status in primitive and advanced social species and, in some cases, have been shown to function as pheromones. CHCs are a mixture of lipids that cover the insect body to prevent water loss and are modified by genotype, physiology, and environmental factors (reviewed in Howard and Blomquist, 2005). In solitary insects, CHCs may play a role in species recognition and identification of mating partners (Wyatt, 2003). CHCs are also critical for nestmate recognition in many social insect species; because CHCs are sensitive to physiological state, it is possible that their use as individual cues may have evolved into queen recognition cues and/or

fecundity signals (for further discussion, see Hölldobler and Michener, 1980; Hölldobler 1984).

In some halictid bees (*Lasioglossum malachurum*, Ayasse et al., 1993; 1999), paper wasps (*Polistes dominulus*, Sledge and Boscaro 2001), and queenless and ponerine ants (*Dinoponera quadriceps,* Monnin and Peeters, 1998; Peeters et al., 1999; *Diacamma ceylonense*, Cuvillier-Hot et al., 2001; *Harpegnathos saltator*, Liebig et al., 2000; *Gnamtogens menadensis* and *Diacamma* sp., Gobin et al., 1999, Kikuta and Tsuji, 1999), differences in CHC profiles among individuals within a colony correlate with differences in ovarian activation levels. Furthermore, differences in CHCs are associated with reproduction in lower termites. Interestingly, CHCs associated with fertility are similar in lower termites and Hymenopteran species studied, suggesting that these mechanisms may represent convergent evolution in chemical communication (Weil et al., 2009).

In only a handful of cases have CHCs been shown to act as functional pheromones that alter behavior and/or physiology. In the ponerine ant, *Pachycondyla inversa*, both fertile queens and dominant workers (in queenless colonies) produce 3,11-dimethylheptacosane. This compound is detected by antennae of workers, and is associated with individual differences in reproductive status, indicating that it is likely a signal of fertility (D'Ettore et al., 2004) although a behavioral bioassay is necessary to demonstrate true pheromonal activity. In *Lasius niger*, the common garden ant, a single CHC (3-methylentriacontane) inhibits worker ovary activation, decreases worker aggression, and elicits a strong response in worker antennae (Holman et al., 2010b). This same compound is present on queen-laid eggs.

Finally, CHC cues also may be used to discriminate different degrees of reproductive output. For example, in the polygynous colonies of *Formica fusca*, queens of different reproductive status (majority of production, minority of production, no production) exhibited differences in CHC profiles and associated worker responses (Hannonen et al., 2002). Queens with the greatest fecundity received the greatest amount of attention from all workers regardless of kinship.

Queen pheromones also may be composed of more chemically complex blends that can arise from multiple sources, including dedicated glands for pheromone synthesis. In the bumble bee species, *Bombus hypnorum*, queens and workers show significant differences in the amount and proportion of volatiles collected from multiple glandular and cuticular sources, and these differences are associated primarily with differences in ovarian activation levels and caste (Ayasse et al., 1995). Similarly, in *Bombus terrestris,* egg-laying queens have a unique chemical bouquet including certain queen-specific compounds (Sramkova et al., 2008). Honey bee queen pheromone is a blend of chemicals produced by multiple glands, including the Dufour's gland, the tergite glands, and the mandibular glands (Slessor et al., 2005; Le Conte and Hefetz, 2008). Five components, (*E*)-9-keto-2-decenoic acid (9-ODA), (*R*,*E*)-(−)- and (*S*,*E*)-(+)-9-hydroxy-2-decenoic acid (9-HDA), methyl *p*-hydroxybenzoate (HOB), and 4-hydroxy-3-methyoxyphenylethanol (HVA), of this pheromone have been identified (Slessor et al., 1988) in the mandibular glands of mated queens (queen mandibular pheromone or QMP), and together they elicit many of the same responses as a live queen, albeit with less potency.

Honey bee queen pheromone can elicit both primer and releaser responses. Primer pheromones elicit behavioral and/or physiological effects that occur over longer timescales, while releaser pheromones elicit immediate behavioral responses. As a primer pheromone, honey bee queen pheromone modulates worker ovarian activation (Hoover et al., 2003), and inhibits rearing of new queens by workers (Melathopoulos et al., 1996; Pettis et al., 1999). It also delays the transition from nursing to foraging (Pankiw et al., 1998), inhibits juvenile hormone synthesis in workers (Pankiw et al., 1998), influences comb building within the colony (Ledoux et al., 2001), and has effects on worker brain gene expression (Grozinger et al., 2003). As a releaser pheromone, it elicits worker attraction to the queen in the form of a retinue response, in which workers surround, lick, and antennate the queen (Keeling et al., 2003). Queen pheromone also helps to coordinate swarming (Winston et al., 1989). Finally, some components of the pheromone are used to attract drones to virgin queens during mating flights (Brockmann et al., 2006). Thus, components of this pheromone can act both as a sex pheromone and a social regulator.

The queens of the red imported fire ants, *Solenopsis invicta*, produce a pheromone that functions similarly to honey bee queen pheromone, eliciting both primer and releaser responses. It is synthesized in the postpharyngeal glands and the poison sac (Vargo and Hulsey, 2000). As a primer pheromone, it prevents virgin queens from shedding wings and activating ovaries (Vargo, 1998), and prevents mated queens from maturing and producing eggs (Fletcher and Blum, 1981). It also affects caste determination of female larvae (Vargo and Fletcher, 1986a,b, 1987), and it may alter aggression levels of workers toward nestmates and acceptance of newly mated queens (Klobuchar and Deslippe, 2002; Vander Meer and Alonso, 2002). As a releaser, it elicits worker attraction to the queen and induces workers to groom and feed the queen (Vander Meer et al., 1980). Three compounds have been identified that elicit this behavioral (releaser) response (Glancey et al., 1984).

In the termite *Reticulitermes speratus,* two chemicals that affect the reproductive division of labor recently have been identified (Matsuura et al., 2010). These two volatile

compounds, *n*-butyl-*n*-butyrate and 2-methyl-1-butanol, are produced by female neotenics (secondary queens) and suppress the development of additional neotenics within the colony. They also are detected on eggs in a colony. Similarly, in the higher termite, *Zootermopsis nevadensis,* four polyunsaturated alkenes (CHCs) have been associated with reproductive status of both males and females (Liebig et al., 2009).

Evidence for Control vs. Cooperation How these pheromones evolved to resolve reproductive conflicts between workers and queens has been long debated (Seeley, 1989; Keller and Nonacs, 1993; Gadagkar, 1997; Le Conte and Hefetz, 2008; Heinze and d'Ettorre, 2009). Traditionally, two main scenarios have been considered: the 'control' and the 'cooperation' scenario. The 'control' scenario proposes that queen pheromones manipulate workers to prevent them from activating ovaries in situations in which there is queen-worker reproductive conflict. Under this scenario, both the queen and the group benefit because the resources produced by the colony are used to support the reproductive output of the highly fecund queen. However, there is a cost to the individual fitness of workers, since they can compete with the queen to lay (usually male) eggs (Keller and Nonacs, 1993; Gadagkar, 1997). As a result, it has been argued that a 'control' scenario should create inherent conflict between queens and workers, and that it would be evolutionarily unstable and therefore unlikely to be maintained (Keller and Nonacs, 1993).

An alternative model has also been posited (Keller and Nonacs, 1993; Zahavi, 1993; Gadagkar, 1997; Heinze and d'Ettorre, 2009): queen pheromones could serve as an honest signal of the queen's fecundity to encourage worker 'cooperation.' In this case, worker inclusive fitness is increased by cooperation with a healthy, highly fecund queen (Gadagkar, 1997), but the queen signal is linked to reproductive state, allowing workers to detect failing or absent queens and initiate egg-laying in conditions most favorable to their inclusive fitness (Keller and Nonacs, 1993). This situation would reflect an evolutionarily stable strategy (e.g., a strategy that is resistant to cheating or invasion over time) because the interests of queens and workers are aligned. Note that honest signals are hypothesized to exert a cost to the producer, while reliable signals are simply correlated with a specific trait. We will refer to queen pheromone as an honest signal, consistent with previous discussions, even though only a handful of studies have demonstrated a cost to production of these pheromones (see discussion below).

Many subsequent studies have attempted to resolve the 'honest signal' vs. 'control' debate (see Table 1). However, it is important to note that the control and honest signal scenarios can be difficult to disentangle in advanced eusocial species because in some cases both scenarios may result in similar evolutionary outcomes. For example, Keller and Nonacs (1993) predicted a control scenario should result in a chemical arms race between queens and subordinates, and would result in a large number of novel components being incorporated into the pheromone and/or an increasing quantity of pheromone being produced. However, a sophisticated honest signaling system should also require a similarly elaborate system of chemical signals that perhaps are related to different aspects of a queen's physiological state. Thus, differentiating the ultimate causes of pheromone complexity is not possible *post hoc* (see also Le Conte and Hefetz, 2008; Keller, 2009; Alaux et al., 2010). Recognizing this, we outline recent studies that have examined these questions, and also highlight some of the caveats related to their findings.

As previously mentioned, one prediction from a control scenario is that a chemical arms race between queens and workers should result in a highly complex pheromone blend. In honey bees, pheromone signaling by the queen includes a large number of compounds produced by at least three glands (reviewed in Katzav-Gozansky, 2006). Furthermore, the chemical blends produced by the individual glands can have overlapping regulatory functions. For example, both mandibular glands and tergite glands elicit a retinue response and inhibit ovary activation even though there are no common chemicals (Slessor et al., 1988; De Hazan et al., 1989; Wossler and Crewe, 1999a, b; Hoover et al., 2003). However, evolution of such a complex chemical blend also is predicted by an honest signaling scenario, as noted above. Interestingly, honey bee queens have evolved a mechanism to bypass the olfactory system and directly alter worker neurophysiological processes. One of the main components of QMP (HVA) acts as a dopamine agonist in workers (Beggs et al., 2007; Vergoz et al., 2007; Beggs and Mercer, 2009). Moreover, treatment of queenless workers with dopamine enhances ovarian development in workers (Dombroski et al., 2003), suggesting that HVA may inhibit ovarian activation by acting agonistically on the dopamine pathway (Beggs et al., 2007; Beggs and Mercer, 2009), and thus providing evidence for queen control. However, the direct effects of HVA on ovarian activation of workers remain to be tested explicitly (Keller, 2009), with full evidence for queen manipulation requiring demonstration that worker fitness is decreased by the manipulation. Furthermore, if HVA did evolve to co-opt an existing neurophysiological system, the system should be conserved in species of *Apis* in which HVA is not used as a pheromone signal.

Keller and Nonacs (1993) also predicted that workers would likely be under strong selection to escape from the queen's control, perhaps by developing a tolerance or immunity to the pheromone. There is evidence for this in

Table 1 Evidence for signal vs. control signal scenarios in social insects

	Workers should attempt to escape queen control	*Apis mellifera*	Moritz et al., 2002; Kocher et al., 2010b

honey bees, in which there are examples of modified worker response to QMP. In one honey bee strain (the 'anarchistic' bees), there appears to be a modification of worker physiological responses to pheromone (workers activate ovaries in the presence of a queen) rather than a change in worker attraction to pheromone or in queen pheromone production (Hoover et al., 2005). In a second strain, *Apis mellifera capensis*, workers with high reproductive potential are less attracted to the queen, potentially reducing their exposure to queen pheromone (Moritz et al., 2002). Interestingly, these bees and a few additional ant species are capable of thelytokous parthenogenesis; reproductive division of labor among workers in these species also may be maintained by pheromones that are correlated with individual fecundity (Monnin 2006, Heinze and D'Ettorre 2009).

Recent work has demonstrated that there is substantial variation in individual worker responses to queen pheromone within colonies of unselected European honey bees, and that workers within a colony with the highest reproductive potential are the least attracted to QMP (Kocher et al., 2010b). This variation in worker pheromone response implies that some workers are attempting to 'escape' queen pheromone. However, as queen pheromone is spread rapidly through the colony by workers (Naumann et al., 1991), it remains to be determined whether queen avoidance is sufficient for reducing the effects of queen pheromone. Furthermore, individual differences in response thresholds to social cues can optimize colony performance; variation in traits such as the initial onset of foraging or sucrose response may increase colony productivity and success (Beshers and Fewell, 2001; Oldroyd and Fewell, 2007, 2008). Similarly, optimization of colony performance could explain the extent of variation in worker responses to queen pheromone rather than evolutionary pressure to 'escape' queen control.

It also has been predicted that if queen pheromones act as honest signals, they should show an association with queen fecundity or mating number. While this association is not necessarily obligatory because workers could potential-

ly assess the level of eggs and brood throughout a queen's life, the majority of studies have demonstrated that queen-specific chemical blends are indeed associated with dominance or fecundity. Several studies of CHCs in ants, wasps, and termites (see above), have demonstrated that these chemical profiles act as pheromones, and are strongly correlated with ovarian activation level and with aggression in primitively eusocial species. Honey bee queen pheromone appears to be linked with ovarian activation (Kocher et al., 2008, 2009), and workers preferentially perform the retinue response on extracts from queens with the greatest amount of ovarian development (Kocher et al., 2009). Furthermore, insemination quantity affects queen mandibular gland composition, as well as its attractiveness to workers (Richard et al., 2007; Richard, F. J., Tarpy, D. R., and Grozinger, C. M., unpublished data). However, comparisons of virgin, drone-laying, and naturally mated queens, did not reveal differences in relative abundances of the six major compounds in the glands, although there did appear to be some shifts in absolute quantities of several of the main QMP components produced, including HVA (Strauss et al., 2008). Instead, minor components in the glands change in relative abundances and, therefore, may be key components associated with mating quantity/quality in queens and also presumably involved in altered worker retinue responses (Richard et al., 2007; Strauss et al., 2008; Kocher et al., 2009). Variation in inhibitory effects of different blends on worker ovarian development, however, remains to be demonstrated.

Studies in pheromone signaling among groups of queenless workers also support a link between ovarian activation and production of queen pheromones. Honey bee workers with activated ovaries will produce queen-like pheromone signals and engage in pheromonal contests, although laying workers produce much lower quantities of these compounds than do queens (Crewe and Velthuis, 1980; Plettner et al., 1993; Katzav-Gozansky et al., 1997; Moritz et al., 2000, 2004; Dor et al., 2005). In the initial stages of signal production, workers increase the levels of queen-like chemicals produced in mandibular glands and as ovarian activation continues, Dufour's glands secretions also begin to mimic the queen's signals. Mandibular gland secretions appear to be used to establish dominance rankings in the early stages of conflict, while the Dufour's glands appear to be strongly linked to worker ovarian activation (Malka et al., 2008). Notably, reproductively active, queenless honey bee workers (and bumble bee workers) revert back to sterility when the queen is reintroduced (Alaux et al., 2007; Malka et al., 2007) suggesting that an honest signaling mechanism is indeed at work (they do not compete with a fecund queen). However, these studies remain correlational; the exact mechanisms that link pheromone production to ovarian activation remain to be determined (but see Malka et al., 2007, 2009b).

There is also surprisingly little known about the energetic costs of pheromone production (Heinze and d'Ettorre, 2009). There is some evidence of a cost associated with pheromone production in honey bee queens in which the output of queen pheromone is thought to decrease in failing queens; however, this needs to be proven conclusively (Winston, 1987). In fact, in queens infected by *Nosema microsporidia*, quantities of queen pheromone increase (Alaux et al., 2011). On the other hand, recent work has demonstrated that *Lasius niger* queens that are immuno-compromised show a decrease in production of 3-methylentriacontane (Holman et al., 2010b), suggesting that there may be a cost associated with pheromone production at least in this species. Finally, reproductively active honey bee workers (Malka et al., 2008), bumblebee workers (Amsalem et al., 2009; Amsalem and Hefetz, 2010), and workers of the ant, *Aphaenogaster cockerelli* (Smith et al., 2009), produce queen-like pheromone blends and are more likely to be attacked by other workers also supporting a cost to production of pheromone.

The Evolution of Pheromonal Signals Examining queen pheromone production and response in an evolutionary context should improve our understanding of how these types of systems evolved in social insects. It has been suggested that pheromone signals evolved from systems regulating more basal pheromone-mediated behaviors, such as mating and defense, which are found even in solitary lineages of wasps (Blum, 1969). In fact, the main component (9-ODA) of honey bee queen pheromone also is used as a sex pheromone to attract males. However, comparative analyses of the compounds that mediate these activities in solitary species with the compounds that regulate division of labor in social species have yet to be produced. These types of studies have the potential to improve our understanding of how some of these basal pathways have led to the evolution of complex communication systems in social insects.

Analysis of queen pheromones of primitively eusocial species provides important insights into the evolutionary origins of queen pheromones. The primitive systems studied seem to possess simple signals that are linked to fecundity, indicating that early pheromones may have evolved from cues associated with fecundity into honest signals that were reinforced by aggression (see above discussion). As societies increase in complexity, greater caste-differentiation should reduce conflict between queens and workers, and pheromone signals may experience a decrease in selective pressures to maintain costs associated with honesty perhaps evolving into simple signals of queen presence. With increased caste differentiation and functional sterility of workers, the reproductive potentials of queens and workers should be disproportionate, and individuals

would no longer benefit from deceiving nestmates. In this situation, low-cost signals ('cheap-talk') are predicted to evolve (Crawford and Sobel, 1982; Bergstrom and Lachmann, 1998). Because a low level of intracolonial conflict is always maintained, these low-cost signals could be added on to the main pheromone component as reinforcement. As a result, we predict that as social complexity increases, pheromone signals should increase in complexity, associated with either (a) reinforcement of honesty via costs or other mechanisms, or (b) increased arms races between queens and workers. However, it is important to note that other mechanisms, such as worker policing, may also help to reduce conflict in the colony (Ratnieks and Visscher, 1989).

There is some evidence to support these predictions in the honey bee queen pheromone. This blend is highly complex, and includes both stable components (those that do not change in absolute or relative quantities with changes in fecundity) as well as variable components (those that vary with changes in fecundity). It is possible that the stable components of these blends may be evolutionary remnants of the low-cost signals, predicted in ancestral monogamous societies to signal queen presence but not necessarily fecundity. In turn, variable components may be the result of queen-worker conflict, and could vary according to the queen's physiological state and fecundity. Thus, we predict that major components of the blend would be associated with caste differences throughout the phylogeny, and would be relatively conserved across species, while minor components would vary according to the queen's physiological state and fecundity and would demonstrate a higher-degree of species specificity. Studies across the *Apis* phylogeny have demonstrated that major components of queen mandibular pheromone (the acids, 9-ODA, 9-HDA) are conserved across species while less abundant phenolics (HVA and HOB) have been found only in cavity-nesting species (Plettner et al., 1997). The acids are found in workers in all species, while HOB is found at very low levels in laying *Apis mellifera* workers, and HVA is not detected (Plettner et al 1993). These results suggest that different biosynthetic pathways evolved independently and potentially have different functions.

Examination of pheromonal blends across a phylogeny is surprisingly uncommon. Aside from the aforementioned studies in *Apis*, the evolution of pheromone signals in bark beetles and fruit flies also have been examined. In these studies, pheromone composition was superimposed onto a phylogeny to examine the evolutionary history of chemical components to infer the mode of evolution (Symonds and Elgar, 2004, 2008; Symonds and Wertheim, 2005). These studies suggest that in bark beetles, aggregation pheromones evolved through large, saltational shifts in composition, while in fruit flies, composition seems to have evolved more gradually, with closely-related species showing greater compositional similarity than divergent species. Similarly, rapid saltational changes of sex pheromones are associated with speciation in *Bactrocera* flies, followed by gradual divergence thereafter (Symonds et al., 2009). Most recently, the same group completed a study of patterns of worker CHC evolution across 56 ant species, and found that these compounds seem to evolve via gradual changes in pheromone composition as opposed to rapid, saltational shifts (van Wilgenburg et al., 2011). A similar, comparative approach could be used to study chemical communication systems in socially-variable lineages, such as halictid and allodapine bees in which life histories span the full range from solitary to eusocial among closely-related species (see Schwarz et al., 2007, for a detailed review of these systems).

Future Applications: Genomics as a Tool for Studying Chemical Communication Previous studies of chemical communication systems in social insects have relied almost exclusively on classical chemical ecology approaches. However, it is now possible to identify genes associated with pheromone production and perception and to study the evolution of pheromone communication systems at the molecular level using large-scale comparative studies across species. Substantially decreased sequencing costs enable transcriptome or whole genome sequencing of a number of Hymenoptera, including bee species (HGSC, 2006; Sadd et al., 2010; Woodard et al., 2011), paper wasps (*P. metricus*, Toth et al., 2007), three species of parasitic wasps (Werren et al., 2010), and six ant species (Bonasio et al., 2010; Smith et al., 2011a, b; Suen et al., 2011; Wurm et al., 2011). Genome projects are underway for other ant, bee, and wasp species. Genomic tools can be used to identify key genes or gene families (e.g., pheromone receptors) involved in chemical communication. There are several approaches to search for these genes. In some cases, it is possible to search for candidate genes that are homologous to known genes of a similar function in other species. For example, genes likely associated with queen pheromone biosynthesis in honey bees were identified based on sequence similarity to insect cytochrome P450 enzymes (Malka et al., 2009a).

In other cases, homologous genes may not have been identified, or these genes evolve so rapidly (such as olfactory receptors) that it is impossible to predict which ones are involved in detection of pheromones vs. other chemical cues. In such cases, finding candidate genes can be accelerated by monitoring expression patterns associated with a behavioral or physiological state using either microarray technology (Gibson 2003) or RNA-sequencing (RNA-seq; Wang et al. 2009). For example, the honey bee

olfactory receptor, AmOR11, was identified as the receptor for 9-ODA (the major component in honey bee queen pheromone) by using microarrays and subsequently verified by an *in vitro* approach (Wanner et al., 2007). Furthermore, microarray studies of brain gene expression demonstrated that queen mandibular pheromone, brood pheromone, and alarm pheromone alter worker-brain gene expression patterns in a manner consistent with their effects on behavioral maturation (Grozinger et al., 2003; Alaux et al., 2009), suggesting that specific pheromone-responsive gene networks have evolved in the brain to translate pheromonal cues into behavioral changes. Finally, microarray studies have identified expression differences associated with variation in responsiveness to queen mandibular pheromone (Kocher et al., 2010a; Fussnecker et al. in press). These studies were made possible by the completion of the honey bee genome (HGSC, 2006) and development of a genome-wide honey bee microarray. RNA-seq enables the search for transcriptional differences among individuals in any organism, regardless of genome availability and, thus, we expect studies similar to those completed in *Apis mellifera* to become commonplace. This should enable a number of evolutionary questions to be addressed. For example, is regulation of social hierarchies by aggression in primitive species similar to pheromonal regulation of these hierarchies in advanced species?

Transcriptional studies can give some indication of the physiological mechanisms that underlie pheromone production and response and also identify genetic variants involved in chemical communication. These must be done in conjunction with genetic mapping or functional studies that seek to identify causal variants. Traditionally, mapping studies have been limited by an ability to identify a large number of randomly-distributed genetic markers; methods such as microsatellites or AFLPs were too labor intensive to produce. Now, development of microsatellite markers can be completed by using high-throughput technology, such as 454, and completed quickly and efficiently using less than a full run on a 454 machine (Abdelkrim et al., 2009). Furthermore, sequencing of parental colonies of crosses used in linkage mapping also can be used to identify a large number of single nucleotide polymorphisms (SNPs) specific to the base population, and a number of genotyping platforms can be employed to characterize these high-density markers in subsequent generations of the mapping population. Thus, identification and genotyping of a large number of genetic markers is no longer rate limiting, and mapping studies can be completed efficiently in any organism that is easy to rear in the laboratory and which can be readily crossed. Despite these advances, mapping studies for traits associated with chemical communication are surprisingly uncommon. One study identified a single QTL containing four odorant receptors that underlie the perception of reproductively isolating sex pheromones of two *Heliothis* moths, *H. subflexa* and *H. virescens*; the functional importance of the region was confirmed through a combination of behavioral and neurophysiological assays (Gould et al., 2010). Another study identified fixed genetic differences associated with differences in CHC production in males of *Nasonia giraulti* and *Nasonia vitripennis* (Niehuis et al., 2010).

It is important to note that in many non-model organisms, laboratory crosses are not readily produced, liniting the ability to map critical genetic variants. Recently, the field of population genomics has enabled association-mapping studies in natural populations without the need for complex crossing schemes (Stinchcombe and Hoekstra, 2008). Using these tools, one can now address questions of genetic relatedness using the recombination generated in natural, field populations. There are several recent reviews that summarize these approaches (Stinchcombe and Hoekstra, 2008; Nadeau and Jiggins, 2010; Stapley et al., 2010).

Molecular evolutionary approaches can be used not only to identify conserved genes across species, but also to characterize the evolutionary forces affecting these genes. For example, searching for genes that show strong signatures of stabilizing selection within a species, but with high divergence between species that are reproductively isolated via chemical communication, could identify candidate genes underlying pheromonal signaling in the respective species. Furthermore, expansion of these comparative studies across multiple species can determine whether the genes and gene pathways regulating pheromone production, detection, or responses to pheromones are conserved or not. A molecular evolutionary approach then can be applied to characterize the patterns of selection on these genes. By placing these genes in a phylogenetic context, one can test theories about how these pheromones evolve.

Following the identification of candidate loci, functional genomic approaches can be used to characterize these regions via transcriptional studies, mapping approaches, and/or comparative genomic studies. These approaches include RNAi, transgenics, or the use of other functional genomic resources available in traditional genetic model systems (e.g., *Drosophila*; Belles, 2010). For example, several candidate moth pheromone receptors were validated by using heterologous expression systems in *Drosophila melanogaster* to identify or confirm putative ligands (Syed et al., 2006).

The combination of powerful genomic technologies and functional testing of candidate genes promises to improve our understanding of the molecular pathways that underlie pheromone production and response. Moreover, the increased accessibility of these tools will enable studies on the molecular basis of chemical communication in a wider range of taxa.

Analysis of these data within a phylogenetic context will facilitate determination of whether similar genes are involved in regulating chemical communication across species and how far the conservation of these mechanisms persists across evolutionary history. For example, do similar genes regulate chemical communication across all ants or only among closely related species? Are some molecular pathways highly conserved while others are more variable within and between species? Finally, molecular evolutionary approaches will help elucidate the selective forces that have played a role in shaping chemical communication systems.

Conclusions

Elucidation of the factors that led to the evolution of complex chemical communication systems is challenging: it requires characterization of both proximate and ultimate factors underlying pheromone production and response. Recent studies have improved our understanding on both levels. Based on the available data, it appears that honest signals are important in the origin and elaboration of queen pheromone blends. However, we hypothesize that later pheromone blends evolved to have both caste-specific components and components that vary according to reproductive state and health. We have outlined a number of functional approaches that should help elucidate the molecular mechanisms underlying signal production and response, as well as comparative approaches that may be used to dissect some of the ultimate factors leading to these chemical repertoires. Through the combination of these complementary approaches, it should be possible to place these mechanisms in a broader phylogenetic context to understand better the evolutionary history of pheromone-mediated communication.

Acknowledgements We thank Andrew Barron, Laurent Keller, Amy Toth, Etya Ansalem, Jim Hunt, Doug Yu, members of the Grozinger lab, and two anonymous reviewers for helpful discussions and constructive feedback that greatly improved the manuscript. The development of this review was supported by an NSF Doctoral Dissertation Improvement Grant to SDK and NSF CAREER grant to CMG.

2002; Shimada and Saitoh 2006). The countermeasure used by the large Japanese wood mouse *Apodemus speciosus* against acorn tannins has been elucidated (Shimada et al. 2006). Captive wood mice could be acclimated to ingest gradually increasing amounts of tannin, whereas those without acclimation suffered severe damage. Production of tannin-binding salivary proteins and increased activity of tannase-producing enterobacteria were the likely mechanisms of acclimation (Shimada et al. 2006).

Proline-rich proteins (PRPs) are the prevalent types of tannin-binding salivary protein and are produced by the Japanese wood mouse (Shimada et al. 2004). As their name suggests, proline comprises about 20–40% of the amino acids in PRPs (Mehansho et al. 1987; Shimada 2006). PRPs have a high affinity for tannins and are recognized as the first line of defense against tannins in some mammals (Hagerman and Robbins 1993; McArthur et al. 1995). PRPs form stable complexes with tannins in the oral cavity, preventing tannins from interacting with other proteins and from degrading into noxious phenolic compounds (Hagerman and Robbins 1993; Skopec et al. 2004; Shimada 2006). Tannin–PRP complexes are stable in the gastrointestinal tract, and are excreted in the feces (Mitaru et al. 1984; Skopec et al. 2004).

Since some animals can acclimate to tannins, the evaluation of prior exposure is the first step to understanding tannin tolerance in a target species. However, it is difficult to quantitatively estimate tannin intake in wild animals, especially in nocturnal small mammals. Their feeding behaviors are difficult to observe in the field and analysis of stomach or fecal contents cannot provide sufficient information on food items at the species level (Hansson 1970; Tatsukawa and Murakami, 1976; Henry 1999). Therefore, we proposed to develop a new method for estimating tannin intake by wild animals by focusing on the proline content of feces as an index of tannin intake.

The first aim of our study was to develop a method for estimating tannin intake in small, free-living rodents. To achieve this, we examined the relationships between dietary tannin content and fecal proline in a feeding experiment conducted with three sympatric forest-dwelling rodent species, the large Japanese wood mouse *A. speciosus*, the small Japanese wood mouse *A. argenteus*, and the gray-sided vole *M. rufocanus*. We applied this method to the three rodent species in a natural forest in Hokkaido, in the northernmost part of Japan, and we revealed interspecific differences in seasonal changes in tannin intake.

Methods and Materials

Rodent Species The two species of *Apodemus* are endemic to Japan, and *M. rufocanus* is distributed widely from Fennoscandia to eastern Asia. These three species are sympatric in Hokkaido (Ohdachi et al. 2009). The two *Apodemus* species are typical forest-dwelling species, whereas *M. rufocanus* is common in both forests and open habitats (Ohdachi et al. 2009). Adult body mass ranges from 20 to 60 g in *A. speciosus*, 10 to 20 g in *A. argenteus*, and 27 to 50 g in *M. rufocanus* (Ohdachi et al. 2009).

Animals Used *Apodemus speciosus* and *A. argenteus* used in the following experiments were caught in October 2007 in the Nakaimura national forest (Iwate Prefecture, northern Honshu 39°81′N, 141°57′E) and *M. rufocanus* individuals were caught in July 2009 in the Uryu Experimental Forest of Hokkaido University (44°03′N to 44°29′N, 142°10′E to 142°20′E). They were weighed, housed separately in plastic cages with paper bedding (Alpha-dri, Shepherd), and allowed free access to distilled water and food, consisting of laboratory chow (MM-3 designed for laboratory mice and rats, Funabashi Farms) and oats, under regulated environmental conditions (20°C; photoperiod, 12 hL: 12 D) until the beginning of the feeding experiments. All procedures in the field and laboratory were approved by the Animal Experimentation Committee of the Forestry and Forest Products Research Institute.

Feeding Experiments In order to examine the relationships between dietary tannin and fecal proline, we performed feeding experiments using a powdered formula diet that had a nutritional composition similar to that of acorns of *Quercus crispula* and *Quercus serrata* in terms of all major constituents except tannins (hereafter referred to as the basal diet; see details in the work of Shimada and Saitoh 2003). Tannic acid (Wako Pure Chemical Industries) was added to the basal diet at 1, 2, 3, or 4% on a dry weight basis (hereafter referred to as the 1–4% TA diets). These diets were supplied in sequence from the basal diet to the 4% TA diet to 7 animals of *A. speciosus* (April 2008), 5 of *A. argenteus* (April 2008), and 9 of *M. rufocanus* (August 2009). Because the tannic acid was well blended with the basal diet, test animals could not avoid the tannic acid, and the dietary tannin content was assumed to be the tannin intake of the rodents. Each diet was supplied for 5 d; to avoid carryover effects of the prior diet, only the feces excreted during the last 2 d were collected for further analysis.

After the conclusion of the TA trial, all of the mice and 6 of the 9 voles were fed the basal diet for 7 d, hereafter referred to as the tannin-free period. During this period, all feces were collected daily to determine the baseline proline content, namely the fecal proline level when rodents were not ingesting tannin

Estimating Tannin Intake in the Field We tested the method on the three rodent species in their natural habitat. The investigation was performed in the Uryu Experimental Forest, which is located in a cool temperate wet climate zone. The yearly average temperature is 3.5°C, annual precipitation is 1,410 mm, and maximum snow depth is 275 cm. The study site was a natural forest of broadleaf trees and conifers. The dominant tree species were *Acer mono*, *Q. crispula*, *Betula ermanii*, *Sorbus commixta*, *Abies sachalinensis*, and *Picea glehnii.* The undergrowth was dominated by dwarf bamboos, *Sasa senanensis* and *Sasa kurilensis*.

Live trapping was performed for three consecutive days once a month from June to October 2008 using Sherman-type live traps. Species, sex, body weight, and reproductive status were recorded upon capture. In addition, feces left in the trap were collected in a plastic bag and stored in a freezer. Each trap was cleaned with water before and after the trapping survey. Some of the captured rodents were transferred to the laboratory, housed separately at a constant temperature (24°C) in plastic cages with paper bedding, and allowed free access to distilled water and the basal diet. For estimating tannin intake, it is necessary to adjust the regression equations for fecal proline to dietary tannin using the baseline fecal proline content (see results). Thus, all feces from the rodents transferred to the laboratory were collected daily for 7 d after rodent capture to determine the baseline.

Chemical Analyses All chemicals used were of either analytical grade or the highest purity grade available. All feces were freeze-dried, milled with a mortar and pestle, and stored in a desiccator until analyzed.

Proline contents were estimated by using the method of Skopec et al. (2004). Briefly, samples (about 20 mg) were hydrolyzed at 110°C for 20 h under nitrogen with 400 μl of 6 N HCl containing 1% phenol. After hydrolysis, the contents were filtered and diluted to 20 ml with distilled water. To remove HCl, 200 μl of the sample were evaporated, the residue was dissolved with 100 μl of distilled water, re-evaporated, and redissolved in 200 μl of distilled water. A 100 μl aliquot was mixed with 400 μl of 1% ninhydrin solution, incubated at 100°C for 1 h, cooled and analyzed at 520 nm using a microplate reader. The method was standardized with a series of standard proline solutions (0–200 μmol/l) and concentrations of proline were expressed on a dry weight basis.

Data Analyses To examine the relationship between fecal proline content and dietary tannin content, linear mixed model regression analyses were conducted; proline in fecal contents was regressed against dietary tannins, and individual rodent ID was considered as a random effect. The 95% confidence and prediction limits also were estimated. To examine the pattern of decline of fecal proline content, linear mixed model ANOVA (with individual rodent ID as a random effect) was performed. Multiple comparisons were conducted with Tukey-Kramer's HSD test.

Tannin intake in the field was estimated by using the regression equations obtained in the feeding experiment. The regression equations were adjusted in accordance with the baselines estimated for each species and for each month. Differences in these baselines were examined by two-way ANOVA (with species and month as fixed effects). Seasonal changes in fecal proline and tannin intake in the three rodent species captured at the study site were analyzed with one-way ANOVA, and multiple comparisons were conducted with Tukey-Kramer's HSD test. All statistical analyses were conducted with the JMP 8 statistical package.

Results

Relationship between Dietary Tannins and Fecal Proline Linear mixed model regression analyses revealed significant positive relationships between dietary tannins and fecal proline in all three rodent species (Table 1 and Fig. 1). The coefficients of determination were high in the two *Apodemus* species (*A. speciosus*, R^2=0.791; *A. argenteus*, R^2=0.888). Unlike in the two *Apodemus* species, the fecal proline content in *M. rufocanus* was slightly lower with the 4% TA diet (mean ± SE, 0.73±0.08) than with the 3% TA diet (0.79±0.06). Therefore, we examined another model in which dietary tannin was limited to 3%, and all of the results obtained with the 4% TA diet were omitted from the analysis. The coefficient of determination was much higher in the limited proline model (R^2=0.885) than in the original proline model (R^2= 0.594).

Fecal proline content decreased in all three species after the supply of dietary tannins was stopped. The fecal proline content on day 1 of the tannin-free period was 13.7% lower than it was on the 4% TA diet in *A. speciosus*, 16.6% lower in *A. argenteus*, and 32.6% lower in *M. rufocanus* (Fig. 2). Fecal proline content reached a minimum by day 3 in *A. speciosus* and *A. argenteus*, and by day 1 in *M. rufocanus* (Fig. 2).

Regression Equations for Estimating Tannin Intake Based on the above results we chose the proline content on day 5 of the tannin-free period as the baseline for each species. Thus, the baselines (means ± SE) in this experiment were 0.57%±0.04% in *A. speciosus*, 0.69%±0.05% in *A. argenteus*,

Table 1 Summary of results of linear mixed model regression analyses

Species	No. of rodents	Response variable	*N*	R^2	Estimation of parameters (± SE)	
					Intercept	Dietary tannins (%)
Apodemus speciosus	7	Proline	35	0.791	0.68±0.08***	0.21±0.02***
Apodemus argenteus	5	Proline	25	0.888	0.84±0.07***	0.31±0.03***
Myodes rufocanus	9	Proline (Dietary tannin level: 0–4%)	45	0.594	0.46±0.05***	0.09±0.02***
		Proline (Dietary tannin level: 0–3%)	36	0.885	0.41±0.04***	0.14±0.01***

* $P<0.05$; ** $P<0.01$; *** $P<0.001$

and 0.34%±0.02% in *M. rufocanus.* The regression equations were adjusted as follows:

$$Pf' = 0.11+(0.21 \times Ti)(\text{for } A.\ speciosus)$$
$$Pf' = 0.16+(0.31 \times Ti)(\text{for } A.\ argenteus)$$
$$Pf' = 0.07+(0.14 \times Ti)(\text{for } M.\ rufocanus)$$

Pf' (%) denotes the difference between the observed fecal proline content (*Pf*) and the baseline, and *Ti* is the tannin intake (% TAE). Tannin intakes in the field were estimated according to these equations based on the observed *Pf* and baseline values.

Seasonal Changes in Estimated Tannin Intake The number of rodents caught in each month ranged from 0 to 10 for each species. No *A. speciosus* were captured in June. Fecal proline content in *A. speciosus* and *A. argenteus* increased in autumn (Fig. 3). This pattern was significant in both species (one-way ANOVA; *A. speciosus,* $F_{3,\ 15}=7.84$, $P<0.001$; *A. argenteus,* $F_{4,\ 24}=11.3$, $P<0.001$). Multiple comparisons also revealed that the fecal proline content in October was significantly higher than in the other months (Fig. 3). Fecal proline content in *M. rufocanus* also exhibited a seasonal change (one-way ANOVA, $F_{4,\ 34}=3.07$, $P=0.029$); the content was significantly but only slightly higher in October than in August (Fig. 3).

The baselines (i.e., fecal proline content on day 5 of feeding of the basal diet) differed significantly among species but not among months (two-way ANOVA; effect of species: $F_{2,\ 53}=13.8$, $P<0.001$; effect of month: $F_{4,\ 53}=0.989$, $P=0.422$; Table 2). Overall, these baselines were higher than those obtained in the feeding experiment, especially in *M. rufocanus*, in which the baseline fecal proline content in the field was even higher than the fecal proline content during feeding of the diet including tannins (Fig. 1c).

Estimated tannin intake varied significantly among seasons in the three rodent species (Fig. 3; one-way ANOVA; *A. speciosus,* $F_{3,\ 15}=17.1$, $P<0.001$; *A. argenteus,* $F_{4,\ 24}=8.93$, $P<0.001$; *M. rufocanus*, $F_{4,\ 34}=9.03$, $P<0.001$). Estimates in *A. speciosus* increased in September and October (Fig. 3a). Those in *A. argenteus* were almost zero from June to September and then increased significantly in October (Fig. 3b). Although estimated tannin intake in *M. rufocanus* fluctuated largely during the observation period, it was mostly below zero and did not show autumnal increase (Fig. 3c). Estimated tannin intake in *M. rufocanus* did not exceed 3% (the upper limit of the model), except in one case in October (3.46%).

Discussion

The feeding experiments demonstrated that tannin intake could be estimated from fecal proline content in the three rodent species examined. To determine the validity and limitations of this method for estimating tannin intake in the field, we investigated the mechanisms underlying the observed relationships.

Relationship between Fecal Proline and Tannin Intake The fate of tannins after their ingestion is not fully understood. Nonetheless, it is recognized that some tannin fractions are bound into insoluble complexes with proteins and other biopolymers in the gut, and some are metabolized by processes such as hydrolysis and glucuronidation (Waterman and Mole 1994; Makkar 2003). Consequently, the feces contain tannin–protein complexes, degraded phenolics, and various metabolic derivatives of tannins.

Tannin–PRP complexes are stable in the gut, and are excreted in the feces (Mitaru et al. 1984; Skopec et al. 2004). Although some of these complexes may be degraded by the action of tannase-producing enterobacteria (Shimada et al. 2006), this degradation affects the structure of the tannins and not the PRPs (Aguilar et al. 2007). Thus, it is likely that the feces contain most of

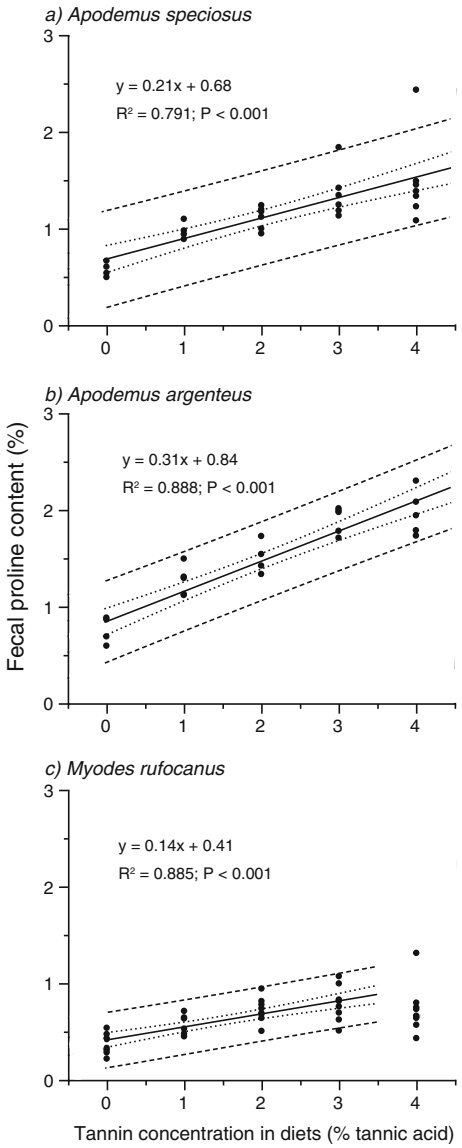

Fig. 1 Relationships between tannin concentration in the diet and fecal proline content in the three rodent species given a powdered formula diet including different levels of tannic acid: **a**) *Apodemus speciosus*, **b**) *Apodemus argenteus*, and **c**) *Myodes rufocanus*. Solid, dotted, and dashed lines represent the regression line, 95% confidence limits, and 95% prediction limits, respectively. The regression line for c) *M. rufocanus* was constructed by using only those results for 0% to 3% intake of tannin

the proline from the tannin–PRP complexes, and that there is a positive relationship between dietary tannin content and fecal proline. Provided that the animal produced enough PRPs to bind the dietary tannins, the amount of tannin–PRP complex would be proportional to the amount of tannins ingested.

Validity and Limitations of this Method This novel method of estimating tannin intake from fecal proline content is useful for several reasons. First, it has sufficiently high predictability for practical use, as shown by the coefficients of determination (Table 1). Second, this method allows us to estimate tannin intake only from the fecal concentration of proline. In other words, we do not need to know the total amount of proline excreted in a day or unit time, which would be difficult to estimate in a free-living animal. This point is especially useful in the field. Third, the method is noninvasive. Finally, considering the underlying mechanisms of this method, it may be applicable to a variety of mammals that induce PRPs to accommodate dietary tannin. The relationship between dietary tannin and fecal proline content would need to be examined in each species. Mammals that have been confirmed to produce PRPs include rodents, which can induce PRPs by ingesting tannins (Shimada 2006). Some species constitutively produce PRPs at high levels (Oppenheim et al. 1971; Austin et al. 1989). The method would not be useful in cases where PRPs are not induced by dietary tannin.

There are some limitations to this method. First, to obtain accurate estimations, feces collected from captured animals

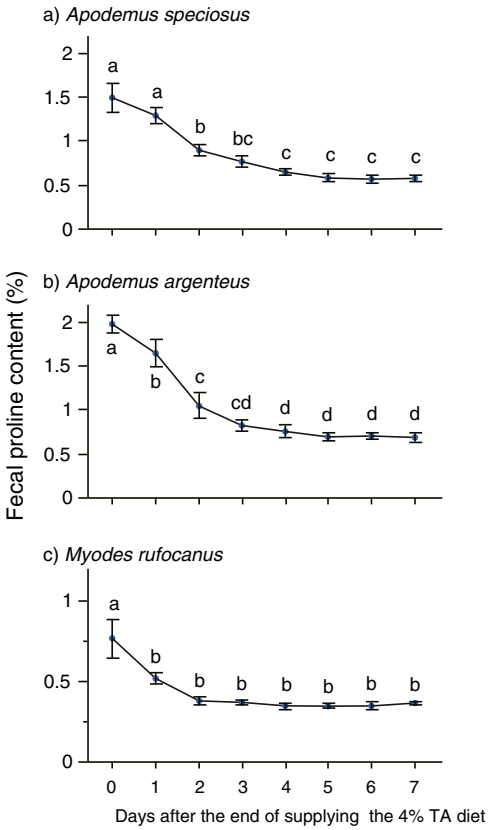

Fig. 2 Changes in fecal proline content (% ± SE) in the three rodent species: **a**) *Apodemus speciosus*, **b**) *Apodemus argenteus*, and **c**) *Myodes rufocanus*. Rodents were fed the basal diet for 7 days after the conclusion of the 4% TA (tannic acid) diet. Different letters indicate significant differences by Tukey-Kramer' s HSD test. Note that the scales on the vertical axes differ among the panels

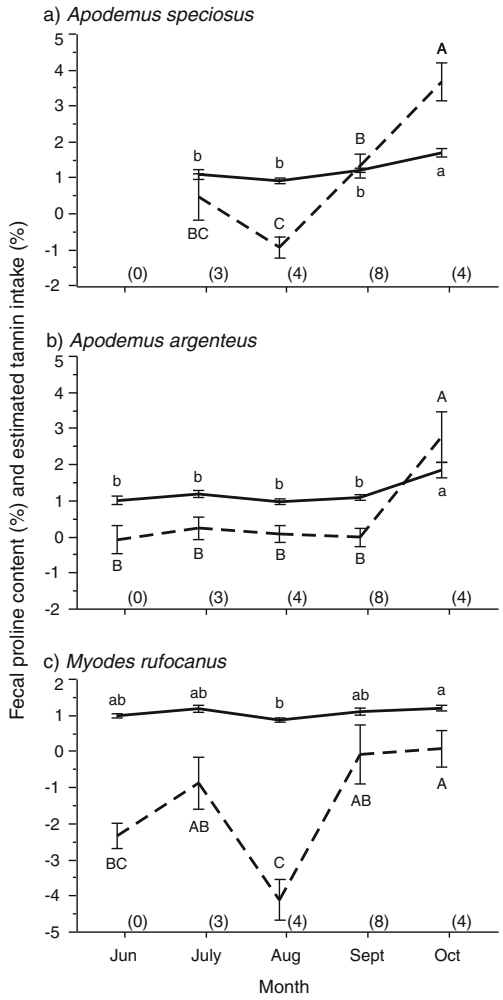

Fig. 3 Changes in fecal proline content (solid line,% ± SE) and tannin intake level estimated based on fecal proline content (dashed line,% TAE ± SE) in the three sympatric rodent species caught in the field (Uryu Experimental Forest, Hokkaido University): **a**) *Apodemus speciosus*, **b**) *Apodemus argenteus*, and **c**) *Myodes rufocanus*. Different letters indicate significant differences by Tukey-Kramer' s HSD test. Numerals in parentheses denote numbers of sample rodents

on laboratory diets should not be used to assess field diets. We found that fecal proline content decreased steeply after the animals were supplied with a tannin-free diet (Fig. 2). The second limitation is related to the baseline values of fecal proline. Ideally, the basal diet should yield a constant baseline level of proline. However, the values obtained with the basal diet varied not only among species but even within a species. Although we have no firm theories to explain this, it is possible that the long period of time that the animals were kept in the laboratory might have influenced the results. The intervals from capture to the feeding experiments were 6 months in the *Apodemus* species and 1 month in *M. rufocanus*. Assuming that fecal proline content could be influenced by physiological factors such as bacterial flora and metabolic status, these long intervals could have altered the synthesis or metabolism of proline. When this method is applied to free-living animals, it is necessary to measure the baseline in each case.

Finally, the validity of this method was confirmed only for tannic acid (a non-uniform mixture of gallotannins), but not for other types of tannins. On the basis of their chemical structures, tannins can be divided into two major groups: condensed and hydrolyzable (Yoshida et al. 2005). Hydrolyzable tannins are further divided into galloyl glucoses, gallotannins, and ellagitannins. These types of tannins differ in characteristics such as the ability to bind proteins (Mehansho et al. 1987), the sensitivity to hydrolysis (Waterman and Mole 1994), and the susceptibility to oxidation (Salminen and Karonen 2011). The regression equations relating fecal proline to dietary tannin would probably be different if another type of tannin were used as the standard. It clearly is important to compare the tannin intake level estimated by this method to tannin content and types of tannins in likely food plants when applying this method. Accordingly, the estimations would be more accurate if the tannins used as the standard were isolated from each of the main food plants for each herbivore.

Table 2 Baseline fecal proline contents (mean ± SE) in the three sympatric rodent species captured in Uryu Experimental Forest, Hokkaido University

Species	June	July	August	September	October	Mean ± SE
Apodemus speciosus		0.87	0.99±0.06	0.80±0.10	0.79±0.09	0.89±0.12 [a]
	(0)	(1)	(2)	(5)	(3)	(11)
Apodemus argenteus	0.89±0.06	0.94±0.06	0.78±0.04	0.92±0.21	0.82±0.06	0.88±0.09 [a]
	(3)	(5)	(4)	(4)	(5)	(21)
Myodes rufocanus	1.22±0.11	1.22±0.04	1.34±0.09	1.03±0.20	1.10±0.08	1.21±0.09 [b]
	(5)	(6)	(7)	(5)	(5)	(28)

Figures in parentheses represent numbers of rodents used for estimation of baselines. Different superscripts indicate significant differences by Tukey-Kramer' s HSD test.

Previous approaches to estimate tannin intake in free-living animals required two steps; first, to identify food plants of a target species by direct observation or analyses of stomach or fecal contents; and then to establish the amount of tannin contained in each food plant. However, it is difficult to quantitatively estimate tannin intake by this approach in small mammals, especially in nocturnal ones, because their feeding behaviors are hard to observe in detail in the field and food items from stomach or fecal contents can be hard to identify at the species level (Hansson 1970; Tatsukawa and Murakami, 1976; Henry 1999). Despite its limitations, the fecal proline method is an innovative tool for evaluating tannin intake in free-living animals that cannot be studied by more direct approaches.

Seasonal Changes in Tannin Intake in the Field Estimated tannin intake increased significantly in autumn for the two *Apodemus* species. The diets of the *Apodemus* species are predominantly granivorous and subdominantly insectivorous (Ohta et al. 1959; Tatsukawa and Murakami 1976). It is well documented that theses species forage heavily on acorns in autumn (Miyaki and Kikuzawa 1988; Takahashi et al. 2007), and that the study year, 2008, was a mast year for *Q. crispula*. The autumnal increase in tannin intake in *Apodemus* species may result from the mice eating acorns. This implies that acorns played an important role as sources of tannins in *A. speciosus* and *A. argenteus*, at least at this site in this year. *Myodes rufocanus* feeds mainly on green plants (Ohta et al. 1959; Ohta 1984). Contrary to the results of the *Apodemus* species, estimated tannin intake in *M. rufocanus* was close to zero throughout the year indicating that this species rarely ingests tannins in this habitat.

These findings are in good agreement with analyses of rodent population dynamics at this study site. In this area, the Field Science Centre of Hokkaido University has monitored the abundance of rodents and of acorns of *Q. crispula* since 1992, and Saitoh et al. (2007) examined the relationships between the population dynamics of the three species and acorn abundance. They found that the influence of acorn abundance on the population dynamics is large in *A. speciosus*, moderate in *A. argenteus*, and small or nonexistent in *M. rufocanus* (Saitoh et al. 2007). This consistency with field data further emphasizes the validity and usefulness of our novel method for estimating tannin intake in free-living rodents.

Acknowledgements We are grateful to M. M. Skopec for providing the protocol for fecal proline analysis and three anonymous reviewers for their valuable suggestions on the manuscript. We also thank M. Hiraide for helpful suggestions on proline analysis, Y. Sasaki, M. Kashiwagi, M. Saitoh, and K. Ohnishi for assistance with laboratory work, and the staff of the Uryu Experimental Forest, Field Science Center, Hokkaido University, for providing support for the field investigation. Funding was provided by Grants-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan [19380091 and 21380101 to T. Shimada].

of protein by half. However, both theoretical analysis (Moran and Hamilton, 1980) and experimental studies (Kuijper et al., 2004) have concluded that reduced protein digestibility is likely to cause compensatory feeding in small mammals (Meyer et al., 2010), and therefore, an increase in daily intake by herbivores. Compensatory feeding is likely in the case of ceacalids, such as the snowshoe hare, that rapidly pass plant biomass through the gut (Kuijper et al., 2004; Stott, 2008). Therefore, an alternative mechanism is needed to explain the negative effects of birch resin on intake by hares.

Hares may reduce intake to maintain concentrations of toxic PSMs below a deleterious threshold in the blood (Wiggins et al., 2003; Boyle et al., 2005; Sorensen et al., 2005; McLean and Duncan, 2006; Mclean et al., 2007; Torregrossa and Dearing, 2009). For example, in no-choice feeding trials with PA-rich CAG twigs of juvenile *B. neoalaskana*, food intake was reduced sufficiently that the hares would rapidly starve to death if an alternative, PA-free, food was not available (Reichardt et al., 1984).

Rigorous testing of the toxicity hypothesis requires knowledge of the presumed toxin's mode of action (MOA) and the concentration of PSM that elicits toxicity and ultimately reduces intake. The link between concentration (pharmacokinetics) and the MOA that elicits a response (pharmacodynamics) is at the heart of the field of pharmacology, and it is used to predict variable response of individuals and populations of humans to drugs (McLean and Duncan, 2006; Sorensen et al., 2006). Likewise, ecologists are typically interested in predicting the variable response of populations of herbivores to plants. In the case of birch and snowshoe hares, there is correlative evidence that populations of birch and hares are involved in a biochemical interaction that has resulted in a mosaic of co-evolution (Bryant et al., 1994, 2009; Swihart and Bryant, 2001). Yet, as is the case in the majority of studies on interactions between plants and vertebrate herbivores (Provenza et al., 1994; Provenza, 1995; Lawler et al., 1998; Forbey and Foley, 2009; McLean et al., 2009), the MOA for chemicals in birch has not been investigated in hares. We propose that pharmacological approaches that reveal the MOA of PSMs (Forbey and Foley, 2009; Sotka et al., 2009) will help ecologists scale up variation observed in plant chemistry and tolerance to PSMs by herbivores from individuals to populations.

Our objective was to use the birch-snowshoe hare system to identify the MOA of the resinous dammarane triterpene, papyriferic acid. This study builds on recent evidence that the MOA of PA in domestic rabbits, laboratory rats, and oxen involves uncompetitive inhibition of succinate dehydrogenase (SDH, McLean et al., 2009). Succinate dehydrogenase is part of both the citric acid cycle and respiratory electron transfer chain in mitochondria (Rutter et al., 2010). Inhibition of SDH interferes with cellular energy production and may be detrimental to health of animals (Wallace and Starkov, 2000). We tested our hypothesis that PA inhibits snowshoe hare SDH in a dose-dependent manner by measuring the effect of PA on the oxidation of succinate in mitochondria isolated from wild hares. In addition, we used molecular modeling to examine the hypothesis that PA inhibits SDH by binding to the ubiquinone sites on complex II.

Methods and Materials

Chemicals Papyriferic acid was prepared from the ether extract of the resin of CAG twigs of winter-dormant *B. neoalaskana* saplings (Reichardt, 1981). Authenticity of PA was confirmed by using ^{1}H NMR with a standard Triple Resonance Inverse probe (Bruker Biospin, Billerica, MA, USA) and Quadrupole Time of Flight mass spectrometry (Q-TOF, Bruker Daltonics, Billerica, MA, USA). The molecular mass (604.367 Dalton) and the ^{1}H spectral data were in agreement with data previously reported for PA (Reichardt, 1981). All other chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA) or Fisher Scientific (Pittsburg, PA, USA) and were of ACS grade.

Laboratory Animals Six-week old male Wistar rats and C57Bl/6 mice were purchased from Simonsen Laboratories (Gilroy, CA, USA). Animals were housed in polycarbonate cages and provided with an NIH-07 diet and water *ad libitum* for 7 d prior to tissue collection. Rats and mice were anesthetized with isoflurane and sacrificed by cervical dislocation. Upon dissection of each euthanized animal, the liver was perfused with 10 ml ice cold 0.9% NaCl. Samples were snap-frozen in liquid nitrogen and stored at −80°C until use. The experiments were approved by the Boise State University Institutional Animal Use and Care Committee (006-AC10-002).

Snowshoe Hares Snowshoe hares were trapped near the Bonanza Creek Experimental Forest, approximately 20 km SW of Fairbanks, AK, USA (64° 41′ 37″ N, 148° 17′ 30″ W) using #3 Havahart live-traps baited with 300 g of fresh carrots and alfalfa cubes. The hares were sacrificed near the site of capture using cervical dislocation, and liver samples were collected immediately from each animal and snap-frozen in liquid nitrogen. Samples then were transported in a liquid nitrogen dry shipper and stored at −80°C until use. The hare experiments were approved by the Boise State University and University of Alaska-Fairbanks Institutional Animal Use and Care Committees (006-AC10-004 and 130970–5, respectively).

Mitochondria Preparation Mitochondria were prepared by thawing liver samples on ice and rinsing the tissue with cold 0.9% NaCl solution to remove blood. Tissues were cut into small pieces, homogenized in 5 volumes of isolation buffer containing 0.32 M sucrose, 1 mM EDTA, 10 mM Tris, pH 7.4, and centrifuged for 10 min (1000×g, 4°C). Supernatants were transferred to clean vials and centrifuged for 15 min (12000xg, 4°C), followed by washing the pellets with isolation buffer and recentrifuging for 15 min (12000xg, 4°C). The final pellets from the same animal were resuspended in isolation buffer, pooled, and stored at −80°C until use.

Succinate Dehydrogenase (SDH) Activity Assay SDH activity was determined as described previously (Rosen et al., 1987; McLean et al., 2009) with adaptations for a 96-well format. Different concentrations of succinate (0–10 mM) were incubated with mitochondria to examine the enzyme kinetics of SDH with and without the addition of various concentrations of PA (10, 40, 80, and 160 μM). A single concentration of malonic acid (MA, 80 μM), a competitive inhibitor of SDH (Wojtovich and Brookes, 2008), was used as a control. In a 96 well plate, 5 μl of mitochondrial preparation were mixed with 5 μl of buffer containing the desired concentration of PA or MA and 220 μl of reaction media containing 2, 6-dichlorophenol indophenol (DCPIP) and sodium azide. The mixture was incubated for 5 min at 37°C before initiating the reactions by the addition of 20 μl of buffer that contained the desired concentration of succinate. The total volume of the reaction mixture was 250 μl, and the final concentrations of DCPIP and sodium azide were 100 μM and 4 mM, respectively. Immediately after the addition of succinate, the plate was placed in a BioTek Synergy MX plate reader (BioTek, Winooski, VT, USA) pre-heated to 37°C, and reaction rates were measured for 3 min at 600 nm. Protein content of the mitochondrial preparations was measured with a Bio-Rad DC protein assay kit (Bio-Rad, Hercules, CA, USA) following the manufacturer's instructions. The reaction rates for each experiment were normalized by protein concentrations and expressed as ΔAU/min/mg protein.

Molecular Modeling We used molecular docking to predict the predominant binding mode(s) of PA with SDA. Successful docking methods search high-dimensional spaces of proteins and use a scoring function that ranks candidate dockings of compounds (i.e., ligands) to the protein. Docking can be used to virtually screen a large number of compounds, rank the results, and propose structural hypotheses that describe how the compounds interact with the target protein. A typical docking experiment involves computationally preparing the protein and the ligand, running the docking software, and evaluating the results. Advanced descriptions and specific methods used in our experiment are described in Supplementary Material 1.

In general, we prepared the mitochondrial respiratory membrane protein complex II (C-II) for molecular docking experiments by obtaining the crystal structure of the protein and using standard approaches to optimize the protein for docking. C-II contains four proteins, the flavoprotein containing the SDH enzyme domain (Chain A, SDHA), the iron-sulfur protein (Chain B, SDHB), the large (Chain C, SDHC; cytochrome b large, CybL) and small (Chain D, SDHD, CybS) trans-membrane proteins. Chains B, C, and D are relevant to binding of ubiquinone, a natural substrate for C-II.

The compounds 2-thenoyltrifluoroacetone (TTFA), ubiquinone-5 (UbQ), α-tocopheryl succinate (TOS), and PA were prepared for docking by using steps similar to those used to prepare the protein. The co-crystal structure coordinates of TTFA and UbQ (Sun et al., 2005) were chosen to validate docking experiments (Supplementary Material 1). In addition, the predicted UbQ binding free energy provides a natural substrate reference to compare to the binding strength of PA. The binding energy for TOS, a known inhibitor of the UbQ binding sites in C-II (Dong et al., 2008), was used in the docking experiment for comparison. Grid maps were created using AutoGrid version 4.2 (Morris et al., 2009) to describe interaction energies for each compound with SDH, one for each atom type in the compound. An affinity grid was created that centered on the protein ubiquinone binding site on C-II, specifically the proximal (Qp) and distal (Qd) sites.

AutoDock version 4.2 (Morris et al., 2009) with the Lamarckian genetic algorithm was used to simulate compound-SDH docking. TTFA was used as a positive control to optimize docking parameters to the Qp and Qd sites of C-II (PDB code 1ZP0). Conformational clustering was used to determine how often a given binding mode was predicted across all the dockings that were run. Docking results were obtained from the lowest binding energy conformations of the most populated cluster. The final docked structures were visualized by using visual molecular dynamics (VMD, Humphrey et al., 1996).

Statistical Analysis Reaction velocities and enzyme kinetics were determined using Microsoft Excel. V_{max} and K_m of the enzyme reaction were derived from Lineweaver-Burk plots. The inhibition constants (K_{iEIS}) were derived from the intercepts on axis of the secondary plots of $1/V_{max}$ vs. inhibitor concentration. The initial experiments indicated that the reaction rate reached maximum velocity with 5 mM succinate in the incubation mixture. Thus, 10 mM succinate was used to ensure enough substrate in the reaction to examine inhibition by PA at various concentrations (10–

160 μM). Percent inhibition by PA or MA was calculated for each inhibitor treatment. V_{max} (without inhibitor) or apparent $V_{max\ app}$ (with inhibitor), K_m (without inhibitor) or apparent $K_{m\ app}$ (with inhibitor), K_{cat}/K_m (catalytic efficiency), K_{iEIS}, and percent inhibition were compared among animal species within inhibitor treatments and within animal species among inhibitor treatments using a one-way analysis of variance (ANOVA). Tukey post-hoc tests were used for comparisons among multiple groups, and Dunnett post-hoc tests were used for comparison between treatments and control. The level of significance was $P<0.05$. Data for V_{max}, K_m and K_{iEIS} are presented as mean±standard error of the mean (SEM).

Results

Kinetics of SDH from Liver Tissues Excellent linearity was observed for progress curves during the 3 min period monitored. There was negligible reaction when succinate was omitted from the incubation mixture. The reaction rate increased with increases in succinate concentration and reached a maximum velocity at 5 mM succinate. Significant differences in V_{max} and K_m were observed among hares, mice, and rats (Table 1). The catalytic efficiencies (k_{cat}/K_m) for the enzyme from snowshoe hares and mice (18.6±1.5 and 15.9±0.9 min^{-1} mM^{-1}, respectively) were higher than the value for rats (13.5±0.6 min^{-1} mM^{-1}). Significant differences in $V_{max\ app}$ were observed among snowshoe hares, mice, and rats for all inhibitor treatments (Table 1). The $K_{m\ app}$ was significantly lower for enzyme from rats compared to enzyme from mice or snowshoe hares at low concentrations of PA, but the $K_{m\ app}$ did not differ when PA was 40 μM or higher or when MA was the inhibitor (Table 2). No difference was found between $K_{m\ app}$ for enzyme from snowshoe hares and mice for any inhibitor treatment.

Inhibition of SDH by PA All concentrations of PA (10–160 μM) inhibited SDH from all three animal species (Supplementary Material 2). PA appeared to act as an uncompetitive SDH inhibitor as indicated by the similar slopes in the Lineweaver-Burk plots (Supplementary Material 3). MA acted as a competitive inhibitor (Supplementary Material 3). Incubation with even very low concentrations of PA (10 μM) decreased $V_{max\ app}$ in a concentration-dependent manner in all animal species (Table 1). Similar patterns also were found for $K_{m\ app}$ (Table 2); K_m decreased with increasing concentration of PA, but $K_{m\ app}$ increased in the presence of MA.

The secondary plot of $1/V_{max}$ vs PA concentrations was linear for the enzyme from all animal species (Supplementary Material 4), confirming that PA is an uncompetitive inhibitor of SDH. The intercept on the X-axis of this plot indicates that K_{iEIS} for snowshoe hares (54.2±6.3 μM), mice (74.8±2.2 μM), and rats (106.7±1.4 μM) differ significantly ($P<0.05$; One-way ANOVA with Tukeys HSD test). SDH from snowshoe hares was more susceptible to PA inhibition (i.e., lower K_{iEIS}) compared to mice and rats (Supplementary Material 4).

The percent inhibition of SDH activity by PA was dose-dependent in all species (Fig. 1), with the enzyme from snowshoe hare most susceptible to inhibition. The inhibition of SDH by 80 μM MA was comparable to inhibition by 40 μM PA, but was significantly lower than inhibition by 80 μM PA, indicating that PA is a stronger SDH inhibitor than MA (Fig. 1).

Table 1 Maximal velocities of succinate dehydrogenase from liver mitochondria of snowshoe hares, C57BL/6 mice, or Wistar rats. Velocities (AU/mg protein/min) were determined in the presence ($V_{max\ app}$) or absence (V_{max}) of the inhibitors papyriferic acid (PA) or malonic acid (MA)

Inhibitor	Snowshoe hares	Mice	Rats

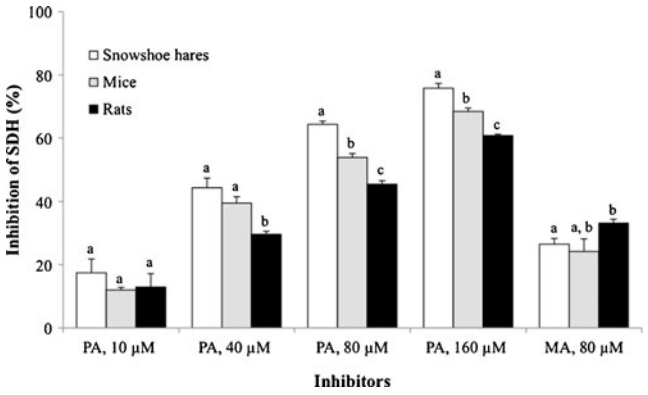

Fig. 1 Inhibition of SDH from snowshoe hares, C57BL/6 mice, and Wistar rats by papyriferic acid (PA) or malonic acid (MA). Inhibition is calculated as a percent of the activity of control samples from the same species. Values represent mean±SEM of 4 animals for PA and 3 for MA. Different letters indicate significant differences in means between species for an individual treatment ($P<0.05$; *Tukeys HSD test*)

Molecular Modeling When evaluating the results of docking, the main criterion to consider is how well the binding mode predicted by the docking matchs structural data, where available. TTFA was used as a positive control to show that AutoDock 4.2 is able to emulate experimental binding with an acceptable degree of accuracy and precision, and to validate further docking experiments with other inhibitors. Specifically, TTFA was re-docked to the proximal UbQ-binding site (Qp) and the distal UbQ-binding site (Qd) of C-II crystal structure (Fig. 2). The overall root mean square deviation of the predicted binding pose compared to the crystal structure pose is 2.67 Å for the Qp site and 2.81 Å for the Qd site. The differences between docked and crystal poses lie primarily in the placement and orientation of the thenoyl group, which is thought to interact with both binding sites through mediating water molecules. Additionally, UbQ was re-docked back to the Qp site. The docked quinone ring coordinates are in good agreement with those in the crystal structure (PDB code 1ZOY, Fig. 2).

Molecular modeling reveals that PA binds to both Qp and Qd sites in a fashion similar to TOS (Fig. 3). In the Qp site, the carbocyclic rings of PA reside in the same binding groove as the phenyl ring of TOS. The carboxylate groups of PA and TOS reside in the central binding pocket where the UbQ ring and the TTFA thenoyl ring are bound, making hydrogen bonds and electrostatic contacts with SER42 and ARG46, and interacting with TYR91 through bridging water. Similar to the isoprenoid tail of UbQ, the remaining hydrophobic side chain of TOS loops around the hydrophobic binding grooves adjacent to the central binding pocket. In contrast, PA adopts a horizontal configuration due to the favorable polar interactions between the carbocyclic ring ester and hydroxyl groups and ARG93, TRP173, and ASN174 residues.

In the Qd site, the carbocyclic rings of PA and the phenyl ring of TOS bind in the same location where the thenoyl ring of TTFA binds, at the center of the binding site. The succinate ester moieties of PA and TOS extend towards the bottom of the binding site. The end carboxylate groups of PA and TOS nearly overlap, indicating key electrostatic interactions and hydrogen bonding with positively charged LYS135 and LYS128 residues. Due to its large size, the carbocyclic rings of PA readily interact with TYR61 and TRP134 side chains without water mediation.

The predicted binding free energies indicate that PA has a higher affinity for both the Qp and Qd sites than TTFA, UbQ, or TOS (Table 3). Furthermore, UbQ, TOS, and PA have higher affinity for the Qd site than the Qp site, whereas TTFA seems to preferentially bind to the Qp site. These findings are corroborated with the crystal structure electron density data (Sun et al., 2005) and a molecular docking study using AutoDock 3 (Dong et al., 2008).

Discussion

We showed that inhibition of mitochondrial SDH is one mode of action of a secondary metabolite in birch that could deter feeding by snowshoe hares. Papyriferic acid, the major PSM of the juveniles of *B. neoalaskana* and *B. pendula*, inhibits SDH by an uncompetitive mechanism in a dose-dependent manner (Supplementary Material 2, 3, and 4). In addition, molecular modeling strongly supports the notion that inhibition of SDH activity is a result of PA targeting the ubiquinone binding sites rather than the catalytic succinate binding site in C-II (Fig. 3). PA and TOS bind to both ubiquinone sites in a similar fashion, which is distinct from TTFA and UbQ binding due to structural differences. However, the core binding regions are consistently occupied by all four ligands, indicating that TTFA, TOS and PA all disrupt ubiquinone binding. The predicted binding free energies generated by AutoDock show that PA is a significantly more potent ligand than TTFA and TOS at both sites (Table 3). Several factors may contribute to the higher potency of PA. First, PA has more polar ester, hydroxyl, and carboxylate groups than TTFA and TOS to enhance the hydrogen bond and electrostatic interactions with binding site polar and positively charged residues. Second, the large ring scaffold of PA increases potential π-π interactions and minimizes the need for water mediation. The *in vitro* and computer modeling results provide a mode of action for toxicity that may be responsible for the concentration-dependent anti-feedant effects of PA observed in snowshoe hares (Reichardt et al.,

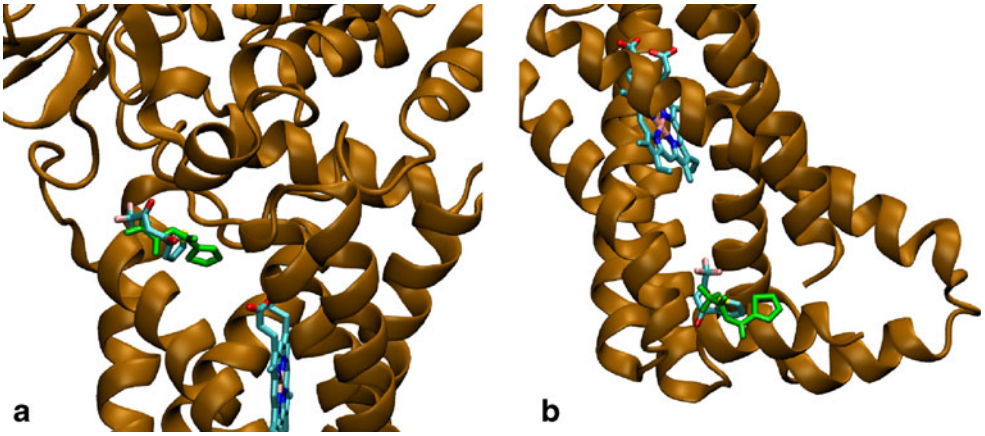

Fig. 2 Re-docking of 2-Thenoyltrifluoroacetone (TTFA) to the crystal structure of Complex II (C-II, PDB code 1ZP0). The predicted TTFA binding pose is colored by element and the crystal structure TTFA binding pose in green. The heme group is shown in cyan. (**a**) Qp site and (**b**) Qd site

1984). We predict that mechanisms that lower systemic concentrations of PA would reduce the toxicity of PA and explain the variable tolerance to PA observed between and within species that consume birch.

Inhibition of SDH may be a general mechanism of action of PA. PA inhibited SDH in a species that has had an ecological history with birch (snowshoe hares, this study) and those that are considered naïve to the chemicals in birch (ox, rabbits, rats, and mice, this study and in McLean et al. 2009). In every species tested thus far, inhibition of SDH by PA was dose dependent, uncompetitive, and more potent than a well-known competitive inhibitor of PA, malonic acid (Pardee and Potter, 1949; Greene and Greenamyre, 1995). From an evolutionary perspective, our *in vitro* results may at first appear somewhat puzzling. One might expect that animals with a 6000 year ecological history of consuming PA (Bryant et al., 2009), would have lower sensitivity to its MOA than naïve species. Lower sensitivity would provide a plausible explanation for the capacity of some hare populations to eat a PA-rich diet

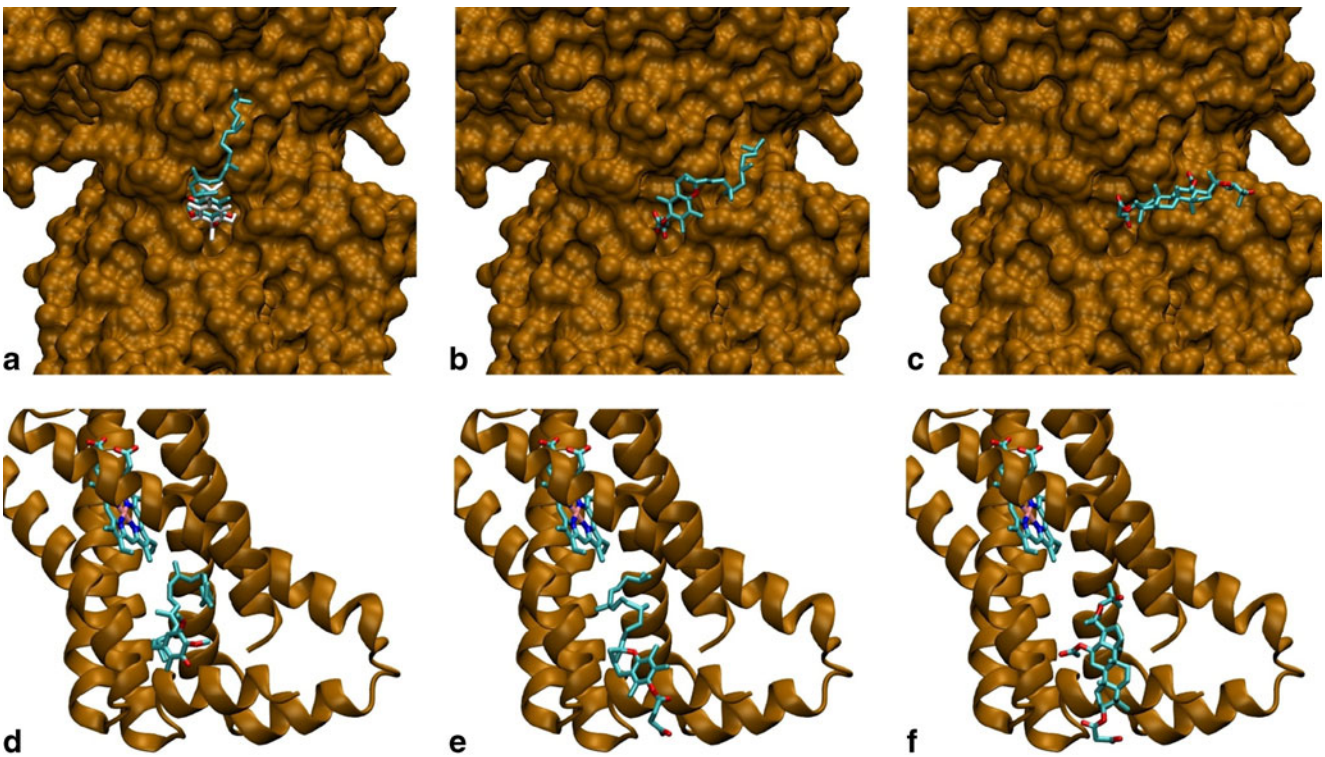

Fig. 3 Predicted binding poses of (**a**) Ubiquinone-5 (UbQ, cyan) and crystal structure UbQ (white), (**b**) α-tocopheryl succinate (TOS), and (**c**) papyriferic acid (PA) for the Qp site rendered in molecular surface representation, and (**d**), (**e**), (**f**) following the same order for the Qd site rendered in cartoon representation. The heme group is shown in cyan situated above the docked ligands

Table 3 Interaction energies (Kcal/mol) for the best-ranked docking conformations for 2-Thenoyltrifluoroacetone (TTFA), Ubiquinone-5 (UbQ), α-Tocopheryl succinate (TOS), and papyriferic acid (PA) in the Qp- and Qd-binding sites of succinate dehydrogenase. More negative interaction energies are indicative of higher binding affinity

Ligand	Qp site (Kcal/mol)	Qd site (Kcal/mol)
TTFA	−4.13	−3.99
UQ5	−5.15	−8.30
TOS	−6.55	−10.58
PA	−8.98	−12.55

(Bryant et al., 1994). In contrast, however, we have shown that snowshoe hare mitochondria are more sensitive *in vitro* than the naïve species tested.

In vitro sensitivity to PA inhibition may not translate to *in vivo* sensitivity for several reasons. First, the gut mitochondria of hares may be less sensitive to inhibition by PA than liver mitochondria. If absorption of PA by hares is low, as is the case in rats (McLean et al., 2009), then PA concentrations could be very low in the liver, and the gut would be a more plausible site of action than the liver. Moreover, the population of snowshoe hares we studied may not represent the species as a whole. Species do differ in their sensitivity to SDH inhibition (this study and Mogi et al., 2009), and we predict that the Alaska population of hares used here may have had higher sensitivity to SDH inhibition due to their "intermediate" tolerance to birch than would have been found in more tolerant populations (Swihart and Bryant, 2001; Bryant et al., 2009). Future studies could be performed to determine whether a geographical mosaic exists for sensitivity to SDH inhibition by PA.

An alternative explanation for our results is that the *in vitro* sensitivity to PA by hares does not account for *in vivo* mechanisms that can influence the systemic dose of PA that interacts with SDH in naturally feeding animals. The dose-dependent inhibition found in a variety of species suggest that variation in tolerance of PA by species or populations could be associated with physiological mechanisms that reduce systemic concentrations of PA rather than mechanisms that influence the sensitivity to inhibition of SDH by PA. Hares can behaviorally reduce the systemic dose of PA by avoiding the highest concentration of PA found in plant parts (Reichardt et al., 1984). In addition, enzymes that regulate absorption and metabolism of chemicals can dictate the concentration of ingested chemicals at the site of action and ultimately influence susceptibility to those chemicals (Danhof et al., 2007; Megarbane et al., 2008; Ploeger et al., 2009; Dahl et al., 2010). Efflux transporters and metabolizing enzymes could regulate the cellular concentrations of ingested PSMs in herbivores (Dearing et al., 2005; McLean and Duncan, 2006; Sorensen and Dearing, 2006; Sorensen et al., 2006; Forbey and Foley, 2009). Additional studies are needed to test whether efflux transporters and metabolizing enzymes can explain the disconnect between sensitivity to PA by snowshoe hares observed in these *in vitro* assays compared to the *in vivo* tolerance to PA by some populations of hares (Swihart and Bryant, 2001; Bryant et al., 2009).

This study is the first to our knowledge to confirm a mode of action of PA in an herbivore. Identifying the mode of action provides the necessary mechanistic data to help explain Thompson's (2005) geographic mosaic of selection in the birch-snowshoe hare system (Bryant et al., 1994, 2009; Swihart and Bryant, 2001). We have established a relatively simple protocol for testing SDH inhibition as a general mechanism of resistance in birch against other herbivores. SDH inhibition also may be a general mechanism of toxicity of other PSMs in other plant-herbivore systems. In addition, we have showcased the value of molecular modeling to further elucidate the mechanism of toxicity of PSMs and other ecologically relevant molecules. This approach has been fruitful in predicting binding of PSMs to metabolizing enzymes in insects (Baudry et al., 2003; Rupasinghe et al., 2003; Jones et al., 2010; Mao et al., 2007) and could prove equally valuable in screening the binding between PSMs and efflux transporters and metabolizing enzymes as well as the mode of action of PSMs in vertebrates.

Acknowledgements We thank Thomas Allen and Dr. Ethan Ellsworth for assistance with the collection of hares and tissues and the field. We thank Dr. Thomas Clausen, Department of Chemistry and Biochemistry, University of Alaska, Fairbanks, for his donation of papyriferic acid. We are grateful to Dr. Stuart McLean for initiating ideas for this study, his assistance in developing assays, and critique of the manuscript. We thank Dr. Rajesh Nagarajan, Department of Chemistry, Boise State University, for assistance with interpretation of enzyme kinetic data. We appreciate the comments from three anonymous reviewers for improving the manuscript. Research was supported by Boise State University, the Bonanza Creek LTER program (NSF-DEB-0423442), and the US Forest Service (PNW01-JV11226952-231).

(Schwachtje and Baldwin, 2008), and will complement our extensive knowledge of herbivory's effect on plant secondary metabolites (Rosenthal and Berenbaum, 1992; Zhao et al., 2005; Pauwels et al., 2009).

Primary metabolic changes related to direct resistance have been investigated on a local scale. For example, leaf wounding can induce increased carbon sink strength through increased invertase activity, which drives influx of sucrose (Roitsch and González, 2004). This additional photosynthate can be allocated to defense-related processes, such as production of defensive enzymes (e.g., polyphenol oxidases in tomato, Bhonwong et al., 2009) or defensive phenolic small molecules via the shikimate pathway (Arnold and Schultz, 2002). For example, in a recent study, Hanik et al. (2010) studied induction of the aromatic amino acids derived from the shikimate pathway tobacco plants treated with methyl jasmonate (MeJA), a known defense elicitor (Koo and Howe, 2009; Pauwels et al., 2009). They observed rapid changes: 4 hr post-treatment, newly synthesized aromatic amino acids were increased, and at 15 hr tryptophan remained at a higher concentration relative to baseline levels. On the other hand, *trans*-cinnamic acid, an upstream compound in phenolic metabolism, did not increase until 15 hr post-treatment, suggesting a time lag between changes in primary and secondary metabolism. Despite findings such as this at the site of elicitation, primary metabolism's role in resistance is less well characterized at the whole-plant level. It is unknown, for example, how these metabolites change systemically or in response to different herbivores.

In addition to contributing to direct resistance, rapid changes in metabolite allocation may serve a role in tolerance to herbivory (Schwachtje et al., 2006). Specifically, induced reallocation can occur rapidly while the herbivore is still present, sequestering the primary metabolites from exposed tissues into storage organs (Orians et al., 2011). This process presumably functions to safeguard resources in herbivore-inaccessible tissues for use in future plant regrowth. Induced tolerance responses of this kind contrast with the traditional notion of constitutive tolerance, where resources are mobilized from storage organs to growing tissues only after the herbivory threat is over (Iwasa and Kubo, 1997; de Jong and van der Meijden, 2000).

Induced changes in resource allocation have been the focus of several recent studies that use radioisotopes to track, in living tissue, carbon/nitrogen uptake, transport, and allocation on the whole-plant level. In the pioneering study by Babst et al. (2005), [^{11}C] radiolabeled CO_2 was used to track how recently assimilated carbon was allocated within *Populus tremuloides* saplings after local application of MeJA. Hormone treatment led to increased speed of leaf carbon export and increased [^{11}C]-photosynthate allocation towards roots and stem (storage organs). A similar study in *Nicotiana attenuata* showed a 10% increase in [^{11}C]-photosynthate export from leaves to roots 4 hr after simulated herbivory (Schwachtje et al., 2006). More recently in tomato (*Solanum lycopersicum*), Gómez et al. (2010) showed that inducing herbivory responses through MeJA treatment increased both [^{11}C]-photosynthate and [^{13}N]-amino acids export from treated leaves and increased [^{13}N]-amino acids into the roots. While these studies suggest that changes in resource allocation may be a general response to damage, the change of specific metabolites in different tissues (e.g., stem, root, and apex) remains unexplored. In addition, most previous studies of primary metabolism have focused only on changes within or between leaves (Staswick, 1994; Zangerl and Berenbaum, 1998; Van Dam and Oomen, 2008; Schmidt et al., 2009), rather than co-occurring responses at a whole-plant level.

The type of whole-plant response also is expected to vary by the type of attacking herbivore. Plants and herbivores that share a co-evolutionary history are in a constant "arms race," and plants show unique responses to specific attackers that optimize defense responses (Agrawal, 2000; Rodriguez-Saona et al., 2010; Chung and Felton, 2011). Different combinations of resistance and tolerance tailored to combat specific herbivores thus should lead to distinct primary metabolic responses in the target plant. Caterpillars of the specialist *M. sexta*, for example, are well-adapted to feed on plants of the Solanaceae family and can detoxify alkaloids such as nicotine (Morris, 1984; Wink and Theile, 2002). Generalist herbivores on the other hand, feed on multiple plant families but have a lower ability to withstand toxins (Ballhorn et al., 2010). Since plants are attacked by multiple kinds of herbivores in nature (Strauss, 1991; Vos et al., 2001), induction of herbivore-specific responses may increase fitness and survival. For example, attacked *Nicotiana attenuata* plants reduce normal wound-induced levels of nicotine production when exposed specifically to *M. sexta*, against which this defense would be ineffective (Kahl et al., 2000). Thus, it is hypothesized that herbivore identity will be a crucial factor in the activation of an induced resistance or induced sequestration strategy (reviewed in Orians et al., 2011).

To compare primary metabolic responses to herbivory, mass spectrometry-based metabolic profiling allows for unbiased measurement of dozens of small primary metabolites and their changes in response to biotic stress (Hofmann et al., 2010). Here, we made use of such tools in order to complement previous carbon and nitrogen radioisotope studies. Our specific goals were: a) to elucidate how tomato plants reprogram primary metabolism at a whole-plant level by looking at different plant tissues (apex, undamaged leaflets of damaged leaves, stem, and roots); and b) whether two tomato attackers with contrasting host specialization (specialist *M. sexta* and generalist *H. zea*) alter plant metabolism

in ways consistent with either an induced tolerance- or induced resistance-like response. We predicted that metabolic changes would be specific to single tissues, and that changes in compounds related to resistance (e.g., phenylpropanoid precursors, Dixon and Paiva, 1995) and tolerance (e.g., storage sugars and N-transporting amino acids) would be herbivore specific.

Methods and Materials

Plant and Herbivore Material "Lady First II" tomato plants were obtained from Hazzard's Wholesale Seeds (Deford, MI, USA), germinated indoors under grow lights in SunGro Metro-mix soil for 15 d, and repotted into 50/50 sand/zeolite growth medium. Plants were grown at Tufts University in a greenhouse from September to October 2009 with no supplemental lighting. Plants were fertilized with 50 ml Hoagland's solution (1306 μM NO_3^-, 603 μM Ca^{2+}, 190 μM PO_4^{3-}, 993 μM K^+, 270 μM Mg^{2+}, 272 μM SO_4^{2-}, 2 μM Mn^{2+}, 0.0085 μM Zn^{2+}, 0.15 μM Cu^{2+}, 20 μM B, 1.44 μM Mo^{2+}, 40.5 μM Fe^{2+}) twice weekly until 20 d post-sowing, when the phosphate component was doubled. Plants were fertilized thereafter with 100 ml of 2x phosphate Hoagland's solution three times weekly until harvest. The group of harvested plants had an average height of 25.7 cm and averaged 7.3 fully emerged true leaves.

Manduca sexta caterpillars were obtained from Tufts University's Department of Biology. *Helicoverpa zea* caterpillars were obtained from Pennsylvania State University's Department of Entomology. Feeding cues of *M. sexta*, a specialist, are known to induce numerous changes in tomato and other Solanaceous plants (Kessler and Baldwin, 2002; Schwachtje et al., 2006; Howe and Jander, 2008). Feeding by *H. zea*, the generalist, is less well studied, but like *M. sexta*, salivary secretions released upon leaf consumption may elicit metabolic shifts (Peiffer and Felton, 2005).

While several studies have used oral secretions from *M. sexta* as a defense elicitor (e.g., Kessler and Baldwin, 2002), it is possible that external application of regurgitant exposes plants to far more elicitor than is actually released in oral secretions during caterpillar herbivory (Peiffer and Felton, 2009). In addition, diurnal and nocturnal patterns of feeding can differentially affect responses (Arimura et al., 2008). Therefore, in order to maintain comparable and realistic damage treatments, we exposed plants to caterpillars rather than to oral secretions.

Damage Treatments and Tissue Collection One individual *M. sexta* or *H. zea* caterpillar was introduced onto the terminal leaflets of three non-orthostichous leaves 60 d post-sowing. The three newest fully expanded (>50% final area) leaves were considered source leaves and exposed to herbivore damage. These leaves were chosen because it has been shown that damaging source leaves (as opposed to sink tissues) is necessary to ensure systemic defense expression in other systems (Gómez and Stuefer, 2006). Damaging multiple leaves ensured a systemic signal despite sectoriality (Orians et al., 2002). *Manduca sexta* usually forages across the whole plant, and late instars can defoliate an entire plant overnight. We thus confined third instars to terminal leaflets by using clip cages in order to preserve leaf tissue for analysis and to standardize damage by the two herbivores. Feeding cages were set up at 9 AM, and caterpillars were allowed to feed for 24 hr. A full day of exposure to herbivory was chosen in order to expose plants to both diurnal and nocturnal herbivory, as well as to allow time for metabolite levels controlled by circadian rhythms (e.g., sucrose vs. starch balance, Smith and Stitt, 2007) to respond to herbivory. This also corresponds with previous studies that have demonstrated that certain tomato defense responses peak at 24 hr (Orians et al., 2000).

As controls, mechanical damage was applied to a separate set of plants by performing a single scissor clip to 3 terminal leaflets three times over the 24-h exposure, with a final removal of 50% leaflet area to achieve an amount comparable to the area removed in the herbivore treatments. Empty clip cages were attached similarly to the 3 mechanically-damaged leaves. Undamaged control plants also received an empty clip cage, and were manually manipulated in the same manner as damage-exposed plants. Plants from all 4 treatments were assorted randomly for the damage exposure period. Both species of caterpillars removed a similar estimated leaf area (32% +/− 19.1 for *M. sexta,* 45.4% +/− 12.8 for *H. zea*), minimizing the effect of damage magnitude on metabolite concentrations.

Four tissue types were sampled 24 hr after initial herbivore exposure: apical leaves (excluding any developing flowers), undamaged leaflets of the 3 damaged leaves (hereafter referred to as "leaves"), stems from uppermost root to base of the first apex leaf, and roots (after washing off soil substrate). Tissues were harvested, immediately submerged in liquid nitrogen, and stored at −80°C until further processing.

Metabolomic Analysis Tissues were kept separated by plant and homogenized after harvesting, being kept on liquid nitrogen for the duration of the grinding process. Leaf and apex tissue was ground with a frozen mortar and pestle, while stem and root tissue were ground in a ball mill for 1 min with pre-chilled milling chambers filled with liquid nitrogen. Tissue extracts were collected as previously described after adding a ribitol internal standard (Lisec et al., 2006). Vacuum concentrated samples were stored at −80°C at Tufts University and shipped to the Max Planck Institute for Molecular Plant Physiology.

Samples were reconstituted, and small metabolites were measured and analyzed by using GC-MS as previously described (Lisec et al., 2006). Metabolite peaks were determined using TagFinder (Luedemann et al., 2008), and metabolite content was normalized to ribitol internal standard. Retention time index and mass spectral tags for individual compounds were compared to in-house library sets (Erban et al., 2007; Hummel et al., 2007), providing a list of positively identified compounds. Because signatures of specific metabolites are determined from raw GC-MS data, this method yields an unbiased list of previously characterized metabolites that are present in a given tissue sample. Peak areas for specific metabolites were compared to undamaged plants, yielding relative metabolite concentrations after each damage treatment (absolute concentrations were unmeasured). Compounds were separated by category (amino acids, organic acids, sugars, and other compounds), and further specific categories (nitrogen-transporting amino acids, abundant cellular sugars, and shikimate-derived amino acid products) were considered for their roles in resource transport and resistance.

Statistical Analysis Principal component analysis (PCA) was performed using JMP 7.0 (SAS Institute 2007). Metabolite peak areas from GC-MS were log transformed, and missing data were replaced with concentration values of 0 (Kaplan et al., 2004).

Two-way MANOVA was performed with JMP, with treatment, tissue, and treatment by tissue interactions as factors and overall PCs 1–3 as responses. One-way MANOVA was performed for tissue-specific analyses, with tissue-specific PCs 1–3 as responses and treatment as the sole effect. A Wilks' *lambda* test was used to determine statistical significance of each effect.

Ribitol-normalized metabolite content for individual metabolites was averaged for 5 to 6 plants per treatment and compared to mean content from undamaged control plants using Student's *t*-test.

Results

Fifty-six primary metabolites were measured in total across all tissues, identifying many differences in metabolite concentrations relative to undamaged plants. Altered compounds included free amino acids, organic acids, sugars, and other detectable metabolites (Fig. 1). Although not all 56 compounds were measurable in every tissue type, individual compound detectability never varied across replicates or damage treatments within a single tissue type (raw data not shown).

As expected, there were extensive differences in metabolite concentrations among tissue types. Data were highly clustered by tissue in principal component analysis (Fig. S1), with the top 3 principal components explaining 94.3% of the total variation. The significance of tissue type on total metabolite profile was highly significant in a two-way MANOVA on the top 3 principal component scores ($F=2622$, $P<0.001$), and a marginal effect of the tissue by treatment interaction was also measured ($F=1.33$, $P<0.13$).

Within the separate metabolic environments of each tissue type (apex, leaves, stem, and roots), MANOVA on principal components revealed that damage treatments also led to broadly different metabolic profiles (Fig. S2). The effect of damage treatment on PC 1–3 scores was significant in all four tissues ($F>2.0$, $P<0.05$). Patterns of differentiation were different for each tissue, with the stem, root, and apex showing the greatest PC differentiation when comparing damage treatments to undamaged control plants.

In accordance with results from PCA, some tissues exhibited a greater number of changes in individual metabolites than others (Fig. 2). Specifically, the number of changes was highest in the apex, where 28 metabolites significantly changed following one or more damage treatment (representing 58.3% of all measured metabolites in this tissue). Root tissue also was highly altered, with 25 metabolites (65.8%) showing induced changes. In contrast, both stems and leaves exhibited only 12 significantly altered compounds. The number of responses only induced by either type of herbivory (but not mechanical damage) also was highest in the apex (33.3%) and in the roots (28.9%).

Damage-induced changes in individual metabolite concentrations ranged in magnitude from a 3.33-fold decrease to a 4.58-fold increase relative to undamaged plants. In each individual tissue, *H. zea* induced as many or more individual metabolite changes than *M. sexta*—counting both increases and decreases (Fig. 2a). *Helicoverpa zea* herbivory also was the only type of damage to induce any concentration increases in the leaflets adjacent to focal damage. Other patterns were notable: *M. sexta* was the only treatment to induce any significant concentration increases in the roots, and mechanical damage induced many more concentration decreases in the roots than either herbivory treatment.

Metabolite concentrations changes tended to be specific to a single type of damage, and relatively few significant changes were induced by all three types of damage (see overlapping center areas in Fig. 2a). Consistent with patterns in PCA clustering, the apex showed the greatest similarity of response across damage treatments, but other tissues showed few or no shared changes in compound concentrations. Shared responses to both types of herbivory also were relatively rare across all four tissues (see *H. zea* and *M. sexta* overlapping areas in Fig. 2a).

Relative to mechanical damage, herbivory tended to increase concentrations of individual metabolites. When

◀ **Fig. 1** Mean relative concentration values of metabolites relative to undamaged control means (normalized to 1.0). Statistically significant differences from undamaged plants (Student's *t*-test, $P<0.05$) are highlighted with a shaded box. Sample size (number of harvested plants) is given above each tissue-treatment combination. Undamaged control sample sizes were 5 plants for apex and leaf (undamaged leaflets of damaged focal leaf) and 6 plants for stems and roots. Treatment labels: "MD", mechanical damage, "Ms", *Manduca sexta* herbivory, "Hz", *Helicoverpa zea* herbivory. Nitrogen-transporting amino acids, abundant cellular sugars, amino acid products of the shikimate pathway, and components of phenylpropanoid metabolism are underlined and highlighted in bold

compared to mechanically damaged plants, 42 measurements of metabolites across all tissues showed increased concentration in either *M. sexta* or *H. zea*-damaged plants, as compared to just 7 showing decreases (Fig. 2b, see Fig. S3 for compound list and relative values). Differences relative to mechanical damage were especially pronounced in the undamaged leaflets, where *H. zea* induced many unique increases, including increases in quinic acid, GABA, and putrescine. Differences also were striking in the roots, where *M. sexta* caused many unique inductions of concentration increases, including increased concentrations of aspartate and phenylalanine relative to mechanical damage.

In addition to showing damage type-specificity, responses also were highly specific to single tissues. The most common damage response for a given metabolite was a change specific to 1 of the 4 tissues (Fig. 3); this held true for responses to all three damage types. Relative to mechanical damage, herbivory led to a larger number of ubiquitous responses for individual metabolites. For example, herbivory altered nearly twice as many metabolites in two or three tissue types simultaneously (Fig. 3). Nonetheless, no single damage treatment caused changes in a compound across all 4 tissues.

In accordance to the number of overall changes in apex and root tissues (Fig. 2a), metabolite changes unique to a single tissue tended to occur in tissues far from the site of damage, rather than in the leaves. For example, for the 30 metabolites measurable in all 4 tissues, herbivore-induced change was most often exclusive to the apex: both *M. sexta* and *H. zea* herbivory induced apex-specific changes in 8 such compounds. For metabolites showing changes in more than one tissue (Fig. 3), simultaneous change in the root and apex was the most common combination of altered tissues: 5 of the 30 compounds showed changes in both tissues after *M. sexta* herbivory, and 3 compounds after *H. zea* herbivory.

To analyze these patterns in relation to tolerance and resistance, we examined specific changes in transport amino acids, sugars, and defense precursors. The levels of four major nitrogen-transporting amino acids—glutamate, glutamine, aspartate, and asparagine—were often altered relative

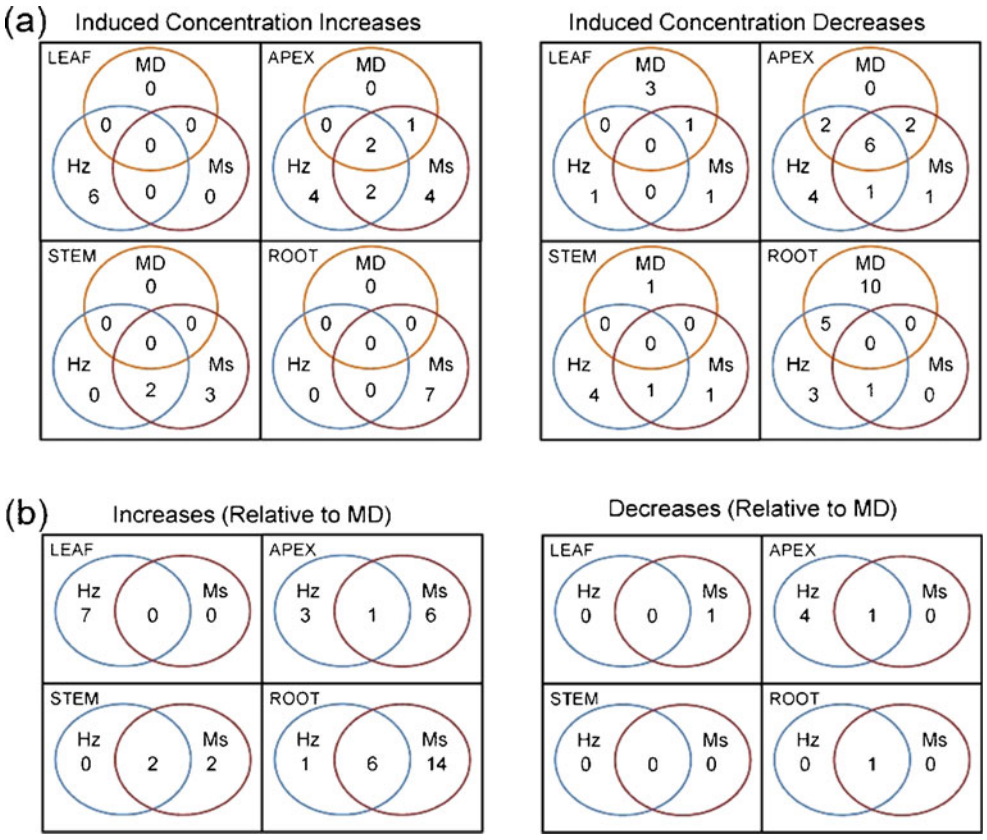

Fig. 2 Analyses of significant changes in individual metabolites relative to undamaged plants (Student's *t*-test, $P<0.05$) across tissues and damage treatments. **a** Venn diagrams of the number of metabolite concentrations that were significantly increased (*left*) or decreased (*right*). The total number of measured metabolites was 48 for leaves, 47 for stems, 48 for apex, and 38 for roots (see Fig. 1 for further information). Treatment categorizations: "MD", mechanical damage, "Ms", *Manduca sexta* herbivory, "Hz", *Helicoverpa zea* herbivory. **b** Venn diagrams of the number of altered metabolites after *M. sexta* or *H. zea* herbivory relative to mechanical damage

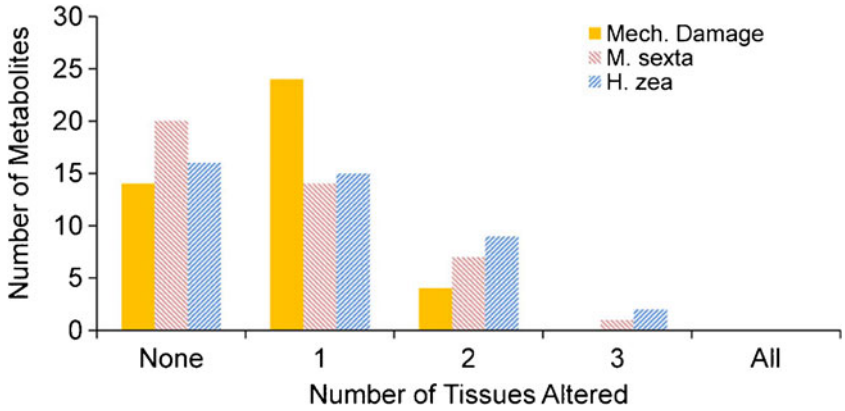

Fig. 3 Tissue-specificity of responses to damage. Histogram of the number of individual metabolites showing alteration after a specific damage type in 0, 1, 2, 3, or all tissues. Only the 42 metabolites measurable in 3 or more tissues were analyzed

to undamaged plants, depending on both tissue type and damage treatment (compound names in bold in Fig. 1). In the stem, glutamine levels increased in caterpillar-damaged plants, but only significantly so after *M. sexta* damage. In the leaf, *H. zea* induced more changes, causing significantly increased levels of aspartate. On the other hand, transport amino acid levels tended to decrease in the apex and root after damage. The apex contained detectable levels of only glutamate and aspartate, but glutamate was nearly significantly decreased after all three types of damage ($P<0.06$). Roots also showed decreases in glutamate and aspartate in response to mechanical damage, but slight increases after *M. sexta* herbivory.

Sugar concentrations, including those of the abundant cellular sugars glucose, fructose, and sucrose, tended to decrease after damage in all tissue types (Fig. 1). Decreases tended to be greater in tissues other than the leaf; herbivory led to only one significant change in any of the cellular sugars in leaf tissue (Fig. 1). Apex sugars in particular often showed significantly lower concentrations after all damage treatments. As with many metabolites measured, however, specific sugars often were altered only after a single type or damage or in a single tissue type.

Herbivory also induced changes in several small secondary metabolites and their immediate metabolic precursors. Changes in the aromatic amino acid products of the shikimate pathway—phenylalanine, tryptophan, and tyrosine—are highlighted in Fig. 1. Effects differed across tissues, but phenylalanine levels tended to decrease after herbivory, while tryptophan levels tended to increase (except in the roots). *Helicoverpa zea* induced the broadest changes in these metabolites, causing a significant decrease of phenylalanine in the leaf and apex, and mirroring increases of tryptophan and tyrosine in the apex. Damage also induced changes in metabolites downstream of the aromatic amino acids—precursors in the phenylpropanoid pathway (Fig. 1). Caffeic acid, quinic acids, and isomers of chlorogenic acid (*cis*- and *trans*- 3-caffeoyl-quinic acid) all showed unique local and systemic changes, often unique to a single herbivore.

Discussion

Herbivory induces primary metabolic responses in plants (Schwachtje and Baldwin, 2008), but the extent and type of these changes across different tissues or by different herbivores is poorly understood. Previous radioisotope work has demonstrated carbon and nitrogen reallocation after herbivory (Gómez et al., 2010) and induction of the shikimate/phenylpropanoid pathway (Hanik et al., 2010), but the specific primary metabolic changes involved in these shifts are less clear. We quantified primary metabolic changes following damage by two herbivores in the apex, undamaged leaflets of damaged leaves, stem, and roots of tomato plants. We observed whole-plant metabolic reconfiguration, with all four tissues showing global changes, as well as significant damage-induced changes in individual metabolites related to resistance and tolerance.

Interestingly, the sink tissues of the root and apex were more heavily altered (in terms of number and magnitude of changes) than tissues more proximal to damage—the leaves and stem. This is consistent with evidence that systemic signals are disseminated rapidly to distal leaves following wounding (Wasternack et al., 2006; Koo and Howe, 2009), and that whole-plant responses can lead to large-scale metabolic reprogramming after 24 h of damage. Despite an overall research focus on responses in the attacked leaf tissue (Kessler and Baldwin, 2002), this finding broadly justifies increasing interest in systemic, whole-plant responses to herbivory.

Responses in the apex and root were not only prevalent, but also showed different patterns unique to either *M. sexta* or *H. zea*. This is consistent with herbivore-specific elicitation of defense responses observed in other systems, relative to both undamaged and mechanically damaged plants (Agrawal, 2000; Kahl et al., 2000; Halitschke et al., 2001; Kessler and Baldwin, 2002). This result also suggests that distinct cues in the leaf are able to trigger dramatically different whole-plant responses, in agreement with recent studies of herbivore-specific salivary components and their different hormonal effects in the locally attacked leaf

(Peiffer and Felton, 2005; Diezel et al., 2009). For example, exposure of *Nicotiana attenuata* to regurgitant of *M. sexta* and *Spodoptera exigua* leads to distinct hormonal responses that lead to differential induction of nicotine and other defenses (Kahl et al., 2000; Winz and Baldwin, 2001; Diezel et al., 2009).

Surprisingly, we found that *H. zea* herbivory induced a wider metabolic reprogramming than other damage treatments in tomato. This contrasts with previous work on generalist-induced defense hormones and downstream defense responses: *S. exigua* regurgitant can antagonize anti-herbivore defenses (Diezel et al., 2009), and other studies have demonstrated defense silencing by generalist herbivores across various plant systems (Musser et al., 2002; Zarate et al., 2007). In our study, *H. zea* induced an equal or greater number of metabolic changes in each tissue relative to *M. sexta*. Changes in shikimate pathway products and simple phenylpropanoids, possibly characteristic of defense induction, also were stronger after *H. zea* herbivory, especially in the apex (see below). The heightened overall response to *H. zea* herbivory suggests that defense silencing by generalist herbivores may not always extend to the level of primary metabolism or whole-plant responses.

Previous studies have shown that herbivore attack leads to reallocation of carbon and nitrogen from the damaged leaves into storage tissues (Staswick, 1994; Beardmore et al., 2000; Babst et al., 2005, 2008; Schwachtje et al., 2006), often in a rapid manner known as induced sequestration (Orians et al., 2011). In tomato specifically, export of nitrogen from leaves into roots has been shown in response to MeJA (Gómez et al., 2010). We thus expected to see damage-induced differences in concentrations of nitrogen and carbon-transporting compounds relative to undamaged plants, especially after herbivory by *M. sexta.*

While whole-plant differences in individual sugars were apparent in response to both herbivores, data for the set of all measured sugars were relatively noisy. There was no consistent increase or decrease in any sugar, for example, in any one tissue in response to either herbivore. This suggests that the broad allocation changes measured by radioisotope analyses may occur at the level of storage compounds, in pools of starch or more complex carbohydrates, rather than in free or transporting forms of sugar represented by the primary metabolites measured by GC-MS. The fact that increased sucrose concentrations were not observed in any tissues, including the stem, also may indicate that translocation of carbon may already have occurred 24 hr after herbivory.

Regarding nitrogen, several whole-plant patterns were apparent in concentrations of the nitrogen-transporting amino acids—glutamine, glutamate, asparagine, and aspartate. While these amino acids did not show large changes in magnitude in response to any type of damage, *M. sexta* herbivory led to a significantly higher concentration of glutamine in the stem, as well as increased levels of aspartate in the root relative to mechanically damaged plants (Fig. 1, Fig. S2). While these changes did not hold for the other N-transporting amino acids, the lack of similar induced changes after *H. zea* herbivory may indicate a *M. sexta*-specific sequestration response. Future experiments that compare metabolite concentrations at different timepoints, along with measurements of storage compounds will help to resolve how herbivores differentially alter patterns of allocation and storage.

In addition to tolerance responses, production of direct defensive compounds is induced after herbivory (Rosenthal and Berenbaum, 1992; Karban and Baldwin, 1997). In tomato, phenolic compounds may play a role in anti-herbivore defenses (Dixon and Paiva, 1995), although the negative effects of specific compounds can be specific to only certain herbivores (Isman and Duffey, 1982; Bi et al., 1997). In the present experiment, *H. zea* induced greater changes in precursor amino acids of the shikimate pathway and simple phenylpropanoids than either *M. sexta* or mechanical damage. Shikimate-derived amino acids and simple phenylpropanoids are precursors for many secondary metabolites (Herrmann and Weaver, 1999), suggesting potential ecological consequences. Assaying additional defensive compounds as well as correlating metabolic changes with *H. zea* biomass gain on tomato could help to confirm a role for these primary metabolic changes.

While further speculation on the fate of carbon and nitrogen is possible based on the present data, more experiments are needed to determine the steps in reallocation of sequestered C and N. First, directly measuring phenolics, starch, protein, and other components of carbon and nitrogen allocation may reveal differences that account for the leaf export and root import of these resources (Gómez et al., 2010). Second, measuring metabolic flux of specific compounds will shed light on the pathways taken to achieve resource reallocation. Interpreting changes in metabolite concentrations along a pathway is complex, as concentration changes do not necessarily reflect turnover through the pathway (Last et al., 2007). Future experiments that measure a timecourse of metabolite concentrations following herbivory are needed to distinguish between general pathway downregulation or increased flux in the conversion of a metabolite to its products. Despite these limitations, the observed single timepoint changes in pathway components relative to undamaged plants – both increased and decreased pool sizes—are enough to suggest a differential prioritization of defense and resource allocation across the whole plant following contrasting damage types.

In summary, we found that primary metabolic responses across the entire tomato plant varied widely from tissue to tissue, were often herbivore-specific, and occurred in

metabolites potentially important to the response of tomato to different agents of damage. Looking at number and magnitude of induced concentration changes, tissues outside of the attacked leaf were most often affected by both *M. sexta* and *H. zea* herbivory, in patterns partially consistent with herbivore-specific defense and tolerance responses. Future findings on the effects of specific metabolites and biological implications of whole-plant change will increase our understanding of how plants defend against herbivory.

Acknowledgements We thank B. Trimmer (Tufts University) and G. Felton (Pennsylvania State University) for provision of *M. sexta* and *H. zea* caterpillars, respectively. We thank T. Korpita for help during sample preparation and D. Marshall and B. Tavernia for statistical advice. F. Chew, G. Ellmore, N. van Dam, and two anonymous reviewers provided valuable comments on a previous version of the manuscript. al., 2011). To date, *de novo* oviposition-induced volatiles have been reported for some tritrophic systems. In some systems, the combination of oviposition and herbivory trigger volatiles that attract egg parasitoids (Colazza et al., 2004; Conti et al., 2010; Michereff et al., 2011).

Apart from oviposition-induced plant volatiles, the orientation of egg parasitoids towards egg-derived odors might be an effective alternative strategy for host location. However, eggs usually emit only small amounts of volatiles and are therefore only useful as short-range cues. Moreover, eggs generally are inconspicuous and deposited on hidden sites, making their location difficult (Vinson, 1998). This is why egg parasitoids are expected to frequently exploit chemical cues from other sources for host location as well. In the case of lepidopteran hosts, this includes, for example, pheromones and compounds released from scales of the wings of ovipositing females (Shu and Jones, 1989; Colazza et al., 1997), but also HIPVs (Lou et al., 2005; Moraes et al., 2005). Although HIPVs do not directly indicate the presence of eggs, their exploitation could be of use if the host has overlapping generations, as the highly abundant and easily detectable plant odors enable them to locate host habitats and communities, and, consequently, eggs (Vinson, 1976, 1984). Furthermore, HIPVs may help phoretic egg parasitoids to locate adults on which they can "catch a ride" to new oviposition sites with eggs (Fatouros et al., 2008).

Despite the possible importance of HIPVs for host location by egg parasitoids, few studies have directly addressed this subject (Reddy et al., 2002; Lou et al., 2005; Manrique et al., 2005; Moraes et al., 2005). Also, little is known about the capacity of egg parasitoids to learn HIPVs for host location (Mumm et al., 2005; Schroder et al., 2008). This is surprising, given the fact that learning is an important strategy for parasitoids that optimizes their host searching strategy (Lewis and Takasu, 1990; Turlings et al., 1993; Vet et al., 1995). To obtain deeper insight into these topics, we tested innate and learned responses of two lepidopteran egg parasitoids towards HIPVs that are released by maize plants upon attack by larvae of the noctuid moth *Spodoptera frugiperda* (JE Smith) (Lepidoptera: Noctuidae). We assessed the behavior of the generalist *Trichogramma pretiosum* Riley (Hymenoptera: Trichogrammatidae), which parasitizes a wide range of hosts, (Zucchi and Monteiro, 1997), and the specialist *Telenomus remus* Nixon (Hymenoptera: Scelionidae), whose host range is limited to the genus *Spodoptera*. To complement this study, we also tested whether or not *S. frugiperda* gravid females show a preference for oviposition on plants that are damaged by conspecifics. We hypothesized that if moths prefer plants that have been damaged by conspecifics, or at least do not actively avoid them, HIPVs may guide egg parasitoids not only to habitats with hosts, but potentially also to plants containing host eggs of later arriving *Spodoptera* females.

Methods and Materials

Plants and Insects Maize seeds (*Zea mays* L., var. Delprim) were planted individually in plastic pots containing about 200 g potting soil ("Hortaliças Basiplant" substrate). Plants were grown in a greenhouse (12/12 h day/night cycle). Maize plants used in the bioassays had been growing for 8–9 d after emergence and had three fully expanded leaves. *Spodoptera frugiperda* caterpillars were collected on maize fields at Escola Superior de Agricultura "Luiz de Queiroz", Piracicaba-SP, Brazil, and reared under laboratory conditions (25±3°C, 60±10% rh, 12/12 h). The caterpillars were reared individually in sterilized glass vials (8.5 cm high, 2.2 cm diam, plugged with cotton) on artificial diet (Greene et al., 1976). Emerging pupae were separated by sex and placed into PVC cages (10.0 cm diam and 22.0 cm high) that were closed at both ends with Petri dishes (14.2 cm diam). The Petri dish in the bottom of the cage was lined with filter paper. In addition, cages were lined with office paper to serve as a surface for oviposition. Adults were fed a 10% honey solution that was renewed every 2 d.

Both *Telenomus remus* Nixon (Hymenoptera: Scelionidae) and *Trichogramma pretiosum* Riley (Hymenoptera: Trichogrammatidae) were reared on 24 h-old *S. frugiperda* egg masses, which were placed in sterilized glass vials (9.0 cm high, 3.0 cm diam, sealed with PVC film) together with the parasitoids. One paper card containing eggs was offered per day in each glass vial. Each card was removed after a 5 h period and placed in a new glass vial. Upon emergence of the parasitoids, small droplets of honey were placed on the internal wall of the vials as food source. All vials were maintained in incubators (25±1°C, 60±10% rh, 12/12 h).

Moth Oviposition Preference In an oviposition preference test, we offered *S. frugiperda* females an undamaged maize plant (treatment UP) next to a caterpillar damaged plant (CD). To obtain CD, 10 sec-instar larvae were placed inside the whorl of the plants at 10:00am until the beginning of preference tests at 6:00pm. Plants of each treatment were placed on the opposite ends of a *voil* fabric cage (55.0 cm high, 60.0 cm long, 10.0 cm wide). At 6:00 pm, five 3-d-old gravid females were released in the cage and left for one night. The following morning, egg masses were removed from the plants, and the eggs were counted. The bioassay was replicated 20 times, and was conducted in a room under controlled conditions (25±1°C, 60±10 rh, 12/12 h).

Olfactometer Bioassays Olfactory responses of the egg parasitoids (*T. remus* and *Tr. pretiosum*) were tested for 3-to-4-d-old individuals that were either naïve or experienced. A Y-tube olfactometer was used to determine their preference, either between two different odor sources or one source and a blank (clean air). Experience was given to parasitoids by allowing

them to oviposit on 100 viable *S. frugiperda* while exposing them to HIPVs released by regurgitant treated (0–1, 2–3, 6–7, and 12–13 h) or to caterpillar damaged plants for 10 min. After this period, we collected only wasps that were parasitizing the egg masses. Wasps that were walking around the vial were not used as experienced wasps. Experienced parasitoids were tested on the subsequent day to the odors of the same treatment they had experienced against the undamaged plant. All bioassays were conducted in the laboratory (conditions as described above) during day time, between 10:00 and 17:00. The Y-tube olfactometer consisted of a bifurcated glass tube (2.5 cm diam), and two arms (9.0 cm long). The odor sources were placed inside glass bottles (11.5 cm i.d., 51 cm high), which were connected to the extremities of the olfactometer. From the main arm of the olfactometer, a tube from a vacuum pump was connected, and the air from the environment was purified with the use of granular activated carbon filter (40 mesh, 11 cm i.d., 35 cm high) before pulling it through the system. The air flow was adjusted to 300 ml/min using calibrated flowmeters connected to each arm. Insects then were positioned individually at the beginning of the central arm of the Y-tube and observed for 5 min. When the wasps crossed the threshold line (located in the middle of each arm) and stayed in the arm end for 20 sec, this was considered as "choice". Only insects that made a choice for one arm within the 5 min were considered for statistical analysis. Each parasitoid was used only a single time to prevent associative learning. After each trial, the olfactometer was disassembled and all glassware was washed with neutral dishwashing soap (v/v 5%), distilled water, acetone, and alcohol (v/v 90%).

To evaluate egg parasitoid responses to HIPVs, bioassays with the following combinations were carried out: (i) undamaged plant (UP) vs. blank (B); (ii) UP vs. regurgitant-treated plant (RT) at intervals 0–1, 2–3, 6–7, and 12–13 h after treatment; (iii) UP vs. caterpillar-damaged plant (CD), which was obtained by having 20 2nd instars feed overnight. The larvae were left feeding on the plant during the entire experiment. The treatment CD thus corresponds to a "host-plant-complex". The regurgitant was manually collected from 3rd-4th instar fall armyworm caterpillars fed on maize for 2 d and stored at −76°C. To simulate herbivory on plants, we scratched the 2nd and 3rd leaf (about 1 cm^2 of each) and applied 10 μl of regurgitant to each damaged site. Regurgitant-treated plants 0–1, 2–3, and 6–7 h were induced during the morning (8:00–10:00), and 12–13 h was induced at 22:00 and tested at 10:00 on the following day. For each bioassay, we conducted at least 30 replicates on 4–5 experimental days using different odor sources.

Volatile Collection and Analysis To analyze the volatiles released by regurgitant-treated (RT) and caterpillar-damaged plants (CD), maize seedlings were grown as described in Erb et al. (2010). Maize seedlings were subjected to *S. frugiperda* feeding and regurgitant treatment as described above and following the same timing as the bioassays. Regurgitant-treated plants (RT) then were placed into glass bottles (9.5 cm i.d., 54 cm high), and volatiles were sampled at intervals 0–1, 2–3, 6–7, and 12–13 h after induction using super-Q® filters. Caterpillar damaged plants (CD) were sampled on the following morning (10:00 am) after one-night of feeding, as wasps were tested at this time for attraction to CD odors. The super-Q® traps were extracted with 150 μl dichloromethane (Suprasolv; Merck, Dietikon, Switzerland), and 200 ng of n-octane and n-nonyl acetate (Sigma, Buchs, Switzerland) in 10 μl dichloromethane were added to the samples as internal standards. All extracts were stored at −76°C until analyses. Traps were washed with 3 ml dichloromethane before they were reused for a next collection. HIPVs of the experiments were identified with a gas chromatograph (Agilent 6890 Series GC system G1530A) coupled to a mass spectrometer that operated in electron impact mode (Agilent 5973 Network Mass Selective Detector; transfer line 230°C, source 230°C, ionization potential 70 eV, scan range 33–280 amu). A 2-μl aliquot of each sample was injected in the pulsed splitless mode onto an apolar capillary column (HP-1, 30 m, 0.25 mm ID, 0.25 μm film thickness; Alltech Associates). Helium at constant flow (0.9 ml/min) was used as carrier gas. After injection, the column temperature was maintained at 40°C for 3 min and then increased to 100°C at 8°C/min and subsequently to 200°C at 5°C/min followed by a postrun of 5 min at 250°C. Detected volatiles were identified by comparison of their mass spectra with those of the NIST 05 library and with the retention times of analyses from previous studies (Turlings et al., 1998; D'Alessandro and Turlings, 2006).

Response of Wasps to Synthetic Volatiles We measured the response of inexperienced *Tr. pretiosum* wasps towards different HIPVs in a Y-tube olfactometer following the procedure described above. First a synthetic GLV mixture comprised of 80% (*Z*)-3-hexanal, 10% (*Z*)-3-hexenol, 8% (*E*)-2-hexenal, and 2% (*Z*)-3-hexenyl-acetate (Sigma Aldrich, Switzerland) (Von Mérey et al., 2011), which corresponds to a typical GLV mix released by freshly wounded plants, was tested. Second, we evaluated the attractiveness of the sesquiterpene (*E*)-*β*-farnesene (Sigma Aldrich, Switzerland), a major sesquiterpene that is released from herbivore-induced maize plants. Hexane solutions of synthetic plant volatiles were prepared at concentrations of 1,000, 500, 50, and 5 μl/ml. For each replicate, 2 μl of synthetic plant volatile solution and hexane (control) were incorporated into filter paper squares of 2 cm^2, which were placed on the ends of olfactometer arms. Maize plants can release 2–3 μg of the tested volatiles following the first 12 h of induction (Erb et al., 2011), which means that the lowest concentration we tested can be reached by a stand of five or more infested plants in a dense canopy with little air circulation.

Statistical Analysis Levene's and a Kolmorogov-Smirnov tests were carried out to determine heteroscedasticity of error variance and normality of the data. Number of eggs from preference tests performed with fall armyworm moths were analyzed by paired *t-tests* (α=0.05). Differences between behavioral responses of parasitoids under pairs of treatments were analyzed by *chi-square* tests (α=0.05 and α=0.01). Individuals that did not make a choice were excluded from the statistical analysis. Statistical analysis was performed using the software Statistica 6.0.

Results

Herbivore Oviposition Choice. Spodoptera frugiperda females laid, on average, 283 eggs on undamaged plants (UP) and 293 eggs on caterpillar-damaged plants (CD). There was no significant difference between the treatments in number of eggs (paired *t* test, N=20, t=−0.0951, P=0.925) or number of egg masses laid by *S. frugiperda* (data not shown).

Parasitoid Response to Maize Volatiles Neither wasps *T. remus* nor *Tr. Pretiosum* distinguished the odor of undamaged plants (UP) and air from blank arms (data not shown). Therefore, for the following bioassays, UP was used as a control. Results in detail were as follows: Naïve *T. remus* females did not show any preference for odors emitted by regurgitant-treated plants (RT) 0–1 h (Fig. 1; Table 1). Experienced females preferred odors from RT 0–1 h to UP (Table 1). The generalist *Tr. pretiosum* showed a significant preference for RT 0–1 h odors independently of previous experience (Fig. 1; Table 1). For the following time point, again, naïve *T. remus* showed no preference for odors emitted by RT 2–3 h (Fig. 1; Table 1), but a significant number of experienced females preferred RT 2–3 h to UP (Table 1). Both naïve and experienced *Tr. pretiosum* females showed a significant preference for RT 2–3 h odors compared to UP (Fig. 1; Table 1). Both *T. remus* and *Tr. pretiosum* showed a similar response towards volatiles released from RT 6–7 h. Naïve wasps showed no preference to RT 6–7 h or UP (Fig. 1; Table 1), while, after oviposition experience, they significantly preferred the RT 6–7 h odors to UP (Table 1). Neither naïve nor experienced *T. remus* and *Tr. pretiosum* showed a preference to RT 12–13 h compared to UP odors (Fig. 1; Table 1). *Telenomus remus* and *Tr. pretiosum* females did not distinguish between the odors of caterpillar-damaged plants (CD) or UP (Fig. 2; Table 1). However, significantly more experienced *T. remus* wasps preferred CD odors to UP (Table 1). *Trichogramma pretiosum* experienced wasps did not distinguish between CD and UP odors (Table 1).

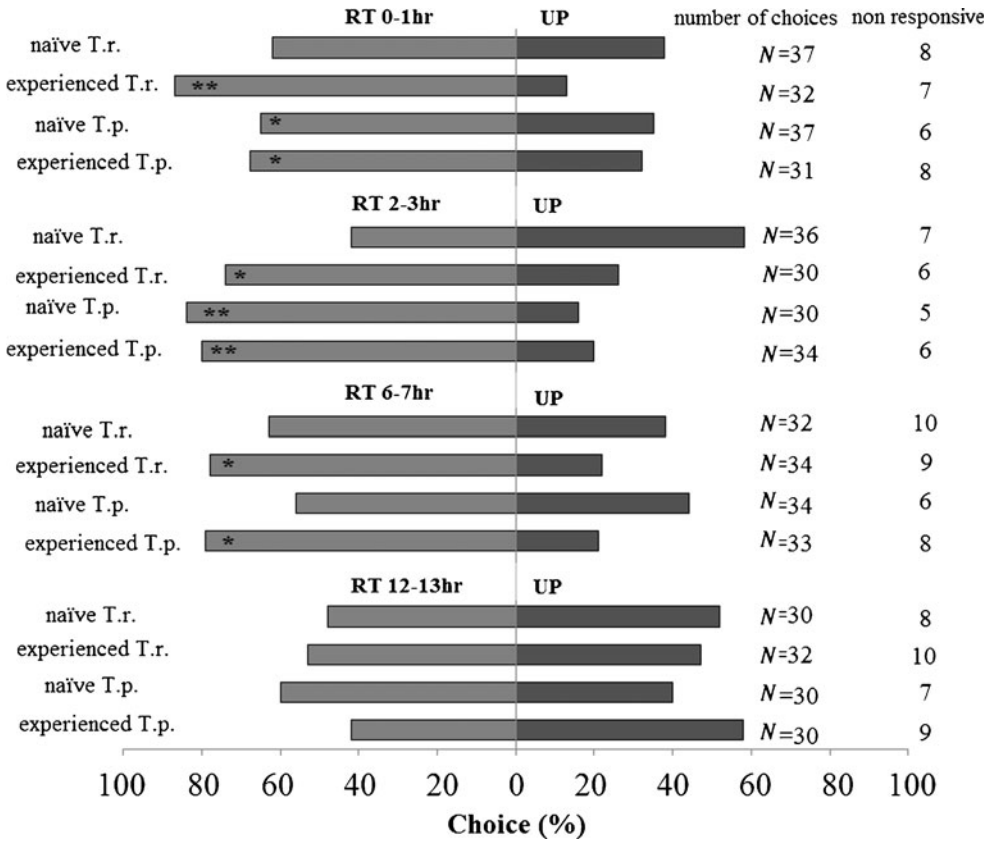

Fig. 1 Response of naïve and experienced *Telenomus remus* and *Trichogramma pretiosum* to volatiles emitted by undamaged plant (UP) and *Spodoptera frugiperda*-regurgitant treated plant (RT) 0–1, 2–3, 6–7, and 12–13 h. T.r. = *T. remus*; T.p. = *Tr. pretiosum*. * significant at 5% according to chi-square; ** significant at 1% according to *chi-square*

Parasitoid Response to Synthetic Volatiles Inexperienced *Tr. pretiosum* wasps showed a significant preference to GLV synthetic mixture at all tested concentrations (Fig. 3; 1,000 µl/ml$N$=35, χ2=6.429, P=0.011; 500 µl/ml$N$=35, χ2=4.829, P=0.028; 50 µl/ml$N$=35, χ2=10.314, P=0.001; 5 µl/ml$N$=35, χ2=4.829, P=0.028). In contrast, wasps did not show any attraction to (*E*)-*β*- farnesene at 5 or 50 µl/ml (Fig. 4; 5 µl/ml$N$=35, χ2=0.257, P=0.612; 50 µl/ml$N$=35, χ2=0.029, P=0.866), and preferred control (hexane) over (*E*)-*β*- farnesene at 500 and 1,000 µl/ml (500 µl/ml N=35, χ2=4.829, P=0.028; 1,000 µl/ml$N$=35, χ2=8.257, P=0.004).

Plant Volatile Collection The composition of the volatile mixture released by the different treatments is shown in Table 2. The proportions of compounds in the mixture are depicted in Fig. 5. It should be noted that, as the absolute quantities of the different volatiles cannot be directly compared with the given method, the approach used here is valid for relative differences between compounds at different time

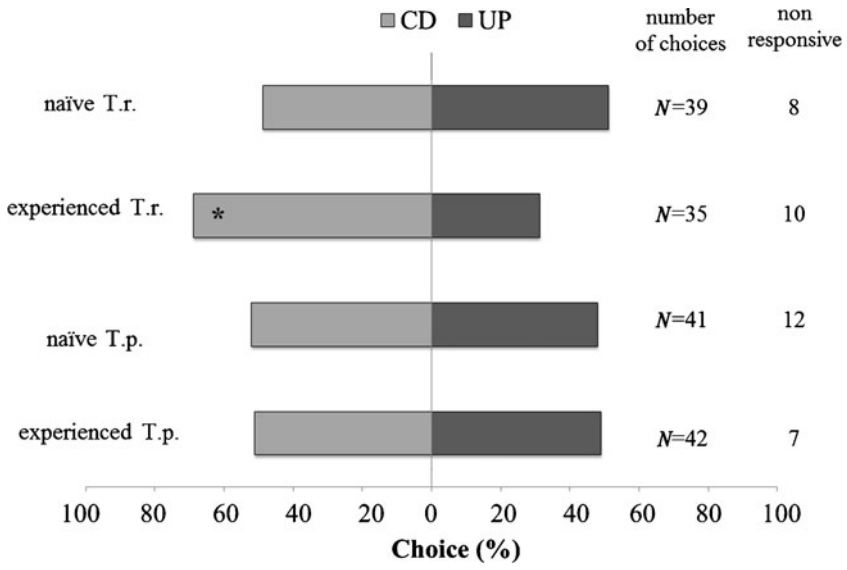

Fig. 2 Response of naïve and experienced *Telenomus remus* and *Trichogramma pretiosum* to volatiles emitted by undamaged plant (UP) and *Spodoptera frugiperda*-caterpillar damaged plant overnight (CD). T.r. = *T. remus*; T.p. = *Tr. pretiosum*. * significant at 5% according to *chi-square*

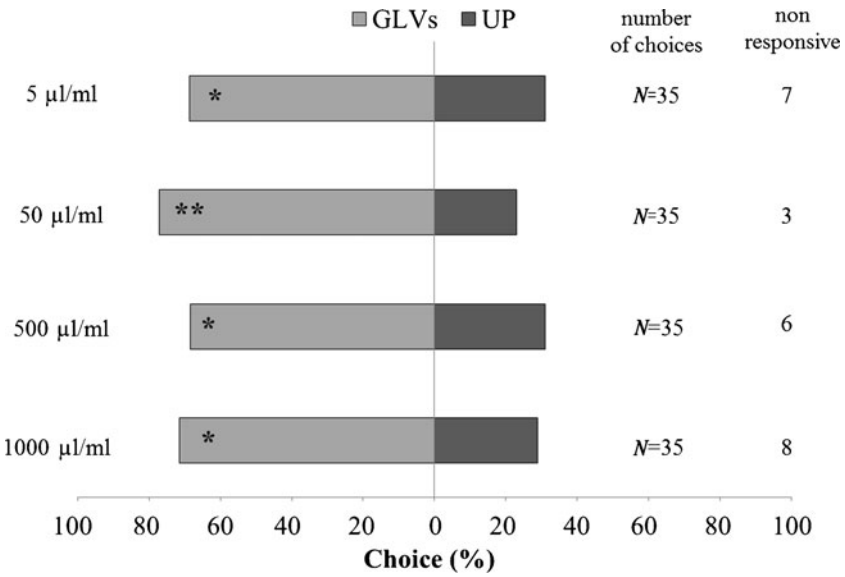

Fig. 3 Response of naïve *Trichogramma pretiosum* to different concentrations of synthetic GLV mixture (GLVs) at 5, 50, 500, and 1,000 µl/ml and hexane as control. * significant at 5% according to *chi-square*; ** significant at 1% according to *chi-square*

points. We observed that GLVs (*Z*)-3-hexenal, (*E*)-2-hexenal, (*E*)-3-hexen-1-ol, and (*Z*)-3 hexenyl acetate are predominantly released by RT 0–1 h, and monoterpenes, such as linalool and β-myrcene are present in small amounts (Fig. 5). On the following time interval, RT 2–3 h, the plants started to emit monoterpenes and aromatic compounds (phenethyl acetate, benzyl acetate, geranyl acetate e indole) in greater amounts, and the homoterpene (3*E*)-4,8-dimetil-1,3,7-nonatriene (DMNT) was abundant in the mixture (Fig. 5). Moreover, at this time interval, sesquiterpene emission commenced. By contrast, emission of GLVs almost ceased, and (*Z*)-3 hexenyl acetate was the only GLV that could still be detected.

At 6–7 h after induction, sesquiterpenes [(*E*)-β-caryophyllene, (*E*)-α-bergamotene, and (*E*)-β-farnesene] were emitted in highest amounts (Fig. 5). All aromatic compounds (except benzyl acetate), DMNT, and monoterpenes also were present in the blend. At this time interval, no GLVs were detected.

The composition of volatiles emitted 12–13 h after induction (induction at night time) was largely similar to the blend at 6–7 h, with exception of geranyl acetate, which was absent. Sesquiterpenes still dominated the mixture, while the proportion of homoterpenes (DMNT) was reduced. Monoterpenes were still present and in higher amounts than at 6–7 h (Fig. 5). In general, overall amounts of volatiles were reduced at 12–13 h compared to emission of RT 6–7 h, with exceptions of (*E*)-β-caryophyllene, which was the major compound among

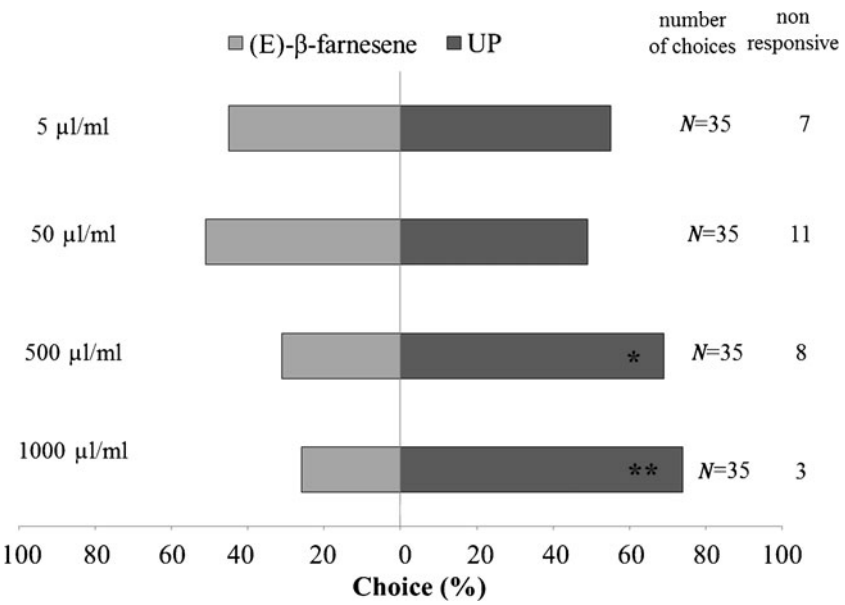

Fig. 4 Response of naïve *Trichogramma pretiosum* to different concentrations of synthetic (E)-β-farnesene at 5, 50, 500, and 1,000 µl/ml and hexane as control. * significant at 5% according to chi-square; ** significant at 1% according to chi-square

Table 2 Amount of volatiles (ng/h) released by *Spodoptera frugiperda* regurgitant- treated (RT) and caterpillar-damaged plant (CD)

Volatile compound	UP	Regurgitant-treated plant				CD
		0–1 h	2–3 h	6–7 h	12–13 h	
Green leaf volatiles (GLVs)						
(*Z*)-3-hexanal		26.3±6.1				122.5±25.1
(*E*)-2-hexanal		103.9±14.9				18.4±2.6

linalool	94.0±13.4	18.4±5.0	33.3±9.5	59.2±34.1	41.6±10.8	93.9±25.2
Homoterpenes						
(3*E*)-4,8-dimethyl-1,3,7-nonatriene			180.6±51.1	161.0±78.8	1.3±1.3	30.4±6.0
Sesquiterpenes						
(*E*)-β-caryophyllene			2.6±1.0	13.5±2.8	75.5±5.5	62.3±6.2
(*E*)-α-bergamotene			14.2±3.9	132.0±55.8	38.4±10.7	24.7±5.5
(*E*)-β-farnesene			27.3±9.3	282.2±119.7	53.8±19.5	39.6±12.5
Total	109.2±43.5	261.7±31.2	360.1±99.7	741.2±205.0	224.6±43.4	701.1±146.9

the sesquiterpenes, and β-myrcene. Continuous attack of *S. frugiperda* caterpillars overnight (treatment CD) triggered the emission of a complex volatile blend on the next day, which comprised all chemical groups simultaneously: GLVs, aromatics, homoterpenes, monoterpenes, and sesquiterpenes (Fig. 5). The relative quantities gave rise to a unique pattern of VOCs (Fig. 5).

Discussion

HIPVs can be detected over long distance, making them important signals in the host finding behavior of parasitoids (Vet and Dicke, 1992). While HIPVs can provide specific information about the attacking herbivore, such as species and herbivore stage (Takabayashi et al., 1995; De Moraes et

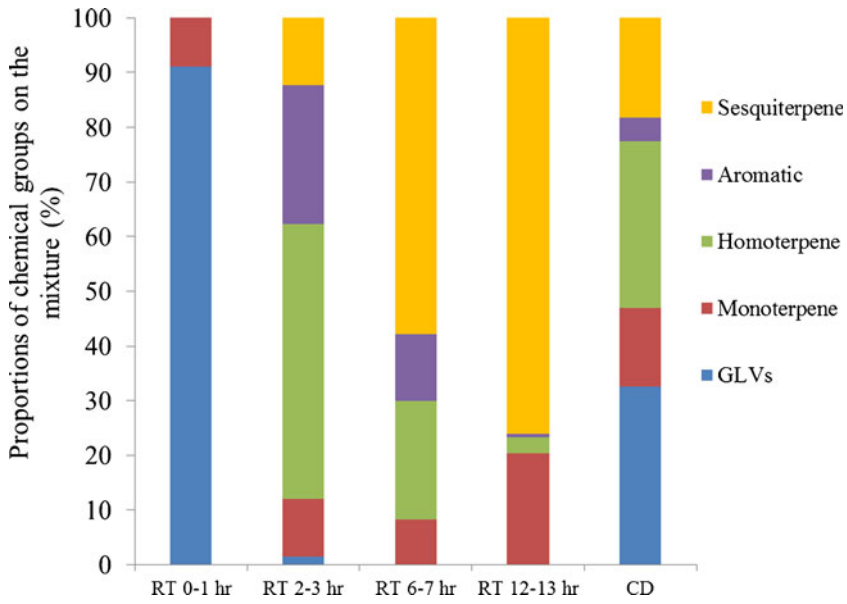

Fig. 5 Proportions of each chemical group present on the mixture released by *Spodoptera frugiperda*-regurgitant induced plant at 0–1 h (RT 0–1 h), 2–3 h (RT 2–3 h), 6–7 h (RT 2–3 h), 12–13 h (RT 12–13 h) and induced by larva feeding overnight (CD)

al., 1998; Mumm et al., 2005), our work shows that they also may serve as indirect cues, possibly giving away the presence of more inconspicuous host stages like eggs. Our results reveal that both generalist and specialist egg parasitoids may use plant volatiles to locate plants with potential hosts. Until now, few other studies have compared the strategies of egg parasitoids with different host ranges, and little has been done regarding their capacity to learn to respond to plant volatiles (Meiners et al., 2003).

The specialist parasitoid, *T. remus*, did not show an innate response towards volatiles emitted by regurgitant-induced maize or by fall armyworm attacked plants (CD). Nevertheless, after experience, *T. remus* was able to learn to associate odors emitted by the artificially induced and attacked plants. This suggests that in a situation where the parasitoid encounters eggs on plants that are attacked by emerging *S. frugiperda* larvae, it can adjust to this situation and use HIPVs as host-finding cues. The plasticity in behavior may be advantageous to the egg parasitoid, as HIPVs may be associated only with eggs under certain environmental situations: In times of high herbivore density, for example, it may be fairly common to find egg masses and larvae occurring simultaneously on the same plants, while in times of low occurrence, this would be less likely. Alternatively, HIPVs might play a role as long-range cues to egg parasitoids. Once wasps find the host community, host odors and subtle oviposition induced cues (Fatouros et al., 2008; Tamiru et al., 2011) from neighboring plants may precisely indicate the presence of the host.

Our results indicate that the multivoltine *S. frugiperda* does not avoid plants infested with conspecifics for oviposition, lending support to the concept that multiple host stages are likely to be present on maize plants under heavy pest pressure.

In contrast to *T. remus*, the generalist *Tr. pretiosum* was attracted innately to volatiles emitted by regurgitant-induced plants at 0–1 and 2–3 h (Fig. 1). These mixtures contained major amounts of GLVs compared to the later time points (Table 2 and Fig. 5). GLVs are thus main candidates for the innate attraction of *Tr. pretiosum*, and our bioassays with synthetic GLVs show that the parasitoid is indeed responding positively to these cues (Fig. 3). Maize larval parasitoids are known to be strongly attracted to fresh damage (Hoballah and Turlings, 2005; Shiojiri et al., 2006; Ngumbi et al., 2009), and other *Trichogramma* species have been shown be reactive to GLVs (Reddy et al., 2002; Romeis et al., 2005; Sen et al., 2005). Interestingly, *Tr. pretiosum* was not attracted to the complete blend elicited by larval feeding, which did contain substantial amounts of GLVs. This suggests that the composition of the HIPVs plays an important role in the attraction of the parasitoid, and some later induced volatiles like aromatic compounds and sesquiterpenes may distort and/or mask the attractiveness of the active volatiles. Additional evidence for the negative impact of these compounds comes from the fact that *Tr. pretiosum* was not attracted to caterpillar induced plants, even after having had a positive oviposition experience (Fig. 2), and from our finding that (*E*)-β-farnesene repelled the parasitoid, at least at high doses. It remains to be determined why *Tr. pretiosum* did not learn the CD blend, although it contained compounds that it was clearly able to perceive and learn. One obvious constraint of the data present here is that volatile collections and olfactometer assays took place in two different locations, and small differences in plant growth conditions may have altered the volatile blends (Gouinguené and Turlings, 2002).

According to the theory proposed by Vet and Dicke (1992), specialist parasitoids should respond innately to volatiles released by host-damaged plants, while generalists should rely more strongly on learning. Our results, however, show the exact opposite: the specialist seemed to rely more strongly on learning, while the generalist showed innate attraction to HIPVs (Fig. 1). This is in accordance with a series of studies showing that innate responses are important in generalists, and specialists retain a high capacity for learning (Dickens, 1999; Shiojiri et al., 2000; Smid et al., 2002; Steidle and Van Loon, 2003; Gouinguené et al., 2005; Hoballah and Turlings, 2005).

Both *T. remus* and *Tr. pretiosum* show innate responses to host odors, such as pheromones and body scales (Beevers et al., 1981; Nordlund et al., 1983; Noldus et al., 1990; Gazit et al., 1996). Similar to HIPVs, these are indirect cues for the egg parasitoids. The innate attraction to such signals may be advantageous because of their relative stability (i.e., pheromones vary very little) and their potential to guide the parasitoids to habitats that are likely to have eggs present within days.

In general, our results are in agreement with findings of Manrique et al. (2005) that studied the egg parasitoid *Anaphes iole* Girault (Hymenoptera: Mymaridae). This parasitoid develops exclusively in hosts of *Lygus* spp. (Hemiptera: Miridae), a group of polyphagous herbivores. In this system, only experienced parasitoids were attracted by volatiles induced by feeding of their hosts. Equally, Moraes et al. (2005, 2009) showed that *Telenomus podisi* (Ashmead) (Hymenoptera: Scelionidae), which is considered a generalist egg parasitoid of pentatomids, is innately attracted by HIPVs released by soybean and chickpea. Taken together, the emerging pattern is that generalist egg parasitoids seem to respond innately to HIPVs, while specialists rely on learning at least when their host is polyphagous. Learning HIPVs could allow specialist parasitoids to exploit odors from different plants and plant genotypes that carry their host (Gouinguené et al., 2001; Degen et al., 2004). This study is, to our best knowledge, the first to compare directly a generalist and specialist egg parasitoid within the same system, and further research comparing several generalist and specialist species is

required to confirm the pattern and explain the observed phenomenon in detail.

Differently from larval parasitoids, egg parasitoids can prevent injuries to crops by killing herbivores before hatching. Our results provide a better understanding on egg parasitoid host searching behavior, and may help to develop techniques that optimize the biological control efficiency of egg parasitoids in the field.

Acknowledgments We are grateful to Ted C. J. Turlings for comments in the manuscript and also for generously providing the laboratory facilities for collection and identification of plant volatiles. We thank INCT Semioquímicos na Agricultura, CNPq, and FAPESP for financial support (Process 07/00906-9 and 573761/2008-6). ME and LAM were supported by the Swiss National Science Foundation (3100A0-122132). This project was partially funded by the National Centre of Competence in Research (NCCR) "Plant Survival", a research program of the Swiss National Science Foundation.

of α-hydroxynitriles (cyanohydrins), biosynthetically derived from amino acids. They generally co-occur with β-glycosidases that can cleave the glycoside and release cyanide and carbonyl compounds upon damage to the plant. Both cyanide and carbonyl compounds are capable of conferring protection from herbivory and/or pathogens (Harborne, 1982). However, recent evidence has shown that high levels of cyanide (HCN) disrupt the enzymatic activity of polyphenol oxidase (PPO), enhancing the plant susceptibility to fungi (Lieberei, 1988; Ballhorn et al., 2010a; Ballhorn, 2011). Thus, there is a chemical trade-off for plants to resist herbivores or pathogens (Ballhorn et al., 2010a).

There have been several studies that compare the viability and development of the two strains when grown on different hosts (Pashley, 1988a; Quisenberry and Whitford, 1988; Whitford et al., 1988; Pashley et al., 1995; Meagher et al., 2007). In general, the rice strain tended to develop faster than the corn strain when fed on its preferred host, *C. dactylon*, (Whitford et al., 1988; Pashley et al., 1995; Meagher et al., 2007). Comparisons of the survivorship of the two strains on different *Cynodon* hosts were less consistent, with either no significant strain differences observed (Pashley et al., 1995; Meagher et al., 2007) or higher corn strain viability (Whitford et al., 1988). In particular, a past study from this laboratory found that stargrass, a *Cynodon* species frequently found in pastures, was a good host for the development of both strains, with high viability and developmental rates (Meagher et al., 2007).

This paper re-examines the issue of differential host plant usage by the two strains from the perspective of cyanide toxicity. The study was based on unexpected results from feeding studies that appeared to vary from past findings by this laboratory. It was found that a stargrass diet caused a substantial mortality in both strains, with significantly higher levels of larval and pupal mortality observed in the corn strain compared to the rice strain. The possibility that this might be due to high, but transient, levels of cyanogenic compounds produced in cut stargrass was examined. The ramifications of these findings to our understanding of strain-specific host preferences and to the interpretation of past feeding studies are discussed.

Methods and Materials

Plants and Insects Plants were cultivated in glass houses (5×8 m; Lord and Burnham, High Falls, NY, USA) under controlled temperature (22°C), humidity (80%) and photoperiod (14:10-h light/dark). 'Trucker's Favorite' corn and 'NuMex Sahara' bermudagrass plants grew from seeds, while stargrass (*C. nlemfuensis* Vanderyst var. *nlemfuensis* 'Florona') and 'Tifton 85' (a F_1 hybrid pentaploid between the bermudagrass PI 290884 (in the literature as 'Tifton 292') and the stargrass 'Tifton 68') (Burton, 2001) grew vegetatively from stolons in a 4:1 standard substrate (Metro mix 500) that was mixed with leveling sand. Plants were watered once a day and fertilized with 3.1 g/l Miracle Grow water soluble 24:8:16 once a week (The Scotts Company, LLC, Marysville, OH, USA). Two fall armyworm host strains were subjected to feeding experiments with corn and stargrass. The corn strain colony originated from collections of larvae made from corn at the University of Florida Dairy Research Unit, Hague, Alachua Co. FL, USA, while the rice strain colony originated from collections of larvae from pasture grasses at the University of Florida Range Cattle Research and Education Center, Ona, Hardee Co. FL, USA. These two host strains were identified by molecular markers (Levy et al., 2002) as modified by Nagoshi and Meagher (2003), and are currently maintained at the USDA, ARS, CMAVE Insect Behavior and Biocontrol Unit in Gainesville, FL, USA.

Larval Excretion and Adult Body Studies The excreta of 75 4th instars comprising 25 that were fed 'NuMex Sahara', 25 that were fed stargrass, and 25 that were fed 'Tifton 85' were collected after 3–5 h of feeding. Larvae were reared in plastic Sterilite tubs (Sterilite Corporation, Townsend, MA, USA) [26 (d) × 12.1 (h) cm] containing metal screens with a mesh size of 0.7 cm. Plant material was placed on top of the screen, and feces was collected on paper towels that lined the bottom of the tubs. The HCNp of the feces was determined as described below. Larvae were allowed to complete development on their host treatment and the emerged adult bodies were tested for cyanogenesis.

Cyanogenic Potential (HCNp) In order to measure the amount of cyanide released from a given tissue, or cyanogenic potential, the primary blades and the stems from corn, stargrass, 'NuMex Sahara' and 'Tifton 85' were assessed for HCNp during the winter of 2009. Feces from the insect trials, and eight adult moths fed on each diet, also were tested for HCNp.

Cyanogenic potential of plants was quantified by the Lambert procedure (Lambert et al., 1975) as modified by Brinker and Seigler (1989). The plant parts were ground to a fine powder in liquid nitrogen and added to a 10-ml vial containing 0.1 M phosphate buffer (pH 6.8). A 5-ml vial containing fresh 1 M NaOH solution then was placed inside the 10-ml vial, and the 10-ml vial was stoppered tightly and incubated at 37°C overnight. Samples were prepared quickly to avoid loss of HCN. During incubation, HCN released from plant tissue was trapped in the NaOH solution and formed NaCN. After incubation, cyanide was quantified spectrophotometrically (Biotek μQuant microplate, Rockville, MD, USA) using the reagents detailed in Brinker and Seigler (1989). The absorbance was measured at 580 nm. A cyanide standard curve was prepared with

0.02 M solution of NaCN in 0.1 N NaOH (0.980 g NaCN/L). The exact amount of cyanide in that solution was determined by a modified Liebig titration method as described by Brinker and Seigler (1989).

On occasion, plants, animals, or feces that are cyanogenic can yield negative results in tests for cyanogens. The organism may lack cyanogenic glycosides, or may contain cyanogenic glycosides, but not the necessary β-glucosidases needed to release the cyanide. In the latter case, the addition of exogenous β-glucosidase is necessary to quantify the HCNp. Since the cyanogenic glycosides in *Cynodon* spp. are unidentified, a low specificity β-glucuronidase (β-glucuronidase Type H-1 from *Helix pomatia* Müller, Sigma Chemical Co., St. Louis, MO, USA), which releases cyanide from all cyanogenic glycosides, was added to all samples (Brimer et al., 1983; Jaroszewski et al., 2002, Hay-Roe, 2004). For analysis of the HCNp in excreta, we added 500 μl of β-glucuronidase (149 units/ml β-glucuronidase) after thawing the samples in 0.1 M phosphate buffer (pH 6.8). The homogenate then was incubated at 37°C, and HCNp was determined as described above. Eight adult moths fed on each diet were tested for cyanogenesis using samples containing 250 μl of added β-glucuronidase per sample.

Subsamples of ground plant tissue, adult moth bodies, or insect excreta prepared for the cyanogenesis analyses were dried separately at 65°C until they reached a constant dry weight. The dry weight was used to calculate the μg HCNp/g dry weight of plant tissue, adult body tissue, or dry feces. Three replicates each were performed for the ground plant tissue and the insect excreta.

Cyanogenic Capacity (HCNc) Plant tissues were assayed to determine the amount of hydrogen cyanide released per unit of time, a metric known as cyanogenic capacity (HCNc). We were interested only in relative comparisons of HCNc to rank the different plant hosts. Feigl-Anger cyanide test strips were used to quickly and economically provide qualitative information (Feigl and Anger, 1966). The primary blades of 'NuMex Sahara', 'Tifton 85', and stargrass were ground and placed in 5-cm vials with a test strip in each vial. The vial was closed immediately, and patterns of HCN released were tracked every hour for 7 h. Color changes in the test strips were ranked as 0, 1, 2, or 3, according to the intensity of the blue color. Three separate samples were analyzed per plant.

Feeding Experiments A subset of our laboratory colonies was raised on natural host plants for at least three generations before subjecting the neonates to feeding experiments. The corn strain was maintained on greenhouse-grown 'Truckers Favorite' corn, while the rice strain was maintained on greenhouse-grown 'Florona' stargrass. These cohorts were maintained in environmental chambers at 26°C, 75% humidity and a 14:10 h L:D photoperiod.

In total, 120 neonates derived from 30 females of both host strains were raised separately in 1-oz. acrylic SOLO cups with cardboard lids. Fresh food was provided every 8 h during the day. Caterpillars were checked for the presence of head capsule apolysis on a daily basis and the developmental time of each instar was recorded. Head capsule measurements were made with a Wild Heerbrugg M5A microscope and an ocular micrometer. The following formula was used to calculate growth rate:

$$\text{Growth rate} = (\ln(H_f) - \ln(H_i))/t,$$

where H_f is the measurement of the last instar head capsule width; H_i is the measurement of the 1st instar head capsule width; and t is the larval developmental time. The growth rate is approximately the relative size increase on any given day.

The day when pupae formed was recorded as the first day of pupation. Pupal development was complete when the adult moth emerged from the pupal case. Each pupa was weighed 2 d after pupation. Adult sex was recorded and wing length was measured from the base of the wing to the apex using a Vernier caliper (Caliper 2,000 mm) graduated to 0.1 mm. Mass measurements were made with an electronic balance accurate to the nearest 0.1 mg.

Tolerance to Sodium Cyanide In order to determine the toxic effects of cyanide, third, fourth, and fifth instars of the corn and the rice strains were reared on a pinto bean artificial diet (Guy et al., 1985) containing either 0.5% or 0.1% NaCN, which was replaced once a day. Control larvae were fed unamended pinto bean diet. Larvae were raised individually in 1-oz. cups, and body weight, larval developmental time, and mortality rates were recorded.

In order to determine possible habituation to high cyanide concentration, three replicates of 20 newly-molted fourth instars of both strains were fed a 0.5% NaCN-containing pinto bean diet, with replacement of the cyanide-containing diet every 8 hr. When larvae began to molt to the fifth instar, they were transferred to 1% NaCN-containing diet that was replaced every 3 hr during the day (Brattsten et al., 1983).

Statistical Analysis Two-way analysis of variance was used to analyze the feeding experiment, the HCNp in plants, and the HCNp in insect excreta. A Tukey test was used to compare differences between different categories of a discrete variable. Head capsule and HCN measurements were transformed to a natural logarithm to alleviate skewness. A regression analysis was performed to correlate pupal weight and adult size. Data collected in the test of tolerance to NaCN-containing diet were compared to the control pinto bean diet data with the Student paired *t*-test. We used SYSTAT v. 12 (SYSTAT Software, Inc. San Jose, CA, USA) to perform statistical analysis.

Results

Cyanogenic Potential (HCNp) in the Primary Host Plants of Fall Armyworm Each species of plant used in this study had a distinct HCNp. The highest concentration of cyanide was observed in stargrass (1.54 mg HCN/g dry leaf tissue). This level was significantly higher ($F_{3, 40}$=348.2, P<0.001) than the levels found in the bermudagrass line 'NuMex Sahara' (0.16 mg HCN/g dry leaf tissue) or in the hybrid 'Tifton 85' (0.10 mg HCN/g of dry leaf tissue) (Fig. 1). In contrast, corn plants had low HCNp (0.01 mg HCN/g dry leaf tissue) (Fig. 1). Cyanogenic potentials in leaves were higher than in stems for both'NuMex Sahara' and 'Tifton 85' (P<0.05). HCNp in corn leaves and stems and in stargrass leaves and stems were not significantly different (P >0.05) (Fig. 1).

Cyanogenic Capacity (HCNc) in Grasses To estimate the temporal pattern of cyanide release from cut grasses, we determined cyanogenic capacity (HCNc). HCNc is a measure of the release of hydrogen cyanide per unit time (Alonso-Amellot and Oliveros-Bastidas, 2005; Ballhorn et al., 2005, 2010b). Large amounts of cyanide were released from stargrass within seconds after tissue injury, and the cyanide slowly dissipated and became undetectable after 8 hr (Table 1). A similar result was obtained with 'NuMex Sahara', but with lower levels of cyanide released during the first 5 hr. 'Tifton 85' had the lowest HCNc, with detectable cyanide only in the first hour after tissue injury (Table 1). This analysis defined the frequency with which host plant clippings had to be replaced in feeding studies in order to maintain exposure to plant cyanogenic compounds.

Feeding Experiments Laboratory feeding studies were used to compare mortality and developmental growth rates of the two host strains fed either corn or stargrass (Table 2). Both strains had <10% mortality when grown on corn. In comparison, using stargrass as a host resulted in high mortality, with the mortality level for corn strain larvae (77%) significantly higher than that for rice strain larvae (50%) (Z=-2.14, P<0.05). Larvae fed stargrass became dark, lethargic, and flaccid before dying. Pupae developed through the third day of pupation, but then became darker and dried out; some pupae were malformed. The difference in mortality between strains was limited to the larval stage. The few corn strain individuals that emerged to adulthood (N=7) were morphologically normal.

Despite the higher mortality, corn strain larvae had higher growth rates (1.06±0.02 mm/day) (mean ± SE) than rice strain larvae (1.00±0.02 mm/day) ($F_{1,107}$=8.3, P<0.005), with both strains displaying higher growth rates on corn (1.08±0.02 mm/day) than on stargrass (0.98±0.02 mm/day) ($F_{1, 107}$=18.8, P<0.001). Corn strain larvae (20.4±0.5 days) took longer to develop than rice strain larvae (17.6±0.3 days) ($F_{1, 89}$=10.8, P=0.001), no matter which diet was consumed. However, larvae of either strain feeding on corn (20.3± 0.3 days) took 4 days longer to develop than those feeding on stargrass (16.1±0.3 days) ($F_{1, 89}$=59.3, P<0.001). Pupal developmental time in the corn strain (12.0±0.2 days) was 1 day longer compared to the rice strain (11.2±0.2 days) ($F_{1, 74}$=4.7, P=0.03) regardless of diet. When both strains were fed corn they had a longer pupation time than when fed stargrass ($F_{1, 74}$=17.3, P<0.0001). A regression analysis showed that adult size was positively correlated with differences in pupal size in both host strains (P <0.001). The few surviving corn strain adults that had been fed stargrass had significantly longer wings than their rice strain counterparts (P=0.02), while no significant adult size difference was observed when both strains were fed corn (Table 2).

Larval Excretion Studies Fecal matter from larvae feeding on cyanogenic grasses was collected and examined for cyanogenic potential per fecal weight (μg HCNp/g). There was no significant interaction between host strain and plant host (ANOVA, P=0.46), so comparisons are shown between host strains and among grass diets. Corn strain larvae excreted significantly higher levels of cyanogenic compounds than rice strain larvae (Fig. 2a). Roughly equal amounts of cyanogenic compounds were excreted when the corn and rice strains fed on stargrass and 'Tifton 85',

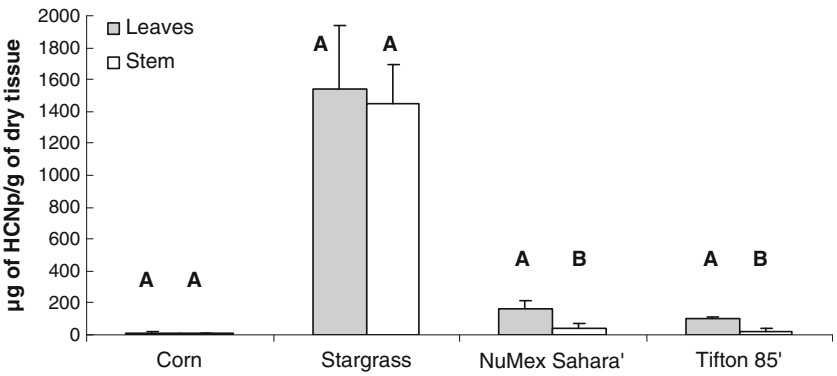

Fig. 1 Spectrophotometric measurement of HCNp from corn, stargrass, 'NuMex Sahara', and 'Tifton 85' leaves and stems. Letters indicate significant differences between plant parts according to *post hoc* analysis (Tukey's HSD P< 0.05). Bars indicate standard error. Mean of three replicates

Table 1 Cyanogenic capacity (HCNc) of injured *Cynodon* spp. plant tissue monitored over an hourly basis with Feigl-Anger strips

Cynodon spp.	1 h	2 h	3 h	4 h	5 h	6 h	7 h	8 h	9 h
Stargrass	3	3	2	2	2	1	1	1	0
'NuMex Sahara'	2	2	1	1	1	0	0	0	0
'Tifton 85'	1	0	0	0	0	0	0	0	0

Progress of hydrolysis: no reaction (0), trace (1), present (2), extreme (3)

and levels for both strains were significantly higher than levels in excretions from larvae consuming the 'NuMex Sahara' diet (Fig. 2b).

Adult moths from both strains were acyanogenic regardless of diet. The addition of β-glucuronidase did not alter the results.

Tolerance to Sodium Cyanide To test more directly whether the two strains differed in their tolerance to cyanide toxicity, feeding studies were performed in which inorganic cyanide (NaCN) was added to an artificial diet. Cyanide concentrations of 0.05% and 0.1% NaCN did not increase larval mortality, but did retard larval development time for both strains. Corn and rice strain 5th instars took a longer time to develop when feeding on either the 0.05% NaCN-diet (corn strain: *t*-test df=25, t=-2.2, P =0.04; rice strain: *t*-test df=28, t=-10.4, P <0.001), or the 0.1% NaCN-diet (corn strain: *t*-test: df=24, t=-3.262, P=0.003; rice strain: *t*-test df=29, t=-8.3, P <0.001) compared to larvae of each strain feeding on the control diet (Table 3). A similar delay in rice strain larval development was reached in the 4th instar for both the 0.05% NaCN-diet (*t*-test df=29, t=-2.8, P=0.009) and 0.1% NaCN-diet (*t*-test df=29, t=-10.0, P<0.001) (Table 3). Neither NaCN treatment produced a significant change in corn strain larval weight. A significant reduction in rice strain larval weight was observed for 3rd instars feeding on 0.1%NaCN (*t*-test df=29, t=2.1, P=0.04) and 5th instars on both NaCN concentrations (0.05%NaCN: *t*-test df=28, t=3.4, P<0.002; 0.1%NaCN: *t*-test df=29, t=4.9, P<0.001) (Table 3).

Substantial mortality was observed at higher concentrations of NaCN. In the habituation study, 58% of corn strain larvae died by the 5th instar on a 0.5% NaCN-diet. The larvae showed evidence of poisoning, such as flaccidness and regurgitation. An additional 19% of the surviving larvae died within 2 days of exposure to the 1% NaCN diet producing a total mortality of 77% by the end of the habituation experiment (Table 4). Only 13 corn strain adults (8 females and 5 males) survived the experiment. Dissection of the dead larvae showed necrosis of the crop and the anterior midgut and a peculiar overgrowth of the salivary glands. In contrast, 80% of the rice strain specimens survived to eclosion. Both strains produced significantly smaller pupae on the high NaCN-diet (Table 4).

Discussion

Corn and stargrass leaves have very different levels of cyanogenic compounds, suggesting that cyanide toxicity may explain elevated fall armyworm mortality when the latter is used as a host plant. Differences in the ability to metabolize or eliminate cyanide may be the physiological basis for the plant host biases exhibited by fall armyworm

Table 2 Percent mortality at different stages of development and adult wing lengths for corn strain (CS) and rice strain (RS) of *Spodoptera frugiperda*. Insects were fed corn or stargrass

Fall armyworm stage	Diet

host strains. There are precedents for this mechanism of conferring host plant specificity. Cyanogenesis is a chemical defense mechanism of plants against herbivores, with cyanide inhibiting the electron transport chain in the cell respiratory pathway (Solomonson, 1974). However, some insects and other organisms have adapted to this toxicity and are able to overcome it by sequestration, synthesis, metabolic detoxification, excretion, or regurgitation of the cyanogenic compounds and/or cyanide (Conn, 1981; Nahrstedt, 1988; Jones, 1988; Zagrobelny et al., 2004). Although the function of cyanogenesis in interactions with generalist and specialist herbivores is not fully understood (Gleadow and Woodrow, 2002), there is evidence that plant selection by generalists differs from specialists due to cyanogenic features of the host plant (Engler-Chaouat and Gilbert, 2007; Ballhorn et al., 2010b).

Evidence that the two fall armyworm strains examined here differ in their response to cyanide exposure is based on two main results. The corn strain has significantly higher mortality levels when fed inorganic cyanide than the rice strain. The relative tolerance of the rice strain to cyanide toxicity is consistent with its preference for *Cynodon* species (Pashley, 1988a; Meagher et al., 2007) that produce substantial concentrations of cyanogenic compounds. The second observation is the statistically significant difference in cyanide levels in the fecal excretions of corn strain larvae when grown on cyanogenic grasses (Fig. 2). This indicates that there are physiological differences between strains for the processing, elimination, or tolerance of ingested cyanogenic compounds.

These results appear to contradict an earlier study from our laboratory that did not demonstrate increased mortality, or any aberrations in the development of fall armyworm, when grown on a stargrass diet (Meagher et al., 2007). We believe this apparent conflict is due to methodological differences in the two studies. In the previous study, plant cuttings used for diet, including stargrass, were replaced every 1–2 days. Given the lability of the cyanogenic compounds in cut plant tissue (Table 1), the availability of cyanide in the diets in our earlier study was probably intermittent at best. In the current study, the stargrass was replaced with fresh cuttings every 8 hr, thereby providing a more consistent exposure to cyanide.

In addition, Meagher et al. (2007) reared larvae in a chamber where the plant cuttings were placed on a water-saturated filter paper (to prolong the quality of the plant material). Because cyanide is water-soluble, this procedure had the potential to leach cyanide from the diets, thereby reducing the levels ingested. To avoid such leaching in this study, rearing containers were kept dry, and fresh plant cuttings were added more frequently. Cyanogenesis in stargrass may also vary substantially, depending on a number of environmental factors (Aguilera et al., 1982a,b, 1984). In particular, seasonal variation in cyanide concentration is a common trait of cyanogenic plants (Cooper-Driver et al., 1977; Kaplan et al., 1983; Jones and Rammani, 1985; Gebrehiwot and Beuselinck, 2001; Hay-Roe and Nation, 2007).

Finally, the young leaves of cyanogenic plants generally contain larger quantities of cyanide than mature leaves and stems (Conn, 1981; Goodger et al., 2007; Hay-Roe and Nation, 2007; Ballhorn et al., 2008). This phenomenon has been associated with higher concentrations of soluble protein in young leaves, compared to mature leaves (Ballhorn et al., 2008). In our present study, we found that leaves and stems of stargrass did not differ in their HCNp. Aguilera et al. (1985) reported that under certain conditions, related to

the amount of fertilizer and the testing period after plant fertilization, cyanide concentration in leaves and stems of *C. nlemfuensis* does not vary. Therefore, comparisons of feeding studies, even from the same laboratory, could be problematic if the potential variability in cyanide levels is not considered.

Cyanide poisoning in larvae generally was characterized by flaccidness in the body and regurgitation behavior, with dead larvae displaying crop necrosis and overgrowth of the salivary glands. Similar phenotypes including flaccid bodies and dried, dark and lacerate pupae, also were observed in the dead larvae and pupae that had been fed the stargrass diet. These observations suggest that cyanide poisoning may account in part for the reduced viability observed on stargrass. We also note that sublethal levels of NaCN in the diet produce significant delays in developmental time and larval weight (Table 3). Previous research showed that pinto bean artificial diet slows larval and pupal developmental time and that rice strain fed on this diet experienced lower growth rates than the corn strain (Quisenberry and Whitford, 1988; Hay-Roe, personal observations), suggesting that this variability is related to the pinto bean diet.

The observation that the two strains differ in the amount of cyanide excreted while feeding on stargrass is intriguing but difficult to interpret (Fig. 2). The data indicate that the corn-strain is more efficient at eliminating cyanide, yet it is also the most susceptible to its toxic effects. These results suggest that excretion is not the primary mechanism used by either strain to detoxify cyanogenic compounds and that the strain difference observed may simply reflect the higher sensitivity of the corn strain to the toxic effects. In other words, the higher HCN levels in the corn strain feces may be an incidental consequence of physiological abnormalities caused by cyanide toxicity. The possibility that the metabolism of the toxic cyanogenic compounds involves insect digestive enzymes or formamide hydrolyase produced by pathogens of cyanogenic plants (Fry and Munch, 1975) cannot be discarded.

Adult moths were acyanogenic in both host strains, and this suggests that cyanogenic glycosides are not sequestered by the larvae and are not used as a protective mechanism by fall armyworm adults, as occurs in some other Lepidoptera (Franzl and Naumann, 1985; Zagrobelny et al., 2004). The larvae do regurgitate gut contents as a defensive mechanism against predators, but regurgitates from fall armyworm fed cyanogenic compounds were not analyzed for cyanogenesis.

In summary, evidence is presented that plant cyanogenic glycosides might play a significant role in defining the host range of the two fall armyworm strains. Differences in cyanide levels were observed in the host plants, and the two strains differed in their sensitivity to cyanogenic compounds and in their capacity to metabolize and/or eliminate these compounds. Host plant specificity could be the force driving the divergence and incipient speciation of the two host strains.

Our analysis of cyanogenic capacity has clarified factors in the variable and often contradictory results reported in previous feeding studies. The way that plant material is

prepared and the frequency with which new material is added to the diet can significantly affect the levels of cyanide exposure in feeding studies, with potential to confound experimental observations of developmental rate, mortality, and larval behavior.

on flowers during nectar consumption may help to protect plants against herbivores and flower-parasites (Yano, 1994; Bleil et al., 2011). However, they are usually floral antagonists that consume nectar without pollination and/or aggressively defend flowers against true pollinators (Galen, 1983; Lach, 2005; Junker et al., 2010a). It has been suggested that the exposure to nectar-thieving ants selects for the emission of ant-repellent floral scents as well as other types of defenses (Junker et al., 2011a). Therefore, floral scents may have both attractive and defensive properties serving as potent filters that promote floral visitation by mutualists but restrict other visitors including antagonists (Kessler et al., 2008b; Raguso, 2008a; Junker et al., 2010b).

Floral scents comprise complex mixtures of chemical compounds that belong to different chemical classes. Terpenoids and benzenoids are two prominent classes of compounds emitted from flowers of most plant species (Knudsen et al., 2006). Recently, two studies proposed a functional dichotomy of these classes: terpenoids, especially monoterpenoids, have been suggested to function as defense compounds, and benzenoids have been supposed to be attractants (Junker and Blüthgen, 2010b; Schiestl, 2010). Schiestl (2010) investigated the correlation between the evolution of floral scents and the chemical communication of insects by comparing volatile organic compounds that are emitted by flowers with those used by insects for inter- and intra-specific communication. He found a strong overlap between individual monoterpenoids that occur in floral scents and those that function in the communication systems of herbivorous insects. On the other hand, benzenoids have been found both in floral scents and as communication substances in taxa of pollinating insects. Meanwhile, Junker and Blüthgen (2010b) conducted a meta-analysis and compared the responses of obligate (usually mutualistic) and facultative (usually antagonistic) flower visitors to a variety of floral scent compounds documented in the literature; they showed that monoterpenoids have strong repellent properties against facultative flower visitors, such as ants and herbivorous animals, while benzenoids are attractants for obligate flower visitors, such as members of many pollinator taxa. The results of these studies indicate that the dual role of floral scent bouquets arises from the complex blend of attractive and defensive components (compare to Kessler et al., 2008a) that may derive from different biosynthetic pathways.

In this study, we focused on the defensive properties of floral scents, testing the hypothesis that floral terpenoids mediate repellent effects against ants. We inhibited terpene biosynthesis in flowers of *Phlox paniculata* (Polemoniaceae) and tested the effect of the inhibited scent bouquet vs. the uninhibited control on the behavior of *Lasius niger* ants. For inhibition, we used fosmidomycin and mevinolin, substances that inhibit the pathways of monoterpene and sesquiterpene biosynthesis, respectively (Dudareva et al., 2005; Schie et al., 2006). The flower odor of *P. paniculata* is composed mainly of monoterpenoids and benzenoids, and to a lesser extent of sesquiterpenoids and fatty acid derivatives (Andersson et al., 2002). Thus, this species is well suited to test our hypothesis about the defensive roles of floral terpenoids. An advantage of this approach is that inhibitor treatment of flowers should reduce the emission of terpenoids without influencing the composition of the benzenoids and fatty acid derivatives. In addition to the experiments with ants, we also examined the attractiveness of treated and untreated flowers to typical pollinator taxa.

Methods and Materials

Study Organisms *Phlox paniculata* plants (Polemoniaceae, variety Peppermint Twist) were obtained from a plant nursery (Gärtnerei Boock, Jena, Germany). The plants were reared without applying insecticides or other plant protection products, neither in the plant nursery nor after purchasing. Plants were kept outdoors and watered daily prior to the start of the experiment in July and August 2009. When we performed the experiments, all plants were flowering. *Lasius niger* (Hymenoptera, Formicinae) ants from three different colonies were collected in the field (Würzburg, Germany) in July 2009. Workers and brood were kept in plastic containers (25×16×12 cm) filled with garden soil as a substrate in a climate chamber (14:10 h. L:D, 26°C/19°C, with a constant relative humidity of 50%.). The walls were coated with a thin layer of Fluon (Whitford, Diez, Germany) in order to prevent ants from escaping. Ants were fed with a sugar solution (30%) offered on filter paper and tuna meat; Additionally, water was provided in tubes sealed with cotton wool. The substrate in the containers was watered regularly, to stay moist.

Inhibition of Floral Terpene Biosynthesis We inhibited terpene biosynthesis with the pathway-specific inhibitors fosmidomycin (Invitrogen, Carlsbad, CA, USA) and mevinolin (Sigma-Aldrich, Taufkirchen, Germany) (Dudareva et al., 2005). Fosmidomycin inhibits 1-deoxy-D-xylulose-5-phosphate reductoisomerase (DXR), an enzyme in the plastidic methylerythritol phosphate pathway of terpene biosynthesis, which usually provides the substrate for monoterpenoid formation (Schie et al., 2006). Mevinolin inhibits 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGR), an enzyme of the cytosolic mevalonate pathway of terpene biosynthesis, which generates the precursors for sesquiterpene synthesis (Schie et al., 2006). Fosmidomycin was dissolved in distilled water to a final concentration of 10 mM. Prior to application, the mevinolin lactone was converted into the open acid form (sodium salt) as described

in Kita et al. (1980) in order to increase water solubility. The mevinolin sodium salt was dissolved in distilled water to a final concentration of 1 mM.

Individual flowers were picked in the evening (around 8 pm) and immediately placed in vials filled with aqueous sucrose solution (5%) and subject to one of the following treatments: (1) control *C*: no addition; (2) addition of the inhibitors fosmidomycin and mevinolin *FM*: fosmidomycin and mevinolin were added to the sucrose solution to a final concentration of 75 μM each. We used both inhibitors simultaneously because, even if the plastidic or cytosolic pathway is blocked, terpene precursors may be transported between these compartments (Dudareva et al., 2005; Schie et al., 2006). Scent sampling and olfactometer trials with ants were performed the next morning between 12 and 18 h after treatment. Flowers were used only if they were in good condition and of normal appearance.

Floral Volatile Collection and Analysis Volatile organic compounds emitted by *Phlox paniculata* flowers treated with fosmidomycin and mevinolin (*N*=4) or untreated controls (*N*=4) were collected in a dynamic headspace collection system located in a growth chamber set at 20°C, 55% relative humidity and 85±5 μmol m^{-2} sec^{-1} photosynthetically-active radiation. At 16 h after treatment application, the flowers were placed individually in 1 l glass desiccators (Schott, Mainz, Germany) tightly closed with a glass lid. Charcoal-filtered air entered the desiccators via a valve at 0.7 $lmin^{-1}$. After being in contact with the plant, the air exited the glass cylinder through a Super Q trap (filled with 20 mg Super Q, ARS, Gainesville, FL, USA), positioned in an opening in the lid to absorb flower volatiles. Volatiles were collected for 2 h starting at noon. Afterwards, the volatile compounds trapped were desorbed by eluting the filters with 150 μl dichloromethane containing nonyl acetate as an internal standard (10 ng μl^{-1}). Samples were stored at -20°C until analysis with GC-MS and GC-FID.

Qualitative and quantitative determination of *P. paniculata* volatiles was conducted using an Agilent 6890 Series gas chromatograph coupled to an Agilent 5973 quadrupole mass selective detector (interface temp.: 270°C; quadrupole temp.: 150°C, source temp.: 230°C, ionization potential: 70 eV) or to a flame ionization detector operated at 300°C. The constituents of the volatile bouquet were separated with a DB-5MS column (Agilent, Santa Clara, CA, USA, 30 m×0.25 mm× 0.25 μm) and He (MS) or H_2 (FID) as carrier gas at 1 ml min^{-1}. A 1 μl sample was injected splitless at an initial oven temperature of 40°C that was kept constant for 2 min and then increased to 155°C with a gradient of 7°C min^{-1}. Thereafter, temperature was increased by 60°C min^{-1} to reach a maximum of 300°C that was kept constant for 3 min.

Most compounds were identified by comparison of their retention times and mass spectra to those of authentic standards. However, four compounds [(*E*)-β-ocimene, lilac aldehydes A and B, and lilac alcohol D] were identified solely by comparison of mass spectra to those of reference spectra in Adams (Adams, 2007) and the Wiley and National Institute of Standards and Technology (NIST) libraries. The absolute amount of all compounds was determined based on their FID peak area in relation to the area of the internal standard using the effective carbon number (ECN) concept as described by Scanion and Willis (1985).

In addition to the scent sampling as described above, we sampled the flowers that were used as scent source for olfactometer trials immediately prior the tests by using SPME (solid phase microextraction) fibers consisting of 100 μm polydimethylsiloxane (Supelco, Bellefonte, PA, USA). These scent samples were used to check for variation in the effect of inhibitors and the natural variation in scent production in *P. paniculata*. For logistical reasons, we used two SPME fibers, but each fiber was used for both control and treated flowers on different days in order to compare the proportional emission of individual volatiles between samples. Statistical comparisons (described below) showed that the individual fiber had no influence on the volatile analysis. Flowers were placed in 1 l glass desiccators covered tightly with glass lids that contained a Teflon plug with a small hole into which the SPME fiber for volatile collection was inserted. Floral headspace volatiles collected in the glass vial were trapped for 20 min. The adsorbed volatiles were analyzed afterwards by directly inserting the SPME fiber into the injector of the gas chromatograph. GC/MS analysis and product identification was performed as described above.

Olfactometer Trials For olfactometer trials, we used the same setup as described in detail in Junker and Blüthgen (2008). In the four-pointed star shaped arena of a Petterson olfactomter (Pettersson, 1970) (length from tip to tip: 330 mm, depth: 15 mm), four distinct odor fields were created in which ants can move and respond to different odors. The arena was covered with a glass plate. Each arm of the arena was connected to an odor supply. Openings for air inlet and outlet were obstructed with aluminum mesh to prevent ants from escaping. A constant airflow of 200 ml min^{-1} was pumped into each of the four arms of the olfactometer, maintained with separate flow meters (Analyt, Müllheim, Germany). Two flowers in a glass vial were placed into a desiccator. Charcoal purified air that previously passed through a bottle filled with distilled water entered the desiccator containing the flowers, and was then pumped into the two opposite arms of the arena. Charcoal filtered moistened air containing no odor was pushed into the two other arms of the arena as a control. A neon lamp (220 V, 11 W) illuminated the arena equally. A central hole (10 mm diam) in the arena allowed the air to flow out of the arena.

Treatments *C* and *FM* were repeated six times for olfactometer trials. In each replication, 8 - 10 trials with 10 ants

each were performed, resulting in a total of 136 olfactometer trials (*C*: *N*=58, *FM*: *N*=78) with 1360 ants. In each trial, ten *L. niger* workers were simultaneously released in the arena, and the number of ants in odor and control fields was counted after 60, 90, 120, and 150 s. The mean number of ants in the odor and control fields at the four time points was calculated, and for each trial the mean difference of number of ants *D* in odor and control fields per 150 s period was calculated (*D*=mean number in odor fields−mean number of ants in control fields) as the basis for the statistical analyses. The positions of odor and control fields within the arena were altered after each 150 s period (odor fields were transformed to control fields and *vice versa*), and ants were replaced by a new group of ten ants. Repellence of floral scents was indicated by a significantly lower mean number of ants in odor fields than in control fields (i.e., $D<0$).

Olfactometer Trials with Individual Substances The results of the previous experiments suggested that linalool—one of five monoterpenoids that are emitted by flowers of *P. paniculata*—primarily triggered the ants' aversion towards these scent bouquets (see below). To verify this result, we performed olfactometer trials with synthetic linalool (Merck, Darmstadt, Germany, ≥ 97% linalool) in six different concentrations. Linalool was dissolved in light paraffin oil (AppliChem, Darmstadt, Germany), and 25 µl of the paraffin-scent solution were applied on a filter paper. Concentrations were chosen in a way that the mass of linalool applied on the filter paper corresponded to the mean hourly linalool emission [ng h^{-1}] of two control flowers and to 1/10x, 10x, 100x, 1000x, and 10,000x the hourly emission. Filter papers were placed in an upright position in a desiccator. A filter paper treated with light paraffin oil only served as the control in another desiccator. Desiccators were connected to the olfactometer setup, and experiments with *L. niger* workers were performed as described above. Per concentration, we performed 24 trials as described above with 10 ants each. Additionally, four further substances [benzaldehyde (Fluka, Munich, Germany, ≥ 99%), eugenol (Merck, Darmstadt, Germany, ≥ 99%), (*Z*)-β-ocimene (mixture of isomers SAFC, Hamburg, Germany, GC-MS analysis revealed that only (*Z*)-β-ocimene is included plus limonene), 2-phenyl acetaldehyde (Sigma-Aldrich, Munich, Germany, ≥ 90%)], which were also detected in the scent bouquet of *P. paniculata*, were used for olfactometer trials in the same dilution series. Note that the flowers emitted (*E*)-β-ocimene, but not (*Z*)-β-ocimene. Per substance and concentration, twelve trials with 10 ants each were conducted.

Visitation by Flying Flower Visitors In order to check the attractiveness of *P. paniculata* flowers to flying flower visitors, 3 flowers of treatments *C* and *FM*, each, were placed in glass vials filled with water next to a blooming *Buddleja davidii* (Scrophulariaceae) shrub. These trials were repeated eight times with a set of 3 control- and 3 treated flowers 18 h after the flowers had been picked and treated. Flower visiting frequency and duration as well as the identity of flower visitors were noted.

Statistical Analysis Scent composition (emission per substance [ng h^{-1} $flower^{-1}$]) of control flowers (*C*) and flowers treated with inhibitors (*FM*)—as revealed after volatile collection using Super Q traps—were compared using "*random forest*", a machine learning algorithm that assigns samples to predefined groups (*C* and *FM*) in multiple iterations and estimates the importance of each compound for a correct classification (Breiman, 2001). This bagging method has been applied successfully in other ecological studies to classify samples based on volatile- and/or community-composition, and its advantages and applicability (i.e., it calculates the importance of each variable for a correct classification independently of all others but also considers multivariate interactions with the others while not over-fitting the data) have been demonstrated (Prasad et al., 2006; Ranganathan and Borges, 2010; Junker et al., 2011b). For our statistical analysis, we drew n_{tree}=100,000 bootstrap samples with m_{try}=4 variables randomly selected at each node. To receive optimal results, it is suggested to set m_{try} equal or close to the square root of number of variables (i.e., in this case number of volatiles=16) used for the classification (Breiman, 2003). The implementation of *random forest* in the statistical software R (R Development Core Team, 2011) returns a confusion matrix that summarizes the results of the classification as well as the variable importance *E* for a correct classification. Substances that are differently emitted by the groups (*C* and *FM*), and thus contribute heavily to the correct classification, receive high positive *E*-values, whereas substances that are uninformative for the classification or work against it (i.e., the substances are emitted equally by the groups) receive negative *E*-values. The results from the random forest analysis were confirmed by Mann–Whitney *U*-tests comparing the emission [ng h^{-1} $flower^{-1}$] of individual substances as well as the total emission of control (*C*) and treated flowers (*FM*).

Ant responses *D* towards control bouquets (*C*) in the olfactometer-arena were compared to responses *D* to treated bouquets (*FM*) with a *t*-test to evaluate whether the changes in the floral scent bouquet resulted in changes in ant behavior. Furthermore, responses *D* to scents of control (*C*) and treated flowers (*FM*) were tested individually against the null hypothesis with a paired *t*-test, i.e., against $D=0$ assuming an equal number of ants in odor and control fields of the arena.

In order to assess how individual floral scent compounds influenced the ants' choices in the olfactometer arena, we pooled the *D* values obtained from individual sets of control (*C*, *N*=6) and treated flowers (*FM*, *N*=6) to a mean $\overline{D}$ (each $\overline{D}$ value included 8-10 150 s periods), and fitted linear

models with the proportion of individual floral scent compounds within the bouquet—as revealed after volatile collection using SPME fibers—as the explanatory variable and $\overline{D}$ as the response variable. Since individual SPME fibers may have different adsorption properties to different volatiles, we used the SPME fiber as an additional explanatory variable and tested for both the interaction between SPME fiber and proportional emission of substances and the influence of the SPME fiber on the responses itself.

All statistical analyses were performed with the statistical software R (R Development Core Team, 2011).

Results

Floral Scent Composition of Control and Treated Flowers Dynamic headspace collection with Super Q filters and subsequent GC-MS analysis revealed that flowers of *Phlox paniculata* emitted 16 substances from four classes (Table 1). Qualitatively, the scent bouquets of control (*C*, $N=4$) and treated (*FM*, $N=4$) plants were the same, i.e., the same substances were found in control and treated flowers. However, we found strong differences in the quantitative composition of the samples, mainly caused by a strong reduction in terpenoid emission (Table 1). Accordingly, *random forest* analysis correctly assigned all of the bouquets of inhibitor-treated flowers to the treated group (*FM*, class error=0%) and three out of four control bouquets to the control group (*C*, class error=25%) indicating that one control sample also contained fewer terpenoids than the others (Table 1). Four out of six terpenoid substances (including monoterpenoids and the sesquiterpene germacrene D) received positive *E*-values, indicating that the bouquets of control and treated flowers can be best discriminated by these volatiles, which was partly supported by the Mann–Whitney *U*-tests (Table 1). Non-terpenoid substances received negative *E*-values (except for methyl eugenol) indicating that they were not differently emitted by control and treated flowers; accordingly no differences were detected by Mann–Whitney *U*-tests (Table 1). Total scent emission [ng h^{-1} $flower^{-1}$] was not significantly different in control and treated flowers (Table 1).

Olfactometer Trials In total, we performed 136 olfactometer trials (*C*: $N=58$, *FM*: $N=78$) with a total of 1360 ants. Ant responses to scents of untreated (*C*) and treated (*FM*) flowers were different (Welch *t*-test: $t_{128.1}=2.8$, $P<0.01$, Fig. 1): the natural floral scent bouquet repelled ants (*t*-test: $t_{57}=3.62$, $P<0.001$, Fig. 1), while the ants responded neutrally towards treated flowers (*FM*) with only low amounts of terpenoids emitted (*t*-test: $t_{77}=0.26$, $P=0.80$, Fig. 1).

For each floral bouquet tested, the mean proportion of ants in odor fields of the olfactometer in relation to control fields $\overline{D}$ correlated negatively with the proportion of linalool in the odor, determined from volatile collection with SPME fibers (Linear model: $F_{11}=5.42$, $P=0.042$). Neither the interaction term proportion of linalool * fiber ($F_9=1.60$, $P=0.24$) nor fiber as an explanatory variable influenced this result ($F_{10}=1.01$, $P=0.34$). We did not find similar relationships between the proportion of other substances emitted by *P. paniculata* and the ants' responses in the olfactometer arena ($F_{11}\leq4.26$, $P\geq0.066$).

Olfactometer Trials with Individual Substances As suggested by the negative correlation between the ants' responses and the proportion of linalool within the scent bouquets, ants were repelled by linalool when individually applied in the olfactometer trials (*t*-test: $t_{139}=2.61$, $P=0.01$), and the ants' responses in the olfactometer arena were negatively correlated to the mass of linalool applied on filter papers (Pearson's product–moment correlation: $t_{138}=3.25$, $P<0.01$, $r^2=0.07$). However, benzaldehyde and 2-phenyl acetaldehyde likewise repelled ants in the olfactometer trials (*t*-test: $t_{71}\geq2.11$, $P\leq0.038$), and their masses applied to the filter papers also influenced the ants' behavior in the olfactometer arena (Pearson's product–moment correlation: $t_{70}\geq2.29$, $P\leq0.025$, $r^2\geq0.07$). None of the three substances was repellent to ants in trials where the mass of substance applied to the filter paper matched the hourly emission of these substances (*t*-test: $t_{11/23}\leq1.62$, $P\geq0.13$). Ants' responses were not different towards these repellent substances at either concentration (ANOVA: $F_{2,33}<1.71$, $P>0.2$). Eugenol and (*Z*)-β-ocimene did not repel ants (*t*-test: $t_{71}\leq0.67$, $P\geq0.51$).

Visitation by Flying Flower Visitors Irrespective of the treatment, flowers were highly frequented by hoverflies (*Episyrphus balteatus*, $N=29$) and occasionally by other dipterans ($N=9$), honeybees (*Apis mellifera*, $N=2$) and one butterfly species (*Aglais urticae*, $N=1$). Control flowers received slightly more visits (mean±*SE*: 7.96±1.65 visits/h) than treated flowers (5.71±1.36 visits/h), but this trend was not significant ($t_7=1.65$, $P=0.14$). The duration of individual visits was slightly, but not significantly shorter on control flowers (mean±*SE*: 13.56±5.51 s) than on treated flowers (17.88±6.34 s) ($t_{34}=0.51$, $P=0.61$). Note that *E. balteatus* accounted for 70.7% of all visits, but as this species is not able to collect nectar that is located in deep nectar tubes in *P. paniculata*, only pollen was collected.

Discussion

Our results partly support the hypothesis formulated by Schiestl (2010) and Junker and Blüthgen (2010b) that the monoterpenoids of floral scent mixtures have defensive roles. The flowers of *Phlox paniculata* emit various volatiles

Table 1 Scent emission of *Phlox paniculata* flowers and results of *random forest* analysis. For each compound, values give median and range of the emission [ng h^{-1} $flower^{-1}$] of substances from control (C, *N*=4) and treated (*FM*, *N*=4) flowers. Substances are listed by chemical class and then by retention time. Substances marked by an asterisk were identified using commercially available standard compounds; others by comparison of mass spectra with those in a reference library (see Methods for details). Classification of the floral scent bouquets emitted by control flowers (C) and flowers that were treated with fosmidomycin and mevinolin (*FM*) based on quantitative emission rates of individual substances is given in the confusion matrix resulting from *random forest* analysis. This matrix shows the number of correctly assigned scent bouquets to either control or treated flowers and class errors. Also given is the variable importance *E* of each floral scent compound, positive values indicate compounds that strongly contributed to a correct assignment to the groups. *P*-values for comparison of the total emission and the emission of individual substances in control and treated flowers using Mann–Whitney *U*-test are also given

of different chemical classes. Nearly a quarter of the natural blend consists of monoterpenoids, and these had a strong repellent effect on *Lasius niger* workers. However, in flowers treated with fosmidomycin and mevinolin, the emission of monoterpenoids was strongly reduced. The scents of the treated flowers were no longer avoided by ants in the olfactometer trials, which indicates that the flower odor bouquet had lost its ant repellent function. The emission of linalool, one of the five detected monoterpenoids, was most strongly affected by the treatment with the pathway specific inhibitors: the treated flowers emitted 7.5 times less linalool than the control flowers on average. The negative correlation between the proportion of linalool within the bouquet and ant responses suggests that this substance may be especially responsible for the aversion of ants to the flower odors. This result was supported by olfactometer trials with pure linalool, which alone had a repellent effect on *L. niger* ants. Linalool was shown earlier in olfactometer trials and other experimental setups to be repellent against various ant species including *L. niger* (Cane, 1986; Junker and Blüthgen, 2008, 2010a).

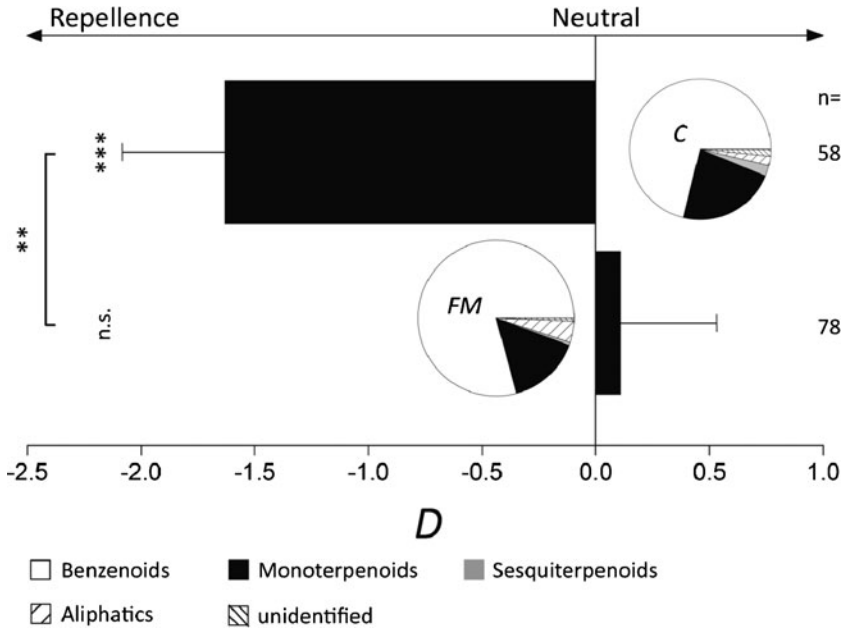

Fig. 1 Results of olfactometer trials. Responses of *Lasius niger* workers (*D*, mean±*SE*) to natural scents of *Phlox paniculata* flowers (control *C*, upper bar) or to scents of flowers that were treated with a mix of fosmidomycin and mevinolin (*FM*, lower bar). *D* is defined as the mean number of ants in odor fields of the olfactometer minus the mean number in control fields. Responses to *C* and *FM* flowers were compared to each other by a *t*-test and each response to *C* or *FM* flowers was tested against the null hypothesis, i.e., equal numbers of ants in scented and neutral fields of the oflactometer-arena ($D=0$). Significance levels of *t*-tests are indicated as n.s. = not significant, ** $P<0.01$, *** $P<0.001$. Pie charts illustrate the mean proportional composition of the scent bouquets emitted by control flowers (*C*) and flowers treated with fosmidomycin and mevinolin (*FM*) as evaluated after dynamic headspace collection

However, two benzenoids, benzaldehyde and 2-phenyl acetaldehyde, also strongly repelled ants when individually applied in olfactometer trials. These and the results from other studies that showed ant repellence due to benzenoids (Junker and Blüthgen, 2010a) challenge the functional dichotomy of benzenoids and monoterpenoids suggested by Schiestl (2010) and Junker and Blüthgen (2010b). While the olfactometer trials with flowers as scent sources suggest that linalool alone elicited the ants' aversion, the results using synthetic scents suggest that in addition to linalool, the benzenoids benzaldehyde and 2-phenyl acetaldehyde also have the potential to repel ants.

The question arises why the modified scent bouquets with a reduced proportion of monoterpenoids including linalool but a similar total emission did not repel ants, although benzaldehyde and 2-phenyl acetaldehyde were still present in comparable amounts. A possible explanation may be that none of the scents was repellent to ants at concentration that matched the natural emission when tested in isolation. Nonetheless, the negative correlation between the proportion of linalool within the samples and the ants' responses still suggests importance of this substance in ant repellence.

The present study demonstrates that the specific terpene pathway inhibitors, fosmidomycin and mevinolin, are effective tools for modifying scent compositions for experiments on the behavior of flower visitors. To inhibit the biosynthesis of terpenoids, the application of both fosmidomycin and mevinolin is recommended, as the transport of isopentenyl pyrophosphate (IPP) from the cytosolic (MVA) pathway into the plastids may compensate for the lack of plastidic pathway product. The transport of IPP the other way around, i.e., from the plastid into the cytosol, is suggested as well (Dudareva et al., 2005; Schie et al., 2006). In a previous study where only fosmidomycin was used to alter herbivore-induced volatile emission from leaves of lima bean and brussels sprouts, significant monoterpenoid inhibition could be achieved only in lima bean, whereas no inhibition of sesquiterpenoids could be attained in either species (Mumm et al., 2008). Consequently, the responses of the predators that are usually attracted to herbivore-induced volatiles of the tested plant species were shown to be weaker in lima bean plants that emitted less monoterpenoids, but no information was available about responses to monoterpenoids in brussels sprouts or about sesquiterpenoids in either species (Mumm et al., 2008).

Despite the enormous complexity of floral scent bouquets, their ecological function has been studied mostly in pollinator attraction. Recently, several alternative functions of floral volatiles have been proposed and investigated (reviewed by Raguso, 2008b). Among these, one important function is the ability to act as floral filters that serve simultaneously as attractive and repellent signals, and thus are able to shape the spectrum of flower visitors, both

mutualists and antagonists (Kessler and Baldwin, 2007; Kessler et al., 2008b; Junker and Blüthgen, 2010b; Junker et al., 2010b; Schiestl et al., 2011). The attractive function of flower odors often has been attributed to whole bouquets, but also to individual components.

Although naïve responses to full odor blends often are stronger than responses to individual compounds within these blends (Stringer et al., 2008), learned responses often are based on "key odorants" within bouquets that serve as recognition cues for a multi-component blend (Laloi et al., 2000; Dötterl et al., 2006; Riffell et al., 2009; Reinhard et al., 2010). The recognition and learning of individual scent compounds associated with rewards is a key process in non-specialized flower-insect interactions (Smith et al., 2006), and the scent compounds involved are widely distributed in flowers of different plant species (Wright and Schiestl, 2009). For example, *Helicoverpa armigera* moths have the ability to use various widespread substances as learned cues to locate nectar bearing flowers (Cunningham et al., 2004). Given this behavior, the scents that insects use to find and consume floral resources of plants need not have any co-evolved links to them, which may explain the commonness of certain floral scent compounds across many plant families (Knudsen et al., 2006). The taxa studied here, *L. niger* and *P. paniculata*, occur sympatrically in North America, but it is unlikely that the repellent effect of the *P. paniculata* flower scent on *L. niger* ants is a result of a species-specific adaptation. Linalool is among the most commonly occurring floral volatiles (Knudsen et al., 2006), and its role in pollinator attraction (Dobson, 2006) but also in defense against antagonists (Junker and Blüthgen, 2010b) has been demonstrated. Thus, in the same way that various scents can be used for associative learning by non-specialized pollinators, floral scent compounds may be universally defensive against facultative and often antagonistic flower visitors (Junker and Blüthgen, 2010b). This notion is supported by the fact that many terpenoids are toxic to arthropods (Gershenzon and Dudareva, 2007).

Our results demonstrate that the presence of terpenoids—especially the monoterpene alcohol linalool—in sufficient amounts triggers the negative responses by ants towards the floral scent of *P. paniculata*. However, other compounds may also be responsible for this defensive function and need to be evaluated in further studies. This result, reinforces those of several recent studies (Kessler and Baldwin, 2007; Kessler et al., 2008b; Junker et al., 2010b; Schiestl et al., 2011) that suggest that the chemical complexity of floral scent bouquets evolved as a response to both mutualists and antagonists.

Acknowledgement We thank Michael Reichelt, Andrea Hilpert, Tamara Krügel, and Norbert Schneider for technical support and Klaus Lunau for helpful comments. The study was funded by the DFG and the Max-Planck Society.

and existing studies suggest that the response is less predictable than for trees. For instance, phenolics did not change under elevated CO_2 in hairy bittercress, common groundsel, or corn spurrey (Hartley et al., 2000), increased in alfalfa (Agrell et al., 2004) and ginger (Ghasemzadeh et al., 2010), increased or did not change in soybean (O'Neill et al., 2010) and increased or decreased in birdsfoot trefoil (Bazin et al., 2002; Goverde et al., 2004).

When damaged, many plant species increase levels of defensive compounds. Such chemical induction is thought to be an integral component of adaptive anti-herbivore chemistry (Karban and Baldwin, 1997). Phenolics are among the most inducible compounds in response to damage (Kaplan et al., 2008). Unfortunately, little is known about the effect of elevated CO_2 on the inducibility of plant defenses. Two opposing hypotheses seem reasonable to us: 1) that increased carbon availability will result in increased inducibility, due to increased substrate availability, or 2) that decreased nitrogen content will result in decreased inducibility, due to decreased availability of nitrogen-rich RNA and enzymes required for rapid induction.

While scores of studies have addressed the effect of elevated CO_2 on constitutive chemical defenses, to our knowledge only seven studies have addressed the effect of elevated CO_2 on the inducibility of plant defenses. Induction of phenolics was not affected by elevated CO_2 in aspen (Lindroth and Kinney, 1998) or oak (Rossi et al., 2004), nor was induction of flavonoids in soybean (O'Neill et al., 2010), phenolics and cyanide glycosides in birdsfoot trefoil (Bazin et al., 2002), or saponins and flavonoids in alfalfa, and terpenoid aldehydes in cotton (Agrell et al., 2004). To our knowledge, only two studies have detected an effect of elevated CO_2 on defense induction in response to damage. Bidart-Bouzat et al. (2005) observed an increase in induction of glucosinolates in *Arabidopsis thaliana* under elevated CO_2, and Zavala et al. (2008) observed a decrease in inducibility of soybean protease inhibitors under elevated CO_2.

In addition to chemical defenses, most plants possess mechanical defenses. Trichomes ("leaf hairs"), which are present in virtually every plant family (Marks, 1997), are the most common mechanical defense. Like phenolics, trichomes can reduce oviposition, consumption, growth, and survivorship of insect herbivores (Simmons and Gurr, 2005; Plett et al., 2010). Despite being identified by Pritchard et al. (1999) over a decade ago as a high priority subject, we are aware of only a handful of studies that address the effect of elevated CO_2 on trichomes. Existing studies report either a decrease (Bidart-Bouzat et al., 2005; Lake and Wade, 2009) or no change (Lau et al., 2008; Riikonen et al., 2010; Vannette and Hunter, 2011) in trichome density under elevated CO_2.

Brassica rapa (oilseed rape or canola) possesses both phenolic and trichome defenses and belongs to a genus that has been the subject of much research on plant-herbivore interactions. In addition, *B. rapa* is ranked behind only soybean as the most important source of vegetable oil in the world (Raymer, 2002). In this study, we asked whether growth under elevated CO_2 affects constitutive levels and inducibility of phenolics, and density of trichomes in leaves of *B. rapa*.

Methods and Materials

Plant Growth *Brassica rapa* seeds were germinated in mid-June in the greenhouse at the University of Michigan Biological Station (UMBS) and transplanted 2 day later to 6-in pots containing topsoil. Plants were watered daily or as necessary, and were inspected periodically for insect herbivory; only undamaged plants were used. Plants were fertilized every 2 week with 100 ml full strength Peter's 20-20-20 to avoid nutrient stress. Three days after transplanting, 3 plants were randomly placed into each of 12 0.5-m^3 open-topped chambers maintained at ambient CO_2 (379±10 ppm) and each of 12 chambers maintained at elevated CO_2 (744± 12 ppm). Chambers were arranged into blocks, with each block containing one ambient and one adjacent elevated chamber. Within blocks, CO_2 treatment was randomly assigned to chambers. The chambers were located in a field near the UMBS greenhouse and were designed to maintain natural temperature and light conditions as much as possible (Karowe, 2007). CO_2 content was elevated by dispensing 100% CO_2 into the inlet port of an outlet blower connected by a dryer hose to the base of each elevated chamber. CO_2 levels were monitored by an infrared gas analyzer approximately every 25 min and CO_2 flow was manually adjusted by a flowmeter when needed.

All surviving plants (N=27 at each CO_2 level, including at least 2 from each chamber) were harvested after 40–44 day in the chambers. Constitutive and induced phenolic levels were quantified from opposite halves of the second fully expanded leaf. A razor blade was used to remove one randomly chosen half of the leaf, leaving the midrib intact. At the same time, a garlic press was used to damage 9 cm^2 in the middle of the 1st, 3rd, and 4th fully expanded leaves. This method allowed us to standardize the amount of damage across plants. Twenty-four hours later, the remaining half of the 2nd leaf was harvested. Immediately after removal, each leaf half was flash frozen in liquid nitrogen, stored at −80°C for 1 week, and freeze-dried. We believe that, relative to the usual approach of using different plants for constitutive and induced levels, this paired design is a more powerful method for detecting induction.

Total Phenolics After each leaf half was ground to a fine powder, 20 mg of tissue were washed x 3 with 1 ml diethyl

ether containing 1% (v/v) acetic acid to remove chlorophyll. After each wash, samples were centrifuged at 4,600*g* for 10 min and the ether was removed. The resulting decolorized pellet was resuspended in 0.5 ml of 70% acetone to extract total phenolics, sonicated on ice for 30 min, and centrifuged at 4,600*g* for 10 min. This was repeated x 3, and the 3 supernatants were combined and brought to a total volume of 1.5 ml using 70% acetone. Total phenolics were quantified using the Folin-Denis method. To each reaction tube, 0.5 ml of supernatant, 1 ml Folin-Denis reagent (75 mM sodium tungstate, 1.3 mM phosphomolybdic acid, 2.8% phosphoric acid), and 1 ml 2 N sodium carbonate were added. Samples were incubated for 1 hr at room temperature for color development. Sample absorbency was determined at 725 nm against a blank of deionized water (FAO/IAEA 2000). All samples were run in duplicate. Total phenolic levels were quantified by comparison to a standard curve prepared from tannic acid.

Simple Phenolics To determine levels of simple phenolics, tannins were removed by adding 100 mg of polyvinyl polypyrrolidone, which binds complex phenolics such as condensed dimers and tannins, to a 100×12 mm test tube containing 1.0 ml deionized water and 0.5 ml of the total phenolic extract (FAO/IAEA 2000, modified by M. Grant). After 15 min at 4°C, the extract was centrifuged at 4,600*g* for 10 min, and the supernatant, presumably containing only simple phenols (phenolic acids, alcohols and amines, flavonoids, anthocyanogens, catechins, and flavanols), was collected. The Folin-Denis method was used to determine relative concentration of simple phenolics. Complex phenolics were calculated as the difference between total and simple phenolics measured from the same extract.

Carbon and nitrogen contents were determined for each ground leaf sample using a Perkin Elmer CHN Elemental Analyzer (Waltham, MA, USA).

Trichomes From a different set of plants than those used for C, N, and phenolic analyses (N=115 plants at ambient CO_2 and 119 plants at elevated CO_2), trichomes on the lower leaf surface from two 0.9 cm^2 disks removed from the distal tip of the second fully expanded leaf were counted under a dissecting microscope. Trichome counts from the two disks per leaf were averaged.

Statistical Analysis The experimental design was a split-plot with repeated measures, with CO_2 as whole plots, and damage as the repeated measure, since carbon, nitrogen, C:N ratio, and phenolics were measured on opposite (pre- and post-damage) halves of the same leaf (Littell et al., 1998). Variables were analyzed with a *Type III ANOVA* (PROC MIXED) with CO_2 level and damage as fixed effects, and block and the CO_2*block interaction as random effects (SAS Institute, 2000). To further determine whether phenolics were inducible at each CO_2 level, paired *t*-tests were used to compare phenolic levels in the half of a leaf sampled immediately before damage and the opposite half of the same leaf sampled 24 hr after damage. To determine whether CO_2 affected inducibility, the magnitude of change in phenolic levels was compared between CO_2 levels by independent samples *t*-tests. Normality of inducibility values was verified by *Kolmogorov-Smirnov* tests and equality of variances was verified by F_{max} tests.

To determine whether leaf percent N influenced constitutive phenolic levels and/or magnitude of phenolic induction, these two variables were regressed against leaf N and C:N ratio.

Trichome density was measured only on undamaged plants. Since variances were unequal and data were not normal, mean trichome density was compared between CO_2 levels by a *Mann–Whitney U* test. The proportion of leaves with at least one trichome was compared between CO_2 levels by a *chi-square* test.

Results

Nutritional Quality Under elevated CO_2, nitrogen content of *B. rapa* leaves decreased significantly (by 16%, from 2.70 to 2.29% of dry weight, means for constitutive and induced combined) and C:N ratio increased significantly (by 20%, from 15.47 to 18.11) (Table 1). Carbon content averaged 40.17% and was not affected by CO_2 level. No measured component of leaf nutritional quality was affected by damage, or showed a significant CO_2*Damage interaction.

Constitutive Phenolics When both constitutive and induced levels were considered together, growth of *B. rapa* under elevated CO_2 did not result in a significant change in levels of simple, complex, or total phenolics (in each case, P>0.2 for the overall CO_2 effect; Table 1). However, when only constitutive levels were considered, elevated CO_2 resulted in a 17% increase in complex phenolics (t=2.83, P=0.007) and a 14% increase in total phenolics (t=2.76, P=0.008). In contrast, constitutive levels of simple phenolics were not affected by growth of *B. rapa* under elevated CO_2 (t=1.65, P=0.10).

Inducibility of Phenolics When all plants were considered together, damage resulted in significant increases in complex (by 20%) and total phenolics (by 14%), but did not affect levels of simple phenolics (see the Damage effect in Table 1). ANOVA analysis detected an effect of CO_2 on inducibility, indicated by the significant CO_2*Damage interaction for each phenolic variable in Table 1. Paired *t*-tests at each CO_2 level revealed that simple, complex, and total

Table 1 Constitutive and induced levels (as a percent of leaf dry weight; mean ± SD) of nitrogen, carbon, C:N ratio, and simple, complex, and total phenolics in *Brassica rapa* leaves grown under ambient and elevated CO_2

[a]Sample size is 27 for each CO_2 × Damage combination

[b]*P*-values from *ANOVA* analyses; significant effects are in bold

[c]Data were normalized by log transformation prior to analysis

[d]Induction was significant at this CO_2 level by a paired *t*-test; $P<0.05$ (*), $P<0.01$ (**), or $P<0.001$ (***); see Fig. 1

phenolics were all more inducible under ambient CO_2 than under elevated CO_2. In response to damage, simple phenolics increased by 11% under ambient CO_2 (*paired* $t=3.03$, $P=0.006$), but did not change under elevated CO_2 (*paired* $t=1.31$, $P>0.2$; Fig. 1); this difference in inducibility was highly significant ($t=5.51$, $P<0.001$). Induction of complex phenolics occurred at both CO_2 levels, but was stronger for plants grown under ambient CO_2 than for plants grown under elevated CO_2. Complex phenolics increased by 33% under ambient CO_2 (*paired* $t=9.39$, $P<0.001$) but by only 12% under elevated CO_2 (*paired* $t=3.67$, $P=0.002$); this difference in inducibility was also highly significant ($t=4.10$, $P<0.001$). Similarly, total phenolics increased by 24% under ambient CO_2 (*paired* $t=9.90$, $P<0.001$) but by only 6% under elevated CO_2 (*paired* $t=2.11$, $P=0.045$). Like that of simple and complex phenolics, inducibility of total phenolics was greater at ambient CO_2 ($t=4.47$, $P<0.001$; Fig. 1).

Correlations between Nitrogen, C:N, and Phenolics CO_2 level affected the strength of correlation between measures of leaf nutritional status (N and C:N) and phenolics. For plants grown under ambient CO_2, neither N nor C:N was significantly correlated with constitutive level or inducibility of simple, complex, or total phenolics. However, for plants grown under elevated CO_2, constitutive levels of simple phenolics were positively correlated with leaf C:N ratio ($R=0.55$,

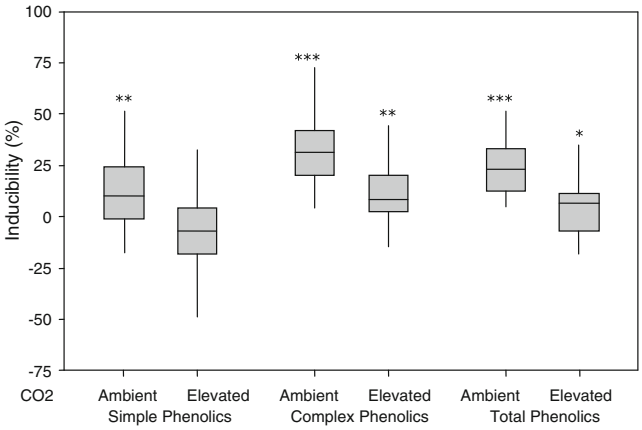

Fig. 1 Inducibility (% change during 24 hr after damage) of simple, complex, and total phenolics in *Brassica rapa* leaves[a]. [a]*Shaded* areas include the first through third quartiles, *horizontal lines* indicate medians, and *vertical lines* indicate the range. *Asterisks* denote significant induction at a given CO_2 level (* $P<0.05$, ** $P<0.01$, *** $P<0.001$). In all cases, inducibility was significantly greater at ambient CO_2 than at elevated CO_2

d.f. = 26, *P*=0.003; Fig. 2) and negatively correlated with leaf nitrogen (*R*=–0.53, *d.f.* = 26, *P*=0.005). In contrast, the inducibility of simple phenolics was positively correlated with leaf nitrogen (*R*=0.54, *d.f.* = 26, *P*=0.004; Fig. 3) and negatively correlated with leaf C:N ratio (*R*=–0.46, *d.f.* = 26, *P*= 0.015). When all plants were considered together (but not at either CO_2 level alone), the inducibility of complex phenolics was not significantly positively correlated with leaf nitrogen (*R*=0.24, *d.f.* = 53, *P*=0.084; Fig. 4) nor significantly negatively correlated with leaf C:N ratio (*R*=–0.23, *d.f.* = 53, *P*= 0.095). When inducibility was expressed as an absolute rather than percent change, the inducibility of complex phenolics was positively correlated with leaf nitrogen (*R*=0.33, *d.f.* = 53, *P*=0.014) and negatively correlated with leaf C:N ratio (*R*=–0.34, *d.f.* = 53, *P*=0.013). In no case was leaf carbon content significantly correlated with any phenolic measure.

Trichomes Growth of *B. rapa* under elevated CO_2 resulted in a significant increase in constitutive trichome density (*Mann–Whitney U*=12,362, *d.f.* = 1, *P*=0.015). Under ambient CO_2, there were 28.2±5.6 trichomes/cm^2 of leaf area, and this value increased by 57% to 44.3±6.4 trichomes/cm^2

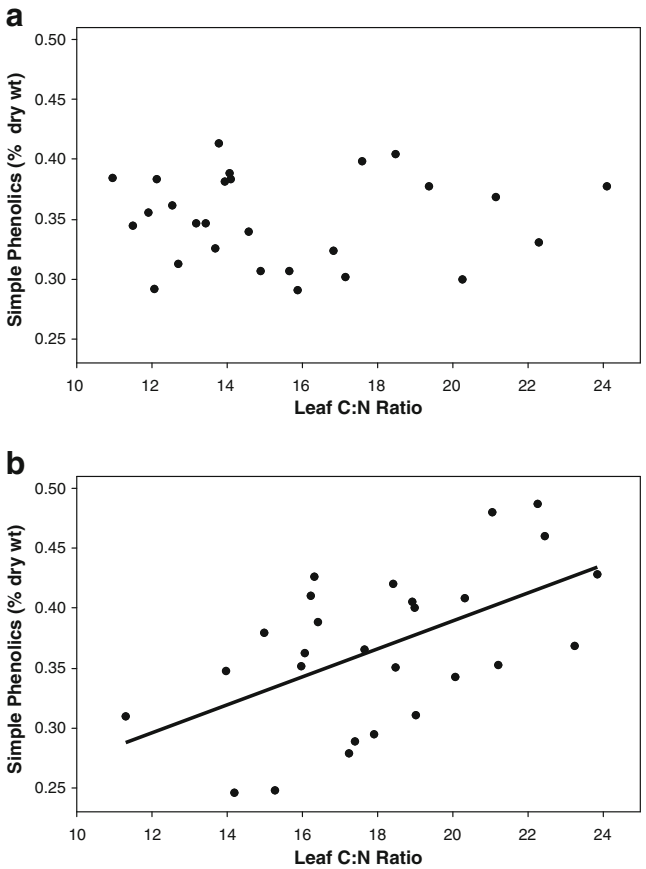

Fig. 2 Relationship between C:N ratio of *Brassica rapa* leaves and constitutive levels of simple phenolics (as a% of leaf dry weight) for plants grown at (**a**) ambient CO_2 (*R*=0.01, *P*>0.9) and (**b**) elevated CO_2 (*R*=0.68, *P*=< 0.001)

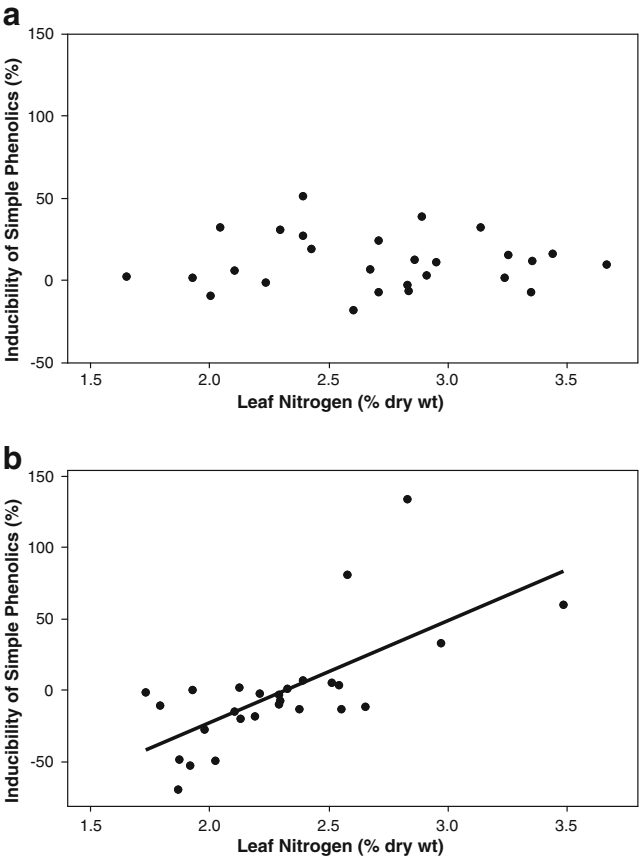

Fig. 3 Relationship between nitrogen content of *Brassica rapa* leaves and inducibility (% change during 24 hr after damage) of simple phenolics for plants grown at (**a**) ambient CO_2 (*R*=0.01, *P*>0.9) and (**b**) elevated CO_2 (*R*=0.54, *P*=0.004)

under elevated CO_2 (Fig. 5). In addition, a significantly lower proportion of leaf discs contained zero trichomes under elevated CO_2 (46.2%) than under ambient CO_2 (61.7%) (χ^2= 5.67, *d.f.* = 1, *P*=0.017). Trichome density was also nearly significantly more variable at ambient CO_2 than at elevated CO_2 (*Levene's statistic* = 3.66, *P*=0.057; Fig. 5)

Discussion

The results of this study indicate that rising atmospheric CO_2 can affect both chemical and mechanical defenses of *Brassica rapa*. To our knowledge, this is only the second study to demonstrate that inducibility of a chemical defense is diminished under elevated CO_2.

The observed 16% decrease in nitrogen and 20% increase in C:N ratio of *B. rapa* leaves under elevated CO_2 are similar to the mean changes reported for non-legume C_3 plants (Cotrufo et al., 1998), herbaceous plants (Zvereva and Kozlov, 2006), and other *Brassica* species (Karowe et al., 1997). Given the observed increase in *B. rapa* C:N ratio under elevated CO_2, it is reasonable to expect that constitutive levels

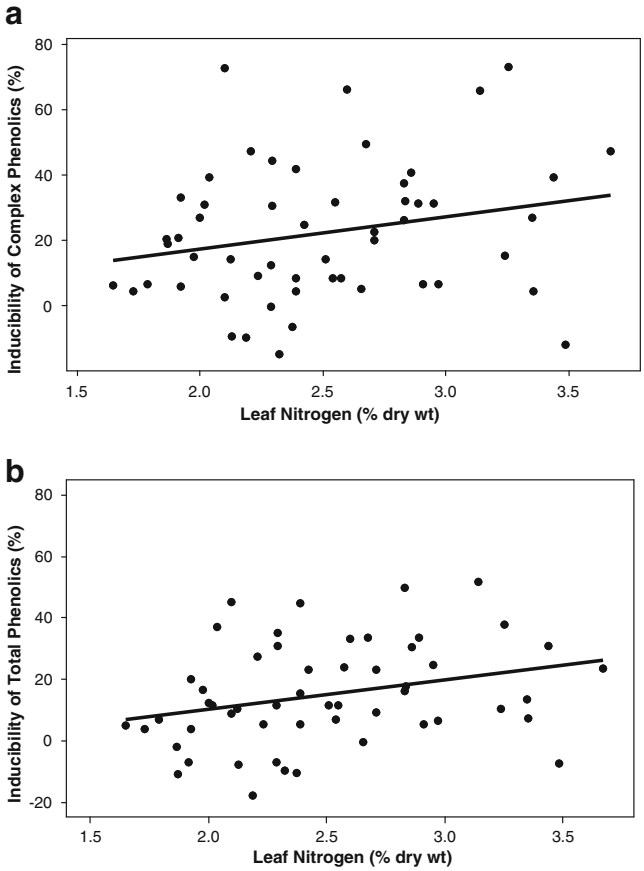

Fig. 4 Relationship between nitrogen content of *Brassica rapa* leaves and inducibility (% change during 24 hr after damage) of (**a**) complex phenolics (R=0.24, P=0.084) and (**b**) total phenolics for plants grown at both CO_2 levels (R=0.29, P=0.033)

of carbon-based phenolics would also be higher (Gayler et al., 2008). Indeed, constitutive levels increased significantly under elevated CO_2 for complex (17%) and total phenolics (14%). These increases are larger than the mean increases of 1% and 5% reported for phenolics in shrubs and forbs, respectively, similar to the 10–14% increases in trees, but smaller than the 29% increase reported for tannins in dicots (Peñuelas et al., 1997; Stiling and Cornelissen, 2007). It is likely that increased constitutive phenolic levels observed in this study will result in more effective defense in *B. rapa*, since phenolic compounds can reduce growth (Ossipov et al., 2001; Haukioja et al., 2002) and survivorship (Karowe, 1989; Haviola et al., 2007) of insect herbivores.

Given the observed increase in constitutive phenolics in *B. rapa* under elevated CO_2, greater inducibility of phenolics under elevated CO_2 might also be expected. However, we observed the opposite: phenolics were less inducible under elevated CO_2. Induction of simple phenolics occurred only for plants grown under ambient CO_2. In addition, although induction of complex and total phenolics occurred under both ambient and elevated CO_2, the damage-induced increases were 64% and 75% smaller, respectively, under elevated CO_2. Therefore, the results of this study suggest that rising atmospheric CO_2 will decrease the ability of *B. rapa* to respond to herbivore damage by rapidly increasing levels of phenolic defenses.

We hypothesize that, in *B. rapa*, decreased leaf nitrogen levels under elevated CO_2 constrain the rapid mobilization of nitrogen required to produce additional jasmonic acid elicitor, mRNA and enzymes required for induction of phenolics, but do not constrain the long-term accumulation of higher levels of constitutive phenolics. In the present study, constitutive phenolic levels under elevated CO_2 were positively correlated with leaf C:N ratio, as would be expected if carbon, rather than nitrogen, availability was the primary determinant of constitutive phenolic levels. In contrast, inducibility of both simple and complex phenolics were positively correlated with leaf N (and negatively correlated with leaf C:N ratio), as would be expected if nitrogen availability were an important determinant of inducibility. Consistent with this hypothesis, Lou and Baldwin (2004) observed that, when grown under low nitrogen, tobacco plants showed decreased induction of chemical defenses, including the phenolics rutin and chlorogenic acid. Moreover, fewer than half of the genes upregulated by herbivore attack under high nitrogen were upregulated under low nitrogen.

Despite the importance of induction to plant defense strategy (Karban and Baldwin, 1997), surprisingly few studies have addressed the effect of elevated CO_2 on the inducibility of chemical defenses in response to herbivory. Most existing studies have not detected an effect of elevated CO_2 on inducibility. For instance, growth under elevated CO_2 did not affect the inducibility of phenolic glycosides or condensed tannin in aspen (Lindroth and Kinney, 1998; Roth et

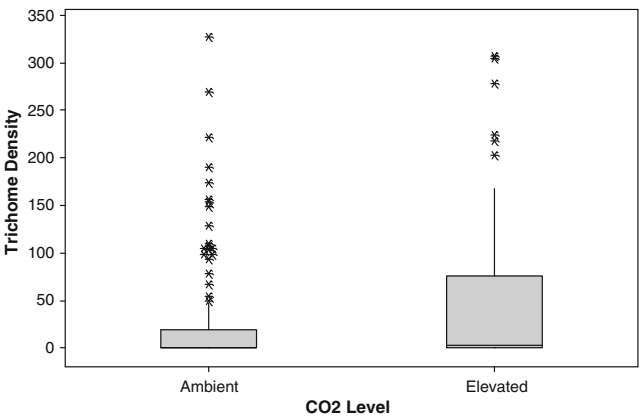

Fig. 5 Number of trichomes per cm^2 of leaf tissue (mean ± SE) in *Brassica rapa* grown under ambient and elevated CO_2[a]. [a]*Shaded* areas include the first through third quartiles, *horizontal lines* indicate medians (median = 0 for ambient CO_2), *vertical lines* indicate the range, and *asterisks* indicate outliers. Sample size is 115 at each CO_2 level. Trichome density was significantly higher at elevated CO_2 (P=0.015)

al., 1998), tannins in myrtle oak (Rossi et al., 2004), or saponins in alfalfa and triterpenoid aldehydes and gossypol in cotton (Agrell et al., 2004). The only two studies to detect a significant effect report contrasting responses: glucosinolates in *Arabidopsis thaliana* induced only under elevated CO_2 (Bidart-Bouzat et al., 2005), while elevated CO_2 reduced induction of soybean cysteine protease inhibitors by 31% (Zavala et al., 2008).

It is possible that the methodology used in this study enhanced the ability to detect an effect of elevated CO_2 on inducibility. In all previous studies of which we are aware, constitutive and induced levels were compared between separate leaves (Rossi et al., 2004) or separate plants (Lindroth and Kinney, 1998; Roth et al., 1998; Agrell et al., 2004; Bidart-Bouzat et al., 2005; O'Neill et al., 2010). These approaches require the assumption that constitutive defense levels are similar between leaves or plants; to the extent that this assumption is violated (Boege and Marquis, 2005), power to detect a difference in inducibility will be reduced. In contrast, the present study compared constitutive and induced levels within a single leaf, and thus only requires the more reasonable assumption that constitutive defense levels were similar between opposite halves of the same leaf.

It should be noted that mechanical damage such as that used in this study can result in patterns of induction that differ from those produced by herbivore damage (Reymond et al., 2000), since herbivore saliva contains elicitors (Musser et al., 2006). However, in general, there is broad similarity in the transcriptional responses to mechanical and herbivore damage (reviewed in Howe and Jander, 2008). For instance, in Sitka spruce, transcriptome changes in response to mechanical wounding overlapped considerably with those in response to beetle and caterpillar herbivory (Ralph et al., 2006). Moreover, differences in response to mechanical vs. herbivore damage may be greater for volatile compounds than for the within-leaf phenolic defenses we assayed here (Howe and Jander 2008). Nonetheless, given that we applied neither herbivore oral secretions nor jasmonic acid to the site of mechanical damage, we cannot say with certainty whether the patterns of defense induction we observed would occur in response to actual herbivory.

We also observed a significant 57% increase in trichome density for *B. rapa* grown under elevated CO_2, and a 41% increase in the proportion of leaf discs that contained at least one trichome. It is likely that an increase of 57% in trichome density would result in enhanced antiherbivore defense, since slower growth and higher mortality of the two most important crucifer specialists, *Pieris rapae* and *Phyllotreta cruciferae*, were associated with a 43% increase in trichome density in a related species, *Brassica nigra* (Traw and Dawson, 2002). Higher trichome density may also increase *B. rapa* resistance to pathogens (Lake and Wade, 2009).

We are not aware of any other study demonstrating an increase in trichome density that is clearly attributable to elevated CO_2. Paoletti et al. (2007) report increased trichome density in *Quercus ilex* growing near a natural CO_2 spring, but plants also were exposed to elevated levels of H_2S and SO_2. In contrast to our results, trichome density decreased under elevated CO_2 in *Arabidopsis thaliana* (Bidart-Bouzat et al., 2005; Lake and Wade, 2009), and did not change in birch (Riikonen et al., 2010), milkweed (Vannette and Hunter, 2011), or round headed bush clover (Lau et al., 2008). Given this variation in response, trichomes should remain a high priority subject for elevated CO_2 studies.

In summary, our results suggest that *Brassica rapa* will possess increased constitutive levels of both phenolic compounds and trichomes as atmospheric CO_2 continues to rise, which are likely to increase resistance to herbivores, but that phenolics will be less responsive to herbivore attack, which is likely to decrease resistance to herbivores. Whether these changes together will be advantageous, neutral, or disadvantageous will depend on the relative importance of chemical vs. mechanical defenses and, particularly, of constitutive vs. induced chemical defenses for *B. rapa*.

from *Tectona grandis* and the assessment of their activity would help to explain the success of this tree culture when it is used in agroforestry. At present, no natural compound with high phytotoxic activity has been isolated from teak in a great enough amount that could explain that activity.

In addition, this species has attracted other scientific interest. The consideration of teak in Natural Products research is based on its ethnobotanical uses, the biological activity shown by its extracts, and the durability of its wood (e.g., Ahuwalia and Seshadri, 1957; Rudman, 1960; Joshi et al., 1977; Marwani et al., 1997; Khan and Mlungwana, 1999; Macías et al., 2008, 2010; Sumthong et al., 2008; Naira and Kaverkar, 2010; Singh et al., 2010; Shukla et al., 2010). In addition to the value of the cultivation of *T. grandis* as source of wood and the extension of forest areas, it also has become an efficient tool for pest control in the context of a sustainable agriculture.

Previously, we reported the isolation of apocarotenoids and terpenoids from bioactive extracts from leaves of *Tectona grandis* (Macías et al., 2008, 2010). As a continuation of our systematic phytochemical and allelopathic study of this species, we describe here the isolation, structural elucidation of two new quinones (one isoprenoid quinone and one anthraquinone) shown in Fig. 1, and the phytotoxic activity of the most abundant one. Naphthoquinones, anthraquinones, and isoprenoid quinones are abundant metabolites in teak. Among naphthoquinones isolated from teak, lapachol (Joshi et al., 1977) and structurally related metabolites (Khan and Mlungwana, 1999) have been reported. Anthraquinones isolated from this species usually have a carbonyl group at positions 9 and 10, and the simplest one is tectoquinone (Ahuwalia and Seshadri, 1957; Agarwal et al., 1965). This compound has shown activity as a termite repellent (Rudman, 1960). These compounds were isolated mainly from the bark. This is the first time that one isoprenoid quinone is described from leaves of teak.

Methods and Materials

General IR spectra (KBr) were recorded on a Perkin-Elmer FT-IR Spectrum 1000 or a Matton 5020 spectrophotometer.

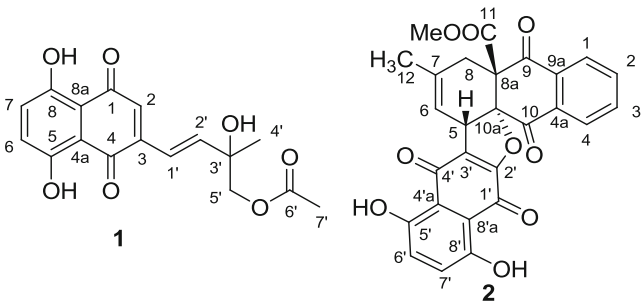

Fig. 1 Quinones isolated from *Tectona grandis*. 1 = *Naphthotectone*, 2 = *Anthratectone*

NMR spectra were run on Varian INOVA-400 and Varian INOVA 600 spectrometers. Chemical shifts are given in ppm with respect to residual ^{1}H signals of $CHCl_3$-d_1 (δ 7.25), and ^{13}C signals are referenced to the solvent signal (δ 77.0). Optical rotations were determined using a Perkin-Elmer model 241 polarimeter (on the sodium D line). HRMS were obtained on a VG AUTOESPEC mass spectrometer (70 eV). HPLC was carried out on a Merck-Hitachi instrument, with RI detection, using two different Merck LiChrospher columns: SI 60 (5 μm, 250×4 mm) and SI 60 (10 μm, 250×10 mm).

Plant Material Leaves of *Tectona grandis* L. f. were collected between the months of February and March (2003) in Ciudad de La Habana and were identified by MsC. Lutgarda González. Voucher specimens (80613) were deposited at the Jardín Botánico de Cuba.

Extraction and Isolation Dried leaves of *Tectona grandis* (5.0 kg) were extracted with water (35 L) for 24 h at room temperature in the dark. The aqueous solution was extracted with CH_2Cl_2 and then with EtOAc at room temperature. The residual vegetal material was extracted with methylene chloride (DCM) and then with methanol. DCM extract was one of the most active ones. Details of the extraction procedure and the bioassays on the extract have been described previously (Macías et al., 2008).

The DCM (120 g) extract was chromatographed on silica gel (2.0 kg) using hexane/ethyl acetate mixtures of increasing polarity to yield eight fractions: A_2–H_2.

Further purification of fraction $C_2$2 ($CHCl_3$, 0.906 g) by CC using hexane/chloroform and chloroform/acetone mixtures on silica gel and hexane/chloroform/methanol (3:1:1) on Sephadex LH-20 and silica gel HPLC (hexane/chloroform, 1:1) afforded 1.0 mg of compound **2** (Fig. 1).

Details of the separation procedure on the fraction D_2 (hexane/EtOAc, 3:3, 7.46 g) have been described previously (Macias et al., 2010). Finally, purification of the fractions $D_2$2B, $D_2$2C, and $D_2$3B using hexane/chloroform and chloroform/acetone mixtures afforded 60 mg of compound **1** (Fig. 1).

Fraction E_2 (hexane/EtOAc, 1:1, 12.0 g) was subjected to CC on Sephadex LH-20 using hexane/chloroform/methanol (2:1:1) to afford 7 fractions ($E_2$1–$E_2$7). Fraction $E_2$4 (2.24 g) was subjected to CC on silica gel using mixtures of hexane/acetone. Fractions were combined into 8 fractions ($E_2$4A–$E_2$4H). Fraction $E_2$4C (0.300 g) was chromatographed on silica gel CC using mixtures of hexane/chloroform and chloroform/acetone. Less polar fractions afforded 8 mg of compound **1**.

*Naphthotectone (**1**)* (Fig. 1): Amorphous red solid; $[\alpha]_D^{25}$= +115.4 (*c* 0.10, $CHCl_3$); IR ν_{max} (KBr) cm^{-1}; 3462 (OH),

1738 (C=O), 1608 (C=C). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 12.67 (1H, s, OH), 12.47 (1H, s, OH), 7.16 (1H, d, J=0.4 Hz, H-2), 7.05 (2H, s, H-6, H-7), 6.90 (1H, d, J=16.2 Hz, H-1′), 6.68 (1H, d, J=16.2 Hz, H-2′), 4.20 (1H, d, J=16.2 Hz, H-5b′), 4.06 (1H, d, J=16.2 Hz, H-5a′), 2.10 (3H, s, H-7′), 1.41 (3H, s, H-4′); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 179.5 (C, C-1), 178.9 (C, C-4), 171.0 (C, C-6′), 166.3 (C, C-5), 165.5 (C, C-8), 142.9 (C, C-3), 142.5 (CH, C-2′), 132.5 (CH, C-6), 132.1 (CH, C-7), 130.4 (CH, C-2), 121.1 (CH, C-1′), 112.0 (C, C-4a), 111.8 (C, C-8a), 72.8 (C, C-3′), 70.6 (CH_2, C-5′), 24.8 (CH_3, C-4′), 20.8 (CH_3, C-7′); HREIMS m/z 332.0892 (calc. for $C_{17}H_{16}O_7$ m/z 332.0896).

Coleoptiles Bioassay Wheat seeds (*Triticum aestivum* L. cv. Duro) were sown in 15 cm diam Petri dishes moistened with water and grown in the dark at 22±1ºC for 3 d (Hancock et al., 1964). Roots and caryopses were removed from the shoots. The latter were placed in a Van der Weij guillotine, and the apical 2 mm were cut off and discarded. The next 4 mm of the coleoptiles were removed and used for bioassays. All manipulations were performed under a green safelight (Nitsch and Nitsch, 1956). Compounds were predissolved in DMSO and diluted to the final bioassay concentration with a maximum of 0.1% DMSO. Parallel controls were also run.

Fractions or pure compounds to be assayed for biological activity were added to test tubes. Phosphate-citrate buffer (2 ml) containing 2% sucrose (Nitsch and Nitsch, 1956) at pH 5.6 was added to each test tube. Five coleoptiles were placed in each test tube (3 tubes per dilution) and the tubes were rotated at 0.25 rpm in a roller tube apparatus for 24 h at 22ºC in the dark. Coleoptiles were measured by digitalization of their images. Data were statistically analyzed using Welch's test (Martín Andrés and Luna del Castillo, 1990). Data are presented as percentage differences from control. Thus, zero represents the control; positive values represent stimulation of the studied parameter, and negative values represent inhibition.

Phytotoxicity Bioassay The selection of target plants was based on an optimization process carried out by us in our search for a standard phytotoxicity bioassay (Macías et al., 2000). Several Standard Target Species (STS) were proposed, including monocots *Triticum aestivum* L. (wheat) and *Allium cepa* L. (onion), and dicots *Lycopersicon esculentum* Will. (tomato), *Lepidium sativum* L. (cress), and *Lactuca sativa* L. (lettuce), which were assayed for this study.

Bioassays were conducted using Petri dishes (50 mm diam) with one sheet of Whatman No.1 filter paper as a support. Germination and growth were conducted in aqueous solutions at controlled pH by using 10^{-2} M 2-[*N*-morpholino]ethanesulfonic acid (MES) and 1 M NaOH (pH 6.0). The compound to be assayed was dissolved in DMSO (0.1, 0.02, 0.01, and 0.002 M), and these solutions were diluted with buffer (5 µl DMSO solution/ml buffer) so that test concentrations for each compound (10^{-3}, $5{\cdot}10^{-4}$, 10^{-4}, $5{\cdot}10^{-5}$, and 10^{-5} M) were achieved. This procedure facilitated the solubility of the assayed compound. The number of seeds in each Petri dish depended on the seed size. 20 seeds were used for tomato, lettuce, cress, and onion. Treatment, control, or internal reference solution (1 ml) was added to each Petri dish. A similar procedure was used for wheat in 90 mm diam Petri dishes with 10 seeds. Four replicates were used for tomato, cress, onion, and lettuce (80 seeds) whereas ten replicates (100 seeds) were used for wheat.

After adding seeds and aqueous solutions, Petri dishes were sealed with Parafilm to ensure closed-system models. Seeds were further incubated at 25ºC in a Memmert ICE 700 controlled environment growth chamber in the dark. Bioassays took 4 d for cress, 5 d for lettuce, tomato, and wheat, and 7 d for onion. After growth, plants were frozen at −10ºC for 24 h to avoid subsequent growth during the measurement process.

The commercial herbicide Logran®, which original formulation from Syngenta is a combination of *N*-(1,1-dimethylethyl)-*N*′-ethyl-6-(methylthio)-1,3,5-triazine-2,4-diamine (Terbutryn, 59.4%) and 2-(2-chloroethoxy)-*N*-{[(4-methoxy-6-methyl-1,3,5-triazin- 2yl)amino]carbonyl}benzene-sulfonamide (Triasulfuron, 0.6%), was used as an internal reference according to a comparison study reported previously (Macías et al., 2000). This reference was used at the same concentrations (10^{-3}, $5{\cdot}10^{-4}$, 10^{-4}, $5{\cdot}10^{-5}$, and 10^{-5} M) and under the same conditions as reported

previously. Control samples (buffered aqueous solutions with DMSO and without any test compound) were used for all of the plant species assayed.

Evaluated parameters (germination rate, root length, and shoot length) were recorded using a Fitomed© system (Castellano et al., 2001), which allowed automatic data acquisition and statistical analysis using its associated software. Data were analyzed statistically using Welch's test, with significance fixed at 0.01 and 0.05. Results are presented as percentage differences from the control. Zero represents control, positive values represent stimulation, and negative values represent inhibition.

IC_{50} values were obtained after adjusting phytotoxicity data to concentration (logarithmic scale), to a sigmoidal dose-response curve, defined by the equation:

$$Y = Y_{\min} + \frac{Y_{\max} - Y_{\min}}{1 + 10^{\log EC50 - X}}$$

Where X indicates the logarithm of concentration, Y indicates the response (phytotoxicity), and $Y_{\max}$ and $Y_{\min}$ are the maximum and minimum values of the response, respectively. Goodness of fit is described by the determination coefficient (r^2). The adjustment and the r^2 value were obtained using GraphPad Prism® software v. 4.00.

Results and Discussion

The study of the allelopathic potential of *Tectona grandis* and its possible use as a source of natural herbicide models was continued with the phytochemical study of DCM extract obtained by direct maceration of the dry leaves. This extract was selected on the basis of the bioactivity levels shown in the wheat coleoptiles bioassay (Macías et al., 2008).

*Naphthotectone (***1.***)* Compound **1** is the major compound of this extract. We estimate that the percentage of **1** is aproximately 0.2% by weight of the original extract. It was isolated as an amorphous red solid. The molecular formula was determined to be $C_{17}H_{16}O_7$ from the molecular ion peak at *m*/*z* 332.0892 (Calcd. 332.0896) in the HR-EIMS. The IR absorptions at 3462, 1738, 1608, and signals in the ^{1}H NMR spectrum at δ 7.16 (1H, d, J = 0.4 Hz, H-2), 7.05 (2H, s, H-6 and H-7), 2.10 (3H, s, $C\underline{H}_3CO$), and two downfield singlets (δ 12.47 and 12.67) indicate the presence of a naphthoquinone derivative with a hydroxy group *peri* to either carbonyl function, and an acetylated alkyl substitution. This proposed formula is further supported by the similarity of these spectroscopic data to those reported for other analogous compounds such as acetylshikonin (Ahn et al., 1995). In the ^{13}C NMR spectrum, the carbonyl carbons resonated at δ_C 179.5 (C-1), 178.9 (C-4), and 171.0 ($CH_3–\underline{C}O$). Besides the carbonyl carbons, the ^{13}C NMR spectrum displayed 14 signals, 2×CH_3, 1×CH_2, 5×CH and 6×C, which were assigned with the aid of g–HSQC and g–HMBC spectra.

Besides the acetyl signal, the ^{1}H NMR spectrum shows 5 signals corresponding to the alkyl side chain located at C-3: a singlet at δ 1.41 (3H, s, H-4′) corresponding to a methyl group attached at to oxygenated carbon; an AB system at δ 4.06 (1H, *d*, J=16.2 Hz, H-5a′) and 4.20 (1H, *d*, J=16.2 Hz, H-5b′), which is consistent with an acetylated methylene; and two vinyl protons at δ 6.68 (1H, *d*, J=16.2 Hz, H-2′) and 6.90 (1H, *d*, J=16.2 Hz, H-1′) whose coupling constants imply an *E* geometry. These data, together with the correlations observed in the g-HMBC spectrum (Fig. 2), allow us to propose structure **1** for this compound. This structure has not been described previously in the literature and we have named this compound naphthotectone.

*Anthratectone (***2***)* Compound **2** was isolated as an orange oil. The IR absorptions at 1731, 1715, 1697, and two downfield singlets (δ 12.61 and 12.02) in the ^{1}H NMR spectrum suggest the presence of a quinone with a hydroxy group *peri* to two of the carbonyl groups. The molecular formula was determined to be $C_{27}H_{18}O_9$ from the molecular ion peak at *m*/*z* 486.0961 (Calcd. 486.0951) in the HR-EIMS.

The ^{1}H NMR spectrum showed two singlets at δ 1.72 (3H, bs) and 3.66 (3H, s), and these are assigned to a methyl group attached to a double bond and a methoxyl group, respectively. Additionally, we observed two geminal protons at δ 3.54 (1H, d, J=20 Hz, H-8b) and δ 2.70 (1H, d, J=20 Hz, H-8a) and two coupled signals δ 4.82 (1H, d, J=6.7 Hz, H-5) and δ 5.91 (1H, dq, J=6.7, J=1.5 Hz, H-6).

The presence of an isoprenyl chain can be inferred from the analysis of the ^{1}H NMR-2D-COSY spectrum. Thus, the signal at δ 1.72 (3H, bs) showed a small coupling with the geminal system at δ 3.54 (H-8b) and δ 2.70 (H-8a), and signals at δ 4.82 (H-5) and δ 5.91 (H-6).

In the aromatic region of the ^{1}H NMR spectrum, two groups of coupled signals can be distinguished. The first one [δ 7.70 (1H, ddd, J=7.6 Hz, J=7.6 Hz, J=0.8 Hz, H-3), δ 7.82 (1H, ddd, J=7.6 Hz, J=7.6 Hz, J=1.6 Hz, H-2), δ 7.96 (1H, d, J=7.6 Hz, H-4) and δ 8.28 (1H, dd, J=7.6 Hz, J=7.6 Hz, J=0.8 Hz, H-1)] suggests the presence of a 1,4-anthraquinone system. The second [(δ 7.13 (1H, d,

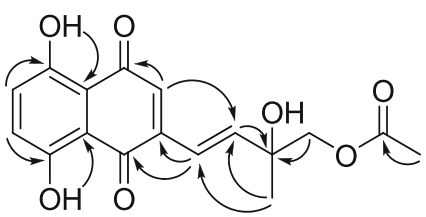

Fig. 2 Heteronuclear Multiple-Bond Connectivity (HMBC) correlations observed for compound **1**

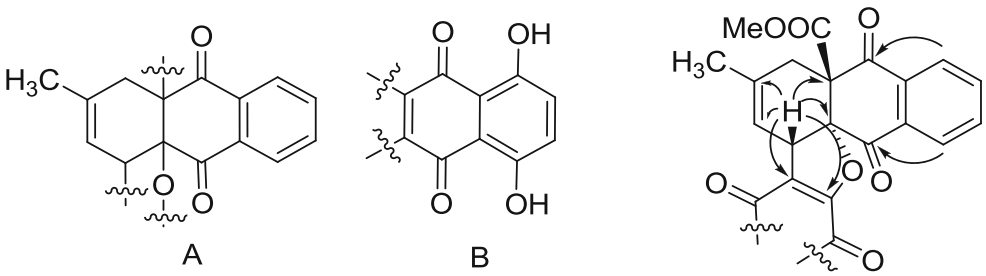

Fig. 3 Selected Heteronuclear Multiple-Bond Connectivity (HMBC) correlations observed for compound **2**

J=9.2 Hz, H-3) and δ 7.22 (1H, d, J=9.2 Hz, H-2)], together with signals at δ 12.61 and 12.02, are typical of a 5,8-dihydroxy-1,4-naphthoquinone.

The ^{13}C NMR spectrum contained 27 signals: 2 methyls, 1 methylene, 8 methynes and 16 quaternary carbons, according to an HSQC experiment. Two of the quaternary carbons are sp^3, at δ 63.8 and 81.3, and this implies that they are attached to withdrawing groups. Five signals appear to be due to carbonyl groups at δ 188.2, 187.9, 187.4, 185.4, and 166.6. The latter signal was correlated with the methoxyl group (δ 3.66) in the HMBC experiment. This indicates the presence of a methyl ester and two quinone units. Other correlations confirm the presence of an isoprenoid chain: H-5 (δ 4.82) with C-10a (δ 81.3) and C-10 (δ 188.2) as well as H-8b (δ 3.54) and H-8a (δ 2.70) with C-8a (δ 63.8) and C-9 (δ 187.4). These correlations led us to propose partial structure A (Fig. 3), with the isoprenoid chain attached to positions 8a and 10b of the 1,4-naphthoquinone unit. Correlations between H-7′ (δ 7.13) and H-6′ (δ 7.22) with C-5′ (δ 157.3) and C-8′ (δ 158.3) establish partial structure B as a 5,8-hydroxy-1,4-naphthoquinone (Fig. 3).

The linkage between these two sub-structures (Fig. 3) was established on the basis of the HMBC correlations between H-5 (δ 4.82) and the carbons C-8a (δ 63.8), C-10a (δ 81.3), C-3′ (δ 126.4), C-2′ (δ 151.8), C-4′ (δ 185.4), C-1′ (δ 187.9), and C-2′ (δ 151.8); as well as the chemical shift of C-2′ and the molecular formula.

The stereochemistries at C-8a and C-5 were deduced from the NOE effects observed on H-5 and H-12 on irradiation of the methoxyl group. Only an alpha configuration for the oxygen at the furan ring is possible with this stereochemistry. This structure has not been described previously and we have named this compound anthratectone.

The biosynthesis of this compound could be explained by the union of the two naphthoquinones I and II (Fig. 4) by a *syn-endo* Diels–Alder reaction, which explains the stereochemistry observed, and the subsequent formation of the furan ring by intramolecular cyclization.

Bioassays The etiolated wheat coleoptiles bioassay is a rapid test that is sensitive to a wide range of bioactive substances (Cutler, 1984; Cutler et al., 2000; Jacyno and Cutler, 1993). A very small amount of compound **2** was isolated and, therefore, only compound **1** could be evaluated. The highest concentration tested was 10^{-3} M. The activity was inhibitory at all concentrations tested and was greater than −80% at the most concentrated, with the activity retained upon dilution: (−81%, 10^{-3} M; −77%, $5{\cdot}10^{-4}$ M; −55%, 10^{-4} M; −46%, $5{\cdot}10^{-5}$ M; −25%, 10^{-5} M). The IC_{50} values were calculated using the sigmoidal dose-response model,

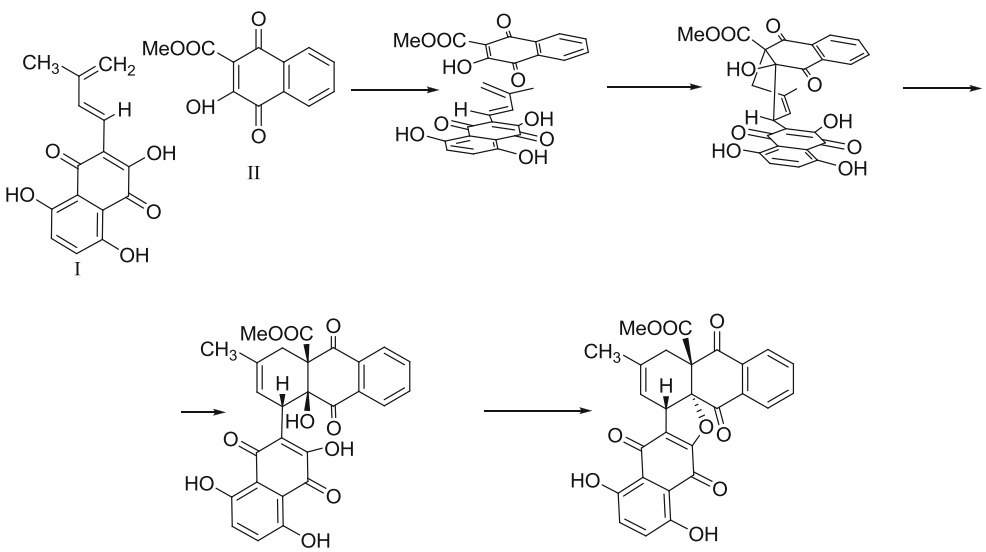

Fig. 4 Biosynthetic proposal for compound **2**

affording a value of 0.138 mM (R^2=0.974). These values are similar to those obtained for the commercial herbicide Logran® (−90%, 10^{-3} M; −87%, $5{\cdot}10^{-4}$ M; −75%, 10^{-4} M; −54%, $5{\cdot}10^{-5}$ M; −18%, 10^{-5} M), used as positive control. If we compare this result with the activities of other compounds isolated and assessed by our research group from teak, only solidagonal acid (IC_{50}=0.078 mM) (Macias et al., 2010) is sligthly more active than naphthotectone. Nevertheless, the ecological and defensive relevance of the activity of this compound should be higher, as it is much more abundant than solidagonal acid in the extract.

Phytotoxicity Bioassay Results The concentrations tested in the phytotoxicity assay were identical to those in the previous bioassay. The standard target species (STS) were *Lactuca sativa* L. (lettuce), *Lycopersicum esculentum* Will. (tomato), *Lepidium sativum* L. (cress), and *Allium cepa* L. (onion) (Fig. 5). Regarding the dicotyledonous species, the compound under investigation did not cause significant effects on germination or growth of *Lepidium sativum*.

The behavior of **1** in the germination and growth of *Lactuca sativa* was inhibitory in almost all cases. The highest inhibitory effect was observed on germination, where compound **1** showed activity values similar to those of the herbicide Logran® at the highest concentrations (10^{-3} M, −89%; $5{\cdot}10^{-4}$ M, −89%; 10^{-4} M, −66%) and higher values at lower concentrations ($5{\cdot}10^{-5}$ M, −55%; 10^{-5} M, −32%). The activities on root and shoot growth were more persistent with dilution than those of Logran®. Thus, we highlight the inhibition of root growth at 10^{-3} M (−62%) and $5{\cdot}10^{-4}$ M (−49%).

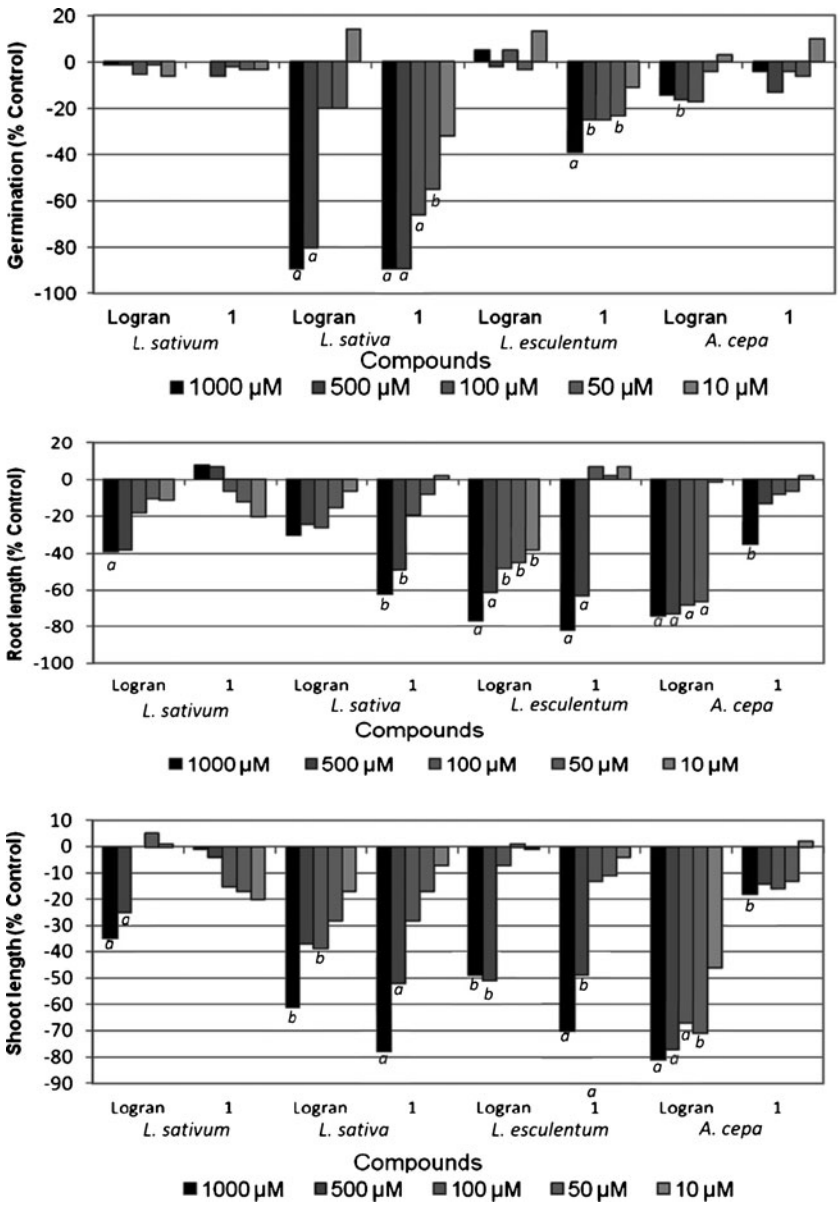

Fig. 5 Effects of the commercial herbicide Logran and compound **1** on the growth of standard target species. Values are expressed as percentages from the control and are not significantly different (P>0.05 for the Mann–Whitney test). [a]Values significantly different with P< 0.01. [b]Values significantly different with 0.01<P<0.05

With regard to the third dicotyledonous species, *Lycopersicum esculentum*, the effects on germination were higher (−40% at 10^{-3} M) than those of Logran®. Root growth of tomato was more inhibited, with values of −82% and −63% at 10^{-3} M and $5{\cdot}10^{-4}$ M, respectively. Shoots were less affected, but once again the effects were higher than those obtained with Logran®.

In the monocotyledon species *Allium cepa*, the most affected parameter was root growth in terms of inhibitory activities. The effects on germination and shoot development were not significant.

Compound **1** presented high activities in both bioassays. This finding could be of importance from the ecological point of view since the new compound identified is one of the most abundant metabolites in *Tectona grandis* and presents a high phytotoxic activity. Natural naphthoquinones and anthraquinones are compounds with a broad spectrum of biological activities (Abad and Bermejo, 2005) against microbes, trypanosomes, viruses, and cancer cells, and it has been demonstrated that some quinones can inhibit enzymes that triggers apoptosis (Silva et al., 2003).

Regarding their allelopathic activity, they were early described as phytotoxic agents, although currently the number of these compounds that have shown activity is comparatively low. Thus, one of the first examples of an allelochemical to be described was juglone (5-hydroxy-1,4-naphthoquinone), isolated from black walnut tree (*Juglans nigra* L.)(Davis, 1928; Shibu, 2002). Another well-known example is sorgoleone and its related compounds (Kagan et al., 2003) that are the responsible for the allelopathic effect of sorghum (Netzly and Butler, 1986). Both juglone and sorgoleone are highly phytotoxic and their modes of action have been studied (Hejl et al., 1993; Dayan et al., 2010). So, compound **1** may be one of the major compounds responsible for the allelopathic activity shown by teak as well as being involved in other defense mechanisms. Explanation of this activity is a major goal of our work. This is the initial study, and it is necessary for further experiments to detect this compound in soil, and in the target species. The fate of this compound should be studied, as well as the bioactivity of the possible degradation products.

quantitatively within species, between sexes, populations, individuals (Soini et al., 2007; Mardon et al., 2010; Whittaker et al., 2010), and age classes (Shaw et al., 2011).

In seasonally reproducing species, many physiological and behavioral changes occur during the transition from non-breeding to breeding condition. Many of these changes are mediated by steroid hormones induced by changes in photoperiod (Farner and Wingfield, 1980). Our study species, the dark-eyed junco (*Junco hyemalis*), is a North American passerine bird that breeds in the summer months. In juncos, like many seasonally breeding birds, circulating testosterone (T) levels increase sharply early in the breeding season, drop when the female lays eggs, and stay low while both parents care for the offspring (Ketterson et al., 2001, 2005). This pattern is observed in both sexes, although T levels typically are higher in males than females at most or all stages of breeding (Ketterson et al., 2001, 2005). Throughout the breeding season, males respond to an injection of gonadotropin-releasing hormone (a "GnRH challenge") with a short-term increase in T (Jawor et al., 2006). The only time that females respond this way is during the 7 days before egg laying, when they are depositing yolk in eggs (Jawor et al., 2007).

In juncos, concentrations of preen oil volatile and semi-volatile compounds are higher in captive birds held in long-day, compared to birds in short-day photoperiods, especially for the linear 1-alkanols, 1-undecanol through 1-hexadecanol, the methyl ketones, 2-undecanone through 2-pentadecanone, and the carboxylic acids, dodecanoic acid, tetradecanoic acid, and hexadecanoic acid (Soini et al., 2007). For convenience, we henceforth will refer to both volatile and semivolatile compounds as "volatile compounds," but acknowledge that the heavier compounds with lower vapor pressures, such as hexadecanoic acid, are considered "semivolatile." Males have significantly higher proportions of two methyl ketones, 2-tridecanone and 2-pentadecanone, in preen oil, while females have a blend with higher proportions of 1-undecanol and the three carboxylic acids above (Whittaker et al., 2010). The function of these compounds is not yet clear, but they appear capable of transmitting information about identity that could be used in mate choice (Mardon et al., 2010; Whittaker et al., 2010). Juncos in breeding condition detect these odors and exhibit preferences based on sex and individual characteristics of the bird that produced the preen oil (Whittaker et al., 2011).

This relationship among volatile compound concentrations, sex, and reproductive condition suggests that changes in preen oil concentration may be linked to hormone levels, even though the role of hormones in mediating changes in avian chemosignal production is not well understood. The uropygial gland contains androgen receptors (Daniel et al., 1977; Shanbhag and Sharp, 1996), and treatment with exogenous T increased rates of protein synthesis in the uropygial gland (Maiti and Ghosh, 1972; Amet et al., 1986). The similarity of the avian uropygial gland and the testosterone-dependent mammalian preputial gland has been noted previously (Maiti and Ghosh, 1972). The mammalian preputial gland can be the source of pheromones related to reproductive behavior, such as the farnesenes secreted by the mouse preputial gland (Novotny et al., 1990). Certain volatile compounds and proteins produced by the rat preputial gland are stimulated by testosterone (Ponmanickam et al., 2010). These observations suggest that, in birds, T might stimulate production of volatile compounds in the uropygial secretion. However, in the only study to examine this relationship so far, concentrations of volatile carboxylic acids decreased in the preen oil of gray catbirds receiving T treatment (Whelan et al., 2010).

We present two studies designed to elucidate the relationship between variation in steroid hormone levels and concentrations of preen oil volatile compounds. The first studied the increase in preen oil volatile compounds during the early spring, when juncos return to breeding grounds and undergo physiological and behavioral shifts into breeding condition. We asked whether the preen oil of wild juncos would have the same or different composition as captive junco preen oil. We also asked whether the effect of day length on preen oil concentration observed in the laboratory (Soini et al., 2007) was repeated under field conditions, and whether any changes would correlate with the rise in testosterone that is known to occur during early spring.

In the second study, we again used male and female juncos in captivity. The birds were held on short days, and had T levels elevated experimentally in order to test whether T alone, without the influence of increased photoperiod, stimulated production of volatile compounds in preen oil similar to the increases observed during long days. We hypothesized that birds with experimentally elevated T levels would show increases in preen oil volatile compound concentrations. We also asked whether birds with higher levels of T would have greater increases in concentrations of those compounds.

Methods and Materials

Study Species Our study subjects were wild and captive dark-eyed juncos (*Junco hyemalis carolinensis*) from Mountain Lake Biological Station (MLBS), Pembroke, VA, USA (previous studies of chemical communication in juncos have included this subspecies as well as *J. h. thurberi* in southern California and *J. h. aikeni* from South Dakota: Soini et al., 2007; Whittaker et al., 2010, 2011). This population has been the subject of a long-term behavioral and endocrinological study since 1983 (Ketterson et al., 2001, 2005; Nolan et al., 2002). From about April 15 to May 15 of every year, juncos are captured using mist nets and traps to census returning

individuals and to band new birds with USFWS bands. From May 15 to July 15, we intensively search for nests and monitor them from laying to hatching to fledging.

Study 1: Early Season Profiles of Preen Oil Volatile Compound Relative Concentrations in Wild Males and Females We collected preen oil from every bird captured opportunistically during the early season census from April to May 16, 2008. Sex was determined by observation of a brood patch (females) or cloacal protuberance (males), and also by plumage and wing length (Nolan et al., 2002). We collected preen oil by gently rubbing the uropygial gland with a 100 µl glass capillary tube (Drummond Scientific, Broomall, PA, USA), which stimulates the gland to secrete 1–3 mg of preen oil (Whittaker et al., 2010). Most samples were collected soon after capture, to minimize the impact of stress hormones. However, unlike circulating hormone levels in blood, which are known to change very quickly (less than 15 min), preen oil content is not expected to change over such a short time period. We have observed, when we collect preen oil from a bird, it can take more than 24 h before that individual has enough preen oil to sample again (Whittaker, personal observation). Preen oil was stored at −20°C within 10 min of collection and kept frozen until analyzed by gas chromatography–mass spectrometry (GC-MS), as described below. We analyzed the volatile compound content of preen oil from all birds captured on at least three different days over the course of this period, for a total of 16 females and 35 males. To compare the change in compounds over time, we binned the collection dates into 4 weeks, and used week as a categorical variable. We measured GC-MS peak areas for 15 volatile compounds that are known to differ between males and females (Whittaker et al., 2010), and between breeding and non-breeding season (Soini et al., 2007). The data were not normally distributed, so we natural-log transformed peak areas. We used a multivariate analysis of variance (MANOVA) to compare ln-transformed peak areas of each compound across the 4 weeks, and used Fisher's LSD *post-hoc* test to determine when changes occurred. All statistics were two-tailed.

Study 2: Response of Preen Oil Volatile Compounds in Captive Male and Female Juncos Held on Short Days to Experimental Elevation of Testosterone In October 2009, we captured adult juncos at MLBS using mist-nets and transported them to Indiana University, Bloomington, where they were held in an indoor, climate-controlled aviary on a natural light:dark cycle. Birds were given *ad libitum* access to water, millet and sunflower seeds, mealworms, orange slices, and a mixture of puppy chow, hardboiled eggs, and carrots (Whittaker et al., 2010). The temperature was maintained at 60–65°C, and photoperiod was set to match the daylight schedule in Pembroke, VA, until late December 2009, when we fixed the light:dark period at 10 L:14D. During short days, juncos are in non-breeding condition and have low levels of T and low concentrations of preen oil volatile compounds (Ketterson et al., 2005; Soini et al., 2007).

Males and females were randomly assigned to one of three treatment groups: control (C), which received empty implants made from 7 mm Silastic ® tubing (Dow Corning, 1.47 mm i.d., 1.96 mm o.d.); low T, which received implants packed with 2.5 mm (females) or 5 mm (males) of crystalline T (Sigma-Aldrich, Inc.); and high T, which received implants with 5 mm (females) or 10 mm (males) of T (Ketterson et al., 1991, 1992). The high T doses were selected to produce circulating T levels similar to natural peaks observed during the breeding season (Ketterson et al., 1991, 1992, 2005; Clotfelter et al., 2004). The implants were inserted subcutaneously along the left flank after anesthetizing birds with isofluorane.

There were a total of 42 birds in the study: 24 males (8 C, 8 low T, 8 high T) and 18 females (5 C, 6 low T, 7 high T). Sex was confirmed using a molecular sexing technique in which we amplified fragments of the CHD gene on the W and Z chromosomes (Griffiths et al., 1998).

Birds were housed in individual cages across three rooms. Birds were assigned to cages and rooms randomly with respect to treatment, but we maintained similar sex ratios across all three rooms (F:M ≈ 0.8). The birds were able to see and hear each other. A blood sample was taken 1 week before, and 1 week after, implantation to assay for T concentration. We took preen oil samples from the implanted birds 1 week before implantation, and 2 and 4 weeks after implantation (Dec. 28, 2009 and Jan. 11, 2010).

Although randomly assigned to treatment groups, differences in pre-implant preen oil volatile relative concentrations were observed between control males and males assigned to one of the testosterone treatments. Therefore, we restricted our analysis to the change in ln-transformed volatile compound relative concentrations at 2 and 4 weeks after implant, relative to pre-implant values. Because the data were not normally distributed, we compared treatment groups using nonparametric tests (Kruskal-Wallis for comparing three groups, Mann–Whitney *U* test for comparing two groups). All statistics are two-tailed.

Hormone Assays We measured T levels in plasma samples using a commercial enzyme immunoassay (EIA) kit (Assay Designs #901-065). Assay methods are described in detail elsewhere (Clotfelter et al., 2004). The primary change to the manufacturer's protocol is that we added 2000 cpm of tritiated testosterone to the samples in order to calculate extraction efficiencies. We determined testosterone concentrations with a 4-parameter logistic curve-fitting program (Microplate Manager; BioRad Laboratories, Inc.) and corrected them for incomplete recoveries.

Gas Chromatography–Mass Spectrometry (GC-MS) Our GC-MS method has been described previously (Soini et al., 2007; Whittaker et al., 2010). We added an internal standard (8 ng of 7-tridecanone, Sigma-Aldrich Chemical Company, Milwaukee, WI, USA) dissolved in 5 μl of methanol (Baker Analyzed®, Mallinckrodt Baker, Inc., Phillipsburg, NJ, USA) to samples, and extracted volatile compounds with the Twister® stir bar (10×0.5 mm polydimethylsiloxane, PDMS) for 60 min (Gerstel GmbH, Mülheim an der Ruhr, Germany). After extraction, the stir bar was rinsed with high-purity OmniSolv® water, dried with a paper tissue, and placed in the thermal desorption autosampler tube. Quantitative analysis was performed using an Agilent 6890N gas chromatograph connected to a 5973i MSD mass spectrometer (Agilent Technologies, Inc., Wilmington, DE, USA) with a Thermal Desorption Autosampler and Cooled Injection System (TSDA-CIS 4 from Gerstel). Samples were thermally desorbed in a TDSA automated system, followed by injection into the column with a cooled injection assembly, CIS-4.

All major compounds were identified by comparison to standard substances obtained from Sigma-Aldrich, using mass spectra and retention times (Soini et al., 2007). Peak areas of the identified compounds were used for quantitative comparisons among the groups. Peak areas were integrated either from the TIC (total ion current) profiles or from the post-run selected ion current (SIC) profiles at *m/z* 55 for linear 1-alkanols, *m/z* 58 for 2-ketones and *m/z* 60 for carboxylic acids. Peak areas of the internal standard (7-tridecanone) were integrated from the post-run *m/z* 113 profiles. Peak areas of the compounds of interest were normalized by dividing each peak area by that of the internal standard in corresponding runs, yielding relative concentrations (i.e., relative amounts per 100 μl of preen oil). Relative standard deviation (RSD, a measure of reproducibility) of the internal standard peak area was 13% (N=12).

All work was conducted in compliance with the Bloomington Institutional Animal Care and Use Committee guidelines (BIACUC protocol 09-037).

Results

Study 1: Early-Season Preen Oil Volatile Compound Profiles We confirmed that wild junco preen oil had the same volatile compound composition as captive junco preen oil. We identified the same 19 volatile compounds in wild junco preen oil as found in captive juncos (Soini et al., 2007; Whittaker et al., 2010). Four of the compounds (1-nonanol, 1-heptadecanol, nonanoic acid, and decanoic acid) were below detectable levels in many individuals and were subsequently left out of our statistical analyses; three of these (1-nonanol, nonanoic acid, and decanoic acid) were shown previously to have low intra-individual repeatability (Whittaker et al., 2010).

Relative concentrations of volatile compounds differed by sex (MANOVA, F=16.506, df=15, P<0.001) and by week (F=1.961, df=45, P=0.001), and there was an interaction between sex and week (F=1.634, df=45, P=0.01). In males, we observed a steady increase across the 4 weeks of early spring in nearly all the measured volatile compounds in male preen oil (Fig. 1, left side). For all 15 volatile compounds that we measured in males, their normalized amounts in week 4 were higher than in week 1 (P<0.05, all comparisons). *Post-hoc* tests showed that the only significant week-to-week increase in *n*-alcohols occurred between weeks 2 and 3 (P<0.01, all comparisons). Two methyl ketones, 2-undecanone and 2-dodecanone, showed an increase between weeks 3 and 4 (P<0.05, both comparisons); 2-tridecanone, 2-tetradecanone, and 2-pentadecanone showed an increase, or near-significant increase, only between weeks 2 and 3 (P<0.1). Carboxylic acids did not increase (P>0.05, all comparisons) over the time period.

The pattern in female juncos was different: no change in any compound was observed between weeks 1 and 2, but all volatile compounds had increased by week 3 (P<0.05, all comparisons; Fig. 1, right side, P>0.1).

We also examined the timing of egg laying in this population. The modal date for first egg laid occurred within week 3, both for the whole population and for birds in this study (Fig. 2). Week 3 was also when female volatile compound relative concentrations peaked (Fig. 1). The later, smaller peaks (Fig. 2) in the population are likely the result of re-nesting attempts by birds whose first clutches were destroyed by a predator before we could find them. There were insufficient data to examine individual correlations between egg laying and volatile compounds, but the population results suggest there may be a relationship between the two.

Study 2: Experimental Elevation of T in Captive Birds Held on Short Days Males (N=24) had pre-implant T levels of 0.52±0.15 ng.ml^{-1} (mean±SD), and post-implant T levels of 0.73±0.26 in C males (N=8), 5.11±1.48 in low T males (N=8), and 11.60±3.09 ng.ml^{-1} in high T males (N=8). Females (N=18) had pre-implant T levels of 0.73±0.58 ng.ml^{-1}, and post-implant T levels of 0.60±0.17 in C females (N=5), 5.05±0.84 in low T females (N=6), and 8.11±3.27 ng.ml^{-1} in high T females (N=7). These post-implant T levels were different among the three treatment groups within each sex [ANOVA, F=60.87 (males) and 18.69 (females), df=2, P<0.001 (both comparisons)].

No differences in changes in preen oil volatile compound relative concentrations were observed between the sexes

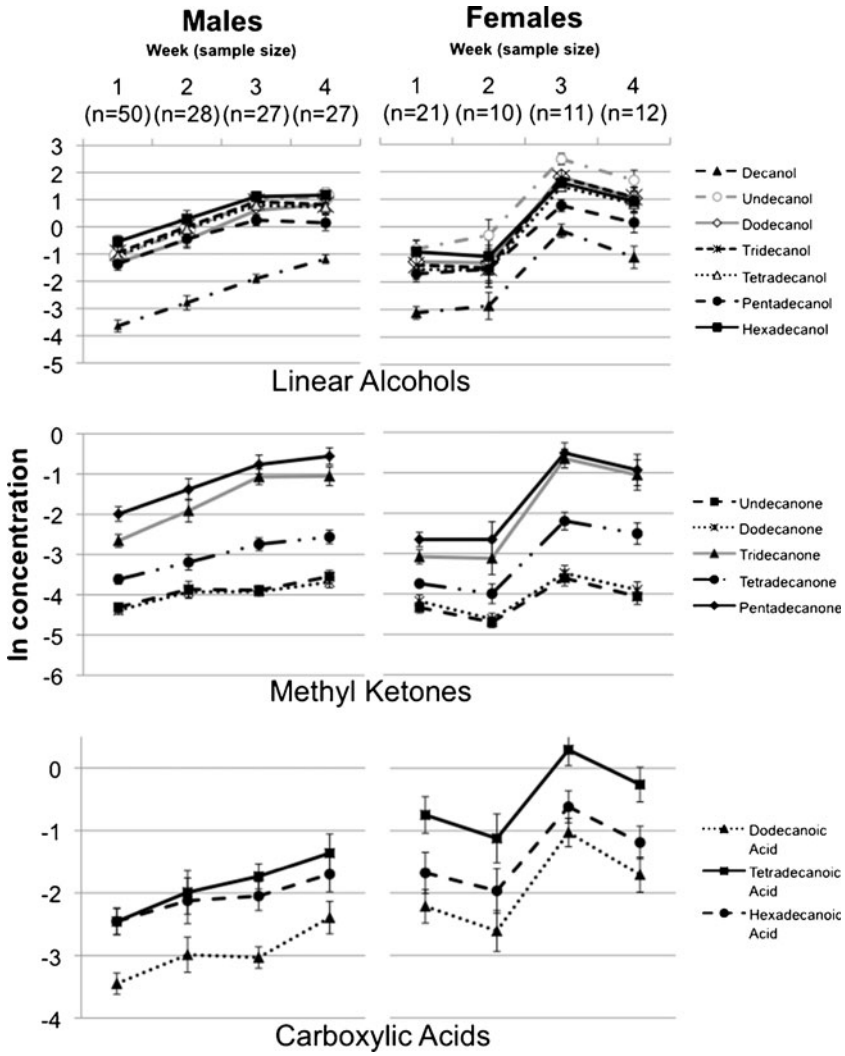

Fig. 1 Mean ln-transformed preen oil volatile compound relative concentrations (relative amounts in 100 μl of preen oil) in juncos, for each week during early season 2008, in males (*left*) and females (*right*). *Error bars* indicate standard error of the mean

(Mann–Whitney *U* test, $P>0.05$, all comparisons), so we combined the data for the two sexes for all subsequent analyses. Changes in volatile compound relative concentrations observed in week 2 were not different among treatment groups (data not shown, $P>0.05$) but, at week 4, birds treated with T showed increases of several volatile compounds (Fig. 3). Control birds also showed increases in many compounds, but these were generally much smaller than observed in T-treated birds. When comparing across the three treatment groups, a dose-dependent response was observed for undecanol (Kruskal-Wallis, $P=0.05$), tridecanol ($P=0.045$), and undecanone ($P=0.011$) (Fig. 4a–c). Because there was not a difference in the response of birds receiving low or high T implants for many of the compounds, we also compared control birds to all birds receiving T implants, regardless of dose. In this comparison, birds receiving T implants had increases in undecanol (Mann–Whitney *U* test, $P=0.015$), dodecanol ($P=0.027$), tridecanol ($P=0.014$), undecanone ($P=0.003$), and hexadecanoic acid ($P=0.045$). As an illustration, Fig. 5 shows the pre-implant and post-implant chromatograms from one individual (a male that received a high T implant). In this individual's preen oil, the absolute amount of the alcohols dodecanol, tridecanol, and tetradecanol increased from 1.3 ng.mg^{-1}, 2.6 ng.mg^{-1} and 6.2 ng.mg^{-1}to 8.3 ng.mg^{-1}, 14.2 ng.mg^{-1}, and 28.8 ng.mg^{-1}, respectively (Fig. 5).

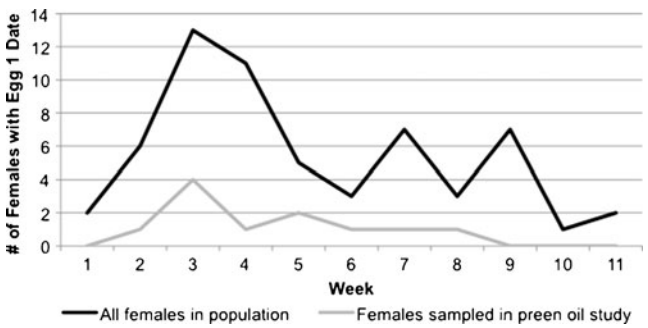

Fig. 2 Date of first egg laid by wild female juncos at Mountain Lake Biological Station, Pembroke, VA in 2008. Weeks correspond to weeks in Fig. 1

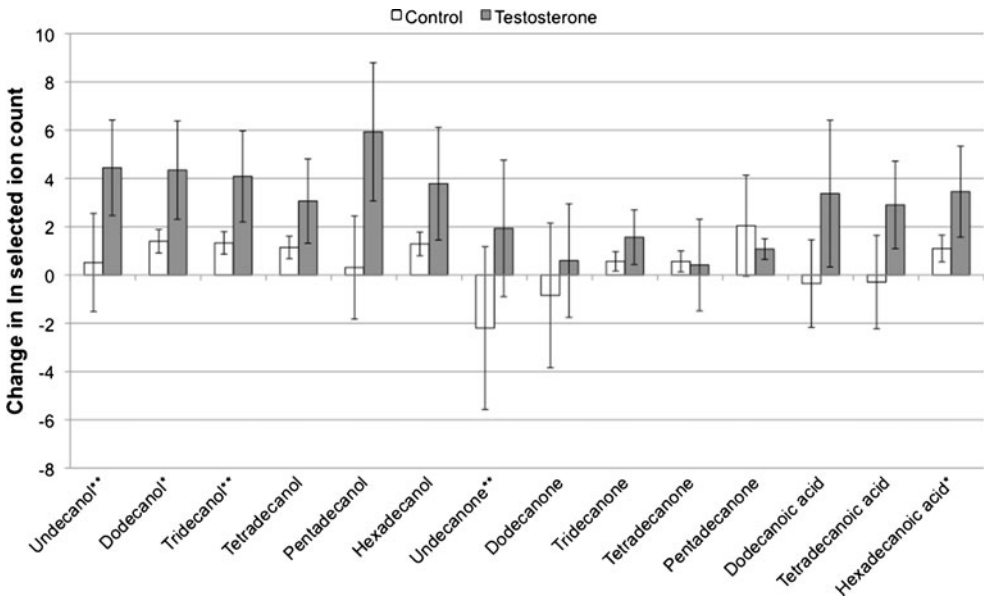

Fig. 3 Changes in ln-transformed volatile compound relative concentrations in juncos 4 weeks after implant with testosterone (T). *Error bars* indicate standard error of the mean. Compounds with increases (Mann–Whitney *U* test, $P<0.05$) in relative concentration in T-implanted birds are noted with an asterisk in the X-axis labels; those that also increased when compared across the three treatments are indicated with two *asterisks*

Discussion

We tested whether testosterone stimulates the production of volatile and semivolatile compounds present in preen oil, and whether the concentrations of these compounds varied in relation to an individual's testosterone levels. We found that volatile compounds increased in concentration during the early breeding season, in tandem with the previously described seasonal increase in circulating levels in T (Ketterson et al., 2005) and seasonal response to GnRH (Jawor et al., 2006, 2007) in wild male and female juncos. Our data showed a concentration peak for females in the same week that most females in the population laid their first egg (week 3), as would be expected if steroid levels influence volatile compound production. In males, we observed a steady increase across the 4 weeks, with volatile compound concentration higher in the fourth than in the first week. Previous studies found that males also experience a drop in T when their mate begins incubating eggs (Ketterson et al. 2005), but the drop is not as sharp as in females. It may be that the males in our study had not yet experienced this decrease in circulating T, or that the decrease was smaller and did not affect volatile compound production. The volatile compounds we observed in wild junco preen oil were the same as those previously described in captive junco preen oil (Soini et al., 2007; Whittaker et al., 2010).

Treatment with exogenous testosterone stimulated the production of some, but not all, preen oil volatile compounds and, for some compounds, birds treated with a high dose of T did not have greater concentrations of preen oil volatile compounds compared to birds that received half the dose. These data suggest that while T in the absence of long days is sufficient to stimulate the production of some volatile compounds, it is not positively correlated with the concentrations of individual compounds. We did not detect differences between the sexes in the implant study, likely due to the fact that both males and females in non-breeding condition are known to display low levels of all preen oil volatile compounds (Soini et al., 2007), and the only manipulation in the study was the circulating level of T. The only volatile compound that is typically in greater concentrations in males than in females, and that responded significantly to T treatment, was 2-undecanone. In another study (Whittaker et al., 2011), we found a positive correlation between the relative proportions of "male-like" volatile compounds (those that make up a greater proportion of the volatile compounds present in male preen oil compared to female preen oil) and a proxy for body size. Thus, there may be another physiological factor involved in producing a male-like chemical profile, and these other factors may not be directly under T control, unlike volatile compounds related to reproductive behavior in rats (Ponmanickam et al., 2010).

Changes in photoperiod affect the production of many different hormones, besides T, which may play a role in stimulating volatile compound production. For example, exposure to light inhibits the production of melatonin from the pineal gland. In mammals, melatonin has been suggested to play a role in regulating the hypothalamic-pituitary-gonadal (HPG) axis, affecting the timing of the production of steroid hormones (Tamarkin et al., 1985). Although melatonin does not appear to be responsible directly for timing reproductive activity in birds, it does play a role in seasonal changes in immune function and song production (Bentley et al., 1999; Bentley, 2001). Thyroid hormone also has been shown recently to play a role in seasonal changes in both mammals and birds (Watanabe et al., 2007). The short photoperiod in the experimental study

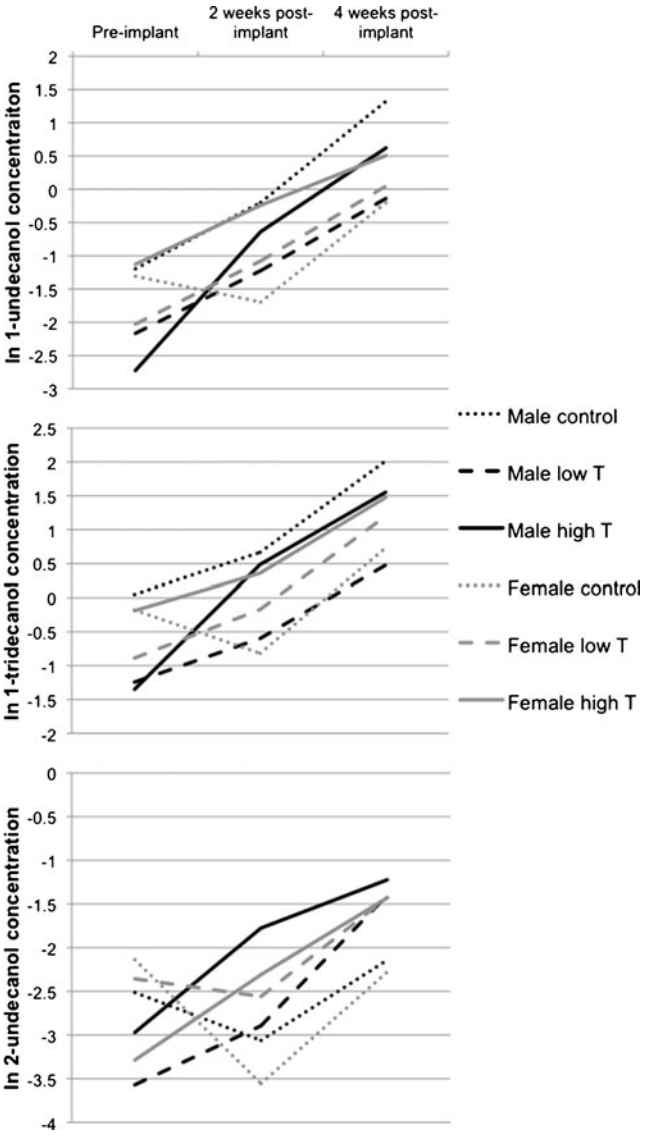

Fig. 4 Average ln-transformed concentrations over time of a) 1-undecanol, b) 1-tridecanol, and c) 2-undecanone in control and testosterone-implanted (at two amounts, low and high) in male and female juncos

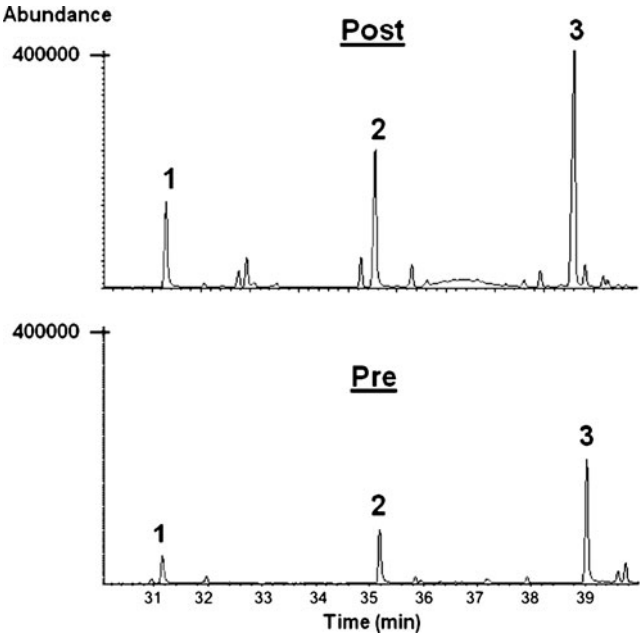

Fig. 5 Selected ion (*m/z* 55) chromatograms (pre- and post-implant), showing comparison of the amounts of selected *n*-alkanols in an individual (ID# 21443) male junco that received a high testosterone implant; 1 = dodecanol (31.1 min), 2 = tridecanol (35.1 min), 3 = tetradecanol (39.0 min)

likely was associated with increased melatonin levels in the birds and decreased levels of the bioactive form of thyroid hormone (T_3), which could have affected the changes in volatile compound concentrations.

The uropygial gland has been described as "androgen-dependent," due to both the high concentration of androgen receptors and the previously observed responses of the gland to treatment with testosterone (Maiti and Ghosh, 1972; Abalain et al., 1983; Amet et al., 1986). In addition to androgen receptors, the uropygial gland contains receptors for other steroid hormones, including receptors for estradiol (Daniel et al., 1977). In order for T to influence target tissues, it must, sometimes, first be converted to an active form, such as dihydrotestosterone (DHT), through the action of 5α-reductase, or estradiol, through the process of aromatization (Massa, 1984). The seasonal changes observed in wild females could have been related to changing estradiol levels, and exogenous T may have been converted to estradiol. Steroid hormone metabolism can take place in the brain to affect behavior (Riters et al., 2001), as well as in peripheral tissues (Edwards et al., 2005), and the abundance of the enzymes involved in this conversion can vary seasonally (Soma et al., 2003). Thus, the inability of our T implant study to replicate volatile compound concentrations observed in breeding birds may be related to differences in concentration of other hormones like melatonin and thyroxine, or a lack of 5α-reductase in males, the quantity of which is known to be decreased in non-breeding birds (Soma et al., 2003).

Other steroid hormones may also play a role in regulating volatile compounds. In the crested auklet, a seabird that produces a citrus-like odorant that does not originate from preen oil, odorant emission was related to levels of the steroid hormone progesterone in males, but not in females (Douglas et al., 2008). Relatively few progesterone, compared to androgen, receptors have been found in the uropygial gland, but progesterone and androgens are known to exhibit cross affinity for receptors (Daniel et al., 1977). Corticosterone, a steroid hormone related to stress, also has been shown to have an effect on cellular activity in the uropygial gland (Maiti and Ghosh, 1969), and corticosterone levels are known to be correlated with T levels in juncos (Ketterson et al., 1991). Thus, a better understanding of the relationship between preen oil volatile

compounds and progesterone or corticosterone levels may be necessary to understand seasonal changes in volatile profiles.

While our results shed light on the role of testosterone on preen oil composition, the role of these volatile compounds in male preen oil remains unknown. Behavioral data suggest female and male juncos are attracted to the scent of males (Whittaker et al., 2011), indicating potential behavioral roles for these compounds. However, their function in females is less clear. The positive relationship between T and "female-like" volatile compounds (those that are typically present in higher proportions in female preen oil) suggests that these compounds could function as a signal of ovulation or receptivity, when T levels are highest. In many species of birds, female T levels peak before or during nest-building (Ketterson et al., 2005), and treatment with T can induce sexual receptivity in many female vertebrates (Adkins-Regan, 1981), most likely as a result of aromatization of T into estradiol (Winkler and Wade, 1998). Data from other avian species also suggest that females produce an olfactory signal that is attractive to males. In domestic chickens, experimental removal of the female's uropygial gland resulted in significantly fewer copulation attempts by males, suggesting that this gland is the source of an attractive signal (Hirao et al., 2009). Female mallard ducks in breeding condition produce preen oil compounds that have been described as pheromones, and these compounds can be induced in nonbreeding males and females by injecting them with exogenous estradiol (Bohnet et al., 1991).

Future research should focus on the action of additional hormones, including estradiol, progesterone, thyroxine, and melatonin, on preen oil volatile compound concentrations. In particular, the relationship between female breeding condition and chemical signals, which is well established in some mammals, should be further investigated in birds.

Acknowledgments We thank Ryan Kiley, Christine Bergeon Burns, Kim Rosvall, and Mark Peterson for assistance in capturing juncos and maintaining them in captivity. Thanks to Jim Goodson for lending equipment and Kevin McLane for help processing samples. We thank Greg Demas for comments on an earlier draft. All work was conducted in compliance with the Bloomington Institutional Animal Care and Use Committee guidelines (BIACUC protocol 09-037) and with permission from the US Department of Fish and Wildlife, the Virginia Department of Game and Inland Fisheries, and the US Forest Service. This research was supported by the Indiana Academy of Sciences, and the Indiana University Faculty Research Support Program. Chemical analysis was sponsored jointly by the METACyt Initiative of Indiana University, a major grant from the Lilly Endowment, Inc., and the Lilly Chemistry Alumni Chair funds (to M.V.N.).

level registered in the western Palaearctic region (Enghoff et al., 2011). Defensive secretions from only 13 species in this family have been analzyed (Trave et al., 1959; Schildknecht and Weis, 1961; Röper and Heyns, 1977; Röper, 1978; Huth, 2000). In this study, we identified the constituents of the secretions from three European Julidae species, *Cylindroiulus boleti* (C. L. Koch, 1847) (distributed in Austria, Germany, mainland Italy, eastern Europe, and the Balkan Peninsula), *Leptoiulus trilineatus* (C. L. Koch, 1847) (distributed in mainland Italy, Austria, Switzerland, and the Balkan Peninsula), and *Megaphyllum bosniense* (Verhoeff, 1897) (distributed in Austria, Hungary, mainland Italy, and the Balkan Peninsula) (Enghoff and Kime, 2010).

Methods and Materials

Collection and Handling of Millipedes Individuals of *C. boleti*, *L. trilineatus*, and *M. bosniense* were collected in September-November 2010 at Drugovačka Šuma, near Smederevo, eastern Serbia. The millipedes were stored in plastic boxes with a layer of partly decomposed litter, and kept in the laboratory for a few days at 10°C in the dark. Humidity in the boxes was kept high by spraying water on the litter every day.

Chemical Extraction For the collection of defensive secretions, 15 males and 15 females of each species were soaked in 2 ml of dichloromethane (DCM) for 3 min. To eliminate the effects of composition-altering oxidation and degradation of compounds, a portion of the extracts was analyzed immediately by gas chromatography–mass spectrometry (GC-MS). The rest of each extract was evaporated under nitrogen, and the residue was dissolved in $CDCl_3$ for ^1H NMR spectrometric analysis.

Chemical Analyses and Identification The GC and GC-MS analyses were performed on an Agilent 7890A GC system equipped with a 5975 C inert XL EI/CI MSD and a FID detector connected by capillary flow technology 2-way splitter with make-up gas. An HP-5MSI capillary column (Agilent Technologies, 0.25 mm i.d., 30 m length, 0.25 μm

[d] four most abundant ions (for EI-MS spectra see Supplemental Figs. S2–S13)

film thickness) was used. Samples were injected in splitless mode, and the injection volume was 1 μl. The carrier gas (He) flow rate was 1.6 ml/min at 40°C (constant pressure mode). The column temperature was programmed linearly in a range of 40–300°C at a rate of 10°C/min, with an initial 1-min and a final 8-min hold. Mass spectra were acquired in electron ionization mode (EI) with ion energy of 70 eV and chemical ionization (CI) mode with ion energy of 150 eV. CI mass spectra were obtained in positive mode with isobutane as the reagent gas. The scan range was *m/z* 35–550 in EI mode, and *m/z* 60–550 in CI mode.

The identification of the compounds was based on comparison of their EI mass spectra with the NIST MS Search 2.0 computerized mass spectral libraries Wiley7 and Nist05, and with the available literature EI-MS data of the compounds previously identified in the defensive secretions of millipedes (Attygalle et al., 1993; Wu et al., 2007). Further, CI-MS spectra of all twelve compounds showed characteristic base peaks at m/z values numerically equal to their respective nominal masses plus one values. The NMR spectra were recorded on Varian Gemini 2000 (200 MHz for ^{1}H) and Bruker Avance III 500 (500 MHz for ^{1}H) spectrometers. Compounds II and IV were confirmed by this method.

Results

From the defensive secretions of three Julidae species (*C. boleti*, *L. trilineatus*, and *M. bosniense*), obtained by whole body extraction in DCM that were analyzed using GC and GC-MS, a total of 12 benzoquinone derivatives were identified: 1,4-benzoquinone (**I**), 2-methyl-1,4-benzoquinone (**II**), 2-hydroxy-3-methyl-1,4-benzoquinone (**III**), 2-methoxy-3-methyl-1,4-benzoquinone (**IV**), 2,3-dimethoxy-5-methyl-1,4-benzoquinone (**V**), 2-methylhydroquinone (**VI**), 2-methoxy-5-methylhydroquinone (**VII**), 2,3-dimethoxyhydroquinone (**VIII**), 2-methyl-3,4-methylenedioxyphenol (**IX**), 2,3-dimethoxy-5-methyl-1,4-benzoquinone (**X**), 2-methoxy-3-methylhydroquinone (**XI**), 2,3-dimethoxy-5-methylhydroquinone (**XII**) (Table 1, Fig. 1). The gas chromatograms of DCM extracts of the three investigated species and the EI-MS spectra of compounds I-XII are shown in Supplemental Figs. S1–S13. The GC and GC-MS data are summarized in Table 1. The relative abundances of the components were computed from the corresponding GC-FID peak areas.

Apart from benzoquinone derivatives, GC chromatograms of the DCM extracts of all three species revealed the presence of other compounds (Supplemental Fig. S1).

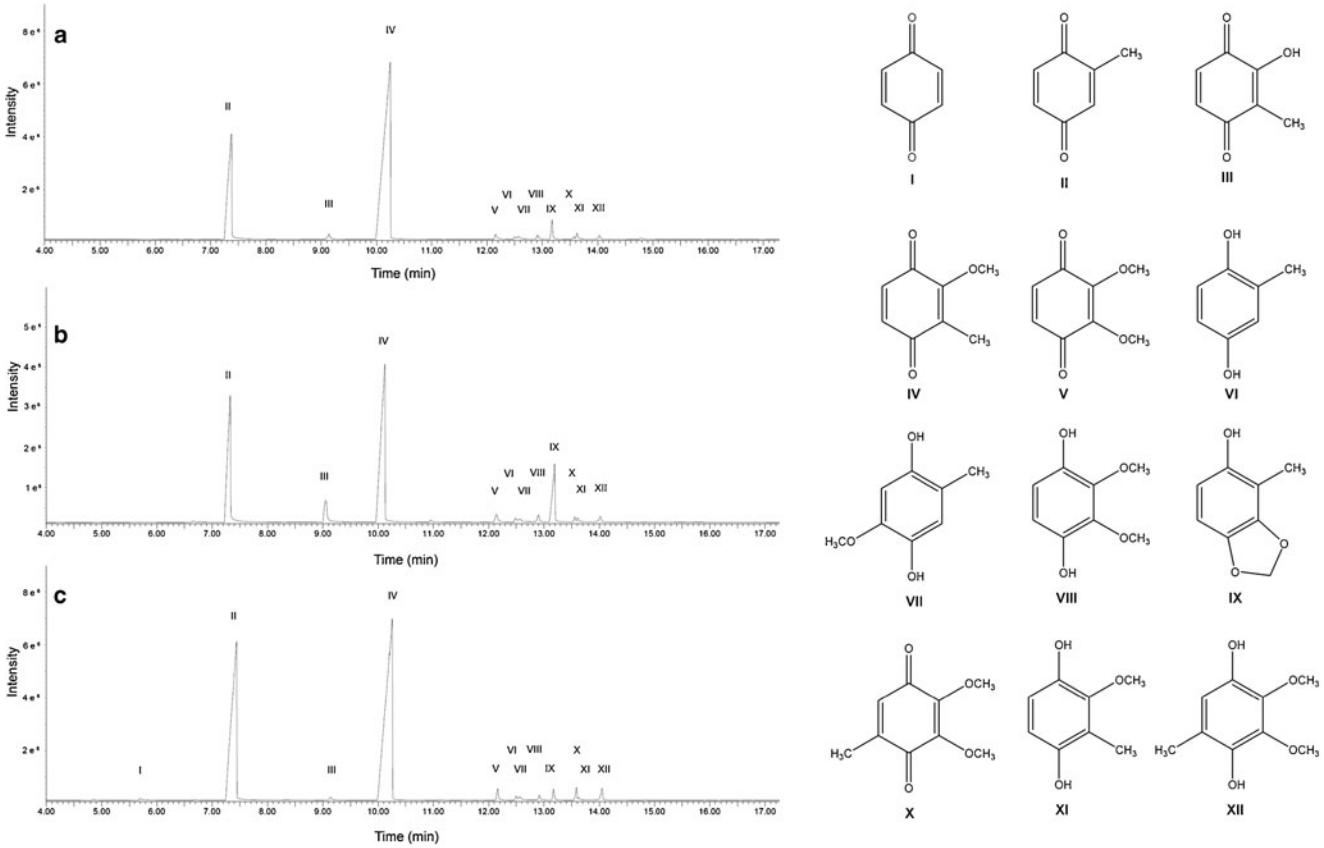

Fig. 1 GC-FID profiles of DCM extracts of julid millipede species *Cylindroiulus boleti* (**a**), *Leptoiulus trilineatus* (**b**), *Megaphyllum bosniense* (**c**), and the structures of identified benzoquinone compounds

Based on their EI and CI mass spectral data, these compounds were identified as hexyl esters of saturated and unsaturated fatty acids with chain lengths from C_{14} to C_{20}. The same compounds were previously detected in the secretions of seven European julids (Huth, 2000), but there is no evidence as to how or whether they contribute to the defensive mechanism of millipedes.

The two main benzoquinone derivatives in all three species were compounds **II** and **IV**, which were structurally confirmed by NMR analysis. In the ^{1}H NMR spectrum of the DCM extract of *M. bosniense* (Fig. 2) and the two other species, the dominant signals arise from hexyl esters of fatty acids detected by GC-MS, but signals characteristic for benzoquinone derivatives also can be observed. Two major doublets at δ 6.69 and 6.60 ppm belong to the most abundant benzoquinone compound **IV**, as do singlets at δ 4.03 ppm (-OCH_3) and 1.95 ppm (-CH_3). Compound **II** is characterized by three benzoquinone protons at δ 6.76, 6.71, and 6.62 ppm, and by a doublet from -CH_3 at δ 2.07 ppm. The ^{1}H and ^{13}C NMR assignments of compounds **II** and **IV**, detailed below, were completed using 2D NMR (HSQC, HMBC, and COSY; Supplemental Figs. S14–S18). These NMR data corresponded well with the literature (Gonzáles et al., 2006; Miyamura et al., 2008), with the exception of the coupling between the -CH_3 group and H-3 of compound **II**. We observed this coupling in the ^{1}H NMR spectrum (Fig. 2), and it was confirmed by COSY correlation (Supplemental Fig. S15), but no such coupling has been reported so far.

2-Methyl-1,4-benzoquinone (**II**): **^{1}H NMR** (500 MHz, $CDCl_3$, *J* in Hz) δ: 6.76 (1H, d, *J*=10, H-6), 6.71 (1H, dd, *J*= 10, 2.5, H-5), 6.62 (1H, dq, *J*=2.5, 1.6, H-3), 2.07 (3H, d, *J*= 1.6, -CH_3); **^{13}C NMR** (125 MHz, $CDCl_3$, ppm) δ: 187.6 (C-1), 183.9 (C-4), 145.9 (C-2), 136.6 (C-5), 136.5 (C-6), 133.3 (C-3), 15.8 (-CH_3).

2-Methoxy-3-methyl-1,4-benzoquinone (**IV**): **^{1}H NMR** (500 MHz, $CDCl_3$, *J* in Hz) δ: 6.69 (1H, d, *J*=10, H-5), 6.60 (1H, d, *J*=10, H-6), 4.03 (3H, s, -OCH_3), 1.95 (3H,

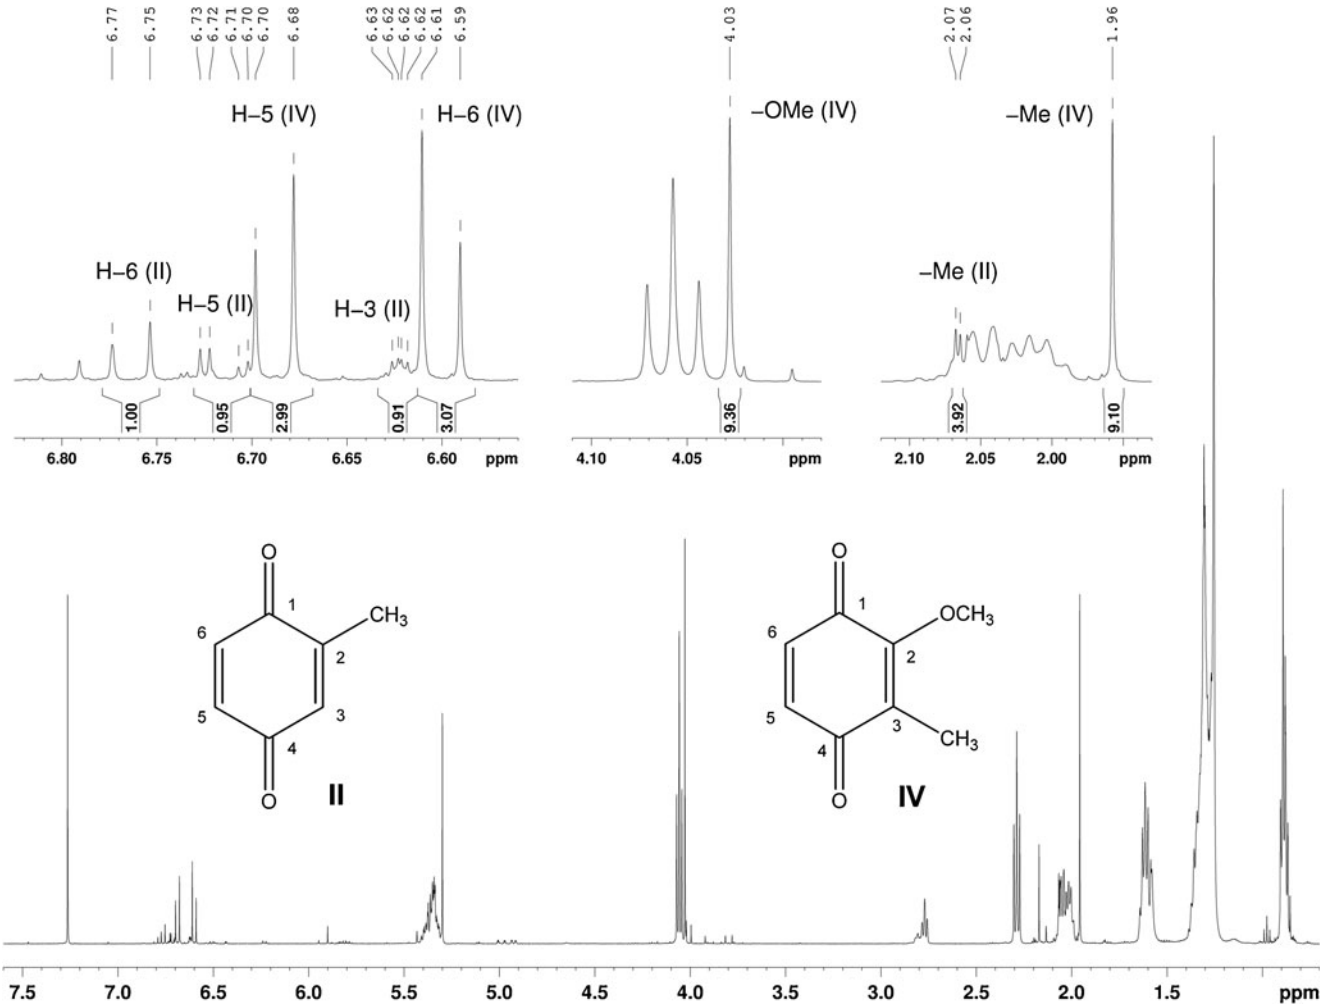

Fig. 2 ^{1}H NMR spectrum (500 MHz, $CDCl_3$) of the DCM extract of *Megaphyllum bosniense*; expansions show signals of compounds **II** and **IV**

s, -CH_3); **^{13}C NMR** (125 MHz, $CDCl_3$, ppm) δ: 188.3 (C-4), 183.3 (C-1), 155.7 (C-2), 136.3 (C-5), 134.7 (C-6), 129.0 (C-3), 60.8 (-OCH_3), 8.6 (-CH_3).

Discussion

Cylindroiulus boleti, *L. trilineatus*, and *M. bosniense* possess pairs of repugnatorial glands on nearly every pleurotergite. When disturbed, these millipedes emit the noxious exudates from the glands through openings along the lateral sides of the body. The chemical components from these species are similar, including several benzoquinones and hydroquinones (Table 1). No differences in the composition of the secretions from males vs. females were noted. Moreover, the two main compounds found in the exudates of the analyzed species, 2-methoxy-3-methyl-1,4-benzoquinone (**IV**) and 2-methyl-1,4-benzoquinone (**II**), also are the major components in other julids (Huth, 2000), as well as in some spirobolids (Attygalle et al., 1993; Wu et al., 2007). Generally these two compounds are the most common components of the defensive secretions of juliformian millipedes. In this study, compound **VII** (2-methoxy-5-methylhydroquinone) has been detected for the first time in representatives of the Class Diplopoda, and compounds **III**, **VIII**, **IX**, and **XII** were detected for the first time in members of the family Julidae (Table 2). Within the Juliformia, compounds **IX** and **XII** had been isolated previously only from the defensive fluids of *Acladocricus setigerus* (Silvestri, 1897) (Spirobolida) from Micronesia (Wu et al., 2007). Wu et al. (2007) hypothesized that the oxidative cyclodehydrogenation of 2-methoxy-3-methyl-1,4-benzoquinone leads to the formation of 2-methoxy-3-methylhydroquinone, and that 2-methyl-3,4-methylendioxyphenol is a product of this reaction as well. Our results are congruent with this assumption, since we found all three compounds.

Previous studies (Huth, 2000; Makarov et al., 2010) demonstrated that in some millipedes differences in the defensive secretions are found among the minor components,

suggesting that chemical patterns in the defensive fluids may be useful in chemotaxonomy. However, our results demonstrate almost identical patterns in the compositions of the defensive secretions from the genera *Cylindroiulus*, *Leptoiulus*, and *Megaphyllum*. We detected only minor intergeneric differences, such as the presence of 1,4-benzoquinone only in *M. bosniense*, and a large quantity of compound **IX** in *L. trilineatus*, suggesting that the secretions have limited chemotaxonomic value (Table 1).

The differences in the chemical defense components between our study and previous work is a result of the general technological advancement in methods for the chemical analysis of defensive fluids, allowing identification of numerous minor substances (Schildknecht and Weis, 1961; Röper and Heyns, 1977; Röper, 1978; vs. this paper). In addition different sampling methods, such as direct extraction from glandular reservoirs (Huth, 2000) vs. whole body extracts (this paper), may lead to different composition data. The chemical compositions of the defensive secretions in the members of the family Julidae are summarized in Table 2. Unfortunately, such differences in the chemical composition of defensive fluids do not allow us to make any comparisons (either among or within genera) or generalizations concerning julid chemotaxonomy.

Our explanation for these differences is supported by the fact that our results are similar to the established chemical composition of Pacific spirobolid millipedes (Wu et al., 2007). Apart from compound **VII**, all the components from our results also are listed by Wu et al. (2007) who used the same sampling method we used in a study of the exudates of *Acladocricus setigerus*. Two compounds (2-ethyl-1,4-benzoquinone and 2-methoxy-3,6-dimethyl-1,4-benzoquinone) were found in this spirobolid that are absent in the present study. Similarities in the defensive compounds in the members of two different orders are probably partly the result of identical sampling methods. The data also support the idea of the chemical consistency of defensive components, at least in the Juliformia taxon (Eisner's "quinone millipedes"; Eisner et al., 1978), as well as the existence of phylogenetically close relationships within juliformian millipedes *sensu lato* (Woo et al., 2007).

A small number of julidean species has been analyzed in comparison to the total number of species, and comparable data often are missing. Further investigations of the defensive chemicals from a wider range of juliformian species could provide more information about chemotaxonomy at different taxonomic levels.

Acknowledgments This study was supported by the Ministry of Education and Science of Serbia (Grants Nos. 173038 and 172053). We wish to thank two anonymous referees for their helpful comments on the manuscript.

creates asymmetric genealogies, such that full sisters are more closely related to each other, than they are to their brothers (Trivers and Hare, 1976). This relatedness asymmetry, however, decreases when the queen has mated more than once (polyandry) or if colonies contain several related queens (polygyny) (Boomsma, 1993). Consequently, when kin structure varies among colonies in the same population, theory predicts that workers can enhance their inclusive fitness by specializing on the sex to which they are most related relative to the population average, i.e., females in monogynous/monandrous colonies (with high relatedness asymmetry), and males in polyandrous or polygynous colonies (with low relatedness asymmetry) (split sex ratio theory; Boomsma and Grafen, 1990, 1991). Indeed, empirical studies, mainly of ant species, have found sex allocation patterns consistent with worker control in response to variation in relatedness asymmetry (Chan and Bourke, 1994; Sundström, 1994; Sundström et al., 1996), although other studies have found sex allocation patterns inconsistent with worker control in response to variation in relatedness asymmetry (Brown and Keller, 2000; Liautard et al., 2003; Bonckaert et al., 2011).

Precise adjustment of sex ratios by colony workers in response to colony kin structure requires a mechanism by which they can assess the genetic diversity within colonies, and manipulate brood composition accordingly, e.g., by removing male larvae (Chapuisat et al., 1997). A parsimonious hypothesis is that recognition cues are at least partly genetically determined, so that within-colony recognition cue variability to a certain extent reflects genetic diversity and, thus, relatedness asymmetry. Ants and other social insects use cuticular hydrocarbons (CHCs) for discriminating colony members from strangers to maintain colony integrity. Typically, each colony is characterized by specific proportions of a set of CHCs (reviewed in van Zweden and d'Ettorre, 2010), the exact relative compositions of which can have strong genetic underpinnings (e.g., Stuart, 1988; van Zweden et al., 2009, 2010). On the other hand, if the individuals' blends of CHCs accurately reflect their genetic lineage within a colony, this could allow workers in colonies that contain different patrilines or matrilines to favor close kin to the detriment of more distant kin, and so promote their own evolutionary interests. Such nepotistic discrimination is expected to carry costs with reduced colony efficiency and social disruption in its wake (Keller, 1997), and may lead to selection against highly diverse recognition cues (Ratnieks et al., 2007). Therefore, the level of information encoded in social insect recognition cues is likely to be the result of these two opposing evolutionary forces, being good enough to allow efficient discrimination against non-nestmates but noisy enough to prevent precise discrimination within colonies (van Zweden et al., 2010). Evidence to date indicates that this is indeed the case in the ant *Formica truncorum* (Boomsma et al., 2003) and the wasp *Vespa crabro* (Dani et al., 2004), where CHC variation explained by patriline affiliation is variable among colonies, although a recent study on *Acromyrmex octospinosus* shows higher kin specificity (Nehring et al., 2010).

Not all components of the CHC profile are of equal importance in inter- and intra-colony recognition. Methyl branched alkanes and alkenes have been especially implicated in nestmate recognition, whereas the role of linear alkanes in nestmate recognition is less clear (Dani et al., 2001, 2005; Akino et al., 2004; Greene and Gordon, 2007; Martin et al., 2008; Guerrieri et al., 2009). Conversely, the relative abundance of linear alkanes appears, for example, to be involved in within-colony recognition of (worker) castes in harvester ants (Wagner et al., 2001; Greene and Gordon, 2003; Martin and Drijfhout, 2009). Therefore, we hypothesize that CHCs associated with nestmate recognition may be uniform within colonies, whereas those involved in the assessment of colony kin structure may be more variable (c.f., van Zweden et al., 2010).

In the ant *Formica exsecta*, both the number of queens that head the colony (monogyny vs. polygyny) and the number of males that mate with a queen (monandry vs. polyandry) vary. A previous study showed sex ratio specialization consistent with the predictions from split sex ratio theory (Sundström et al., 1996). This implies that workers can assess colony kin structure also when the relatedness asymmetry varies solely due to queen mating frequency. The CHC profile of *F. exsecta* typically consists of five to six linear alkanes (*n*-C_{21}: *n*-C_{31}) and five to six alkenes ((*Z*)-9-$C_{21:1}$: (*Z*)-9-$C_{31:1}$), of which the latter have been implicated as nestmate recognition cues (Martin et al., 2008). In this study, we compared the CHC variability among workers in monogynous/monandrous, monogynous/polyandrous, and polygynous colonies of *F. exsecta*, to assess whether workers have enough information to act in their best inclusive fitness interests. We predicted that CHC variability would be greater in polyandrous and polygynous than in monogynous/monandrous colonies, thus reflecting lower relatedness asymmetry. The second prediction was that greater CHC variability corresponds to colonies with male-biased sex ratios. We then combined the information on CHC and genetic diversity with sex ratio data for the same colonies to evaluate the degree to which sex allocation corresponds to colony relatedness on the one hand and CHC variability on the other.

Methods and Materials

Study Organisms and General Procedures Workers of F. exsecta were collected from 9 colonies in June 2007 and from 6 colonies in June 2009 (Table 1), on islands off the

Tvärminne Zoological Station, southwestern Finland. The population comprises largely monogynous colonies headed by queens mated with 1 to 3 males, with the exception of a few polygynous colonies (Haag-Liautard et al., 2009). This is the same population where Sundström et al. (1996) found that colonies headed by a singly mated queen specialize in female brood, and those headed by a multiply mated queen specialize in male production. Altogether we chose 5 colonies with a single queen that had mated once (monogynous-monandrous, MG/MA), 5 colonies where the queen had mated multiply (monogynous-polyandrous, MG/PA) and 5 colonies with multiple queens (polygynous, PG) (Table 1). From each colony, 18–24 workers were collected and killed by freezing at −20°C for later genetic and chemical analysis.

Sex ratios of the study colonies were assessed by sampling 50–60 sexual pupae from each colony, in June-July 2007 and 2009 after all the larvae had pupated and before any sexuals had emerged. The sex of the pupae was determined based on morphology, and the sex ratio was calculated as the proportion of queens of all sexual brood (*c.f.*, Vitikainen et al., 2011).

Genetic Analysis To confirm the kin structure of the sampled colonies and to determine patriline or matriline affiliation, the 18–24 workers of each colony were genotyped at ten loci: Fe11, Fe13, Fe17, Fe37, Fe38, Fe42, Fe49 (Gyllenstrand et al., 2002), Fl21 (Chapuisat, 1996), P22 (Trontti et al., 2003), and Fy3 (Hasegawa and Imai, 2004). Further details of PCR conditions are equal to Haag-Liautard et al. (2009). The PCR-products were separated by using automated capillary sequencer (MegaBACE 1000) and sized against ET400-R standard (GE Healthcare). The genotypes were scored with the program Fragment Profiler v1.2 (GE Healthcare), and allele calling was confirmed manually.

We used maximum likelihood methods to confirm the genetic composition of the colonies, and to assign workers into groups of full- and half-sisters, as implemented in the program COLONY 1.3. (Wang, 2004). Average within-colony relatedness was calculated as the pedigree relatedness, based on the equations in Bourke and Franks (1995), assuming r=0.75 for MG/MA colonies, and using the observed paternity shares in MG/PA colonies. For the PG colonies, we inferred the number of matrilines from the genotype data assuming the queens were unrelated (r=0). The true value may be higher, so we ran each test also with higher values without finding any differences in the outcome. Pairwise relatedness estimates between individuals and colonies were calculated based on individual genotypes at each of the ten loci using Relatedness 5.0.8 (Goodnight and Queller, 1999), and colony inbreeding (HL) following the procedure by Aparicio et al. (2006). We used the background population genetic data from 102 colonies (c.f. Haag-Liautard et al., 2009) to enhance the accuracy of allele frequency and relatedness estimates.

Table 1 Basic data for the sampled colonies

Colony	Year	*N*	Sex ratio	Inbreeding coefficient	Gene diversity	Allelic richness	Nr. of matri/ patrilines	Pedigree relatedness	All compounds	(Z)-9-Alkenes	*n*-Alkanes
MG/MA 1	2007	20	0.85	0.29	0.513	2.275	1 m/1p	0.750	1.664	1.021	1.525

Colony name also reflects colony type (*MG/MA* monogynous-monandrous, *MG/PA* monogynous-polyandrous, *PG* polygynous). *N* equals the number of individuals screened per colony. Sex ratio is expressed as the number of females as a proportion of the total number of sexual offspring. Pedigree relatedness is calculated based on the assumption that queen relatedness is zero. All compounds, (Z)-9-Alkenes, and *n*-Alkanes refer to cuticular hydrocarbon (CHC) variability measures based on the respective sets of compounds.

Colony-specific gene diversity and allelic richness were calculated with colony defined as population using Fstat 2.9.3 (Goudet, 2001). As the two measures correlated strongly (r=0.94, df=15, P<0.001), we used the factor scores from the first axis in a PCA encompassing the two measures. Comparisons between the different categories of colonies were done with a one-way ANOVA.

Chemical Analysis Cuticular lipids were obtained by individually immersing the 18–24 freshly killed workers (before genotyping them) in 200 µl HPLC-grade pentane for 10 min, with gentle vortexing for 15 sec at the start and end of the 10 min. The pentane was left to evaporate at room temperature under a laminar air-flow hood. Extracts were resuspended in 50 µl pentane, 2 µl of which were injected into an Agilent Technologies 6890 N gas chromatograph (GC), connected to an Agilent Technologies 5975 mass selective detector (MS), using 70 eV electron impact ionization. The GC was equipped with an HP-5MS capillary column (30 m×0.25 mm ID, 0.25 µm film thickness) and a split-splitless injector. The carrier gas was helium at 1 ml/min. After an initial hold of 1 min at 70°C, the temperature rose to 180°C at a rate of 30°C/min, and then to 320°C at 4°C/min with a final hold of 5 min.

The areas of five (*Z*)-9-alkenes and five linear alkanes found on the cuticle of all workers (c.f. Martin et al., 2008) were integrated for further analysis with Agilent ChemStation v. D.02.00.237. Peak areas were normalized for each individual by using a Z-transformation (Aitchison, 1986).

Statistics We estimated within-colony CHC variability both for single compounds and for sets of multiple compounds [all compounds (10 variables), (*Z*)-*9*-alkenes only (5 variables), and linear alkanes only (5 variables)]. For single compounds, we calculated the within-colony standard deviation from the Z-transformed values. For sets of multiple compounds, we first scaled the Z-transformed variables to zero mean and unit variance, and then calculated the absolute Euclidean distance to the mean of the colony. CHC variability then was expressed per colony as the mean distance of its individuals.

To assess which factors may influence within-colony CHC variability, we used ANCOVAs with within-colony CHC variability as the dependent variable, and colony kin structure (MG/MA, MG/PA, PG) or within-colony relatedness, year of sampling (2007 or 2009), within-colony genetic diversity (as captured in the factor scores for gene diversity and allelic richness combined), and colony inbreeding (HL) as the predictor variables. We included HL in the analysis, given that two earlier studies have indicated a significant effect of inbreeding on sex ratios (Haag-Liautard et al., 2009; Vitikainen et al., 2011). To test the effects of within-colony CHC variability, relatedness, genetic diversity, and inbreeding on colony sex ratio we used a multiple regression with stepwise backward elimination. These analyses were done in Statistix 9 (Analytical Software, USA).

To test for an association between genetic and CHC similarity of colonies and individuals within colonies, we created distance matrices, one with the pairwise genetic relatedness based on the ten genotyped loci, and one with the pairwise Euclidean CHC distance. Pairwise Euclidean CHC distance was calculated for sets comprising either all compounds (10 variables), (*Z*)-*9*-alkenes only (5 variables), or linear alkanes only (5 variables). The correlation between the genetic and CHC matrices then was tested using Mantel tests in the program Genodive (v. 2.0b20) (Meiermans, 2010). Correlations between relatedness and CHC distances were performed both between individuals within colonies (i.e., for each colony separately) and between colonies.

Finally, to estimate variation among hydrocarbon profiles explained by patriline or matriline affiliation, we performed a PCA using the MGPA and PG colonies, based on the three sets of multiple compounds [all compounds, linear alkanes only, and (*Z*)-*9*-alkenes only]. This was followed by a MANOVA in the program R (v. 2.12.0) with those PCs explaining >95% of the variation as dependent variables, and colony and patri- or matriline nested within colony as the explanatory variables. We repeated this analysis for each colony separately, except that colony was not used as an explanatory variable in the MANOVA. We corrected the above analyses for multiple testing by using the false discovery rate as appropriate (Benjamini and Hochberg, 1995).

Results

All putative MG/MA colonies were confirmed to be composed of full sisters only. All five MG/PA colonies had two patrilines, and the samples from PG colonies contained between 4 and 9 matrilines (Table 1). The diversity of (*Z*)-*9*-alkenes was in both sampling years significantly lower than that of *n*-alkanes, and the diversity of both was lower in 2009 than in 2007 (full factorial ANOVA, compound type: $F_{1,26}$=46.3, P<0.001, year: $F_{1,26}$= 23.5, P<0.001, compound type x year: $F_{1,26}$=1.08, P=0.31). We found no significant differences in CHC variability between PG, MG/PA, and MG/MA colonies, neither when all compounds were considered together, nor when the subsets of (*Z*)-*9*-alkenes or *n*-alkanes were considered separately [Fig. 1; one-way ANOVA with colony type as explanatory variable: (*Z*)-9-alkenes: $F_{2,12}$=0.57, P=0.58,

n-alkanes: $F_{2,12}$=0.31, P=0.74, all compounds: $F_{2,12}$=0.84, P=0.46]. Similarly, in the more comprehensive model, neither within-colony relatedness, genetic diversity (factor scores for the combined effects of allelic diversity and gene diversity), nor colony inbreeding were significantly associated with CHC variability in any of the three multi-compound sets [all compounds, (*Z*)-*9*-alkenes, *n*-alkanes; Table 2], or any of the individual compounds (Appendix 1). The outcome was qualitatively the same when colony type (PG, MG/PA, and MG/MA) was used instead of within-colony relatedness (Appendix 1). Indeed, within-colony CHC variability was not significantly correlated to any of the other measures, except for sampling year (Table 2). However, genetic diversity did not significantly differ among the three colony types either (PG, MG/PA, MG/MA) ($F_{2,12}$=3.25, P=0.07), suggesting that the increased number of genetic lineages in MG/PA and PG colonies did not necessarily increase genetic diversity.

We found a portion of CHC variation was explained by patri- and matrilines when all compounds or (*Z*)-*9*-alkenes only were considered (all compounds: Wilks' λ=0.333, approx. $F_{148,632.1}$=1.36, P<0.01; (*Z*)-*9*-alkenes: Wilks' λ=0.420, approx. $F_{111,477.1}$=1.44, P<0.01; *n*-alkanes: Wilks' λ=0.521, approx. $F_{111,477.1}$=1.05, P=0.367), although these differences were only pronounced in some of the colonies (Table 3). Matrilines differed significantly in their CHCs in one of the five PG colonies, regardless whether all compounds or only (*Z*)-*9*-alkenes were used. Similarly, in one of the five MG/PA colonies patrilines differed significantly with respect to the (*Z*)-*9*-alkenes (all corrected for false discovery rate; Table 3). We also found a negative correlation between pairs of colonies for pairwise relatedness and (*Z*)-*9*-alkene distance after correction for false discovery rate (r=−0.342, P=0.001), but not for *n*-alkanes or when all compounds were considered (r=−0.021, P=0.401, and r=−0.213, P=0.016, respectively) (Fig. 2). This shows that the relative abundance of (*Z*)-*9*-alkenes has a strong genetic component with respect to between-colony variation. However, within colonies, we found no significant associations between genetic and CHC distances for any of the considered compound sets (Appendix 2).

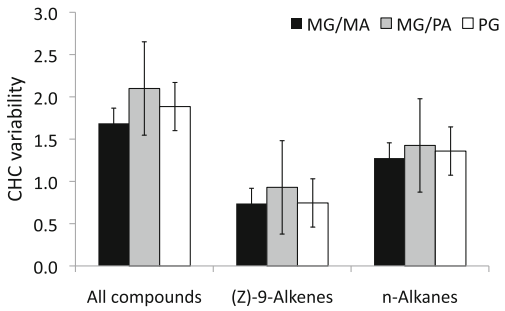

Fig. 1 CHC variability, colony type and CHC group (mean ±95%CI; *MG/MA* monogynous-monandrous, *MG/PA* monogynous-polyandrous, *PG* polygynous)

Table 2 Ancova results for effects on CHC variability

Effect	All compounds		(*Z*)-*9*-Alkenes		*n*-Alkanes	
	F	*P*	*F*	*P*	*F*	*P*
Year	5.63	0.04	20.09	0.001	3.71	0.08
Relatedness	0.12	0.73	0.33	0.58	0.01	0.92
Genetic diversity	0.39	0.55	0.12	0.73	0.07	0.80
Inbreeding	0.25	0.63	1.64	0.23	0.06	0.81

Within-colony relatedness was calculated assuming zero relatedness among queens, and genetic diversity as the combined effects of allelic richness and gene diversity captured in their factor scores. *df*1=1, *df*2=10 in all cases.

The sex ratios of all PG colonies were highly male biased, as expected based on their low relatedness (Fig. 3). The monogynous colonies were more variable. Two of the five MG/PA colonies produced a female biased sex ratio, and two of the five MG/MA colonies produced mainly males (Fig. 3). When the effects of colony-specific CHC variability on sex ratio were considered in conjunction with within-colony relatedness and colony inbreeding (HL), the only significant determinant of colony sex ratios was within-colony relatedness (full model including relatedness and HL as explanatory factors: R^2=0.40, $F_{2,12}$=4.04, P=0.045; HL: $F_{2,12}$=3.13, P=0.102; relatedness $F_{2,12}$=8.07, P=0.015; all other variables, year, all compounds, (*Z*)-*9*-alkenes, *n*-alkanes: $F_{2,12}$<0.35, P>0.50).

Discussion

In this study, we showed that in *Formica exsecta* the within-colony CHC variability is not contingent on colony kin structure, yet genetically related colonies have more similar chemistry, showing a genetic component to the cuticular chemistry without a direct link with the genetic composition of the colony. Nonetheless, genetic lineages were chemically distinct in some but not all colonies. This suggests that chemical cues by which workers can assess colony kin structure are occasionally available, but that these cues generally are unreliable, so that workers would make too many mistakes when using them as a proxy for the sex ratio to be produced by the colony.

Polygynous and monogynous/polyandrous colonies showed no higher amounts of CHC variability than monogynous/monandrous ones. This is in agreement with the result obtained by S.J. Martin et al. (unpublished data) for the same species, but stands in stark contrast with the general expectation of greater CHC variability in genetically more heterogeneous, i.e., polygynous and/or mono-

Table 3 Discriminant analyses between genetic lineages within MGPA and PG colonies

Colony	All compounds (3 PCs)			*(Z)-9*-Alkenes (2 PCs)			*n*-Alkanes (2 PCs)		
	Wilks' λ	*F*	*P*	Wilks' λ	*F*	*P*	Wilks' λ	*F*	*P*

A PCA was performed on the Z-transformed CHC data of either all colonies together or single colonies; PCs explaining >95% of the variation were then included as the dependent variable in a MANOVA with genetic lineage (nested within colony, when all colonies were considered together) as the explanatory variable.

gynous/polyandrous societies, which has formed the foundation for assuming lower discrimination abilities in polygynous societies (e.g., Fletcher and Michener, 1987; Starks et al., 1998). However, we also found that the within-colony genetic diversity was not higher in the polygynous and the monogynous/polyandrous colonies than in the monogynous/monandrous ones. Indeed, although within-colony relatedness varied 15-fold, the corresponding ranges for both gene diversity and allelic richness were only 1.7 fold in both cases (Table 1). Thus, the genetic basis for a greater diversity is not present, which may explain the lack of correlation between colony kin structure and CHC variability.

The (*Z*)-*9*-alkenes overall were less variable within colonies than *n*-alkanes. This supports the existing evidence that mainly alkenes mediate nestmate recognition in *F. exsecta*, whereas alkanes are less informative in this respect (Martin et al., 2008). Moreover, the between-colony CHC distance for (*Z*)-*9*-alkenes, but not the *n*-alkanes, decreased significantly with increasing between-colony pairwise relatedness. This, in conjunction with the result that within-colony CHC variability showed no clear association with genetic diversity, suggests a strong genetic foundation of the (*Z*)-*9*-alkene profile that is to a large extent blurred within colonies by odor cue transfer between nestmates (c.f. van Zweden et al., 2010). It also suggests unequal mixing

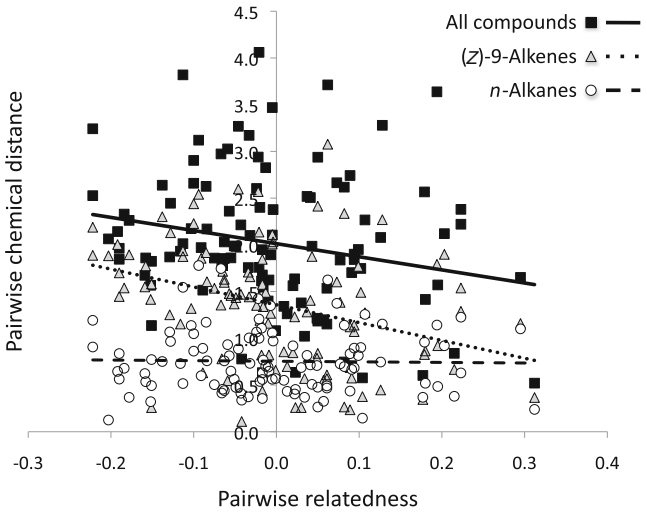

Fig. 2 Correlations between colony pairwise relatedness and colony CHC distances. Association is significant, after correction for false discovery rate, for *(Z)*-9-alkenes (Mantel's test; *(Z)*-9-alkenes, $r=-0.342$, $P<0.001$), but not when *n*-alkanes or all compounds were considered (*n*-alkanes, $r=-0.021$, $P=0.401$; all compounds, $r=-0.213$, $P=0.016$)

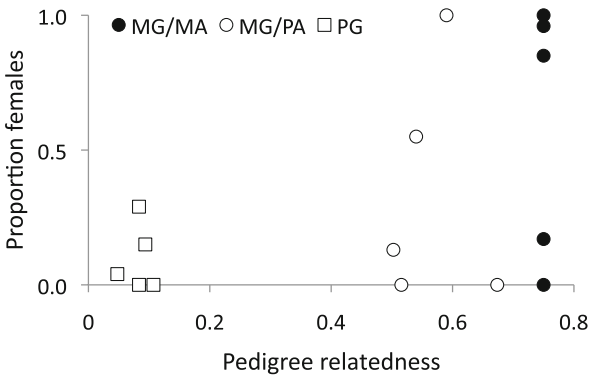

Fig. 3 Sex ratios (numerical proportion of females in the brood) as a function of within-colony relatedness, grouped according to colony type (*MG/MA* monogynous-monandrous, *MG/PA* monogynous-polyandrous, *PG* polygynous)

of CHCs, which could be achieved by accumulating alkenes to a greater extent than alkanes in the postpharyngeal gland (PPG; Soroker et al., 1994). The PPG does not synthesize hydrocarbons, but acts as a reservoir for these compounds to be homogenized and exchanged via grooming and trophallaxis (Soroker et al., 1994). Thus, inequalities in diversity could arise if alkenes are released more readily, or workers metabolize alkanes more rapidly, with alkenes becoming better mixed than alkanes among colony members. Altogether, these results suggest a pattern similar to that observed in *F. rufibarbis*, where cues used in nestmate recognition are genetically determined but preferentially mixed among nestmates (van Zweden et al., 2010).

Although the within-colony CHC variability showed no correlation with colony kin structure, relatedness, or any of the measures of genetic diversity, we found significant CHC divergence between genetic lineages within colonies. This was, however, only the case in two of the ten colonies that comprised more than one lineage. Earlier analyses in the wasps *Polistes dominulus*, *Vespa crabro* (Dani et al., 2004), and *Dolichovespula saxonica* (Bonckaert et al., 2011), and the ant *Acromyrmex octospinosus* (Nehring et al., 2010), found more consistent CHC differences between matrilines and patrilines. However, the CHC profile of *F. exsecta* exhibits far fewer hydrocarbons with fewer structural groups than these species (*P. dominulus*: 44 compounds; *V. crabro*: 25 compounds; *D. saxonica*: 56 compounds; *A. octospinosus*: 38 compounds), and so offers less scope for both divergence and statistical discrimination between genetic lineages. However, in *F. truncorum*, Boomsma et al. (2003) nonetheless were able to discriminate a greater fraction of patrilines although the analysis entailed only nine compounds.

At least two mutually non-exclusive explanations for the relative lack of CHC discrimination among genetic lineages are possible. First, active cue scrambling may render the colony odor more uniform or blur the recognition code. This may be an evolved response that either mitigates the opportunities for workers to selfishly favor close kin and disfavor more distant kin with social disruption in its wake, or increases discrimination between members of different colonies (Keller, 1997; van Zweden et al., 2010). Theory predicts depauperate CHC profiles and cue mixing when potential conflicts are rife in the colony (e.g., Sundström and Boomsma, 2001). This is indeed the case in *F. exsecta*, but many more compounds have been found in *F. truncorum* (Akino, 2006), which goes against this interpretation. Second, given that inbreeding is rife in the population of *F. exsecta* studied here (Sundström et al., 2003; Haag-Liautard et al., 2009; Vitikainen et al., 2011), genetic variation for cue diversity may have been purged. We found no significant effects of inbreeding on CHC variability, but the measure we used as a covariate in the analyses does not reflect the absolute level of inbreeding, only the relative level. Thus, a significant effect of inbreeding may not be detectable.

Within-colony CHC variability had no significant predictive value on sex ratio, but colonies with higher relatedness produced more females, when also accounting for colony inbreeding. This suggests that workers do not use the CHC variability of adult individuals as a proxy for sex ratio decisions, in contrast to the results obtained by Boomsma et al. (2003) for *F. truncorum*. It begs the question by what mechanism this is achieved. All polygynous colonies produced a male-biased brood, but against expectations based on the kin value of brood, one polyandrous colony produced only female brood and one monandrous colony only male brood. In the case of polyandrous colonies, errors in the assessment of colony kin structure may occur if the two fathers are closely related, and so mediate similar CHC profiles to their offspring. However, the polyandrous colony that produced an all-female brood had the lowest relatedness between fathers, and not an exceptionally unequal contribution by the two fathers (Table 1). It remains to be shown what information the workers use to assess colony kin structure, and why such apparent errors occur. A possibility is that CHC information on eggs or larvae more accurately reflects the genetic make-up of the colony, owing to no or less transfer of cues between genetic lineages, and that nurse workers bias the sex ratio accordingly. Another possibility is that nurse workers can assess the number of queens directly or by colony egg production, and use this as a proxy to adjust sex ratio in polygynous colonies. This is consistent with split-sex ratio theory (Boomsma, 1993), because polygynous colonies will tend to have higher egg-production and a lower than population-level-average relatedness asymmetry, and also with the idea that specialization in the cheaper sex (males weigh less in *F. exsecta*; Vitikainen et al., 2011) requires greater initial egg-production for equal total biomass production. On the other hand, this does not explain the tendency of monogynous/polyandrous colonies to specialize in male production. Environmental factors also are likely to influence the optimal sex ratio for a colony, and hence may explain the discrepancies between the observed pattern and the outcome expected based on purely inclusive fitness arguments (Nielsen et al., 1999; Liang and Silverman, 2000).

In summary, we found no support for the suggested association between colony kin structure and variability of recognition cues (c.f. Fletcher and Michener, 1987), but this lack of relationship may be explained by the uniform levels of genetic variation we found among the different colony types. The breeding patterns and the genetic structure of the population, which indicate non-trivial levels of inbreeding (Sundström et al., 2003; Haag-Liautard et al., 2009; Vitikainen et al., 2011), may have contributed to the

depauperate chemical profile through genetic purging, a question which will have to be addressed in future studies. We also found that the within-colony CHC variability does not allow accurate assessment of colony kin structure, and that workers do not seem to use any single compound or set of compound as a proxy for sex ratio adjustments. Rather, genetically informative cues appear to be mixed among workers to create a colony odor that is used in between-colony discrimination. The cuticular hydrocarbon variability of *Formica exsecta* may thus be subject to balancing selection on the accuracy of genetic variability, allowing colony members to serve their collective but not selfish fitness interests, possibly blended with loss of genetic diversity owing to inbreeding in this population.

Acknowledgements We thank V. Nehring for his help in analyzing the chemical data, J.J. Boomsma for critical discussions, and all members of the Copenhagen Centre for Social Evolution for providing a stimulating working environment. each species was cultured on potato dextrose (PD) agar. Isolations of single-hypha strains of all ambrosia-like morphotypes (*Ambrosiella*, *Ambrosiozyma*, or *Raffaelea*) followed previously published protocols (Kolarik and Hulcr, 2008). Morphotyping to genus was confirmed by amplification of ITS1 or SSU rDNA sequences using the primers ITS1 and ITS4, or NS1 and NS4, respectively (White et al., 1990; Gardes and Bruns, 1993), followed by identification in NCBI-BLAST (see Table S1 for results).

Behavioral Assays Using a 2-choice Teflon olfactometer (Analytical Research Systems, Gainesville, FL, USA) thoroughly described in Mann et al. (2011), we measured responses of beetles to volatiles from *R. lauricola* (symbiont of *X. glabratus*), *Ambrosiella xylebori* (symbiont of *X. crassiusculus*), *Ambrosiozyma ambrosiae* (symbiont of *X. ferrugineus*), *Trichoderma* sp. (antagonist of fungi and insects common in ambrosia beetle galleries), and ethanol, a known attractant of many ambrosia beetles. Fungus odor sources consisted of individual 0.25 cm^2 pieces of actively growing mycelium on PD agar medium; sterile medium was used as blank control. In case of ethanol, 1 ml of absolute alcohol was pipetted onto 5 cm of cotton wick; an untreated cotton wick was used as a blank control. A constant airflow of 0.1 l/min was maintained through both olfactometer arms, and a 0.5 l/min suction flow vacuumed the odor mixture from the olfactometer. The olfactometer was housed within a temperature controlled room (26±1°C, 60±2% RH) inside a fiber board box for uniform light diffusion from a fluorescent 900 lx light bulb. We confirmed the lack of positional bias by exposing a batch of beetles to two clean air treatments (blank odor fields).

Approximately 20 newly emerged beetles of a single species were assayed per replicate; each species replicated at least 5 times, always with new beetles. An odor source was randomly assigned to one of the olfactometer arms at the beginning of each assay and reversed after every replication. After each run, the olfactometer and the glass tubes were washed in soapy water and rinsed with distilled water. The glass tubes then were rinsed with acetone and oven dried overnight at 93.3°C, and the olfactometer stage was cleaned with absolute alcohol and air-dried. The numbers of beetles choosing the control arm vs. the treatment arm were compared with the *Chi square* test. Beetles not moving normally (exhibiting difficulty of walking or in poor condition) were excluded from analysis.

Results

We isolated diverse communities of fungi and yeasts from beetle mycangia (for details see Table S1). *Xyleborus glabratus* consistently yielded *Raffaelea lauricola* and *R. subalba* (Ascomycota, Ophiostomatales). *Xyleborus ferrugineus* commonly yielded *Raffaelea albimanens* (Ascomycota, Ophiostomatales), *Ambrosiozyma ambrosiae* (Ascomycota, Saccharomycetales), and an unidentified *Ambrosiozyma*-like strain. We selected *A. ambrosiae* as the experimental symbiont. *Xylosandrus crassiusculus* yielded *Ambrosiella xylebori/hartigi* (ambiguous BLAST assignment; Ascomycota, Microascales). We did not isolate symbionts of *Xyleborinus saxesenii*. To test responses of beetles to a non-symbiotic antagonistic fungus, we chose *Trichoderma* sp. isolated from our samples.

Beetle Responses Each beetle species for which a symbiont was available showed statistically significant attraction to its respective symbiont (Fig. 1). The two representatives of the genus *Xyleborus* were also attracted to certain symbionts from other beetle species (Fig. 1, Table 1). The non-symbiotic *Trichoderma* never triggered attraction from any beetle species. Ethanol was attractive to *X. ferrugineus* and *X. crassiusculus*, and did not elicit significant response from *X. glabratus* and *X. saxesenii* (Fig. 1).

Discussion

The tested fungus-farming ambrosia species responded positively to volatiles from their symbiotic fungi. Specificity of the reaction varied by beetle genus. In both *Xyleborus* spp., we observed attraction to several ambrosia fungi, but *Xylosandrus crassiusculus* was attracted only to its own symbiont. *Xyleborus* spp. are often associated with more symbionts than *Xylosandrus* spp. (Six et al., 2009; Harrington et al., 2010). We suggest that symbiont specificity and odor-perception specificity may be correlated traits. Attraction of ambrosia beetles to volatile cues from their fungal symbionts may function as a mechanism to locate established fungal gardens of conspecific beetles (suitable microhabitat), but also as an orientation cue within a gallery.

Our results are not consistent with Hanula et al. (2008), who did not observe attraction of *X. glabratus* to trees infested with its symbiont as compared with non-infested trees. The difference may have been caused by the unknown vigor of the fungal colonies in the logs exposed for several months in Hanula et al., or perhaps because fungal odors do not transpire readily from the inside of logs. The beetle responses to ethanol, in general, confirmed previous reports (Hanula and Sullivan, 2008; Ranger et al., 2010), except in *Xyleborinus saxeseni*.

Responses of beetles to odors of fungal symbionts were statistically significant, but often weak (Fig. 1). Further experiments may require a modified assay (ambrosia beetles are poor walkers), varying release rates of attractants, and a

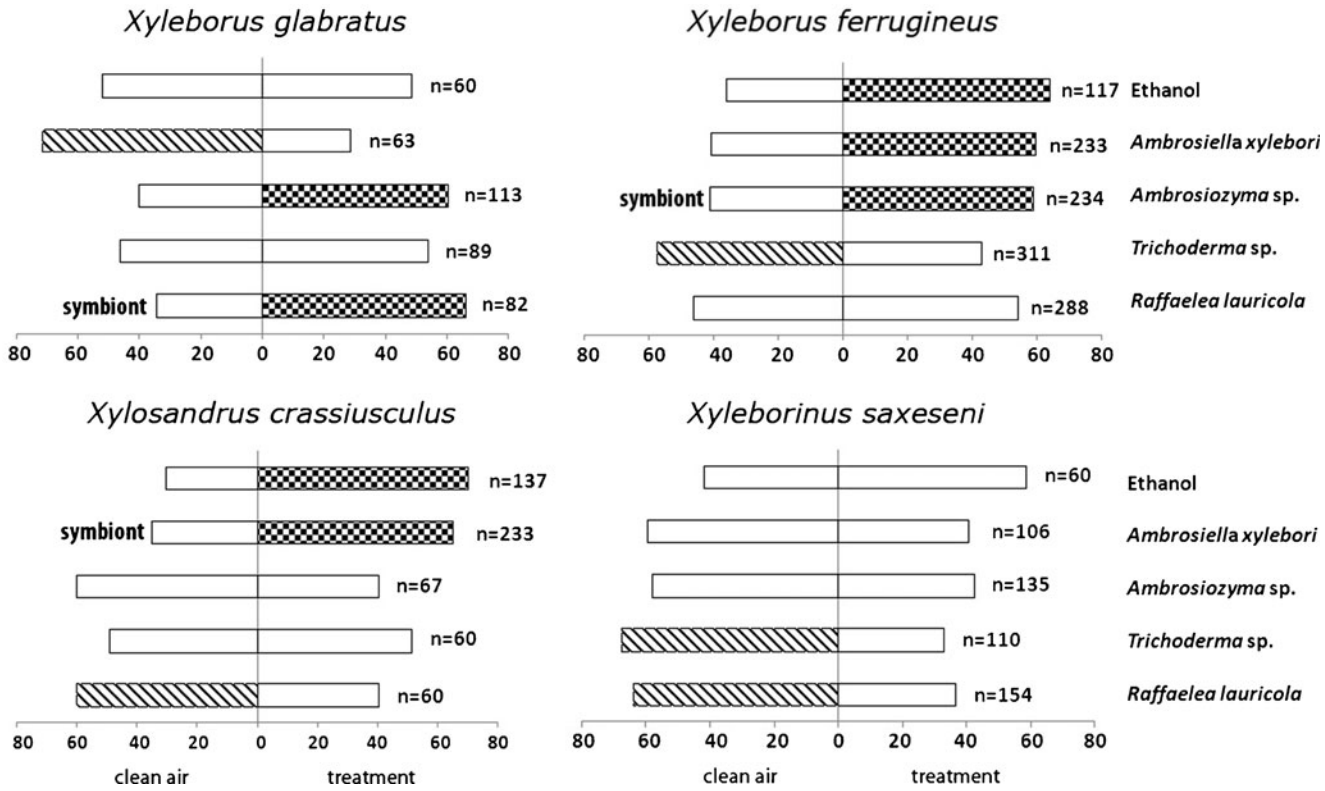

Fig. 1 Percentage of beetles attracted to fungal odors (*right bars*) vs. blanks (sterile agar media, *left bars*), and total numbers of tested individuals. Non-moving beetles were excluded. *Highlighted bars* indicate statistically significant differences (*stripes*: repulsion, *squares*: attraction). The symbiont of each beetle is highlighted (*X. saxesenii* did not have a symbiont in the study)

test of synergy with host tree volatiles. Our results indicate that fungal symbiont volatiles are a source of attractants, with a potential for development of lures for monitoring invasive ambrosia beetles.

Table 1 Responses of ambrosia beetles to volatiles from ambrosia fungi, antagonistic fungus, or ethanol. Fractions: absolute numbers of "beetles in treatment arm/beetles in control arm" summed across all trials. NA: non-active beetles

Beetle species	Response to:				
	Raffaelea lauricola	*Ambrosiozyma sp.*	*Ambrosiella xylebori*	*Trichoderma*	*ethanol*
Xyleborus glabratus	attracted SYMBIONT 54/28, $\chi2$=8.24; df = 1; *P*=0.004, NA = 36	attracted 68/45, $\chi2$=5.05; df = 1; *P*=0.02, NA = 57	repelled 18/45, $\chi2$=11.57; df = 1; *P*=0.001, NA = 19	no response 48/41, $\chi2$=0.55; df = 1; *P*=0.46, NA = 78	no response 29/31, $\chi2$=1.90; df = 1; *P*=0.27, NA = 32
Xyleborus ferrugineus	no response 156/132, $\chi2$=2; df = 1; *P*=0.16, NA = 98	attracted SYMBIONT 138/96, $\chi2$=7.54; df = 1; *P*=0.006, NA = 35	attracted 139/94, $\chi2$=8.69; df = 1; *P*=0.003, NA = 8	repelled 133/178, $\chi2$=6.51; df = 1; *P*=0.01, NA = 102	attracted 107/60, $\chi2$=13.23; df = 1; *P*<0.001, NA = 33
