Abstract A variety of glycosylated and unglycosylated saponins from seven different plant families (Aquifoliaceae, Asparagaceae, Caryophyllaceae, Dioscoreaceae, Leguminosae, Rosaceae, Sapindaceae) were tested against the corn earworm, *Helicoverpa zea*, and the fall armyworm, *Spodoptera frugiperda*. The corn earworm feeds readily on both monocots and dicots, while the fall armyworm is primarily a grass feeder. Most of the saponins were similarly effective or ineffective against both insect species, with the glycosides being the primary active form (compared to aglycones). However, one aglycone possessed antifeedant properties toward the fall armyworm. Thus, in contrast to many plant secondary metabolites effective against either of these two species where the aglycone is more effective, in the case of the saponins the opposite is generally true. This appears to be a contradictory strategy of plant defenses that requires further consideration. The activity of protodioscin against insects is reported for the first time and may be important in insect defense by the bioenergy crop switchgrass.

Key Words *Helicoverpa* · *Spodoptera* · Soyasaponin · Quillaja · Mate · Plant defense

Introduction

A variety of plant secondary chemicals can act as defenses against insects, including alkaloids, flavonoids, glucosinolates, and phenolic acids (Rosenthal and Janzen 1979). An additional group of compounds active against insects are the saponins, which have diverse chemical structures typically consisting of a triterpenoid or steroidal nucleus with a variety of glycosylation patterns (Hostettmann and Marston, 1995). Saponins are found in over 100 different plant families, although they often are more common in species from specific families or genera, such as Leguminosae and Liliaceae (Harborne and Baxter, 1993). As such, a wide variety of specialist and generalist insects would be expected to encounter them.

Initial information on activity of saponins against insects was limited to reports of leguminous sources and extracts (Applebaum and Birk, 1979). Later work indicated several high saponin plant parts from diverse families, including Aquifoliaceae and Theaceae in addition to Leguminosae, are resistant to insects (Hostettmann and Marston 1995). Since then, the number of studies showing activity of concentrated saponin fractions or pure saponins against insects has greatly expanded, and affected insects include aphids, beetles, caterpillars, and flies (De Geyter et al., 2007). However, comparative studies of the effects of multiple saponins of diverse sources against insects of different feeding specialization is still limited.

The corn earworm, *Helicoverpa zea*, feeds on plants in a variety of families, including Gramineae, Leguminosae, Malvaceae, and Solanaceae (Metcalf and Metcalf, 1995). The fall armyworm, *Spodoptera frugiperda*, also is an omnivorous caterpillar, but specializes more on Gramineae (Metcalf and Metcalf, 1995). The activity of saponins from a variety of host and nonhost plants against these two insect

species were evaluated against first instar caterpillars, and differential effects were noted, as reported herein.

Methods and Materials

Insects Corn earworms and fall armyworms were reared at 27±1°C., 50±10% relative humidity and a 14:10 h L:D photoperiod on pinto bean diet as described previously (Dowd, 1988). First instars were used in bioassays.

Chemicals (Structures Fig. 1, plant host sources Table 1). *Gypsophila* saponins (S1252, lot 6F0539, original source *Gypsophila*)(Dowd, 1989), quillaja bark saponin (S4521, lot 57H9524), and oleanic acid, 97% (original source *Saponaria officianalis*) were obtained from Sigma Chemical Company. Due to their complexity (Guo et al., 2000) the quillaja bark saponins were not purified further, but characterization using HPLC and MS determinations described below indicated they consisted of several dozen saponins, mainly consisting of quillaic acid aglycone (Fig. 1) with different combinations of galactose, glucuronic acid, and xylose at position 3 and apiose, rabinose, fucose, rhamnose, and xylose at position 28, with approximately 25% sapogenin aglycones (total of approxmately 80% saponins); a composition consistent with prior reports of this material (Chapagain and Wiesman, 2006). Using the same methodology to characterize the gypsoside preparations, total saponin content was greater than 80% with 4 main glycosides, including at least one gypsogenin derivative, (probably gypsoside A), saponeside D, and quilliac acid desmosides, based on prior reports of composition of a similar material (Higuchi et al., 1985; Frechet et al., 1991) and our available HPLC and MS analysis. Caffeine, diosgenin, glycyrrhizic acid, and protodioscin were obtained from ChromaDex (Irvine, CA, USA) and were 100, 96.0, 95.6, and 95% pure, respectively. Sapogenol B and B group soyasaponins were obtained from soybean seeds (Berhow et al., 2006), and final purity was over 95% for the aglycones (consisting of 90% of sapogenol B and minor amounts of sapogenol A and E) and glycoside mix (see below and Fig. 1). Mate (yerba mate, *Ilex paraguariensis*) leaves were obtained from a local distributer, and ursolic saponins were purified to greater than 95%

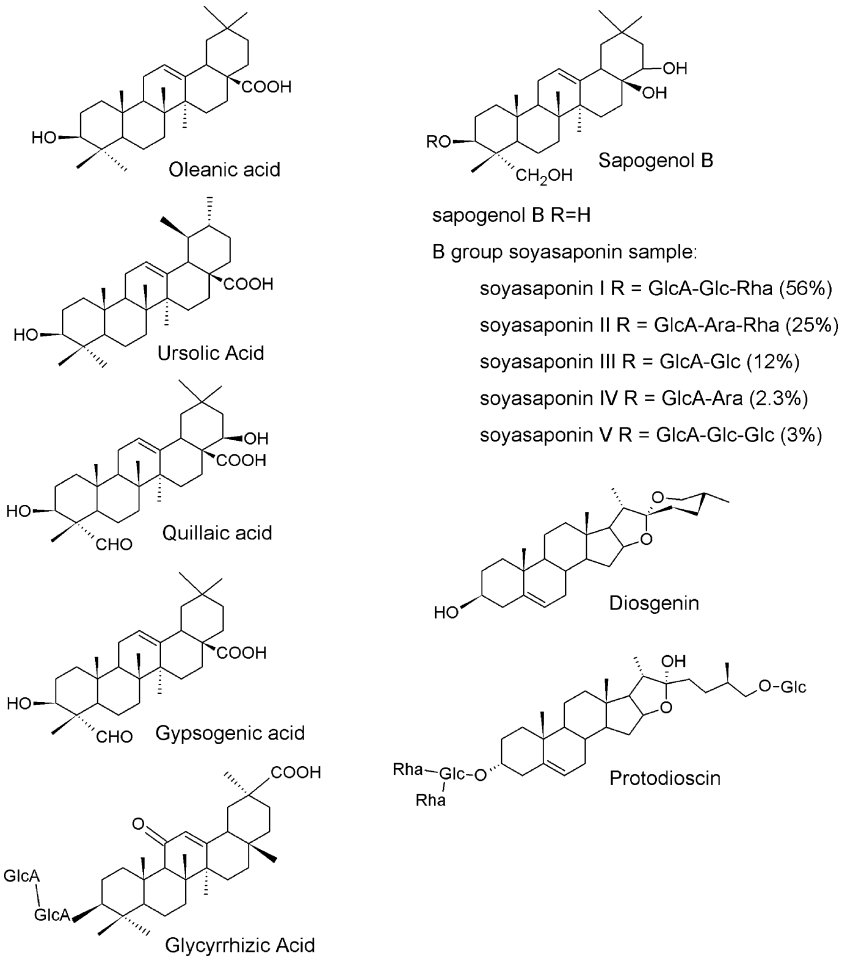

Fig. 1 Sapogenins and saponins tested against corn earworms (*Helicoverpa zea*) and fall armyworms (*Spodoptera frugiperda*). See Methods and Materials for further descriptions

Table 1 Saponins tested and plant sources

Saponin	Major source	Family	Tissue
diosgenin	Mexican wild yam	Dioscoreaceae	root
glycyrrhizic acid	licorice	Leguminosae	root
Gypsophila saponins	baby's breath	Caryophyllaceae	root
oleanic acid	soapberry	Sapindaceae	fruit
protodioscin	aspargus	Asparagaceae	shoot
quillaja acid saponins	quillaja	Rosaceae	bark
B group soyasaponins	soybean	Leguminosae	leaves/seed
sapogenol B	soybean	Leguminosae	leaves/seed
ursolic acid saponins	yerba mate	Aquifoliaceae	leaves

Compiled from Hostettmann and Marston, 1995; Lacaille-Dubois, 2000; Ganzera et al., 2001; Wang et al., 2003.

glycosides by methods similar to those used for the soyasaponins, and structures were identified by LC-MS (below). Purified saponins consisted of a mixture of 7 glycosides, and included mate saponin 1 and 2, plus 5 additional uncharacterized saponins, but no mate saponin 3, 4, or 5.

Chemical Separation and Purification of Saponins from Extracts

A Buchi (Newcastle, DE, USA) Sepacore flash chromatography system with dual C-605 pump modules, C-615 pump manager, C-660 fraction collector, C-635 UV photometer, with SepacoreRecord chromatography software was used. A Buchi C-670 Cartridger system was used to load 40× 150 mm flash columns with approx. 90 g of preparative C-18 reverse phase bulk packing material (125 A, 55–105 μm, Waters Corp., Milford, MA, USA). Columns were installed in the flash chromatography system and equilibrated with 30% acetonitrile and 70%, 0.5% acetic acid (in water) for 5 min at a flow rate of 30 ml per min. After samples (10–15 ml) were injected, the column was developed to 100% acetonitrile over 20 min, and the effluent was monitored at 210 nm. Fractions based on absorbance were collected in the fraction collector controlled by the software program. Fractions containing saponins were determined by analytical chromatography and LC-MS. After evaporation to remove the organic solvent, saponins were recovered as white solids by precipitation/crystallization or freeze-drying.

Further purification was achieved by reverse phase preparative liquid chromatography. A Shimadzu (Columbia, MD, USA) preparative HPLC system was used with dual 8A pumps, SIL 10 vp autoinjector, SPD M10Avp photodiode array detector, SCl 10Avp system controller all operating under the Shimadzu Class VP operating system. Ten ml of sample aliquots in methanol were injected on a Phenominex (Torrence, CA, USA) Luna C18(2) semi-preparative reverse phase column (10 μ, 100A, 250×50 cm). The column was pre-equilibrated with 1% acetic acid, 30% acetonitrile and 69% water at a flow rate of 50 ml per min, and the effluent was monitored at 210 nm. The column was developed to 70% acetonitrile over 45 min. UV absorbing peaks were collected by hand. The procedure was repeated to obtain sufficient purified material. Pooled material was allowed to evaporate, and the resulting fractions were evaluated by LC-MS for saponin content.

HPLC analysis was conducted on a Shimadzu LC-20 HPLC system (LC-20AT quaternary pump, DGU-20A5 degasser, SIL-20A HT autosampler, and a SPD M20A photodiode array detector, running under Shimadzu LC solutions version 1.22 chromatography software, Columbia, MD, USA). The column used was an Inertsil ODS-3 reverse phase C-18 column (5 μM, 20×4.6 mm, with a Metaguard column, from Varian). For saponin analysis, the initial conditions were 30% acetonitrile and 0.025% trifluroacetic acid (TFA) in water, and a flow rate of 1 ml per min. The effluent was monitored at 210 nm with the detector. After injection (typically 20 μl), the column was developed to 50% acetonitrile and 0.025% TFA in a linear gradient over 45 min. Standard curves based on nanomoles injected were prepared from a characterized mix of B group soyasaponins previously prepared (Berhow et al., 2006). The molar extinction coefficient for soyasaponin I was used to quantitate the mate saponins. The identities of the mate saponins were confirmed by purification and LC-MS.

For LC-MS analysis, samples were run on an Applied Biosystems/MDS Sciex Qstar Elite Q-TOF mass spectrometer with a Turboionspray electrospray source, and an Agilent 1100 series HPLC system (G1379 degasser, G1357A binary capillary pump, G1389A autosampler, G1315B photodiode array detector, and a G1316A column oven) all running under Applied Biosystems Analyst 2.0 (build 1446) LC-MS software. The MS was calibrated at least daily with a standard calibration mixture recommended by Applied Biosystems, and the signal detection was optimized as needed. Data were acquired with the MOF MS mode, negative. The MS parameters were as follows:

accumulation time—1 sec, mass range—2,100–1,000 daltons, source gas—1–50 units, source gas 2–35 units, curtain gas—25 units, ion spray voltage—4,500, source heater—400°C, declustering potential—80, focusing potential—265, declustering potential 2–15, ion release delay—6, ion release width—5. The column was a 3×150 mm Inertsil reverse phase C-18, ODS 3, 3 μm column (Metachem, Torrence, CA, USA) with a Metaguard guard column. Solvent systems were A: water with 0.25% formic acid, and B: acetonitrile. The column was equilibrated with 30% B at a flow rate of 0.25 ml per min. After injection (15 μl), the column was developed with a linear gradient to 80% B over 60 min. Column effluent was monitored at 210 nm in the PDA detector. The software package was set to collect mass data between 150–1,000 AMUs. Generally, the most significant sample ions generated under these conditions were [M-1]- and [M + HCOO]-.

Bioassays: Various Saponins Initially, chemicals were absorbed into freeze-dried diet disks in either ether, acetone, or water solutions at a rate of 25 μl per 15 mg disk to yield a final concentration of 1% when the disk was hydrated, using assay setups as described previously (Dowd et al., 2007). When acetone or ether was used as a solvent, the disks were placed in a fume hood for 10 min to evaporate solvent. Water was added at a rate of 25 μl per disk. For water solubilized preparations of saponins, liquid was added directly to the disk. Disks were allowed to equilibrate for 2 h prior to bioassay setup. At least 10 individual caterpillars were set up in each saponin or solvent treatment. Assays ran for 2–3 d, depending on whether cannibalism was noted (which is more of a problem with corn earworms). At the end of the assay period, caterpillars were frozen, and later weighed using a Mettler AE163 analytical balance, which has a precision of 0.01 mg.

Larger volume heated diet incorporation also was used to further examine activity of several of those compounds with significant activity at 1% (*Gypsophila*, mate, and quillija saponins, sapogenol B and B group soyasaponins). Assays were run with a lower concentration of each saponin (1,000 ppm) for 7 d. Materials were dissolved in 125 μl of water or acetone, and added to warm, still liquid agar as described previously (Dowd, 1988). After solidifying, diets with acetone were placed in a fume hood for 1/2 h in order for the solvent to dissipate. Corn earworms and fall armyworms were caged separately in this case using 24 well plates (Dowd, 1988). For 10 d-assays with quillija saponins at 1,000 ppm, diet prepared as described above was dispensed into 35 ml plastic cups, and larvae again were individually added to the cups. At the end of the assay period, caterpillars were frozen and weighed as described above.

Significant differences between survivor weights of caterpillars feeding on saponin containing diets and corresponding solvent control diets were determined by analysis of variance using SAS Proc GLM statistical analysis software Version 8.0 (SAS Institute, Cary, NC, USA).

Bioassays: Sapogenol B Due to the activity noted for the acetone soluble sapogenol B against fall armyworms (Results), it was possible to set up choice assays. Choice assays were performed using maize (*Zea mays*) leaves (which do not contain saponins—see Discussion) from the 10th position of a 12 leaf plant from four inbred B73 plants grown as described previously (Dowd et al., 2007). Three paired sections of each leaf were used, and each assay pair consisted of 4 cm^2 sections from opposite sides of the midvein. Sapogenol B was dissolved in acetone at a concentration that would yield a 1,000 ppm concentration once it was added to both sides of the leaf. For each side of a leaf piece, 100 μl of acetone or acetone solution of soyasapogenol B were added to a side, and the acetone was allowed to evaporate between applications. The paired leaf sections were placed in a 5 cm Petri dish as described above, along with a 4.25 mm piece of Whatman #1 filter paper (Whatman International, Maidstone, England) to which 120 μl of sterile distilled water were added. Twenty first instars were added to each dish, and feeding on each leaf section was rated by counting 0.25 mm^2 hole (approx. head capsule size) equivalents for 2 d, as described previously (Dowd et al., 2007).

Data were analyzed for significant antifeedant effects using a paired *t*-test (within SAS Proc Means).

Results

In only one case was mortality noted (11.1% for corn earworms fed mate in diet for 2 d), so reported results are limited to weights of larvae fed respective diets. Although none of the saponins was as active as caffeine, some showed significant activity against corn earworm and/or fall armyworm larvae after 2–3 d at 1% in diet disks (Table 2). The *Gypsophila* saponins, protodioscin, and the quillija saponins were similar in activity towards both insect species, and inhibited growth by approximately 20–50%. The quillija saponins appeared somewhat more active than *Gypsophila* saponins or protodioscin towards both species based on the degree of reduction in growth rates they caused. The mate saponins were more active towards the corn earworm (50.6% control weight) than the fall armyworm (75.4% control weight), while diosgenin and glycyrrhizic acid had no significant activity towards either species tested compared to solvent control diet. Interestingly,

Table 2 Saponin (1%) activity against first instar larvae of *Helicoverpa zea* (corn earworm) and *Spodoptera frugiperda* (fall armyworm)

Compound	Percent of control weight			Assay days
	Fall armyworm	Assay days	Corn earworm	
water	100.0	3	100.0	2
caffeine	26.9*	3	14.7*	2
Gypsophila saponins	76.6*	3	80.4	2
mate saponins	75.4	2	50.6*	2
protodioscin	70.6*	3	71.2*	2
quillaja saponins	60.9*	3	56.9*	2
B group soyasaponins	108.6	3	74.5*	2
acetone	100.0	3	100.0	2
diosgenin	96.2	3	93.2	2
glycyrrhizic acid	90.2	3	90.9	2
sapogenol B	66.4*	3	118.4	2
ether	100.0	3	100.0	2
oleanic acid	92.2	3	90.9	2

Values followed by an "*" were significantly different from corresponding solvent control values at $P<0.05$ by analysis of variance.

B group soyasaponins were significantly active against corn earworms (74.5% control weight) while the aglycone (sapogenol B) was not; the opposite was true for fall armyworms (larvae fed diet containing sapogenol B weighed 66.4% those fed control diet).

For the compounds run at the lower dose rate (1,000 ppm) over a 7 d period of time, only quillija saponins showed a statistically significant effect, and only on fall armyworms (74.3% control weight, $F=9.45$, $P=0.004$). There also was a trend for fall armyworms to be smaller when fed diet containing *Gypsophila* saponins at 1,000 ppm (80.9% control weight) similar to that noted for the 1% dose range of *Gypsophila* saponins. In the 10 d assay run with the quillaja saponins, most larvae that fed on the control diet reached the fifth (last) instar, but most larvae fed on the treated diet only reached the fourth instar. Corn earworms fed the quillaja saponin containing diet were 72.7% the weight of those fed control diet ($F=17.39$, $P<0.001$). Results with fall armyworms were similar to those noted with the corn earworms, as those larvae fed diet with 1,000 ppm of quillija saponins weighed 51.7% of those fed solvent control diet ($F=20.96$, $P<0.001$).

Sapogenol B appeared to have antifeedant properties toward fall armyworm larvae when applied to maize leaves. On day 1 of the assay, the mean difference in feeding on sapgenol-treated leaves and controls was $14.3\pm4.2\text{mm}^2$ ($t=3.38$, $P=0.006$) and on day 2 the mean difference was $49.2\pm9.2\ \text{mm}^2$ ($t=5.32$, $P<0.001$).

Discussion

Various plant saponins have insecticidal activity against flies, beetles, caterpillars, and aphids (De Geyter et al., 2007). We found several saponins with insecticidal activity against the caterpillar pests *H. zea* and *S. frugiperda*. Some we tested also are active against other species of insects. Levels of a gypsoside glycoside have been correlated with resistance of yellow rocket *Barbarea vulgaris* to the flea beetle *Phyllotreta nemorum* (Nielsen et al., 2010). Quillija saponin extracts are active against mosquito larvae (Pelah et al., 2002; Wiesman and Chapagain, 2003) aphids (*Acyrthrosiphum pisum*) and caterpillars (*Spodoptera littoralis*) (De Geyter et al., 2007). We also noted activity of sapogenol B against fall armyworms, a compound that is inactive compared to some other alfalfa saponins to *S. littoralis* (Adel et al., 2000). Green holly (*Ilex opaca*) fruits, which have high levels of saponins compared to ripe fruits, were more toxic to larvae of *S. frugiperda* than ripe fruits (Kreuger and Potter, 1994). To our knowledge, the activity of protodioscin and mate saponins against insects is reported here for the first time.

The saponins we tested can occur at ranges of up to 22%, but are typically 0.1–1% dry weight (Shi et al., 2004). While doses of saponins we used initially were somewhat higher than those naturally occurring in leaves (e.g., B group soyasaponins, protodioscin), results based on bio-assays with artificial diet and saponins may lead to an underestimaion of the bioactivity of saponins, since larvae do not need to cope with the stress factors typically encountered additionally in natural plant sources (Smith et al., 1994). Longer term studies also have indicated significant effects on growth and developmental rates at lower concentrations (e.g., Adel et al., 2000). We also noted more significant effects when exposing larvae to the compounds (such as quillija saponins) over a longer period of time. The antifeedant effects we noted with fall armyworms and sapogenol B may be due to an interference in

the ability to perceive sweet compounds, as has been reported for the gymnemic acid saponins (Eisner and Halpern, 1971).

Typically, plant secondary metabolites are more active toward insects as the aglycones than they are as the glycosides, including cardiac glycosides, cyanogenic glycosides, flavonoids, glucosinolates, iridoid glycosides, phenolics, sesquiterpene lactones, and triterpenoid glycosides (e.g., Dowd et al., 1983; Spencer, 1987). For saponins, the type of sugar attached to the saponin determined the effectiveness against *S. littoralis* (Adel et al., 2000). Another study indicated saponins need both a hydrophilic and a lipophilic portion for maximum activity against *S. littoralis* (Saha et al., 2010). These prior findings may explain some of the differences in activity of the saponins tested in the present study. However, the requirements for saponin toxicity to the two insect species examined in this study appear to be more complicated, as some of the saponins were similar in activity against *H. zea* and *S. frugiperda*, while others were quite different. Notably, the sapogenol B aglycone was more active against *S. frugiperda* than against *H. zea*, while the opposite was true for the glycosylated form.

Despite the different host ranges of the two moth species examined, responses were similar except for the B group soyasaponins vs. sapogenol B, and to some degree, for mate saponins. Based on prior reports of plant host ranges for the corn earworm and fall armyworm (Metcalf and Metcalf, 1995) and the plant tissues where the saponins we analyzed are located (see Table 1), we suspect the insect species we tested are not exposed to these compounds in nature. The exceptions are the saponins from soybean, baby's breath (*Gypsophila*), and asparagus. However, these saponins had activity against the corn earworms and fall armyworms that was comparable to the activity of the saponins from quillaja and yerba mate, which are not host plants. Future studies need to investigate whether insects are less able to develop resistance to saponins compared to other classes of plant defensive compounds.

The presence of saponins in plants has implications beyond conferring insect resistance. Practically, saponins from *Quillaja saponaria* (USEPA PC code 097095) and *Chenopodium quinoa* (USEPA PC code 097094) have been registered as biopesticides for fungal control (USEPA 2002, 2007). Saponins have been implicated as important resistance molecules targeted at plant pathogens, but typically are absent in modern lines of grain crops (Papadopoulou et al., 1999). Our results suggest they may also be important in insect resistance in different plants for two major insect pests which feed on grain crops such as maize, as several different forms reduced growth rates in both of the lepidopteran species tested. Hence, enhancement of saponins may provide multiple resistance benefits against both insects and plant pathogens. However, the plants that may be bred or engineered for enhanced insect resistance through presence/increases in appropriate saponin levels need to be considered for end uses, as some saponins can adversely affect ruminants (Flaoyen, 2000, Francis et al., 2002), while others can even improve animal health (Francis et al., 2002). A number of reports also have indicated human health benefits from a variety of saponins (Rao and Gurfinkel, 2000; Shi et al., 2004, Güçlü-Üstünda and Mazza, 2007), suggesting that pest resistance and human health benefits can be promoted by use of these molecules. Selective increases in saponin content of soybean leaves suggest that increased resistance to the soybean pest *H. zea* could occur. Presence of saponins in switchgrass (Lee et al., 2009) suggests not only implications in insect resistance, but also for bioenergy, as fermentation byproducts may contain useable saponins for steroid precursors (Harborne and Baxter, 1993) or insecticidal/fungicidal extracts.

Abstract We examined the extent to which three *Fraxinus* cultivars and a wild population that vary in their resistance to Emerald Ash Borer (EAB) could be differentiated on the basis of a suite of constitutive chemical defense traits in phloem extracts. The EAB-resistant Manchurian ash (*F. mandshurica*, cv. Mancana) was characterized by having a rapid rate of wound browning, a high soluble protein concentration, low trypsin inhibitor activities, and intermediate levels of peroxidase activity and total soluble phenolic concentration. The EAB-susceptible white ash (*F. americana*, cv. Autumn Purple) was characterized by a slow wound browning rate and low levels of peroxidase activity and total soluble phenolic concentrations. An EAB-susceptible green ash cultivar (*F. pennsylvanica*, cv. Patmore) and a wild accession were similar to each other on the basis of several chemical defense traits, and were characterized by high activities of peroxidase and trypsin inhibitor, a high total soluble phenolic concentration, and an intermediate rate of wound browning. Lignin concentration and polyphenol oxidase activities did not differentiate resistant and susceptible species. Of 33 phenolic compounds separated by HPLC and meeting a minimum criterion for analysis, nine were unique to Manchurian ash, five were shared among all species, and four were found in North American ashes and not in the Manchurian ash. Principal components analysis revealed clear separations between Manchurian, white, and green ashes on the basis of all phenolics, as well as clear separations on the basis of quantities of phenolics that all species shared. Variation in some of these constitutive chemical defense traits may contribute to variation in resistance to EAB in these species.

Introduction

Qualitative and quantitative variation in chemical defenses has long been associated with variation in the resistance of plants to particular attackers (Levin, 1976). While relationships between host-plant defenses and herbivore attack rates have been relatively well studied in the foliage of herbaceous and woody plants, and for conifer/bark beetle interactions, less is known about defenses of angiosperm trees to wood-boring herbivores (e.g., Dunn et al., 1990). Our lack of understanding of such relationships is of particular concern in the face of the increased number of invasive wood-boring insects that have emerged in novel habitats in recent years.

Larvae of the emerald ash borer, *Agrilus planipennis* Fairmaire (Coleoptera: Buprestidae; EAB), feed on phloem tissue of ash trees (*Fraxinus* spp.). In its home range in Eastern Asia, EAB utilizes several ash species, including Manchurian ash (*F. mandshurica*), but it typically attacks

(and sometimes kills) only stressed ash trees (Gould et al., 2005; Liu et al., 2007). In its introduced range in North America, EAB also utilizes several species of ash, including white (*F. americana*) and green (*F. pennsylvanica*) ash, but even healthy trees are susceptible to attack (Poland and McCullough, 2006). In a common garden study in Michigan near the core infestation zone of EAB, white and green ash cultivars were attacked more heavily by EAB and were more likely to die from attack than a Manchurian ash cultivar (Rebek et al., 2008). Some of this variation may be attributable to as yet undetermined adult oviposition preferences (Pureswaran and Poland, 2009), but these findings suggest that physical and biochemical defense mechanisms of the phloem may limit the feeding, growth, and survival of EAB larvae in Manchurian ash. Mechanisms of resistance to wood-boring insects of angiosperm trees have not been well studied, but they likely involve antibiotic secondary metabolites common in woody tissues (e.g., phenolics), defensive proteins in the phloem, and physical defenses such as sap flow to wounded areas and the capacity to rapidly heal wounds (e.g., Dunn et al., 1990; Wainhouse et al., 1990, 1998; Kehr, 2006).

We hypothesized that the susceptibility of North American ashes may stem from a lack of an evolutionary history with EAB, and an inability to defend against larval feeding with appropriate chemical defenses (Rebek et al., 2008). Thus, we predicted that Manchurian ash would constitutively express either higher levels of chemical defenses or a unique profile of defenses in the phloem compared to North American ashes. In a companion paper, we showed that the profile of constitutive phenolic secondary metabolites in phloem from bare-root dormant stems of a cultivar of Manchurian ash was distinguishable from white and green ash cultivars by its unique content of hydroxycoumarins (particularly fraxin, mandshurin, and fraxidin hexoside), calceolariosides A and B, and significantly higher concentrations of pinoresinol glucoside and pinoresinol, along with some other minor differences (Eyles et al., 2007). While the factors specifically conferring resistance to EAB in Manchurian ash remain elusive, these sorts of compounds are potentially involved.

Here, we compared the constitutive activities of three defense proteins, lignin and total soluble protein content, and phenolic profiles in the phloem of actively growing Manchurian, white, and green ash cultivars, and in green ash originating from a wild population. Use of a wild population of green ash allowed comparisons of its chemistry to that of a cultivated variety. Although little studied in relation to wood borer feeding, defensive proteins in the phloem are recognized as potentially important resistance factors to phloem-feeding insects (Kehr, 2006). Polyphenoloxidase and peroxidase activity are associated with resistance of plants to both insects and pathogens (Felton et al., 1989; Dowd and Norton, 1995; Cipollini and Redman, 1999; Cipollini et al., 2004), presumably by increasing the toxicity of phenolics or by increasing cell wall toughness. Trypsin inhibitor activity may slow herbivore growth and feeding by decreasing protein assimilation by inhibiting the action of serine proteases, and thus slow larval growth rate (e.g., Cipollini et al., 2004). Recently, transcripts of serine proteases have been found in the midgut of EAB larvae (Mittapalli et al., 2010). We also examined the rate at which phloem extracts browned due to the action of constitutive phenoloxidases on endogenous soluble phenolics present in the extract, which represents the generation of toxic quinones and other polyphenolics that can be associated with resistance and wound healing (Cheng and Crisosto, 1995). Finally, we examined constitutive levels of total phenolics and individual phenolic metabolites by HPLC, as in Eyles et al. (2007), but in this work we examined both qualitative and quantitative variation in expression of phenolic metabolites in actively growing stems sampled during a time when EAB larvae would be active, as opposed to sampling dormant stems.

Methods and Materials

Plant Material and Growth Four-year-old saplings of Manchurian, white, and green ash were planted in a common garden on the campus of Wright State University in May 2007. We grew 8 individuals of Manchurian ash (cv. Mancana), 11 individuals of white ash (cv. Autumn Purple), 11 of green ash (cv. Patmore), and 11 of green ash grown from seed from a wild population. The ash cultivars were obtained from Bailey Nurseries (St. Paul, MN, USA), and the wild green ash was supplied by the USDA Forest Service Northern Research Station (Delaware, OH, USA). The cultivars used were the same as those used in studies of phenolic chemistry by Eyles et al. (2007) and of field resistance to EAB by Rebek et al. (2008), but neither of those studies included plants from any wild populations. Trees were planted in a grid spaced approximately 3 m from each other, with mowed grass in between. Tree trunks were protected from deer and other mammal damage with 1 m tall plastic tree guards. All trees were watered three times throughout the first growing season in addition to natural rainfall to promote establishment. Trees were grown under these conditions for 14 months prior to their use, and were healthy when sampled. On July 2008, phloem samples were taken from 2-year-old sections of a single branch on each tree. Branches on different trees were matched for the relative position on the tree. A 10 cm long section of each branch was cut, placed immediately in a plastic bag on dry ice, and held at −20° C in the laboratory until extraction and analysis of chemical defenses.

Defense Protein Extraction and Analysis Bark (containing phloem) samples of each species were obtained by dissecting branches with a razor blade. Approximately 1 g of bark (from the periderm to vascular cambium) was stripped from each branch, chopped with a razor blade, and ground in a mortar and pestle with liquid nitrogen. Soluble proteins were extracted from ground tissues in ice-cold 0.01 M sodium phosphate buffer pH 6.8 containing 5% polyvinylpolypyrrolidone (PVPP). Homogenates were centrifuged for 10 min at 7,000×g, and the cleared supernatants were transferred to fresh tubes. Acetone precipitation of soluble proteins was performed on the cleared homogenates. Ten ml of cold acetone were added to 2 ml of extract and vortexed. Tubes were placed at −20° C for 30 min. After centrifugation at 7,000×g for 10 min, the supernatant was removed, and the pellet was air dried for 30 min. Pellets were resuspended in 1.5 ml of 0.01 M sodium phosphate buffer pH 6.8 by vortexing, and extracts were stored at −20° C until they were analyzed. Activities of polyphenol oxidase, peroxidase, and trypsin inhibitor were assessed in soluble protein extracts as in Cipollini et al. (2004). Briefly, polyphenol oxidase and peroxidase activity were assessed using caffeic acid and guaiacol as substrates, respectively. Trypsin inhibitor activity was assessed by examining the inhibition of trypsin in a radial diffusion assay. Transcripts of serine proteases, like trypsin, recently have been found in the gut of EAB larvae (Mittapalli et al., 2010). Phenol oxidizing activities were expressed and statistically analyzed as $\Delta Abs_{470nm} \cdot min^{-1} \cdot$ mg extract protein^{-1} and $\Delta Abs_{470nm} \cdot min^{-1} \cdot$ g fresh mass^{-1} . Trypsin inhibitor activities were expressed and statistically analyzed as mg Tryspin Inhibitor · g extract protein^{-1} and mg Trypsin Inhibitor · g fresh mass^{-1}.

Browning Reaction The browning reaction can be observed within a few minutes around wounded phloem tissues of ash, and is driven in plant tissues primarily by the action of phenoloxidases (including both peroxidase and polyphenol oxidase) on endogenous phenolics resulting in quinone formation and subsequent polymerization (Cheng and Crisosto 1995; Dehon et al. 2002). New extracts were made for the browning rate analysis. The extraction procedure was similar to that for defense protein analysis except that the original extraction buffer did not contain PVPP in order to keep water-soluble phenolics in the extracts, and no precipitation step was performed. The browning reaction was examined immediately after removal of supernatants from the centrifuged phloem homogenates. Aliquots (0.3 mL) of each soluble extract were placed in duplicate in a standard 96-well plate, and the absorbance at 470 nm was recorded twice; once before and once after a 1 hr incubation at room temperature. The rate of the browning reaction was expressed as $\Delta Abs_{470nm} \cdot hr^{-1} \cdot g\ FW^{-1}$.

Total soluble protein in extracts was measured using bovine serum albumin as a standard and Bio-Rad protein dye reagent, as described in Bradford (1976). We used these estimates to calculate total soluble protein of the phloem on a fresh mass basis. All assays were performed in duplicate.

Soluble Phenolic Extraction and Total Phenolic Analysis - Phloem samples of each species were ground in liquid nitrogen, weighed to 100 mg, and extracted twice with 0.5 ml of HPLC grade 100% methanol for 24 h in the dark at 4° C. Extracts were centrifuged for 5 min at 13,400×g and the two supernatants were pooled into ~1 ml of extract. Supernatants were used for soluble phenolic analyses, and the pellet was used for lignin analyses. Total soluble phenolic content was analyzed using the Folin-Ciocalteau method, modified from Bonello and Pearce (1993). In brief, 0.002 ml of methanol extract was added to 0.075 ml of methanol and 0.5 ml of water and mixed, then 0.0375 ml of Folin's Phenol Reagent was added (Sigma, St. Louis, MO, USA). Three minutes later, 0.0375 ml 1 M $NaHCO_3$ was added, and the solution was mixed thoroughly. After a 1 hr incubation at room temperature, the samples were analyzed spectrophotometrically against a standard curve of gallic acid at 725 nm, and total soluble phenolic concentration was expressed as mg phenolics (gallic acid equivalents) per g fresh mass.

Quantification and Identification of Soluble Phenolics with HPLC-UV Analysis of phenolic compounds was performed on an Alliance 2690 separation module (Waters, Milford, MA, USA) equipped with an autosampler, and a 996 Photodiode Array Detector (Waters). The autosampler and column temperatures were set to 4 and 30° C, respectively. The binary mobile phase consisted of water/acetic acid (A) (98:2, *v*/*v*) and methanol/acetic acid (B) (98:2, *v*/*v*), with a flow rate of 1 ml/min. The elution program followed that of Eyles et al. (2007). The injection volume for all samples was 0.010 ml. Samples were passed through a Photodiode Array Detector (PDA) (scanning range, 200–400 nm). Analysis of individual compounds was achieved by combining 0.100 ml from each biological replicate into a pooled sample for a total of 4 sample pools [Manchurian, white, green (wild), and green (cv.)]. Sample pools then were run using the HPLC-UV conditions above, and individual compounds with peak areas exceeding 0.05 absorbance units (AU) were chosen for further analyses in individual samples. Compound identities were based on an exact match to λ_{max} and retention time (RT) data presented in Eyles et al. (2007) and Chen et al. (2011). These sources present compound identities based on congruence of mass spectral information, λ_{max}, and RT with that of the literature, and in some cases generate NMR data in order to provide definitive structural information of individual

unknown compounds. Instrument and gradient parameters used in our analyses were conducted following the methods of Eyles et al. (2007) and Chen et al. (2011) using the same instrument, column, methods, and parameters. The identity of compound 32 (luteolin) was unequivocally confirmed by comparing λ_{max} and retention time (RT) against an external standard. Relative amounts of individual compounds were quantified by peak areas observed at 280 nm.

Lignin Extraction and Analysis Extraction of lignin was accomplished following the method of Bonello et al. (1993), with minor modifications. Pellets left over from extraction of soluble phenolics were washed once each with 1 ml of Milli-Q water and HPLC grade methanol (Fisher). Pellets then were washed with 0.9 ml of tert-butyl methyl ether (Sigma) and allowed to air dry in a fume hood overnight. Pellets were incubated with the addition of 0.4 ml of 1 M NaOH on a shaker at 40 ° C for 21 hr. The reaction mixture was acidified with 0.2 ml of 1.5 M formic acid (Sigma), followed by 0.4 ml of HPLC grade methanol. Pellets were washed with 1 ml of HPLC grade water and resuspended in 0.8 ml of 2 M HCl and 0.3 ml of thioglycolic acid (Sigma). Samples were incubated at 86 ° C for 4 hr, and supernatants were discarded. Pellets were rinsed twice with 1 ml of water. Pellets were resuspended in 1 ml of 0.5 M NaOH, and the tubes were placed on a shaker for 18 hr at 200 rpm twice, and supernatants were pooled from each sequential extraction. The combined solution was acidified with 0.3 ml of concentrated HCl at room temperature for 4 hr, centrifuged for 5 min, and supernatants were discarded. The lignin–thioglycolic acid pellets were air dried in a fume hood and then re-solubilized in 1 ml of 0.5 M NaOH. In all steps, tubes were vortexed after adding solutions, and supernatants and pellets were separated by centrifugation. Lignin was quantified spectrophotometrically by comparing the absorbance of a 40:1 dilution of samples in 0.5 M NaOH at 280 nm against a standard curve of spruce lignin and is expressed as mg lignin per g fresh biomass (Sigma-Aldrich, St Louis, MO, USA).

Statistical Analysis Defense protein activities, total protein concentration, lignin concentration, total phenolic concentration, and rates of the browning reaction were compared among the three ash cultivars and one wild population using one-way ANOVA in SAS (SAS Institute, Cary, NC, USA). Transformations were applied to the data as needed to meet the assumptions of ANOVA. Means were separated using Tukey's tests.

Differences in phenolic profiles among the ash species and cultivars (based on peak areas) were evaluated with Principal Components Analysis (PCA) using the "ade4" package (Version 1.4–14, Dray and Dufour, 2007) in R (Version 2.10.1, R Development Core Team, 2009). We used the methods of Doledec and Chessel (1987) to estimate the contribution of tree identity to inertia decomposition in the model. Briefly, the method estimates the variation between classes (from the centroid of data associated with each class relative to that of all other classes) relative to variation within each class (from the individual data points within a class to the centroid of that class); this between-classes inertia is represented as a percentage of the total inertia in the data. Statistical significance is determined by a Monte-Carlo test, in which the observed between-classes inertia is compared to a distribution of estimates obtained after repeated randomization of the data matrix.

Two analyses were performed. The first included all 33 phenolic compounds, some of which were absent from one or more of the tree species. This analysis was performed on rank-transformed data to account for variance scaling with the concentration of detected compounds and overdispersion resulting from certain compounds not being detected in several samples. Where concentrations were equal among individual trees, observations were ranked in random order; estimates of between-classes inertia were robust in our tests of this ranking method, remaining consistent up to seven places after the decimal. The second analysis included only those compounds that were found in all tree species, although not necessarily in all trees within each species (oleoside/syringin, nunzenhide-related compound, pinoresinol-related compound, oleuropein, and apigenin); data also were rank-transformed prior to this analysis. For each analysis, we estimated contrasts for the specific comparison between the resistant species (Manchurian ash) and the other species. We also estimated contrasts between white and green ash cultivars and between the green ash cultivar and the green ash grown from wild seedlings, based on subsets of the rank-transformed data used in the first analysis.

Results

Peroxidase Activity Peroxidase activity varied among species, both per unit protein ($F_{3,\ 35}$=4.17, P=0.013) and per unit fresh mass ($F_{3,\ 35}$=10.5, P<0.001) (Table 1). Per unit protein, the green ash cultivar and the wild population showed the highest peroxidase activity, white ash was lowest, and Manchurian ash was intermediate. Per unit fresh mass, the green ash cultivar, the wild green ash, and Manchurian ash had similarly high activities, and white ash had lower activity.

Polyphenoloxidase Activity Polyphenoloxidase activity did not vary among species either per unit protein ($F_{3,\ 35}$=2.06, P=0.123), or per unit fresh mass ($F_{3,\ 35}$=1.48, P=0.236).

Table 1 Mean (± SD) levels of several defense traits in phloem of branches from 5 year old ash saplings grown in a common garden. means with different lower case letters are significantly different at α=0.05

Tree identity	POD/mg protein	POD/g FM	PPO/mg protein	PPO/g FM	mg TI/g protein	Total protein	Total phenolics	Browning rate
Manchurian	158.9(104.5)^{ab}	22.0(9.3)^{a}	25.2(19.4)	3.4(2.3)	28.1(8.70)^{b}	0.48(0.16)	7.21(1.8)^{ab}	1.04(0.26)^{a}
Green cv.	266.2(61.3)^{a}	25.9(5.8)^{a}	47.0(17.1)	4.5(1.6)	50.7(25.9)^{a}	0.31(0.12)	9.86(3.0)^{a}	0.86(0.22)^{ab}

POD Peroxidase Activity, *PPO* Polyphenoloxidase Activity, *TI* Trypsin Inhibitor Activity, *FM* Fresh Mass

Trypsin Inhibitor Activity Trypsin inhibitor varied among species per unit protein ($F_{3,\ 35}$=3.26, P=0.033, Table 1), but not per unit mass ($F_{3,\ 35}$=0.275, P=0.843, data not shown). Per unit protein, the green ash cultivar and the wild green ash had the highest activity, Manchurian ash had the lowest, and white ash was intermediate.

Protein Content There was a tendency for total soluble protein concentration to vary among species ($F_{3,\ 35}$=2.44, P=0.081) (Table 1). In particular, Manchurian ash tended to have higher protein concentrations in the phloem than white and green ash.

Rate of Browning Reaction The browning rate of phloem extracts varied among species ($F_{3,\ 35}$=6.34, P=0.002) (Table 1). Manchurian ash had the fastest browning rate, the green ash cultivar and wild green ash had intermediate rates, and the white ash cultivar had the slowest rate.

Soluble Phenolic Concentration Significant differences in total soluble phenolic concentrations were found among ash species ($F_{3,\ 35}$=6.88, P<0.001, Table 1). Phenolic concentrations in the green ash cultivar and the wild green ash were similar and highest, Manchurian ash was intermediate, and white ash had the lowest level.

Lignin Concentration Lignin concentration averaged 16± 2 mg/g fresh mass and did not vary significantly among species ($F_{3,\ 35}$=0.299, P=0.825).

Phenolic Profiles Phloem phenolic profiles generally were consistent within a species (or cultivar) and distinct between species (or cultivars) with tree identity accounting for 47.8% (all compounds, P<0.001) and 41.8% (common compounds, P<0.001) of inertia decomposition in the PCA. Patterns in the expression of all phenolic compounds suggested a separation between Manchurian ash and the other ash species, with this contrast accounting for 26.0% (all compounds, P<0.001) of inertia decomposition (Fig. 1). Much of this pattern is due to the presence of certain compounds in Manchurian ash that are absent in the other species, and *vice versa*. However, this contrast was also significant (26.3%, P<0.001) when restricting the analysis to five compounds that were expressed in all species (Fig. 2).

Phenolic profiles also indicated differences among the ash species that were due to the concentrations of expressed compounds. Green and white ash cultivars were easily separated, with 20.7% of inertia decomposed between the two species (P<0.001). The green ash cultivar and the wild green ash were also distinguished (P<0.001) but with reduced contribution of cultivar identity (15.7%).

Of the 33 compounds in the analysis, Manchurian ash contained nine compounds not found in the other species, including homovanillic alcohol, esculin, caffeoyl quinic acid, fraxidin hexoside, fraxetin, pinoresinol dihexoside, calceolarioside A, calceolarioside B, and one unknown (Table 2 and Fig. 3). It also had high concentrations of mandshurin and fraxin, which were found at lower levels in some of the other species. Four compounds were found in North American ash species but not in Manchurian ash, including pinoresinol, luteolin, and two unknowns. However, the profile of North

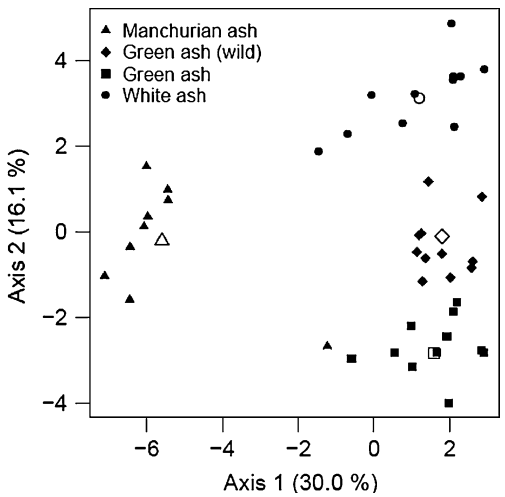

Fig. 1 Principal component analysis of phenolic compounds in phloem extracts from branches of 5-year-old ash trees grown in a common garden. Data were rank-transformed prior to analysis. Closed symbols represent the coordinates of each sample, while open symbols represent the estimated centroid of the points for each of the cultivars. Percentages indicate the inertia decomposition associated with each of the two axes

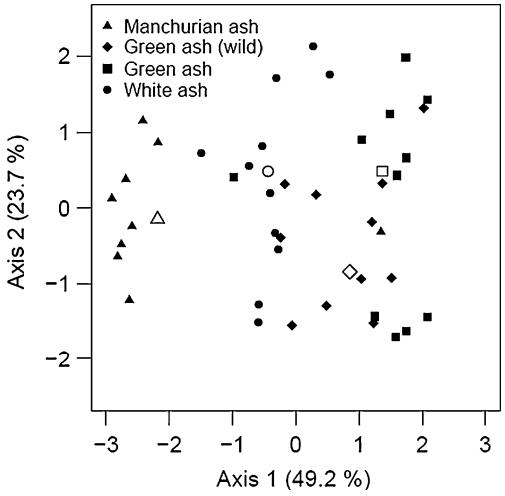

Fig. 2 Principal component analysis using only the phenolic compounds that were detected in all ash cultivars in this study. Compound concentrations were estimated from phloem extracts from branches of 5-year-old ash trees grown in a common garden. Data were rank-transformed prior to analysis. Closed symbols represent the coordinates of each sample, while open symbols represent the estimated centroid of the points for each of the cultivars. Percentages indicate the inertia decomposition associated with each of the two axes

American ash was dominated strongly by syringin/oleoside, which was present in much smaller amounts in Manchurian ash. They shared four other compounds: apigenin, a pinoresinol-related compound, nunzenhide-related compound, and oleuropein, with Manchurian ash having a higher concentration of the pinoresinol-related compound. Verbascoside was found in all but white ash, and hydroxytyrosol hexoside was found in all but the wild green ash. Rutin and a rutin-related compound were found only in white ash. The green ash cultivar and wild population were similar in most instances, but tyrosol, a hydroxytyrosol related compound and one unknown were found only in the cultivar, and verbascoside, verbascoside hexoside, and one unknown were found only in the wild population.

Discussion

Manchurian ash, which shares an evolutionary history with EAB in northeastern Asia, exhibits much higher resistance to attack to this insect than North American ash species (Rebek et al., 2008). The central objective of this experiment was to determine if a suite of constitutive chemical defense traits in the phloem of Manchurian ash, sampled during the growing season phenologically coincident with feeding of EAB larvae, vary qualitatively or quantitatively from susceptible North American ash species in ways that may help to explain this pattern. In particular, we hypothesized that Manchurian ash would exhibit higher levels of selected defense traits and/or possess unique defense attributes. Manchurian ash (cv. Mancana) exhibited such features as higher total soluble protein concentration and a higher rate of the browning reaction in phloem extracts, and contained several soluble phenolic metabolites not found in the North American ash species. In addition, quantitative differences were found in soluble phenolics that Manchurian ash shared with the North American ashes, and it lacked a few compounds that were found in North American species. White ash (cv. Autumn Purple), a highly susceptible cultivar, generally showed the lowest levels of several defense traits, but a susceptible green ash cultivar (cv. Patmore) and green ash plants grown from a wild population did not. While specific resistance mechanisms to EAB in ash are still unknown, constitutive variation in some of these putative defense traits may help to explain variation in EAB attack rates and survival among different ash species.

While the highly resistant Manchurian ash did not exhibit the highest activities of the phenol oxidizing enzymes, total phenolic concentration and trypsin inhibitors, white ash, a highly susceptible species, tended to have low activities of phenol oxidizing enzymes, a slow rate of browning, and a low total protein concentration. White ash generally shared the same phenolic profile as green ash, as expected based on their phylogenetic relatedness (Wallander, 2008), but was clearly separable from both green ash and Manchurian ash based on having reduced quantities of phenolics that all species shared (as well as lacking several compounds produced by Manchurian ash) and lower activities of some defense proteins. Each of these findings is consistent with expectations of a highly susceptible species. However, green ash is also susceptible yet had high activities of phenol oxidizing enzymes, total phenolic concentrations, and relatively high activities of trypsin inhibitors. Since it largely shared a phenolic profile with white ash, either its susceptibility to EAB is explained in part by its lack of some of the unique compounds that Manchurian ash possesses, or the susceptibility of both white and green ash is due to feeding stimulants or other insect growth-promoting traits not possessed by Manchurian ash. In addition, we found that the green ash cultivar (cv. Patmore), and the green ash from the wild population were similar on the basis of nearly all protein, browning, lignin traits measured, but some variation was seen between them on the basis of individual phenolic metabolites. This suggests that findings on field resistance to EAB and resistance mechanisms using this cultivar of green ash should largely represent that found in wild green ash.

While the mechanisms of resistance in ash species to insects are largely unknown, phenolics as a class commonly are implicated in resistance to insects in many plants (Levin, 1976). Our multivariate analysis, based on 33

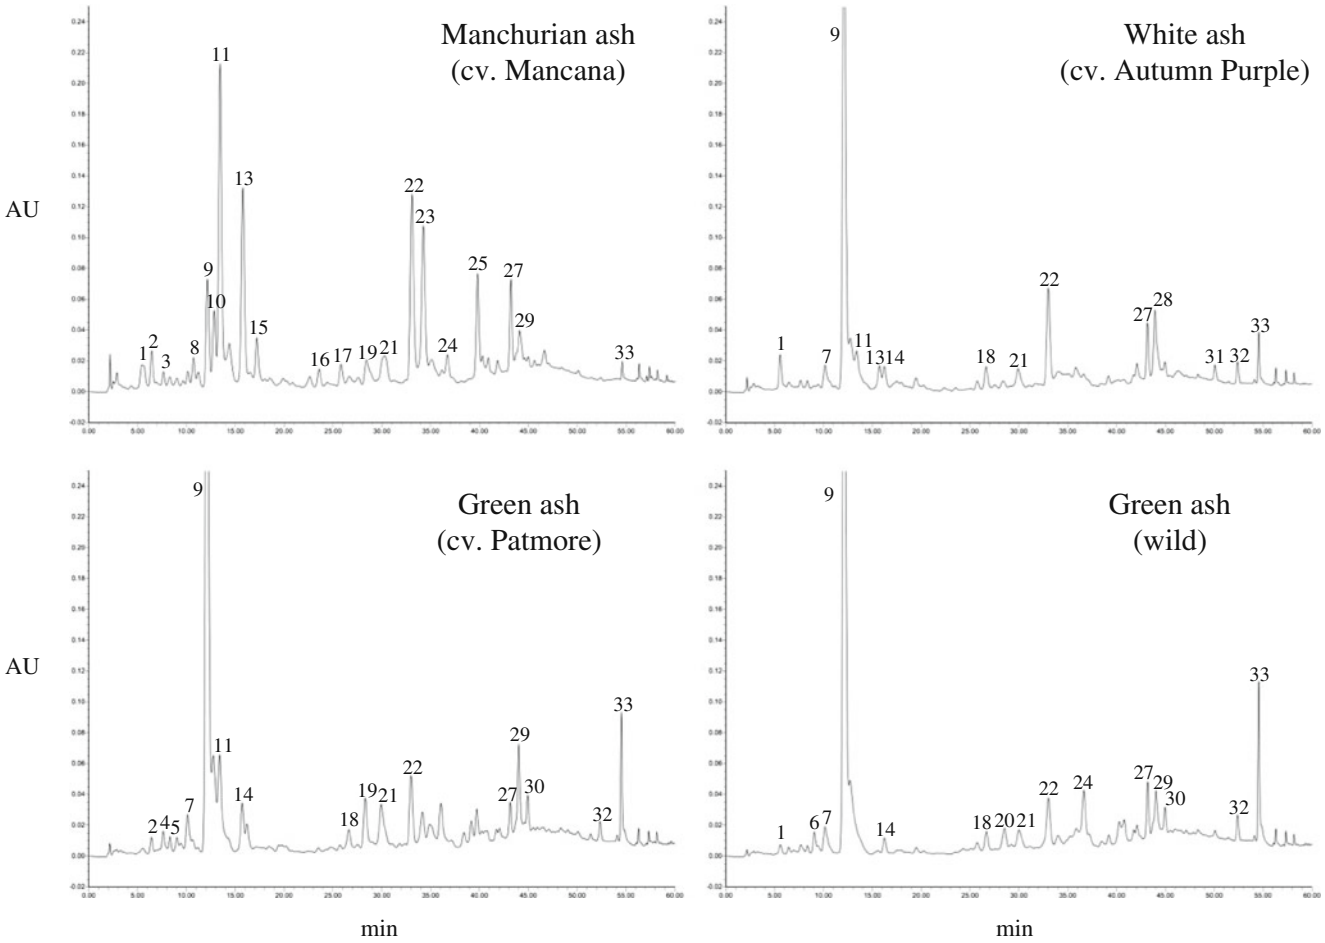

Fig. 3 HPLC chromatograms at 280 nm of pooled phloem extracts of 5-year-old ash trees grown in the common garden. *AU* absorbance units. Peak numbers correspond to Table 2

compounds, showed that Manchurian ash and white ash were both clearly distinguishable from each other, and both were distinguishable from green ash. While the green ash cultivar and wild green ash also differed from each other in multivariate space, this difference was less than the among-species differences. Many of our findings using growing saplings were consistent with findings using bare-root dormant stems (Eyles et al., 2007), but some differences were observed. Manchurian ash had nine compounds not found in the other species, which included several hydroxycoumarins, lignans, and phenylethanoids. These were mostly the same as those identified by Eyles et al. (2007), except that we did not find methylesculin or esculetin in growing stems of Manchurian ash that were found previously in dormant stems. In both studies, the phenolic glycoside syringin dominated the phenolic profile of green and white ash, and was absent or at low levels in Manchurian ash. Since we sampled trees growing in the field during a time period when EAB larvae would be actively feeding, results of the current study may be particularly relevant.

The mechanisms of resistance to EAB in Manchurian ash have not been determined, but some of the phenolic compounds it produces have been examined for their biological effects on insects and pathogens. Hydroxycoumarins like esculin have been suggested by Silva et al. (2006) to retard insect development by inhibiting trehalase, a major enzyme that controls glucose availability in insects. In cassava, some of the same hydrocoumarins as those found in Manchurian ash, were shown by Rodriguez et al. (2000) to have possible anti-microbial activities against a variety of fungi and bacteria.

Manchurian ash had high levels of some lignans, including pinoresinol dihexoside and a pinoresinol related compound. Pinoresinol was found at high levels in dormant stems of Manchurian ash (Eyles et al., 2007), but found only in North American ashes in this study. Lignans have wide biological activities, and effects on insects have been well documented for some of them (Cabral et al., 1999; Garcia et al., 2000; Rios et al., 2002; Schroeder et al., 2006). Other compounds found either exclusively or at higher levels in Manchurian ash, such as homovanillic

Table 2 Characteristics, identity, and mean (± sd) peak areas ($\times 10^{-5}$) of 33 unknown and tentatively identified phenolic compounds in phloem extracts from branches of 5-year old ash trees grown in a common garden

[a] Identity confirmed with authentic standard

[b] Compound identities were based on an exact match to λ_{max} and retention time (RT) data presented in Eyles et al. (2007) and Chen et al. (2011). These sources present compound identities based on congruence of mass spectral information, λ_{max}, and RT with that of the literature, and in some cases generate NMR data in order to provide definitive structural information of individual unknown compounds. Instrument and gradient parameters used in our analyses were conducted following the methods of Eyles et al. (2007) and Chen et al. (2011) using the same instrument, column, methods, and parameters

alcohol, fraxin, fraxidin hexoside, mandshurin, and calceolariosides A and B have not been examined for their bioactivity against insects, but several of them have shown anti-oxidant, anti-cancer, and other medically relevant biological activities (e.g., Deiana et al., 2008). Syringin, which was present at high levels in white and green ash and absent in Manchurian ash, has shown antifeedant effects against some beetle species (Cis et al., 2006), but does not appear to confer resistance to EAB given the susceptibility of these two species. It is possible that some compounds found exclusively in the North American ashes serve as feeding stimulants or growth promoting traits for EAB larvae.

The elevated wound browning rate of Manchurian ash is driven presumably by the action of phenol oxidizing enzymes on water-soluble phenolics present in the extracts. As such, this measure integrates both phenol oxidizing enzyme activity and phenolic content. While Manchurian

ash did not show increased phenol oxidizing enzyme activities in this study, the unique phenolic content and/or increased concentrations of certain phenolics in phloem extracts of Manchurian ash may have contributed to its elevated browning rate. For example, metabolism of some hydroxycoumarins by peroxidase contributed to the browning reaction in cassava root (Buschmann et al., 2000). While this trait has been associated with anti-microbial effects in structures such as fruits (Cheng and Crisosto 1995), it has been assessed infrequently in the context of insect resistance, especially towards wood-boring insects. Dowd and Norton (1995) showed that several simple phenolics in corn callus tissues could be oxidized (browned) through the action of endogenous peroxidases, and browned tissues were poor quality food for the corn earworm, *Helicoverpa zea*. Since the oxidation status of phenolics can determine their toxicity to insects (Appel, 1993), the rapid wound browning of Manchurian ash phloem may contribute to its resistance to EAB if it is an indication of the oxidation status of its particular phenolic mixture.

Resistance to wood boring insects in deciduous trees is little understood (Dunn et al., 1990), and little work has been done specifically on chemical mediation of ash resistance to EAB larval feeding. The results presented here, along with those of Eyles et al. (2007), suggest that clear differences in the chemical defense profile exist between a resistant ash species and its susceptible counterparts in North America. These characteristics may represent defined molecular and biochemical targets for conventional or molecular breeding of ash species, and suggest that the examination of resistant Asian ash species will facilitate the discovery of QTLs or particular resistance genes linked to expression of biochemical and physical defenses. Conventional hybrids between Asian and North American ashes exist (J. Koch, personal communication), but the possibility of enhancing EAB resistance of North American ashes will rely on their ability to appropriately express biosynthetic machinery necessary to express resistant traits, whether it is transferred through traditional breeding efforts, or through genetic transformation. Although we focused on constitutive phloem defenses in this paper, feeding- or wound-induced changes in chemical defense profiles also may be important for resistance to EAB and are the subject of current investigation. We are also examining the direct effects of putative resistance traits on EAB in artificial diets, and further characterizing the browning reaction and its role in resistance.

Boron Fertilization Enhances the Induced Defense of Silver Birch

Abstract Boron (B) deficiency is a common micronutrient deficiency that has been reported to affect the phenolic metabolism of plants. Thus, it may play a role in defense against herbivorous animals. However, the role of B in a plant's resistance to herbivores has not received any particular attention from researchers. In this study, we tested the effects of B nutrition 1) on the biochemical and mechanical defenses of birches and the growth of seedlings, and 2) the resistance of seedlings to larvae of the autumnal moth, *Epirrita autumnata*. Boron fertilization improved the resistance of birch, which was shown as reduced pupal weight of the herbivore. However, B fertilized trees suffered from heavier defoliation than unfertilized ones due to compensation feeding of larvae. The growth of the seedlings was diminished, and several biochemical changes occurred in leaves of herbivore seedlings, and B also played a role in these changes. Polyphenoloxidases (PPOs) and peroxidases (PODs) and their substrates, chlorogenic acids, were induced by herbivory in B fertilized seedlings but not in unfertilized seedlings. The lower pupal weights and increased consumption of the herbivores were probably linked to the plants' phenoloxidase-mediated production of reactive quinones, which decrease the nutritive value. Herbivory upon new stems led to an increase in the number of resin glands that provide defense against mammalian herbivores. Herbivory also had a substantially negative effect on B concentration in leaves of B fertilized seedlings. We postulate that B nutrition of trees may play a significant role in the induced defense of birches.

Key Words Birch · Boron · Defense · *Epirrita autumnata* · Herbivory · Immune function · Phenols · Resistance

Introduction

Boron deficiency is said to be the world's most common micronutrient deficiency among forest trees (Shorrocks, 1997). In Finland, trees suffering from B deficiency often are growing in nutrient rich soils such as in groves, reforested fields, and pastures, or in drained peatlands that have been fertilized with macronutrients (Saarsalmi and Tamminen, 2005). In conifers, B deficiency causes leader dieback and disturbs apical dominance (Hopmans and Clerehan, 1991). The crown of a B deficient tree may be bushy and show several main shoots (Braekke, 1979). In deciduous trees, morphological symptoms of B deficiency are not always as clear as those for conifers.

Physiologically, B deficiency causes several impairments such as cessation of root elongation and growth of apical meristems. Boron plays a role in the establishment of the primary cell wall and the integrity of the plasma membrane. Boron cross-links two pectic polysaccharide rhamnogalacturonan II (RGII) monomers with a borate bridge, thus stabilizing the cell-wall matrix (O'Neill et al., 2004). Interestingly, B deficiency causes effects on phenol metabolism similar to those of herbivory. Both stresses trigger the activity of polyphenol oxidases (PPO) and the accumulation of quinones (Cakmak and Römheld, 1997; Ruuhola et

al., 2008; Anttila et al., 2010). Additionally, the level of reduced ascorbic acid decreases in response to B deficiency (Lukaszewski and Blevins, 1996) and herbivory (Bi and Felton, 1995), which also contribute to the enhancement of quinone formation and reactive oxygen species (ROS) production.

Earlier studies have shown that induced birch PPO activities may explain the rapidly induced resistance (RIR) of mountain birch (*Betula pubescens* sp. *czerepanovii*) to its major defoliator, *Epirrita autumnata* Borkhausen, autumnal moth (Ruuhola et al., 2008; Anttila et al., 2010). Both quinones and ROS are harmful to plant eating animals, decreasing the assimilation of nutrients and producing, for example, mid gut lesions (Bi and Felton, 1995). Foliar PPO activity (Ruuhola et al., 2008) and phenolic concentrations (Ruuhola et al., 2007) correlated negatively with the growth of autumnal moth larvae on previously wounded trees, but had no negative association on unwounded control trees.

Boron may improve the innate immunity of vertebrate animals (Ardó et al., 2008), but there have been no studies conducted with insects. The immunity of insects resembles the innate immunity of vertebrates comprising physical barriers, hemocytes, and induced synthesis of antibacterial compounds (Gillespie et al., 1997). Insects are defended against parasites and diseases with a process called encapsulation, in which an intruder is capsuled by a cell layer. In melanotic encapsulation, this layer is hardened by melanin (Gillespie et al., 1997). Both the cellular and humoral immune systems are involved in the encapsulation process, which can be considered a general measure of the activity of the immune system (Ratcliffe, 1993). It has been demonstrated on Lepidoptera that the ability to encapsulate a foreign antigen correlates with resistance to entomopathogenic fungal disease (Rantala and Roff, 2007), and is associated also with resistance to parasitoids (Smilanich et al., 2009). In earlier studies, we showed that the encapsulation response of *E. autumnata* pupae was strengthened by a mild stress, such as the priming of the host plant (Kapari et al., 2006) or by moderate heavy-metal pollution (van Ooik et al., 2007). However, this response was mitigated by severe stress, such as starvation (Yang et al., 2007) or exposure to acid rain (Ruuhola et al., 2009). Host plant species and quality also affect the encapsulation response of *E. autumnata* (Klemola et al., 2007; Yang et al., 2008).

No previous studies were found that examine the effects of B fertilization on the herbivore resistance of trees. We expected that both a B deficiency and the correction of B deficiency through fertilization might affect herbivore resistance. Boron deficiency could increase resistance *via* an enhanced production and oxidation of phenols. However, fertilization with B has been shown to improve plants' resistance to pathogens (Dordas, 2008), and optimal B nutrition improved the resistance of soybean to herbivores (Beanland et al., 2003). According to the mineral balance hypothesis, optimal balance among minerals enhances plants growth and improves their herbivore resistance (Phelan et al., 1996).

To test these two alternative hypotheses that either boron deficiency or boron fertilization enhances the resistance of trees, we fertilized silver birch seedlings (*Betula pendula* Roth) with a complete nutrient solution either containing an optimal B level, in relation to other nutrients, or without B (See Table 1). We studied the performance of autumnal moth (*E. autumnata*) larvae that fed on these seedlings and the combined effects of the B and herbivory treatments on the biochemical and mechanical defenses and the growth of the seedlings.

Methods and Materials

Study Species Autumnal moth, *E. autumnata*, is a well-studied species. A characteristic feature of this species is its massive outbreaks in northernmost Scandinavia at 10–11 year intervals (Haukioja et al., 1988; Ruohomäki et al.,

Table 1 Time schedule of the experiment and fertilization treatments

[a] Seedlings were fertilized three times per week with 100 ml of the complete nutrient solution

2000). Larvae hatch early in spring in synchrony with the bud burst of mountain birch, *B. pubescens* ssp. *czerepanovii* (Kaitaniemi et al., 1997).

Silver or European white birch (*B. pendula*) is widely distributed throughout Eurasia (Hämet-Ahti et al., 1998). Silver birch is a host for a wide variety of insect and mammalian herbivores, and its resistance to these herbivores has been intensively studied (e.g., Rousi et al., 1991; Mutikainen et al., 2000; Huttunen et al., 2008).

Study Design The study was conducted from February to March in 2009, within a greenhouse located at the Botanical Gardens of the University of Joensuu, Finland. We used 1-year-old seedlings of *B. pendula* obtained from a commercial nursery (Finforelia) and a laboratory stock of autumnal moth larvae that were descendants of insects collected as larvae from northernmost Scandinavia. Winter dormant seedlings in their intact peat plug were transferred to 2 l pots filled with quartz sand (particle size 1.5 mm). The day temperature was raised gradually to a maximum range of +22–24°C, whereas the night temperature was set to a minimum of +13°C. The light:dark -cycle was set to 20:4 h, to mimic the light conditions of spring at the same latitude (N 62° 36.059′ E 029° 45.813′). Seedlings were placed into eight large cages (70×120×125 cm) that were divided into two crosswise parts separated by a voile fabric wall (Anttila et al., 2010). The wooden framed sides of the cages were covered with light permeable voile fabric, and the tops with a polyethene filter that transmitted photosynthetically active radiation (PAR). During the experiment, seedlings were fertilized three times per week with 100 ml of a complete nutrient solution (Aphalo and Lehto, 1997), either with an optimal level of B (+B) or a B level of zero (−B) (Table 1). When necessary, seedlings were watered with tap water. Fertilization treatments started 1 week after the potting of the seedlings (Table 1). Newly hatched neonate larvae were allocated to the seedlings synchronized with the bud burst, which was 11 day after potting.

The study setup was factorial: Seedlings were randomly allocated to two treatments with four combinations: no B supply with intact control (–B–H), no B supply with larval treatment (–B+H), B supply with intact control (+B–H), and B supply with larval treatment (+B+H). Six birch seedlings were placed in each half of a cage so that branches of one seedling did not touch another, to prevent the larvae from roaming between seedlings. One half of each cage served as an unwounded control, while the other had six newly hatched larvae released on each seedling at the time of bud burst (altogether 36 larvae per cage). Four of the cages were allocated to the B deficiency treatment (–B), and the other four received the B fertilization treatment (+B).

Larval Performance Larvae were allowed to feed on birch seedlings until they reached the final stage (fifth instar) when they prepared to pupate (3 week). Shortened larvae were collected onto moist unfertilized peat in 48 ml plastic vials where they were allowed to pupate. After 7 day, pupae were weighed, and their sex was determined. Their encapsulation rate was measured by inserting a 2 mm long sterile nylon filament into the pupa (Kapari et al., 2006). The encapsulation reaction was allowed to continue at +23°C for 1 h, after which the filament was removed. Then, the pupae were flash frozen in liquid nitrogen and stored at −80°C prior to analysis. Later, the implanted portions of the filament were photographed from two different angles under a light microscope with a digital camera. These images were analyzed using the image processing software, Image J program. The degree of melanotic encapsulation was analyzed as grey values of reflected light from the implants. As a measure of the encapsulation response, the average grey values from two digital images were used. The data were transformed so that the darkest grey values corresponded to the highest encapsulation response. The transformation was carried out by subtracting the observed grey values from the control grey value (clear filament) (see Rantala and Kortet, 2003).

Sampling of Seedlings When all larvae had pupated, qualitative visual assessments of the seedlings' defoliation percentages were made. Seedlings were allowed to grow and develop new shoots and leaves for a further 2 week, after which they were harvested to measure their defenses (Table 1). Leaves used for enzymatic assays were collected from long shoots: the young (3–4th node) leaves were carefully removed with their petiole, then immediately frozen in liquid nitrogen and stored at −80°C prior to analyses. Leaves for chemical analyses were collected from the main shoots from the 2nd to 4th node; these leaves were dried at room temperature (RT) for 1 week after which leaves were stored at −20°C prior to extraction and high-pressure liquid chromatography (HPLC)-analyses. Phenolic and enzymatic analyses were made for two seedlings from each half of a cage (eight seedlings/treatment). The other four seedlings per cage were used for inductively coupled plasma (ICP)-analysis of the B concentration (16 seedlings/treatment).

The number of new shoots and the number of resin glands per cm^2 on the stems of new main shoots were counted 3 week after larval pupation (Table 1). Since the length of new stems differed greatly between the herbivore and control treatment (from 0.5 to 10 cm), the number of glands in the middle of the new shoot was counted over a 2 mm^2 area. This was later converted to the number of resin glands/cm^2. There appeared to be a clear difference between the control and the herbivore-treated seedlings with respect to the hairiness of their new shoots. To test this

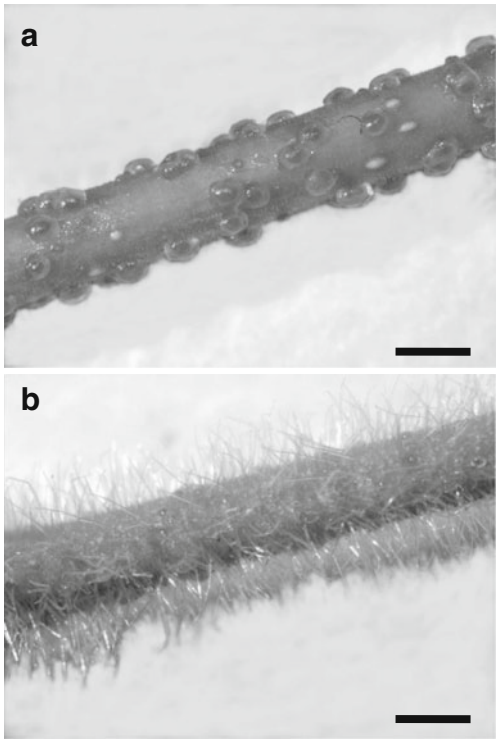

Fig. 1 Stems of *Betula pendula* control seedlings (**a**) and herbivore-treated seedlings after the defoliation by *Epirrita autumnata* larvae (**b**). Differences in stem hairiness between the control and herbivore-treated seedlings were visually grouped to six qualitative classes: first class is a bald stem without hairs (**a**) and the sixth class is a stem covered with long and dense hairs (**b**)

difference we created a qualitative visual pilosity classification system with a range of from 1 to 6 according to the length and density of the hairs on the stem: 1 = bald without hairs, 2 = nearly bald, 3 = dense downy hairs, 4 = dense with thicker and longer hairs, 5 = denser with longer hairs, and 6 = densest with longest hairs (Fig. 1).

The heights of seedlings were measured prior to any treatments (Time 0; Fig. 4) and twice during the experiment: when all shortened larvae had been removed from the seedlings (Time 1; Fig. 4) and after a 2-week-recovery period (Time 2; Fig. 4). The stem biomass was determined by cutting the stems into two pieces, the current and previous season's stems, then drying these parts at +105°C for 3 day, before they were weighed.

Chemical Analyses For the phenolic compound analysis, leaf samples were dried at room temperature for 1 week, then 3–4 leaf disks, without any midrib, were cut from them. Leaf disks (3–4 mg) were homogenized for 30 s, at 5,500 rpm in 600 µl of 100% (v/v) methanol using a Precellys® 24 homogenizer (Bertin Technologies, France). Homogenized samples were kept in an ice bath for 15 min and centrifuged at 13 000 rpm for 5 min at +4°C (Eppendorf® centrifuge 5415 R, USA). The supernatant was taken to a 6 ml tube; extraction was repeated × 3, and with standing on ice for 5 min between extractions. The methanol from the combined extracts (2.4 ml) was evaporated to dryness in the vacuum centrifuge (Eppendorf® concentrator, Germany). Dried samples were redissolved in a solvent of 300 µl of 100% methanol and 300 µl of dH_2O. Dissolved samples were analyzed with Agilent's Series1100 high-pressure liquid chromatography (HPLC) system (Agilent Technologies, Germany) equipped with Agilent's G1315B diode array detector (DAD), and a reversed-phase (RP) octadecyl carbon chain (C18) column (Agilent Technologies, USA) was used for the separation of the compounds as described by Julkunen-Tiitto and Sorsa (2001). Compounds were quantified at 320 nm based on their UV-spectra and retention times, except (+)-catechin and 3,4′-dihydroxypropiophenone-3-β-D-glucopyranoside (DHPPG), which were quantified at 220 and 270 nm, respectively. Concentrations were calculated with the following standards: kaempferol 3-rhamnoside for kaempferol 3-rhamnoside, apigenin 7-glucoside for apigenin derivatives, hyperin for quercetin derivatives, myricetin 3-rhamnoside for myricetin derivatives, (+)-catechin for catechin, chlorogenic acid for chlorogenic acid derivatives, and cinnamic acid for cinnamic acid derivatives. Condensed tannins (CTs) were determined with an acid-butanol test (Porter et al., 1986) on both the soluble methanol fraction (soluble CTs) and the extraction remnants (cell wall-bound CTs), with quantification based on a purified *B. nana* leaf tannin.

Proteins were extracted similarly to the procedure described in Ruuhola and Yang, (2006), except that a raw extract, without purification through desalting columns, was used. The protein extracts were stored at −80°C prior to enzymatic assays. Polyphenol oxidase (PPO) activity was measured with 20 mM catechol as a substrate in 0.1 M K-phosphate buffer, pH 6.4, and the rate of change at 420 nm was followed at room temperature for 5 min with a spectrophotometer (Cary 50 bio UV-VIS spectrophotometer; Varian, Mulgrave, Australia). Peroxidase (POD) activity was measured with 3 mM guaiacol and 0.25 mM H_2O_2 as substrates in 0.1 M K-phosphate buffer, pH 5.8, and the rate of change at 470 nm was followed at room temperature for 5 min. Protein contents of the enzyme extracts were determined with a Bichinchonic Acid Protein Assay Kit (Sigma) based on the Lowry et al. (1951) method. Enzyme activities were expressed as U mg $protein^{-1}$ or U g fw^{-1}: one unit being the amount of enzyme required to increase the absorbance by 0.001 min^{-1}.

Boron concentrations of leaves were determined with an inductively coupled plasma atomic emission spectrometer (ICP-OES, Iris Intrepid, Thermo Elemental, Franklin, MA, USA) after microwave wet digestion in HNO_3 (suprapur, Merck) plus H_2O_2 with a method based on SFS-EN ISO 17025 and Epa 3051.

Statistical Analyses Mixed model analysis (SPSS 17.0.) was used on the data. Normal distribution of the residuals was checked with the Kolmogorov-Smirnov test and visually, with predicted values vs. residuals and Q-Q-plot. The effects of the B treatment on the pupal weight, development time, and encapsulation rate of *E. autumnata* were tested with the following model: B treatment, sex, and their interaction were fixed factors, and a tree was nested within a cage as a random factor. To study the effects of treatments in more detail, pair-wise contrasts were tested with LSD-method.

The mixed model analysis also was used to test the chemistry of leaves. The model in this case had the B and herbivore treatments as fixed factors, and the cage was set as a random factor. For the analysis of the stem weights, number of lateral shoots, and mechanical defenses, the initial height of a seedling was set as a covariate in the model to diminish the possible differences in these initial sizes. The height growth of seedlings was tested with repeated mixed model analysis (SPSS 17.0). In this model, time, B treatment, and herbivore treatment were set as fixed factors; time was a repeated item, the tree was a subject, and the cage was a random factor; the initial height of a seedling was a covariate. Pair-wise contrasts were tested with the LSD-method. The effect of the B fertilization on the defoliation percentage of the herbivore-treated trees was tested with Kruskal-Wallis non-parametric test (SPSS 17.0). The correlations between percentage defoliation and growth of seedlings were analyzed with the Spearman's correlation test.

Results

Boron Concentrations The concentration of B in the birch leaves increased markedly (ca. 50%) and significantly ($F_{6.2}$= 26.48; P=0.002) with B fertilization (Fig. 2). However, the B concentration substantially decreased (27%) with herbivory in the +B seedlings ($F_{48.4}$=7.528; P=0.008) but was not significantly affected in the –B seedlings (Fig. 2).

Performance of Autumnal Moth Pupal weights of the *E. autumnata* females grown on the +B seedlings were significantly ($F_{36.80}$=4.515; P=0.040) lower than those of grown on the –B seedlings, while there was no difference in the male pupal weights for these treatments (Fig. 3a). The sex of a moth had no effect on pupal weight ($F_{205.9}$=0.033; P=0.855); the B treatment × sex interaction also was non-significant ($F_{205.9}$=2.574; P=0.110). Development time for females was longer than that for males ($F_{204.5}$=21.99; P<0.001; Fig. 3b), but the B treatment did not affect development rates of either sex ($F_{36.63}$=2.107; P=0.155),

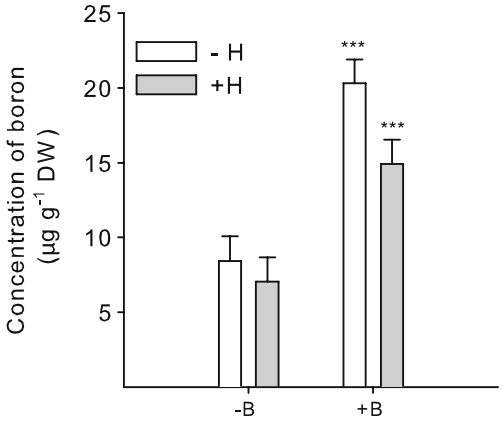

Fig. 2 The boron concentrations (µg g^{-1} DW) in the leaves of *Betula pendula* seedlings exposed to two treatments, boron and herbivory, and their four combinations (−H=unwounded control, +H =herbivore-treated, –B=B unfertilized, +B=B fertilized seedlings). Significant differences (LSD contrasts) between control and herbivory treatments are marked with asterisks (*P≤0.05, **P≤0.01, ***P≤0.001). Data show ESmeans+S.E. (Mixed model analyses, SPSS 17.00). N=16 per treatment

and there was no significant B treatment × sex interaction ($F_{204.5}$=1.774; P=0.194). The encapsulation rate of the pupae tended to be lower in +B treatment than in –B treatment ($F_{33.13}$=2.796; P=0.104; Fig. 3c). Females had a higher encapsulation rate than males ($F_{212.9}$=26.21; P<0.001), but again there was no significant B treatment × sex interaction ($F_{212.9}$=0.161; P=0.689).

Defense of Silver Birch Seedlings Herbivory significantly affected the concentrations of most of the measured phenolic compounds, either by increasing or decreasing their levels, but B fertilization alone had no significant effect. However, there were two significant and three close to significant B treatment × herbivory interactions (Table 2). Quantities of 14 of 26 individual phenolic compounds and the total quercetins, apigenins, and HPLC phenolics increased as a response to herbivory whereas amounts of five compounds decreased with herbivory (Tables 2 and 3). The effect of herbivory on flavonoids was intriguing: myricetin and quercetin 3-arabinosides decreased in the herbivory exposed seedlings, whereas levels of myricetin, quercetin, and kaempferol 3-rhamnosides increased, respectively (Table 3). Equally intriguing was the decrease in soluble condensed tannins (CTs) and total CTs (but not cell wall bound CTs) in the herbivory wounded seedlings. This decrease, however, was significant only for the +B seedlings (Table 3).

More detailed examination of the contrasts (LSD) revealed that herbivory effects were not usually significant for both treatments (Table 3): quantities of 16 compounds were affected in the +B seedlings (e.g., chlorogenic acids and soluble CTs), seven in the –B seedlings (e.g., apigenins

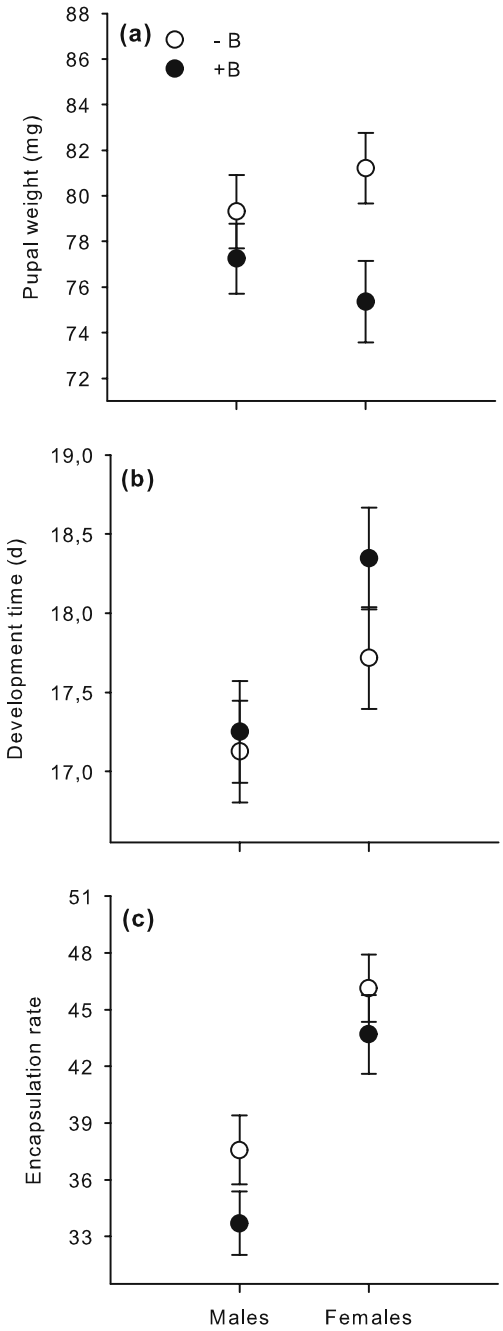

Fig. 3 Pupal weights (**a**), development times (**b**) and encapsulation rates (**c**) of *Epirrita autumnata* males and females grown either on boron unfertilized (−B) or boron fertilized (+B) birch seedlings. Data show ESmeans+S.E (Mixed model analyses, SPSS 17.00). N=112 (−B) and 109 (+B)

and (+)-catechin), and seven were affected in both B treatments (e.g., DHPPG, total cinnamic acids, quercetins, and HPLC phenolics) (Table 3).

Herbivory also seemed to induce the activities of polyphenol oxidases (PPOs) and peroxidases (PODs) as measured both per fresh weight and protein content (Table 2). However, this induction was significant only for the +B seedlings, not for –B seedlings (Table 3). Herbivory exposed seedlings fertilized with B showed a significantly higher POD activity than herbivory seedlings that did not receive B (Table 3).

The number of resin droplets and the hairiness of the stems of new shoots were significantly increased by herbivory (Tables 2 and 3; Fig. 1). There were no significant effects on either of these traits due to the B treatment or a B treatment × herbivory interaction.

Growth of Silver Birch Seedlings The height growth of *B. pendula* seedlings was significantly decreased by herbivory, and there was also a significant B treatment × time interaction, and a nearly significant B treatment × herbivory interaction (Table 4). The growth of +B unwounded control plants tended to be higher than the growth of –B control plants, whereas, the growth of +B seedlings was decreased more than the growth of –B seedlings by the herbivory treatment due to a higher defoliation percentage of +B seedlings (Fig. 4). Boron fertilization led to a higher defoliation percentage (89±4.21%) of the herbivory treatment seedlings ($X^2_1 = 5,904$; P=0.015) than no fertilization (78±4.58%).

Biomasses of the old and new stems and branches also were decreased by herbivory (Tables 5 and 6), indicating that both the growth in height and in diameter was depressed. In contrast, B treatment had no effect on the biomass of stems, and the interaction with the herbivore treatment was not significant either (Tables 5 or 6). The defoliation percentage correlated negatively with the weight of the new (r=−0.675, P=0.004) and old stems (r=−0.704, P=0.002) (data not shown). The number of new lateral shoots increased with herbivory (Tables 5 and 6), apparently due to the loss of apical dominance. The most heavily defoliated seedlings had no clear main shoot and had a bushy appearance at the top. The boron treatment had no effect on the number of lateral shoots (Table 5). However, the effect of herbivory on the number of lateral shoots was significant, but only for the –B seedlings, not for +B seedlings (Table 6).

Discussion

The resistance of silver birch seedlings to autumnal moth was affected by boron (B) fertilization: pupal weights of female moths grown on the B fertilized seedlings were significantly reduced compared to pupal weights of females grown on seedlings that received no B in their nutrient solution. In addition, the immunity of moths, measured by their encapsulation rate, tended to be lower for those that fed on +B seedlings than for those that fed on –B seedlings; however, the moths' development rates were not affected. A lower body weight of a female moth decreases its fitness,

since fecundity correlates directly with the body weight of females (Haukioja and Neuvonen, 1985). We found no earlier studies conducted with woody plants wherein the effects of B on their resistance to herbivores were investigated. However, in a study conducted with annual soybean plants, B fertilization increased the resistance of the plants, such that the weights of soybean looper pupae, velvetbean larvae, and Mexican bean beetles were lowered

when they fed on B fertilized plants (Beanland et al., 2003). The smallest insects also were produced on plants that received an optimal B:Fe:Zn -ratio for the growth of the plants (Beanland et al., 2003); this suggests that an optimal balance to the nutrition of plants may play a role in their defense against insect herbivores (see Phelan, 1996).

The induced chemical defensive responses of birch seedlings, which were measured from the new leaves that

developed after herbivory, also were affected by B fertilization; specifically both polyphenoloxidases (PPOs) and peroxidases (PODs) were induced, but only in the +B seedlings. Similarly the levels of two *o*-diphenolic compounds, putative substrates for PPOs and PODs, namely chlorogenic acid and neochlorogenic acids, were elevated in the +B seedlings. The resistance of the +B seedlings to subsequent herbivores also was probably enhanced by the priming of trees (see Ruuhola et al., 2007), since in our earlier studies of the mountain birch—autumnal moth system, we demonstrated that herbivory enhanced the oxidation of phenols by inducing PPO and POD activities (Ruuhola and Yang, 2006; Ruuhola et al., 2008; Anttila et al., 2010) that was related to a decrease in the growth rates of the most voracious fifth instars (Ruuhola et al., 2008). For other tree species, phenoloxidases also have been shown to play a role in their defense against herbivores (e.g., Tscharntke et al., 2001; Wang and Constabel, 2004); overexpression of PODs was even shown to enhance the resistance of primed hybrid poplars (Barbehenn et al., 2010).

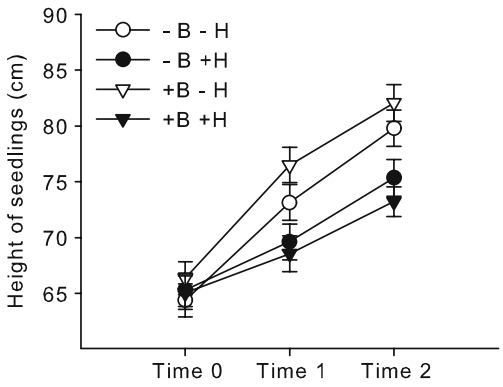

Fig. 4 The heights of *Betula pendula* seedlings at the beginning of the experiment (Time 0), after the pupation of *Epirrita autumnata* larvae (Time 1) and after a 2-week-recovery period (Time 2). The seedlings were exposed to two treatments, boron and herbivory, with their four combinations (−H=unwounded control; +H=herbivore-treated, –B=B unfertilized; +B=B fertilized seedlings). Data show ESmeans+S.E (Mixed model analyses, SPSS 17.00). $N=32$ per treatment

The B fertilized seedlings suffered from heavier defoliation than the –B seedlings, apparently due to compensation feeding of larvae, indicating that the B fertilization decreased the leaf quality for larvae. Quinones produced by phenolic oxidation are highly reactive compounds that readily bind many nutritionally important substances, especially essential amino acids, decreasing the plants' quality for their consumers (Felton et al., 1989). Many herbivores may increase their consumption when the nutritive value of their diet declines (Haukioja, 2003). Compensation feeding may, however, lead to the ingestion of toxic amounts of harmful secondary chemicals (Slansky and Wheeler, 1992; Haukioja, 2003); this can be seen as lowered utilization efficiencies, reduced feeding, a slowed growth rate, and increased mortality (Slansky and Wheeler, 1992). The effect of the greater defoliation of the +B seedlings was seen as a reduced height growth for these trees compared to the –B trees. The biomasses of seedlings for both B treatments were markedly decreased by herbivory, so that the defoliation percentage correlated negatively with the stem biomass. However, given more time, the B fertilized seedlings may have had better compensation abilities than the B deprived seedlings, so that they might make up for this reduced growth later in the present growing season or in future seasons.

In our earlier study, the induced resistance of birch trees was shown to increase the immunity of moths; that may explain the rapid population build-up in the increasing phase of population cycle *via* decreased rate of parasitism (Kapari et al., 2006). In our current study, the immunity of animals that were grown on the +B seedlings tended to be lower than that of animals grown on the –B seedlings, but if we had measured the effects of induced resistance on the next generation of moths (as in Kapari et al., 2006), the results might have been different.

Boron fertilization markedly increased the B concentration in birch leaves; however, the B concentration in the +B seedlings was substantially decreased (ca. 30%) by herbivore wounding with no significant decrease detected in the –B seedlings. The –B seedlings may not have been totally B deprived since the original peat plug may have contained some. The concentration of B in the leaves of the –B seedlings was low (7–8 μg g^{-1} dw), but was probably not yet below the critical deficiency limit, which in conifers is 4–5 μg g^{-1} dw (Braekke, 1979), since we did not detect marked decrease in the biomasses of –B seedlings. Neither did we detect visible deficiency symptoms. The average B concentration in the leaves of the +B seedlings was lower (20 μg g^{-1} dw) than the average value for the leaves of mature *B. pendula* trees (32 μg g^{-1} dw) that were collected

from three different European countries (Hagen-Thorn and Stjernquist, 2005). However, our samples were collected early in the growth season, whereas those for the mature trees were collected in autumn.

Low B level in leaves of–B seedlings did not cause a phenolic accumulation nor the induction of PPOs or PODs in the leaves of birch seedlings. This is contrary to the results of earlier studies conducted with herbaceous species (Ruiz et al., 1998; Cakmak and Römheld, 1997; Camacho-Cristóbal et al., 2002). Similarly, in a study of the conifer, Norway spruce, B deficiency had a minor effect on phenolic contents; the level of condensed tannins (CTs) and monocoumaroyl-astragallin derivative were slightly induced in the B deficient trees (Rummukainen et al., 2007). Olive trees growing in the field with visible B deficiency symptoms also did not accumulate phenolics in their leaves, whereas potted B deficient olive seedlings cultivated in the growth chamber did (Liakopoulos and Karabourniotis, 2005). Perennial plants may store B in their stems and use these stores during bud burst (Lehto et al., 2004). Thus, they are not so vulnerable to a deficiency as herbal plants, especially under field conditions (Lehto et al., 2010). However, the silver birch has a limited ability to remobilize B from mature (Lehto et al., 2004) or senescing leaves (Ruuhola et al., 2011), suggesting that B is a rather immobile element in this species.

The levels of several phenolic compounds increased in the leaves of the herbivore-wounded seedlings, whereas the concentrations of other compounds decreased, reflecting changes in the allocation preferences towards defensively more effective compounds. For example, in the herbivore-treated seedlings, the level of 3,4′-dihydroxypropiophenone-3-β-D-glucopyranoside (DHPPG) increased, while the level of soluble condensed tannins (CTs) decreased. DHPPG is considered to be a defense against herbivory (Keinänen et al., 1999; Mutikainen et al., 2000; Huttunen et al., 2008), while CTs may decrease the defensive properties of other phenolics (Barbehenn et al., 2006). In earlier studies, the level of DHPPG also was increased by herbivory (Keinänen et al., 1999; Mutikainen et al., 2000; Huttunen et al., 2008), while the level of soluble CTs decreased in silver birch (Huttunen et al., 2008) and their precursors did in mountain birch (Anttila et al., 2010).

Herbivory caused the production of hairy new stems with a greater number of resin glands, whereas the B treatment had no effect on these mechanical defenses. Feeding by insect herbivores also has been shown to increase the density of trichomes in other studies (Mutikainen et al., 2000; Rautio et al., 2002; Dalin and Björkman, 2003; Valkama et al., 2005). Resin glands on birch stems have been identified as a mechanical defense against mammalian herbivores (Rousi et al., 1991; Tahvanainen et al., 1991; Laitinen et al., 2002). Based on the observations of this study, it seems that severe defoliation by insect herbivores induces the resistance of silver birch to both insect and mammalian herbivores.

In summary, B fertilized seedlings displayed a stronger induced resistance to herbivores and a stronger induction of

Estimeated mean ± standard error (Mixed model analysis, SPSS 17.00). Statistically significant differences between control and herbivory treatments are marked with asterisk and bold face (LSD contrasts;$^{*}P \leq 0.05$, $^{**}P \leq 0.01$, $^{***}P \leq 0.001$), $N=32$

leaf phenoloxidases and their substrates than low-B counterparts; herbivores feeding on B fertilized seedlings showed reduced pupal weights and a slightly lower encapsulation response. These results indicate that adequate B nutrition of trees might play a role in the induced defense of birches against herbivory.

Acknowledgements We thank Tero Klemola for providing the eggs of *E. autumnata* for the culturing of larvae. We also thank the staff of Botania for their co-operation and help. Gratitude goes to Jaakko Heinonen for guidance with the statistical analyses and to Matti Rousi for helpful comments on the manuscript. Mark Richman checked the English of the manuscript. This study was financially supported by the Academy of Finland, decision no. 123637. The authors declare that they have no conflict of interest and that their experiments presented here have complied with the current laws of Finland.

Wheat Gene Expression is Differentially Affected by a Virulent Russian Wheat Aphid Biotype

Abstract An improved understanding of the complex interactions between plants and aphids is emerging. Recognition of aphid feeding in plant tissues involves production of several defense response signaling pathways and downstream production of defense and detoxification compounds. Feeding by Russian wheat aphid, *Diuraphis noxia* (Kurdjumov), a serious pest of cereal crops worldwide, induces foliar deformity and chlorophyll loss during compatible wheat-*D. noxia* interactions. Experiments described here revealed significant differences in level and pattern of gene expression in defense response signaling and metabolic pathways between compatible and incompatible *D. noxia*-wheat interactions. The jasmonate (JA)-signaling genes *LOX, AOS,* and *AOC* were significantly more upregulated (~3- to 7 fold) in incompatible interactions than in compatible interactions (~2.5 to 3.5 fold) as early as 1 h post *D. noxia* infestation (hpi). Cellulose synthase, responsible for strengthening plant cell walls via cellulose production, was also more upregulated in incompatible interactions (4 to 7 fold) than in compatible interactions (1 to 3.5 fold). In contrast, glycolysis and citric acid cycle genes were significantly downregulated (~1.5 to 2 fold) in incompatible interactions and upregulated or less downregulated in compatible interactions from 6 to 72 hpi. Differences in expression of JA-signaling genes between feeding site tissues and non-feeding site tissues suggest that *D. noxia* defense response signals in wheat are restricted primarily to aphid feeding sites in the initial 6 hpi. This is the first report of differential upregulation of plant genes at 1 hpi in incompatible interactions involving aphid herbivory. Early wheat plant defense responses in incompatible *D. noxia* interactions at 1, 3, and 6 hpi appear to be important aspects of *D. noxia* resistance in wheat.

Key Words Aphids · *Diuraphis noxia* · Plant gene expression · qRT-PCR · *Triticum aestivum* · Wheat · Jasmonate signaling genes

Introduction

Selection of a plant tissue substrate before and during the initiation of insect feeding depends on a suite of well-coordinated interactions between evolutionarily conserved protein(s) encoded by the attacking insect and the host plant that result in a compatible interaction, in which the insect successfully manipulates the host plant, or an incompatible interaction, in which the insect is unsuccessful (Kaloshian, 2004). Complex and dynamic interactions between plants and herbivorous insects have been documented for the response of plants to attack by herbivorous chewing insects (Walling, 2000; Kessler and Baldwin, 2002; Hatcher et al., 2004). However, much less is known about the more complex interaction between plants and insects with piercing-sucking mouthparts (Smith and Boyko, 2007).

Plant defense responses to herbivore-derived signaling compounds, including oral secretions, saliva, and oviposition fluids, represent herbivore-associated molecular patterns (HAMPs) that result in production of direct and

indirect chemical defenses (Mithofer and Boland, 2008). HAMPs that include fatty acid conjugates and peptide elicitors in oral secretions of Coleoptera, Lepidoptera, and Orthoptera have been documented (Doss et al., 2000; Schmelz et al., 2006; Alborn et al., 2007), but to date, elicitors secreted by aphids and other Hemiptera that contribute to these HAMPs remain unknown.

Aphids induce plant defense signaling pathways commonly activated by pathogens, and molecules eliciting these reactions may be directly synthesized by insects or may be products of endosymbiotic bacteria (Kaloshian and Walling, 2005). During these interactions, plants actively deploy defensive compounds to counter both aphid and pathogen attacks (Tjallingii and Hogen Esch, 1993; Walling, 2000; Kaloshian, 2004).

Recognition of aphid feeding in both dicot and monocot tissues involves generation of reactive oxygen species that elicit production of defense response signal cascades involving jasmonic acid (JA), salicylic acid (SA), ethylene (ET), abscisic acid (ABA), and giberellic acid; and downstream production of defense response and detoxification genes (see reviews by Couldridge et al., 2007; Smith and Boyko, 2007; Gao et al., 2008; Li et al., 2008). JA, OPDA (12-oxo-phytodienoic acid), and JAZ (Jasmonoyl-amino acid conjugates, governed by jasmonate ZIM [Zinc finger protein expressed in inflorescence meristem] repressor proteins) (Chini et al., 2007; Thines et al., 2007), control the expression of insect-induced JA early response genes (see review by Howe and Jander, 2008). Although cross-talk between JA and SA pathways occurs in response to aphid herbivory and phytopathogen infection (Balbi and Devoto, 2008; Kazan and Manners, 2008), biotrophic pathogens induce SA-mediated induced defenses, and necrotrophic pathogens and herbivorous insects induce JA/ET-mediated defenses (Kessler and Baldwin, 2002). However, considerable variation occurs in the JA-SA ratios of dicot and monocot foliage after aphid herbivory (Ellis et al., 2002a; Moran et al., 2002; Martinez De Ilarduya et al., 2004; Zhu-Salzman et al., 2004; Voelckel et al., 2004; Boyko et al., 2006).

In contrast to defense signaling genes, less information exists regarding expression of plant metabolic pathway genes elicited in response to insect herbivory. In general, expression of metabolism genes occurs over a more prolonged time course (days) than in defense signaling genes (hours). Divol et al. (2005) demonstrated greater expression of celery foliar genes associated with carbon and nitrogen metabolism in response to herbivory by green peach aphid, *Myzus persicae* Sulzer, at 7 days post infestation (dpi) than at 3 dpi. In incompatible interactions between wheat plants and the Russian wheat aphid, *Diuraphis noxia* (Kurdjumov), Botha et al. (2006) determined that genes involved in cell structure, cell maintenance, and photosynthesis that were down-regulated during initial infestation at 2 dpi were later up regulated at 8 dpi. Similar patterns of results have been observed in incompatible interactions between rice plants and the brown planthopper, *Nilaparvata lugens* Stahl, (Cho et al., 2005) and between wheat plants and the Hessian fly, *Mayetiola destructor* (Harris) (Zhu et al., 2008).

Diuraphis noxia is a serious pest of wheat (*Triticum aestivum*) and barley (*Hordeum vulgare*) in all cereal-producing areas except Australia (Quisenberry and Peairs, 1998). During compatible interactions with *D. noxia*, susceptible wheat plants react to saliva injection by failing to unfurl leaves longitudinally around the main leaf vein, thus forming a tubular refuge that protects *D. noxia* from predators; plants suffer extensive leaf chlorophyll and carotenoid loss (Burd and Elliot, 1996; Heng-Moss et al., 2003). During incompatible interactions involving resistant plants, chlorophyll loss is minor, and *D. noxia* population growth is significantly reduced (Khan et al., 2009; Lazzari et al., 2009). Although several *D. noxia* resistance genes exist in barley and wheat, virulent *D. noxia* populations occur on all continents except Australia (Liu et al., 2010).

Results of recent studies involving the incompatible interaction of North American *D. noxia* biotype 1 and wheat plants containing the *Dnx* R gene demonstrated that an aphid HAMP exists in wheat, and consists of 16 carbon fatty acids; JA-, ABA-, and ET-signaling genes; and direct aphid defense genes (Smith et al., 2010). Upregulation of this HAMP increased significantly from 6 to 24 h post infestation (hpi), but expression of HAMP genes in compatible interactions (when present) was delayed until 48 to 96 hpi. In contrast, few carbon/nitrogen metabolism genes were expressed in incompatible interactions. On the basis of these results and those of Boyko et al. (2006), we hypothesized that incompatible *D. noxia* -wheat plant interactions are more dependent on unique JA-signaling transcripts than on SA-signaling transcripts for production of downstream *D. noxia* defense proteins, and that unique resistance gene transcripts are produced more rapidly in incompatible interactions than in compatible interactions.

The objectives of this study were to develop an improved understanding of the temporal nature of wheat defense signaling genes and metabolic pathway genes expressed during incompatible *D. noxia* -wheat plant interactions. A series of qRT-PCR experiments revealed unique significant differences in the expression patterns of several JA pathway genes and glycolysis and citric acid cycle pathway genes involved in plant carbon/nitrogen metabolism as early as 1 h after the onset of *D. noxia* feeding.

Methods and Materials

Plants and Insects The wheat cultivar 'Yumar' was used. Yumar carries the *Dn4* gene for resistance to *D. noxia*

biotype 1, which results in an incompatible interaction, but is susceptible to biotype 2, which results in a compatible interaction. Seeds of Yumar are currently maintained by the Plant Resistance Laboratory, Department of Entomology, Kansas State University, Manhattan, KS, USA. Biotype 1 aphids used originated from a culture established with aphids collected from Hays, KS, in 2004 and were provided courtesy of Dr. J. P. Michaud, Department of Entomology, Kansas State University. Biotype 2 aphids used were from an aphid colony originally collected near Briggs, CO, in 2004 and were supplied courtesy of Dr. Frank Peairs, Department of Bioagricultural Sciences and Pest Management, Colorado State University. Each biotype was cultured on biotype 1- and 2-susceptible 'Jagger' wheat plants in separate greenhouse rooms at 24:20°C day/night and a photoperiod of 14:10 h (L:D). The genetic identity of each colony has been verified yearly since 2005 in diagnostic plant differential assays at Manhattan, KS.

Experimental Design and Sample Collection Experimental treatments were a compatible interaction (*Dn4* plants infested by *D. noxia* biotype 2), an incompatible interaction (*Dn4* plants infested by *D. noxia* biotype 1), and control uninfested *Dn4* plants. Each treatment consisted of 6 plants grown in one pot. All plants were grown in an incubator at 25:22°C day/night and a photoperiod of 14:10 h (L:D). At the two-leaf stage, a mixture of 180 *D. noxia* biotype 1 or biotype 2 adults and large nymphs (30 per plant) were transferred to a small piece of paper that was placed in the center of the pot against the bases of the plant stems. A separate set of pots contained uninfested control plants. All pots then were covered with tight-fitting mesh cages. At 15 min after transfer, aphids had moved onto plants and begun settling. This event was designated as the zero time point. Results of previous EPG experiments indicate that there are no significant differences between *D. noxia* resistant- and susceptible plants for the mean time until initiation of the first *D. noxia* probe or the mean interval from the first probe to the first sieve element phase feeding event (Lazzari et al., 2009).

RNA Isolation and Real-Time PCR Aphids were completely removed from plant leaves with a camel's hair brush and a 1 × 1 cm section of leaf tissue from aphid feeding sites of each infested plant was collected at 1, 3, 6, 24, and 72 hpi. Expression of selected pathway genes in leaf tissue sections at aphid feeding sites was compared with expression in similar-sized leaf tissue sections from non-feeding sites in the same plants at 1, 3, 6, and 24 hpi. Using a previously developed RT-PCR protocol for the *D. noxia*-wheat system (Smith et al., 2010), there were two biological replicates for each set of tissues. Each replicate consisted of tissues pooled from 3 plants and two technical replicates for each genotype–tissue–post-infestation time combination sampled. Total RNA then was extracted from plant tissue sections using TRI reagent (Molecular Research Center Inc, Cincinnati, OH, USA) following the manufacturer's protocol. RNA quality and concentration were determined with a NanoDrop™ 1000 spectrophotometer (Thermo Scientific, Wilmington, DE, USA). After purification using TURBO™ DNA-free (Ambion, Austin, TX, USA), 5 μg of total RNA were reverse transcribed into cDNA with a SuperScript III First-Strand cDNA Synthesis System (Invitrogen, Carslbad, CA, USA) following the manufacturer's protocol. Diluted (20x) cDNA and iQ™ SYBR Green Supermix (BIO-RAD) were amplified by Real-Time PCR (RT-PCR). The reaction was prepared in a 25-μl final mixture containing 12.5 μl 2X Supermix (2X reaction buffer with dNTPs, iTaq DNA polymerase, 6 mM $MgCl_2$, SYBR Green 1, fluorescein, stabilizers); 10.5 μl cDNA; and 10 μM forward and reverse primers and performed under the following protocol: 5 min denaturation at 95°C, 40 cycles of 20 sec at 95°C, 20 sec at 58°C, and 30 sec at 72°C. Comparisons of product melting curves were used to confirm that each reaction generated a single PCR product.

On the basis of wheat expressed sequence tag sequences from GenBank, RT-PCR primers for SA and JA pathway genes, metabolism genes, and a cellulose synthase gene (Zhu et al., 2008) were designed using Beacon Designer software (Table 1). Wheat actin (AB181991) was used as an internal control. Genes tested for the involvement of SA in resistance included the shikimate pathway genes chorismate mutase (*CM*) and isochorismate synthase (*ICS*), involved in SA synthesis (Wildermuth et al., 2001); the phenylpropanoid pathway gene phenylalanine ammonia lyase (*PAL*), also involved in SA synthesis; and the SA marker pathogenesis-related 1 protein (*PR1*). Jasmonate pathway genes tested were Ω-3 fatty acid desaturase (*FAD*), which produces an 18:3 fatty acid precursor, lipoxygenase (*LOX*), allene oxide cyclase (*AOC*), allene oxide synthase (*AOS*), and 12-oxophytodienoate reductase (*12-OPR*).

Cellulose, a strengthening component of plant cell walls, is produced by a family of cellulose synthases (CES) (Scheible et al., 2001). Two members of the family (*CslA*, *CSLD2*) are upregulated in incompatible wheat interactions with either *M. destructor* or *D. noxia* (Liu et al., 2007; Smith et al., 2010). Ellis et al. (2002b) proposed that cellulose synthesis inhibition activates JA-dependent stress responses. *CES* expression was evaluated to determine its role in plant defense responses to *D. noxia* feeding and the relationship, if any, between *CES* expression and JA pathway gene expression.

Sixteen genes from the glycolysis, tricarboxylic acid (*TCA*), pentose phosphate, and amino acid synthesis pathways were examined. Glycolysis pathway genes examined were fructose 1-,6-biphosphate aldolase (*ALD*), glyceraldehyde-3-phosphate

Table 1 Primer sequences used to amplify selected defense response signaling pathway genes in wheat in response to feeding by the Russian wheat aphid, *Diuraphis noxia*

Accession	Gene name (abbreviation)	Primer sequences

dehydrogenase-like gene (*G3PDH*), cytosolic phosphoglycerate kinase (*PGK*), phosphoglycerate mutase (*PGM*), enolase (ENOL), and cytosolic pyruvate kinase (*PK*). TCA cycle genes evaluated were cytosolic malate dehydrogenase (*MD*), NAD^+-dependent isocitrate dehydrogenase (*ICD*), succinate dehydrogenase (*SD*), and α-ketoglutarate dehydrogenase (*OD*). Plastid enzymes $NADP^+$-dependent malic enzyme (*ME*) and phosphoenolpyruvate carboxylase (*PEPC*), and glucose-6-phosphate dehydrogenase (*G6PD*), a component of the pentose phosphate pathway, also were examined. Amino acid synthesis pathway genes evaluated were glutamine synthetase (*Gln-S*), pyrroline-5-carboxylate synthetase (*P5CS*), and methionine synthase (*Met-S*). Accession numbers, names, and functions of genes and their primer sequences are listed in Table 2.

Relative gene expression levels were determined as described by Pfaffl (2001). For ease of comparison, fold change values were converted to log2 values by using the $2^{-\Delta\Delta Ct}$ method (Livak and Schmittgen, 2001). Differences between control and experimental groups were measured as relative values, and relative values greater than 1.5 fold in difference were considered biologically significant. Data for each gene were subjected to ANOVA using the SAS GLM procedure (SAS 2001). Significant treatment means were separated using the LSD at $P=0.05$.

Results

Salicylate Pathway Expression of ICS, an enzyme of the isochorismate branch of the SA pathway, decreased steadily in both plant-biotype interactions from 1 to 72 hpi (Fig. 1) except at 1 hpi in the incompatible interaction. The decrease was more pronounced in the compatible interaction; the 1.1-fold upregulation at 1 hpi and (−) 0.1-fold downregulation at 3 hpi were significantly greater than the (−) 1.1-fold downregulation at 72 hpi. In the incompatible interaction, differences were significant only between 1 hpi [(−) 0.3 fold] and 6 hpi [(−) 1.3 fold]. With the exception of the 1 hpi time interval, there were no significant differences in ICS expression between compatible and incompatible interactions.

In contrast to ICS, the SA-signaling downstream protein PR1 displayed an increasing temporal expression pattern that shifted from downregulation at 1, 3, and 6 hpi to upregulation at 24 and 72 hpi (Fig. 1). There were no significant differences in expression between compatible and incompatible interactions at any time point, but PR1 was significantly ($P<0.05$) more upregulated at 72 hpi than at all other time points in the incompatible interaction and significantly more upregulated at 72 hpi than at 1 or 6 hpi in the compatible interactions (Fig. 1). There were no significant differences in expression of CM, a second isochorismate SA pathway enzyme, in either plant-biotype interaction at any time point. All changes in expression levels were different by less than 1.5 fold (data not shown).

Expression of PAL, an enzyme in the phenylpropanoid branch of the SA pathway, was upregulated in both compatible (2.7 to 5.2 fold) and incompatible (4.4 to 5.8 fold) interactions at aphid feeding sites (Fig. 2). However, there were no significant differences between any time point or interaction comparisons.

Jasmonate Pathway Expression of FAD was upregulated in both incompatible (3.3 fold to 4.4 fold) and compatible (2.0 to 3.4 fold) interactions in tissues sampled from aphid feeding sites. However, differences in expression at each post-infestation time point were not significant (Fig. 2). Expression of LOX was not different over time within either compatible or incompatible interactions, but LOX upregulation was significantly ($P<0.05$) greater in incom-

patible interactions than in compatible interactions at both 3 and 6 hpi (Fig. 2).

AOS also was more upregulated in incompatible interactions (3.1 to 6.8 fold) than in compatible interactions (0.5 to 3.3 fold) across all post-infestation time points, and these differences were significant ($P<0.05$) at 6 and 24 hpi (Fig. 2). Within interactions, there were no differences in AOS expression in compatible interactions; however, in incompatible interactions, significantly more AOS was produced at 6 hpi than at 1 hpi. AOC demonstrated a similar pattern of expression. At 3, 6, and 72 hpi, upregulation in incompatible interactions (3.5, 3.7, and 0.9 fold, respectively) was significantly ($P<0.05$) greater than in compatible interactions (1.1, 1.7, and −1.1 fold,

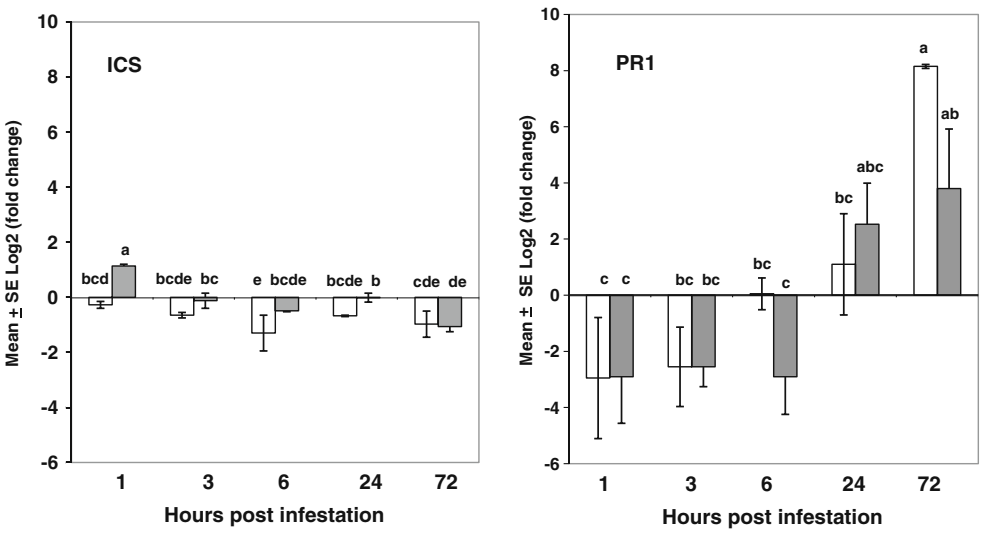

Fig. 1 Mean ± SE log2 (fold change) expression of wheat SA synthesis and SA-related genes induced by *Diuraphis noxia* feeding at 1, 3, 6, 24, and 72 h post infestation. White bars represent incompatible interactions; gray bars represent compatible interactions. ICS - Isochorismate synthase protein; PR1 - Pathogenesis-related protein. Means with a different letter differ significantly at $\alpha = 0.05$

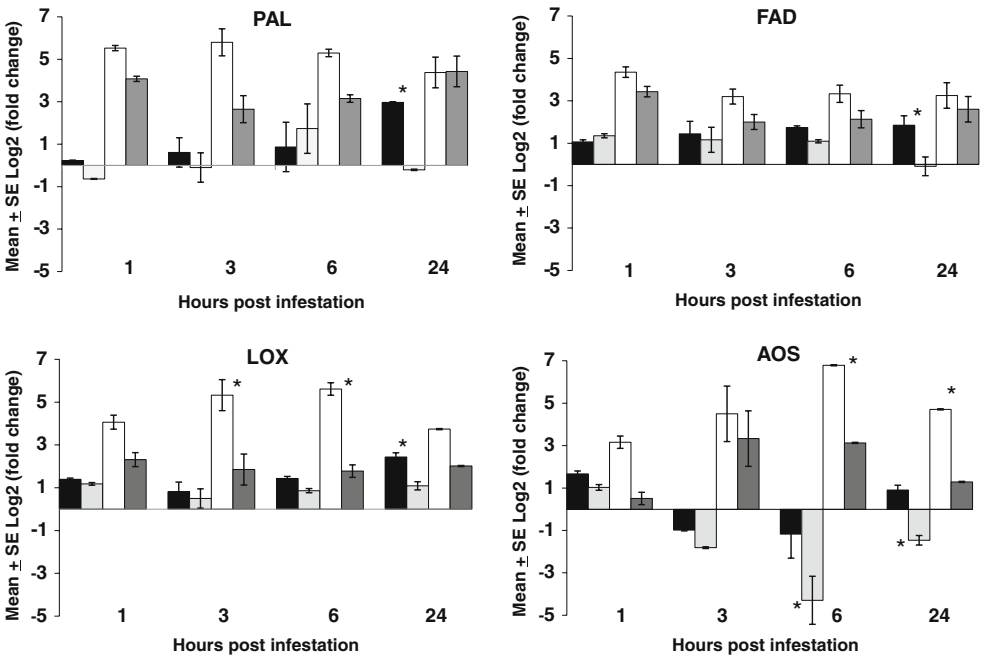

Fig. 2 Mean ± SE log2 (fold change) expression of wheat signaling genes at feeding sites and non-feeding sites of plant tissues from *Diuraphis noxia* compatible and incompatible interactions collected at 1, 3, 6, and 24 h post infestation. Black bars - non-feeding site tissues, incompatible interactions; light gray bars - non-feeding site tissues, compatible interactions; white bars - feeding site tissues, incompatible interactions; dark gray bars - feeding site tissues, compatible interactions. PAL - Phenylalanine ammonia lyase; FAD - Ω-3 fatty acid desaturase; LOX- Lipoxygenase; AOS - Allene oxide synthase. *=Treatment differences in mean expression within each feeding site or non-feeding site tissue comparison at each post infestation time differ significantly at $\alpha = 0.05$

respectively) (data not shown). Within incompatible interactions, expression was significantly greater at 3 and 6 hpi than at 24 or 72 hpi, and within compatible interactions, AOC expression was significantly greater at 1, 3, and 6 hpi than at 72 hpi (data not shown).

12-OPR was upregulated 1.9 to 3.9 fold in both incompatible and compatible interactions, but there were no significant differences in expression between time points or interactions (data not shown). Expression of CES was upregulated in both interactions at all post-infestation time points; within interactions there were no significant differences in expression at any time point. Upregulation was significantly ($P<0.05$) greater in the incompatible interaction (5.3 fold) than in the compatible interaction (1.3 fold) at 24 hpi (data not shown).

Gene Expression at Feeding Sites and Non-feeding Sites In general, expression of PAL, FAD, LOX, and AOS was much higher at *D. noxia* feeding sites than at non-feeding sites in both incompatible and compatible interactions (Fig. 2). As indicated previously, PAL expression at *D. noxia* feeding sites did not differ between incompatible and compatible interactions. Within each interaction, there were no significant differences in PAL expression in non-feeding site tissues between post-infestation times. However, PAL expression in non-feeding site tissues was significantly greater in incompatible interactions than in compatible interactions at 24 hpi (Fig. 2). FAD expression was similar to that of PAL, declining approximately 1 fold from 1 to 24 hpi (Fig. 2), and as indicated previously, expression in feeding site tissues did not differ. However, in non-feeding site tissues, FAD was significantly more upregulated in compatible interactions than in incompatible interactions at 24 hpi (Fig. 2).

The trend in LOX and AOS expression in feeding and non-feeding site tissues differed from that of PAL and FAD (Fig. 2). At *D. noxia* feeding sites, LOX upregulation peaked at significantly greater levels in incompatible interactions than in compatible interactions at 3 and 6 hpi (Fig. 2). In non-feeding site tissues, the trend in LOX expression was similar to that of PAL and FAD, with significantly greater expression between interactions occurring at 24 hpi. Further, at 24 hpi, there were no significant differences between LOX upregulation in non-feeding sites tissues of incompatible interactions and feeding sites tissues of compatible interactions (Fig. 2).

AOS expression in feeding site and non-feeding site tissues was similar to that of LOX (Fig. 2), with significantly greater upregulation in feeding site tissues in incompatible interactions than in compatible interactions at 6 and 24 hpi. In non-feeding sites tissues, AOS was significantly downregulated at 3 and 6 hpi within incompatible interactions compared with 1 and 24 hpi. Within compatible interactions, downregulation was significant only at 6 hpi. As with PAL, FAD, and LOX, AOS expression in non-feeding site tissues was significantly greater in incompatible interactions than in compatible interactions at 24 hpi. The significant increase of AOS in non-feeding sites tissues in incompatible interactions at 6 hpi was unique among the four signaling genes assayed.

Glycolysis Pathway In contrast to SA- and JA-signaling pathway genes, expression of all glycolysis pathway genes in feeding site tissues was greater in compatible interactions

than in incompatible interactions. Expression of PGM and PK was significantly more upregulated or less downregulated in compatible interactions than in incompatible interactions. PGM expression was greater at 6 and 72 hpi, whereas PK expression was greater at 24 and 72 hpi (Fig. 3). There were also within-interaction differences in expression of both genes. Although PGM expression in incompatible interactions was similarly downregulated at all time points, expression in compatible interactions was significantly upregulated at 6, 24, and 72 hpi compared with 1 hpi (Fig. 3). PK expression within incompatible interactions was also downregulated at all time points, and downregulation was significantly greater at 72 hpi than at 1 or 3 hpi (Fig. 3). In contrast, there were no differences in PK expression over all time points within compatible interactions (Fig. 3). In non-feeding site tissues, PGM and PK expression did not differ between interactions (data not shown).

Tricarboxylic Acid Cycle Pathway The trend in gene expression in the TCA cycle in feeding site tissues was downregulation during the early and late stages of *D. noxia* feeding and upregulation or decreased downregulation at 3 and/or 6 hpi. Downregulation was greatest for all genes at 72 hpi. There were no differences in expression either within or between interactions for ICD, MD, OD, and PEPC (data not shown). ME expression was significantly greater in incompatible interactions at 3 hpi than at 1, 24, or 72 hpi (Fig. 3). There were no differences in ME expression between the two interactions at all time points except 72

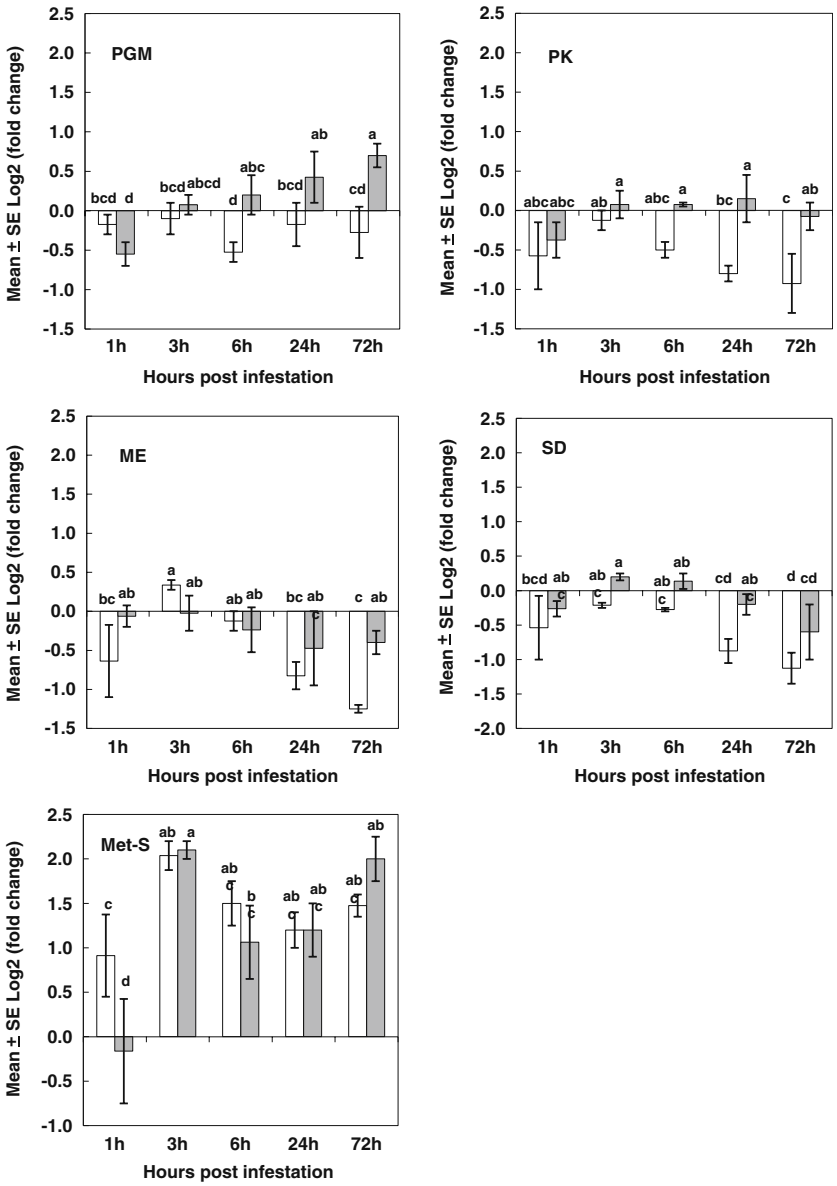

Fig. 3 Mean ± SE log2 (fold change) expression of glycolysis, tricarboxcylic acid, and amino acid synthesis genes induced by *Diuraphis noxia* feeding at 1, 3, 6, 24, and 72 h post infestation. White bars represent incompatible interactions; gray bars represent compatible interactions. Glycolysis - PGM (phosphoglycerate mutase), PK (cytosolic pyruvate kinase); Tricarboxcylic acid - ME (NAD^+ dependent malic enzyme), SD (succinate dehydrogenase); Amino acid - Met-S (methionine synthase). Means with a different letter differ significantly at $\alpha = 0.05$

hpi, when downregulation in incompatible interactions was greater than that in compatible interactions. SD expression did not differ between interactions at any time point, but within both interactions, expression was significantly greater at 3 and 6 hpi than at 72 hpi (Fig. 3). SD expression in tissues from non-feeding sites followed a similar trend in both interactions (data not shown).

Pentose Phosphate Pathway The pentose phosphate pathway gene G6PD was significantly more upregulated at 3 hpi (1.14 fold) than at 72 hpi ([−] 0.15 fold) in feeding site tissues in incompatible interactions (data not shown). There were no differences between any other time points or between either interaction at any post-infestation time points in non-feeding site tissues.

Methionine Synthase Synthesis Met-S upregulation increased significantly from 1 hpi to 3, 6, 24, and 72 hpi in compatible interactions and from 1 to 3 hpi in incompatible interactions (Fig. 3). At 1 hpi, Met-S expression was significantly greater in the incompatible interaction than in the compatible interaction. There were no differences in Met-S expression among treatments in tissues collected from non-feeding sites. Differences in expression levels of Gln-S and P5CS in tissues from both feeding and non-feeding sites were nonsignificant, both within and between interactions (data not shown).

Discussion

ICS and PAL participate in production of SA through conversion of chorismate in different branches of the salicylate pathway (Lee et al., 1995; Wildermuth et al., 2001). One branch involves ICS-catalyzed conversion of chorismate to isochorismate, and a second brings about conversion of phenylalanine to *trans*-cinnamic acid and benzoic acid via PAL. The lack of upregulation of ICS in either compatible or incompatible interactions at any time point suggests the isochorismate branch does not function in SA production in wheat in response to *D. noxia* feeding. Liu et al. (2007) reported similar results in wheat plants resistant to larvae of the Hessian fly, *Mayetiola destructor* (Harris). The early (1 to 6 hpi) expression of PAL at feeding sites involved in both compatible and incompatible interactions (Fig. 2) also suggests a lack of involvement of SA in wheat in resistance to *D. noxia* feeding. Finally, the delay in a significant increase in PR1 gene expression in incompatible interactions until 72 hpi suggests that PR1 is of limited importance in wheat defense responses to *D. noxia* feeding.

Although LOX, AOS, AOC, and CES were all significantly more upregulated in incompatible than in compatible interactions after *D. noxia* infestation, FAD expression, also often associated with JA synthesis, was no different between incompatible and compatible interactions. FAD and LOX are uniquely upregulated in incompatible interactions involving the wheat *Dnx* gene and *D. noxia* biotype 1 (Boyko et al., 2006; Smith et al., 2010). The absence of FAD expression may be related to the fact that in the present study, *D. noxia* interactions were compared using plants containing the *Dn4* resistance gene, not *Dnx*. Furthermore, Turner et al. (2002) determined that wound-induced JA production is regulated by the amount of substrate available to AOS. In incompatible interactions in our experiments, infested plants sustained minimal foliar damage, suggesting that reduced foliar chloroplast damage limited the release of fatty acids from chloroplast lipids for JA metabolism. Finally, plant mechanisms providing initial stimulation of the JA pathway remain largely unknown. However, factors such as SA-induced protein kinases and cell wall fragments now are known to activate production of various forms of methyl jasmonate (Howe and Jander, 2008; Bonaventure and Baldwin, 2010).

Microarray and related gene expression studies reveal differential expression of SA- and JA-signaling pathway genes in plants in response to biotic stress, as well as cross-talk between these and other defense response signaling pathways (Koornneef and Pieterse, 2008). However, our results fit insect herbivore-induced JA-signaling pathway models (Kessler and Baldwin, 2002; Howe and Jander, 2008) and demonstrate that several genes involved in methyl jasmonate synthesis play a major role in the very early events of wheat plant defense response signaling in response to *D. noxia* herbivory. In contrast, we found little evidence of the involvement of SA signaling in wheat plants in response to *D. noxia* feeding damage.

Diuraphis noxia feeding resulted in significant increases in expression of LOX (3 and 6 hpi) and AOS (6 and 24 hpi) in feeding site tissues collected from incompatible interactions compared to feeding site tissues from compatible interactions (Fig. 2). Similar response trends were not apparent in PAL or FAD expression. However, in non-feeding site tissues, PAL, FAD, and LOX expression in incompatible interactions did not increase significantly until 24 hpi. Increased AOS expression in non-feeding site tissues also occurred earlier, at 6 hpi. The lack of differences in PAL, FAD, and LOX expression in feeding site tissues at 24 hpi coupled with the significantly increased expression of these same genes and AOS in non-feeding site tissues at 24 hpi suggests that a systemic wheat leaf defense response signal may be transmitted from tissues damaged by *D. noxia* feeding to undamaged tissues within 24 hpi.

Li et al. (2002) demonstrated the existence of a mobile wound signal in tomato requiring JA perception for its

recognition in unwounded tissues, and Zhu et al. (2008) determined that wheat gene response to *M. destructor* larval herbivory is localized in both compatible and incompatible interactions. Future experiments measuring JA pathway gene expression in both feeding site and non-feeding site tissues at 24 hpi and beyond will be required to determine if such a mobile wound signal exists in wheat plants responding to *D. noxia* feeding.

Aphid feeding is known to enhance the plant nutrient "source-sink" by altering amino acid composition and level in host plant tissues (Telang et al., 1999; Forslund et al., 2000). However, in incompatible interactions, removal of amino acids and carbohydrates by *D. noxia* during source-sink rearrangements of feeding site tissues appears to be negated by the reduced plant upregulation of glycolysis and TCA cycle genes (Fig. 3) and upregulation of signaling genes in non-feeding site tissues on the same leaves (Fig. 2).

The level and pattern of expression of signaling genes differed from those of metabolic pathway genes in wheat plants responding to *D. noxia* attack. Upregulation of the jasmonate intermediates LOX, AOS, and AOC ranged from approximately 3 to 7 fold in incompatible interactions but upregulation was lower (approximately 2.5 to 3.5 fold) in compatible interactions. Similarly, CES was upregulated more (4 to 7 fold) in incompatible interactions than in compatible interactions (1 to 3.5 fold).

The trend and range of expression of glycolysis and TCA cycle genes were different from JA-signaling pathway genes. Expression of glycolysis and TCA genes (1.5 to 2 fold) was comparatively much less than JA pathway genes. In addition, PGM, PK, and ME were downregulated in incompatible interactions and upregulated in compatible interactions - a trend opposite to that observed in expression of JA pathway genes (Fig. 3). The upregulation of the PGM and PK glycolysis genes in compatible interactions increased degradation of sugars and other carbohydrates, likely resulting in stunted growth and development of susceptible plants. Zhu et al. (2008) noted similar results in incompatible interactions between wheat plants and *M. destructor* larvae.

One of the objectives of our experiments was to contrast patterns of expression of genes in signal pathways to those in metabolic pathways, in order to draw inferences about relationships between these pathways. Our results and those of others (Botha et al., 2006; Zhu et al., 2008) indicate that in gene expression studies conducted to date involving incompatible plant-insect interactions, plant carbon and nitrogen metabolism genes are initially downregulated and eventually upregulated days after infestation. In contrast, defense signaling genes are often highly upregulated in the initial hours after infestation, with expression declining continually over the course of 1 to 2 days after initial insect herbivory. Thus, this relationship between signaling and metabolic genes in wheat plants resistant to *D. noxia* appears to allow plant metabolism to slow down for several hours in order to expend the energy required to produce chemical and physical defenses resulting from defense response signal cascades.

Very early events occurring during interactions between aphids and host plants are poorly understood, especially incompatible interactions involving biotype or race-specific resistance (Thompson and Goggin, 2006). However, results of Lazzari et al. (2009) indicated that sustained ingestion of wheat phloem by *D. noxia* occurs within 1 h after initiation of feeding probes during compatible interactions and within 2 h after the beginning of feeding in incompatible interactions. Couldridge et al. (2007) demonstrated the expression of *Arabidopsis* esterase and extracellular glycoproteins in compatible interactions with the green peach aphid, *Myzus persicae* (Sulzer) at 2 hpi. Nevertheless, plant gene expression in response to aphid feeding during incompatible interactions has not been demonstrated to occur prior to 6 hpi (Li et al., 2008; as reviewed by Smith and Boyko, 2007). Thus, our results are of major significance because they are the first report of differential upregulation of plant signaling (LOX, AOC) and metabolism (Met-S) genes at 1 or 3 hpi in incompatible interactions involving aphid herbivory. Early defense responses of wheat plants in incompatible *D. noxia* interactions appear to be a very important aspect of *D. noxia* resistance in wheat.

Acknowledgments We thank Murugan Marimuthu and Paola Sotelo for helpful comments in discussion of the data and Ming-Shun Chen and Subbarat Muthukrishnan for critical reviews of an early draft of the manuscript. This research was supported by grants to CMS from the Kansas Wheat Commission, the USDA CSREES NC-IPM program and the Kansas Agricultural Experiment Station. This is contribution No. 10-304-J of the Kansas Agricultural Experiment Station. This research was performed in the Gene Expression Facility at Kansas State University, which is supported through the National Science Foundation grant, DBI 0421427.

Abstract Trimedlure is the most effective male-targeted lure for the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann). A similar response is elicited by plant substances that contain α-copaene, a naturally-occurring sesquiterpene. α-Copaene is a complex, highly-volatile, widely-distributed plant compound, and male *C. capitata* respond to material from both hosts (e.g., *Litchi chinensis*) and non-hosts (e.g., *Ficus benjamina*) that contain α-copaene. Avocado, *Persea americana*, recently was found to contain varying amounts of α-copaene in the bark and underlying cambial tissue. Short-range attraction bioassays and electroantennography (EAG) were used to quantify responses of sterile male *C. capitata* to samples of rasped wood from four avocado genotypes, *L. chinensis*, and *F. benjamina*. Gas chromatography-mass spectral (GC-MS) analysis was used to identify and quantify the major sesquiterpenes. Attraction and EAG amplitude were correlated, with *L. chinensis* eliciting the highest and *F. benjamina* the lowest responses. Responses to the avocado genotypes were intermediate, but varied among the four types. GC-MS identified 13 sesquiterpenes, including α-copaene, from all samples. Amounts of α-copaene in volatile collections from samples (3 g) ranged from 11.8 μg in *L. chinensis* to 0.09 μg in *F. benjamina*, which correlated with short-range attraction and EAG response. α-Copaene ranged from 8.0 to 0.8 μg in the avocado genotypes, but attraction and EAG responses were not correlated with the amount of α-copaene. Differences in enantiomeric structure of the α-copaene in the different genotypes and/or presence of additional sesquiterpenes may be responsible for the variation in male response. EAG responses were correlated with the amount of several other sesquiterpenes including α-humulene, and this compound elicited a strong antennal response when tested alone.

Key Words *Ceratitis capitata* · *Persea americana* · *Litchi chinensis* · *Ficus benjamina* · α-Copaene · Electroantennography · Bioassays · Diptera · Tephritidae

Introduction

The Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann), is considered the most polyphagous tephritid fruit fly species due to its broad range of host plants, primarily tropical and subtropical fruits and vegetables (Liquido et al., 1990). For this reason, *C. capitata* is presently ranked first among economically important fruit fly pests due to both damage to crops and costs of eradication (Hagen et al., 1981). This pest is established in Hawaii, and *C. capitata* outbreaks have occurred periodically in the continental US, including California and Florida. Rapid responses to these outbreaks led to declarations of eradication (Carey, 1996). Costs due to the 1980 California infestation included $59 million for chemical control, $38 million for quarantine and fumigation, $260 million in crop losses, plus an additional one-time cost of $497 million for construction of fumigation facilities (Burk and Calkins, 1983). It is estimated that it cost $26 million to eradicate the 1997 infestation in Tampa, FL (Stewart and Johanson, 1999). Highly effective detection and

monitoring systems along with weekly release of sterile males are important components of the preventative release program that has been established for *C. capitata* control and eradication (Dowell et al., 2000).

Jackson traps baited with trimedlure are the standard male-targeted traps for *C. capitata* (IAEA 2003). Trimedlure is a synthetic chemical that is highly attractive to males (Beroza et al., 1961). Trimedlure is not an insect-produced chemical nor has it been found in nature. Functionally, it acts as a pheromone that attracts sexually mature males, and has been coined a parapheromone (Cunningham, 1989). Natural substances have been found that attract male *C. capitata*, including angelica seed oil, which was used to bait traps during the *C. capitata* eradication in Florida in the 1950s (Steiner et al., 1957). The sesquiterpene α-copaene (8-isopropyl-1,3-dimethyl-tricyclo[4.4.0.0(2,7)]dec-3-ene) is the chemical found to be primarily responsible for this response, although other co-occurring chemicals may contribute to attraction (Jacobson et al., 1987). α-Copaene is a widely-distributed plant compound, and is found in many essential oils in addition to angelica seed oil (Flath et al., 1994a). While α-copaene is reported to be 2 to 5 times more attractive than trimedlure, difficulties in obtaining α-copaene in quantities sufficient for large scale trap deployment have prevented its use as field lures (Cunningham, 1989). Its concentration in natural substances generally is very low, and so there are no convenient plant extracts available as a practical source for this chemical (Flath et al., 1994b). The major problem with artificial synthesis of α-copaene lies in the chiral complexity of its 15-carbon structure, which makes synthesis not economically viable (Heathcock, 1966; Heathcock et al., 1967; Corey and Watt, 1973; Flath et al., 1994b). Essential oils containing α-copaene have been found to increase mating competitiveness of males that have been previously exposed to it, an approach termed aromatherapy since the males do not have to contact the oil to gain the benefit (Shelly, 2001a; Shelly et al., 2004). A recent study by Kouloussis et al. (2011) demonstrated that a mixture of volatile chemicals from citrus species (geraniol, α-pinene, limonene, β-myrcene, and linalool), which do not contain α-copaene, also increased the mating success of male medflies.

Male *C. capitata* responding to synthetic parapheromones or essential oils containing α-copaene tend to land near to but not make contact with the attractant (Steiner, 1957; Shelly et al., 2004). McInnis and Warthen (1988), however, observed that male *C. capitata* were attracted to and fed on the milky sap (latex) present in *Ficus benjamina* L., a non-host tree that they were using in research on mating behavior. In a survey of exudates from leaves and/or stems of 50 trees, they found levels of short-range attraction/feeding to exudates from *Litchi chinensis* Sonn., a *C. capitata* host, equal to responses to α-copaene purified from angelica seed oil and to trimedlure. Similar observations were made in field cage tests in which males aggregated and fed on the bark of some guava trees (*Psidium guajava*), but not all (active and inactive trees, respectively; Shelly and Villalobos, 2004). Chemical analysis found higher concentrations of α-copaene in active trees than in inactive trees. Males on active trees were observed to flatten their body against the bark and rapidly move their mouthparts up and down, frequently contacting the bark. Natural sources of α-copaene elicit a wide array of behaviors from male *C. capitata*. Studies of natural α-copaene sources may help determine the role of these phytochemicals in fruit fly biology as well as to quantify behavioral differences due to concentration of these chemicals (typically much lower in natural substrates vs. synthetic lures) and/or due to co-occurring chemicals (Raghu, 2004).

As part of a study on sesquiterpene content of tree bark and underlying cambial tissue, we found that avocado, *Persea americana* Mill., contained α-copaene and that levels were highly variable among different genotypes (R. R.H. unpublished data). Therefore, studies were conducted to determine if the α-copaene from *P. americana* is biologically active for male *C. capitata* and to evaluate the relationship between fruit fly response and sesquiterpene content. In addition to tests of avocado trees, studies were conducted with *L. chinensis* and *F. benjamina*, substrates that have been shown to be biologically active (McInnis and Warthen, 1988). We tested response of male *C. capitata* using short-range bioassays and electroantennography (EAG), and we quantified the sesquiterpene content. Information from this research will be used to further understand the role of phytochemicals in the biology of this fruit fly.

Methods and Materials

Insects Sterile male *C. capitata* were obtained from the Moscamed mass rearing facility (El Pino, Guatemala), where they were irradiated as pupae 2 d prior to emergence with 95 Gy of gamma radiation from a Co^{60} source. These are the temperature sensitive lethal strain flies (Franz, 2005) that are used for the preventative release program (Dowell et al., 2000), thus only males were obtained, and only virgin males were used for testing. Irradiated pupae were shipped initially to the USDA-APHIS Medfly Project (Sarasota, FL, USA), and then to the ARS Subtropical Horticulture Research Station (SHRS) in Miami, FL, USA. Holding conditions at SHRS consisted of a 12/12 h L/D photoperiod, 25±2°C, and 75±5% RH. After eclosion, adult flies were maintained in rearing cages (185×185×185 mm, ~100 flies per cage; BioQuip) and provided with water (agar blocks) and food (4:1 mixture of cane sugar and

yeast hydrolysate) *ad libitum* until collected for laboratory experiments. Flies used for all studies were 5 to 10 d-old and were sexually mature.

Sample Preparation Trees evaluated were *P. americana* (avocado, Lauraceae), *L. chinensis* (lychee, Sapindaceae), and *Ficus benjamina* (weeping fig, Moraceae) obtained from the USDA germplasm collection at the Subtropical Horticulture Research Station, Miami, FL. Samples were collected from six trees: 1-3) three half-sibling avocado trees (open pollinated seedlings), 14 yr-old (PAM 1-3), mother West Indian/Guatemalan hybrid cv. Melendez, father(s) unknown; 4) one Mexican race avocado cv. Seedless Mexican (PAMEX), 79 yr-old; 5) one *L. chinensis*, 78 yr-old; and 6) one *F. benjamina,* 77 yr-old. Samples were obtained by manually rasping the outer layers from freshly-cut tree branches (4.4±0.6 cm diam), which included bark and cambial tissue (defined as the lateral meristem including the vascular cambium and cork cambium in vascular plants, which carries the secondary metabolites). All samples were tested within 24 h of collection.

Binary Choice Tests Bioassays were performed to quantify the short-range attraction of sterile male *C. capitata* to samples using a modified version of the binary choice tests used by McInnis and Warthen (1988). All observations were carried out at room temperature as described above in rearing cages into which about 40 flies (average of 31 to 54 flies depending on the bait attractiveness) were introduced 1 h prior to the start of each experiment. Choice tests were initiated by introducing two Petri dishes (53 mm diam., 12 mm height) with substrates (sample bait or blank) positioned symmetrically (90 mm distance between the centers). After 15 min, the number of flies at each dish was recorded. Experiments were replicated four times, and the position of substrates reversed between replicates. Flies and Petri dishes were used only once, and cages were washed with acetone between experiments to eliminate potential residual chemicals. The attraction of each bait was tested initially against a blank (Petri dish with a cotton ball; 311 flies tested) before testing all possible two-at-a-time bait combinations (bait 1 vs. bait 2) (2336 flies tested).

Electroantennography EAG responses were recorded with a Syntech® system (Hilversum, The Netherlands) using methods described previously (Kendra et al., 2005). Test substrates were prepared by placing rasped samples (10 g) into hermetic bottles (250-ml) fitted with septum port lids. Samples were allowed to equilibrate overnight at 24°C to reach saturation. Freshly dissected antennal preparations were mounted between micropipette electrodes using conductive gel (Spectra 360; Parker Laboratories, Fairfield, NJ, USA) and placed under purified air flow. Using gas-tight syringes (VICI Precision Sampling, Baton Rouge, LA, USA), 2 ml samples of saturated vapor were withdrawn from the sample bottles, injected into the airstream, and presented to the antennae. There was a 2 min interval of clean air flow between sample injections to prevent antennal adaptation. EAG responses were measured initially in millivolts (peak height of depolarization) and then normalized to percentages relative to a standard reference sample, 100 µl 2-butanone saturated vapor (99% pure; Sigma-Aldrich, St. Louis, MO, USA) using EAG 2000 software. Normalization corrected for time-dependent variability in antennal performance, and all statistical analyses were conducted using normalized responses. For each sample, EAG responses were recorded from 5–10 insects, and response from each insect was the mean of three replicate measurements.

EAG response to α-humulene (>98% pure, Sigma-Aldrich, St. Louis, MO, USA) was tested as above. Test samples consisted of volumetric doses ranging from 125–4000 µl saturated vapor delivered as a series of two-fold increases in headspace volume. EAG responses were recorded from 10 insects, and response from each insect was the mean of three replicate measurements.

Gas chromatographic (GC)-EAD responses were recorded using Syntech® GC-EAD 2000 software (Hilversum, The Netherlands). One microliter samples of volatile collections from rasped samples from *L. chinensis* were injected into an HP6890 GC equipped with an Alltech Associates, Inc. column (Deerfield, IL, USA; 30 m EC-5, 320 µm diam, 25 µm film thickness) equipped with a 1:1 effluent splitter that allowed simultaneous FID and EAD detection of the separated volatile compounds. Helium was used as the gas carrier (1.2 ml. min^{-1}), and the injector was set at 250°C. Oven temperature was programmed from 50–130°C at 10°C. min^{-1} and from 130–220°C at 15°C. min^{-1}, then held at 220°C for 2 min. The column outlet for the EAD was held in a water-cooled humidified air stream (20°C) over a *C. capitata* antennal preparation.

Chemical Collection and Analysis Volatile chemicals were collected from rasped branch samples (6 g, 3 replicates per tree) using traps with super-Q as the adsorbent (Analytical Research Systems, Inc., Gainesville, FL, USA) as previously described (Heath and Manukian, 1992; Heath et al., 1993). Samples were spread in a cylindrical glass chamber (4.5 cm diam., 25 cm length), purified air was introduced into the chamber (1 L per min), and headspace volatiles collected for 15 min. Collector traps were cleaned by Soxhlet extraction using methylene chloride for 24 h and dried in a fume hood prior to use. Volatile chemicals were eluted from the super-Q adsorbent using 200 µl of high purity methylene chloride (99.5% pure; ACROS, Morris

Plains, NJ, USA). An aliquot of C_{16} standard (5 μg) was added to each sample for quantitative analysis. All chemical sampling was performed within 2 h of collecting the branch material.

Chemical extracts were analyzed using a ThermoQuest 2000 Trace GC (Austin, TX, USA). The column used was a fused silica, 25 m long, 0.25 mm I.D, DB-5MS phase (J&W Scientific, Agilent Technologies, Santa Clara, CA, USA), programmed from 50–130°C at 15.0°C min^{-1}, then from 130–220°C at 10.0°C min^{-1} and held at 220°C for 4 min. The column used in the GC interface to the mass spectrometer (Agilent Technologies 5975B, Santa Clara, CA, USA) was 25 m long, 0.25 mm I.D, DB-5MS phase (J&W Scientific, Agilent Technologies, Santa Clara, CA, USA), programmed from 40°C held for 2 min, 40–130°C at 10.0°C min^{-1}, then from 130–220°C at 20.0°C min^{-1} and held at 220°C for 4 min. Chemicals were identified tentatively by using the NIST mass spectral (MS) program version 2.0 d and NIST/EPA/NIH mass spectral library (NIST05) when reverse matches and matches were >950 and 900‰, respectively. The average reverse match for all identified chemicals was 980±14‰. The Kovats Retention Indexes (RI) were compared with previously published data or with the RI calculated from synthetic chemicals when commercially available [RI=1358, 1391, 1442, 1477 for α-cubebene (Bedoukian Research Inc., Danbury, CT, USA), α-copaene (Fluka analytical, Stenheim, Germany), β-caryophyllene (Sigma chemical Co, St. Louis, MO, USA), and α-humulene (Sigma chemical Co, St. Louis, MO, USA), respectively].

Statistical Analysis Bioassay results were analyzed using *Chi-square* tests (Statistica® 6.0 Software) to determine differences in attraction between choices. Differences in EAG responses and chemical content of the substrates were evaluated using non parametric Kruskall Wallis tests followed by Mann-Whitney tests. For each chemical, both the percentage of flies attracted and the EAG responses were compared to the quantity of chemical per substrate using Pearson correlation tests (Statistica® 6.0 Software). Regression analysis was used to describe the relationship between α-humulene dose and amplitude of EAG response (SigmaPlot® 10). Results are presented as mean ± SD unless otherwise noted.

Results

Binary Choice Tests Male *C. capitata* were more attracted to the rasped wood sample than to the paired blank regardless of the source. Percentages of tested males that were attracted by the baits were 48, 52, 35, 46, 38, and 49% for *L. chinensis*, PAM 1, PAM 2, PAMEX, PAM 3, and *F. benjamina* (χ^2=18.18, 30, 21, 34, 10, and 13 compared to blanks respectively, $P<0.01$). In binary choice experiments, flies made clear choices over each pair presented (Table 1), and overall pattern of preference from most to least attractive was *L. chinensis*, PAM 1, PAM 2, PAMEX, PAM 3, and *F. benjamina*.

Electroantennography Comparative EAG measurements (Fig. 1a) indicated that there were significant differences in amplitude of antennal response to fixed doses of vapor from the six rasped branch samples (z=2.193; $P<0.05$). EAG responses were correlated with the fly's preferences obtained in the bioassays (r^2=0.857, $P<0.05$), following the same hierarchy. Highest EAG response was recorded from *L. chinensis*, lowest response from *F. benjamina*, with

Table 1 Attraction (Mean ± SD) of sterile male *Ceratitis capitata* in binary choice tests between 3 g rasped branch samples (baits) from *Litchi chinensis* (litchi), *Persea americana* 'melendez' hybrids (Pam 1-3), *P. americana* "seedless Mexican" (PAMEX), and *Ficus benjamina* (ficus). Fig. 1 **a**. Electroantennogram response (EAG) (mean ± SE) of sterile male *Ceratitis capitata* to fixed doses (2 ml saturated vapor) of volatiles emitted from 10 g rasped branch samples from *Litchi chinensis* (LITCHI), *Persea americana* 'Melendez' hybrids (PAM 1–3), *P. americana* 'Seedless Mexican' (PAMEX), and *Ficus benjamina* (FICUS). Responses were expressed as a percentage of the standard reference response (2-butanone). **b**. Quantity (mean ± SE) of α-copaene emitted from 6 g rasped branch samples, as determined by Super-Q collections and GC-MS analysis. Bars topped with the same letter were not significantly different (Mann-Whitney tests, $P<0.05$)

intermediate responses recorded from the various avocado samples. Among the avocado samples, EAG responses to PAM 1 and PAM 2 were significantly greater than response to PAM 3, with intermediate response to PAMEX.

Chemical Analysis A total of 51 volatile chemicals were isolated and identified by Super-Q collections and GC-MS analysis of the rasped wood samples. Of these, 13 compounds were found in common to all of the trees evaluated (Table 2). Chemical content (per gram) varied both qualitatively and quantitatively among the samples, with many of the chemicals detected only in trace amounts from *F. benjamina*.

EAG response was not correlated with the quantity of α-copaene emitted from the rasped wood samples (Table 2; $r^2=0.8036$, $P>0.05$; Fig. 1b) when results from all six trees were tested. Amount of α-copaene was highest in *L. chinensis* and lowest in *F. benjamina*, which was correlated with short-range attraction and EAG response. However, the lack of correlation was observed among the avocado samples, with low level response to PAMEX in spite of a high level of α-copaene. EAG response was correlated with the quantities of four other chemicals, all sesquiterpenes, specifically α-humulene (also known as α-caryophyllene) ($r^2=0.9341$, $P<0.01$), β-caryophyllene ($r^2=0.9261$, $P<0.01$), and both unidentified compounds (RI=1422, 1447) (suggested to be *cis*- and *trans*- enantiomers of α-bergamotene by the NIST library) ($r^2=0.8352$, $P<0.05$ and $r^2=0.691$, $P<0.05$, respectively). GC-EAD analyses were conducted to determine whether these chemicals elicited an antennal response. The analysis showed that α-copaene and α-humulene triggered the two main antennal responses.

α-Humulene was evaluated further by EAG. There was a relationship between dose of α-humulene and amplitude of EAG response, which was best fit by regression with a hyperbolic model (Fig. 2; $R^2=0.994$; $y=53.69x/0.30+x$; where x is the substrate dose in milliliters saturated vapor, and y is the normalized EAG response).

Discussion

Male *C. capitata* showed distinct preferences among the rasped branch samples in the laboratory bioassays. No calling behavior was observed in males responding to the samples, at least in the short time period of the bioassay, so males were responding to volatile chemicals from the rasped material. Attraction to these substrates was correlated directly with the amplitude of EAG responses. In combination, these results suggest that olfactory cues emitted from branches may play a role in location of trees where males are likely to encounter potential mates or in site selection for male aggregations. Males of *C. capitata* form mating aggregations, known as leks, which are by definition not resource-based. Leks are characterized by a loose aggregation of males performing sexual calling (pheromone emission) on the foliage of both host and non-host tree species (Steiner et al., 1957; Beroza and Green, 1963; Prokopy and Hendrichs, 1979; Whittier et al., 1992; Shelly and Whittier, 1996; Nishida et al., 2000; Shelly, 2004). Males hang on the undersurface of leaves, defending them as mating territories and displaying pheromone calling behaviors to attract potential mates (Arita and Kaneshiro, 1986). Olfaction has been shown to play a role in tree selection for lekking, but there are conflicting conclusions concerning male-produced aggregation cues (see Kaspi and Yuval, 1999; Shelly, 2001b). The nature of the olfactory cues used by male *C. capitata* for lek site selection remains elusive, and identification of

those volatile chemicals may provide a new approach for management of pest populations. Previous investigations have focused on α-copaene as a lekking cue (Nishida et al., 2000; Shelly et al., 2008). However, leks have been observed in both *L. chinensis* and *F. benjamina* (Whittier et al., 1992; Shelly and Whittier, 1996; Shelly, 2004), two trees that differ greatly in α-copaene content. Although not a preferred host, some avocado varieties are known to be susceptible to *C. capitata* (Back and Pemberton, 1918; Willard and Mason, 1929; Oi and Mau, 1989; De Graaf, 2009), but the amount of α-copaene in those varieties is unknown.

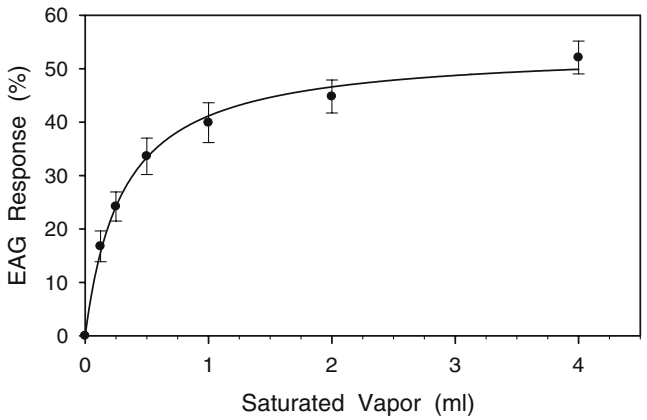

Fig. 2 Electroantennogram response (mean ± SE) and hyperbolic regression of sterile male *C. capitata* to a range of doses (saturated vapor) of α-humulene. Responses are expressed as a percentage of the standard reference response (2-butanone)

We identified 51 different volatile chemicals from these 6 trees. Among these secondary metabolites, 13 compounds were common in all the trees tested. These volatiles were mostly sesquiterpenes, which are widely spread in the plant kingdom and are often used by herbivorous or parasitoid insects to find their host trees. *Ceratitis capitata* is a generalist herbivorous pest attacking a wide range of hosts, more than 300 plant species (USDA, 1983). Thus, these flies may be attracted by one or a few volatile compounds better than by a mixture of several chemicals in a specific ratio. The amount of α-copaene in the rasped wood was not directly related with the fly preferences in our study. Indeed, flies showed less preference and lower antennal response for seedless Mexican (PAMEX) avocado, which released three times more α-copaene than another variety PAM 1. α-Copaene represented 31% of the sesquiterpenes in PAMEX but only 12% in PAM 1. There may be additional differences in isomeric and/or enantiomeric structures from the different trees that need to be evaluated further.

There were four sesquiterpenes for which the amount present was correlated with EAG response; specifically, α-humulene, β-caryophyllene, and two unidentified chemicals (RI=1422 and 1447). Beroza and Green (1963) reported β-caryophyllene as a *C. capitata* attractant, but Warthen and McInnis (1989) were unable to reproduce their results. It has been suggested that presence of α-copaene as a contaminant in their sample may explain the observed attraction (Cossé et al., 1995). Grové et al. (1998) subsequently showed that

male *C. capitata* were not attracted by β-caryophyllene in field tests. In our results, the amount of β-caryophyllene was much higher in PAMEX and PAM 3 than in PAM 2, the latter of which was one of the most attractive trees in this experiment. Thus, our study supports the hypothesis that β-caryophyllene is not a *C. capitata* attractant. The two other correlated chemicals were unidentified, but are suspected to be *cis*- and *trans*-α-bergamotene based upon NIST library matches. It was not possible to confirm the identification since α-bergamotene enantiomers were not available commercially, so they were not evaluated further; but additional studies were conducted with α-humulene.

α-Humulene is widely distributed in the plant kingdom (>40 families) and is known as an attractant for several insect families (Heteroptera: Pentatomidae and Pyrrhocoridae; Hymenoptera: Braconidae and Ichneumonidae; Coleoptera: Buprestidae, Cerambycidae, and Curculionidae; Lepidoptera: Torricidae; and Neuroptera: Chrysopidae) (Flint et al., 1979; Elzen et al., 1984; Ndiege et al., 1991; Farine et al., 1992; Hou et al., 1997; Weissbecker et al., 2000; Bedard et al., 2002; Carrasco et al., 2005; Crook et al., 2008; Yasui et al., 2008). This volatile chemical triggered a dose-dependent antennal response in sterile males, which reached a plateau at ~2 ml of saturated vapor. Hyperbolic equations have been shown to serve well for characterizing EAG dose-response relationships; the generic equation is expressed in the form $y=ax/b+x$, where the coefficients a and b indicate maximal EAG response (receptor saturation) and receptor binding affinity, respectively (Kendra et al., 2009). The normalized EAG response of *C. capitata* to α-humulene is much higher than the EAG response of *Anastrepha suspensa* (Loew) to putrescine (1,4-diaminobutane) (Kendra et al., 2008), a component of a synthetic attractant for this fruit fly. Although not attractive alone, putrescine has been shown to be a strong synergist to ammonium acetate for capture of both *A. suspensa* (Kendra et al., 2008) and *A. ludens* (Loew) (Heath et al., 1995, 2004). Consequently, α-humulene may play a role either directly as an attractive compound or indirectly as a synergist to α-copaene and/or the two unidentified chemicals (RI=1422 and 1447). Additional studies are needed to evaluate α-humulene as a potential semiochemical for male *C. capitata.*

Results of this study may lead to a better understanding of the role of phytochemicals in the biology of *C. capitata*. The biological significance of these compounds, which appear in both host and non-host plants, is still unknown. The phytochemical methyl eugenol is a parapheromone for the oriental fruit fly, *Bactrocera dorsalis* (Mendel). In addition to being a strong attractant, males that feed on methyl eugenol-containing substrates gain a significant mating advantage in both increased signaling and production of a more attractive pheromone blend (Shelly and Dewire, 1994) through sequestration of methyl eugenol metabolites (Nishida et al., 1988). Methyl eugenol is also a parapheromone and feeding attractant for the guava fruit fly, *Bactrocera correcta* (Bezzi). Tokushima et al. (2010) found that methyl eugenol metabolites, which were different from those sequestered by *B. dorsalis*, and also sesquiterpenes including α-humulene and β-caryophylene were sequestered in the male pheromonal rectal glands. In contrast, male *C. capitata* do not interact with essential oils that contain α-copaene, and unless the α-copaene is present in a low concentration, males tend to arrest near the essential oil but not contact it (e.g., Steiner et al., 1957). Males exposed to volatile chemicals from ginger root oil or orange oil slightly increase their pheromone signaling but do not produce a more attractive pheromone blend (Shelly, 2001a, Papadopoulos et al., 2006). Females, however, are more attracted to dead aromatherapy-treated males, extracts from hexane-rinsed aromatherapy-treated males, and treated males with very short (30 sec) exposure periods than similar presentations from non-treated males (Shelly, 2006, Shelly et al., 2007). Thus, it is hypothesized that the phytochemical odors interact with the male exoskeleton and provide chemical cues to females that are used for mate selection. Unlike essential oils, males have to make physical contact with fruit or bark substrates to gain a mating advantage (Shelly et al., 2007). Comparisons of chemical profiles of avocado, lychee, and ficus wood with profiles from essential oils, as well as biological effects of these substrates may provide new information on phytochemicals that are biologically active for *C. capitata*.

Although only sterile males were used in our studies, previous studies have shown similar response patterns to parapheromone-baited traps by wild and sterile males (e.g., Wong et al., 1982; Jang et al., 2010; N.D.E. unpublished data). Additionally, exposure to substances that contain α-copaene enhances mating success of both wild and sterile males (Shelly, 2001a). However, additional tests with wild males are needed to determine if they show similar behaviors in response to these substrates. Tests of short-range attraction or quantification of EAG response of sterile males to natural substrates may provide new methods to assess quality of mass-produced sterile males as the ability to locate plant-based bioactive chemicals may contribute to the effectiveness of released males in finding lek sites and competing with wild males.

RAPID COMMUNICATION

Host Plant Invests in Growth Rather than Chemical Defense When Attacked by a Specialist Herbivore

Alberto Arab · José Roberto Trigo

Received: 18 February 2011 / Revised: 21 February 2011 / Accepted: 14 April 2011 / Published online: 27 April 2011

Abstract Plant defensive compounds may be a cost rather than a benefit when plants are attacked by specialist insects that may overcome chemical barriers by strategies such as sequestering plant compounds. Plants may respond to specialist herbivores by compensatory growth rather than chemical defense. To explore the use of defensive chemistry vs. compensatory growth we studied *Brugmansia suaveolens* (Solanaceae) and the specialist larvae of the ithomiine butterfly *Placidina euryanassa,* which sequester defensive tropane alkaloids (TAs) from this host plant. We investigated whether the concentration of TAs in *B. suaveolens* was changed by *P. euryanassa* damage, and whether plants invest in growth, when damaged by the specialist. Larvae feeding during 24 hr significantly decreased TAs in damaged plants, but they returned to control levels after 15 days without damage. Damaged and undamaged plants did not differ significantly in leaf area after 15 days, indicating compensatory growth. Our results suggest that *B. suaveolens* responds to herbivory by the specialist *P. euryanassa* by investing in growth rather than chemical defense.

Key Words *Brugmansia suaveolens* · Compensatory growth · Lethal plant defense paradox · *Placidina euryanassa* · Tropane alkaloids

Introduction

The lethal plant defense paradox (Fordyce, 2001) postulates that although plant secondary metabolites provide a benefit against generalist herbivores, they may be a cost to plants under attack by specialists. Specialist feeders can tolerate or detoxify plant defensive compounds, sometimes sequestering them for defense or mating, or using them as cues for host finding (Trigo, 2011). Decreasing levels of chemical defenses in response to damage by specialists may be an adaptive plant response (Lankau, 2007). Alternatively, herbivory by a specialist might result in tolerance (Strauss and Agrawal, 1999) such as compensatory growth, which allows damaged plants to replace tissues lost to herbivores (Belsky, 1986).

We investigated the defense paradox using *Brugmansia suaveolens* (Solanaceae), which produces tropane alkaloids (TAs) and is attacked by larvae of the specialist ithomiine butterfly *Placidina euryanassa* (formerly *Placidula euryanassa*) (Freitas et al., 1996). Larvae of *P. euryanassa* show warning coloration, and sequester TAs that remain in the pupae and adults (Freitas et al., 1996), thus conferring protection against predators, such as birds and ants (Arab and Trigo unpublished results). The TA scopolamine is inducible in the leaves after artificial damage, and negatively affects larval performance of the generalist fall armyworm *Spodoptera frugiperda* (Alves et al., 2007).

We hypothesized that leaves of *B. suaveolens* would not induce TAs when attacked by *P. euryanassa*, and would invest in compensatory growth as an alternative defense strategy. To test our hypothesis we examined the levels of TAs in leaves 24 hr and 15 d after damage, and leaf area 15 d after damage. We used these time intervals based on the timing of TA induction and relaxation after artificial damage (Alves et al., 2007).

Methods and Materials

Organisms Several stems of *B. suaveolens* (*ca.* 15 cm high) were cut from individuals (hereafter genets) at the Serra do Japi forest, Jundiaí, SP, Brazil. Four stem clones of each genet were rooted in 5-L plastic pots filled with soil in a greenhouse at 25±3°C and 12:12 hr L:D photoperiod, and allowed to grow for 45 d. Afterwards, each stem was about 30 cm high and had 4 to 12 fully expanded leaves. The 4th instars of *P. euryanassa* were obtained from one egg batch that was collected from leaves of *B. suaveolens* at the same site.

Treatments The effect of 24 hr larval feeding on the level of TAs in *B. suaveolens* was assessed by using 13 genets. For the feeding treatment, 4th instars of *P. euryanassa* were confined individually within a clip-cage at the half distal portion of the leaves 1 and 4 (assigned from the apical meristem). The half distal portion was considered half of the leaf length without petiole. Clip-cages were made from the tops of Petri dishes (5 cm diam) attached to either side with a rubber band. Each cage was supported by a wooden stake to avoid weighing down the leaves. After 24 hr, clip-cages and larvae were removed. At this time, the half distal portion of each leaf was consumed. The first four expanded leaves with petioles (the two damaged ones, i.e., leaves 1 and 4, and the two undamaged ones, i.e., leaves 2 and 3) were harvested. The damaged and undamaged leaves were taken together for TA analyses (see below) since they showed no significant differences in TA concentration (data not shown). For the undamaged control treatment, plants had the same clip-cages, without larvae in the cages, and leaves 1 to 4 were harvested. The harvested leaves were oven dried at 50°C for 2 d, ground, and maintained at −10°C until TA extraction and analysis.

The concentration (μg/g) data for each TA were ln (x+1) transformed to meet the assumption of homoscedasticity and compared between the treatments using a one-way randomized block MANOVA, since the four TAs are not independent variables; they share the same biosynthetic pathway (Hashimoto et al., 1991). The genets were stated as blocks, and the treatments as the factor. Separate univariate ANOVAS were conducted when a significant effect was found in the MANOVA (Scheiner, 1993).

The TA levels in *B. suaveolens* damaged by 24 hr feeding by *P. euryanassa* also were assessed 15 d after damage. The procedures were carried out as above, using one additional genet, and the leaves were harvested after 15 d instead of immediately after the 24 hr feeding period. To test whether or not *B. suaveolens* has leaf compensatory growth after damage, we estimated the leaf areas at beginning and end of the experiment (see below), and calculated the total leaf area for the damaged plants as the sum of the leaf area at final harvest plus the leaf area removed by larvae. We calculated the ratio between the total leaf area for damaged plants at final harvest and the leaf area of undamaged plants at final harvest, and we compared the ratios with a single sample *t*-test with a hypothesized mean of one. If the result was not significantly different from one, there is compensatory growth (Belsky, 1986).

Analysis Chemical extraction and TA analysis by GC-MS and GC-FID were carried out according Freitas et al. (1996). Before both GC analyses, samples were derivatized with *N*-Methyl-*N*-(trimethylsilyl) trifluoroacetamide (Acros Organics™) for 30 min at 75°C to prevent the pyrolysis of scopolamine and atropine. Only the four most abundant TAs were quantified by GC-FID using sparteine (Acros Organics™) as internal standard.

Leaf area was estimated from leaf length. Digitalized images of leaves of non-experimental undamaged and damaged plants were used initially to calculate the leaf areas with the software Area Measure 1.00© (1995–97 MYKA Lab.). These areas were used to establish the equation that relates leaf length (cm) to leaf area (mm^2) in undamaged leaves ($ln\ leaf\ area = 0.792\ ln\ leaf\ length + 2.268$, N=51, r^2=0.951, $F_{1,49}$=942.807, P<0.001) and to the area of the half distal portion of the leaves for the damaged leaves ($ln\ leaf\ area = 0.791\ ln\ leaf\ length + 2.376$, N=51, r^2=0.942, $F_{1,49}$=597.672, P<0.001). The first equation was used to assess the leaf area in undamaged and damaged leaves at the beginning and end of the experiment, since after 15 d all leaves had similar geometry. The second equation was used to assess the area of leaf tissue removed by *P. euryanassa* during the 24 hr feeding bout.

Results and Discussion

When considering all expanded leaves, the percentage (mean±SE) of leaf area removed by the larvae during the 24 hr feeding period was 16.7±1.1% in the 24 hr experiment, and 18.7±1.9% in the 15 d experiment. These data did not differ significantly (arc sin transformed data, *t*-test, t=−0.833, df=25, P=0.413) showing that similar damage by larvae was inflicted in both experiments.

Scopolamine and 3-hydroxy-6-tigloyloxytropane were the most abundant TAs found in both undamaged and *P. euryanassa* damaged plants (Fig. 1). The concentration of TAs in damaged plants decreased significantly (around 75%) after 24 hr when compared to undamaged controls (MANOVA, *Wilk's lambda*=0.284, $F_{4,9}$=5.680, P=0.015).

The concentration of scopolamine, 6-hydroxy-atropine, and 3-hydroxy-6-tigloyloxytropane decreased significantly after damage, but atropine was not affected by damage (Fig. 1a). After 15 days, the concentration of TAs between damaged and undamaged plants was not significantly different (MANOVA, *Wilk's lambda*=0.866, $F_{4,10}$=0.390, P=0.813, Fig. 1b).

Brugmansia suaveolens leaf area before the experiment did not differ significantly between treatments (undamaged plants: 401±32; damaged plants: 409±34 mm^2; paired t-test, t=−0.591, df=13, P=0.565). The total area after the 15 day experiment for damaged plants was 785±88 mm^2 and that of undamaged plants at final harvest was 672±77 mm^2. The ratio between the two variables was 1.3±0.1, which did not differ significantly from 1.0 (single t-test, t=1.946, df=13, P=0.074), thus indicating leaf compensatory growth.

The lethal plant defense paradox postulates that the maintenance of defensive compounds at constitutive or induced levels, when plants are attacked by specialists, would be non-adaptative, since they are costly, and not effective against these herbivores (Fordyce, 2001). When *B. suaveolens* was damaged by larvae of the specialist *P. euryanassa* during 24 hr, TA concentration decreases. This plastic response seems to solve part of the paradox. However, when plants were no longer under attack during 15 days, the levels of TAs recovered to their constitutive levels. This recovery may occur since once the attack has stopped, the maintenance of only low levels of defense would be harmful to the plant since TAs may protect it against generalists (Alves et al., 2007). Furthermore, by 15 days after attack, the plants had compensated for loss of tissue due to herbivory. Whether compensatory growth occurs at the expense of chemical defenses (as proposed by Van Der Meijden et al., 1988) or at the expense of roots or other tissues is an open question. Although *B. suaveolens* decreases the TA content and grows when attacked by a specialist, responses to generalists or other specialists are not known. Alternative defense strategies such as the biosynthesis of non sequestrable defensive compounds such as proteins inhibitors, which are not used as defensive compounds by specialists, or attraction of natural enemies also can be used by *B. suaveolens* against both kind of herbivores, and they remain to be investigated.

Acknowledgments We thank the Prefeitura Municipal de Jundiaí, SP, Brazil, for permission to work at the Serra do Japi. We acknowledge A. Linhares for help in MANOVA analyses, D. Rodrigues, G. Romero, C. Orians, and two anonymous reviewers for suggestions and criticisms, and J. Rincones for the assistance with the English language. This work was supported by FAPESP, CNPq, and IFS grants.

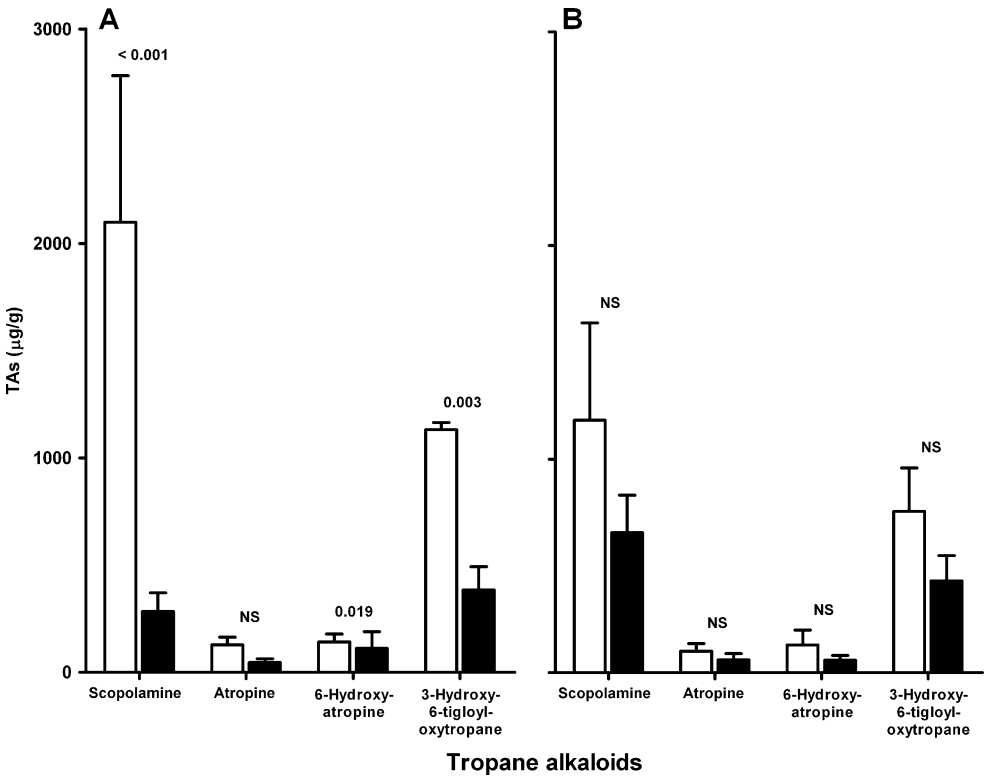

Fig. 1 TA concentrations (µg/g, mean±SE) after 24 hr (**a**) and 15 days (**b**) in leaves of *Brugmansia suaveolens* plants submitted to the treatments: (i) undamage (control=*white bars*) and (ii) damage by larvae of *Placidina euryanassa* (*black bars*). The values above the bars indicate the P value in a separate univariate ANOVA for comparison between undamaged and damaged plants within each TA. For the 24 hr experiment, 13 replicates were used, for 15 days, 14 replicates

RAPID COMMUNICATION

A Comparison of Sample Preparation Techniques for Quantifying Iridoid Glycosides Sequestered by Lepidopteran Larvae

Evan C. Lampert · M. Deane Bowers

Received: 15 February 2011 / Revised: 18 March 2011 / Accepted: 28 March 2011 / Published online: 8 April 2011
© Springer Science+Business Media, LLC 2011

Abstract This study compared different methods of tissue preparation for extraction of iridoid glycosides sequestered by three species of lepidopteran larvae. *Junonia coenia* is a specialist on plant species that produce iridoid glycosides, while the arctiids *Estigmene acrea* and *Spilosoma congrua* are both polyphagous and will eat plants that produce iridoid glycosides. Larvae of all three species were reared on leaves of *Plantago lanceolata*, which produces two primary iridoid glycosides, aucubin and catalpol. Three methods of preparing the specimens before extraction in methanol were compared in all three species: 1) larvae were flash-frozen in liquid nitrogen, 2) larvae were macerated fresh in boiling methanol, or 3) larvae were macerated fresh in room temperature methanol. A set of *J. coenia* larvae was oven-dried before maceration as an additional treatment for this species only. *Junonia coenia* sequestered the most iridoid glycosides, while *E. acrea* sequestered the least, and *S. congrua* was intermediate. *Estigmene acrea* was poor at sequestering catalpol. Tissue preparation method only significantly influenced iridoid glycoside recovery from *S. congrua*, with maceration in room-temperature methanol being the most effective of the three methods. This study shows that treatment of insects prior to iridoid glycoside extraction can influence recovery of the compounds, and that the effects of treatment may vary among different species.

Introduction

An accurate measurement of insect or plant defensive chemistry is necessary for answering a variety of questions in ecology and evolution. The accuracy of measurements can depend on the instrumentation used to measure the chemistry and the methods used to prepare the sample. In this study, we compared three methods of sample preparation for extraction of iridoid glycosides (IGs) from insect species that have the ability to sequester ingested IGs, thus using them for their own chemical defense (Bowers, 1991; Opitz and Müller, 2009).

Iridoid glycosides are polar molecules that are highly soluble in hydrophilic solvents, including water and methanol (Suomi et al., 2000, 2001). These solvents are typically used to recover IGs and other polar compounds from the tissue matrix. Glycosidase enzymes present in the tissues can catalyze glycoside degradation as the sample is prepared for extraction. Insect samples usually are freeze-dried before extraction, or extracted fresh, whereas plant samples may be oven-dried or freeze-dried (e.g., Jamieson and Bowers, 2010). In most studies, insect samples have been frozen in a freezer, although liquid nitrogen also has been used. In one comparison, more IGs were recovered from *Melitaea cinxia* (Nymphalidae) larvae placed in a freezer than from larvae frozen with liquid nitrogen (Suomi et al., 2001). Another potential method to delay or prevent enzymatic breakdown is to boil the sample in order to denature glycosidases before extraction.

We compared three methods of sample preparation before extracting IGs with methanol from three species of lepidopteran larvae that differ in their ability to sequester these compounds (Lampert and Bowers, 2010). *Junonia coenia* Hübner (Common Buckeye) (Nymphalidae) is oligophagous and specializes on plants that produce IGs (Bowers and Stamp, 1997). Larvae exhibit aposematic black and orange coloring and sequester high concentrations of IGs, as much as 20–25% dry weight (Bowers and Stamp, 1997). *Junonia coenia* larvae were contrasted with two polyphagous members of the Arctiidae, *Spilosoma congrua* (Walker) (Agreeable Tiger Moth) and *Estigmene acrea* (Drury) (Saltmarsh Caterpillar). Both of these arctiid species graze among a variety of plant species as larvae and readily consume species that produce IGs (Robinson et al., 2002). Previous work has demonstrated that *S. congrua* sequesters moderate concentrations of IGs, and that *E. acrea* sequesters much smaller amounts (Lampert and Bowers, 2010).

Each species was reared on *Plantago lanceolata* L. (Plantaginaceae), a host plant species that produces aucubin and catalpol, two IGs particularly well studied in association with sequestration and unpalatability (Opitz and Müller, 2009). The amount of IGs recovered was compared among three methods of preparing the insect for extraction: 1) larvae were flash-frozen in liquid nitrogen; 2) larvae were macerated fresh in boiling methanol; or 3) larvae were macerated fresh in room temperature methanol. A fourth method of oven-drying larvae before extraction in methanol was also done for *J. coenia* alone.

Methods and Materials

Larvae were reared in groups of 10 in 500 ml plastic containers on freshly excised *Plantago lanceolata* leaves in a growth chamber (25°C, 16:8 h L:D). Larvae were weighed to the nearest 0.1 mg and processed for IG extraction immediately upon reaching the final instar (5th for *J. coenia*, 6th for *S. congrua* and *E. acrea*). The final instars were handled in three ways (four ways for *J. coenia)* before a standard extraction in methanol. One set of larvae of each species was flash-frozen using liquid nitrogen, pulverized with a mortar and pestle, and extracted in 5 ml room temperature (~20°C) 95% methanol for 48 hr. A second set of larvae of each species was anesthetized with carbon dioxide, then macerated fresh with sand in 5 ml room temperature 95% methanol, and extracted for 48 hr. A final set of larvae of each species was anesthetized with carbon dioxide, then macerated fresh with sand in 5 ml boiling (~65°C) methanol, and extracted at room temperature for 48 hr. An additional fourth treatment was included for *J. coenia.* The larvae were frozen in a freezer at −20°C, oven-dried for 72 hr at 55°C, then macerated with sand in 5 ml room temperature methanol, and extracted for 48 hr. Samples were vortexed at ~8 hr intervals during the 48 hr extraction, and were otherwise undisturbed.

Sample sizes were 10 individual larvae for all extraction procedures. The aim of this study was to compare tissue preparation rather than chromatography methods, and all samples were analyzed by using the same methods for sample preparation and analysis with gas chromatography with a flame-ionization detector (GC-FID) (Bowers and Stamp, 1997). In short, the sample was filtered to remove solid material; the methanol was evaporated; and the internal standard, phenyl-β-D-glucopyranoside (PBG) (Sigma-Aldrich), dissolved in water (0.500 mg per ml), was added. The sample was partitioned between water and ether, the ether layer was discarded, the water was evaporated, and the residue was redissolved in 1 ml methanol. A 100 µl aliquot was evaporated and derivatized with 100 µl Tri-Syl-Z (Pierce Chemical Company, Rockford, IL, USA) in pyridine before injection. Amounts of aucubin and catalpol were measured by using Agilent ChemStation A.03.34 software with pure standards of the compounds. To directly compare the results from the different methods, the dry weight of fresh larvae was estimated by using a separate set of larvae of each species, weighing them fresh, drying them to a constant weight in an oven, and then weighing them dry (N= 25 for each). A conversion factor was calculated and applied to larvae that were extracted fresh to obtain a dry weight for each caterpillar.

A series of Bonferroni-adjusted 1-way analyses of covariance (ANCOVA) were performed for each species to compare the amount (mg/larvae) of aucubin, catalpol, and total IGs among the three (*S. congrua*, *E. acrea*) or four (*J. coenia*) preparation methods, treating caterpillar dry mass as a continuous covariate. A separate set of 1-way analyses of variance (ANOVA) was used to compare the concentration (% dry mass) of aucubin, catalpol, and total IGs among preparation methods. Concentrations were treated as proportions and arcsine square-root transformed prior to analysis. Because only 6 of 30 *E. acrea* individuals contained measurable amounts of catalpol, analyses were done only on amount of aucubin and total IGs for this species. Both amounts and concentrations of IGs were compared among preparation methods using Tukey's Honestly Significant Difference *post-hoc* tests. Tests were conducted separately for each measure for each caterpillar species where appropriate.

Results and Discussion

Junonia coenia sequestered, on average, the largest amounts of IGs, particularly catalpol, compared to the

other species (Table 1). This variation in sequestration ability among species was consistent among all tissue preparation methods, and consistent with a previous study (Lampert and Bowers, 2010).

There was no significant effect of sample preparation method on amount (mg) or concentration of IGs in either *J. coenia* or *E. acrea* ($P>0.05$ for all comparisons, Table 1). Although not compared statistically, in all treatments *Junonia coenia* larvae sequestered larger amounts and higher concentrations of catalpol than aucubin (Table 1). *Estigmene acrea,* in contrast, was poor at sequestering both compounds, and most larvae (24/30) contained no catalpol at all.

Results were quite different for *S. congrua*. Although *S. congrua* larvae were fed from the same batches of *P. lanceolata* leaves as were *J. coenia* and *E. acrea*, they sequestered larger amounts and higher concentrations of aucubin than catalpol. In a previous study (Lampert and Bowers, 2010), *S. congrua* was relatively efficient at sequestering catalpol, although the experimental design and leaf material fed to larvae were different. These differences in results may have been due to differences in the IG content of leaves on which caterpillars were fed.

For *S. congrua,* the amount of total iridoid glycosides (mg) per insect recovered was significantly influenced by sample preparation method ($F=6.170$, $P=0.007$), as were amounts of aucubin ($F=3.411$, $P=0.049$) and catalpol ($F=3.998$, $P=0.031$). The covariate of insect dry mass was not significant in any of the analyses ($P>0.30$ for each analysis). *Post-hoc* comparisons showed that amounts of aucubin extracted after all treatments was the same ($P>0.075$ in all cases). More catalpol and more total iridoid glycosides were obtained with maceration in room temperature methanol compared with boiling methanol (Table 1). Likewise, the concentration of total IGs was significantly influenced by sample preparation method in this species ($F_{2,25}=10.05$, $P=0.001$) (Table 1). Similar results were obtained for concentrations of both aucubin ($F=5.968$, $P=0.007$) and catalpol ($F=6.612$, $P=0.005$). *Post-hoc* comparisons showed that for concentrations of aucubin, catalpol, and total IGs, room temperature methanol resulted in the highest levels of recovery, and this was significant when compared with liquid nitrogen, but not boiling methanol (Table 1).

Secondary compound recovery can be influenced by how the sample is extracted (Suomi et al., 2000, 2001), and the comparison of extractions in different solvents is important. Suomi et al. (2000) compared water to ethanol and methanol as an extraction solvent for aucubin and catalpol from plant tissues, and found water to be more effective for both compounds. Since plant and insect tissues store IGs differently, it is unknown whether water and methanol are equally effective solvents for extraction. In a preliminary study, we did not find significant differences between water and methanol extraction of *J. coenia* iridoid glycosides (unpublished data).

We found that recovery of sequestered IGs using a single detection method (GC-FID) can be influenced by the way the insect sample is handled prior to extraction. Iridoid glycoside recovery was more variable in one insect species than in two others, possibly due to differences in how the species sequester these compounds or the biochemical pathways or enzymes used for metabolism of these ingested compounds. Notably, for *S. congrua,* there was a significant effect of preparation method on IG recovery, and macerating the insect fresh in room-temperature methanol resulted in the highest recovery of IGs. Neither boiling methanol nor flash-freezing, both of which were hypothesized to inhibit enzymatic breakdown of IGs, improved recovery. These

Table 1 Average (±1 SEM) amounts (mg per individual) and percentage of insect dry weights of the iridoid glycosides aucubin and catalpol recovered from 3 caterpillar species

Species	Preparation method	aucubin (mg)	catalpol (mg)	total IGs (mg)	aucubin (%)	catalpol (%)	total IGs (%)

Estigmene acrea	liquid nitrogen	0.16±0.10	0.015	0.17±0.099	0.20±0.12	0.005	0.20±0.12
	methanol	0.02±0.015	0.001	0.02±0.015	0.04±0.02	0.002	0.04±0.02
	boiling methanol	0.06±0.03	0.025±0.02	0.07±0.04	0.07±0.03	0.008±0.007	0.08±0.04

Ten individuals of each species, all reared only on *Plantago lanceolata* leaves, were sampled. Lowercase letters indicate significantly ($P<0.05$) different means according to Tukey's Honestly Significant Difference *post-hoc* tests. *Post-hoc* tests were conducted separately for each measure for each species. IG = iridoid glycoside

data suggest that maceration in room-temperature methanol is a suitable initial step in extracting IGs from insect larvae. Future research should compare extraction solvents and instrumentation to determine the most accurate methods to extract and measure iridoid glycosides.

Acknowledgements We thank Mike Singer and Dave Wagner for providing *Estigmene acrea* and *Spilosoma congrua*, Frances Drachenberg and Angela Knerl for rearing assistance, and two anonymous reviewers for providing helpful feedback related to an earlier draft of this manuscript. This study was funded by NSF grant DEB 0614883 to Deane Bowers and Lee Dyer.

Abstract The relationships between changes in energy metabolism and the antioxidant defense system in the weed species *Ipomoea triloba* L. during seed germination and early seedling growth were investigated. The effects of some common allelochemicals on these parameters also were studied. Respiratory activity and the activities of alcohol dehydrogenase, superoxide dismutase, catalase, guaicol peroxidase, ascorbate peroxidase, glutathione reductase, and lipoxygenase were measured. Mitochondrial oxidative phosphorylation resumed shortly after the seed imbibition period, as indicated by considerable KCN-sensitive respiratory activity in embryos of *I. triloba*. The occurrence of superoxide dismutase, catalase, guaicol peroxidase, and lipoxygenase activities in the embryos, along with significant KCN-insensitive respiration, suggest that production of reactive oxygen species (ROS) is initiated as soon as mitochondrial respiration is resumed. All assayed antioxidant enzymes were present in the embryos except ascorbate peroxidase, which appeared only in primary roots. The activities of antioxidant enzymes increased after completion of germination, especially in primary roots. Superoxide dismutase, catalase, and guaicol peroxidase probably were the crucial enzymes involved in the neutralization of ROS, since they had higher levels of activity compared with other enzymes, such as ascorbate peroxidase and glutathione reductase. When seeds were grown in the presence of α-pinene, coumarin, quercetin, and ferulic acid, there was an additional increase in activities of antioxidant enzymes, as well as increases in lipoxygenase activity and KCN-insensitive respiration, suggesting a further increase in ROS generation. The antioxidant defense system of *I. triloba* was not effective in preventing lipid peroxidation caused by α-pinene. The data indicate that during seed germination and initial growth of *I. triloba*, a period when antioxidant enzyme activity increases to counteract the harmful ROS effects produced during mitochondrial metabolism resumption, the presence of allelochemicals, which cause further oxidative stress, may leave the seeds/seedlings more vulnerable to cellular dysfunction and cell death.

Key Words Antioxidant enzymes · *Ipomoea triloba* L. · Germination · Allelochemical · Respiration

Introduction

Seed germination is a critical step in the plant life cycle. When quiescent dry seeds imbibe water, their oxygen uptake increases, and mitochondrial energy metabolism becomes active, allowing for macromolecule biosynthesis and solute transport that are required to complete germination. Reactivation of mitochondrial metabolism also provides an important source of reactive oxygen species (ROS). Under normoxic conditions, approximately 2–3% of the oxygen used by mitochondria can be converted into superoxide and H_2O_2 (Puntarullo et al., 1988).

The toxicity of ROS, which causes oxidative damage to cell macromolecules, is well documented (Gidrol et al., 1994; Bailly et al., 1996; McDonald, 1999). There now is evidence that ROS also play normal physiological roles, acting as signaling molecules in many processes, including seed germination and dormancy alleviation (Kwak et al., 2006; Bailly et al., 2008; Oracz et al., 2009). The shift from

e-mail: eliiwamoto@uem.br

a normal role in cell signaling to a toxic role with deleterious effects is probably related to changes in ROS homeostasis that result from a shift in the balance between ROS-producing and ROS-scavenging processes. Plants contain soluble antioxidant compounds, such as ascorbic acid, vitamin E, and glutathione (Noctor and Foyer, 1998; De Tullio and Arrigoni, 2003), and a battery of enzymes that can efficiently destroy superoxide radicals and hydrogen peroxide, including superoxide dismutase, catalase, peroxidases, thioredoxin system enzymes, and ascorbate glutathione cycle enzymes (Navrot et al., 2007).

Most studies of antioxidant enzyme activities during seed germination have evaluated changes caused by aging or abiotic stress conditions such as drying (Bailly et al., 2001), high temperature, and high humidity (Gidrol et al., 1994; Bailly et al., 2002). There are few studies that are concerned with the relationships between mitochondrial respiratory activity and the antioxidant defense system during seed germination and initial seedling growth, particularly in weed species.

Common weeds are relatively difficult to control in field crops due to high seed production and their long viability. *Ipomoea triloba* L. (syn *Ipomoea grandifolia* (Dammer) O'Don), a tropical and subtropical weed, commonly known as morning glory (Holm et al., 1997) is a dicot of the family *Convolvulaceae*. It causes yield losses of several crops, particularly soybean (*Glycine max* L.) (Holm et al., 1997). In addition to intrinsic and extrinsic factors, (Boyd and Acker, 2004), allelochemicals in the soil also can affect seed germination by altering an essential biochemical or physiological process, such as mitochondrial energy metabolism (Ishii-Iwamoto et al., 2006).

Numerous allelochemicals of the phenolic, flavonoid, and terpenoid classes have been suggested as the compounds implicated in the plant growth suppression, including that of weed species (Vaughn and Spencer, 1993; Dudai et al., 1999; Reigosa et al., 1999; Duke et al., 2000; Singh et al., 2006; Batish et al., 2004, 2007; Chon and Kim, 2004; Kohli et al., 2006). When these compounds decrease plant growth, the phenomenon is considered to be a biotic stress termed "allelochemical stress" (Cruz-Ortega et al., 2002; Romero-Romero et al., 2002).

Perturbation of the pathways that generate ROS, such as the mitochondrial respiratory chain or the activities of antioxidant enzymes, could be a mechanism underlying allelochemical stress during seed germination and initial seedling growth. It has been demonstrated, for example, that the monoterpene α-pinene induces oxidative stress in seedlings through a direct action on mitochondrial metabolism (Abrahim et al., 2003a, b; Ishii-Iwamoto et al., 2006). In mitochondria isolated from primary roots of maize (*Zea mays*), α-pinene uncouples electron transport from ATP synthesis, decreases the membrane potential, and inhibits the alternative oxidase pathways (Abrahim et al., 2003a). Consistent with these effects, in intact primary roots, α-pinene inhibits KCN-sensitive respiration, stimulates KCN-insensitive respiration and lipoxygenase activity, and increases the level of conjugated dienes (Ishii-Iwamoto et al., 2006). Singh et al. (2006) also reported that α-pinene induces oxidative stress in roots of *Cassia occidentalis*. It increases the levels of malondialdehyde, proline, and hydrogen peroxide, and it elevates the activities of antioxidant enzymes. Oxidative stress induction has been suggested to be the mode of actions of other allelochemicals, including coumarin (Abenavoli et al., 2006; Pergo et al., 2008), catechin (Bais et al., 2003), and 2-benzoxazolinone (Batish et al., 2006).

It is plausible that the ability of seeds to germinate might be related, in part at least, to their capacity to regulate the levels of ROS that are generated during resumption of mitochondrial oxygen consumption, and also to neutralize the pro-oxidant activities of allelochemicals present in the medium.

Thus, this study was undertaken to investigate the relationship between the resumption of respiratory activity and the kinetics of the changes in the activities of the main antioxidant enzymes during seed germination in the weed species, *Ipomoea triloba* L., and the influence of phytotoxic allelochemicals on these processes. Fourteen different natural plant compounds were screened for activity on *Ipomoea triloba* L. They represent the phenolic and terpenoid classes, namely, vanillic acid, *p*-coumaric acid, protocatechuic acid, ferulic acid, caffeic acid, caffeine, aconitic acid, quercetin, rutin, coumarin, eucalyptol, camphor, α-pinene, and limonene.

The parameters of mitochondrial respiratory activity, the activities of alcohol dehydrogenase (ADH), and the activity of antioxidant enzymes implicated in ROS balance were measured. The enzyme activities measured include superoxide dismutase (SOD), catalase (CAT), guaicol peroxidase (POD), ascorbate peroxidase (APX), and glutathione reductase (GR). Membrane damage by means of lipid peroxidation was evaluated by measurements of malondialdehyde (MDA) content and lipoxygenase activity (LOX). The content of oxidized (GSSG) and reduced glutathione (GSH) in allelochemical-treated seedlings also was examined.

Methods and Materials

Reagents KCN, NAD^+, ascorbate, GSSG, NADPH, linolenic acid, 2-thiobarbituric acid, vanillic acid, *p*-coumaric acid, protocatechuic acid, ferulic acid, caffeic acid, caffeine, aconitic acid, quercetin, rutin, coumarin, eucalyptol, camphor, α-pinene, and limonene were purchased from Sigma Chemical Co. (St. Louis, MO, USA).

Seed Germination and Initial Growth Seeds of *Ipomoea triloba* L., were purchased from a commercial supplier (Cosmos Agrícola Produtos e Serviços Rurais Ltda, Brazil). Seeds were placed on double sheets of germination paper in plastic germination boxes (110×110 mm) and moistened with 10 ml of distilled water or 500 μM allelochemicals. Vanillic acid, p-coumaric acid, protocatechuic acid, ferulic acid, caffeic acid, caffeine, aconitic acid, quercetin, and rutin were dissolved in distilled water. Coumarin, eucalyptol, camphor, α-pinene, and limonene were dissolved in a 0.1% dimethylsulfoxide (DMSO) solution. Controls were performed to exclude the interference of dimethylsulfoxide. Each treatment was applied to three plates (replicates), and each replicate consisted of 60 seeds distributed among the germination boxes. Boxes were placed in a germination chamber programmed for a 12-hr photoperiod (photon flux density of approximately 230 μmol m^{-2} s^{-1}) at 30°C. Seeds that had germinated at 24, 48, and 72 hr were selected for growth tests. The hypocotyl and the primary roots were excised for measurements of their length and fresh weight. Dry weight was evaluated after incubation of the fresh materials at 80ºC for 24 hr.

Mean germination time was calculated by means of Eq. 1 (Labouriau and Osborn, 1984):

$$\bar{t} = \sum n_i t_i \Big/ \sum n_i \quad (1)$$

$\bar{t}$ Mean germination time
n_i Number of germinated seeds between the times $t_{i\text{-}1}$ and t_i

The speed of germination was calculated by means of Eq. 2 (Chiapuasis et al., 1997):

$$S = (N_1/T_1) + (N_2 - N_1) \times 1/2 + (N_3 - N_2) \times 1/3 + \ldots (N_n - N_{n-1}) \times 1/n \quad (2)$$

AS Speed of germination
N Proportion of germinated seeds obtained in the first (T_1), second (T_2), third (T_3)…, (n-1) hr.

The speed of accumulated germination was calculated by means of Eq. 3 (Chiapuasis et al., 1997):

$$AS = (N_1/T_1) + (N_2/T_2) + (N_3/T_3) + \ldots (N_n/n) \quad (3)$$

S Speed of accumulated germination
N Proportion of germinated seeds on time (T_1), time (T_2), time (T_3)…, hr.

For measurements of respiratory activity and antioxidant enzyme activities, the embryos, cotyledons, and primary roots were removed from imbibed seeds or seedlings that had been incubated for 12, 24, 36, and 48 hr after the onset of seed imbibition. The data collected at 12 hr refer to embryo tissues. After at least 24 hr, the germinated seeds were selected. The primary roots were excised, and the cotyledons were separated from the remaining seeds.

Measurements of Respiratory Activity Embryos and cotyledons were carefully separated after removal of seed coats. Primary roots were cut into segments 5–10 mm long as measured from the growth apex, and then weighed. After weighing, samples were placed immediately in the oxygen electrode vessel with 2 ml of nutrient solution (pH 5.8) containing 2 mM $Ca(NO_3)_2$, 2 mM KNO_3, 27 μM $FeCl_3$, 0.43 mM NH_4Cl, 0.75 mM $MgSO_4$, and 20 μM NaH_2PO_4 (Larkin, 1987). To estimate the contributions of mitochondrial cytochrome oxidase (COX; KCN-sensitive respiration), alternative oxidase (AOX), and the extramitochondrial oxidases (KCN-insensitive respiration) to the overall O_2 uptake, 200 μM potassium cyanide (KCN) was added to the reaction medium. Oxygen uptake rates were calculated from the polarographic records, assuming an initial concentration of dissolved oxygen of 240 μM at 25°C (Estabrook, 1967).

Preparation of Enzyme Extracts Embryos, cotyledons, and primary roots were removed from imbibed seeds or seedlings, and samples of approximately 200 mg fresh weight of each tissue were transferred to a mortar and thoroughly mixed with 2.0–4.0 ml of extraction medium containing: for alcohol dehydrogenase, 50 mM Tris–HCl (pH 7.4), 1.0 mM EDTA, and 2.0 mM dithiothreitol (DTT); for peroxidase and catalase, 67 mM K-phosphate (pH 7.0) and 2% PVP (w/v); for ascorbate peroxidase and glutathione reductase, 50 mM K-phosphate (pH 7.0), 1 mM EDTA, 1 mM ascorbate, and 2% PVP (w/v); for superoxide dismutase, 50 mM K-phosphate (pH 7.8), 1.0 mM EDTA, 1% PVP (w/v), and 0.1% Triton X-100 (v/v); and for lipoxygenase, 50 mM K-phosphate (pH 7.0) and 0.1% Triton X-100 (v/v). Extracts were centrifuged for 20 min at 4000 rpm and 4°C. The supernatant was decanted and used as the enzyme source. The protein concentration of each enzyme extract was determined according to Lowry et al. (1951). Bovine serum albumin was used as a standard.

Determination of Enzyme Activities Alcohol dehydrogenase activity was measured in a medium containing 50 mM Tris–HCl (pH 7.4), 1.0 mM NAD^+, 120 μM n-propanol, and 0.1–0.3 mg protein of enzyme extract (Lee, 1982). The rate of NAD^+ reduction was monitored at 340 nm.

Peroxidase activity was measured in a medium containing 25 mM K-phosphate (pH 6.8), 10 mM H_2O_2, 2.6 mM

guaiacol, and 0.1–0.4 mg protein of enzyme extract. Tetraguaicol formation (ε, 25.5 mM^{-1} cm^{-1}) was measured at 470 nm (Pütter, 1974).

Catalase activity was measured in a medium containing 67 mM K-phosphate (pH 7.0), 10 mM H_2O_2, and 0.1–0.4 mg protein of enzyme extract. The consumption of H_2O_2 was monitored at 240 nm (ε, 0.036 mM^{-1} cm^{-1}) (Aebi, 1984).

Ascorbate peroxidase activity was measured in a medium containing 50 mM K-phosphate (pH 7.0), 0.5 mM ascorbate, 2 mM H_2O_2, and 0.1–0.4 mg protein of enzyme extract. Ascorbate oxidation was measured at 290 nm (ε, 2.8 mM^{-1} cm^{-1}) (Nakano and Asada, 1981).

Glutathione reductase activity was measured in a medium containing 50 mM K-phosphate (pH 8.0), 2 mM EDTA, 0.5 mM GSSG, 0.15 mM NADPH, and 0.1–0.4 mg protein of enzyme extract. The rate of NADPH oxidation was monitored at 340 nm (ε, 6.2 mM^{-1} cm^{-1}) (Foyer and Halliwell, 1976).

Superoxide dismutase activity was measured according to Giannopolitis and Ries (1977). The medium contained 50 mM K-phosphate (pH 7.8) 6.5 mM methionine, 150 μM nitro blue tetrazolium NBT, 4 μM riboflavin, and 0.02–0.1 mg protein of enzyme extract. The reaction was started by switching on a light (20 W) and illuminating the medium for 20 min at 30ºC. One unit of SOD activity (U) was defined as the amount of enzyme required to cause 50% inhibition of the (NBT) photoreduction rate read at 560 nm, and the results were expressed as U of SOD×mg $protein^{-1}$.

Lipoxygenase activity was measured polarographically with a Clark-type oxygen electrode in a medium containing 200 mM K-phosphate (pH 7.0), linolenic acid (1.5 mM final concentration, dissolved in Tween 20), and 0.1–3.0 mg protein of enzyme extract (Siedow and Girvin, 1980). The enzyme activity was expressed as μmol O_2 consumed×min^{-1}×mg $protein^{-1}$.

Determination of MDA, Oxidized Glutathione (GSSG) and Reduced Glutathione (GSH) Primary roots were excised from seedlings grown for 48 hr in the absence or presence of 500 μM of each allelochemical. The level of lipid peroxidation was measured relative to the thiobarbituric acid reacting substance, malondialdehyde (MDA) (Heath and Packer, 1968). Approximately 0.6 g fresh weight of roots were extracted with 3.0 ml of 96% (v/v) ethanol. An equal volume of 20% TCA containing 0.5% TBA (w/v) was added to the homogenate. The mixture was heated at 95°C for 30 min. After centrifuging, absorbance of the supernatant at 532 nm was read. The non-specific absorbance at 600 nm was subtracted. The concentration of MDA was calculated by using its extinction coefficient of 155 mM^{-1} cm^{-1}. For a glutathione content measurement, samples of primary roots (0.6 g fresh weight) were ground in liquid nitrogen. The frozen powder was homogenized in 5% sulfosalicylic acid and centrifuged at 10,000×g for 15 min at 4°C. Total glutathione was determined in a medium containing 0.5 M potassium phosphate buffer (pH 7.5), 50 mM sodium phosphate buffer (pH 7.5), 5 mM EDTA, 1.0 mM dithionitrobenzoic acid (DTNB), 2 Uml^{-1} glutathione reductase, and 0.17 mM NADPH (Smith, 1985). After 10 min, the absorbance at 415 nm was read. For measurement of the oxidized glutathione, the enzyme extract was previously treated with 1.7 mM β-vinylpyridine dissolved in 2% Tween 20 (v/v) for 1 hr at room temperature. The concentration of GSSG and GSH was calculated using the extinction coefficient of 13.6 mM^{-1} cm^{-1}.

Statistical Analysis The data shown in the graphs and tables are expressed as means ± standard errors of the mean (SEM) of independent preparations. Data were analyzed using the Student's *t*-test or variance analysis (ANOVA). Significant differences between means were identified by Duncan's multiple range test. $P \leq 0.05$ was adopted as the minimum criterion of significance. Statistical analyses were performed using the Statistica™ software package.

Results

Background Information on the Germination and Growth Behavior of Ipomoea triloba Seeds of *I. triloba* started to germinate at nearly 24 hr after imbibition, achieving a maximum germination percentage of 33% at 72 hr (Fig. 1a). The growth of primary roots and hypocotyls from the germinated seeds, in contrast, increased progressively, as indicated by their lengths (Fig. 1b). Between 24 and 72 hr of incubation, primary root and hypocotyl lengths increased 3.9-fold and 10.3-fold, respectively. Fresh weights (Fig. 1c) and dry weights (Fig. 1d) of primary roots and hypocotyls also increased progressively. After 72 hr of incubation, the first leaves were visible, indicating that photosynthesis had started to contribute to seedling energy metabolism. Thus, the subsequent experiments were performed with seedlings grown for a maximum of 48 hr, assuring that the contribution of mitochondrial respiration to the energy metabolism of the seedlings was predominant.

Respiratory Activity and ADH Activity in Embryos, Cotyledons and Primary Roots There was considerable respiratory activity in embryos during the seed imbibition period (12 hr of incubation) (Fig. 2a). After germination completion (24 hr), the activity in cotyledons was nearly 2-fold higher, and remained elevated until 36 hr. At 48 hr, it had

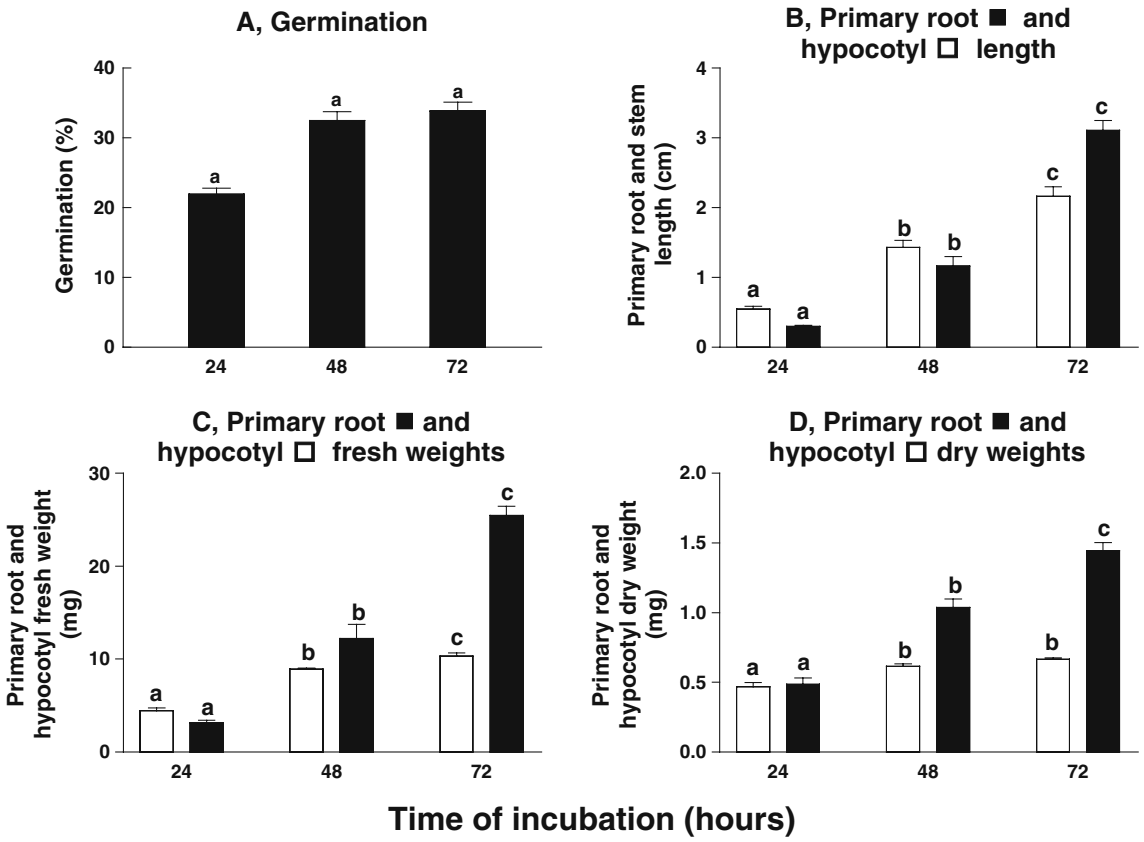

Fig. 1 Germination (**a**), primary root and hypocotyl lengths (**b**), root and hypocotyl fresh weights (**c**), root and hypocotyls dry weights (**d**) of *Ipomoea triloba.* The values are the means ± SE (*N*=4–5). *White bars* in panels **b**, **c**, and **d** are the values of hypocotyls and black bars are the values of primary roots. Different letters within each parameter and in the same tissue (hypocotyls or primary root) indicate significant differences according to ANOVA with Duncan's multiple range test at 5% level significance

decreased by nearly 50%. The relative contribution of KCN-insensitive respiration to the overall respiration varied from 22% to 34.3%. The primary roots presented a lower total respiratory activity when compared with their respective cotyledons (Fig. 2b). There was a gradual decrease during the growth period, and at 48 hr it was reduced by 40.4% compared to the value found at 24 hr. The relative contribution of KCN-insensitive respiration to the overall respiration in primary roots was, in general, higher than that found in cotyledons. It increased to 32.5% and 60% at 24 and 48 hr, respectively.

The activity of ADH was higher in embryos (12 hr) than in cotyledons at 24 hr (Fig. 2c). ADH activity in the primary roots at 24 hr was similar to that in the embryo (Fig. 2d). From 24 to 48 hr of incubation, there was a progressive decline of enzyme activity in both cotyledons and primary roots (Fig. 2c, d).

Changes in Enzyme Activities in Germinating Seeds SOD activity was detected in embryos during the seed imbibition period (Fig. 3a). After germination (24 hr), SOD activity in the cotyledon was not different from that in the embryo. On the other hand, SOD activity in the primary roots was nearly two-fold higher. During the subsequent growth period, enzyme activity did not change significantly in either the cotyledons or the primary roots.

The pattern of changes in CAT (Fig. 3b) and POD (Fig. 3c) activities were similar: the activity in cotyledons did not differ from that in embryos and did not change during the subsequent growth periods. In primary roots, however, the activity of both enzymes increased. At 48 hr, the activities of CAT and POD increased nearly 2- and 3-fold, respectively, relative to the corresponding values found at 24 hr.

As shown in Fig. 3d, the activity of GR was very low in *I. triloba* in all tissues throughout the experimental growth period.

APX was not detected during seed imbibition (Fig. 3e), and in cotyledons significant activity was found only after 48 hr of incubation. Enzyme activity appeared, however, in primary roots after the completion of germination (24 hr) and increased during the subsequent growth period. At 48 hr, the activity was 4-fold higher than the values found at 24 hr.

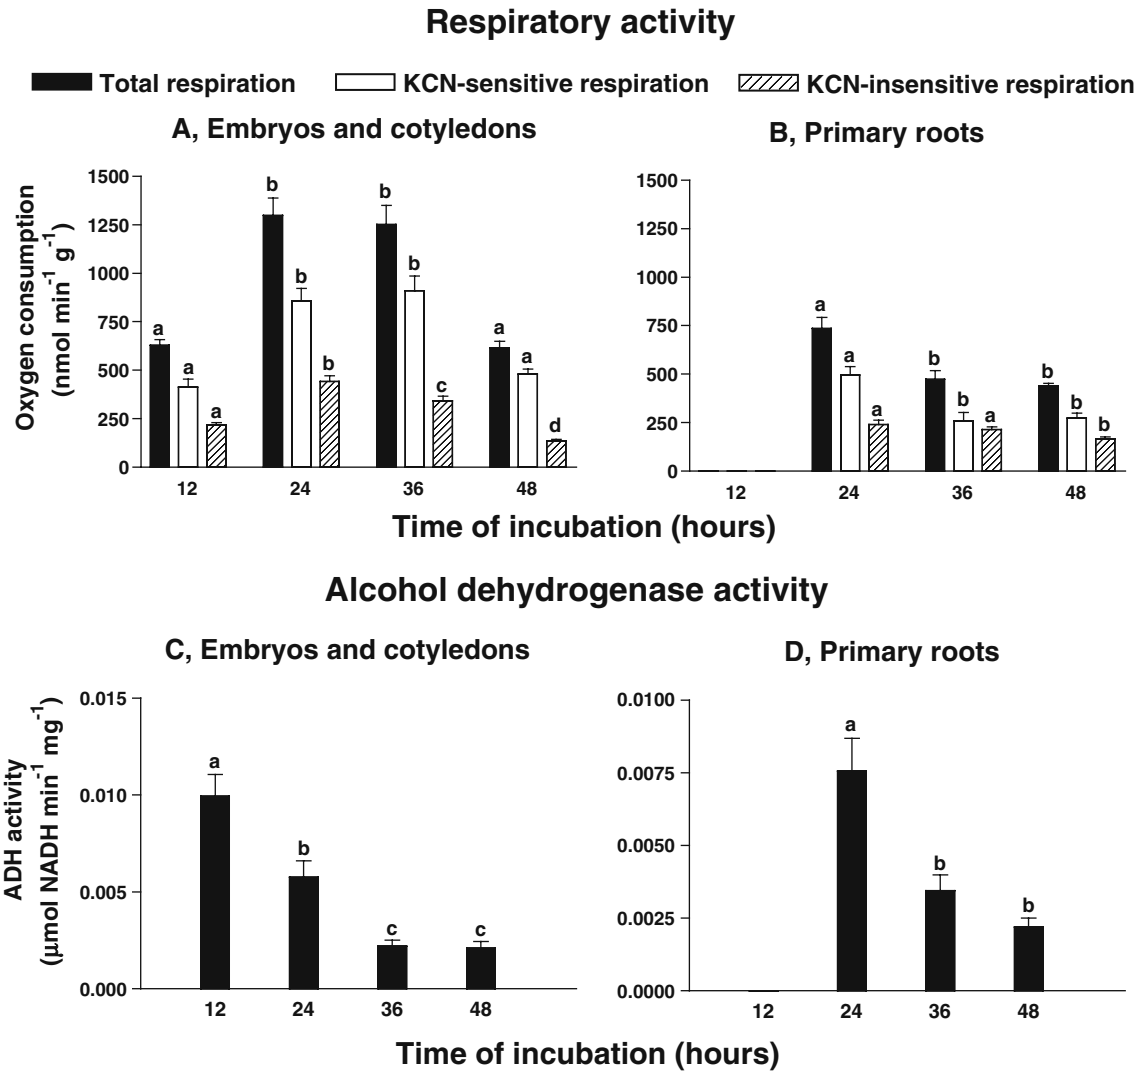

Fig. 2 Time-course of respiratory activity (**a**, **b**) and alcohol dehydrogenase (ADH) activity (**c**, **d**) of embryos, cotyledons (**a**, **c**) and primary roots (**b**, **d**) of *Ipomoea triloba*. Total respiration: oxygen consumption in the absence of KCN; KCN-insensitive respiration: oxygen consumption in the presence of KCN; KCN-sensitive respiration: difference between total respiration and KCN-insensitive respiration. The values are the means ± SE (N=4 for respiratory activity and N=5 for ADH). Different letters within each parameter indicate significant differences according to ANOVA with Duncan's multiple range test at 5% level significance

The activity of LOX (Fig. 3f) was relatively negligible in embryos of *I. triloba*, but there was an accentuated increase after the completion of seed germination. At 24 hr, the activity of this enzyme was higher in cotyledons than in primary roots. The activity did not vary in cotyledons during the growth period, but it increased in primary roots by 3.7-fold at 36 hr and by 4.1-fold at 48 hr relative to the value recorded at 24 hr.

Effects of Fourteen Allelochemicals on Germination and Growth of Ipomoea triloba L. None of the assayed allelochemicals caused significant modification in germination indices of *I. triloba* (Table 1). However, the growth of the resulting seedlings was reduced, especially the primary root growth (Table 2). At 48 hr, root length was reduced by vanillic acid (−27%), coumaric acid (−33%), ferulic acid (−31%), caffeine (−25%), quercetin (−22%), eucalyptol (−16%), camphor (−26%), α-pinene (−22%), and limonene (−17%). Coumarin was more active; it reduced root length by 62% and also affected hypocotyl length (−47%). Hypocotyl length also was reduced by camphor (−28%). A parallel decrease in the fresh weight of primary roots was found for vanillic acid, coumaric acid, ferulic acid, quercetin, and α-pinene. Rutin did not cause any change in primary roots length, but it reduced the fresh weight of primary roots. None of the assayed allelochemicals modified the fresh weights of hypocotyls. For subsequent experiments, we selected among the active compounds a representative of the

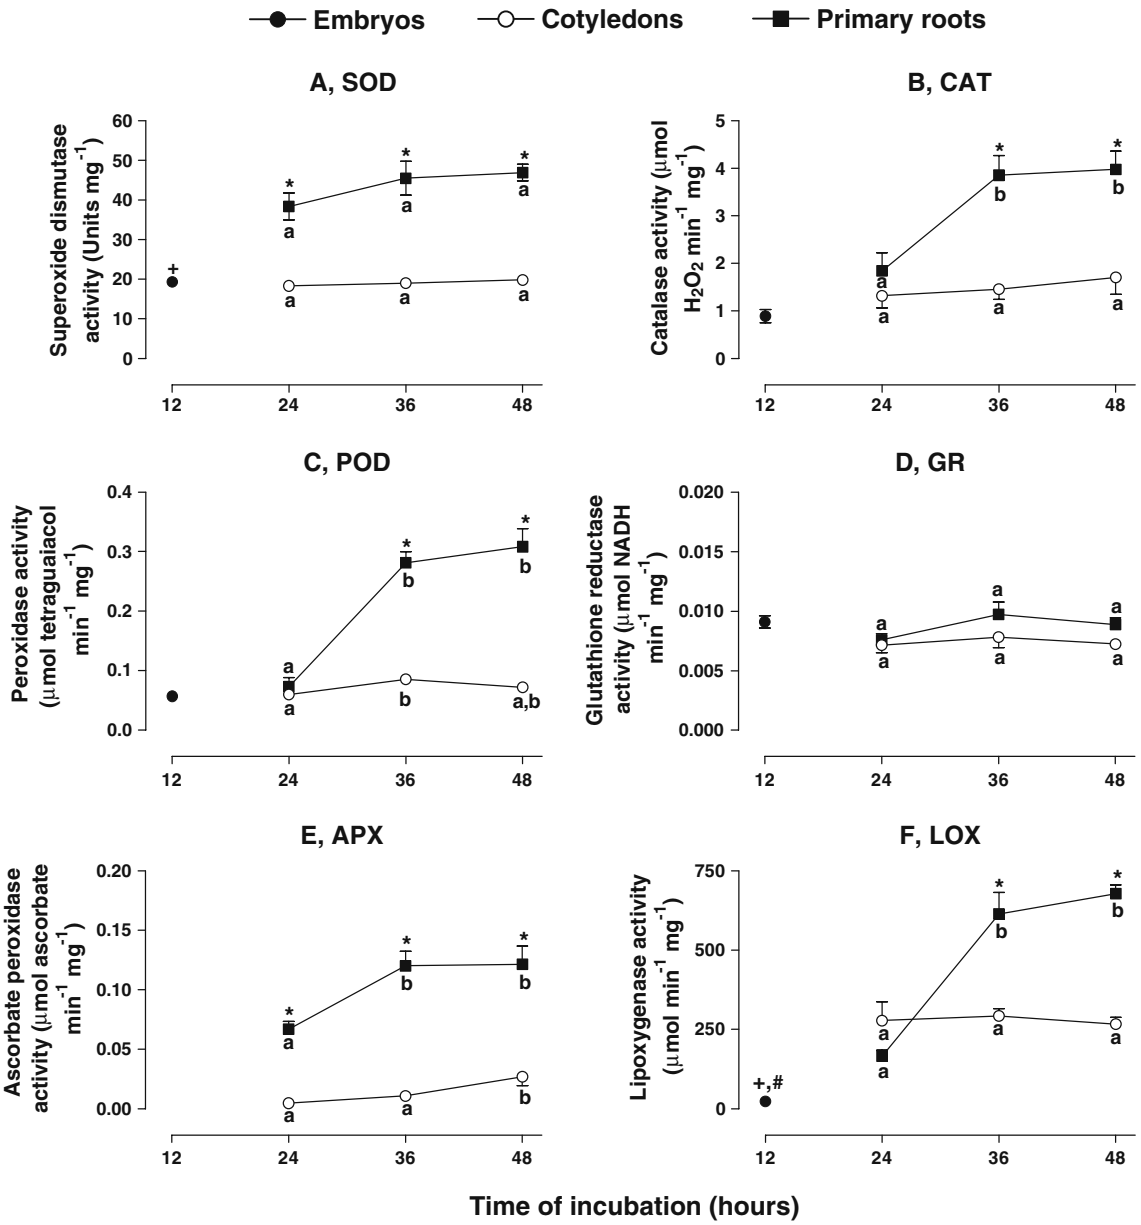

Fig. 3 Time-course of superoxide dismutase (**a**), catalase (**b**), peroxidase (**c**), glutathione reductase (**d**), ascorbate peroxidase (**e**) and lipoxygenase (**f**) activities in embryos, cotyledons and primary roots of *I. triloba*. Each data point is the mean ± SE (N=4–7). Significant differences between means were identified by ANOVA with Duncan's multiple range test (P<0.05). Different letters indicates mean values of enzymatic activities in embryos and cotyledons or in primary roots that are significantly different; (*) Values of primary roots differing statistically from values of cotyledons at the same experimental time; (+) Values of embryo (12 hr) differing statistically from values of primary roots at 24 hr; (#) Values of embryo (12 hr) differing statistically from values of cotyledons at 24 hr

terpene (α-pinene), phenolic (ferulic acid), and flavonoid (quercetin) class, and coumarin, the most active compound. The respiratory activity, the enzyme activities, and the content of MDA and glutathione were measured in primary roots from seedlings grown for 48 hr in the presence of these selected allelochemicals.

Effects of α-Pinene, Coumarin, Quercetin and Ferulic Acid on Root Apex Respiration, Enzyme Activities and Parameters of Oxidative Stress All selected allelochemicals, with the exception of coumarin, stimulated the total respiratory activity of primary roots (Table 3). This increase was due essentially to stimulation of the KCN-insensitive pathway. In comparison with the control, KCN-insensitive respiration increased nearly 4- to 5-fold in the presence of α-pinene, quercetin, and ferulic acid.

None of the assayed allelochemicals significantly affected the activity of SOD and APX (Fig. 4a and e). CAT activity

Table 1 Mean germination time, speed of germination, speed of accumulated germination of *Ipomoea triloba* L. incubated for 24, 48, or 72 hr in water (control), 1% (v/v) DMSO or in 500 μM allelochemicals

Allelochemical [500 μM]	Mean germination time ($\bar{t}$)	Speed of germination (S)	Speed of accumulated germination (AS)

and oxidized forms were modified by any of the assayed allelochemicals. Alfa-pinene increased MDA content by 42%. Other allelochemicals did not change MDA content.

Discussion

Our results reveal that mitochondrial oxidative phosphorylation in embryos of *I. triloba* resumes shortly after the seed imbibition period, as indicated by considerable KCN-sensitive respiratory activity. After germination completion, the mitochondrial respiratory activity in cotyledons was increased further, probably due to increased metabolic activity linked to mobilization of reserved nutrients. The respiratory activity of primary roots, on the other hand, was similar to that of embryos, and it decreased gradually during the growth period. As the ADH activity in primary roots also decreased progressively, these findings most likely represent a decrease in ATP demand after germination completion. A similar pattern of changes in respiratory activity and ADH activity has been observed in two other weed species, *Bidens pilosa* L. (Pergo et al., 2008) and *Euphorbia heterophylla* L. (Kern et al., 2009).

The occurrence of SOD, CAT, and POD activities in embryos, along with significant KCN-insensitive respiration, suggests that production of reactive oxygen species is initiated as soon as mitochondrial respiration is resumed during seed imbibition. KCN-insensitive respiration accounts for oxygen that is converted into superoxide and H_2O_2 (Puntarullo et al., 1988), or utilized by mitochondrial alternative oxidase (AOX) and other cytosolic or membrane-bound oxidases, including lipoxygenases. Although the relative contribution of each process to KCN-insensitive respiration cannot be inferred from our data, all these processes have been demonstrated previously to be stimulated in oxidative stress conditions (Siedow and Moore, 1991; Baker and Orlandi, 1995; Thaler, 1999; Porta and Rocha-Sosa, 2002; Blokhin et al., 2003).

After the completion of germination, there was a distinct pattern of change in the activities of antioxidant enzymes in cotyledons and primary roots. The activity levels of SOD, CAT, GR, and POD in cotyledons remained similar to their levels in embryos. In primary roots, in contrast, the enzyme activities increased substantially over the experimental time period, possibly reflecting a further increase of ROS production. This probably was due to higher oxygen availability for primary roots in comparison with cotyledons, an interpretation that is in agreement with the observations of Wojtyla et al. (2006) in pea seeds. Those authors verified an increase in the concentration of free radicals in embryo axes after radicle protrusion, but they reported no significant changes in cotyledons. Goodman et al. (1986) also reported a large and rapid change in free radical levels in roots as a direct consequence of the oxygen content in the surrounding atmosphere.

The comparison of the activities of the assayed enzymes reveal that SOD and catalase are probably the main antioxidant enzymes involved in the scavenging of ROS in *I. triloba* during germination. The species also contains accessory enzymes that neutralize H_2O_2, such as the peroxidases. PODs exist in a large number of isoenzymatic forms, and they are implicated in a broad range of physiological processes (Passardi et al., 2005). Peroxidases bind to cell wall polymers by ionic or covalent interactions, and the bonds are believed to participate in lignin biosynthesis and the formation of cross-linking in the cell wall, (Müsel et al., 1997; Quiroga et al., 2000). Guaicol-specific PODs have been used as indicators of oxidative stress (Almagro et al., 2009).

It is unlikely that the ascorbate-glutathione cycle significantly contributes to H_2O_2 scavenging in *I. triloba* during seed germination. Glutathione reductase, which catalyses the last step of the cycle, presented low activity in the embryos and seedlings, and ascorbate peroxidase, the first enzyme in this cycle, appeared only in primary roots after germination completion (24 to 48 hr). There are other possible explanations for the presence of APX in *I. triloba*. It is known that ascorbate serves as a chemical scavenger for reactive oxygen in non-

enzymatic reactions (Noctor and Foyer, 1998), and a correlation between APX activity and the levels of ascorbic acid has been demonstrated by Wojtyla et al. (2006). Ascorbate, thus, could play a role in non-enzymatic antioxidant defense systems in primary roots of *I. triloba*.

LOX activity was not detected in embryos of *I. triloba*, but it appeared in cotyledons and primary roots after germination. LOX is another enzyme present in many isoforms in a wide range of organs and tissues, including in axes and cotyledons (Axelrod et al., 1981; Holtman et al., 1996; Feussner et al., 1997). The physiological roles of this family of enzymes in seed germination and seedling growth, however, are not completely known. It has been suggested that they function in tissue hydration (Hildebrand, 1989), cell elongation (Rodriguez-Conception et al., 1995), nitrogen storage (Tranbarger et al., 1991), and breakdown of storage lipids (Feussner et al., 1997). Because of the high lipid content that has been demonstrated in seeds of members of the *Ipomoea* genus (Stoller and Weber, 1970), the possibility exists that the higher activity of LOX in germinating seeds represents its role in lipid storage and mobilization. We cannot exclude, however, the possibility that LOX activity was increased in response to cellular oxidative stress. Lipid peroxidation has been reported to occur along with mitochondrial respiration during seed germination when the moisture content is higher than 0.25 g H_2O per g dry matter (Staniek and Nohl, 2000), and the activation of lipoxygenase is believed to be one of the immediate responses to changes in cell membrane structure induced by over production of reactive oxygen species (Siedow and Moore, 1991; Baker and Orlandi, 1995; Thaler, 1999; Porta and Rocha-Sosa, 2002; Blokhin et al., 2003).

In summary, the occurrence of SOD, CAT, POD, APX, and LOX in embryos and seedlings of *I. triloba* is probably related to ROS production resulting from mitochondrial metabolism resumption during germination and initial growth.

When the seeds were incubated in the presence of fourteen selected allelochemicals, each compound was observed to have different effects on *I. triloba*. At 500 μM, coumarin was the most active among all assayed compounds. The phenolic derivatives, vanillic acid, coumaric acid, ferulic acid, caffeine, and quercetin also inhibited primary roots growth, as did the terpenes eucalyptol, camphor, α-pinene, and limonene.

It should be mentioned that the range of activity of allelochemicals of different classes has been demonstrated to be variable (10^{-2} to 10^{-9}M), and differences of sensitivity among species also are common. Moreover, the allelochemical levels in the soil under natural conditions also can be considerably variable (Einhellig, 1995; Macías, 1995; Batish et al., 2006; Singh et al., 2006; Pergo et al., 2008). Nevertheless, the ecological relevance of an allelochemical activity at concentrations near 500 μM seems to be plausible (Einhellig, 1995; Macías, 1995).

The phytotoxic effect of α-pinene, quercetin, coumarin, and ferulic acid in the primary roots of *I. triloba* could be due, at least in part, to the induction of oxidative stress as indicated by the stimulation of antioxidant enzyme activities. α-Pinene increased the activities of GR and POD, coumarin stimulated POD activity, and ferulic acid stimulated the activities of GR and CAT. Also in agreement with this assumption, an increased lipoxygenase activity was found in the presence of α-pinene, quercetin, and ferulic acid.

The activation of H_2O_2 neutralizing enzymes is probably a defense mechanism that counters higher ROS production. Apparently, this antioxidant mechanism provides protection against oxidative stress induced by quercetin, coumarin, and ferulic acid, but not against oxidative stress induced by α-pinene because an increased malondialdehyde content was found only in the presence of this monoterpene. A higher production of ROS by 500 μM α-pinene might explain these different responses to assayed allelochemicals.

Differences in the mechanisms by which each allelochemical induced oxidative stress also should be considered. Mitochondria and chloroplasts are the main ROS sources (Puntarullo et al., 1988; Foyer et al., 1994; Mittler, 2002). It is possible that a direct action of α-pinene on mitochondria increases mitochondrial ROS generation, as this is in accordance with its effects found in the primary roots of maize (Abrahim et al., 2003a; Ishii-Iwamoto et al., 2006). Quercetin and ferulic acid also affect mitochondrial functions (Takahashi et al., 1998; Sert et al., 1998; Abrahim et al., 2003b). Although we have not measured the direct effects of these allelochemicals in mitochondria isolated from *I. triloba* seedlings, they both caused a strong stimulation of KCN-insensitive respiration of primary roots. Besides an increase in the fraction of oxygen converted to ROS, mitochondrial alternative oxidase (AOX) stimulation likely contributed to higher rates of KCN-insensitive respiration. AOX stimulation has been suggested as a compensatory mechanism that reduces ROS generation by the electron transport chain (Maxweel et al., 1999; Mittler, 2002; Clifton et al., 2005).

We emphasize that relatively little is known about the primary mechanism by which the allelochemicals induce oxidative stress in plant seedlings. Although molecular mechanisms have been reported (Bais et al., 2003; Weir et al., 2004; Golisz et al., 2008), it is difficult to discern whether they are causes or consequences of ROS production. For example, Bais et al. (2003) presented evidence that the allelochemical (-)-catechin triggers a wave of ROS that is initiated at the root meristem of *Arabidopsis thaliana*, leading to a Ca^{2+} signaling cascade followed by genome-wide changes in gene expression resulting in the death of the root systems. Golisz et al. (2008) also reported a higher expression of several genes including those that are up-regulated during biotic and/or abiotic stresses in *Arabidopsis thaliana* in

response to the allelochemicals fagomine, gallic acid, and rutin. Rudrappa et al. (2007) showed that gallic acid secreted by roots of the noxious weed *Phragmites australis* led to increased ROS that disrupted the root architecture of susceptible plants by affecting microtubule assembly. In *Chlorella vulgaris*, Qian et al. (2009) found that the oxidative stress caused by the allelochemical N-phenyl-2-naphthylamine is associated with photosynthesis inhibition and altered gene transcription.

Regardless of the primary mechanisms of allelochemical-induced oxidative stress, our data suggest that during seed germination and initial growth, a period when antioxidant enzyme activity increases and counteracts the harmful ROS effects produced during mitochondrial metabolism resumption, the presence of allelochemicals, which cause further oxidative stress, may leave the seeds/seedlings more vulnerable to cellular dysfunction and cell death.

In agro-ecosystems, allelochemicals with high oxidative stress-inducing potential can be released from cultivated plants or cover crops and cause inhibition of both growth and development of weed species. Identification of these allelochemicals may contribute to the discovery of natural compounds with herbicide potential (Duke et al., 2000; Inderjit and Duke, 2003). In fact, it is known that some commercial herbicides cause cellular death by inducing oxidative stress. This is a consequence of either electron flow interference in photosystem II (PSII) or the inhibition of anti-oxidant compound synthesis, including carotenoids (Kruse et al., 2006). It is reasonable to suggest that among the tested allelochemicals, α-pinene has a high potential to act as a herbicide in *I. triloba* through its effect in inducing oxidative stress during seed germination and the initial seedling growth.

Abstract Colony-specific cuticular hydrocarbons are used by social insects in nestmate recognition. Here, we showed that hydrocarbons found on the mound of *Pogonomyrmex barbatus* nests facilitate the return of foragers to the nest. Colony-specific hydrocarbons, which ants use to distinguish nestmates from non-nestmates, are found on the midden pebbles placed on the nest mound. Midden hydrocarbons occur in a concentration gradient, growing stronger near the nest entrance, which is in the center of a 1–2 m diameter nest mound. Foraging behavior was disrupted when the gradient of hydrocarbons was altered experimentally. When midden material was diluted with artificial pebbles lacking the colony-specific hydrocarbons, the speed of returning foragers decreased significantly. The chemical environment of the nest mound contributes to the regulation of foraging behavior in harvester ants.

Key Words *Pogonomyrmex barbatus* · Hydrocarbons · Homing · Chemical ecology · Foraging behavior

Introduction

Ant foragers use both individual and collective processes to find their way to and from the nest. The best-known example of navigation by foraging ants uses both. First, a scout navigating on its own searches for food, and when it finds food, returns to the nest while laying a chemical trail. The trail initiates a collective process that guides many other ants to the food source, while each ant lays a trail on the way back. In some species, this collective process regulates the number of foragers according to the abundance of food (Walsh et al., 1965). Other species use a different collective process that involves chemical trails. For example, workers of the polydomous Argentine ant *Linepithema humile* lay trail pheromone as they travel (Aron et al., 1989), thus leading all the ants to follow a shared trail system from one nest to another.

In the desert seed-eating ant, *Pogonomyrmex barbatus*, foragers do not use trail pheromone to recruit to specific locations (Greene and Gordon, 2007). Instead, foragers leave the nest together in a direction influenced by the patrollers, a small group of ants that scout the foraging area early in the morning, and a forager's memory of where it last collected food. The patrollers place a chemical cue from the Dufour's gland on about 20 cm of the nest mound, and this influences the directions foragers will travel up to 20 m from the nest (Greene and Gordon, 2007). The choice of direction allows colonies to avoid overlap with the foragers of neighboring conspecific colonies (Gordon, 1992; Gordon and Kulig, 1996). Each forager leaves the nest with a stream of other ants and searches for food. Once it finds food, it returns immediately to the nest. The colony uses another process, the rate of forager return, to regulate foraging activity; foragers are stimulated to leave the nest by the return of other foragers with food (Schafer et al., 2006; Gordon et al., 2008). The rate of forager return is a measure of the availability of food, because the more food is available, the more quickly foragers find it and return to the nest. Since foraging is regulated by the rate of return of

successful foragers, any process that facilitates the rapid return of foragers would promote the accuracy of this measure of food availability.

Olfactory cues on the nest mound or foraging area of ants play an important role in orientation and homing behavior (Cammaerts and Cammaerts, 1987; Wu, 1989; Jaffé et al., 1990). Cuticular hydrocarbons are vital chemical cues used by ants in discrimination between nestmates and non-nestmates (Singer, 1998; Wagner et al., 2000; d'Ettorre and Lenoir, 2010). Hydrocarbons (HCs) have been found in and on the nests of some ant species (Grasso et al., 2005; Lenoir et al., 2009). Hydrocarbons are transferrable, stable, species- and colony-specific compounds that make them ideal candidates for homing signals on the nest mounds of ants.

Nests of *P. barbatus* have large, flat, circular mounds about 1–2 m in diameter (Fig. 1a). Harvester ant nest mounds are generally, but not always, covered with small midden pebbles collected by the foragers (Fig. 1b; see Gordon, 1984a). The midden pebbles surround the nest entrance, which is located approximately in the center of the nest mound. Mounds with midden pebbles typically are cleared of vegetation by the ants.

Observations suggest that midden material is coated with HCs. Harvester ants of a related species, *Pogonomyrmex badius,* collect bits of charcoal, which absorb organic compounds, for their nest middens. The charcoal middens prevent incursion on the mound by ants of other species (Gordon, 1984b), which suggests that midden material may contain species-specific HCs or other discriminatory olfactory cues. Hölldobler, (1971) found that secretions from the Dufour's gland act as homing signals for *P. badius* foragers locating the nest. Dufour's gland secretions in several *Messor* harvester ant species contain HCs (Brand and Mpuru, 1993; Co et al., 2003; Tullio et al., 2003).

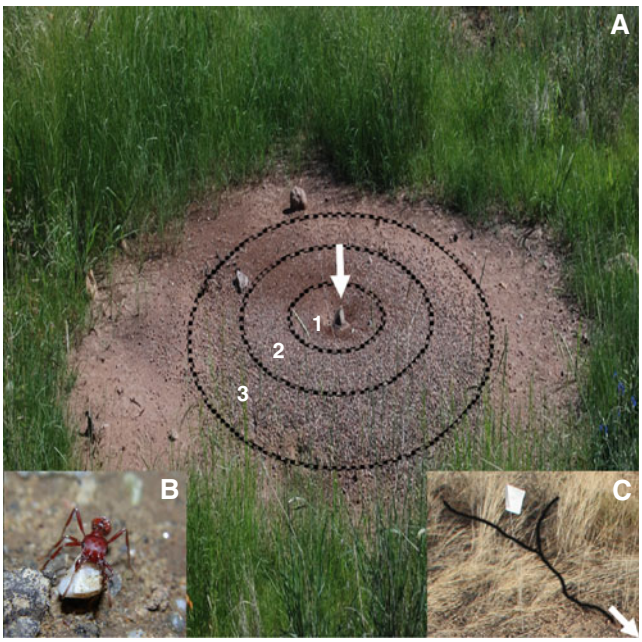

Fig. 1 **a** Anatomy of a *Pogonomyrmex barbatus* nest mound. Midden zones are indicated by dashed circles; 1 = center, 2 = middle, and 3 = outer zone. The white arrows indicate the nest entrance (center of midden zone 1). **b** Photograph in the lower left corner shows a *P. barbatus* forager carrying a midden pebble. **c** Photograph located in lower right corner shows an established foraging trail at the edge of the nest mound. The black line marks the trail. The white arrow points towards the nest entrance

Midden workers of *P. barbatus* arrange midden pebbles on the nest mound (Gordon, 1984a), and have been observed manipulating midden pebbles with their mouthparts (Gordon and Mehdiabadi, 1999). Hydrocarbons can be passively distributed through contact with the ant cuticle (Soroker et al., 1995; Vienne et al., 1995) or secreted onto objects from glands inside the ant (Soroker et al., 1995, 2003). It is unclear whether ants are actively or passively marking midden pebbles. Returning foragers can be seen attennating midden pebbles on their way back to the nest entrance (SJS personal observation), which suggests that there may be a spatial pattern in the concentration of midden HCs.

Here, we examined how HCs on *P. barbatus* nest mounds influence the speed at which foragers travel from the edge of the nest mound to the nest entrance. (1) We tested for the presence of HCs in *P. barbatus* midden pebbles. (2) We tested whether ants can discriminate between their own midden HCs and foreign midden HCs. (3) We examined the spatial pattern of HC abundance in midden pebbles on the nest mound. (4) To determine the effects of nest mound chemical cues on foraging behavior, we experimentally manipulated the distribution of midden material.

Methods and Materials

Study Site. All experiments were conducted with *P. barbatus* colonies at the site of a long-term field study near Rodeo, NM, USA, in which colonies have been censused since 1985 so that colony ages are known (census methods in Gordon and Kulig, 1996).

1 Are there Hydrocarbons (HCs) in the Midden?

Hydrocarbon Extraction and Analysis To determine whether midden pebbles contain HCs, midden pebbles were collected from 10 mature *P. barbatus* colonies (ages 6–18 year). HCs were extracted from 5 g of midden pebbles by immersing the pebbles in 5 ml of 100% pentane (Sigma, St. Louis, MO, USA) for 30 min. For comparison, ant cuticular HCs were extracted from individual ants by immersing the ants in 0.5 ml of 100% pentane (Sigma) for 7 min. Suspensions of

both midden pebbles and ants were lightly shaken during the first and last minute of the soak period. The suspension solution was eluted from a 1-cm silica gel (28–200 mesh, Sigma) column with a 1 ml wash of 100% pentane. The eluant was dried overnight, and the samples were redissolved in 100 µl of pentane for midden pebble HCs or 25 µl of pentane for ant cuticular HCs, including an internal standard (27 ng per µl of triatriacontane,$C_{33}H_{68}$; Fluka Analytical, Buchs, Switzerland). The amounts of midden HCs were quantified by comparing their peak areas with that of the internal standard. Samples were analyzed by gas chromatography (GC). GC analyses were performed on a Varian 3900 GC with a CP-8400/8410 auto sampler and a flame ionization detector (Tissot et al., 2001; Greene and Gordon, 2003). Aliquots of 8 µl were introduced by split-less injection onto a capillary column (DB-1, 30 m, 0.25 mm ID, 0.25-µm film thickness; Agilent J&W Scientific, Santa Clara, CA, USA), with helium as the carrier gas flowing at 1 ml/min. The injector temperature was 300°C. The temperature was 170°C during injection, and was then increased to 220°C at 25°C/min, 220°C–310°C at 3°C/min. Retention times were verified on the GC for 6 *n*-alkanes using a standard mixture containing *n*-tricosane, *n*-tetracosane, *n*-pentacosane, *n*-heptacosane, *n*-hexacosane, and *n*-nonacosane (Sigma) interspersed among runs.

There were no readily available standards for methyl alkane and alkene identification. Tentative methyl alkane and alkene identifications were based on analyses of a subset of midden pebble (N=3), and *P. barbatus* worker (N=3) HC samples by coupled gas chromatography/mass spectrometry (GC/MS), and by cross reference with previously published work (Wagner et al., 1998; Tissot et al., 2001). GC/MS was conducted at the Department of Environmental Sciences, Policy and Management at the University of California Berkeley, using a 7890A Agilent GC (Agilent Technologies, Santa Clara, CA, USA) coupled with a 5975 C Agilent Mass Selective Detector (electron impact ionization at 70 eV). Aliquots of 1 µl were injected by using an Agilent 7683B automatic injector operated in split mode (5:1) onto a capillary column (DB-5, 30 m, 0.32 mm ID, 0.25-µm film thickness; Agilent J&W Scientific), with helium as the carrier gas flowing at 0.7 ml/min. Mass Selective Detector (MSD) scanning parameters ranged from 50 to 550 amu, with a sampling rate of 2.91 scans/sec and a threshold detection of 150 counts.

Statistical Analysis Nest mounds were divided into three zones; center, middle, and outer, for all colonies (Fig. 1a; 3 zones per colony, 10 colonies, N=10 replicates per midden zone). The average concentrations in nanograms (SD) of each HC and HC class present in the midden pebble samples were calculated for each midden zone. Nonparametric Kruskal Wallis one-way ANOVAs were used to compare the average individual and average total HC concentrations of the 3 midden zones. To compare the concentrations of HCs on midden pebbles and on forager cuticles, the average concentration in ng (SD) of each HC and HC class was calculated for 50 *P. barbatus* foragers.

2 Can *P. barbatus* Workers Discriminate between their own Midden and that of Another Nest?

Bioassay We tested whether harvester ants recognize chemical cues on midden pebbles, and HCs extracted from the surface of midden pebbles, by measuring the ants' agonistic response to midden pebbles and objects coated with a chemical stimulus (Wagner et al., 2000). Stimulus objects, either a pile of midden pebbles or a 5×5×10 mm glass block (Wagner et al., 2000) coated with a chemical stimulus, were placed on the nest mound approximately 10 cm from the nest entrance, but never directly along a foraging trail. After placement of the stimulus objects, we recorded every 30 sec for 5 min the number of ants biting or stinging the objects, and the total number of ants in contact with the objects, either with antennae, abdomen, legs, or any other body part.

Trials were conducted on 4–6 August 2001 and 8–17 May 2002. We measured the proportion of ants that exhibited agonistic behavior, biting, and stinging. The first experiment tested the response of workers to midden pebbles of their own and of another nest. About 20 midden pebbles were placed in a small pile on the nest mound. On a single day, colonies (ages 3–16 year; N=15 colonies) were offered midden pebbles from its own nest, and from another nest, once in a randomized sequence. The second experiment tested the response of workers to midden HCs and worker cuticular HCs of their own and of another colony. On a single day, colonies (ages 3–16 year; N=8 colonies) were offered one 5×5×10 mm glass block either coated with nestmate cuticular HCs from same-colony workers, non-nestmate cuticular HCs from foreign-colony workers, HCs from same-colony midden pebbles, HCs from foreign-colony midden pebbles, and pentane (solvent control), once in a randomized sequence.

Statistical Analysis For both experiments, we calculated the angular transformation (Zar, 1999) of the proportion of ants that displayed either biting or stinging, out of the total number of ants that made contact with the pile of midden pebbles or the glass blocks coated with a chemical stimulus. For the first experiment, the angular transformed data were compared for the two midden pebble treatments (same-colony and foreign-colony midden pebbles), using a *t*-test. For the second experiment, all 5 treatments (same-colony worker cuticular HCs, foreign-colony worker cuticular

HCs, same-colony midden pebble HCs, foreign-colony midden pebble HCs, and solvent control) were compared using an ANOVA with Fisher's PLSD for *post hoc* analysis.

3 Is there a Spatial Pattern of Hydrocarbon Abundance in Midden?

Midden Collection Midden pebbles were collected from 10 mature *P. barbatus* colonies (ages 6–18 year) in August 2008. Pebble cover on mounds, estimated by sight, ranged from 40–100% of the total mound surface area, with the remainder of the nest mound as bare soil. Nest mounds were defined as the entire area around the nest entrance of a colony extending either to the edge of the vegetation or of the pebble cover. Nest mounds were divided into 3 zones of approximately similar radii: center (closest to nest entrance), middle, and outer (Fig. 1a). From each zone, we gathered ~10 g of midden pebbles using nylon gloves, and placed the midden pebbles into separate plastic bags. Analysis of samples stored in the bags indicated that there was no detectable contamination from the plastic. In each of the three zones, on five nest mounds, ~2 g of soil were collected from the surface beneath the midden pebbles. Samples were stored at −20°C. All samples were transferred to 16×100 mm glass culture tubes (VWR Scientific Products, West Chester, PA, USA) before HC extraction. Five grams of midden pebbles and 2 g of surface soil were extracted by immersing the pebbles or soil in 5 ml of 100% pentane (Sigma) for 30 min. Hydrocarbon extraction and analysis of both midden pebbles and surface soil were performed as above. Samples were redissolved in 100 μl of pentane before GC analysis.

Statistical Analysis We calculated the mean total HC concentration in ng (SD) for midden pebbles and surface soil from each zone. Nonparametric Kruskal Wallis one-way ANOVAS were used to test for differences between midden zones. Dunn's Multiple Comparison tests were used for post-hoc analysis.

4 Does the Hydrocarbon Gradient in the Harvester Ant Midden Influence Foraging Behavior?

Colony Selection Twenty colonies, all at least 5 year old, were selected in August 2009. Nest mound size ranged from 2.62 m^2 to 10.50 m^2, and pebble cover ranged from 50–99%. Each colony was located at least 10 m away from the nearest neighboring colony. All nest mounds were approximately circular. The area of each nest mound was calculated using the longest chord of the irregularly-shaped circular nest mounds.

Data Collection before Experimental Manipulation We measured the time foragers took to reach the nest entrance from the edge of the mound. In all 20 colonies, measurements were made during peak foraging hours, from 7 am to 10:45 am daily, for 5 day from 12–16 August 2009. Because foraging activity changes in the course of the activity period (Gordon, 2002), the sequence of colonies in which foraging was observed was reversed from 1 day to the next. For each colony we chose a foraging trail cleared of vegetation that had been used by foragers for at least two consecutive days (Fig. 1c). A flag was placed at the perimeter of the nest mound to mark the beginning of the trail. Distances from the flag to the nest entrance ranged from 0.84 m to 2.03 m. We recorded the time it took individual foragers to return to the nest entrance from the flag, and calculated forager speed as the return time divided by the distance from the flag to the nest entrance. We counted only returning foragers, which could be distinguished from other workers because the returning forager carried a food item in its mandibles. For each colony, and each of the 5 day of observation before treatment, we measured the speeds of 3 foragers. In a total of 60 observations from 10 of the 20 colonies, there was no foraging activity, and these 60 observations were excluded. A total of 240 observations from 20 colonies were used in the analysis.

Experimental Manipulations To determine the effect of chemical cues on the return of foragers, we either (a) diluted nest middens by adding an inert substance to the nest mound, or (b) deprived nests of midden material. To test the effect of colony-specific HCs on forager return speed, we diluted midden pebbles with expanded Perlite (Scotts Miracle-Grow®, Maryville, OH, USA), a substance similar in structure and size but lacking colony-specific HCs. Perlite is an amorphous volcanic glass that has been softened under extreme heat for commercial use. Perlite consists of 70–75% silicon dioxide, 12–15% aluminum oxide, 3–4% sodium oxide, 3–5% potassium oxide, and trace amounts of iron oxide, magnesium oxide, and calcium oxide. Chemically, there are only minor differences between Perlite and midden pebbles. Midden pebbles found on *P. barbatus* nest mounds and Perlite are both volcanic rocks which contain the same major elements found in all silicate minerals (Elston et al., 1973). Expanded Perlite clumps together to form small balls that are roughly the size of midden pebbles. To deprive nests of midden material, we removed all midden pebbles from the nest mound and left the soil bare.

Nest mounds were divided into 3 zones of approximately similar radii: center (closest to nest entrance), middle, and outer (Fig. 1a). There were 4 treatments: 1) Midden pebbles in the center and middle zones were diluted with Perlite. The center and middle zones were combined because the

results of the experiment described in the previous section showed no significant difference between the zones in HC concentration. 2) Midden pebbles in the outer zone were diluted with Perlite. 3) Midden pebbles for all 3 zones were diluted with Perlite. In treatments 1, 2, and 3, we applied Perlite to the indicated zones twice, on days 1 and 4 of the 6-d observation period. Perlite was reapplied after 2 day because in all colonies, the Perlite treatment was almost completely removed by d 3, probably due to wind, rain, and the activity of nest maintenance workers in the afternoon, when no observations of foraging activity were made. 4) All midden pebbles were removed, leaving the bare soil that had been covered by midden pebbles.

An alternative design would have been to remove pebbles, extract HCs and return them to mounds. This was not feasible due to the large quantity of pebbles on the mound and because extracted pebbles would have been difficult to return to the mound in a homogenous manner.

Data Collection after Experimental Manipulation We measured the speed at which foragers returned to the nest entrance from the edge of the mound using the methods described above once a day for 6 day from 17–22 August 2009. In a total of 76 observations from 11 of the 20 colonies, the colony was not foraging actively, and these observations were excluded. A total of 284 observations of forager return speeds from the 20 colonies were used in the analysis.

Statistical Analysis For each treatment, we compared forager return speeds before and after treatment within each treatment group using unpaired *t*-tests. Data were square-root transformed to meet the assumptions of normality.

To compare forager return speeds in the 4 treatment groups, we first normalized for variation among colonies in forager speed. We found for each colony the difference between mean forager return speed before and after treatment, and divided this difference by that colony's mean forager return speed. Using the normalized mean colony difference in forager return speed before and after treatment, we tested for differences among treatments using an ANOVA.

Results

1 Are there Hydrocarbons (HCs) in the Midden?

Midden pebbles contained HCs tentatively identified as identical to those found on the ants' cuticles (Fig. 2). Twenty-one HCs that occur on the *P. barbatus* cuticle were detected in the midden (Table 1). It is possible that other HCs were also present in trace amounts. Hydrocarbon compounds were of four classes, *n*-alkanes, monomethylalkanes, dimethylalkanes, and alkenes. HCs present in the highest abundances were *n*-alkanes. The 5 most abundant HCs in the midden were *n*-hentriacontane (C31), *n*-nonacosane (C29:0), *n*-pentacosane (C25:0), *n*-heptacosane (C27:0), and *15-, 13-, 11-, 9*-methylhentriacontanes (C31:0), respectively. There was an overall difference among midden zones in individual HC concentration for all HCs except *n*-tricosane and *n*-tetracosane. There was a significant difference among midden zones in the average concentration of HCs for each HC class (Kruskal Wallis tests: alkanes: H_3=8.87, N=10, P=0.012; monomethylalkanes: H_3=11.66, N=10, P=0.003; dimethylalkanes: H_3=10.55, N=10, P=0.005; alkenes: H_3=12.21, N=10, P=0.002). There were about 10 times more HCs on one forager's cuticle than on 5 g of midden pebbles; the mean concentration of HCs in ng (SD) on one forager's cuticle, and on 5 g of midden pebbles were 562.30 (252.27) and 57.81 (67.78), respectively.

2 Can *P. barbatus* Workers Discriminate between their own Midden and that of Another Nest?

Midden pebbles contain colony-specific HCs that are recognized by workers. Ants were more likely to respond aggressively toward midden pebbles from another colony's nest than toward midden pebbles from their own colony's nest (Fig. 3a; Paired *t*-test: t_{26}=4.1, P<0.001). The mean proportion of ants biting/stinging (SD) midden pebbles from their own and conspecific nests were 0.06 (±0.08) and 0.42 (±0.19), respectively.

Pogonomyrmex barbatus workers recognized the HC blend extracted from midden pebbles of their own colony. Workers distinguished HCs extracted from midden pebbles of their own nest from those extracted from the midden pebbles, or workers of another colony. A higher proportion of contacts were aggressive in response to extracts of midden pebbles and whole ants from other colonies than to extracts of midden pebbles or extracts from ants of their own colony (Fig. 3b; ANOVA: $F_{4,\ 35}$=8.8, P<0.001). The mean proportions of workers biting/stinging (SD) glass blocks treated with nestmate cuticular HCs from same-colony workers, non-nestmate cuticular HCs from foreign-colony workers, HCs from same-colony midden pebbles, HCs from foreign-colony midden pebbles, and solvent were 0.40 (±0.33), 0.84 (±0.18), 0.40 (±0.23), 0.84 (±0.27), and 0.24 (±0.20), respectively [Fisher's PLSD (Protected Least Signficant Difference): non-nestmate (foreign) cuticular HCs (FCHCs), foreign midden HCs (FMHCs): mean difference = 11.606, P=0.262; cuticular HCs from nestmates (CHCs), colony midden HCs (MHCs): mean difference = 17.249, P=0.099; CHCs, solvent: mean difference = 11.953, P=0.249; MHCs, solvent (pentane): mean difference = 5.296, P=0.606; FCHCs vs CHCs, MHCs, solvent: mean difference = 32.511, 49.760, and 44.464, P=0.003, <0.001, and <0.001 respectively;

FMHCs vs CHCs, MHCs, solvent: mean difference = 20.905, 38.154, and 32.858, P=0.047, <0.001, and 0.003, respectively].

3 Is there a Spatial Pattern of Hydrocarbon Abundance in Midden?

There is a HC concentration gradient on the midden pebbles and on the soil below the midden pebbles on the surface of nest mounds. Hydrocarbon concentration in both the midden pebbles and soil is higher near the nest entrance (Fig. 4). The mean total HCs in ng (SD) for the midden pebbles were 82.75 (56.00), 73.73 (92.97), and 16.94 (14.03) for the center, middle, and outer zones, respectively (Kruskal Wallis test, H_3=10.41, N=10, P=0.006); the center zone differed significantly from the outer zone (Dunn Multiple Comparison test, difference in rank sum = 12.2, P<0.01). The mean total HCs in ng (SD) for the soil were 40.08 (13.84), 11.91 (6.15), and 8.20 (2.14) for the center, middle, and outer zones, respectively (Kruskal Wallis test: H_3=9.78, N=5, P=0.008); the center and outer zone differed significantly (Dunn Multiple Comparison test, difference in rank sum = 8.6, P<0.01).

4 Does the Hydrocarbon Gradient in the Harvester Ant Midden Influence Foraging Behavior?

The HCs on the nest mound facilitate the return of foragers to the nest. Diluting midden pebbles with Perlite reduced the speed with which returning foragers reached the nest entrance (Fig. 5; Unpaired t-test: t_{522}= 3.689, P<0.001). The mean speed at which returning foragers reached the nest entrance (SD) before and after treatment was 5.9 (3.0) cm/s (N=240) and 5.0 (3.0) cm/s (N=284), respectively. The average forager speed to nest entrance (SD) in the center and middle zones (treatment 1) was 6.4 (3.3) cm/s before treatment and 5.1 (3.1) cm/s after treatment (*Unpaired t-test:* t_{132}=2.21, P=0.029). In the outer zone (treatment 2), the average speed to the nest entrance (SD) before treatment was 5.4 (2.3) cm/s and 4.0 (2.0) cm/s after treatment (Unpaired t-test: t_{136}=3.99, P=0.001). In all 3 zones (treatment 3), the average speed to the nest entrance (SD) before treatment was 6.6 (3.5) cm/s and 5.1 (3.0) cm/s after treatment (Unpaired t-test: t_{124}=2.589, P=0.011). The speed of returning foragers to the nest entrance increased slightly but not significantly after the removal of pebbles, with bare soil remaining (treatment 4). When all pebbles were removed, the average speed of returning foragers to the nest entrance (SD) before treatment was 5.1 (2.7) cm/s and 5.8 (3.2) cm/s after treatment (Unpaired t-test: t_{124}=1.17, P=0.243).

Forager return speed did not differ according to the midden zone from which Perlite was added. Diluting the midden with Perlite (treatments 1–3) reduced forager return speeds more than the removal treatment (treatment

4), but there was no difference among treatments, and thus no effect of the zone from which Perlite was added (*ANOVA*: $F_{3,\ 16}$=1.498, P=0.2531). The average changes in forager speed to nest entrance (SD) for treatments 1–4 were 0.91 (0.12), 0.87 (0.12), 0.84 (0.12), and 1.03 (0.20), respectively.

The Perlite itself did not disrupt the foraging behavior of the ants. To determine that adding inert pebbles to the nest mound, by modifying the nest structure, did not itself affect the speed at which foragers return to the nest, we compared the speeds of returning foragers from colonies with midden pebbles ranging from 50–99% pebble cover to the speeds of returning foragers from colonies whose midden pebbles were removed. The two groups did not differ in the speed of returning foragers (*Unpaired t-test:* t_{262}=0.9241, P=0.356), indicating that the amount of midden pebbles on the nest mound does not affect forager return speed. In response to extraneous material on the nest mound, *P. barbatus* increase the numbers performing nest maintenance and decrease the numbers foraging (Gordon, 1986, 1987). Here, we saw no difference in the number of nest maintenance workers before and after treatment (*Mann–Whitney U test:* U=5841, N_1=100, N_2=120, P=0.727), and the proportion of colonies that did not forage did not differ before and after treatment (before treatment = 19%, after treatment = 19.1%).

Discussion

Our results show that colony-specific chemical cues on the midden pebbles of *P. barbatus* colonies help the foragers return to the nest more quickly. These cues on the midden pebbles are the same HCs that *P. barbatus* workers use in nestmate recognition (Fig. 2; see Wagner et al., 2000). Workers can distinguish their own colony's midden from that of other colonies, and can distinguish their own colony's midden HCs from the midden HCs of other colonies.

The concentration of HCs in midden pebbles and on the soil surface below the midden pebbles increases as a forager moves closer to the nest entrance (Fig. 4). A possible mechanism for the HC gradient is ant density. *P. barbatus* worker densities are greater per cm^2 nearer the nest entrance than away from the entrance (unpublished data). Therefore,

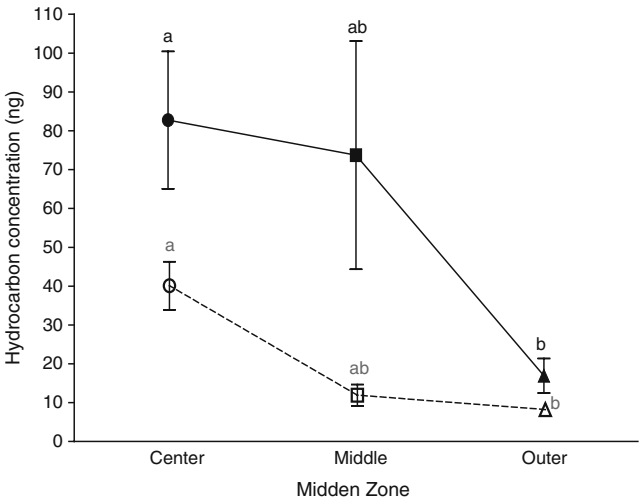

Fig. 4 Mean hydrocarbons in ng per 5 g of midden pebble samples and 2 g of soil samples for the center, middle, and outer midden pebble (closed shapes, solid line), and surface soil (open shapes, dashed line) zones. Center (*circle*), middle (*square*) and outer (*triangle*) zones as in Fig. 1. Lowercase letters above the shapes indicate significant differences. Error bars represent the standard error of the mean

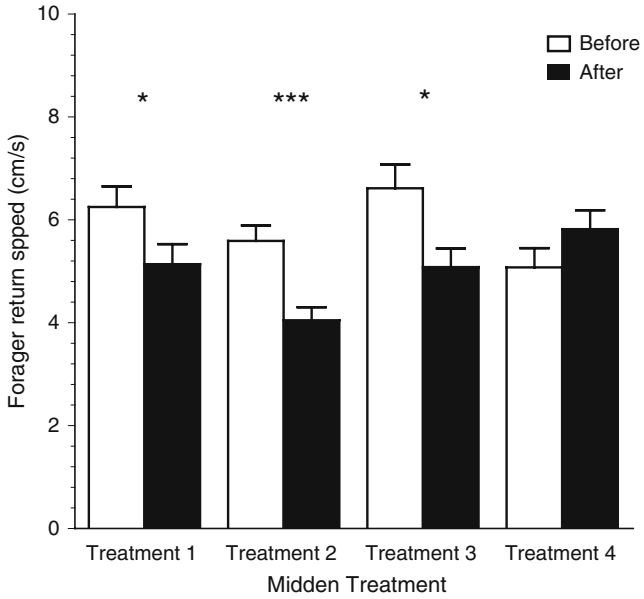

Fig. 5 Comparison of the mean forager return speed (cm/s) before and after treatment within each treatment group. Treatment 1: midden pebbles in the center and middle zones were diluted with Perlite. Treatment 2: midden pebbles in the outer zone were diluted with Perlite. Treatment 3: midden pebbles for all 3 zones were diluted with Perlite. Treatment 4: all midden pebbles were removed, leaving the bare soil that had been covered by midden material. *P*-values were obtained by comparing the square-root transformed forager return speeds before and after manipulation for each treatment group using unpaired t-tests. Error bars represent the standard error of the mean.* $P<0.05$, ** $P<0.01$, *** $P<0.001$

ant footfall or marking behavior occurs more in the center zones than the outer zones. The reduction in the concentration in the outer zones could be due to the difficulty in detecting HCs as their concentrations decrease or due to the greater volatility of certain HCs and the lack of sufficient ant footfall or marking to replace them.

Experimental manipulation of midden pebbles did not disrupt foraging, but it caused a decrease in the walking speed of returning foragers. When midden material was diluted with artificial pebbles lacking the colony-specific HCs, the speed of returning foragers decreased significantly. These effects did not vary according to the region of the nest mound on which the midden was diluted or removed.

The reduction in forager return speed is unlikely due to any physical or chemical properties of Perlite, which was of similar size and shape to the midden pebbles. If midden pebbles texture, size, shape, and/or color were significant factors in guiding ants to the nest, we should have seen a decrease, however slight, in the forager return speed in the removal treatment (treatment 4). Instead, there was a slight, although not statistically significant, increase in forager return speed after the removal treatment.

The rate at which inactive foragers leave the nest depends on the rate at which other foragers return with food (Gordon et al., 2008). Midden HCs influence forager return speeds, which influences forager return rates. Foraging activity affects food intake and interactions with neighbors, because encounters between foragers of neighboring colonies help to maintain foraging territory (Gordon, 1992). Thus chemical cues on the midden play a role in food intake, and in relations among conspecific neighbors.

We found a concentration gradient in HCs by zone on the midden, with a higher concentration toward the nest entrance, but our experiments did not elucidate the function of this gradient, at least in returning forager velocity. Our experiments compared the effect of disrupting the gradient by dividing the nest mound into three concentric zones. It may be that the gradient is important, but that the zones we chose arbitrarily do not correspond to areas that are functionally significant for the ants. Small gradients of HCs in the midden may be important, and finer scale manipulations are needed to investigate this. Perhaps, the chemical concentration gradient is used by *P. barbatus* foragers as a primary means of navigating the nest mound.

Chemical extractions from the top soil on the nest mound revealed the presence of a HC gradient on the soil as well as on the midden pebbles (Fig. 4). The presence of HCs, with a concentration gradient in the surface soil of nest mounds suggests that even in the absence of midden pebbles, there were sufficient HCs to be used by returning foragers. A colony usually stays in the same nest for its 20–30 year lifespan (Gordon, 1992). An accumulation of HCs in the midden and on the soil is not unexpected because of the stable nature of these compounds (Martin et al., 2009).

An interesting mechanism explaining the accumulation of HCs on the nest area as a form of colony recognition system was first reported for other harvester ants (see Grasso et al., 2005) whose fecal spots deposited on the nest surroundings contain colony-specific HCs. Interestingly these HCs are the same as those found on the cuticle of the ants. This mechanism also may be valid for *P. barbatus* and could explain the HC accumulation, not only on the pebbles, but also on the soil surface as a consequence of massive area marking with feces by the ants. Hydrocarbons may be deposited by footprints from glands in the legs of ants (Billen, 2009; Lenoir et al., 2009) or by the Dufour's gland located near the tip of the abdomen (Greene and Gordon, 2007). Another possible source of colony specific HCs may be the post-pharyngeal gland which, at least in some ant species, is clearly involved in the formation of the colony specific label (see for example Soroker and Hefetz, 2000). Further research is needed to determine the origin of midden HCs, and whether specific task groups deposit and maintain HCs in the midden.

We do not rule out the role of olfactory cues, apart from HCs, in foraging behavior. When experimentally offered unusually abundant seeds, *P. barbatus* scouts lay phero-

mone trails from the feeding site to the nest with poison gland secretions (Gordon, 1991; Hölldobler et al., 2001). However, although we did not interfere with any marking behavior on the foraging trail or anywhere outside the nest mound, disturbing the midden clearly affected the behavior of returning foragers. This means that short-term cues alone, if they are used at all, cannot be the only means of guiding returning foragers to the nest entrance.

Harvester ants use midden HCs, a chemical cue applied collectively, to aid in the return of foragers. Several ant species use pheromonal or environmental cues when returning to the nest (Cammaerts and Rachidi, 2009; Steck et al., 2009, 2010). Hydrocarbons, on the other hand, are more stable, are colony-specific, and are regularly transferred from ants to their surroundings. Nest mound HCs have been associated with territorial behavior in ants (Grasso et al., 2005; Lenoir et al., 2009). The use of nest mound cuticular HCs contributes to the regulation of foraging activity because it helps foraging harvester ants to return to the nest more quickly, and thus adds to the precision with which forager return rate measures the current availability of food.

Abstract Intraspecific attraction depends both on the cues provided by the attracting individual and the response of the attracted individual. These attracting cues are related not only to current conditions, but also are a reflection of individual and population life history. These relationships were examined by placing red flour beetle, *Tribolium castaneum* (Herbst.), adults in flasks at increasing densities and monitoring the changes in volatile chemical emission over time. Only certain chemicals were quantified: methyl benzoquinone, ethyl benzoquinone and 4,8-dimethyldecanal, all of which are known to impact the biology of *T. castaneum*. The flasks were used as sources for both quantification of the chemicals and for bioassays. Additional bioassays were conducted with synthetic 4,8-dimethyldecanal, a known aggregation pheromone component, to evaluate attraction with respect to population density. *Tribolium castaneum* density affected both the release of volatile chemicals and the responses of conspecifics to those chemicals. The results indicated that while there were important effects of beetle density on chemical emission and response, none of the chemicals evaluated emerged as promising synergists to the current aggregation pheromone 4,8-dimethyldecanal. The benzoquinones released in response to stress and density acted as anti-aggregation pheromones along with their accepted defensive function.

Introduction

Tribolium flour beetles (Coleoptera: Tenebrionidae) have long been used as models for studying inter- and intraspecific competition (Park, 1948, 1962). They are an ideal model of these relationships, because they can complete their life cycle in small laboratory containers with a flour and yeast mixture. They also are long-lived and tolerate a broad range of environmental conditions (Sokoloff, 1974). Stored products, like other poorly defended nutrient rich resources, are very attractive to a wide range of consumers, and thus competition is fierce. Selection favors those individuals that can quickly find, utilize, and successfully defend their claim to the resource (Ziegler, 1976). Once the resource is occupied, it is depleted by many different forces, environmental, microbial, as well as animal. Other selecting forces come into play on this depleted resource, selecting for different features in colonizers and causing the primary colonists to disperse or migrate to other resources (Dingle, 1972; Ziegler, 1976). The red flour beetle, *Tribolium castaneum* (Herbst.) is an excellent colonizer of cracked grains with a high reproductive rate and cannibalistic offspring, enabling both resource utilization and defense (Park, 1962).

Population density plays an important role in both the composition of chemicals emitted by certain insect species and also their response to those chemicals. There is a large body of information about how the *T. castaneum* population reacts to various stimuli (Sokoloff, 1974). The chemicals produced by *T. castaneum* and by the confused flour beetle,

T. confusum (du Val) include an aggregation pheromone, 4,8-dimethyldecanal (DMD), which is emitted by males and attracts both sexes (O'Ceallachain and Ryan, 1977; Suzuki, 1980); a defensive secretion containing methyl and ethyl-1,4-benzoquinones as toxicants (Wirtz et al., 1978); and 1-pentadecene as a solvent, spreading, absorption agent, and as a copulation pheromone in *T. confusum* (von Endt and Wheeler, 1971; Keville and Kannowski, 1975; Markarian et al., 1978). There are at least two isomers of DMD that are biologically active, with an 8:2 mixture of the 4*R*,8*R*- and 4*R*,8*S*- mimicking the aggregation pheromone of *T. castaneum* (Suzuki et al., 1984). Previous research has examined the relative emission of these chemical components related to density (Faustini and Burkholder, 1987), but the behavioral response and a more precise measure of emission over time have not been addressed.

Insect density can affect development, both in terms of physical crowding and also density dependent chemicals (Roth and Howland, 1941; Hodjat, 1970). *Tribolium* larvae exposed to the benzoquinones given off by adults, particularly at high densities, may develop abnormalities (Mondal, 1990). Thus, the need to disperse from a previously colonized medium is not only brought about by a decrease in the quality of diet, but also by the toxicity of benzoquinone secretions. Many insects change their behavior in response to chemical cues related to density. For example, the southern pine beetle, *Dendroctonus frontalis* Zimmermann (Coleoptera: Scolytidae), releases an antiaggregation pheromone (verbenone) at high population densities that causes conspecifics to stop their mass attack of one tree and instead disperse to surrounding trees (Thatcher et al., 1980). Social insects such as honey bees, *Apis mellifera* L. (Hymenoptera: Apidae), use density cues to manage brood rearing, caste development, and other colony and individual behaviors (Wright, 2009). These examples cover cues that are related to individuals or groups perceiving chemical or physical cues and then changing their own behaviors, but they do not address the question of how responses to chemical cues change with population density.

Although a number of studies have been conducted on the biological responses of *T. castaneum* to the aggregation pheromone or the defensive benzoquinones, few have assessed the interactions of the two classes of volatiles particularly with respect to effects of population density on biology. The central questions herein addressed were: What was the most attractive blend of chemical signals released by *T. castaneum* and under what conditions was it released? This research showed how behavioral responses and volatile chemical releases change with *T. castaneum* population density and the interaction between both the aggregation pheromone and the defensive benzoquinones. Behaviorally active chemicals that had not previously been described for *T. castaneum* were searched for, but none were found.

Methods and Materials

Insects Insects were reared in 0.95 l glass mason jars in an incubator at 27.7°C and 60% RH, each jar contained 200 g of diet that consisted of whole wheat flour, enriched white cornmeal, and brewers' yeast (1:1:0.4).

Volatile Collection The first exploratory volatile collection was from one of these colony jars at the end of a generation (ca. 3500 insects per jar, the end result of 200 adults added to 200 g flour, volatile pull conducted after 8 wk had passed). Headspace volatiles were pulled from above the diet in the jar described above that still contained beetles of mixed life stages. The collection method consisted of inserting a piece of Teflon tubing through each of two holes in the lid and sealing them in place with Teflon tape. The inflow tube was inserted nearly to the surface of the diet, but the vacuum tube was inserted only 2 cm into the jar, ensuring that air was circulated throughout the jar to maximize capture of volatiles from both the diet and the beetles. Teflon tubing was used for inflow outside the jar, and Tygon tubing was used for vacuum downstream from the filter. Airflow into and out of the jar was regulated by flow meters (Aalborg, Orangeburg, NY, USA) to maintain a constant flow rate of 40 ml/min. An inline filter packed with 30 mg Super Q (Alltech, Nicholasville, KY, USA) was attached between the Teflon outflow tube and the end of the vacuum tube outside the jar to capture volatile chemicals in the air stream. Volatiles were collected for 24 h to account for any circadian fluctuations.

For the density volatile collection experiments, adult beetles were collected from culture jars by sifting and placed in 250 ml Erlenmeyer flasks containing 10 g of flour. Three experiments were conducted. In the first, there were 10, 50, 250, 500, 750, or 1,250 beetles per flask, with 3 flasks (replicates) for each density. In the second, beetle density was 50, 500, or 1,250 beetles per flask, with six replicates per density, and in the third, there were 12 flasks, each with 1,250 beetles. In all three experiments, volatiles were collected with Teflon tubing inserted through the holes of a two-hole Neoprene stopper inserted into the neck of the flask. As before, the inflow tube extended nearly to the surface of the flour, and the vacuum tube extended only 2 cm into the flask, thus ensuring good mixing. Collection and extraction of volatiles was the same as described above. For the first set of densities, volatile chemicals were collected on days 2, 4, 7, and 10. For the second set,

volatiles were collected on days 2, 4, 9, and 22, and for the third set on days 2, 4, 7, 10, 12, 15, 19, 22, 24, 27, and 29.

Chemical Extraction and Analysis Chemicals were extracted from filters with 200 μl of methylene chloride (Sigma-Aldrich, St. Louis, MO, USA), after 5 μl of an internal standard (80 ng/μl of nonyl acetate (Sigma-Aldrich) in methylene chloride) had been added to the top of the packing material. Chemicals in the initial samples were preliminarily identified with GC-MS (Hewlett Packard HP6890 with HP5973 MS in EI mode with a 30 m x 0.25 mm i.d. HP1 capillary column with a 0.25 μm film of methyl silicone. The injector inlet temperature was held at 240°C with He carrier gas moving through the column at 30 cm/sec. The oven held an initial temperature of 35°C for 1 min followed by a 10°C/min temperature ramp to 230°C and then held for 5 min. The transfer line to the MS was kept at 240°C. Chemicals were then quantified by analysis with GC-FID (HP 6890 with the same column and parameters as above except the FID detector was held at 250°C). Standards for methyl- and ethyl-1,4-benzoquinones and 1-pentadecene were purchased (Sigma-Adrich), and DMD identification was confirmed by a volatile pull from an attractant septum (Trécé, Adair, OK, USA).

Gas Chromatography-Electroantennal Detection (GC-EAD) Analysis To determine which chemicals *T. castaneum* could detect from the old jar, we used coupled gas chromatography-electoantennographic detection (GC-EAD). One μl of the methylene chloride extract of the old jar headspace volatiles from Super Q was run on the GC (Hewlett Packard HP 6890 with an Alltech Econo-Cap EC-1 30 m× 0.25 mm capillary column with a 0.25 μm film of methyl silicone). The cool on column injection inlet was kept at a constant 220°C with a 40 cm/sec flow rate through the column, the FID detector was kept at 250°C, and the transfer line to the antenna at 230°C. The oven temperature started at 38°C for 1 min then increased at 10°C per min to 230°C before holding at that temperature for 4.5 min. For GC-EAD, both antennae were removed from two beetles with a razor blade, and each antenna was carefully placed across a gold plated electrode (Syntech, Netherlands) with both ends resting on a thin layer of electrode gel (Spectra 360, Parker Labs, Fairfield, NJ, USA). After each run, the electrodes were wiped clean and four new antennae were mounted for the next run. Five runs were conducted consecutively and none was discarded. Noise removal with a filter of 8 was used and the baseline calculated by the Syntech software (EAD 2000, Ver. 2.6) was used as the baseline.

Laboratory Walking Behavioral Assays For background response bioassays, males and females were sexed as pupae and then raised in 26 ml plastic vials with a small amount of flour. An oblong bioassay chamber (elliptical, 17.5 cm long, 0.95 cm high and 5 cm wide at the widest point) was used for all two-choice bioassays (Duehl et al., 2011). Insects were introduced into a chamber that connected between a vacuum manifold and the center of the arena, and air was pushed in at the thinnest points at either end of the ellipse. Sexed beetles were added to the chamber at least 12 h before the bioassays were conducted. One inlet of the bioassay chamber was clean air and the other was air passing through a jar containing old diet and beetles as described above. The rearing jar functioned better than a sealed volatile collection chamber because beetles and diet were not disturbed by a transfer. Six trials for males and 9 trials for females were conducted with 8 beetles per trial, and each trial gave the beetles 5 min to respond to the volatiles by moving from the introduction chamber to one of the ends of the ellipse. An additional set of 6 trials per sex was run with older (53 d), more conditioned diet that had originally contained 10 g of flour and 1,250 adult beetles as a volatile source. Many of the beetles in this colony had died, and the surface of the diet had taken on a blackened color.

An additional set of three separate bioassay-based experiments were conducted to evaluate the responses of *T. castaneum* individuals to density related cues. The first two assays used the oblong arena; eight individuals per replicate were removed from a flask (with a specific population density) with an air pencil and placed in the insect introduction chamber without diet overnight (about 16 h) to calm (Duehl et al., 2011). Bioassay 1 (beetles to other beetles): assays were conducted to determine the behavioral response of beetles to volatiles from flasks containing different densities of beetles (10, 50, 250, and 1,250 individuals). Each flask was set up as the volatile source and tested against beetles from each of the other densities but not the same density. Bioassay 2 (beetles to attractant): with beetles from flask densities of 50, 500, and 1,250, assays were conducted to examine response to volatiles from commercial attractant septa (Trécé RFB/CFB attractant). The attractant septum was placed in a glass volatile collection chamber (Analytical Research Systems, Gainesville, FL, USA), and air was passed through the chamber at the same volume that it passed through the flasks in the previous bioassay. Bioassay 3 (beetles to attractant): a beetle was released onto a 53 micron opening nitex (monofilament nylon mesh) sheet stretched over two small Petri dishes, one containing a DMD (Trece; 1:1 4*R*,8*R*- and 4*R*,8 *S*-DMD) septum and the other empty. Ethovision XT (Noldus, Leesburg, VA,USA) tracked the movement of individual beetles (Duehl et al., 2011). The movements of 8 beetles from the 50, 500, and 1,250 density cultures were recorded for 10 min per individual, and the

time spent in the attractant and control zones was examined. The movements of beetles from the 50 density culture were the most variable and so an additional 11 assays were conducted.

Statistical Analyses All test statistics were calculated in SAS (SAS 9.2, Cary, NC,USA) and significance was judged at α=0.05. ANOVAs were conducted with PROC GLM; series were analyzed with PROC MIXED; and two-way comparisons were made with PROC TTEST, whereas correlations were calculated with Pearson's correlation coefficient in PROC CORR.

Results

The background response bioassays showed that volatiles released from the old jar were repellent (T_{15}=−6.09, P< 0.001) and that the repellency did not vary with sex of the responder (P=0.999) (Table 1). Additional bioassays were conducted with conditioned diet, and beetles that had been confined longer with less diet per beetle and odors from that material showed even greater repellence than did the rearing jar (T_{27} =−4.42, P<0.001). The relationships by sex for both old and older jars showed that both sexes were repelled by volatiles from those jars (Table 1). The decrease in response rate with jar age likely was related to beetles not moving upwind in response to the high levels of repellent compounds. Coupled GC-EAD demonstrated that the antennae of *T. castaneum* responded to the methyl- and ethyl-1,4-benzoquinones and the aggregation pheromone, DMD (Fig. 1). The magnitude of the responses to the chemicals differed significantly (P<0.05, N=5).

Conditioned medium clearly was repellent even though it contained a detectable level of aggregation pheromone. None of the volatiles from the densities examined produced significant attraction in bioassays (Table 2), but some high density cultures were significantly repellent, as indicated by *t*-test. Analyses of volatiles from jars with differing beetle densities showed that only the jar with the highest density differed significantly in the amount of volatiles released from the others (Fig. 2). Because of the variability among samples, the low, middle, and high densities were replicated, but only the highest density showed significant differences (Fig. 2). Although there was variability among jars and collections, beetles in bioassays did not show clear attraction to any beetle density. So while the aggregation pheromone was emitted by all flasks at levels detectable by GC and beetles, individuals in bioassays did not show attraction as they did to the DMD attractant.

Beetles taken from cultures of variable density and exposed to other culture densities, showed no significant attraction to any of the other culture densities and had significant repellence from the high density culture, similar to the response from the old rearing jar (Table 2). This led to assays to test the response of beetles from different density cultures to the commercially packaged aggregation pheromone. These assays showed that the attraction response was not related to the density of beetles in the source culture, although the Ethovision assay showed all were attracted to the septa (T_{34}=−5.93, P<0.001). The results by time spent in DMD zone were; 50 beetle density 77.9±18.8 sec, 500 beetle density 60.9±18.2 sec, 1250 beetle density 103.5±23.3 sec, while the total mean for the control was 9.48±1.18 sec. The results from both the two-choice test ($F_{2,72}$=0.12, P=0.89) and Ethovision non-contact bioassay ($F_{2,35}$=0.79, P=0.46) showed no significant differences between the responses of beetles from different densities to the aggregation pheromone.

Behavioral response across culture density was important but so too was an understanding of volatile emission patterns over time. The chemical emission rates quantified were those of chemicals detected in GC-EAD and also the other major component, 1-pentadecene. Volatiles collected from beetles at different densities after 2 d on fresh diet showed that the total amount of aggregation pheromone released reached a peak at about 500 beetles (Fig. 2). Benzoquinone emission increased as the number of individuals increased, but not linearly over time. Additional volatile collections on days 4 and 9, as well as a second set on the densities 50, 500, and 1,250, showed that by day 9 the benzoquinones increased while the amount of aggregation pheromone decreased. The analysis then was extended over a longer time period, first with the three

[a] Significantly different by a *t*-test comparison of the responses to the jars and the control (P<0.001),

when sexes were pooled by density challenge the responses towards the different cultures were also significantly different (t_{27}=−4.42, P<0.001).

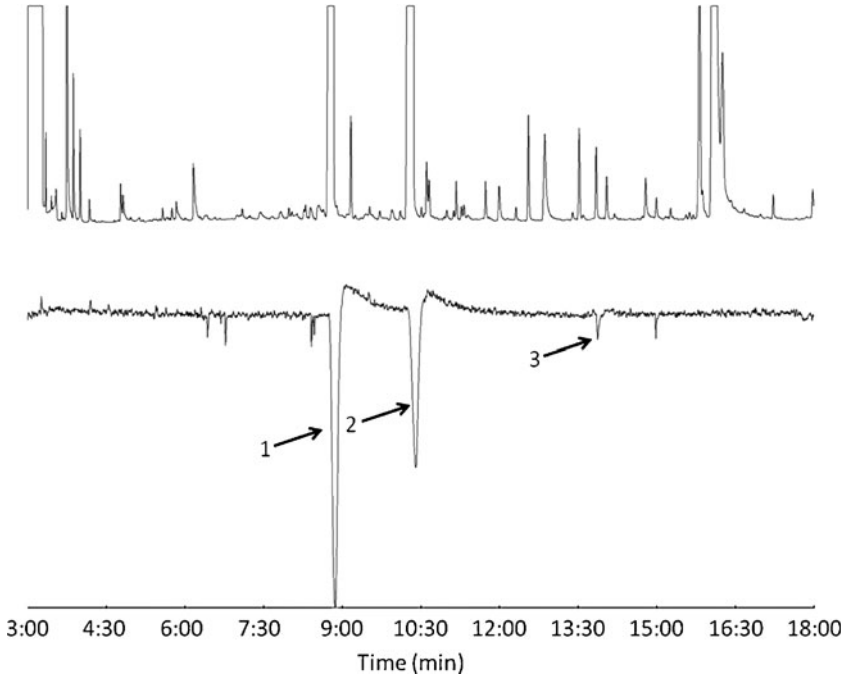

Fig. 1 GC-EAD recordings from unsexed *Tribolium castaneum* antennae to the volatile collection of the headspace of a *T. castaneum* infested culture medium. The bottom line represents the antennal response and the top line is the FID chromatogram. There are three important peaks, listed here with their average electrantennographic response: they correspond to 1, the methyl-1,4-benzoquinone (8.9±1.5 mV); 2, the ethyl-1,4-benzoquinone (5.2±0.7 mV); and 3, the aggregation pheromone 4,8-dimethyldecanal (1.0±0.1 mV). Each chemical elicited a significantly different electrical response, PROC GLM SAS α=0.05, N=5

densities to 22 d, and then with only one density, 1,250 beetles, to 29 d, to see what effect time would have on volatile emission (Fig. 3).

The last experiment examined volatiles from flasks with 1,250 beetles and 10 g flour over a month. It showed an initial increase in benzoquinone emission between introduction and 7 d, followed by 2 wk of decreased emission and then a final increase leading to the death of many beetles (Fig. 3). The methyl and ethyl benzoquinones were highly correlated throughout time (Pearson's correlation coefficient = 0.95, N=115, P<0.001); 1-pentadecene also was highly correlated with the two benzoquinones (Pearson's=0.83 and 0.87, respectively, P<0.001); while DMD was weakly negatively correlated with all three although not significantly correlated with 1-pentadecene (Pearson's= −0.20, -0.19, -0.16, P=0.032, 0.047, 0.092). Very few larvae were in the flasks during the experiment due to the high number of cannibalistic adult beetles. We sifted the flour in half of the flasks every week to remove larvae and found larvae only seven times, all after the third and fourth weeks, and only 1–10 larvae per flask.

Discussion

In these experiments, when *T. castaneum* adults from populations at different densities were exposed to the

[a] NR = no response.

[b] Statistical comparisons were made between responses by beetles from known density containers to control clean air and a flask with beetles at the density listed under volatile source. Significance calculated in SAS with PROC GLM, N=6.

[c] NS = comparison not significant.

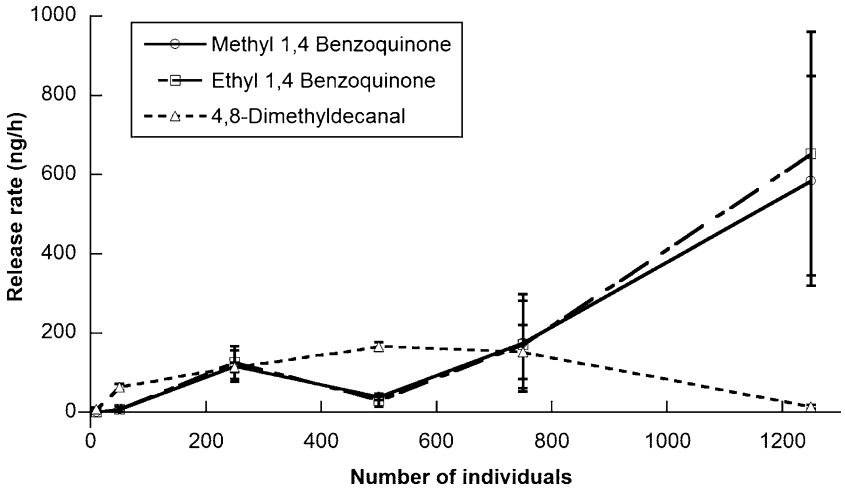

Fig. 2 The release rates of chemicals after each number of individual *Tribolium castaneum* had been in a 250 ml flask with 10 g flour for 2 d. The two benzoquinones increase along with the number of individuals, whereas the 4,8-dimethyldecanal production is maximized around 500 individuals

volatile compounds released by conspecifics held at different densities, no significant attraction was observed. Males alone in clean diet, however, are significantly attractive (Ryan and O'Ceallachain, 1976). We showed significant repellence and determined that at the highest density (1,250 beetles in 10 g of flour), the beetles consistently emitted volatiles that were repellant in our assays. This may be correlated with the release of very high levels of the benzoquinones that are repellant to larvae and adults at high concentrations (Mondal, 1985; Verheggen et al., 2007) or to the reduced release of the aggregation pheromone DMD (Fig. 2). The results of the bioassays showed no relationship between flask source density and the response to DMD. Thus, source colony density seems not to play a role in the response of individuals to DMD. As such, the repellency of the volatiles from high density colonies probably results from the high concentrations of the benzoquinones (ca. 600 ng/h of each) released at the 1,250 beetle density. Our analysis across beetle densities found benzoquinones were a consistent component of the volatile blend, and this may explain why beetles were not attracted in any of our studies using naturally released volatiles. This indicates that benzoquinones counteract the attraction of DMD at densities as low as 10 beetles/flask (Table 1) for *T. castaneum*. Nonetheless, DMD is clearly an aggregation pheromone, and our results suggest that it may act as a marker signifying good conditions as opposed to functioning only as an aggregation pheromone. In this scenario, beetles dispersing from high density cultures would search for fresh flour, and then indicate that they found a good location by releasing more of the DMD.

These responses to chemical stimuli by *T. castaneum* fit with their ecological niche. *Tribolium castaneum* is a better early colonizer of stored products than *T. confusum*; the latter are more attracted to and competitive in conditioned medium (Park, 1948; Ghent, 1963). Since *T. castaneum* has the competitive advantage in clean flour, it would avoid higher benzoquinone concentrations, basing attraction on DMD. Thus, while DMD is the commonality in the attraction of the two most pestiferous *Tribolium* species,

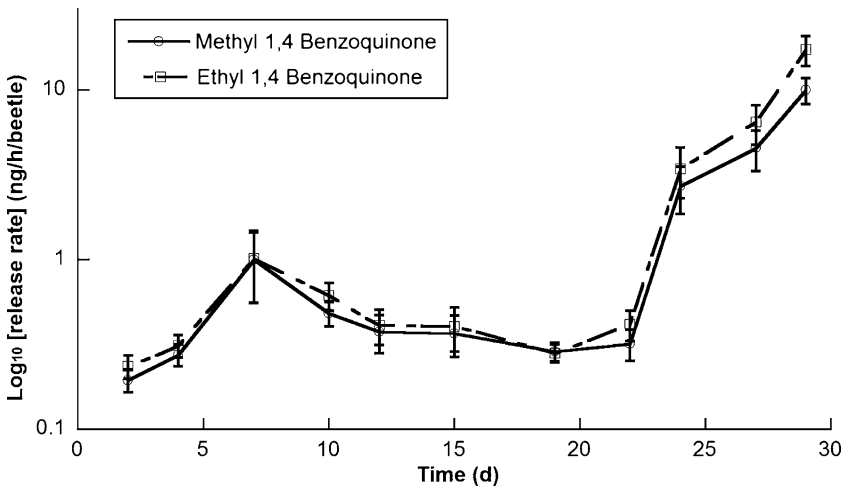

Fig. 3 Levels of methyl- and ethyl-1,4-benzoquinone released by 1,250 *Tribolium castaneum* in a 250 ml flask containing 10 g of flour. The benzoquinone levels increased for the first week; decreased for the next two weeks; and then increased to very high levels that killed many of the beetles in the flask. The axis scale is $\log_{10}$ to best display the change over time

the addition of benzoquinones as a synergist (Verheggen et al., 2007) most likely would increase attractant specificity and exclude *T. castaneum*. The bioassay results described here looked only at walking movement in response to volatile cues. Over flour, density cues both direct movement into the medium and also away from it (Ghent, 1963). Translating these results to a large three dimensional flour environment could mean beetles moving away from high density areas but staying in the flour or moving to the surface and dispersing.

A thorough examination of the volatile chemicals released over time by *T. castaneum* from cultures at different densities indicated that both exposure time and density strongly influenced the relative composition of the chemical blend. The total amount of DMD was greatest at intermediate densities, 500 individuals in 10 g of flour, although individual emission was greatest at the lowest densities. Levels of constitutive benzoquinones in *T. castaneum* increase during the first 30 d of adult life and then remain constant (Wirtz et al., 1978; Unruh et al., 1998). Therefore, the observed pattern of volatile emission was surprising; benzoquinones increased for the first week (Faustini and Burkholder, 1987) but then decreased for the following two weeks, before increasing exponentially. An explanation for this pattern should be sought through further experimentation, but the pattern was not related to immature individuals in the diet and did not match the amount of benzoquinones sequestered inside the beetles (Unruh et al., 1998). We suggest that the initial emission peak may be related to dispersal and the following decrease to the acceptance of the location and high density. The final exponential increase in volatile emission needs to be further investigated. An examination of the quality of the diet could show if toxicity leads to a new impetus for dispersal and stimulates additional benzoquinone release. The latter assertion is supported here by the death of 690±103 of the original 1,250 beetles per flask by the end of the experiment, with very few dying before the last few days.

This research indicated that none of the chemicals released by *T. castaneum* was likely to synergize DMD attraction. Additionally, the benzoquiones released under high density and stress functioned as antiaggregation cues, with high levels representing strong repellence. Low levels of benzoquinones were consistently released and were detected in all samples across densities; intermediate levels indicate antiaggregation, and very high levels seem correlated with resource exhaustion and mortality. The constitutive internal concentrations that increase during their youth (Wirtz et al., 1978; Unruh et al., 1998) did not correspond to the volatile levels observed, and they probably serve a defensive function (Sokoloff 1974). Future searches for attractants should focus on cues other than intra-specific attraction, instead looking to food and environmental cues.

Abstract Camptothecin (CPT), a monoterpene indole alkaloid, is a potent inhibitor of eukaryotic toposiomerase-I. Several derivatives of CPT are in clinical use against ovarian and lung cancers. CPT has been reported from several plant species belonging to the order Asterids, with the highest concentration in *Nothapodytes nimmoniana* (family Icacinaceae). In this paper, we report an intriguing observation of chrysomelid beetles *(Kanarella unicolor* Jacobby) feeding on the leaves of *N. nimmoniana* without any apparent adverse effect. LC-MS/MS analysis of the beetles indicated that 54.9% of the ingested CPT's was recovered from the wings, followed by lesser amounts in the head and abdomen. LC-HRMS analysis revealed that most of the CPT in the insect body was in the parental form available in the plants without any major metabolizable products, including sulfated and glucuronilated forms. The mechanism by which the beetles are able to tolerate substantially high levels of CPT in their body tissue is under investigation.

Introduction

Camptothecin (CPT), a monoterpene indole alkaloid, is one of the most potent cytotoxic compounds (Hsiang et al., 1985; Pommier, 2006). It is toxic to most eukaryotes including insects such as termites (Li, 2002) and drosophila (Cunha et al., 2002). CPT inhibits the enzyme topoisomerase I, which is required in DNA replication and transcription (Hsiang et al., 1985). Because of this property, several derivatives of CPT are in clinical use against ovarian, small lung and refractory ovarian cancers (Pommier, 2006). CPT is naturally distributed in several plant families of the order Asterids (Larsson, 2007). Among these, leaves and stem bark of *Nothapodytes nimmoniana* (Grahm) Mabb. (Icacinaceae), a small tree in southern India, accumulate the highest content of CPT (0.3–0.5%) (Ramesha et al., 2008). In this paper, we report an intriguing observation of specialist chrysomelid beetles (*Kanarella unicolor* Jacobby) that feed on leaves of *N. nimmoniana* without any apparent adverse effect. Liquid Chromatography-Mass Spectrometry-Mass Spectrometry

(LC-MS/MS) and Liquid Chromatography-High Resolution-Mass Spectrometry (LC-HRMS) analysis was performed to evaluate the fate of the ingested CPT in the insect body. We found that most of the ingested CPT is sequestered in the wings without any major metabolizable products. We discuss these results in the light of the possible mechanisms by which the beetles are able to tolerate substantially high levels of CPT in their body tissue.

Methods and Materials

Sampling and Maintenance of Adult Beetles We collected chrysomelid beetles feeding on leaves of *N. nimmoniana* from Biligiri Rangaswamy Temple (BRT) Wildlife Sanctuary (11.40° to 12.09° N and 77.05° to 77.15° E) in the state of Karnataka, India. The beetles were brought to the laboratory, School of Ecology and Conservation, University of Agricultural Sciences, Bangalore, India and maintained in culture jars on excised leaves of *N. nimmoniana*. Leaves were replaced every day. Adults fed actively under captivity. Throughout the culture period, the pellets (excreta) were collected. Beetles also laid eggs during this period (some of these eggs failed to hatch even after several months of incubation and hence were considered 'sterile'). These also were collected. Voucher specimens of the beetle (*Kanarella unicolor* Jacobby, subfamily Galerucinae, tribe Luperini, order Coleoptera) have been deposited in the Insect Museum, Department of Entomology, University of Agricultural Sciences, Bangalore, India.

Extraction of Camptothecins At the end of 25 days of culture, beetles (N=33) were collected, pooled, and processed for analysis of CPT and related compounds. Beetles were dissected into different parts; head, abdomen (including legs), and wings (hind and fore wings). While separating the abdomen, care was taken to ensure removal of undigested leaf material in the gut to avoid contamination of CPT from the host tissue. Insect pellets and sterile eggs collected over the culture period also were used for chemical analysis. The respective body parts, pooled from the 33 beetles, were ground in a pestle and mortar, and resultant fine powder was extracted for camptothecins. A known amount of tissue powder from each of the samples was extracted in 10 ml of 80% ethanol at 60°C for 3 hr in a shaking water bath. After cooling to room temperature, the extract was centrifuged at 10,000 rpm for 10 min at 10°C (Hermle, Germany). The supernatant was passed through a 0.2 μ filter (Tarsons, India) and analyzed for camptothecins.

LC-MS/MS Quantification of Camptothecins LC-MS/MS analysis of the extracts was performed using a Luna C18 column (0.3×150 mm, 3 μm Phenomenex, Torrance, CA, USA), with a mobile phase of H_2O with 10 mM NH_4OAc (solvent A) and CH_3CN with 0.1% HCO_2H (solvent B). All separations were performed at 30°C. NH_4OAc, HCO_2H, CH_3CN (Merck, Germany) and ultra-pure H_2O (Millipore, Schwalbach, Germany) were HPLC grade. Gradient elution consisted of the following ratios of solvent A/solvent B: 95:5, 48:52 and 0:100, with a total run time of 12 min. The column was then returned to the initial condition of 95:5 over about 0.5 min. After each run the column was re-equilibrated for 2 min. The flow rate was 0.3 ml/min with an injection volume of 10 μl.

Selected reaction monitoring (SRM) was performed using a highly sensitive TSQ quantum ultra AM mass spectrometer (Thermo, Finnigan) equipped with an ESI ion source (Ion Max) operating in positive mode. Nitrogen was employed as both the drying and nebulizer gas. Each mass transition was monitored at a peak width of 1 and a dwell time of 0.3 sec. External calibration was performed with the authentic standards in the concentration range of 0.005-10 μg/ml for CPT and 10-OH-CPT, and 0.005-1 μg/ml for 9-MeO-CPT. Limits of detection (LOD) for CPT, 10-OH-CPT and 9-MeO-CPT were 10, 5, and 4 ng/ml, respectively, providing further evidence of the high sensitivity of the system.

LC-HRMS Identification of Carboxylate, Glucuronilated and Sulfated Forms of Camptothecins Carboxylate, glucuronilated, and sulfated forms of CPT were identified based on their exact mass and retention times in LC-HRMS. Exact mass of all these CPT forms were calculated based on the molecular formula of the respective derivatives. The spectrometer was equipped with a Dionex micro-HPLC system Ultimate 3000 consisting of pump, flow manager and auto sampler with an injection volume of 0.6 μl. Nitrogen was used as sheath gas (6 arbitrary units), and helium served as the collision gas. Separations were performed by using a C18 column (0.3×150 mm, 3 μm, Phenomenex Gemini Torrance, CA, USA) with mobile phase H_2O containing 0.1% HCO_2H (solvent A) and CH_3CN with 0.1% HCO_2H (solvent B) and with a flow rate of 4 μl/min. Samples were analyzed using a gradient program with the following ratios of solvent A/solvent B: 95:5, 70:30, 30:70, 0:100, with run times of 0–5, 5–12, 12–24, 24–30 min, respectively. After 100% B, the system returned to its initial condition of 95% A within 1 min. After each run, the system was re-calibrated for 6 min. Owing to the relatively high solubility of carboxylate, glucuronilated and sulfated forms of CPT compared to parental CPT, we expected the elution of these forms to be much earlier than CPT or 10-OH-CPT.

The spectrometer was operated in positive mode with nominal mass resolving power of 60000 at *m/z* 400 (1 spectrum/*s* and with a mass range of 200–800). The scan rate

Fig. 1 Chrysomelid beetle feeding on *Nothapodytes nimmoniana* leaf

was 1 Hz with automatic gain control to provide high-accuracy mass measurements within 2 ppm deviation. Bis-(2-ethylhexyl)-phthalate (DEHP) was used as internal lock mass of *m/z* 391.28429.

Results and Discussion

During an extensive survey of the natural populations of *Nothapodytes nimmoniana* in its distributional range (8° to 15° N) in southern India, we found a fairly consistent occurrence of chrysomelid beetles (*Kanarella unicolor* Jacobby, subfamily Galerucinae, tribe Luperini, order Coleoptera) feeding on the leaves (Fig. 1). Only adult beetles were found on the plant; we did not recover larvae and pupa. The adults feed exclusively on *N. nimmoniana* by making small perforations on the leaf lamina. Beetles

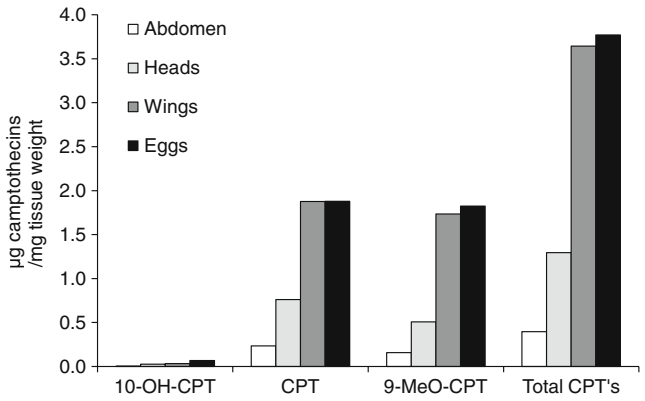

Fig. 3 Concentration of CPT and its metabolites in different body parts of beetles as quantified by LC-MS/MS. All data refer to a single analysis of all beetles (N=33) pooled

fed randomly on leaves irrespective of the leaf age and their CPT content (supplementary material Fig. S1).

For a set of laboratory maintained beetles that were fed exclusively on *N. nimmoniana* leaves for 25 days, we examined the relative proportions of CPT and related compounds in different body parts. LC-MS/MS of samples revealed the presence of CPT in head, abdomen, wings (both hind and fore wings) and also in the eggs laid by the beetles (Fig. 2). Other natural derivatives of CPT such as 10-hydroxy camptothecin (10-OH-CPT) and 9-methoxy camptothecin (9-MeO-CPT) that are known to be present in host leaves also were detected. Concentration of CPT was highest in wings (1.87 µg/mg-tissue weight), followed by head (0.76 µg/mg-tissue weight), and least in the abdomen (0.23 µg/mg-tissue weight). A similar pattern also was observed for 10-OH-CPT and 9-MeO-CPT, except the concentration of 10-OH-CPT was 10–15 fold less compared to other two compounds. In some samples, its concentration was negligible (Fig. 3).

We also examined whether or not the beetles metabolize CPT into its inactive forms, the carboxylate, glucuronilated or sulfated forms. None of the sulfated and glucuronilated forms

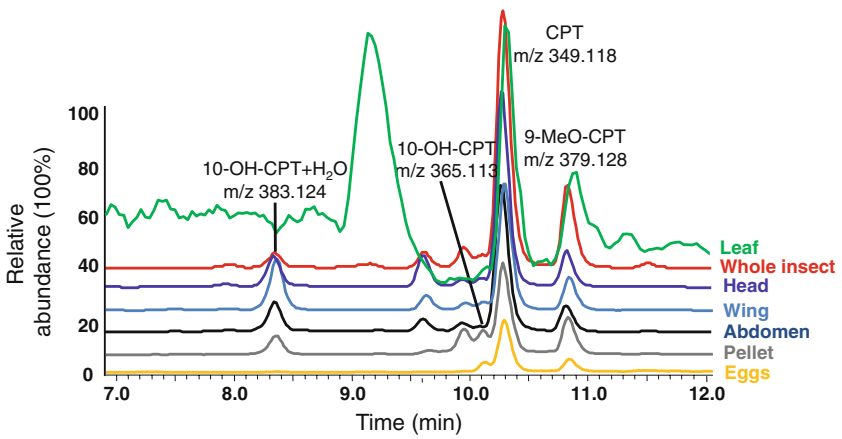

Fig. 2 Extracted total ion chromatograms (TIC) of *N. nimmoniana* leaf and different body extracts of beetle including eggs and pellets. TIC's of different samples were overlaid on each other and hence, except TIC of eggs, TIC's of other extracts does not start from 0% ionic abundance. Intensity of the peaks does not correlate with concentration of metabolites in different body parts. The large peak at ~9 min in the leaf sample is n-butyl benzenesulfoamide, plasticizer ($[M+H]^+$ 214.08963)

of CPT was detected in any of the body parts, when analyzed for their exact mass traces in LC-HRMS; sulfated CPT (cald; m/z 429.0750), sulfated 10-OH-CPT (cald; m/z 445.072), sulfated 9-MeO-CPT (cald; m/z 459.085), glucuronilated CPT (cald; m/z 525.152), glucuronilated 10-OH-CPT (cald; m/z 541.147), glucuronilated 9-MeO-CPT (cald; m/z 555.162). However, we did recover the carboxylate form of 10-OH-CPT (Rt 8.3 min, m/z 383.124) (Supplementary material Fig. S2) in all body parts including the pellets. The low concentration of carboxylate form of 10-OH-CPT (based on intensity in TIC spectra) compared to its parental form, however, suggests that the insects do not metabolize CPT to any substantial degree (Fig. 2).

In summary, the highest concentration of CPT and related compounds (10-OH-CPT and 9-MeO-CPT) was located in the wings (3.64 μg/mg-tissue weight amounting to 54% of total body CPTs), followed by abdomen (0.39 μg/mg-tissue weight, amounting to 28%), and head (1.29 μg/mg-tissue, amounting to 18%). On a single beetle body weight basis, disregarding the loss of CPT through pellets, the beetles accumulated about 3.02 μg of CPT at any given point of time, much higher than 1.7 μg/larvae that are lethal to Drosophila larvae (Cunha et al., 2002).

Sequestration of plant secondary metabolites, as predator deterrence behavior is well documented in insects, including beetles (Hartmann et al., 2001; Willinger and Dobler, 2001). A number of insects have developed adaptations to sequester pyrrolizidine alkaloids from their host plants and utilize them against their own predators (Hartmann et al., 2001). Frequently, the ingested plant secondary metabolite are either metabolized into products that are not detrimental to the insects or sequestered from the haemolymph into exocrine glands or into metabolically poor tissues such as the pronotum and elytra (Aregullin and Rodriguez, 2003); the latter serves as a "defense shield" against predators. Our results are the first to report the sequestration of CPT, a cytotoxic compounds by beetles. As indicated,, most of the CPT is sequestered in the parental chemical form in the elytra, without any major chemical conversion or metabolism. While we have not yet established the evolutionary significance of such sequestration, it is likely that the beetles use this compound to deter predators (Schroeder et al., 2006; Despres et al., 2007). It would be interesting to examine the mechanism through which the beetles tolerate high levels of CPT. Recently, Sirikantaramas et al. (2008) showed that plant species that produce CPT have specific mutations in their topoisomerase I that make these enzymes resistant to CPT. We are currently investigating if beetles have such mutations in their topoisomerase I.

Abstract Lysophospholipids (LPLs) are recognized as important signaling molecules in metazoan cells. LPLs seem to be widely distributed among marine invertebrates, but their physiological role remains poorly known. Marine sponges produce original phospholipids and LPLs whose isolation and structural elucidation rarely have been reported. Two LPLs were isolated for the first time from the Mediterranean Homoscleromorph sponge *Oscarella tuberculata*: a bioactive lyso-PAF already identified in some other sponge species; and the new lysophosphatidylethanolamine C20:2 (LPE 1). The expression of LPL metabolites was investigated over time to determine their baseline variations and to relate them to the sponge reproduction pattern in order to better understand their putative role in the sponge life cycle. Expression levels of both compounds appeared to be highly correlated displaying significant seasonal fluctuations with maximal values in summer and minimal in winter. A significant higher LPL content was detected in reproductive sponges and especially in females, with a peak occurring during embryogenesis and larval development. The results suggest that LPLs could play a role of mediators in sponge embryogenesis and morphogenesis.

Introduction

Phospholipids (PLs) are essential constituents of cell membranes, but their importance in living organisms is not restricted to this role (Vance, 2002; D'Arrigo and Servi, 2010). Among them, lysophospholipids (LPLs) represent only 0.5 to 6% of the whole PL content of cell membranes (Birgbauer and Chun, 2006; Torkhovskaya et al., 2007), their structural role being considered minor. However, they are recognized as second messenger molecules in cellular signal transduction processes (Torkhovskaya et al., 2007; D'Arrigo and Servi, 2010). These molecules exhibit a wide range of biological activities, and are among the most interesting lipids for pharmaceutical applications (Moolenaar, 2000; Birgbauer and Chun, 2006). For example, LPL receptors are required for the proper development and functioning of cardiovascular, nervous, immune, respiratory, and reproductive systems in mammals (Rivera and Chun, 2008). They also seem to play a critical role in pathological processes such as inflammatory reactions, autoimmune diseases, cancer, and atherosclerosis (Mills and Moolenaar, 2003; Gardell et al., 2006). The best known lysophospholipid messenger is a naturally occurring "platelet activating factor" (PAF or 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphorylcholine), which mediates cellular interactions through a membrane-

bound G-glycoprotein receptor (Snyder, 1995; Prescott et al., 2000). PAF and its analogues were first identified as defense molecules involved in pathological processes such as anaphylaxis and inflammatory reactions (Archer et al., 1985; Vadas et al., 2008). Among the analogues, Lyso-PAF (2-*sn*-deacetyl) also exhibits cancerostatic properties (Mangold and Weber, 1987; Brachwitz and Vollgraf, 1995) and potent antimicrobial activity (Steel et al., 2002). Both PAF and lyso-PAF analogues are abundant in invertebrates and widespread among marine invertebrate metazoans, but their physiological roles remain to be defined (Sugiura et al., 1992).

Among aquatic invertebrates, sponges have the simplest body-plan adapted for filtrating suspended particles in the water column. Sponges produce a diversity of secondary metabolites that often have valuable biological activities (Sipkema et al., 2005). Marine sponge organic extracts contain a high proportion of lipids that may contribute to the entire bioactivity of the organism (Djerassi and Lam, 1991; Dembitsky et al., 2003). In general, sponge lipids differ from lipids of other metazoans in their chemical structure and biochemical properties (Djerassi and Lam, 1991). Sponges harbor a unique composition of membrane bilayer, where phospholipids containing very long alkyl chains (C_{24}-C_{38}), the so-called "demospongic fatty acids", coexist with a high proportion of unusual sterols (Djerassi and Lam, 1991). In addition to the usual ester-linked PLs, sponges produce ether-PLs such as lysophosphatidylcholines (LPCs), which have been reported for their cytotoxic and antimicrobial properties (Dembitsky et al., 1989; Dembitsky, 1996; Shin et al., 1999; Alam et al., 2001; Lee et al., 2003; Zhao et al., 2003; Müller et al., 2004; Mansoor et al., 2005).

After our work on the chemical diversity of Mediterranean Homoscleromorph sponges (Ivanišević et al., 2011), we focused attention on the species *Oscarella tuberculata*. In its environment, this thinly encrusting species has several colors (yellow to blue), has no known predator, and can cover in some places a high percentage (up to 100%) of the rocky substrate. It is able to overgrow other sessile invertebrates (sponges, gorgonians, and bryozoans), a particular habit that might be related to the production of efficient allelochemicals. *Oscarella tuberculata* previously has been reported to produce unusual lipids such as rare and long alkyl chain 5-substituted pyrrole-2-carbaldehydes and sterol endoperoxides (Cimino et al., 1975; Aiello et al., 1991; Loukaci et al., 2004). However, our metabolic fingerprinting approach indicated a larger chemical diversity than previously reported (Ivanišević et al., 2011). The same approach was used to evaluate the *O. tuberculata* intraspecific variability in secondary metabolite production on a large geographic scale (along the Mediterranean coast). No significant variation in metabolite composition was found in different color morphotypes, with the intraspecific variability being essentially quantitative, marked by variation in the expression level of major compounds (Ivanišević et al., 2011). Spatial and temporal variations in concentrations of major secondary metabolites have been documented previously in a few sponges, ascidians, and other sessile marine invertebrates (Page et al., 2005; Lopez-Legentil et al., 2006; Abdo et al., 2007). Long-term temporal variations often have been explained by ecological and environmental factors (Page et al., 2005; Abdo et al., 2007). However, the influence of primary biological functions has been rarely investigated to explain secondary metabolite variations (Lopez-Legentil et al., 2006). Production of secondary metabolites is energy consuming, however, it should require an optimized allocation of resources with respect to primary processes such as growth and reproduction (McClintock and Baker, 2001).

The primary aim of this study was to perform a chemical study of *O. tuberculata* in order to isolate and characterize the major non described metabolites. The second objective was to study the seasonal variability in the production of these metabolites, to relate it to seawater temperature fluctuations and to the sponge reproductive cycle. If LPLs have an ecological or physiological role, we would expect a pattern of variation of their expression level related to biotic or abiotic factors. On the other hand, if their role is mainly structural, only slight variation of their expression level over time with no special trend would be expected.

Methods and Materials

Biological Material Oscarella tuberculata (Schmidt 1868) (Fig. 1) is one of the most common Homoscleromorpha sponges in western coralligenous Mediterranean habitats. It is found in shallow waters, on rocky bottoms (coralligenous and semi-dark cave communities) from 4 to 35 m deep, and

Fig. 1 *In situ* picture of *Oscarella tuberculata* within the coralligenous community

from the Gibraltar Strait to the Eastern Mediterranean. The sponge is thinly encrusting with a lobate surface and thickness of 2–5 mm. Several color morphotypes have been observed *in situ*, varying from yellow, greenish to blue.

Sampling Procedure *Oscarella tuberculata* samples for metabolite isolation and structural elucidation were collected by SCUBA off the Marseille coast (France) in April 2008. A population monitoring for reproductive cycle and secondary metabolite production was performed between October 2001 and August 2003 (two annual cycles) at 13 m depth in Maire Island (Grotte à Corail, Marseilles). During this period, six different individuals per month of the yellow color-morph were randomly collected. A small part of every individual (about 1 mm^3) was cut off and fixed for histological analysis; the rest being immediately frozen at −20°C, freeze-dried, and conserved at −20°C for the chemical survey.

Reproductive Cycle Description To characterize the life cycle and assess reproductive effort, samples were fixed in Bouin fixative. Tissue fragments were dehydrated through an ethanol series, and embedded in paraffin. Serial sections of 6 μm in thickness were mounted on glass slides, stained with Trichrome of Masson and Goldner hematoxylin, and then observed under a light microscope. Digital pictures were captured in order to quantify the reproductive elements (spermatocyste, oocyte, embryo, and larva) using the ImageJ Software (http://rsb.info.nih.gov/ij/index.html). For each reproductive sponge, the reproductive effort was expressed as a percentage of sponge volume.

Chemical Equipment NMR experiments were performed on a 500 MHz spectrometer. Chemical shifts (δ in ppm) are referenced to the carbon (δ_C 49.0) and residual proton (δ_H 3.31) signals of CD_3OD, the solvent with multiplicity (s singlet, d doublet, t triplet, m multiplet). HPLC-MS analyses were performed using a VWR-Hitachi HPLC system and a Bruker Esquire 3000 Plus mass spectrometer equipped with electrospray ionization. Mass spectra were recorded in the positive mode. The HPLC system also was equipped with an autosampler (VWR-Hitachi L-2220), a Diode Array Detector (DAD, VWR-Hitachi L-2455), and an Evaporative Light-Scattering Detector (ELSD, Chromachem, Eurosep, France). High-resolution mass spectra (HRESIMS) were conducted on a LTQ Orbitrap mass spectrometer (Thermo Finnigan). HPLC purification were carried out on a Waters 600 system equipped with a Waters 717 plus autosampler, a Waters 996 photodiode array detector, and a Sedex 55 evaporative light scattering detector (Sedere, France). Gas Chromatography–Mass Spectrometry analyses were performed on a Hewlett-Packard HP-5890 chromatograph linked to an HP-5989-A mass spectrometer (70 eV) equipped with a HP-9000-345 integrator.

Extraction and Isolation of Major Compounds The lyophilized sponge (51.3 g) was extracted three times with $MeOH/CH_2Cl_2$ 1:1 (500 ml) at room temperature yielding 11.1 g of dry crude extract. The crude extract was fractionated by RP-C_{18} Vacuum Liquid Chromatography (elution with a decreasing polarity gradient from H_2O, H_2O/MeOH 1:1, H_2O/MeOH 1:3, MeOH, $MeOH/CH_2Cl_2$ 1:1 to CH_2Cl_2). The MeOH and $MeOH/CH_2Cl_2$ 1:1 fractions, showing similar HPLC profiles, were pooled and further fractionated by normal phase Diol flash chromatography (elution with a gradient of increasing polarity from Hexane/AcOEt 1:0 to 0:1, then AcOEt/MeOH 1:0 to 0:1). Control of the presence of phospholipid content was determined by TLC. The presence of the already known 5-alkylpyrrole-2-carbaldehydes was evidenced in the Hexane/AcOEt 9:1 fraction by using ^1H NMR and MS analyses. The AcOEt/MeOH 1:1 and MeOH fractions containing the phospholipids were pooled and subjected to C_6-phenyl semi-preparative HPLC (Phenomenex, Luna C_6-Phenyl, 250×10 mm, 5 μm) eluting with an isocratic MeOH/H_2O/Formic Acid 85:15:0.1 to afford pure lyso-PAF (1.5 mg) and LPE 1 (7 mg).

GC-MS Analysis of the Fatty Acid of LPE 1 A preparation of Fatty Acid Methyl Esters (FAMEs) and *N*-Acyl Pyrrolidides (NAPs) of LPE 1 (1 mg) was made prior to GC-MS analysis. FAMEs were obtained by methanolysis of LPE 1 (40 min under reflux in the presence of methanolic HCl 5%). NAPs were prepared by treatment of the resulted FAMEs with pyrrolidine/acetic acid (10:1, v/v) under reflux for 2 h. GC-MS analyses were obtained using a 30 m x 0.32 mm i.d. fused silica capillary column coated with DB-1 (0.25 μm phase thickness). The carrier gas was helium. Temperatures of the injector and the source were held at 240°C, and the temperature of the GC–MS interface at 290°C. The column temperature was programmed for FAMEs and NAPs from 180 to 310°C at 3°C/min. The fatty acid pyrrolidide of LPE 1 was identified at t_R 27.7 min (C20:2, Δ5,11).

Temporal Series Treatment by Metabolic Fingerprinting Freeze-dried samples were ground to obtain a homogenous powder, and 0.4±0.005 g of the powder was extracted in 5 ml of $MeOH/CH_2Cl_2$ 1:1 for 10 min in an ultrasonic bath. This operation was repeated three successive times. Filtrates of each extraction were combined and evaporated to dryness. Dry crude extracts then were dissolved in distillate water, and up to 2% acetone was added to complete the dissolution. Five ml of each dissolved extract

were loaded onto conditioned C_{18} SPE (Solid Phase Extraction) cartridges (0.2 g, Phenomenex Strata). After desalting with water, the organic extracts were eluted with 1 ml of MeOH/CH_2Cl_2 1:1. They were analyzed by HPLC-DAD-ELSD-MS. HPLC separation was achieved on a C_{18} column (Gemini, Phenomonex, 250×4.6 mm, 5 μm) using a linear gradient elution of H_2O/ACN/formic acid from 90:10:0.1 (isocratic from 0 to 5 min), to 0:100:0.1 (isocratic from 35 to 45 min, flow 1 ml/min). The column temperature was maintained at 30°C. The injection volume was set to 20 μl. The mass spectrometry detector (MSD) parameters were set as follows: nebulizer sheath gas, N_2 (50 psi); dry gas, N_2 (12 L/min); capillary temperature, 350°C; capillary voltage, 4000 V in negative ion ESI mode, 4000 V in positive ion ESI mode; lens 1 voltage, −5 V in (+) ESI; lens 2 voltage, −60 V in (+) ESI; isolation width for the MS experiments, *m/z* 1.0; collision gas, He; and collision energy, 35%. Data were collected between *m/z* 50 and 1200. The ELSD fingerprints were obtained after mobile phase nebulization at 38°C following evaporation at 50°C. The resulted metabolic fingerprints: ELSD and ESI-MS(+) (Base Peak Chromatogram) raw chromatogram data were processed by Data Analysis software. Filtering and baseline correction for ELSD chromatograms were defined by the following parameters: RT (Retention Time) range 0–50 min, Signal/Noise threshold≥5, Minimum relative area≥10% and Minimum Relative Intensity≥10%. A relative quantification of major, identified compounds was performed on ELSD chromatograms by the peak area integration and expressed as a relative peak area in% of the whole chromatogram.

Bioactivity Assays The standardized Microtox® bioassay (Microbics, Carlsbad, CA, USA) (Marti et al., 2003) was used to assess the bioactivity of *O. tuberculata* crude extract. Crude organic extracts were dissolved in artificial seawater, and up to 2% of acetone was added to improve dissolution of the extracts. Solution was tested in four diluted concentrations. The initial concentration was set at 500 μg/ml, and a dilution factor of 2 was applied between each following tested concentration. Bioactivity was quantified by measuring the direct effect on the metabolism of the bioluminescent bacterium *Vibrio fischeri* indicated by a decrease in light emitted and expressed as an EC50 value.

An antimalarial assay was performed using the *Plasmodium falciparum* FcB1 strain, grown *in vitro* according to Trager and Jensen (Florenta et al., 2000). Parasite culture medium contained RPMI 1640 medium (Life Technologies, Inc.), 25 mM Hepes, 27.5 mM $NaHCO_3$, and 11 mM glucose (pH 7.4), and was supplemented with 7.5% (v/v) compatible heat-inactivated human serum. Human red blood cells (RBC) were added at hematocrit of 2%, and the parasite culture was maintained at 37°C under an atmosphere of 3% CO_2, 6% O_2, and 91% N_2, with daily medium changes. The effect of extracts on the intra-erythrocytic development of *P. falciparum* was performed with cultures containing mixtures of all stages at a final parasitemia of ~1% that then were distributed in 96-well microplates (Trager and Jensen, 1976). Extracts were added to the wells, in parasite culture medium, at final concentrations of 10, 1, and 0.1 μg/ml in duplicates. Parasites were allowed to grow in a candle jar system and after 24 h in culture, ^{3}H-hypoxanthine was added (0.5 μCi/well). After an additional 24 h incubation period, parasites were harvested on filters after a freeze-thawing cycle. Dried filters were submerged in a liquid scintillation mixture (OptiScintHisafe, Perkin Elmer) and counted in a 1450 Microbeta counter (Wallac, Perkin Elmer). Parasite growth inhibition was calculated from the parasite-associated radioactivity (incorporated into nucleic acids) in treated cultures compared with control cultures performed in the presence of equivalent amounts of DMSO but without tested compounds. Each extract was tested in duplicate on a *P. falciparum* strain (FcB1) (Desjardins et al., 1979).

Antitumor assay was performed on KB cell lines that were plated in 96-well tissue culture plates in 200 μl medium, and were treated 24 h later with compounds dissolved in DMSO; compound concentrations ranged from 0.025nM to 6 mM, and were prepared by use of a Biomek 3000 (Beckman). Control cells received the same volume of DMSO (1% final volume). After 72 h exposure to the drug, MTS reagent (Cell titer Aqueous, Promega, Madison, WI, USA) was added and incubated for 3 h at 37°C: the absorbance was monitored at 490 nm, and results are expressed as the inhibition of cell proliferation calculated as the ratio [1 - (OD_{490} treated/OD_{490} control) x 100] (Zampella et al., 2009).

Data Analyses Normality of data distribution (Shapiro-Wilk test) and homogeneity of variances (Levene test) assumptions were satisfied. Therefore, one-way analyses of variance (ANOVA) were used to test the effects of month/season and sponge life stage on the compound's expression levels. Pearson's correlation coefficient was used to assess the correlation between the relative expression level of compounds and the water temperature. Temperature data were provided by the MEDCHANGE project (N. Bensoussan & J. C. Romano). The average weekly and monthly temperatures were calculated by the integration of daily temperatures for 7 and 30 days that preceded the sampling date.

Results

Major Compounds Identifications Two already known 5-alkylpyrrole-2-carbaldehydes were obtained in a mixture

from an apolar fraction of the purification process. Comparison of the ^{1}H NMR and MS data with those of compounds already isolated from the same species enabled us to confirm their structures (Fig. 2).

Two major compounds unknown for Homoscleromorpha sponges also were isolated and characterized from a more polar fraction of the *O. tuberculata* organic extract. Both compounds appeared to be LPLs: the new compound LPE 1, and a lyso-PAF previously reported from a few other sponge species (Fig. 2).

2-O-Docosa-5,11-dienoyl-sn-glycero-3-phosphatidylethanolamine (LPE 1): amorphous solid; ^{1}H NMR (500 MHz, CD_3OD) δ 5.40 (m, 2 H, H-11' and 12'), 5.35 (m, 2 H, H-5' and 6'), 5.00 (quint, ^3J=5.3 Hz, 1 H, H-2), 4.06 (m, 2 H, H-1"), 4.00 (m, 2 H, H-3), 3.70 (m, 2 H, H-1), 3.18 (m, 2 H, H-2"), 2.36 (t, ^3J=7.6 Hz, 2 H, H-2'), 2.10 (q, ^3J= 7.0 Hz, 2 H, H-4'), 2.04 (m, 6 H, H-7', H-10' and H-13'), 1.67 (quint, ^3J=7.6 Hz, 2 H, H-3'), 1.29 (m), 0.90 (t, ^3J= 6.6 Hz, 3 H, H-20'); ^{13}C NMR (125 MHz, CD_3OD) δ 175.0 (C, C-1'), 132.0 (CH, C-12'), 131.1 (CH, C-11'), 130.9 (CH, C-6'), 129.9 (CH, C-5'), 74.6 (CH, C-2), 64.9 (CH_2, C-3), 63.0 (CH_2, H-1"), 61.4 (CH_2, C-1), 41.6 (CH_2, C-2"), 34.7 (CH_2, C-2'), 33.2 (CH_2, C-8' and 9'), 31.0-30.5 (CH_2), 28.3-27.7 (CH_2, C-4', 7', 10' and 13'), 26.2 (CH_2, C-3'), 23.9 (CH_2, C-19'), 14.6 (CH_3, C-20'); ESIMS *m/z* 528.3 $[M+Na]^+$; MS^2(528.3) *m/z* 485.2 $[M–C_2H_4NH_2+Na]^+$, 467.3 $[M–C_2H_4NH_2–H_2O+Na]^+$; MS^3(485.2) *m/z* 387.2 $[M–C_2H_4NH_2–H_2O–HPO_3+Na]^+$; HRESIMS *m/z* 506.32480 $[M+H]^+$ (calcd for $C_{25}H_{49}NO_7P^+$, 506.32466).

LPE 1 was isolated as an amorphous solid contaminated with an inseparable phosphocholine derivative, as evidenced in the ^{1}H NMR spectrum (20% contamination). This impurity made irrelevant the measure of the rotatory power and its biological activity, but the characterization of this new compound nevertheless was undertaken by interpretation of NMR and HRMS data, as well as by GC-MS data after hydrolysis of the fatty acid side-chain. The molecular formula of LPE 1 was established as $C_{25}H_{48}NO_7P$ on the basis of HRESIMS data (*m/z* 506.32480 $[M+H]^+$, Δ +1.35 ppm). An easily identified ^{1}H-^{1}H spin coupling system between δ_H 2.36 (t, ^3J=7.6 Hz, 2 H, H-2'), 1.67 (quint, ^3J=7.6 Hz, 2 H, H-3'), 2.10 (q, ^3J=7.0 Hz, 2 H, H-4'), 5.35 (m, 2 H, H-5' and 6'), 2.04 (m, 2 H, H-7') ppm revealed a $\Delta^{5,6}$ unsaturated acyl chain. A second unsaturation was evidenced with the signals at δ_H 5.40 (m, 2 H, H-11' and 12') in the ^{1}H NMR spectrum. The exact structure of the acyl chain was determined finally after acid catalyzed methanolysis and pyrrolidide derivatization. The position of the second double bond was determined by examination of the GC-EIMS fragmentation pattern. In particular, the pyrrolidide derivative afforded a molecular ion peak at *m/z* 361 $[M]^+$ and a succession of fragments separated by a mass difference of *m/z* 14 except for *m/z* 222 and 234, but also 140 and 152, which placed the unsaturations at C-5' and C-11' of the fatty acid. This acyl chain was placed at the 2-*sn* position of a glycerol core due to the key H-2', H-3', and H-2/C-1' HMBC correlations. The signal at δ_H 5.00 (quint, ^3J=5.3 Hz, 1 H, H-2) ppm, COSY correlated with two signals at δ_H 4.00 (m, 2 H, H-3) and 3.70 (m, 2 H, H-1) ppm, was indeed characteristic of a 1-lysophospholipid. The phosphatidyl part at 3-*sn* was identified finally as a phosphatidylethanolamine due to the COSY correlated signals at δ_H 4.06 (m, 2 H, H-1") and 3.18 (m, 2 H, H-2") ppm. Configurations of the double bonds were assigned as *Z* because of shielded ^{13}C NMR chemical shifts of the allylic carbons C-4', C-7', C-10' and C-13' around 28.0 ppm. Finally, the impurity was strongly suggested to be the previously described lyso-PAF as indicated from similar ^{1}H NMR and MS data.

The known 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine (lyso-PAF) was first characterized by ^{1}H NMR analysis, which revealed characteristic COSY correlated signals of an unsaturated *O*-alkyl chain at δ_H 3.47 (t, ^3J=6.6 Hz, 2 H, H-1'), 1.56 (quint, ^3J=6.5 Hz, 2 H, H-2'), 1.29 (m), and 0.90 (t, ^3J=6.6 Hz, 3 H, H-16') ppm. Substitution of this chain at C-1 of the glycerol core was inferred from HMBC interpretation and chemical shifts of H_2-1 and H-2. Another spin correlated system at δ_H 4.42 (m, 2 H, H-1"), 3.70 (m, 2 H, H-2") ppm together with the singlet at 3.23 ppm (9 H, N-$C\underline{H}_3$) suggested the presence of a phosphatidylcholine. Structure of this known compound was confirmed by HRESIMS data interpretation, which were consistent with the molecular formula $C_{24}H_{53}O_6NP$ (*m/z* 482.3610 $[M+H]^+$, Δ +1.14 ppm). After comparison with the literature, all NMR

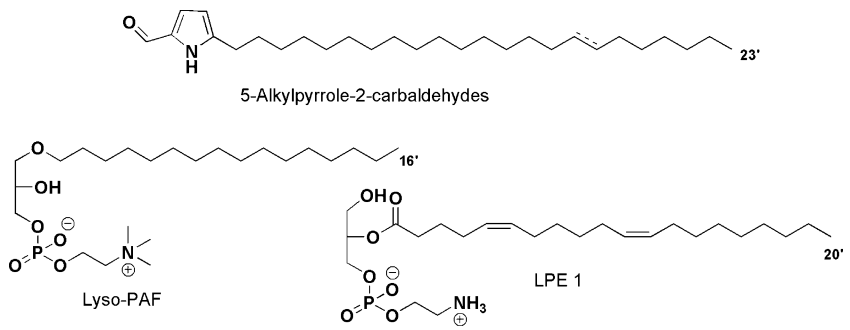

Fig. 2 Chemical structure of the major secondary metabolites isolated from *Oscarella tuberculata*

and MS data were fully in accordance with the known lyso-PAF (Shin et al., 1999).

LPL Temporal Variability LPL expression levels were studied by using metabolic fingerprinting with ELSD detection. Overall, the expression level of LPE 1 was about three times higher than the expression level of lyso-PAF. Both compounds showed significant seasonal fluctuations in their expression levels (Fig. 3), which appeared to be highly correlated (Fig. 4). Over 2 years, maximal values were observed in the summer period, from June to August (4.11% for lyso-PAF and 10.69% for LPE 1 in August 2003). Minimal values were detected from December 2001 to February 2002 (1.68% for lyso-PAF and 3.34% for LPE 1) as well as in September 2002 (1.22% for lyso-PAF and 3.53% for LPE 1). We did not find any significant effect of the natural fluctuations of seawater temperature (average daily, weekly and monthly temperature) on the lyso-PAF or LPE 1 level of expression. However, we observed a progressive increase in LPL production following the warming up of the seawater (from February to August 2002), with the highest expression levels recorded in summer (Fig. 3).

LPL Expression Level in Relation to Sponge Life Cycle Oscarella tuberculata is an ovoviviparous and gonochoric species. It has a seasonal reproductive cycle with gametogenesis starting in January, overlapped and followed by embryogenesis and larval development in summer (from mid-June to early September). Peak reproductive effort was observed during the summer season, with the highest values in June 2002 (8.59%) for males and July 2003 for females (6.79%). For the latter, the maximal reproductive effort thus corresponds to the period of embryogenesis and larval development.

The expression levels of both LPLs varied significantly in relation to the sponge reproductive stage (gametogenesis vs. embryonic and larval development) (Fig. 5). The LPL expression level increased progressively from June, corresponding to the beginning of embryogenesis, and reached the highest values in August during the final stage of larval development (Figs. 3 and 5). The expression level peak was followed by a steep decrease at the end of summer after larval release (Fig. 3). Overall, we observed that LPL expression levels were significantly higher in reproductive sponges than in non-reproductive sponges, and in females rather than in males (Fig. 6).

Crude Extract Bioactivity Oscarella tuberculata crude extract displayed a large panel of bioactivities. An effect on metabolism of the bioluminescent marine bacterium *Vibrio fischeri* was detected at EC_{50}=35.9 µg.ml^{-1} (standardized Microtox® bioassay). A moderate antitumoral activity of *O. tuberculata* crude extract against human cancer KB cell line was also observed at 10 µg.mL^{-1} (96.5% of cytotoxicity). Finally, the same extract exhibited antimalarial activity against the *Plasmodium falciparum* (FcB1 strain) at the same concentration (38.9%).

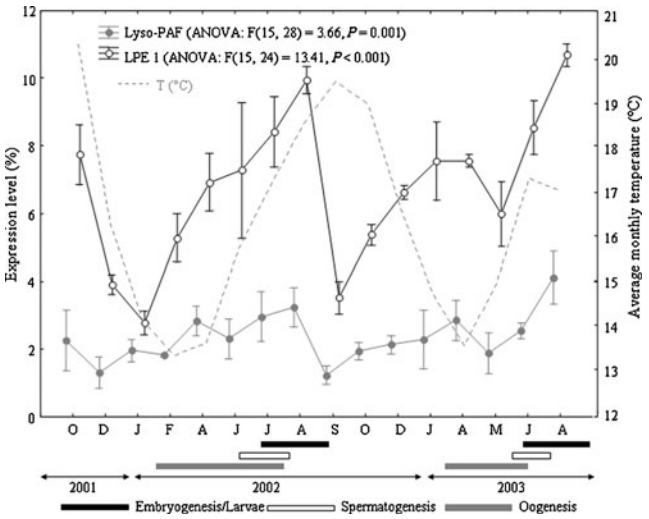

Fig. 3 Temporal variability in lyso-PAF and LPE 1 expression level (%), from October 2001 to August 2003, in parallel to seasonal fluctuations of seawater temperature. The expression level of each compound is calculated according to peak area, and expressed as a percentage of the whole chromatogram. Different stages of the reproductive cycle (oogenesis, spermatogenesis, and embryogenesis) are indicated on the temporal scale

Discussion

Although PL and LPL class composition and their relative abundance in different sponge species have been studied

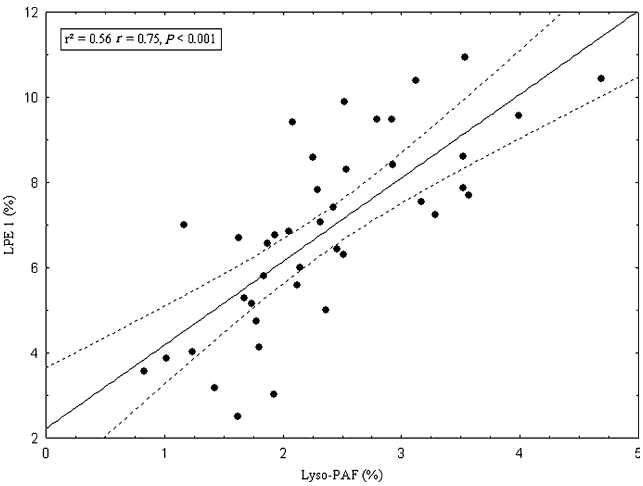

Fig. 4 Correlation between expression levels of lyso-PAF and LPE 1. The expression level of each compound is calculated according to peak area, and expressed as a percentage of the whole chromatogram

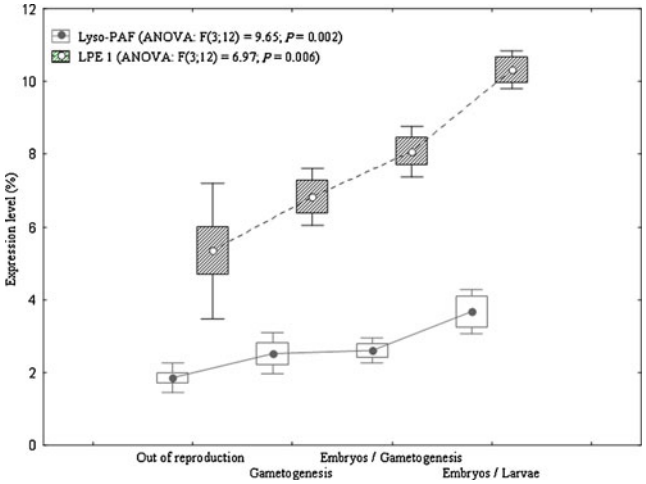

Fig. 5 Variation of lysophospholipid contents according to the different periods of the sponge life cycle. The expression level of each compound is calculated according to peak area and expressed as a percentage of the whole chromatogram

previously (Dembitsky et al., 1989; Genin et al., 2008), only a few chemical studies have reported the isolation and structural elucidation of LPLs in this taxonomic group (Butler et al., 1996; Shin et al., 1999; Alam et al., 2001; Lee et al., 2003; Zhao et al., 2003; Müller et al., 2004; Mansoor et al., 2005). We isolated and identified two LPLs that were unknown for *O. tuberculata*, a lyso-PAF C16, previously reported in a few other sponge species (Table 1) and a new lysophosphatidylethanolamine C20:2 (LPE 1). Phosphatidylcholine (PC) and phosphatidylethanolamine (PE) seem to be two major PL classes in sponges together with their LPL counterparts (Dembitsky et al., 1989; Genin et al., 2008). The new LPE is original because of the presence of C20:2 fatty acid with unsaturations Δ5,11. The occurrence

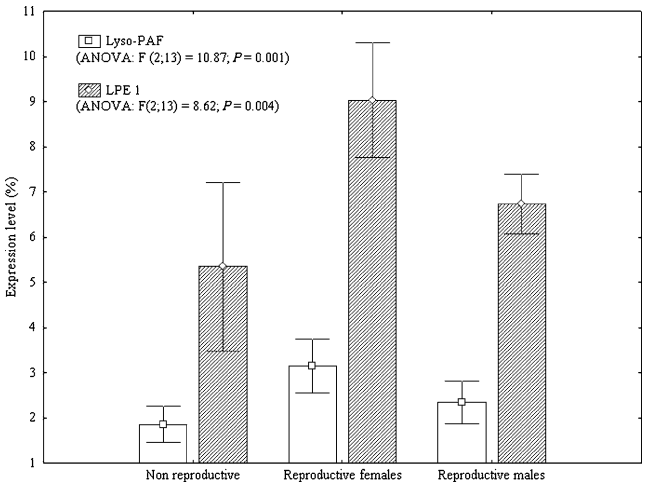

Fig. 6 Mean expression levels of lysophospholipids according to sponge sex. The expression level of each compound is calculated according to peak area, and expressed as a percentage of the whole chromatogram

of non-methylene-interruped fatty acids and especially 20:2 Δ5,11 has been reported previously from marine invertebrates, and mostly from mollusks, but they are less frequent in marine sponges (Barnathan, 2009).

The discovery of potent biological activities associated with LPLs has stimulated the research on their metabolic functions and potential physiological roles. Bioactivities of some sponge LPLs have been investigated by using various *in vivo* and *in vitro* bioassays. For example, the sponge *Suberites domuncula* showed an adaptive antibacterial reaction, which appeared to be linked to an increase in the level of lyso-PAF derivatives in response to endotoxins production (Müller et al., 2004). A lyso-PAF isolated from *Crella incrustans* was identified as an active antifouling agent by using a series of bioassays (Butler et al., 1996). Its activity was suggested to be related to the LPL amphiphilic nature and its surfactant properties that can prevent biofilm formation. Additionally, lyso-PAF analogues isolated from *Spirastrella abata* and *Stelletta* sp. have shown cytotoxicity against human tumor cell lines and an inhibitory effect on cholesterol biosynthesis (Shin et al., 1999; Alam et al., 2001; Zhao et al., 2003). The lyso-PAF structural features also underline their ability to interfere with ion transport mechanisms, thus exerting an effect on channel proteins and/or membranes that are involved in intracellular communication processes. *Oscarella tuberculata* crude extract showed the highest bioactivity among Homoscleromorph species as detected by the standardized Microtox test. Another well-studied Homoscleromorph, *Corticium candelabrum,* which produces cytotoxic and antibacterial aminosterols (plakinamines), had a bioactivity about five times lower than *O. tuberculata* (Ivanišević et al., 2011). *Oscarella tuberculata* antitumoral and antimalarial activities also are comparable to that of *C. candelabrum* (unpublished data). These biological assays, of course, do not relate directly to the ecological function(s) of the compounds, but rather provide insight into their pharmacological potential. However, their antibacterial and cytotoxic activity may be a good indication of the sponge's ability to prevent biofilm formation during the fouling process.

Regarding the displayed activity of *O. tuberculata* crude extract and the activity reported for lyso-PAF analogues in other sponges, the isolated lyso-PAF from *O. tuberculata* may indicate an allelochemical function as a fouling deterrent. Such a chemical defense is particularly important in benthic hard substrate communities where sessile organisms are subjected to fouling and competition for space and resources (Becerro et al., 1997). The hypothesis is supported by our in situ observations; indeed *O. tuberculata* is never overgrown by other invertebrate species, and it is often observed as an epibiont on other massive sponges or erected cnidarians.

LPL expression levels showed a strong seasonality, with a minimum in winter and a maximum in summer.

Variations in expression levels of both LPLs appeared to be highly correlated, which suggests that their production is probably related and/or dependent on the same metabolic pathways. Similar seasonality in the production of secondary metabolites has been observed previously in marine invertebrate species (Turon et al., 1996; Page et al., 2005; Abdo et al., 2007). Variability in metabolite expression levels may be linked to the fluctuation of environmental parameters such as temperature and/or nutrient bioavailability. We noticed that the highest LPL expression levels were recorded in summer, although no correlation was found between variations in LPL expression levels and natural fluctuations of seawater temperatures. However, moderate elevated temperature could have a stimulating effect on metabolite biosynthesis. We also assume that biotic factors and especially the physiological state of the organism should have a significant higher effect on secondary metabolite production. Indeed, seasonal variability of secondary metabolism may result from a trade-off with primary biological functions such as reproduction. LPL variability, with peak expression during the period of embryogenesis and larval development is noteworthy, suggesting a physiological function rather than an ecological role. It is known that some LPLs act in a wide range of animal cells as growth factors with hormone-like biological activities. They initiate and regulate cell proliferation including mitosis, cell differentiation and migration, and affect cell viability through anti-apoptosis properties (Birgbauer and Chun, 2006; Torkhovskaya et al., 2007). Considering their role among metazoans, one hypothesis is that they act as signaling molecules or metabolic intermediates during embryogenesis. The strong decreased concentration in sponges with released offspring is another clue to their putative role in larval development. Additionally, a secondary role as precursors of *de novo* synthesized glycerolipids used as energetic reserves cannot be excluded.

To summarize, we identified two lysophospholipids that are major and novel molecules for *O. tuberculata*. The isolation of sponge lysophospholipids has been rarely reported. Rather than a lack of interest, this probably has been due to purification difficulties. The recording of potent bioactivities justifies further research on their biological functions. In this regard, we have provided baseline expression levels of two major LPLs from *O. tuberculata,* and put forward a hypothesis concerning their putative biological function. The results suggest that they may have a key role in sponge embryogenesis and morphogenesis, either as signaling molecules that regulate cell division and differentiation, or simply as lipid reserves. Considering the high energy costs of chemical defenses, an optimized allocation of resources should be to produce secondary metabolites with multiple functions (Hartmann, 2007). Regarding the LPL amphiphilic character and the reported antimicrobial and cytotoxic activities, *O. tuberculata* LPL also might play an additional role as antifouling agents to prevent overgrowing or predation by other dwellers of hard substrate communities. In order to confirm these hypotheses, further research is necessary.

Acknowledgments This study was funded by ECIMAR project (ANR-06-BDIV-001), and partly by the "Institut de Chimie des Substances Naturelles (ICSN)" and the Pôle Mer PACA. We thank M. Gaysinski and the PFTC of Nice for recording the NMR spectra and J.-M. Guigonis for recording the HRMS spectra. We acknowledge the assistance of Ainara Gonzalez for the study of the sponge life cycle and I. Florent (Muséum National d'Histoire Naturelle de Paris) for the antimalarial bioassay, and the ICSN for the antitumoral assay.

OBITUARY

For Love of Eisner

Thomas Eisner (1929–2011)

Robert A. Raguso

Published online: 28 April 2011
© Springer Science+Business Media, LLC 2011

On March 25, 2011, Chemical Ecology lost one of its original guiding lights, Thomas Eisner, after a long and courageous battle with Parkinson's Disease. By now, numerous obituaries have detailed his prolific career as a research scientist, photographer, musician and champion of environmental and human rights. Equally well documented is his intriguing personal odyssey, beginning as a child refugee from fascist Europe and ending as a beloved professor emeritus at Cornell University. Others have profiled his numerous awards in recognition of his excellence in research (National Medal of Science, Carty Award of the National Academy of Sciences), his ability to communicate the joy of scientific discovery (Lewis Thomas Prize, New York Film Festival Grand Prize) and his tireless dedication to conservation (Tyler Prize for Environmental Achievement). Instead, in this brief essay I celebrate Tom's unusual scientific vision, rooted in the synergism between natural history and the experimental study of mechanism, and nurtured through collaborations across the physical sciences. The Eisner Vision figured prominently in the establishment of Chemical Ecology as a field, as well as the founding of my home department (Neurobiology and Behavior) at Cornell. It is carried forward today by his former students and remains a unifying philosophy among the new generation of chemical ecologists at Cornell, with whom I have the privilege of working.

Tom Eisner's keen interest in natural history was kindled during his childhood in Uruguay, described glowingly in his autobiographical "For Love of Insects". Aside from Niko Tinbergen's "Curious Naturalists", I find this book unrivaled in its humble and joyous account of a life spent pondering nature. Its passages resonate with anyone whose scientific career was sparked by early encounters with the natural world and was sustained by a desire to understand its inner workings. As an adult, Tom continued to seek inspiration through critical observations of natural history, accompanied by his wife and lifelong collaborator Maria (Loebell) Eisner, the naturalist Mark Deyrup, and their students. These observations invariably were followed by bioassays in which hapless frogs, birds, spiders, ants or fish were duped into approaching a would-be prey item, only to get splattered with some noxious defensive secretion. Although Tom's explorations required increasingly more sophisticated tools, these only enhanced, rather than diminished, the Eisnerian sense of wonder so familiar to generations of Cornell students.

Tom was a great aficionado of analytical equipment, especially anything that pushed the limits of optics, microscopy and high speed/resolution photography. So many of his group's seminal contributions, including the mechanisms of benzoquinone emission by bombardier beetles, the adhesion of the palmetto beetle's tarsal bristles to leaf surfaces, and the "hidden" patterns of UV reflectance in flower petals, were communicated through stunning photographic images. As accomplished a photographer as Tom was, he benefited from (and lovingly acknowledged) Maria's mastery of SEM, and frequently recounted in lectures his awestruck encounter with Harold "Doc" Edgerton, MIT's pioneer of strobe photography, whose high speed wizardry revealed the cooling mechanism for the abdominal emission chambers of bombardier beetles. Tom also enjoyed a long and fruitful collaboration with Dan Aneshansley, an engineer who devised elegant methods for measuring the physical properties (e.g. heat evolution, force transduction) by which beetles defend

themselves against predators. Of course, it was Tom's career-long partnership with Jerry Meinwald, whose group provided critical expertise in analytical chemistry, which had the greatest impact on our field. Tom and Jerry's decades of identifying strange compounds from even stranger glands led them through a forest of natural products, from the C10 cyclopentanoid constituents of catnip (nepetalactone) and walking stick defensive sprays (anisomorphal), to carminic acid, lucibufagin steroids and pyrrolizidine alkaloids that protect cochineal bugs, fireflies and tiger moths, respectively, from a grisly death. In the quality and quantity of their collaborative output, Eisner and Meinwald were the "Lennon and McCartney" of Chemical Ecology, and their "greatest hits" continue to inspire students of chemical defense, counter-defense and mimicry. As interest (and expertise) in natural product elucidation continues to wane among university chemistry departments, we are reminded of how crucial such collaborations are to the continued growth of our field. During his last years, this remained one of Tom's greatest concerns.

Tom sometimes lamented that his research had been criticized for its "lack of conceptual framework", but this criticism was shortsighted. In his foreword to "For Love of Insects", Tom's friend and intellectual gadfly E.O. Wilson likened him to a pointillist painter, from whose body of focused, detailed case studies emerges a canvas rich with patterns "of evolutionary adaptation, molecular evolution, behavior and life cycles that likely would not have been revealed by other means". As a group, chemical ecologists have been slow to grasp evolutionary theory and slower to embrace conditionality in the interactions whose mechanisms they dissect with such care. Not so with Tom and his students, whose studies of butterfly courtship, tiger moth alkaloid acquisition, spider web construction or herbivore-induced nicotine mobilization were rife with fitness tradeoffs, cost-benefit analyses and contingency. The students responsible for these studies are among today's most conceptually sophisticated interpreters of animal (and plant) behavior. Like Tom, their current research builds upon the foundation of natural history with sophisticated experimental manipulations of visual and acoustic as well as chemical and metabolic signals, in studies designed to explicitly measure fitness consequences.

Finally, Tom felt that by combining aesthetically appealing patterns with rigorous experimental elucidation of their underlying processes, he could more effectively communicate the splendor and importance of the natural world to a broader public, and educate them on the dire need to conserve nature's pharmacopoeia for future generations. In the final passage of "For Love of Insects", Tom described the mutual dependence between the role of nature in sustaining human curiosity and the increasingly urgent role of human curiosity (and its valuation) in preserving the world's remaining wild places. "Will the collective urge to discover keep natural history alive?" he asked. "Without [human] curiosity, without a passion for discovery, nature cannot endure. And without nature, curiosity will fade…It is so fundamentally human to thirst for knowledge and to turn to nature for visions of the unknown".

Thomas Eisner inspired generations of chemical ecologists to turn to nature for chemical visions of the unknown, visions that have given form and structure to the increasingly complex interaction webs that we now study in terrestrial, aquatic and marine environments across the globe, as communicated in this journal. He will be sorely missed by those who were inspired by his vision and his unquenchable sense of wonder about the natural world. I will remember him fondly, along with his tales of toxic steroids and *femmes fatales*, whenever fireflies light up the humid summer evenings of Ithaca.

RAPID COMMUNICATION

Near-Infrared Imaging Spectroscopy as a Tool to Discriminate Two Cryptic *Tetramorium* Ant Species

Abstract Correct species identification is a precondition for many ecological studies. Morphologically highly similar, i.e., cryptic, species are an important component of biodiversity but particularly difficult to discriminate and therefore understudied ecologically. To find new methods for their rapid identification, thus, is important. The cuticle's chemical signature of insects often is unique for species. Near-infrared spectroscopy (NIRS) can capture such signatures. Imaging NIRS facilitates precise positioning of the measurement area on biological objects and high-resolution spatial capturing. Here, we tested the applicability of imaging NIRS to the discrimination of cryptic species by using the ants *Tetramorium caespitum* and *T. impurum*. The classification success of Partial Least Squares Regression was 98.8%. Principal Component Analysis grouped spectra of some *T. impurum* individuals with *T. caespitum*. Combined with molecular-genetic and morphological evidence, this result enabled us to pose testable hypotheses about the biology of these species. We conclude that discrimination of *T. caespitum* and *T. impurum* with imaging NIRS is possible, promising that imaging NIRS could become a time- and cost-efficient tool for the reliable discrimination of cryptic species. This and the direct facilitation of potential biological insight beyond species identification underscore the value of imaging NIRS to ecology.

Key Words Cuticular hydrocarbons · Ant worker · Infrared spectroscopy · Chemical fingerprinting

Introduction

Species are basic units of ecology. However, species identification can be difficult, especially with morphologically nearly identical, i.e., cryptic, species. This situation hampers the ecological study of cryptic species, now known from many groups of organisms.

Near-infrared spectroscopy (NIRS) can afford an opportunity to make cryptic species accessible to ecology. By using the characteristic reaction of functional groups to infrared light in order to assign peaks to these functional groups, a fast and 'easy-to-use' identification tool has resulted (Workman and Weyer, 2008). It is increasingly used in many disciplines, including in entomology, as the cuticle's chemical signature is important for species discrimination in insects (Steiner et al., 2002; Martin and Drijfhout, 2009; Sikulu et al., 2010; Seppä et al., 2011). However, an exact positioning can be difficult for small specimens. Imaging-NIRS technology allows precise positioning of the measurement area and spectra capturing at a high spatial resolution (up to 6.25×6.25 μm), and thus has potential advantages over classical, fiber-optic-probe NIRS, where each spectrum represents an area of several square millimeters.

Imaging NIRS has not been used for cryptic-species discrimination so far. Here, we investigated whether the cryptic ant species *Tetramorium caespitum* and *T. impurum*, which otherwise can be identified only via molecular genetics or high-precision morphometrics (Schlick-Steiner et al., 2006), can be discriminated by their NIR spectra.

Methods and Materials

We selected 15 nest samples for each species from various European countries, collected in –2007 and already species-identified using mitochondrial (mt) DNA and morphometrics (Schlick-Steiner et al., 2006; Steiner et al., 2010). Individuals had been killed with and stored in 99% ethanol p.a. A plane measurement area that could be identically positioned in all individuals was chosen, i.e., a 400×400 μm frons area. Thus, the heads of three workers per nest were stuck on a microscope slide with wallpaper paste in such a way that head width and length were maximum. We excluded incompletely colored, i.e., very young workers.

Spectra were recorded using a Spectrum 400 (Perkin Elmer) spectrometer and a Spotlight 400 microscope with a nitrogen-cooled MCT detector array (16×2). At a resolution of 25×25 μm, we collected 256 spectra per individual from the 400×400 μm area, for wavelengths 7,800–2,000 cm^{-1}. The 256 spectra were reduced to one spectrum representing the measurement area. Data were analyzed using The Unscrambler 10.0.1 (Camo).

Spectra obtained from a smaller region (150×150 μm) for the individuals of nests TM45, TM308, i62, TM235, TM290, and i36 were used in a pre-test (data unpublished). As spectra of the TM45 and TM308 individuals could not be separated from *T. caespitum* spectra by Principal Component Analysis (PCA; see results), DNA was extracted from these six decapitated individuals, and a cytochrome-C-oxidase subunit one fragment of mtDNA was reverse sequenced as in Schlick-Steiner et al. (2006), with slight modifications.

For statistical analysis, an unsupervised method, PCA, and a supervised method, Partial Least Squares (PLS) Regression (NIPALS algorithm) were used. We randomly chose 14 *T. caespitum* and 15 *T. impurum* spectra as a validation set. For PCA, data were mean-centred; the first and second PC were plotted. For PLS Regression, data were mean-centred and converted to first Savitzky-Golay derivative. We set the constituent to 1 and 2 for *T. caespitum* and *T. impurum* individuals, respectively. Calibration quality was evaluated using R^2, root mean standard error of calibration (RMSEC), root mean standard error of prediction (RMSEP), and validation BIAS.

Regression coefficient plots were noisier in regions 7,800–5,500 and 2,500–2,000 cm^{-1}; therefore, we compared the regression coefficient plots of region 5,500–2,500 cm^{-1}.

Results

Heads of four individuals were destroyed during the measurement procedure. After checking spectra manually

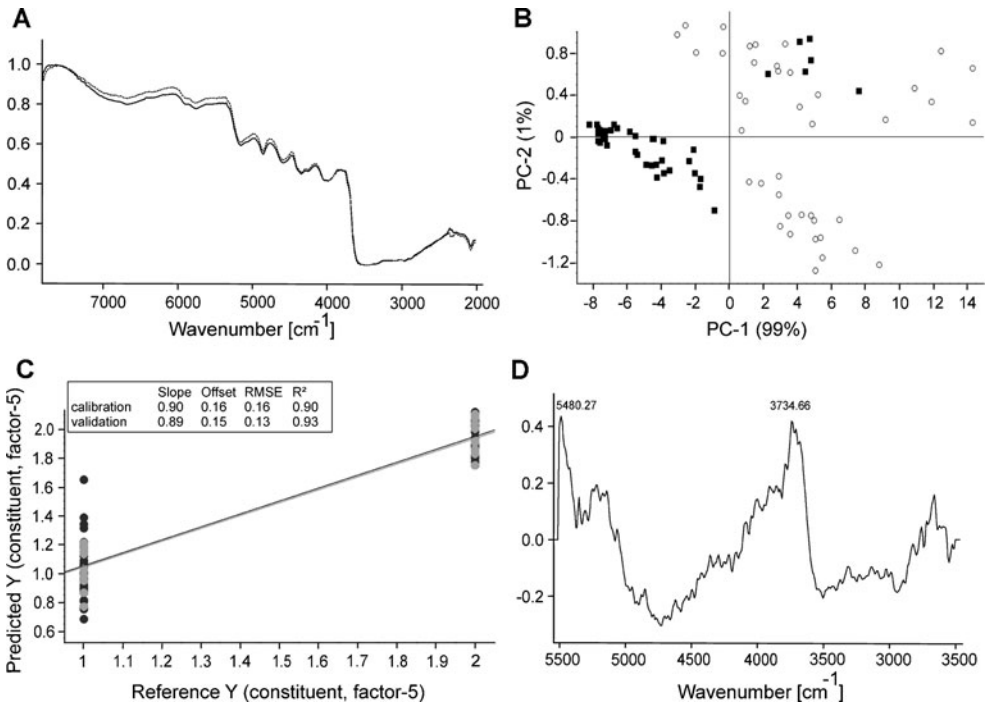

Fig. 1 Differences between species. **a** Example mean spectra (normalized 0–1) of a *Tetramorium caespitum* (*dotted line*) and a *T. impurum* (*solid line*) individual. **b** PCA of 84 individuals' mean spectra. Circle: *T. caespitum*; square: *T. impurum*; the six squares in the range of *T. caespitum* represent the individuals of *T. impurum* nests TM45 and TM308. **c** PLS Regression, predicted vs. reference plot using five factors of 84 individuals for the calibration set (*black*) and 29 individuals for the validation set (*grey*). **d** Regression coefficient plot of region 5,500–2,500 cm^{-1} for five factors

and via PCA, two outlier mean spectra were excluded. The remaining 84 spectra (for examples, see Fig. 1a) were used for the analyses.

In the PCA, the two species were separated, except for two nests (TM45, TM308; Fig. 1b) genetically and morphologically assigned to *T. impurum* by Schlick-Steiner et al. (2006). Our mtDNA analysis here of exactly those TM45 and TM308 individuals analyzed by NIRS also resulted in *T. impurum*. However, the independent imaging-NIRS pre-test had led to the same discrimination problem in PCA (data unpublished). When not considering TM45 and TM308, *Tetramorium impurum* showed less variability in its spectra than *T. caespitum*.

The PLS calibration was performed using five factors, and resulted in a correct classification of 98.8%, an R^2 of 0.90 for calibration and of 0.93 for validation. RMSEC and RMSEP were 0.16 and 0.13, respectively, and validation BIAS was −0.01, meaning that the spectra used for calibration supported the separation and prediction of the two species (Fig. 1c).

The regression coefficients had two distinct peaks in the five-factor plot at 3,730 and 5,481 cm^{-1} (Fig. 1d).

Discussion

Our results suggest that cryptic ant species can be separated by their near-infrared spectra. The two distinct peaks in the regression-coefficient plots correspond to hydrocarbon overtone vibration (Workman and Weyer, 2008), suggesting that these peaks represent species-diagnostic characters.

Concerning the two *T. impurum* nests not assigned to this species via PCA, we exclude sample confusion and misidentification, because the six scanned individuals were assigned to *T. impurum* by mtDNA, and spectra of these individuals also clustered with *T. caespitum* in the NIRS pre-test. An influence of the preservation method over time (cf. Perez-Mendoza et al., 2002) is also unlikely to be causal to the situation because samples did not group according to age in the PCA, and other samples collected in the same years as TM45 (2000) and TM308 (2002) were discriminated correctly. Instead, we are aware of three possible biological explanations, now available for future testing: (*i*) Interspecific hybridization was inferred for the *T. caespitum/impurum* complex (Steiner et al., 2010). Mitochondria are passed uniparentally rendering hybridization undetectable by mtDNA alone. If, for example, TM45 and TM308 were older hybrids, i.e., not F1 hybrids, different identification results from morphometrics and NIRS (*T. caespitum*) could reflect different selection pressures on the morphological and the chemical phenotype. (*ii*) We had excluded very young workers, but the age of the included individuals could still influence CHC profiles as known from other insects (Sikulu et al., 2010). (*iii*) TM45 and TM308 could have rare CHC profiles, and our *T. impurum* sample might under-represent the true variability of that species. Possibly in line with this, *T. impurum* was less variable in its spectra than *T. caespitum* when the two 'problematic' nests were excluded. However, two *Formica* ant species also differed strongly in CHC variability (Seppä et al., 2011), and such pattern could, alternatively, be common for closely related ant species.

With imaging NIRS, hands-on time for sample preparation and measurement was 25 min per individual, at 0.01 Euro costs. Imaging NIRS, thus, is faster than COI sequencing and morphometrics (85 and 75 min, respectively) and cheaper than COI sequencing (10.20 Euro); morphometrics causes no costs. Fiber-optic NIRS is even faster (Sikulu et al., 2010) and, like morphometrics, incurs no costs, but our imaging-NIRS-based PLS-classification success was higher when compared to that in fiber-optic-probe NIRS studies (e.g., Jia et al., 2007; Sikulu et al., 2010). Not included in the scanning area, the surface a specimen is placed on cannot influence measurements with imaging NIRS, and this might be one reason for the particularly good discrimination result. Biological insight beyond species identification may be facilitated by capitalizing on the incongruence for two nests across the results of the NIRS-based PCA and mtDNA- and morphometrics-based species identification. Finally, by allowing exact positioning of the measurement area and image capturing at a high resolution, investigating whether the chemical signature differs across body parts will be possible. This could open up additional possibilities for, e.g., NIRS-based behavioral-ecological studies (e.g., Newey et al., 2008). Thus, imaging NIRS gives a time- and cost-efficient opportunity to make cryptic species accessible to ecology and to further investigate their ecological significance.

Di- and Tri-fluorinated Analogs of Methyl Eugenol: Attraction to and Metabolism in the Oriental Fruit Fly, *Bactrocera Dorsalis* (Hendel)

Abstract Oriental fruit fly, *Bactrocera dorsalis* (Hendel), males are attracted to the natural phenylpropanoid methyl eugenol (ME). They feed compulsively on ME and metabolize it to ring and side-chain hydroxylated compounds that have both pheromonal and allomonal properties. Previously, we demonstrated that mono-fluorination at the terminal carbon of the ME side-chain significantly reduced metabolic side-chain hydroxylation, while mono-fluorination of ME at position 4 of the aromatic ring blocked ring-hydroxylation but surprisingly enhanced side-chain hydroxylation. Here, we demonstrated that the introduction of fluorine atoms on both the ring and side-chain of ME blocks both positions that undergo enzymatic hydroxylation and, in particular, completely inhibits oxidative biotransformation of the allyl group. In laboratory experiments, *B. dorsalis* males initially were more attracted to both 1-fluoro-4,5-dimethoxy-2-(3,3-difluoro-2-propenyl)benzene (**I**) and 1-fluoro-4,5-dimethoxy-2-(3-fluoro-2-propenyl)benzene (**II**) than to ME. However, both **I** and **II** were taken up by flies at rates significantly less than that of ME. Flies fed with difluoroanalog **II** partially metabolized it to 5-fluoro-4-(3-fluoroprop-2-en-1-yl)-2-methoxyphenol (**III**), and flies fed with trifluoroanalog **I** produced 4-(3,3-difluoroprop-2-en-1-yl)-5-fluoro-2-methoxyphenol (**V**), but the rates of metabolism relative to rates of intakes were much lower compared to those of ME. Flies that consumed either the tri- or difluorinated analog showed higher post-feeding mortality than those that fed on methyl eugenol. In field trials, trifluoroanalog **I** was ~90% less attractive to male *B. dorsalis* than ME, while difluoroanalog **II** was ~50% less attractive. These results suggest that increasing fluorination can contribute to fly mortality, but the trade off with attractancy makes it unlikely that either a di or trifluorinated ME would be an improvement over ME for detection and/or eradication of this species.

Key Words Oriental fruit fly · *Bactrocera dorsalis* (Hendel) · 1-(3,3-Difluoroprop-2-en-1-yl)-2-fluoro-4,5-dimethoxybenzene · 1-Fluoro-2-(3-fluoroprop-2-en-1-yl)-4,5-dimethoxybenzene · Methyl eugenol · Metabolism inhibition · Field attraction · Bioassay · Male annihilation

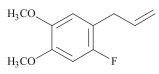
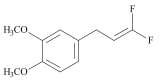
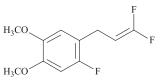
Introduction

The Oriental fruit fly, *Bactrocera dorsalis* (Hendel), is a serious pest of crops of tropical agriculture, attacking over 173 varieties of fruits and vegetables (Metcalf and Metcalf, 1992). *Bactrocera dorsalis* males are strongly attracted to, and compulsively feed on, methyl eugenol (ME, Scheme 1; Steiner, 1952), a commonly occurring plant phenylpropanoid (Metcalf, 1990). The use of ME in traps and killing

Scheme 1 **a** Syntheses of difluoroanalog **II** and trifluoroanalog **I**, as well as metabolites **III** and **V**. **b** Metabolism of methyl eugenol (ME), difluoroanalog **II**, and trifluoroanalog **I** in *Bactrocera dorsalis*







stations is an integral part of successful detection, control, and eradication strategies for *B. dorsalis* populations worldwide (Steiner et al., 1965; Koyama et al., 1984). The attraction to, and consumption of, ME by *B. dorsalis* and sibling species of the *dorsalis* complex, *B. papayae* and *B. carambolae*, also have ecological significance in the communication system of the fly. Mature males, after feeding on ME, metabolize it primarily to 2-(2-propenyl)-4,5-dimethoxyphenol (DMP) and (*E*)-coniferyl alcohol (CA), which exhibit pheromonal and allomonal properties (Nishida et al., 1988; Tan and Nishida, 1996).

One of the potential problems with the continued use of ME for fruit fly control is its reported carcinogenicity (Sekizawa and Shibamoto, 1982; Miller et al., 1983; Schiestl et al., 1989). Metabolic activation of ME and production of 1′-hydroxy metabolites through enzymatic side-chain hydroxylation are thought to be primarily responsible for hepatotoxicity and carcinogenicity of this compound (Smith et al., 2002). The search for safer alternative attractants has led to the evaluation of a number of phenylpropanoids with structural similarities to ME (Metcalf et al., 1975; Mitchell et al., 1985; Khrimian et al., 1993, 1994, 2006, 2009; Liquido et al., 1998).

Two such analogs of ME are 4-[(2*E*)-3-fluoroprop-2-en-1-yl]-1,2-dimethoxybenzene (FME, Table 1), an analog fluorinated at the terminal carbon of the ME side chain, and 1-fluoro-4,5-dimethoxy-2-(prop-2-en-1-yl)benzene (RFME, Scheme 1), an analog fluorinated at the 4 position of the ME aromatic ring. In field tests, FME was as attractive to *B. dorsalis* males as ME (Khrimian et al., 1994), while RFME was ~50% less attractive than ME (Khrimian et al., 2009). In tests, the release rates of RFME and ME were not different (Khrimian et al., 2009), whereas FME was more persistent than ME and, remarkably, about twice as active behaviorally as the corresponding *Z* isomer (Khrimian et al., 1994; Liquido et al., 1998). In laboratory experiments, both FME and RFME attracted, and were readily consumed by, *B. dorsalis* males at rates similar to that of ME (Khrimian et al., 2006, 2009). Interestingly, the degree of biotransformation inhibition is different between the fluorinated analogs, with RFME being completely blocked to enzymatic hydroxylation to DMP (Khrimian et al., 2009), whereas FME is only partially blocked to enzymatic hydroxylation to fluorinated CA (Khrimian et al., 2006). This is probably because FME still has a potential hydroxylation site, following isomerization, at the terminal double-bond position. Overall metabolism by flies also was differentially affected, with RFME enhancing the overall rate while FME did not.

The inhibition of ME biotransformation pathways of FME and RFME is particularly interesting in light of *B.*

Abbreviation	RFME	ME	DFME	**I**	**II**	FME
Structure						
Half-life ± SE (days)	0.59 ± 0.01a	0.97 ± 0.04ab	1.2 ± 0.1b	1.4 ± 0.3b	2.14 ± 0.07c	3.27 ± 0.07d

dorsalis mortality caused by ME ingested in large amounts (Steiner, 1952). Additionally, the discovery that Melon fly males are attracted to wild orchids (*Bulbophyllum* sp.), which contain ME and in some instances CA and DMP (Tan et al., 2002, 2006), and utilize the metabolized byproducts as pheromonal semiochemicals (Tan and Nishida, 1996), further piqued our interest. In particular, we were interested as to whether or not blocking the metabolic pathway could lead to a single molecule that would be both attractive and more toxic, thus dispensing with the need for additional toxicants. While consumption of neither FME nor RFME increased mortality in *B. dorsalis* males, we were interested to observe whether ME analogs fluorinated at both hydroxylation sites would cause mortality through higher concentrations of unmetabolized phenylpropanoid.

Here, we present the results of our studies on behavioral bioassays and metabolism of two additional fluorinated ME analogs, 1-(3,3-difluoroprop-2-en-1-yl)-2-fluoro-4,5-dimethoxybenzene (**I**, Scheme 1), a ME analog trifluorinated at the 4 position of the aromatic ring and at the terminal carbon of the side chain, and 1-fluoro-2-(3-fluoroprop-2-en-1-yl)-4,5-dimethoxybenzene (**II**, Scheme 1), a ring and side-chain difluorinated analog. Of particular interest is how fluorination of both key metabolic hydroxylation sites of ME affects the overall biotransformation in *B. dorsalis*. Thus, we quantified the attractiveness of compounds **I** and **II**, compared to ME and the previously synthesized analogs FME, RFME, and 4-(3,3-difluoroprop-2-en-1-yl)-1,2-dimethoxybenzene (DFME, Table 1).

Methods and Materials

Analytical Procedures ^{1}H NMR spectra were obtained either at 400 MHz on a Bruker AV-400, or at 500 MHz on a Bruker DRX-500, using TMS as an internal standard. Chemical shifts are reported in δ units, and coupling constants in Hz. Electron-ionization (EI) mass spectra were obtained at 70 eV with an Agilent Technologies 5973 mass selective detector (MS) interfaced with a 6890 N gas chromatograph (GC) equipped with a 30 m×0.25 mm i.d. x 0.25 μm film HP-5MS column. Column temperature was held at 100°C for 2 min and then raised to 260°C at 10°C. min^{-1}. Helium was used as a carrier gas at a constant flow of 1 ml.min^1. GC analyses were performed on a Shimadzu 17A (Shimadzu Scientific Instruments, Inc., Columbia, MD, USA) equipped with a flame ionization detector, an auto sampler (AOC-20s) and auto injector (AOC-20i), and an HP-5 capillary column (30 m×0.25 mm×0.25 μm film). Hydrogen was used as carrier gas at 1 ml.min^1. Column temperature was maintained at 100°C for 2 min and then raised to 260°C at 10°C.min^1. Thin layer chromatography (TLC) analyses were conducted using Whatman AL SIL G/UV plates, with hexanes/ethyl acetate as a mobile phase and a 20% solution of phosphomolybdic acid in ethanol and/or UV for visualization of spots. Flash chromatography was carried out with 230–400 mesh silica gel (Fisher Scientific, Fair Lawn, NJ, USA).

Chemicals All reagents and solvents were purchased from Aldrich Chemical Co. unless otherwise specified. Dichloromethane (DCM) was distilled from calcium hydride, and tetrahydrofuran (THF) was dried by distillation from sodium benzophenone-ketyl. Methyl eugenol metabolites, 4,5-dimethoxy-2-(2-propenyl)phenol (DMP) and (*E*)-coniferyl alcohol (CA) were prepared from ferulic acid (Quideau and Ralph, 1992) and 3,4-dimethoxyphenol (Benbow and Katoch-Rouse, 2001), respectively. 4-Fluoro-1,2-dimethoxy-5-(2-propenyl)benzene (RFME) was synthesized following Khrimian et al. (2009). 4-(3,3-Difluoro-2-propenyl)-1,2-dimethoxybenzene (DFME-2) and 4-(3-fluoro-2-propenyl)-1,2-dimethoxybenzene (FME) were prepared following Khrimian et al. (2006).

*1-(3,3-Difluoroprop-2-en-1-yl)-2-fluoro-4,5-dimethoxybenzene (**I**)* To a solution of RFME (3.92 g, 20 mmol) in ether (200 ml) was added a solution of OsO_4 (1.017 g, 4 mmol) in acetone (40 ml). The resulting dark-brown solution was

stirred for 10 min. prior to addition of water (200 ml). Finely powdered $NaIO_4$ (19.2 g, 0.09 mol) was added in five portions over a 2-h period, and the reaction progress was followed by TLC. The mixture was stirred for 1 h, diluted with ether (100 ml), and the layers separated. The organic phase was washed with brine, dried (Na_2SO_4), and purified by flash chromatography on SiO_2 (hexanes/ethyl acetate, 2:1) to yield 2-fluoro-4,5-dimethoxyphenylacetaldehyde (2.12 g, 54%). GC-MS (*m/z*, %): 198 (M^+, 59), 169 (100), 153 (63), 125 (20). A solution of this aldehyde (1.922 g, 9.7 mmol) in THF (10 ml) was added at room temperature to a Wittig reagent, prepared by addition of dibromodifluoromethane (1.78 ml, 19.4 mol) to a solution of hexamethylphosphorus triamide (HMPT, 6.98 ml) in dry THF (40 ml) at 0°C. The resultant mixture was gradually warmed to room temperature, stirred for 1.5 h, then poured into ice-water, and extracted with hexanes/ether (1:1). The organic layer was washed with water, dried, and evaporated. Flash chromatography with hexanes/ethyl acetate (5:1) furnished benzene **I** (1.530 g, 62% from 2-fluoro-4,5-dimethoxyphenylacetaldehyde). GC-MS (*m/z*, %): 232 (M^+, 100), 217 (26), 201 (30), 189 (9), 169 (12), 145 (12), 139 (10), 127 (12), 77 (33). ^{1}H NMR (500 MHz, CD_3CN): 3.25 (br. d, *J*=8.0, CH_2), 3.75 (s, 6 H, OCH_3), 4.50 (dtd, *J*=25.5, 8.0, 2.5, CH=), 6.71 (d, *J*=11.5, H-3), 6.77 (d, *J*=7.4, H-6).

*1-Fluoro-2-(3-fluoroprop-2-en-1-yl)-4,5-dimethoxybenzene (**II**)* A solution of trifluoroanalog **I** (928 mg, 4 mmol) and Red-Al® (3.6 ml of 3.34 M in toluene, 12 mmol) in dry toluene (15 ml) was refluxed, and the reaction progress monitored by GC-MS. After 44 h, the mixture was diluted with ether (50 ml), cooled to −10°C, acidified with 10% HCl to pH 3, and extracted with ether/hexane (1:1). Combined organic extracts were washed with brine, dried, and concentrated. Flash chromatography with hexanes/ethyl acetate (5:1) afforded benzene **II** (632 mg, 74%) in a 89:11 ratio of *E* and Z isomers. GC-MS (*m/z*, %) **II***E*: 214 (M^+, 100%), 199 (30), 183 (37), 151 (12), 139 (14), 137 (15), 127 (23), 109 (12), 59 (23). **II***Z* had an almost identical mass-spectrum. ^{1}H NMR (400 MHz, CD_3CN): 3.18 (br.d, *J*=8.0 Hz, CH_2 **II***E*), 3.37 (br.d, 2 H, *J*=7.2 Hz, CH_2 **II***Z*), 3.75 and 3.76 (both s, CH_3O, **II***E* and **II***Z*), 4.99 (dtd, *J*=42.8, 8.0, 4.8, $CH_2C\underline{H}$=, **II***Z*), 5.58 (ddt, *J*=18.4, 11.0, 8.0, $CH_2C\underline{H}$=, **II***E*), 6.69 (ddt, *J*=85.6, 11.2, 1.2, CH_2CH=$C\underline{H}F$, **II***E*), 6.71 (d, *J*=11.2, H-3, **II***E* and **II***Z*), 6.76 (d, *J*=7.6, H-6, **II***E* and **II***Z*). 6.51 (dt, *J*=4.4, 1.2, 1/2 CH_2CH=$C\underline{H}F$, **II***Z*; the other half of this signal split on F with $^2J_{HF}$~85 Hz was buried under other signals).

*5-Fluoro-4-(3-fluoroprop-2-en-1-yl)-2-methoxyphenol (**III**)* To a solution of **II** (39 mg, 0.18 mmol) in dry DCM (200 μl) was added, under N_2 atmosphere, boron trichloride (0.2 mmol, 200 μl of 1.0 M in DCM) at 0°C. The solution was allowed to warm to 25°C and stirred at that temperature for 4 h. The mixture was quenched with ice water (2.0 ml) and extracted with DCM (total 10 ml). The combined organic extracts were washed with a sodium bicarbonate solution to pH 7, then dried and concentrated. Flash chromatography with hexanes/ethyl acetate (3:1) provided a mixture of phenols (20 mg) that, according to GC-MS, consisted of four peaks in a 2.8:34.3:5.1:55.9 ratio, assigned by GC-MS and NMR as **IV***Z*, **IV***E*, **V***Z*, and **V***E*, respectively. GC-MS (*m/z*, %): **IV***E*: 200 (M^+, 100%), 185 (10), 167 (21), 165 (16), 155 (8), 140 (12), 137 (17), 127 (8), 109 (25). Phenols **IV***Z*, **V***E*, and **V***Z* have very similar mass spectra to **IV***E*. ^{1}H NMR (400 MHz, CD_3CN): 3.12 (br.d, *J*=8.0 Hz, CH_2 **V***E*), 3.16 (br.d, *J*=7.5 Hz, CH_2 **IV***E*), 3.32 (br.d, *J*=7.6 Hz, CH_2 **V***Z*), 3.35 (br. d, *J*=7.6 Hz, CH_2 **IV***Z*), 3.80 (br. s, OCH_3), 4.97 (dtd, *J*=42.8, 7.6, 4.4, $CH_2C\underline{H}$=, **IV***Z*, **V***Z*), 5.50 (m, $CH_2C\underline{H}$=, **IV***E*, **V***E*), 6.32 (br. s, OH), 6.57 (d, *J*=10.8, H-6, **III**), 6.66 (d, *J*=7.6, H-6, **IV**), 6.69 (ddm, *J*=85.6, 10.8, CH_2CH=$C\underline{H}F$, **IV***E*, **V***E*), 6.71 (d, *J*=11.2, H-3, **IV**), 6.76 (d, *J*=7.2, H-3, **III**).

*4-(3,3-Difluoroprop-2-en-1-yl)-5-fluoro-2-methoxyphenol (**V**)* Analogous to the experiment with difluoroanalog **II**, a solution of **I** (40 mg, 0.17 mmol) in dry DCM (200 μl) was treated with boron trichloride (0.2 mmol, 200 μl of 1.0 M in DCM). After the work up described above and flash chromatography with hexanes/ethyl acetate (3:1), we isolated a mixture of phenols **V** and **VI** (24 mg) in a 42:58 ratio, according to GC-MS. GC-MS (*m/z*, %): **V**—218 (M^+, 100%), 203 (16), 187 (12), 186 (10), 183 (17), 167 (11), 158 (10), 155 (32), 127 (35), 77 (10). **VI**—218 (M^+, 100%), 203 (6), 201 (12), 186 (8), 183 (12), 167 (10), 158 (18), 155 (25), 127 (28), 77 (11). ^{1}H NMR (500 MHz, CD_3CN): 3.21 (br.d, *J*=8.0, CH_2, **VI**), 3.24 (br.d, *J*=8.0, CH_2, **V**), 3.80 (br. s, OCH_3), 4.47 (dtd, *J*=25.5, 8.0, 2.0, $CH_2C\underline{H}$=), 6.34 (br. s, OH), 6.59 (d, *J*=10.5, H-6, **V**), 6.68 (d, *J*=7.5, H-6, **VI**), 6.72 (d, *J*=11.2, H-3, **VI**), 6.78 (d, *J*=7.3, H-3, **V**).

Insects Laboratory-reared *B. dorsalis* (strain: "Punador", initiated in 1988–1989 and monitored by mating and survival tests) were obtained from the USDA-ARS-PBARC rearing facility in Honolulu, Hawaii. Pupae were placed in a screened aluminum cage (30×30×30 cm) and allowed to emerge. Flies were given water, sugar, and hydrolyzed yeast protein and held at 25–26°C, 50–70% relative humidity and a 12/12 hL/D cycle before use in laboratory trials. Field bioassays were conducted with sterile laboratory-reared *B. dorsalis*, obtained as pupae, from a laboratory colony at the USDA-ARS-PBARC rearing facility in Honolulu, HI. Emerged adults were kept in an insectary at 24–27°C, 65–70% RH, and a photoperiod of 12:12 h (L:D). Adults were fed water and a diet of three parts sucrose, one part protein yeast hydrolysate (Enzymatic,

United States Biochemical Corporation, Cleveland, OH, USA), and 0.5 part torula yeast (Lake States Division, Rhinelander Paper Co., Rhinelander, WI, USA). Sexually mature, 10- 11-d-old flies were used in the field studies.

Bioassays

Laboratory Feeding and Metabolism A single laboratory experiment was conducted to assess the relative behavioral responses (including attraction and feeding) of male *B. dorsalis* to trifluoroanalog **I**, difluoroanalog **II**, ME, and a water control. Additionally, flies from this experiment were extracted and analyzed to determine phenylpropanoid consumption and metabolism. The lab experiment was conducted using 200 laboratory-reared mature (9-10-d-old) *B. dorsalis* males placed in 20 ~1-l plastic containers (10 flies/container) equipped with water inserts and screened covers. Fifty flies were used for each of the four treatments. Flies were offered 10 μl of ME, trifluoroanalog **I**, or difluoroanalog **II**, on a slip of filter paper (25×5 mm) taped to a blank water vial. A control group of 50 male flies was presented with a filter paper treated with 10 μl water. Responses of flies to the treated or control filter paper were observed for 1 h, with the number of flies present on the filter papers (landings) recorded at 5 min intervals. After the observation period, the filter papers were removed, water containers were introduced, and the flies left overnight with a sugar cube on the cover for consumption. Numbers of dead flies were counted at 18, 24, 36, and 48 h following the observation period. Eighteen hours after feeding, the rectal glands of 10 flies, each fed with ME difluoroanalog **II** and trifluoroanalog **I**, as well as 10 control flies, were dissected and placed in conical plastic vials, each containing 20 μl ethanol. The glands were crushed with a wire rod, sealed with Parafilm, and centrifuged at~4000 rpm for 10 min. The supernatants were diluted with ethanol to 100 μl, and analyzed by GC-MS in splitless mode. External standards of CA, DMP, and phenols **III** and **V**, were used for quantification.

The remainder of the dissected flies were placed individually into 20 μl ethanol, crushed, and then flash-chromatographed on a short SiO_2 column (30×5 mm) with hexanes/ethyl acetate (1:1). The fractions containing unmetabolized ME, and fluorine analogs **I** and **II**, were combined, concentrated to 1 ml, and quantified by GC using external standards.

Field Attractiveness and Release Rate

Dispenser Preparation and Field Trapping A field experiment was conducted to assess the attraction of male *B. dorsalis* to various phenylpropanoids. Lures from this experiment were extracted and analyzed to determine lure longevity. The following compounds were tested in this field trapping experiment: ME, trifluoroanalog **I**, difluoroanalog **II**, RFME, DFME, and FME. Cotton dental wicks (9 mm diam.×14 mm length) were treated with aliquots of a hexane-acetone stock solution (2:1 v/v) containing a test compound. Each wick (total 17 for each treatment) was treated with 250 μl of the stock solution, a volume calculated to deliver ca. 10 mg of a test chemical. After allowing the solvent to evaporate (20–25 min), 3 wicks were kept for day 0 analyses, and the remaining 14 wicks sealed in vials and sent to Hawaii for field testing. Wicks were enclosed by screen material (to prevent feeding) and placed under tarpaulins for trapping and weathering studies. Using metal clips, baskets containing wicks were hung inside Jackson traps. Each Jackson trap had a sticky basal insert and half a Vaportape II pest strip (2.54×10.16-cm strip, weighing 5.9 g, containing 10% 2,2-dichlorovinyl dimethyl phosphate, Hercon Environmental, Emigsville, PA, USA). Field tests were conducted in a macadamia (*Macadamia integrifolia* Maiden and Betche) orchard near Hilo, Hawaii. A natural low-density population of wild Oriental fruit flies, subsisting on wild hosts inside and outside this orchard, was used. The experimental design was a randomized complete block with eight replications (day 1 had 14, d 2 had 11, and d 7 had 8 replicates). For weathering analysis (see below), 3 wicks were retrieved on d 1, d 2, and d 7. Traps were placed 10 m apart in each row, with 20 m between rows. After 24 and 48 h, inserts with trapped adults from each trap were recovered, and new inserts placed in the traps (3 lures were also removed each time, see below). After 7 d, the remaining wicks and inserts were recovered from each trap and brought back to the laboratory. The total numbers of trapped *B. dorsalis* males were determined for each retrieved insert.

Weathering of Wicks and Residue Analyses Concurrent with the attractancy field tests (above), three wicks were retrieved on d 1, 2, and 7. Wicks were placed in glass vials and kept in a freezer. On d 1, replicates 3, 8, and 11 were retrieved for analysis. On d 2, replicates 4, 7, and 12 were retrieved for analysis. On d 7, 3 wicks were randomly selected from the remaining eight replicates left in the field. Upon completion of the experiment, weathered wicks were sent to the ARS lab in Beltsville for analysis. Wicks were extracted in 15 ml of acetone for 12 h and analyzed using appropriate external standards.

Data Analysis All results were analyzed using ANOVA followed by Student Newman–Keuls test (alpha=0.05). Means of fly landing and mortality were compared at each time interval and also combined across an experi-

ment. Lure weathering residual analysis data showed first order exponential decay; lure volatilities are, therefore, reported as half-lives. All statistical analyses were performed using SPSS version 15.0 (SPSS, Inc. Chicago, IL, USA).

Results

The syntheses of trifluorinated and difluorinated methyl eugenol analogs **I** and **II**, as well as phenols **III** and **V**, are shown in Scheme 1a. The oxidative cleavage of the double bond of RFME, following Benbow and Katoch-Rouse (2001), furnished intermediate 2-fluoro-4,5-dimethoxyphenylacetaldehyde, which was difluoroolefinated *in situ* with HPMT/CBr_2F_2 (Hayashi et al., 1979) to give trifluoroanalog **I**. Selective reduction of **I** with Red-Al® gave predominantly **II***E* difluoroanalog (**II***E*/**II***Z*, 87:13) as expected (Hayashi et al., 1979; Khrimian et al., 2006). Cleavage of both difluoroanalog **II** and trifluoroanalog **I** proceeded non-regioselectively, providing mixtures of phenols (Scheme 1a), in which desired phenols **III** and **V** were minor components. Structures of these phenols were assigned without separation from major components by applying nuclear Overhauser effect (NOE), analogously to that previously reported (Khrimian et al., 2009). In the case of the difluoroanalogs mixture, irradiation of CH_3O groups, resonating at about the same frequency in both **III** and **IV**, resulted in a NOEDIF spectrum with enhanced signals at 6.71 (d, J=11.2 Hz) and 6.76 (d, J=7.2 Hz). Based on the literature evidence of a larger proton-fluorine coupling constant in the *ortho* position ($^3J_{HF}$), compared to that in the *meta* position ($^4J_{HF}$) and the actual values of these interactions (Silverstein et al., 1980), we assigned the first doublet (of higher intensity) to the proton on C-3 of phenol **IV**, and the second to the proton on C-3 of phenol **III** (Scheme 1a). In the ^{1}H NMR spectrum of the mixture of **V** and **VI**, NOE effects from CH_3O groups were observed on the signals at 6.72 (d, J=11.2 Hz) and 6.78 (d, J=7.3 Hz). Thus, the bigger doublet at 6.72 ppm with larger coupling constant was assigned to H-3 proton of phenol **VI**, and the smaller doublet at 6.78 to H-3 of phenol **V**. Retention times and mass spectra of synthetic phenols **III** and **V** matched those of compounds isolated from glands of *B. dorsalis* males fed with difluoroanalog **II** and trifluoroanalog **I**, respectively (Figs. 1 and 2).

Feeding and Metabolism Observed responses of male *B. dorsalis* to phenylpropanoid treated filter papers included, flying to and alighting on the paper, arrestment on the paper without feeding, and arrestment with mouthparts engaging the paper (feeding). All behaviors were similar to those previously observed in this bioassay (Khrimian et al., 2009). Comparing male *B. dorsalis* responses to the phenylpropanoids (Fig. 3), the average numbers of flies observed (landing) on trifluoroanalog **I** or difluoroanalog **II** were both higher (F=7.42; P=0.002) than those on ME at 5 min, and difluoroanalog **II** landings and feeding were also higher (F=9.30; P=0.001) than those of ME at 10 min. At 10 min. there was no difference between the responses to fluorine analogs and to ME, but there was at 30 min (F=6.93; P=0.003), when trifluoroanalog **I** no longer appeared to be attractive. When mean landings are combined across the experiment, difluoroanalog **II** landings were higher than those of ME and trifluoroanalog **I**, which were, in turn, higher than the control (F=18.0; P< 0.001). Only one fly landing was observed in the control cages.

Flies fed with trifluoroanalog **I** and difluoroanalog **II** suffered higher levels of mortality than those fed with ME or water (control) (Fig. 4), at each time interval (18 h: F=10.70; P<0.001, 24 h: F=10.95; P=0.001, 36 h: F=8.77; P=0.002, and 48 h: F=9.83; P=0.001). There were no differences in mortality between flies fed on trifluoroanalog **I** or difluoroanalog **II** at any time interval. No fly mortalities were observed in control cages, and only one fly died in ME treatment cages.

Chemical analyses of rectal glands and remaining body parts of 10 flies from the laboratory bioassay showed differences in the total amount of phenylpropanoid intake and metabolites produced by flies (Fig. 5). Representative gas chromatograms of gland extracts of individual *B. dorsalis* males fed trifluoroanalog **I** or difluoroanalog **II** (Figs. 1 and 2) revealed peaks from compounds that matched synthetic phenols **III** and **V** in both retention times and mass spectra. As expected, flies fed with ME produced the well-described metabolites CA and DMP (Fig. 5). Unmetabolized test phenylpropanoids were not found in rectal glands, but were present in extracts of fly remains after dissection. Flies exposed to ME had significantly more unmetabolized phenylpropanoid (ME) than those exposed to trifluoroanalog **I** or difluoroanalog **II** (F=10.93; P<0.001) (Fig. 5). Similarly, a remarkable difference among treatments was observed in the amounts of metabolites relative to amounts of intake, with higher amounts of CA and DMP detected compared to metabolites **III** and **V** (F=10.13; P=0.001). At this feeding level, *B. dorsalis* males were able to metabolize, after 18 h, an average of 13±4 μg/fly of ME (12±3% of ME consumed; CA: 4.46 μg/fly, DMP: 8.10 μg/fly), but only 0.3±0.1 μg/fly of trifluoroanalog **I** (10±5% of consumed), and 0.2±0.1 μg/fly of difluoroanalog **II** (2±2% of consumed). Control flies were not analyzed, as previous work (Khrimian et al., 2006, 2009) had failed to detect phenylpropanoids in the glands or body parts of flies exposed only to water.

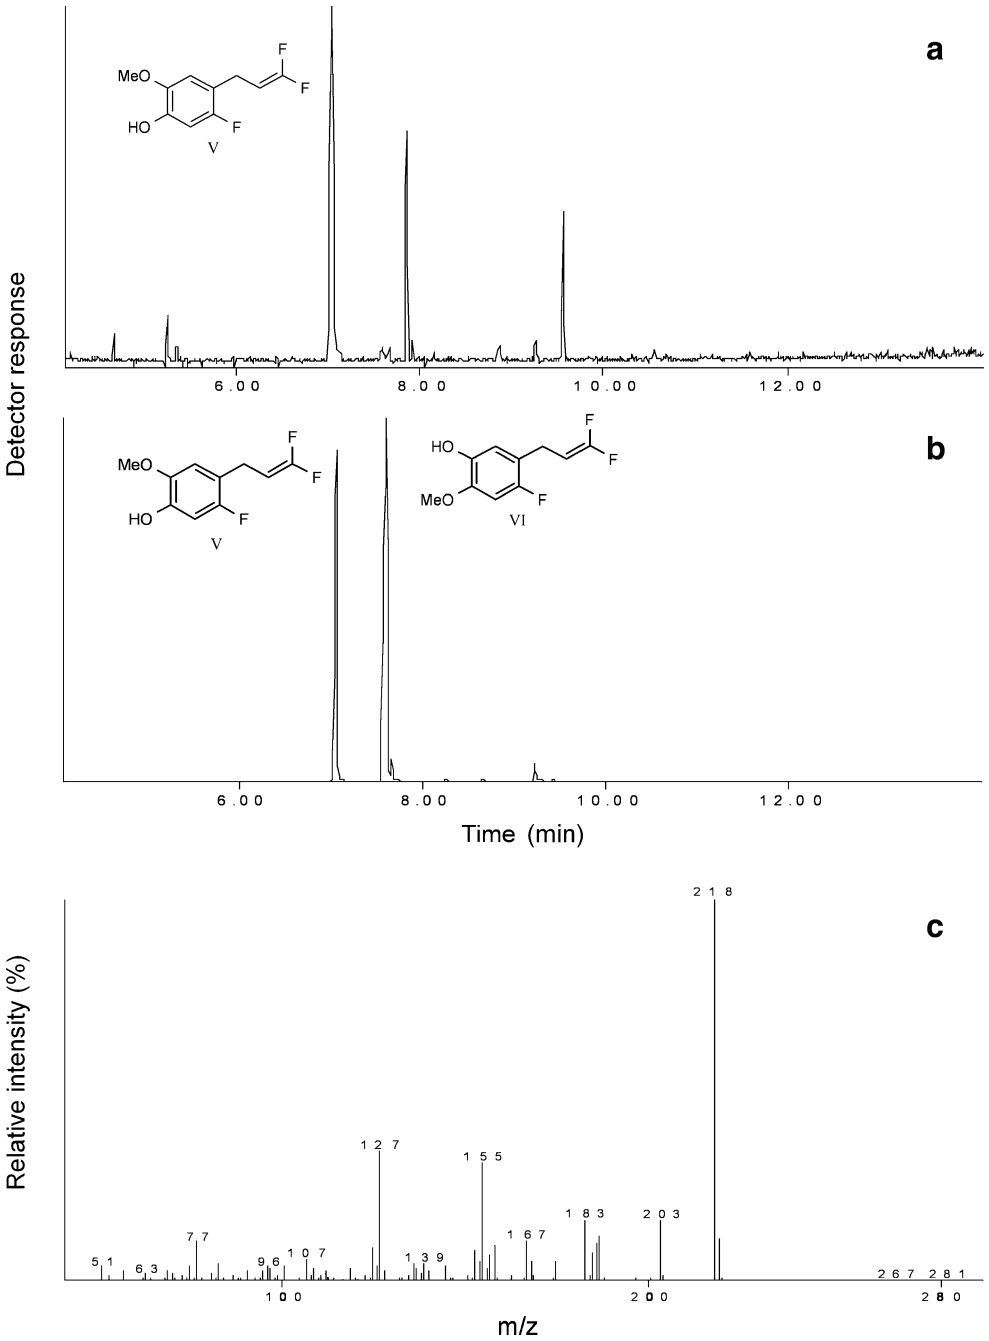

Fig. 1 **a** Representative total ion chromatogram (TIC) of a gland extract of a single *Bactrocera dorsalis* male fed with trifluoroanalog **I**; **b** TIC of a mixture of the synthetic metabolite **V** and isomeric phenol **VI**; **c** Mass-spectrum of the metabolite **V** [4-(3,3-difluoroprop-2-en-1-yl)-5-fluoro-2-methoxyphenol]

Field Bioassay Trap captures of male *B. dorsalis* are presented in Fig. 6. At 24 h (day 1), traps baited with ME and FME captured more flies than traps baited with any other lure, while trifluoroanalog **I**-baited traps caught fewer flies than any of the traps baited with other lures ($P<0.001$, $F=10.627$). At 48 h (day 2), the differences among lures of numbers of flies caught in traps was less pronounced ($P<0.001$, $F=7.10$). At day 7, FME-baited traps caught more flies than all other traps, while RFME-, DFME- or trifluoroanalog **I**-baited traps caught fewer flies than traps baited with other lures ($P<0.001$, $F=26.75$). Overall, traps baited with trifluoroanalog **I** were outperformed by traps baited with any of the other lures, while traps baited with difluoroanalog **II** caught numbers of flies that were always intermediate (Fig. 6).

Analysis of weathered lures showed marked differences in amounts of phenylpropanoid residues (Table 1). RFME had the shortest half-life ($P<0.001$, $F=2.82$; and, therefore, was the most volatile), although it was not different from that of ME. The half-life of FME was longer (and, therefore, the

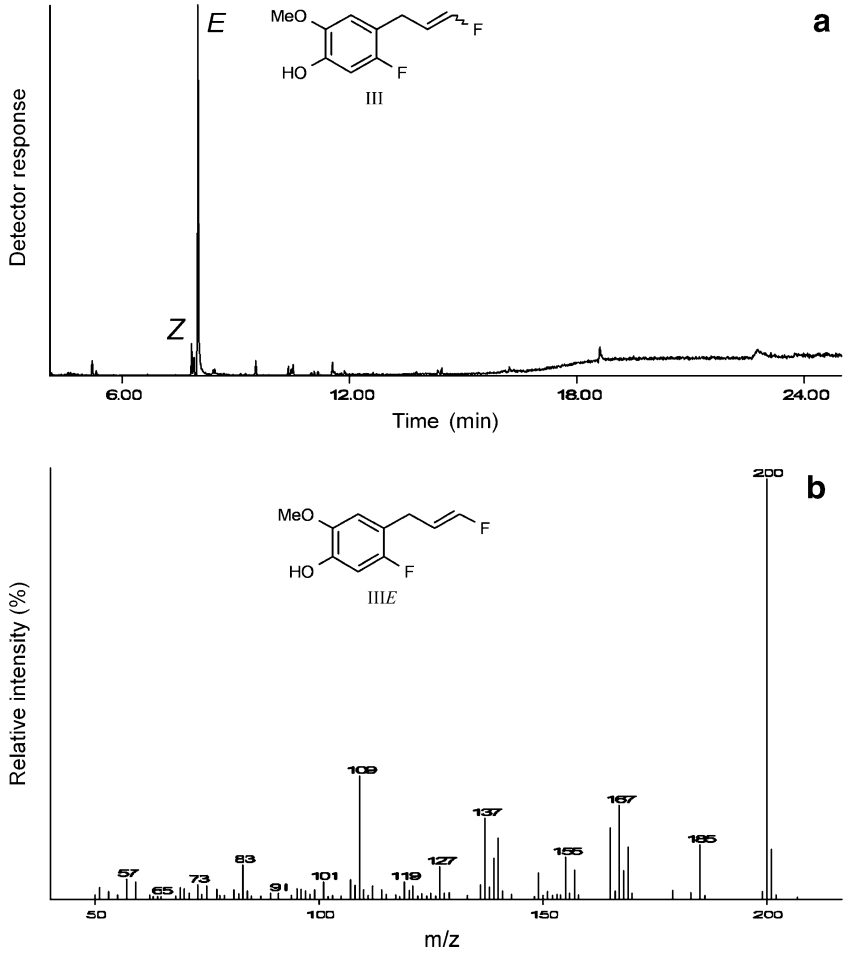

Fig. 2 **a** Representative total ion chromatogram (TIC) of a gland extract of a single *Bactrocera dorsalis* male fed with difluoroanalog **II,** and (**b**) the mass spectrum of the main metabolite **III***E*

least volatile) than for all other phenylpropanoid lures. As a general observation, ring-fluorination decreased half-life time (i.e., increased volatility), while side-chain fluorination increased half-life (i.e., decreased volatility).

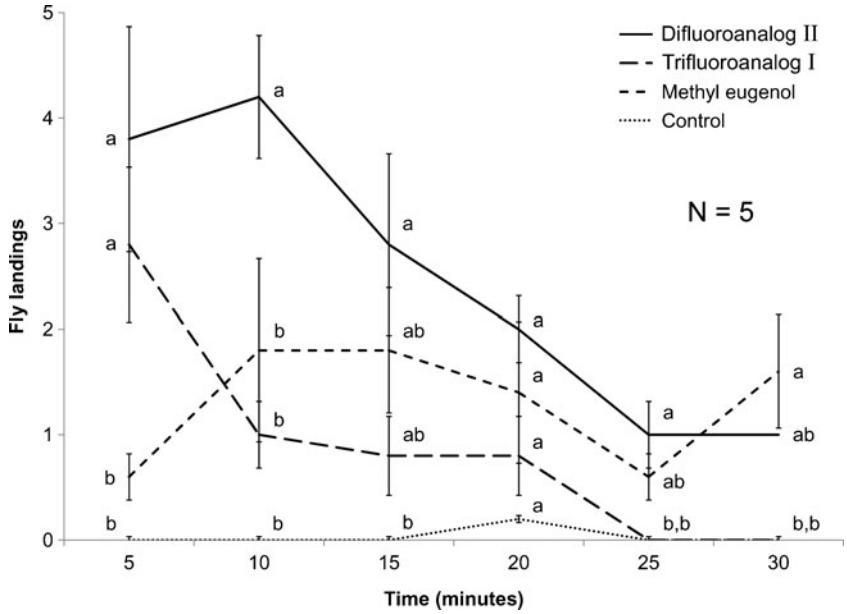

Fig. 3 Mean numbers (± SE) of male *Bactrocera dorsalis* landings every 5 min on papers treated with different chemicals. Different letters represent differences ($P<0.05$) among the mean numbers of fly landings at a given time interval (ANOVA, followed by SNK test)

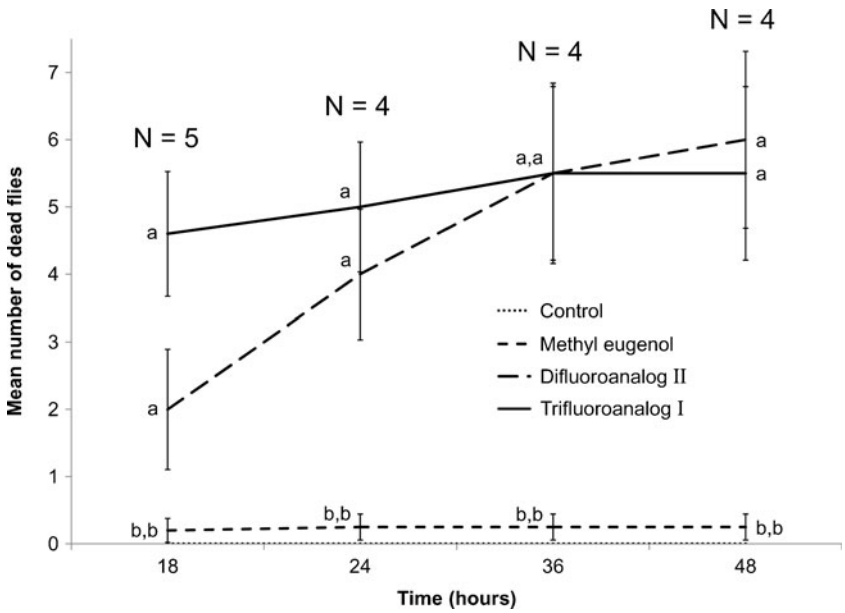

Fig. 4 Mean numbers (± SE) of dead male *Bactrocera dorsalis* at various times after exposure to different chemicals. Different letters represent differences ($P<0.05$) among mean numbers of dead flies at a given time interval (ANOVA, followed by SNK test)

Discussion

Our laboratory studies demonstrated that the di- and trifluorinated analogs **I** and **II** are perceived by *B. dorsalis* males and evoke responses similar to that of the natural phenylpropanoid methyl eugenol. In close-range experiments, flies were attracted to trifluoroanalog **I**, difluoroanalog **II**, and ME in similar numbers, but flies absorbed more ME. Flies did not need to contact the filter papers directly to absorb appreciable amounts of vaporized trifluoroanalog **I**, difluoroanalog **II**, or ME. This is shown by the high concentration of ME found in flies, despite only a moderate number of landings. This is consistent with previous observations of phenylpropanoid intake in *B. dorsalis* (Khrimian et al., 2006, 2009).

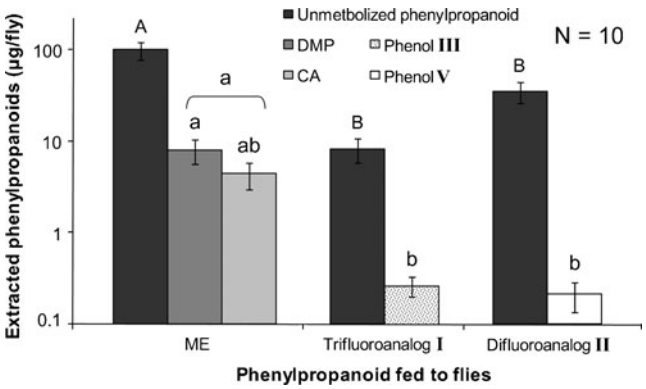

Fig. 5 Mean amounts (± SE) of unmetabolized phenylpropanoids and metabolites in *Bactrocera dorsalis*, 18 h after exposure to various phenylpropanoids. Metabolites **III** and **V** were in rectal glands, while unmetabolized methyl eugenol (ME), difluoroanalog **II** and trifluoroanalog **I** were from other body parts. Different capital letters represent differences ($P<0.05$) among amounts of unmetabolized phenylpropanoids, while different lowercase letters represent differences among amounts of phenylpropanoid metabolites (ANOVA, followed by SNK test). ME metabolites, (*E*)-coniferyl alcohol (CA) and 2-(2-propenyl)-4,5-dimethoxyphenol (DMP), were grouped to allow comparison of total metabolites produced from each phenylpropanoid (shown above bracket)

Introduction of fluorine atoms on both the ring and side-chain of ME blocks both positions that undergo enzymatic hydroxylation, all but completely inhibiting these phenylpropanoid biotransformation pathways. While this was not particularly surprising for trifluoroanalog **I**, it is interesting that difluoroanalog **II** did not undergo hydroxylation on the side-chain as does FME (Khrimian et al., 2006), which shares a mono-fluorinated side-chain moiety with **II**. The terminal double bond of **I** appears to be more resistant to enzymatic hydroxylation than either **I** or FME, but there is little structural difference between these two ME analogs. It seems likely that ring fluorination, via inductive and/or resonance effects, completely inhibits side-chain hydroxylation in **II**. Although enzymatic hydroxylation was blocked in **I** and **II**, two new metabolites were produced through demethylation of the methoxy group positioned para to the side-chain. This *O*-demethylation is part of the metabolic pathway leading to the formation of coniferyl alcohol from ME or FME (Khrimian et al., 2006). However, in the formation of phenols **III** and **V**, this *O*-demethylation appears to operate independently of oxidative biotransformations. Additionally, it is interesting to note that almost equal amounts of trifluoroanalog **I** and difluoroanalog **II** were metabolized (Fig. 5), in spite of differences in intake, suggesting that there is a finite limit to the amount of di-/trifluorinated phenylpropanoid that can be metabolized. The amounts of trifluoroanalog **I** and difluoroanalog **II** metab-

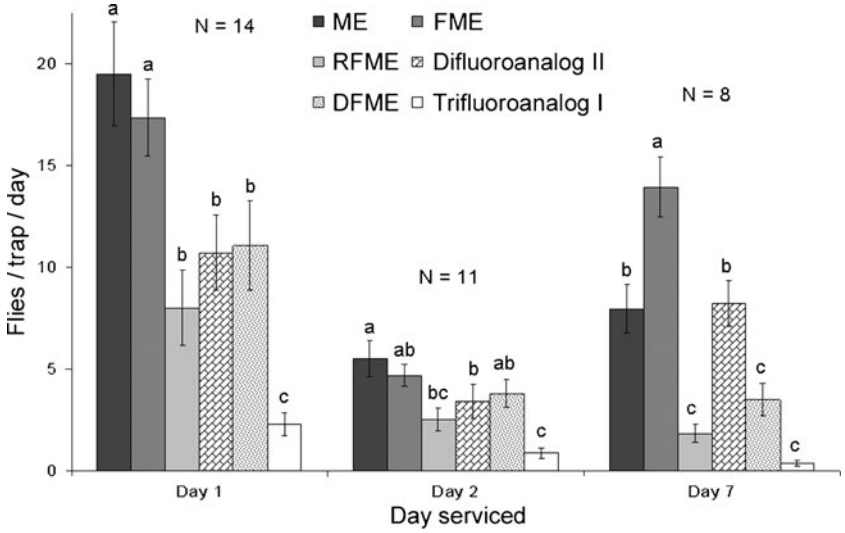

Fig. 6 Mean numbers (± SE) of male *Bactrocera dorsalis* caught per trap in a macadamia orchard near Hilo, Hawaii. Different letters represent significant differences ($P<0.05$) among treatments at a given time interval (ANOVA, followed by SNK test). Differences in the replicate number reflect the removal of treated lure wicks for analysis. ME=methyl eugenol; RFME=1-fluoro-4,5-dimethoxy-2-(prop-2-en-1-yl) benzene; DFME=4-(3,3-difluoroprop-2-en-1-yl)-1,2-dimethoxybenzene; FME=4-[(2*E*)-3-fluoroprop-2-en-1-yl]-1,2-dimethoxybenzene

olized were less than those of FME and RFME (Khrimian et al., 2006, 2009). However, the amount of fluorinated ME consumed by *B. dorsalis* males varied for each analog, with **I** and **II** being the least taken in.

Intake (consumption or vapor absorption) of both trifluoroanalog **I** and difluoroanalog **II** resulted in increased mortality in *B. dorsalis* males compared to flies fed with ME or water (control). ME has been reported to cause death in the Oriental fruit fly when ingested in large amounts (Steiner, 1952). Thus, the fitness of *B. dorsalis* males is evidently linked (among other factors) to their ability to metabolize phenylpropanoids efficiently, as consumption appears to be compulsive. The significant inhibition of fluorinated phenylpropanoid metabolites in *B. dorsalis* appears to be caused by complete blocking of the key metabolic hydroxylation sites in trifluoroanalog **I** and difluoroanalog **II**. Hydroxylation often is the first step (Phase I) in the detoxification pathways used by insects (Dauterman and Hodgson, 1978). Given the reported toxicity of ME to *B. dorsalis*, when consumed in large quantities, (Steiner, 1952), it is possible that trifluoroanalog **I** and difluoroanalog **II** interrupt 'normal' phenylpropanoid metabolism and thereby cause increased mortality. However, blocking metabolism, with a resultant buildup of unmetabolized phenylpropanoid, does not in itself explain the higher mortality from **I** and **II** compared to ME. ME-exposed flies had much higher overall levels of phenylpropanoids in their bodies when analyzed, suggesting that **I** and **II** may also be more inherently toxic to *B. dorsalis*.

Attract-and-kill techniques have been used to control a number of pest insects, including fruit flies (El-Sayed et al., 2009). In this technique, pests are attracted to a point source by a semiochemical lure and die after being exposed to a killing agent. In most cases, the semiochemical lure and killing agent are different compounds. The toxicity of trifluoroanalog **I** and difluoroanalog **II** suggests an alternative, in which a single compound may function as both attractant and killing agent. Many specialist insect herbivores use plant secondary compounds as attractants and feeding stimulants (Metcalf and Metcalf, 1992; Harborne, 1993). These compounds often are toxic to generalist insect herbivores, while the specialists have circumvented toxic effects through either behavioral or biochemical mechanisms. In the case of ME, *B. dorsalis* appears to be physiologically tolerant of this phenylpropanoid, with mortality occurring only after large amounts have been ingested (Steiner, 1952). The molecular modifications of trifluoroanalog **I** and difluoroanalog **II** cause increased mortality of *B. dorsalis*, while retaining some attractant and phagostimulatory activity toward *B. dorsalis*. However, the moderate level of *B. dorsalis* mortality caused by trifluoroanalog **I** and difluoroanalog **II** in this study is unlikely to be useful for control (especially compared to the current methods of inclusion of a toxicant with ME). This concept, of modifying attractive/phagostimulatory semiochemicals to be toxic to insects based on specific knowledge of attractant/consumption metabolism, may, however, be applicable to other pests.

Although *B. dorsalis* males were attracted strongly to, and fed on, trifluoroanalog **I** and difluoroanalog **II** in a field cage experiment, the captures of male oriental fruit flies to traps baited with either of these compounds was markedly

lower than to traps baited with ME. Traps baited with trifluoroanalog **I** captured roughly 10% of the number of flies caught in traps baited with ME at similar release rates. Traps baited with difluoroanalog **II** captured roughly half the number of flies caught in traps baited with ME on day 1, but by day 7 catches were roughly equal (overall **II** captured two thirds that of ME captures). The release rate of difluoroanalog **II** is significantly less than that of ME, suggesting at similar release rates that their catches could be similar. We did not determine the release rate of DFME, but traps baited with this compound captured roughly half the number of flies caught in traps baited with ME.

Metcalf et al. (1975; 1981) studied the molecular parameters of attractants and olfaction in *B. dorsalis* that involved a number of substituted orthodimethoxybenzenes. Two chemical structure postulates were derived from those studies: (1) unshared electron pairs of the orthodimethoxy groups were essential for receptor depolarization, yet the methoxy group in the para position to the allyl group of ME is of primary importance; (2) electron-donating side-chain groups produced stronger attractants than those withdrawing electrons. We did not find in the literature any activity correlations with the substitution pattern of trifluoroanalog **I** and difluoroanalog **II**, but because the fluorine atom is isosteric with hydrogen (and being such has been widely pursued for altering the properties of biologically active substances), it seems that it is the electronic factor of fluorine substitution that is responsible for the reduced attractiveness of trifluoroanalog **I** and difluoroanalog **II** compared to ME. A strong electronegative effect of the fluorine atom should decrease electron density about the CH_3O groups in **I** and **II** but would primarily affect the methoxy group in the para-position to F (meta to allyl group), thus diminishing, but not abolishing, the attraction to *B. dorsalis*. In any case, a moderate (**II**) or poor (**I**) ability to attract flies in the field, and likely higher costs of syntheses, make trifluoroanalog **I** and difluoroanalog **II** unlikely replacements for ME as attractants for the Oriental fruit fly. Our field tests, however, showed good catches in traps baited with FME, confirming our earlier findings (Khrimian et al., 1994, 2006, 2009; Liquido et al., 1998) that this compound is equally attractive to *B. dorsalis* and also a longer-lived lure.

In summary, we developed tri- and difluorinated analogs of methyl eugenol that were attractive to *B. dorsalis* males in a laboratory cage experiment, but which were only moderately (**II**) or poorly (**I**) attractive in field trials. These new fluorine analogs are metabolized more slowly than ME after being consumed by *B. dorsalis* males. As a result of blocking the key enzymatic hydroxylation sites, both compounds undergo enzymatic demethylation of the methoxy group positioned para to the side-chain.

Abstract The tomato leafminer *Tuta absoluta* (Lepidoptera: Gelechiidae) is a devastating pest of cultivated tomato *Solanum lycopersicum* throughout South and Central America and Europe. We aimed to characterize the behavioral mechanisms and the chemical cues involved in host selection of *T. absoluta* females by chemical analysis of tomato leaf volatiles, wind tunnel attraction assays, and oviposition bioassays. Tomato leaf odor elicited in mated females upwind orientation flight followed by landing as well as egg-laying, demonstrating the essential role of plant volatiles in *T. absoluta* host-finding behavior. In wind tunnel and oviposition choice experiments, *T. absoluta* females significantly preferred tomato *S. lycopersicum* over wild tomato *Solanum habrochaites*, which is resistant to larval feeding. This indicates that leaf volatiles provide information on the suitability of plants as larval hosts. Mated females also discriminated three cultivars of *S. lycopersicum* according to their volatile profiles. Headspace collections from leaves of these three cultivars contained large amounts of β-phellandrene, followed by limonene, 2-carene, and (*E*)-β-caryophyllene, which together accounted for more than 70% of tomato foliage headspace. Most leaf volatiles were released by all three cultivars, but they showed significant differences with respect to the presence of a few minor compounds and blend proportion. This is an initial study of the volatile signatures that mediate attraction and oviposition of tomato leafminer *T. absoluta* in response to its main host, tomato.

Key Words *Tuta absoluta* · Host plant volatiles · Kairomone · Headspace collection · Chemical analysis · *Solanum lycopersicum* · Lepidoptera · Gelechiidae

Introduction

Plants release a variety of volatile organic compounds that play multiple roles in interactions with other plants and animals (Dudareva *et al.*, 2004; Knudsen *et al.*, 2006; Pichersky *et al.*, 2006). Insect herbivores exploit these volatiles to locate their host plants at a distance, for feeding, mating, and egg-laying (Linn *et al.*, 2003; Bengtsson *et al.*, 2006; Tasin *et al.*, 2006; Pinero and Dorn, 2009; Cha *et al.*, 2008; Schmidt-Busser *et al.*, 2009; Sole *et al.*, 2010). In addition to olfaction, vision and contact chemoreception (taste) could play a role at a short distance (Renwick and Chew, 1994; Calatayud *et al.*, 2008; Pontes *et al.*, 2010). Knowledge of the chemicals and mechanisms that mediate host plant location by insect herbivores is essential for our understanding of plant—insect relationships, and also will lead to the development of novel tools for insect management (Szendrei and Rodriguez-Saona, 2010; Witzgall *et al.*, 2010).

Plant volatiles are products of diverse metabolic pathways, but many are derived from the isoprenoid or terpenoid pathways (Sacchettini and Poulter, 1997; Degenhardt *et al.*,

2009). Solanaceous plants, like tomato, produce a suite of terpenes that likely serve as defense agents against herbivores (Kennedy, 2003; Bleeker *et al*., 2009; Kang *et al*., 2010). The constitutive headspace of undamaged plants varies with genotype, phenological stage, and environmental conditions. It is conceivable that insects use the volatile signals that correlate with this variation to distinguish the most suitable hosts (Bengtsson *et al*., 2001; Vallat and Dorn, 2005; Karlsson *et al*., 2009).

The tomato leafminer *Tuta absoluta* (Meyrick) (Lepidoptera, Gelechiidae) feeds on several solanaceous species, and preferentially on tomato *Solanum lycopersicum* (Siqueira *et al*., 2000). It is a serious threat to commercial tomato production in South and Central America. Since its introduction, it has become an economically important insect in Europe (Torres *et al*., 2001; Desneux *et al*., 2010). It is anticipated that *T. absoluta* will even spread from Central America into Mexico and the USA. Control of *T. absoluta* relies on multiple insecticide sprays, but resistance to these chemicals is growing (Siqueira *et al*. 2000; Lietti *et al*., 2005). Synthetic sex pheromones are used to monitor population levels, but also for control by mass trapping of males in greenhouses (Salas, 2004; Witzgall *et al*., 2010).

Tomato plants are infested at any developmental stage, with females ovipositing preferentially on leaves. After hatching, larvae feed on leaf parenchyma tissue, on tender portions of the stems (especially axillary buds), and in developing and mature fruit, causing bud drop, fruit malformation, fruit rot, and a drastic reduction in leaf area (Torres *et al*., 2001). No tomato cultivars are entirely resistant to *T. absoluta*, but not all cultivars are equally susceptible (Bogorni *et al*., 2003; Oliveira *et al*., 2009). In addition, the wild tomato species *S. habrochaites* (syn. *Lycopersicon hirsutum*) is more resistant to *T. absoluta* and several other tomato herbivores than *S. lycopersicum* (Leite *et al*., 2001; Kennedy, 2003).

The aim of this study was to determine the role of tomato volatiles in host finding and oviposition behavior of tomato leafminer *T. absoluta*. We identified the volatiles released from leaves of three different cultivars of tomato *S. lycopersicum* and investigated the question whether tomato leafminer uses these volatiles for the discrimination of suitable larval hosts.

Methods and Materials

Insect Rearing A laboratory colony of tomato leafminer *T. absoluta* originated from pupae and larvae collected in a commercial tomato plantation located in Viçosa, Minas Gerais (Brazil). The colony was maintained at 24±1°C, 70±10% r.h., and a 12:12 hL:D photoperiod. Adults were fed with sugar water and provided with tomato (cv. Aromata) leaves for egg-laying. Leaf stems were cut and placed through a hole in the transparent plastic lid of a 500-ml recipient containing water and a nutrient solution. Larvae were provided with fresh leaves every 2nd d, and rolls of corrugated paper were added for pupation. Pupae were sexed and placed in plastic cages for eclosion (100×40×40 cm).

Plant Material For behavioral experiments and volatile analysis, three tomato *Solanum lycopersicum* Mill. (Solanaceae) cultivars were used: cv. Santa Clara and cv. Carmen, which are known to be highly susceptible, and cv. Aromata, which is less susceptible (Svalöf-Weibull Trädgård AB, Hammenhög, Sweden) (Bogorni *et al*., 2003; Oliveira *et al*., 2009; Lima *et al*. unpublished data). In addition, the wild tomato species *S. habrochaites*, which is resistant to *T. absoluta*, was used for wind tunnel and oviposition bioassays. Tomato seeds were pre-cultivated in rock wool cubes in the greenhouse for 4 week (r.h.: 75%, light intensity: 200 $\mu molm^{-2}$ $s\text{-}^{1}$). Plants were transplanted to a hydroponic system and fertilized daily with a nutrient solution. Standard values (in mM) for the composition of the nutrient solution were: 6.0 $Ca(NO_3)_2$, 8.0 KNO_3, 5.0 $MgSO_4$, 1.0 NH_4NO_3, 2.3 KH_2PO_4 and for micronutrients: 0.4 Fe–EDTA, 0.01 $MnSO_4$, 0.025 H_3BO_3, 0.005 $ZnSO_4$, 0.00075 CuC_{l2},2 H_2O, 0.0005 Na_2MoO_4,and pH 5.8±0.1.

Flight Behavior Bioassay Female attraction to plants was tested in a wind tunnel (flight section 63×63×200 cm; Tasin *et al*., 2006). Filtered air (24 cylinders with active charcoal, 14.5×32.5 cm, Camfil, Trosa, Sweden) was blown into the tunnel by a centrifugal fan (Fischbach GmbH, Neunkirchen, Germany) at 25 cm/s. Outcoming air was aspirated by another fan and cleaned by two additional sets of charcoal filters. The flight section was lit diffusely from the side at 10 lux, and the room was kept at 23±2°C and 40–60% r. h. Cut tomato plants (ca. 35 cm high) were placed into vials with water in the center of the upwind end of the flight tunnel. Two h before the end of the photophase, females were placed individually into cylindrical plastic containers. They were kept until testing in the wind tunnel room. Moth behavior was scored for upwind oriented flight in the center of the wind tunnel (over at least 60 cm from the downwind end) and for approaching tomato plants. By using this method, we tested (1) the attraction of 2-d-old mated (N=190) and virgin (N=150) females to *S. lycopersicum* cv. Aromata, and (2) the attraction of mated female (N=150) to *S. lycopersicum* cv. Santa Clara and *S. habrochaites*.

Oviposition Bioassays Experiments were done with 2-d-old mated females during 24 hr. Females were individually kept in a glass tube (15.0×3.0 cm) covered on both sides with a

plastic film. To keep the females in one side of the tube, it was divided in half with a nylon grid. The female and the tomato leaf were put on the same (N=48) or different sides of the tube (N=48). This experiment was done with the three tomato *S. lycopersicum* cultivars. After 24 h, the eggs laid on the glass wall and the nylon grid were counted.

In choice tests, mated females were kept in a plastic container (12×10 cm) either with one leaf of cv. Aromata, cv. Carmen and cv. Santa Clara (N=81 females), or with one leaf of Santa Clara and wild tomato *S. habrochaites* (N=37 females), and the leaves were scored for eggs after 24 h.

Plant Volatile Analysis Freshly cut plants of the three cultivars of *S. lycopersicum* were confined separately in a 2-L glass jar that was closed with a ground-glass fitting. The cut end of the branch was held in a 10-ml vial of water. A charcoal-filtered airstream was pulled over the plant material from the bottom to the top of the jar, and over a 35-mg Super Q trap (80/100 mesh; Alltech, Deerfield, IL, USA) which was held between plugs of glass-wool in a 4×40 mm glass tube. Before use, traps were rinsed sequentially with 3 ml methanol, ether, and redistilled hexane, after 15 min treatments in ultrasonic baths in ether and hexane, respectively. The air flow was 150 ml/min, exchanging the headspace in the jar 4.5 times/h. Collections were done for 24 h, at 20–22°C and 10–30 lux. The charcoal filter for incoming air and the Super Q trap for outcoming air were connected with glass fittings to the jar. All glassware was heated to 350°C for 10 h before use. After volatile collections, traps were extracted immediately with 0.5 ml hexane (redistilled; LabScan, Malmö, Sweden). Sample volumes were reduced to 50–60 µl, at ambient temperature in Francke-vials with an elongated tip (5 cm× 2 mm i.d.). Samples were stored in sealed glass capillary tubes at −18°C (Bengtsson *et al*., 2001).

Odor samples were analyzed on a gas-chromatograph coupled with a mass-spectrometer (GC-MS). Volatile compounds in trap eluents were injected in aliquots of 2 µl into a Hewlett- Packard 5970 B MS instrument, with electron impact ionization at 70 eV, and interfaced to an HP 5890 GC (Hewlett- Packard, Palo Alto, CA, USA). The GC was equipped with a fused silica capillary column (30 m×0.25 mm) coated with DB-wax (df=0.25 µm; J&W Scientific, Folsom, CA, USA) using helium as carrier gas (35 cm/s). The temperature program was from 35°C (hold 5 min) at 8°C/min to 230°C (hold 5 min). The Kovats retention index (KI) of each compound was calculated. Tentative identification of compounds was based on comparison of matching of mass spectra with the NIST 98 MS and Wiley databases and a reference library built by measuring commercially available standards, and comparison of KIs on similar columns. Identification of some components was confirmed by comparison with mass spectra and GC retention data with those of standards.

Statistical Analysis All statistical analysis was done using R (version 2.8.0; R Development Core Team, www.R-project.org) following the method of Crawley (2005).

The effect of either mating status or test plant (*S. lycopersicum* and *S. habrochaites)*, on the proportion of females, grouped per day, that were attracted to and that landed on the plant was tested with a Generalized Linear Modelling (GLM) under quasibinomial distribution.

Similarly, the effect of contact with the host plant and the effect of the tomato cultivar (Carmen, Santa Clara, Aromata) on the total number of eggs laid in the non-choice bioassays were tested using a GLM under quasipoisson distribution. In the choice experiments, the effect of *S. lycopersicum* cultivars or tomato species on the proportion of eggs laid on leaves was tested using a GLM with quasibinomial distribution. In all analyses, a full model was fitted, from which terms were deleted in a stepwise fashion to obtain the minimal adequate model (MAM). Significance (P<0.05) was assessed by testing the change in deviance after the removal of a term from the model. Differences among treatment levels were examined by contrast analysis. Candidate similarity levels were amalgamated to compose a new model, which was then compared with the previous un-amalgamated model. The new, simplified model was accepted if it did not differ from the previous, more complex model. Amalgamation proceeded until all treatment levels were checked. Models were checked by residual analyses, and eventually corrected for overdispersion as well as for the correctness of the assumed distribution (Crawley, 2005).

Headspace composition was compared among samples by multivariate analyses using R with Vegan and labdsv packages (Oksanen *et al*., 2008; Roberts, 2010). Non-metric multidi-

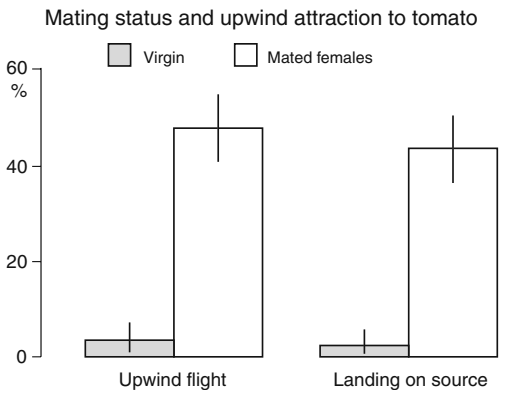

Fig. 1 Proportion of mated and virgin females of tomato leafminer *Tuta absoluta* flying upwind and landing on tomato leaves (*Solanum lycopersicum* cv. Aromata) in the wind tunnel (mean±SE/day). For both behavioral responses, differences between mated (N=190) and virgin females (N=150) are significant (N=17 days, GLM, P<0.05)

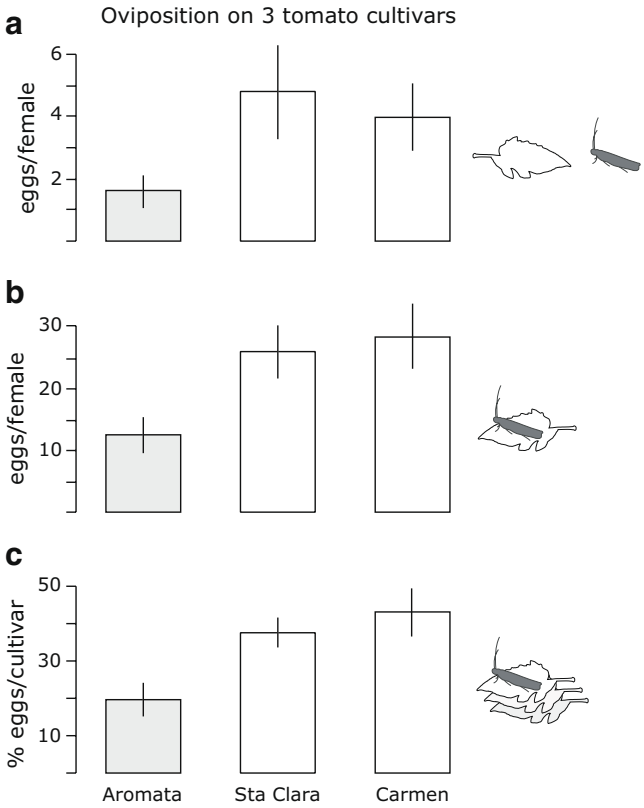

Fig. 2 Oviposition rate (mean±SE) of mated tomato leafminer *Tuta absoluta* females on three tomato cultivars Aromata, Santa Clara, and Carmen, in (**a**) a non-choice experiment without leaf contact (N=48), (**b**) a non-choice experiment with leaf contact (N=48), and (**c**) a choice experiment with leaf contact (N=81). For each experiment, treatments represented by filled and empty bars are significantly different (GLM with contrast, P<0.05)

mensional scaling (NMDS) was used to detect similarities among samples (using amounts relative to total peak area). Data were square-root transformed and standardized before calculating Bray–Curtis similarities (Bray and Curtis, 1957). In oviposition bioassays, *T. absoluta* prefers cv. Santa Clara and cv. Carmen over cv. Aromata with no difference between Santa Clara and Carmen. Thus, based on *T. absoluta* oviposition preference, variation in odor composition among tomato cultivars and between cv. Aromata *vs.* cvs. Santa Clara and Carmen (pooled), was tested for significance using permutational multivariate analysis of variance (permanova) with the Bray–Curtis dissimilarity measurement and 10000 permutations (McArdle and Anderson, 2001).

Differences in the occurrence and abundance of compounds in the headspace of the cv. Aromata *vs.* the cvs. Santa Clara/Carmen were determined according to the method of Dufrêne and Legendre (1997) by calculating 'indicator compound' (*e.g.*, Proffit *et al.*, 2009). For each compound, an observed indicator value (*IV*) was calculated. The deviation of the observed *IV* from a random distribution of *IVs* was tested using a Monte Carlo test with 10000 randomizations. Indicator compounds have an observed *IV* significantly different from the random *IV*, and designate the most characteristic compounds in headspace samples of a group, either because of their occurrence in different samples and/or because of their relative abundance.

Results

Wind Tunnel Experiments Mated tomato leafminer *T. absoluta* females flew upwind over 180 cm towards tomato plants (45% of the females tested) and landed (42%) on these plants. In contrast, unmated females showed no attraction response to tomato (N=17; for flight, $F_{1,15}$=192.63, P<0.001; for landing, $F_{1,15}$=122.09, P<0.001; Fig. 1).

Oviposition Experiments with Tomato Cultivars In non-choice tests, the cultivar had a significant effect on oviposition (df=2, χ^2=132.71, P<0.001; Fig. 2a and b). Tomato leafminer females laid more eggs in response to cvs. Santa Clara and Carmen as compared cv. Aromata (df=1, χ^2=110.39, P<0.001 and df=1, χ^2=95.75, P<0.001), both with and without leaf contact: the interaction between leaf contact and cultivar was not significant (df=2, χ^2=3.38, P=0.82).

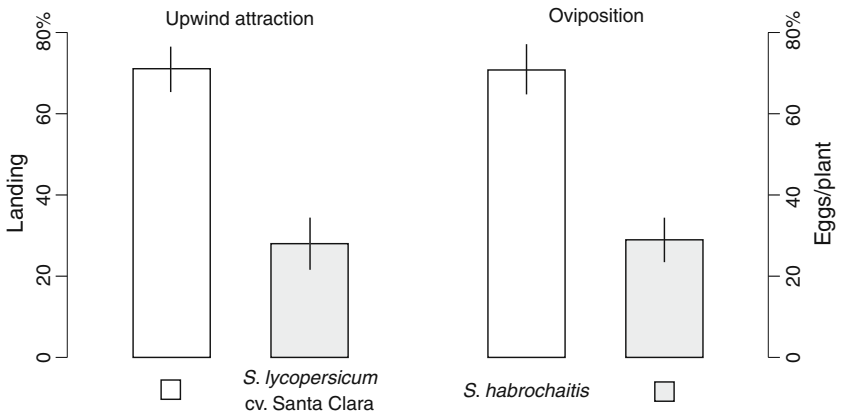

Fig. 3 Upwind attraction (N=22 days, mean±SE/day) and oviposition choice tests (N=37, mean±SE) of mated tomato leafminer *Tuta absoluta* with cultivated *Solanum lycopersicum* cv. Santa Clara and wild tomato *Solanum habrochaites.* The effect of the tomato species was significant in both experiments (GLM, P<0.05)

[a] Identification according to retention times and mass spectra in comparison with authentic standards

[b] Identification according to mass spectra and Kovats retention indices (KIs) in comparison with reference libraries and comparison of KIs on similar columns

[c] Kovats retention index

[d] Number of headspace samples in which the compound was present

[e] Indicator compounds are volatiles with a significant observed indicator value (*IV*), which is a measure for the occurrence of volatiles in different samples and/or their relative abundance (*IV*max=1). The deviation of the observed *IV* from a random *IV* was tested using a Monte Carlo test with 10000 randomizations. Bold-faced compounds are characteristic for the respective group, either for Aromata or for Santa Clara/Carmen, according to the *IV*

A choice test (Fig. 2c) confirmed the effect of the cultivar on oviposition ($F_{1,78}$ 32.08, P<0.001). Here again, the females preferred Santa Clara and Carmen over Aromata ($F_{1,78}$=22.96, P<0.001 and $F_{1,78}$=36.11, P<0.001, respectively). In both non-choice and choice tests, there was no difference in the preference between Santa Clara and Carmen (df=1, χ^2=0.56, P=0.79, and $F_{1,78}$=1.53, P=0.22, respectively). Females laid significantly more eggs when in contact with tomato leaves of *S. lycopersicum* cv. Aromata, Carmen and Santa Clara, compared to when they were exposed only to leaf headspace (df=1, χ^2=766.55, P<0.001; Fig. 2).

Comparison Between Cultivated and Wild Tomato Both in the wind tunnel as well as in oviposition bioassays, *T. absoluta* preferred cultivated tomato *S. lycopersicum* over wild tomato *S. habrochaites* ($F_{1,20}$=109.30, P<0.001; $F_{1,72}$=46.42, P<0.001, respectively). The proportion of insects preferring *S. lycopersicum* was similar in both experiments (Fig. 3).

Chemical Analysis of Tomato Headspace We found 52 volatile compounds in the headspace collection of cv. Aromata, Santa Clara, and Carmen (Table 1). Terpenoid compounds largely dominated the tomato leaf headspace. Beta-phellandrene was the most abundant compound by far and represented more than half of the total volatile emission. In addition, limonene, 2-carene, as well as (*E*)-β-caryophyllene were major compounds in tomato headspace of the three cultivars.

Although most volatiles were released by all three cultivars (Table 1), leaf headspace composition differed among them (Permanova $F_{2,19}$=5.95, P<0.001; Fig. 4), headspace differed between Aromata and Santa Clara/Carmen (Permanova

$F_{1,20}$=2.23, P=0.001). According to a Monte Carlo test, 26 of the 52 compounds were good indicators of the leaf headspace of either Aromata or Santa Clara/Carmen (Table 1), most of which are minor terpenoid compounds, with a mean leaf headspace proportion of<1%. Aromata did not produce extra compounds compared to the two other cultivars.

In contrast, Carmen and Santa Clara released 6 compounds that were absent from the headspace of Aromata: carvacrol, α-copaene, (*Z*)-limonene oxide, an unidentified monoterpene (unknown 4), an unidentified sesquiterpene (unknown 11), and one unindentified compound (unknown 18). In addition, 9 other compounds that were characteristic for Santa Clara/Carmen were present in smaller amounts in Aromata leaf headspace. On the other hand, 10 compounds were characteristic for Aromata and more abundant than in Santa Clara and Carmen headspace (Table 1).

Discussion

Combined headspace analysis and behavioral assays show that tomato leaf volatiles are essential cues for host finding and oviposition in tomato leafminer *T. absoluta* (Figs. 1, 2 and 3). The females detected small variations in volatile signatures of the different tomato cultivars (Table 1, Fig. 4), and the ensueing behavioral response (Figs. 2 and 3) matched the suitability of tomato cultivars and species as larval hosts (Leite *et al*., 1999, 2001; Oliveira *et al*., 2009).

Long Range Attraction Cues Mated *T. absoluta* females responded to tomato leaves by upwind oriented flight, followed by landing (Fig. 1). Host volatiles have been shown to elicit attraction of several other moths (Tasin *et al*., 2006; Arab *et al*., 2007; Masante-Roca *et al*., 2007; Knudsen *et al*., 2008; Pinero and Dorn, 2009; Sole *et al*., 2010).

Only mated females were attracted to tomato leaves (Fig. 1). In most herbivorous insects, host-searching behavior is based not only on the perception of suitable olfactory information, but also on the insect's internal state. Physiological changes such as ovarian maturation, egg production, and mating status can influence the response of insect females to host cues (Thompson and Pellmyr, 1991; Yan *et al*., 1999; Masante-Roca *et al*., 2007). For example, mated grapevine moth *Lobesia botrana* or Egyptian cotton leafworm *Spodoptera littoralis* females are attracted to their larval host plants, not unmated females (Masante-Roca *et al*., 2007; Saveer *et al*. unpublished data).

Oviposition Cues Tomato leaf volatiles alone elicited an oviposition response in *T. absoluta* (Fig. 2a). Moreover, ovipositing females discriminated among different tomato cultivars and between cultivated and wild tomato on the basis of volatile cues (Figs. 2 and 3). However, leaf contact significantly increased the number of eggs laid (Fig. 2a and b), and leaf surface morphology and chemistry is accordingly of importance for oviposition. *Tuta absoluta* females lay eggs uniformly on the under- and upper-side of leaves that are covered with trichomes that provide chemical and mechanical stimuli (Torres *et al*., 2001).

Tomato leafminer females lay their eggs directly on leaves (Torres *et al*., 2001). Accordingly, there is no spatial separation between the oviposition site and plant part that releases the chemical signal that elicits host-finding. In contrast, two closely related species from potato, *Tecia solanivora* and *Phthorimaea operculella*, oviposit in the soil close to the plant, rather than on leaves or stems (Fenemore, 1988; Horgan *et al*., 2007; Karlsson *et al*., 2009).

Variation of Volatile Profile Among Tomato Cultivars The volatile profile of tomato leaves of the cultivars Aromata, Santa Clara, and Carmen was dominated by monoterpenes, in particular β-phellandrene (major compound), limonene, and 2-carene, and the sesquiterpene (*E*)-β-caryophyllene (Table 1), which is in accordance with headspace analysis of other tomato cultivars (Buttery *et al*., 1987; Zhang *et al*., 2008). Nonetheless, overall headspace composition of Aromata differed significantly from Santa Clara and Carmen (Fig. 4), due to differences in blend proportions of minor compounds and due to the absence of several compounds, mostly terpenes, in Aromata (Table 1). Our oviposition

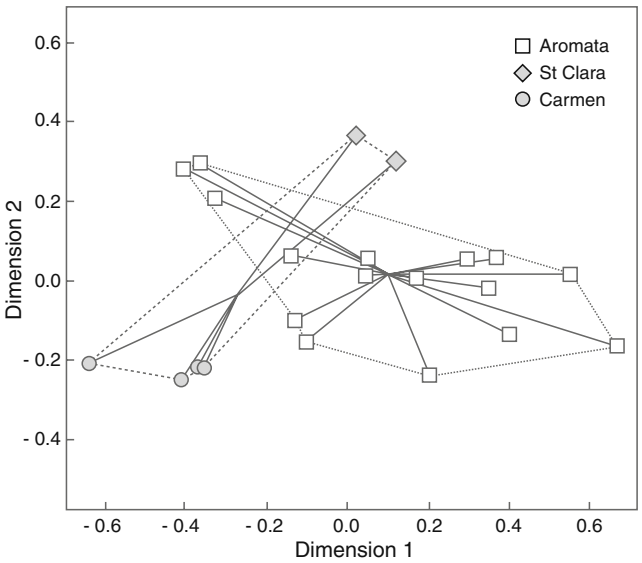

Fig. 4 Non-metric multidimensional scaling (NMDS) plot visualizing the samples of three tomato cultivars, Aromata, Santa Clara, and Carmen based on the similarity (Bray-Curtis distance) of their leaf headspace composition, rotated by principal component, so that the variance of points is maximized on the first dimension (stress=0.15). Samples are grouped (*dashed lines*) according to tomato leafminer *Tuta absoluta* oviposition preference. The centroids of cv. Aromata *vs*. the preferred cvs. Carmen/Santa Clara are the focal points of the *solid lines*

bioassays shows that *T. absoluta* females were able to detect this inter-cultivar variation in leaf headspace, since they laid more eggs in response to headspace from Santa Clara and Carmen than Aromata (Fig. 2).

Tomato Leaf Headspace as an Indicator of Host Suitability Herbivorous moths are attracted to host plant volatiles at specific blend ratios in laboratory assays (Fraser *et al*., 2003; Tasin *et al*., 2006). However, more recent studies in Oriental fruit moth *Cydia molesta* and grapevine moth *Lobesia botrana* show that females are attracted to plant volatile blends that show considerable variation with respect to proportions and composition (Tasin *et al*., 2007, 2010; Najar-Rodriguez *et al*. 2010). A response to a broad spectrum of plant volatile blends could represent an adaptation to differences in volatile signatures from genotypes and to variation during phenological changes and would accordingly facilitate host finding even in specialist herbivores.

This is contrasted by the differential response of tomato leafminer to comparatively small variations in tomato headspace components and proportions (Table 1, Fig. 2). A tentative explanation for discrimination of minor blend variations is that the females are less tolerant and respond strongly to those compounds that are direct cues of host plant suitability. Trichome-borne terpenoids, which account for much of the difference between the cultivars Aromata, Santa Clara, and Carmen (Table 1) have been suggested to influence host plant selection and fitness in tomato insects (Bleeker *et al*., 2009, 2011; Kang *et al*., 2010).

The idea that volatile cues provide information of host suitability at a distance is further substantiated by attraction and egg-laying choice tests with wild tomato *S. habrochaites*, where females clearly preferred cultivated over wild tomato (Fig. 3). Leaf headspace of wild tomato *S. habrochaites* was dominated by β-ocimene, β-myrcene, and undecan-2-one (Smith *et al*., 1996; Bleeker *et al*., 2009). Glandular trichomes of wild tomato also contain many sesquiterpenes, including caryophyllene, curcumene, elemene, humulene, and zingiberene, that play a role in tomato resistance against beet armyworm and whitefly (Eigenbrode *et al*., 1994; Smith *et al*., 1996; van der Hoeven *et al*., 2000; Bleeker *et al*., 2009, 2011). Resistance of wild tomato to tomato leafminer has been attributed to tridecan-2-one, undecan-2-one, and zingiberene, which have not been found in the three cultivars studied here (Leite *et al*., 1999; Azevedo *et al*., 2003).

This initial study of the attraction and oviposition response of tomato leafminer *T. absoluta* in response to its primary host tomato will support the identification of the odor template that encodes host recognition, and the development of new methods to control this important tomato pest worldwide. Tomato volatiles can be used directly for trapping mated females, and the differential behavioral response to tomato cultivars indicates the potential of plant breeding for improved resistance. While a complete description of the bioactive compounds is a considerable undertaking, the wind tunnel bioassay is already available for efficient screening of plant genotypes.

Acknowledgements This study was supported by the Swedish University of Agricultural Sciences (SLU) and by the Swedish Foundation for International Cooperation in Research and Higher Education (STINT) and EL was supported by FAPEMIG.

Abstract *Papilio maackii* females prefer a rutaceous plant, *Phellodendron amurense*, for oviposition, whereas another semi-sympatric Rutaceae feeder, *Papilio protenor*, never exploits this plant as a host in nature. However, the larvae of both species perform well on this plant in the laboratory. Phellamurin, a flavonoid present in the organic fraction from *P. amurense* inhibits egg laying by *P. protenor*. We examined whether phellamurin is involved in the differential acceptance of *P. amurense* by the two butterflies. The ovipositing females of *P. maackii* readily accepted *P. amurense* and a methanolic extract of the foliage, while *P. protenor* rejected them entirely. However, the aqueous fraction derived from the extract elicited significant oviposition responses of similar levels from the two species. Phellamurin did not induce oviposition behavior in *P. protenor* females. In contrast, *P. maackii* was stimulated to oviposit by phellamurin at concentrations exceeding 0.2%. The response was dose-dependent and reached ca. 70% at 2% phellamurin, which is approximately equivalent to its natural abundance in young leaves of *P. amurense*. Since the aqueous fraction was very stimulatory to both species, the combined effect of phellamurin and the aqueous fraction on oviposition was tested. The addition of phellamurin to the aqueous fraction enhanced the ovipositional activity of *P. maackii*, but dramatically suppressed the oviposition response of *P. protenor* even at 0.1% concentration. These results, taken together with those obtained from electrophysiological recordings with foretarsal chemosensilla, indicate that phellamurin acts as an oviposition stimulant for *P. maackii*, and as a potent deterrent for *P. protenor*. The results suggest that host range expansion or host shifts may be made by ovipositing females that overcome phytochemical barriers.

Introduction

Plant secondary metabolites can be exploited by phytophagous insects during host selection. In general, some compounds serve as stimulants/attractants for feeding or oviposition, while others act as deterrents/repellents (e.g., Schoonhoven et al., 2005; Honda et al., 2010). Although the host range or host-preference hierarchy of an insect is regionally variable, the majority of herbivorous insects use only a limited range of plant species, mostly of a single or few families, or only one plant species at the extreme. Such host specificity may be due to a species-specific capacity for metabolizing allelochemicals (Berenbaum, 1991; Feeny, 1991) and/or limitations on processing information in the central nervous system (Bernays, 2001). Extensive work on chemical mediators in oviposition by lepidopterans has demonstrated clearly that chemical attributes of plants serve as the crucial cues that permit females to discriminate and recognize their hosts (Renwick and Chew, 1994; Honda, 1995, 2005; Honda et al., 2010).

In butterflies, assessment of potential hosts is achieved mainly by drumming on the surface of foliage with foretarsi endowed with chemotactile sensilla that can perceive plant chemicals (Inoue, 2006). Acceptance or rejection of a given plant by ovipositing females is governed not only by the presence or absence of stimulatory substances, but also by other co-occurring constituents that exert inhibitory activities, hence, by a reciprocal balance of positive and negative sensory inputs received upon contact with the plant (Renwick and Chew, 1994; Honda, 1995).

While host-plant affiliations for papilionid butterflies include many plant families, 80% of butterflies in the genus *Papilio* feed on rutaceous plants. A wide array of phytochemical stimulants and deterrents responsible for oviposition has been reported for *Papilio* butterflies that feed on Rutaceae, Apiaceae, or Lauraceae (Honda, 1995; Honda et al., 2010). Major compounds identified include amino acid derivatives, sugar-related acids, alkaloids, flavonoids, and hydroxycinnamic acid derivatives. Among the stimulants for *Papilio* butterflies, some are common stimulants for other species, and others are structurally related to one another, thereby strongly suggesting the involvement of phytochemicals in host specialization on one hand, and expansion of host range on the other (Feeny, 1991). Many investigations have been conducted on assumed host shifts of papilionids, presumably originating from Aristolochiaceae, via Lauraceae, Magnoliaceae, Annonaceae, and Rutaceae, eventually leading to Apiaceae and Asteraceae (e.g., Aubert et al., 1999; Scriber et al., 2007, 2008).

In this study, we focused attention on two Rutaceae specialists, *Papilio maackii* and *P. protenor*, that have quite different host ranges in order to clarify the phytochemical and electrophysiological bases for the differential acceptance of *Phellodendron amurense* by ovipositing females. The two butterfly species range from temperate to boreal regions of Japan, with broad overlapping habitats on the main island (Honshu). *Papilio maackii* is rather montane, and prefers cool climates, while *P. protenor* is common in warm districts but relatively rare in montane or northern districts. Therefore, their occurrence is somewhat allopatric in most temperate regions. *Papilio maackii* utilizes *P. amurense* as a primary host plant in almost all habitats but *P. prontenor* females completely reject this species although the larvae perform well on this plant in the laboratory (Honda and Hayashi, 1995a). By contrast, *Papilio protenor* exclusively utilizes *Citrus* plants throughout its habitats.

Phellamurin [3,5,7,4′-tetrahydroxy-8-(3-methylbut-2-enyl)flavanone-7-*O*-ß-glucoside], which is present in *P. amurense*, strongly deters oviposition in a Kanagawa population of *P. protenor demetrius* (Honda and Hayashi, 1995b). Although many studies have investigated oviposition stimulants for *Papilio* butterflies, less attention has been paid to ecologically significant oviposition deterrents. It is important to understand how inhibitory phytochemicals may have played a role in establishing present-day host use and host-range evolution. The aim of this study was to examine how *P. maackii* females respond to phellamurin in their ovipositional behavior, and how the compound stimulates the foretarsal chemosensory receptors in both *P. maackii* and *P. protenor*. We also evaluated the oviposition response to *P. amurense* and phellamurin in a population of *P. protenor demetrius* from Hiroshima for comparison to previous work on a population from Kanagawa.

Methods and Materials

Insects Larvae of *Papilio maackii* and *P. protenor demetrius* were reared at 25°C under a photoregime of 16:8 hL:D on potted plants of *Phellodendron amurense* and *Citrus* spp., respectively. These were laboratory stock cultures that originated from females collected in Hiroshima Prefecture. Adults of both species used for the behavioral bioassays were 3- to 10-d-old gravid females, which had been hand-paired or allowed to copulate in an outdoor cage (7×10 m, 3.5 m high). Females were hand-fed with 15% aqueous sucrose solution once daily throughout the experiments.

Extraction and Fractionation of Plant Materials Young leaves of *P. amurense* (600 g) were extracted with methanol (4 l) at room temperature for 1 mo. The methanolic extract was concentrated *in vacuo* below 50°C, and an aliquot of the whole concentrate, after being dispersed in water, was successively partitioned with chloroform and isobutanol to give 3 fractions (1 aqueous and 2 organic). The chloroform-soluble fraction (Fr. 1) and isobutanol-soluble fraction (Fr. 2) were evaporated to dryness below 50°C, and each residue was re-dissolved in chloroform and in methanol, respectively. The water-soluble fraction (Fr. 3) was lyophilized and dissolved in 50% aqueous methanol. All fractions were stored below 0°C until use. Phellamurin was isolated from Fr. 2 (Honda and Hayashi, 1995b).

Bioassay for Oviposition Response Behavioral bioassays were conducted by a method similar to that reported previously (Honda, 1990), employing a green heart-shaped plastic plate (2–5 cm^2) as a leaf surrogate. Before testing, females were screened daily to assess their responsiveness, and only those that exhibited positive responses to the foliage of *P. amurense* (for *P. maackii*) or *Citrus natsudaidai* (for *P. protenor*) and negative responses to water alone (control) were chosen. In each trial (sample presentation), the response of an individual was scored as 100% for actual egg laying or an equivalent behavior

(trying to bring the ovipositor in contact with the underside of the leaf without egg deposition), 50% for half-curling the abdomen with continuous drumming (this behavior took place infrequently), and 0% for drumming only, with no attempt to oviposit (Nakayama et al., 2002). Trials were replicated at least three times for each individual, and the responses of an individual to a given sample were averaged. For all trials, merely alighting on ovipositional substrates without drumming was not counted. Oviposition response to each sample was eventually represented as the mean percentage of responses recorded from at least 10 females.

Concentrations of test solutions are all expressed as % w/v. The amount of dry test materials on the artificial leaf was estimated. For example, if a 0.5% solution of test sample was applied to the leaf, the amount of material was estimated at 50 μg/cm^2. Test samples prepared from the initial extract, the three partitioned fractions (Frs. 1 to 3), and phellamurin were tested at several concentrations for their stimulatory activity in ovipositioning. For test samples of a binary mixture, Fr.3 (0.5%) was used as a base component, since it exhibited potent oviposition-stimulatory activity (more than 90% response) for both species.

Electrophysiological Recordings The 5th tarsomere of the female foretarsi of both species possesses bristles with a large number of long (major) and short sensilla trichodea (Ryan, 2002) that are situated between 2 lateral and a midline row of spines. The foretarsi also bear a small number of similar lateral sensilla. The responses of the foretarsal chemosensilla to phellamurin, Fr. 3, and their mixtures were examined electrophysiologically. To record responses from the sensilla, tip recording was performed using an ER-1 extracellular amplifier (Cygnus Technology, Inc., USA) and a PowerLab 4/25 converter (ADInstruments Pty Ltd., Australia). Data sampling was conducted at the rate of 10 k/s (low pass filter: 3 kHz; high pass filter: 100 Hz; and sampling gain: 100). Forelegs were amputated at the base of the tibia and fixed on the stage with double-faced adhesive tape. A sharpened tungsten needle (indifferent electrode) was inserted into the first tarsomere. Under a binocular microscope, a glass capillary tube (recording electrode) filled with a test solution was brought into contact with the tip of a medial long trichoid sensillum of the 5th tarsomere. Successive stimulations of a sensillum were of 1 s duration and were separated by an interval of at least 3 min. One to 5 sensilla of the same type were randomly selected from the same preparation. A total of 18 sensilla from 6 females of *P. maackii* and 19 sensilla from 7 females of *P. protenor* were subjected to the measurement. Spike trains were analyzed with Spike Histogram software (ADInstruments Pty Ltd., Australia). The frequencies (F) and average intensities (I) of spikes with amplitudes higher than 10 μV were quantified, regardless of their spike types, using 5 recordings for each stimulus. Test materials (stimuli) were dissolved in 6–12% aqueous ethanol containing 10 mM NaCl as an electrolyte.

Results

Oviposition Responses to the Foliage, Extract, and Fractions of Phellondendron amurense Ovipositing *P. maackii* females responded strongly to the foliage, methanol extract, and Fr. 3, and moderately to Fr. 2., while Fr. 1 (a mixture of less polar substances) was weakly active (Fig. 1). It was noteworthy that *P. maackii* females responded positively to Fr. 2, as this isobutanol-soluble fraction has been reported to be almost inactive by itself for the Rutaceae-specialized *Papilio* species thus far investigated (Honda and Hayashi, 1995a; Nakayama et al., 2002; Murakami et al., 2003; Chachin et al., 2007).

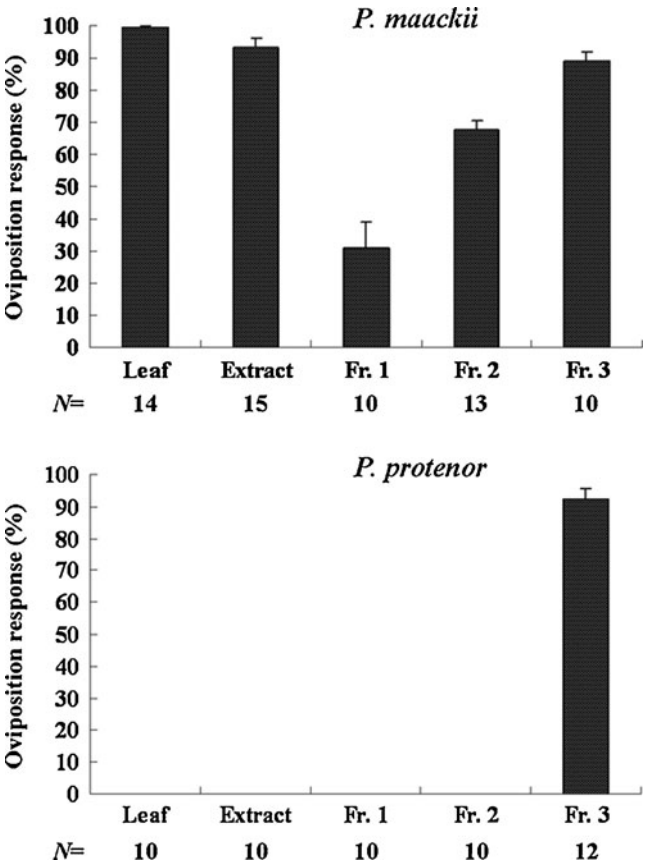

Fig. 1 Oviposition responses (mean±SE) of the two species (*Papilio maackii* and *Papilio protenor*) to the foliage of *Phellodendron amurense*, the methanol extract of the foliage, and fractions of the extract prepared as described in the text. The extract and fractions were tested at 0.5%

In marked contrast, *P. protenor* females responded positively only to Fr. 3, and totally rejected the other fractions (Fig. 1). The response of *P. protenor* females of the Hiroshima population to each sample was virtually identical to that of the Kanagawa population reported previously (Honda and Hayashi, 1995a, b).

Oviposition Response to Phellamurin Females of *P. maackii* had positive oviposition responses to phellamurin in a dose-dependent manner (Fig. 2). With 2.0% phellamurin, corresponding to the concentration of the compound found in young leaves of *P. amurense* (Honda and Hayashi, 1995b), the response was 72.4%. Ovipositing females of *P. protenor* did not respond to phellamurin.

Mixtures of Phellamurin and Fr. 3 As shown in Fig. 3, the addition of phellamurin enhanced oviposition responses of *P. maackii* females to Fr. 3. In *P. protenor*, the stimulatory activity of Fr. 3 was suppressed upon addition of a very small dose (0.1%) of phellamurin. There was almost complete rejection at higher doses (0.2% or more). This tendency is similar to that reported previously for the Kanagawa population (Honda and Hayashi, 1995b), though individuals of the Hiroshima population appear to be more sensitive to phellamurin.

Electrophysiological Responses Recordings from foretarsal taste sensilla were conducted with aqueous solutions of ethanol (solvent), phellamurin, Fr. 3, and their mixtures. Sucrose was used as the reference stimulus. Figure 4 shows typical recording traces for *P. maackii* and *P. protenor*. The sensilla of both species were unresponsive to the solvent

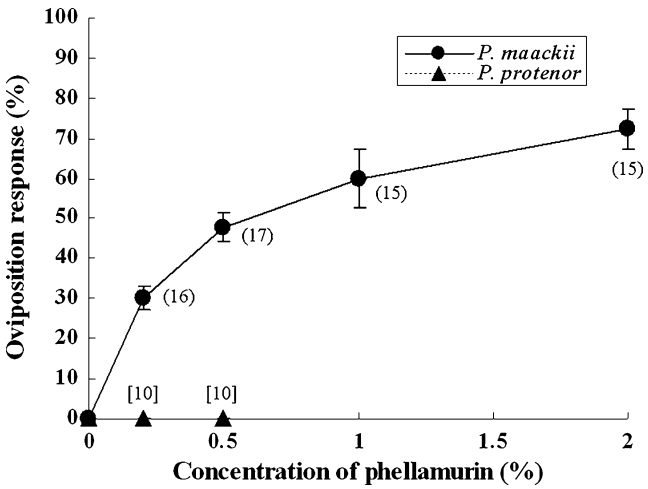

Fig. 2 Oviposition responses (mean±SE) of the two species (*Papilio maackii* and *Papilio protenor*) to various concentrations of phellamurin . The number of individuals tested is given in parentheses or brackets

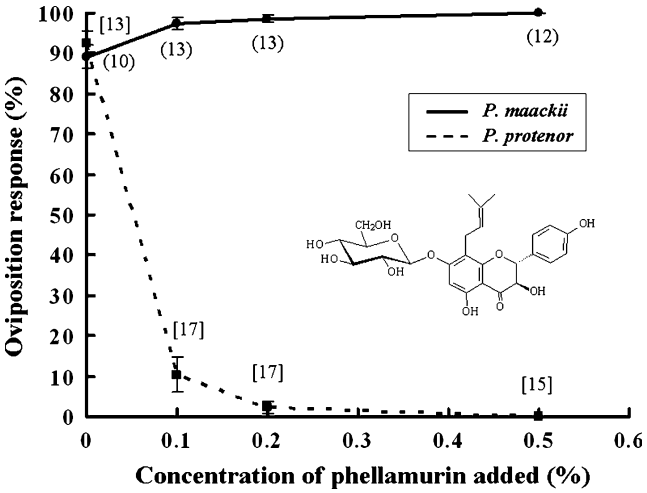

Fig. 3 Dose-response relationships for phellamurin mixed with Fr. 3. The oviposition behavior of the two species (*Papilio maackii* and *Papilio protenor*) expressed as mean±SE for various concentrations of phellamurin mixed with Fr. 3 (0.5%). The number of individuals tested is given in parentheses or brackets

(12% ethanol) and 62.5 mM sucrose (traces 1 and 6), but exhibited unambiguous responses to stimulation with the other solutions. The sensilla of *P. maackii* were more intensely stimulated with phellamurin and/or Fr. 3 than were those of *P. protenor*, with the former displaying spikes of lower amplitude. In both species, phellamurin appeared to evoke regular spikes from 1 neuron (trace 2). The frequencies (F; mean±SD) and intensities (μV) (I; mean±SE) of spikes evoked in the sensilla of *P. maackii* and *P. protenor* were (F) 39±19, (I) 210±14, and (F) 29±9, (I) 341±15, respectively.

In contrast, Fr. 3 , which contained less than 62.5 mM sucrose, elicited several types of spikes with different amplitudes, and its stimulation mode for *P. maackii* was diverse as compared to that for *P. protenor* (trace 3). The spike trains of both species were so complicated that we were only able to approximately evaluate their response patterns by lumping together all spike types. The mean spike frequencies and intensities of *P. maackii* and *P. protenor* were (F) 102±9, (I) 312±19, and (F) 26±6, (I) 407±20, respectively.

Although the spike trains of *P. maackii* in response to the mixtures of phellamurin and Fr. 3 (traces 4 and 5) were too complicated to analyze with the software available, the mean spike frequency and intensity [(F) 104±4 and (I) 271±27] recorded by stimulation with 0.5% Fr. 3 plus 0.2% phellamurin (trace 5) were similar to those observed with Fr. 3 alone. The sensory response pattern in *P. protenor* to the same mixture (trace 5) was less complex. The impulses evoked by stimulation with mixture [(F) 68±20 and (I) 426±21] may have represented an additive response because the

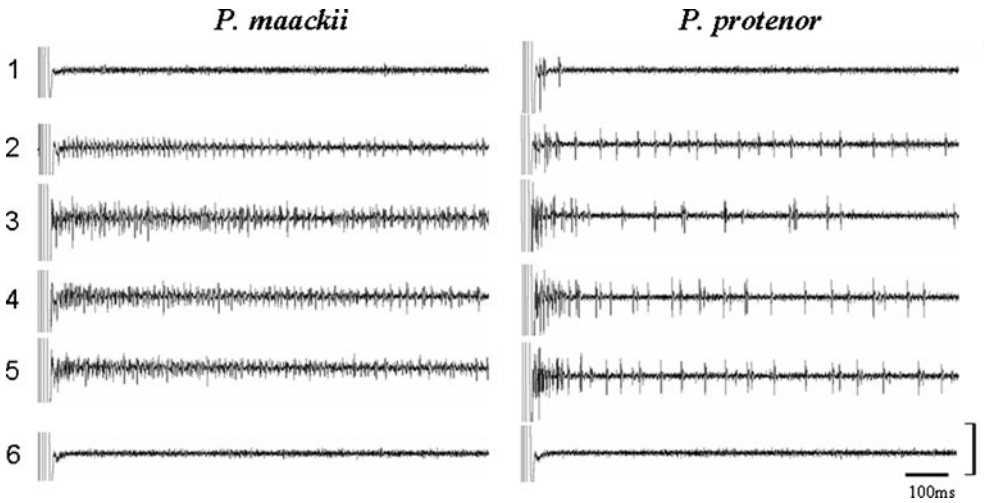

Fig. 4 Electrophysiological recordings from the foretarsal medial large sensilla (s. trichodea) for the two species (*Papilio maackii* and *Papilio protenor*). Examples of traces in response to aqueous solutions of (1) 12% ethanol, (2) 0.2% phellamurin +12% ethanol, (3) 0.5% Fr. 3+10% ethanol, (4) 0.5% Fr. 3+0.1% phellamurin +6% ethanol, (5) 0.5% Fr. 3+0.2% phellamurin +12% ethanol, and (6) 62.5 mM sucrose. Each sample contained NaCl (10 mM) as an electrolyte and all traces were from the same sensillum. Amplitude scale bar: 500 μV

spike count of the mixture was virtually equivalent to the sum total of spikes evoked by the respective samples.

Discussion

The rejection of *Phellodendron amurense* by ovipositing females of *Papilio protenor* can be ascribed to negative effects of phellamurin in the foliage. Fraction 1 had no oviposition-inhibitory effect (Honda and Hayashi, 1995a). The mixture we tested (Fig. 3) composed of 0.5% Fr. 3 and 0.25% phellamurin, approximated the relative concentrations in the living plants., We conclude that the deterrent activity of phellamurin far outweighs the potent stimuli evoked by water-soluble substances (Fr. 3), thus resulting in persistent avoidance of the plant by females. The essential agreement on the dose-response relationship for phellamurin between Kanagawa and Hiroshima populations (located 650 km apart) indicates that the circumvention of phellamurin by *P. protenor* females is not a regionally-expressed but species-specific trait.

Fraction 2 (isobutanol-soluble substances) consists mainly of flavonoid glycosides, including phellamurin as a major component (Honda and Hayashi, 1995b). Thus, phellamurin is most likely responsible for the positive response to Fr. 2 by *P. maackii* females. Phellamurin alone exerted considerable oviposition-stimulatory activity for *P. maackii*, in contrast to other flavonoid stimulants that are effective only when they operate together with other structurally unrelated substances (Ohsugi et al., 1985; Nishida et al., 1987; Honda, 1990). Furthermore, marked synergism of multiple components in host recognition generally prevails in *Papilio* butterflies (Renwick and Chew, 1994; Honda, 1995; Honda et al., 2010). In addition to its direct action in stimulation of oviposition, phellamurin synergistically enhanced the responses of *P. maackii* females to Fr. 3 (Fig. 3). Thus, for *P. maackii*, phellamurin acts as an independent or a synergistic oviposition stimulant probably involved in host preference.

The foretarsal sensilla of the two butterfly species exhibited species-specific electrophysiological responses to Fr. 3 and phellamurin. In both species, the spikes generated by stimulation with Fr. 3 (trace 3) seem to originate from at least 2 or more different sensory receptor cells that are responsive to some as yet uncharacterized oviposition stimulants present in the fraction. Despite an enormous difference in its effect on the two butterflies' behavior, phellamurin elicited one type of spikes from both species. In *P. protenor*, phellamurin (a deterrent), which is received by a specific cell distinct from those involved in the reception of stimulant(s), would transmit a behaviorally negative signal to the central nervous system. In *P. maackii*, however, phellamurin might stimulate one of the neurons that are responsive to components in Fr. 3.

Electrophysiological experiments have been carried out for some butterfly species in relation to oviposition behavior (e.g., Roessingh et al., 1991; Du et al., 1995; Städler et al., 1995). Investigations of 2 pierids, *Pieris napi* and *P. rapae*, revealed that one of the taste neurons responsive to glucosinolates (oviposition stimulants) is also sensitive to cardenolides (oviposition deterrents), and further have provided evidence for peripheral interactions of stimulant compounds with a neuron responding to deterrents (Du et al., 1995; Städler et al., 1995). Other instances of interference with chemoreceptor activity caused by inhibitory chemicals have been reported for other lepidopterans (e.g., Schoonhoven and Fu-Shun, 1989; van Loon, 1996; Qiu et al., 1998). None of the recordings we observed, however, found clear indications of such peripheral interaction of phellamurin with Fr. 3 sensitive cells (trace 5). Therefore, sensory events at the periphery,

unlike an interference mechanism, seem likely to underlie the rejection of phellamurin-containing plants by ovipositing *P. protenor* females.

The genus *Citrus* is one of the plant taxa exploited worldwide by Rutaceae-feeding *Papilio* butterflies. Phytochemical data compiled to date show that flavonoid compounds abundant in *Citrus* species are flavones, flavanones, and flavonols, while compounds like phellamurin, which is a *C*-prenyl substituted 2,3-dihydroflavonols (flavanonols), are rarely found in *Citrus* (Tripoli et al., 2007; Ribeiro et al., 2008; Abad-García et al., 2009). *Citrus* plants are not sympatric with *P. amurense* at most locations in Japan; *Citrus* plants generally lack cold hardiness, and thus grow along coastal areas in temperate to warm regions. *Phellodendron amurense* is distributed in lowlands in cold latitudes but usually occurs at higher elevations in temperate regions. Therefore, it seems likely that not only *P. protenor* but other *Citrus* feeders, including *P. xuthus* (Honda and Hayashi, 1995b), have had little chance in their evolutionary history to encounter *P. amurense*. It is surprising that the larvae are able to ingest phellamurin given the female aversion (Honda and Hayashi, 1995a). The genetic grounds for such differential adaptation of adults and larvae to a given plant have been studied in other *Papilio* butterflies (e.g., Thompson et al., 1990).

Some flavonoids are known as oviposition stimulants for some papilionid butterflies (Ohsugi et al., 1985; Nishida et al., 1987; Honda, 1995), whereas flavonoids present in non-host plants often play a significant inhibitory role in regulation of oviposition (Nishida et al., 1990). We previously proposed that the ancestors of Papilionidae might have most heavily relied in host recognition on simple phytochemicals such as amino acid derivatives, hydroxycarboxylic acids, and/or polyols that are closer to primary metabolites (Nakayama et al., 2003). By contrast, flavonoids are relatively advanced secondary metabolites (Harborne and Baxter, 1993). In this context, we presume that flavonoids serve as modulators that govern host choice by ovipositing female, and that positive responses to flavonoids may be an apomorphic trait in the Papilionidae.

According to mitochondrial DNA phylogeny of the Papilionidae (Yagi et al., 1999; Zakharov et al., 2004), Japanese swallowtails in the tribe Papilionini comprise at least 2 subclusters; the subgenus *Menelaides* that includes typical *Citrus* feeders such as *Papilio protenor* and *P. memnon*, and the subgenus *Achillides* that includes *Papilio maackii* and *P. bianor*, both of which utilize *Phellodendron amurense* as a natural host. *Papilio protenor* and *P. maackii* may have diverged from a common ancestor, eventually exploiting distinct host plants and establishing their respective niches. It is noteworthy that other *Menelaides* members, *Papilio polytes* and *Papilio helenus*, also can complete their immature stages on *P. amurense*, and its aqueous fraction exerts strong to weak oviposition-stimulatory activity to *P. xuthus* and *P. polytes* (Honda and Hayashi, 1995a; Nakayama et al., 2002). *Papilio maackii* prefers to live in cool and montane zones, where rutaceous plants available for larval food are restricted to *P. amurense* only, particularly in northern Japan. In light of the present-day species richness of Papilionidae in tropical and temperate regions (Scriber, 1995), it is hypothesized that female chemosensory adaptation of the ancestors of *P. maackii* to an unusual (prenylated) flavonoid might have enabled them to colonize *P. amurense* and to extend their habitat further to boreal regions (as far as ca. 53°N latitude). In addition, *P. bianor*, another member of *Achillides*, has been observed in the field to lay eggs on *Citrus* plants on rare occasions and can marginally survive on them up to adulthood (Endo and Nihira, 1990). Positive oviposition responses to ancestral host plants also have been reported for species of the *Papilio glaucus* group (Mercader and Scriber, 2008). These and our finding that *P. protenor* females are very susceptible to phellamurin also seem to lend support to a possible host shift from *Citrus* plants to *P. amurense* by the common ancestor of *Menelaides* and *Achillides*.

The present finding that the stimulus evoked by a single phytochemical is interpreted differently by related butterfly species, suggests the involvement of chemoreceptor mutation(s). This may afford an opportunity for investigating the sensory and evolutionary mechanisms of chemical mediation of host range expansion and host shifts in the Papilionidae.

Abstract Plant volatile compounds induced by herbivore attack have been demonstrated to provide a signal to herbivore enemies such as parasitic wasps that use these volatiles to locate their hosts. However, in addition to herbivore-induced volatiles, plants often release volatiles constitutively. We assessed the interaction between herbivore-induced and constitutively released volatiles of maize in the attraction of the wasp *Cotesia marginiventris* that parasitizes herbivorous lepidopteran larvae feeding on maize. Experiments were carried out with olfactometers in which the sources of volatiles were transgenic *Arabidopsis thaliana* plants overexpressing maize sesquiterpene synthases that produce blends of herbivore-induced or constitutive compounds. We found that the constitutive volatiles of maize terpene synthase 8 (TPS8) were attractive to *C. marginiventris*, just like the herbivore-induced volatiles of TPS10 studied earlier. A mixture of both the TPS8 and TPS10 volatile blends, however, was more effective in parasitoid attraction, indicating that constitutively released sesquiterpenes enhance the attraction of those induced by herbivores. While *C. marginiventris* did not distinguish among the volatiles of TPS8, TPS10, nor those of another maize sesquiterpene synthase (TPS5), when these blends were combined, their attractiveness to the wasp appeared to increase with the complexity of the blend.

Key Words *Cotesia marginiventris* · *Arabidopsis thaliana* · *Zea mays* · *Spodoptera littoralis* · Sesquiterpenes · Volatile organic compounds (VOCs) · Herbivore-induced volatiles · Constitutive volatiles · Plant defense · Parasitoid attraction

Introduction

Plants emit a plethora of volatile organic compounds (VOCs) from their vegetative organs into the surrounding atmosphere. The most common are green leaf volatiles (GLVs, C_6 alcohols, aldehydes, and derivatives), and terpenes, especially monoterpenes and sesquiterpenes (Dudareva et al., 2004). VOCs are released abundantly after herbivore attack, but undamaged plants, especially tree species, also show high emission rates (Kesselmeier and Staudt, 1999). For example, undamaged poplars (*Populus* spp.) can invest more than 10% of their photosynthetically fixed carbon into the emission of isoprene (Brilli et al., 2009). The majority of studies on vegetative VOCs have focused on herbivore-induced volatiles and provided ample evidence for their role

in attraction of herbivore enemies. These studies include agronomically important crops (e.g., maize, tomato, soybean, cabbage) as well as wild species, both herbaceous and woody (reviewed by Unsicker et al., 2009). Much less is known about the role of constitutively emitted volatiles in plant indirect defense, as these rarely have been studied separately from the herbivore-induced ones. Attraction of herbivore enemies to uninfested plants has been documented for some aphid parasitoids (Hymenoptera: Braconidae) (reviewed by Hatano et al., 2008) and for two lepidopteran parasitoids (Elzen et al., 1986, 1987).

Herbivore-induced and constitutive VOCs often are released in complex blends (Dicke et al., 2009). Since these natural mixtures are difficult to manipulate or to reproduce synthetically, most studies have tested arthropod attraction to either whole blends, or to single VOCs available in pure form. For example, the GLV (*E*)-3-hexenol is attractive to the braconid wasp *Apanteles* (=*Cotesia*) *kariyai* (Watanabe) (Takabayashi et al., 1991), and the sesquiterpenes γ-bisabolene and (*E*)-β-caryophyllene attract *C. sonorensis* females. These ichneumonids oviposit in noctuid larvae that feed on cotton plants, whose vegetative parts are rich in sesquiterpenes (reviewed by Rutledge, 1996). Single volatiles responsible for the attraction of herbivore enemies also have been identified in a few aphid-parasitoid systems (reviewed by Hatano et al., 2008) and in one mite - predatory mite system (de Boer and Dicke, 2004; de Boer et al., 2004). However, there are cases in which the whole volatile blend released by a plant is necessary for the parasitoid to locate its host's habitat. A study with the egg parasitoid *Closterocerus ruforum* (Krausse) (Hymenoptera: Eulophidae) demonstrated that the whole VOC blend emitted by Scots pine (*Pinus sylvestris* L.) after oviposition by the herbivorous sawfly *Diprion pini* (L.) attracts the parasitoid (Mumm and Hilker, 2005). This blend differs from that of uninfested plants by having greater amounts of (*E*)-β-farnesene. However, neither (*E*)-β-farnesene, nor the VOC blend of uninfested plants by itself was attractive to the parasitoids; both were required.

Maize (*Zea mays* L.) is one of the best studied species for the role of volatiles in indirect plant defense. The volatile bouquet emitted by seedlings after feeding by generalist lepidopteran caterpillars (*Spodoptera littoralis* (Boisd.), *S. exigua* (Hübn.)) has been well characterized and studied for over two decades (D'Alessandro et al., 2009; Turlings et al., 1990). Important components of this odor are GLVs (esters and aldehydes) with their abundance dependent on the extent and intensity of herbivore damage. The monoterpene alcohol linalool, the C_{11} homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and indole also are present often in high amounts. However, the biggest proportion of the blend is made up of (*E*)-β-farnesene, (*E*)-α-bergamotene, and other sesquiterpene hydrocarbons (Turlings and Ton, 2006). This herbivore-induced blend is attractive to parasitic wasps (Turlings et al., 1990, 1991), raising the question of whether the entire mixture or individual components are responsible for the attraction. In order to tackle this question, the volatile mixture was fractionated (D'Alessandro and Turlings, 2005), and plants have been engineered to emit only a specific fraction of the terpene blend. Transgenic *Arabidopsis thaliana* plants emitting the volatiles formed by maize terpene synthase 10 (TPS10), which make up most of the herbivore-induced sesquiterpenes of maize leaves, were more attractive than untransformed controls to the parasitoid wasp *Cotesia marginiventris* (Cresson) (Hymenoptera: Braconidae) in olfactometer experiments (Schnee et al., 2006).

In addition to herbivore-induced terpenes, many lines of maize emit an additional sesquiterpene mixture, which is constitutively emitted by the roots and aboveground vegetative tissues of young plants. These terpenes are synthesized by TPS8 (Fig. 1a), a terpene synthase that is expressed independently of herbivory in the inbred line B73 as well as in several other cultivars and wild ancestors of maize (Köllner et al., 2004b, 2008, 2009). The ecological role of maize TPS8 products has been investigated in the context of plant-pathogen interactions and deterrence of insect herbivory, and these substances have been shown to act as defenses against fungi, but not against herbivores (Fontana et al. unpublished data). The terpene blend produced by TPS8 is extraordinarily complex,and one major component of this mixture, (*E*)-β-caryophyllene, has been implicated in the attraction of herbivore enemies both above and below ground (Köllner et al., 2008). A third sesquiterpene blend dominated by sesquithujene and β-bisabolene is produced by TPS5 in the husks and at lower levels in the leaves of mature maize plants (Köllner et al., 2004a). As young instars of generalist lepidopteran larvae are not normally found on these plant parts, the TPS5 blend is unlikely to be used by their parasitoids for host location.

Here, we studied the function of the constitutively emitted TPS8 terpenes in indirect plant defense. The study system involved the generalist parasitic wasp *C. marginiventris,* which oviposits on lepidopteran larvae feeding on maize. The constitutively emitted TPS8 volatiles may act: 1) together with the herbivore-induced (TPS10) terpenes to strengthen attraction of the wasps; 2) antagonistically with the herbivore-induced signal to weaken the parasitoid attraction; or 3) without effect, neither enhancing nor diminishing the parasitoid response to the herbivore-induced odor. To test these hypotheses, we performed a series of olfactometer experiments where we measured the attraction of *C. marginiventris* females to the TPS10 or TPS8 terpene blends, either singly or in combination, as emitted from transgenic *A. thaliana* lines. We also tested whether the

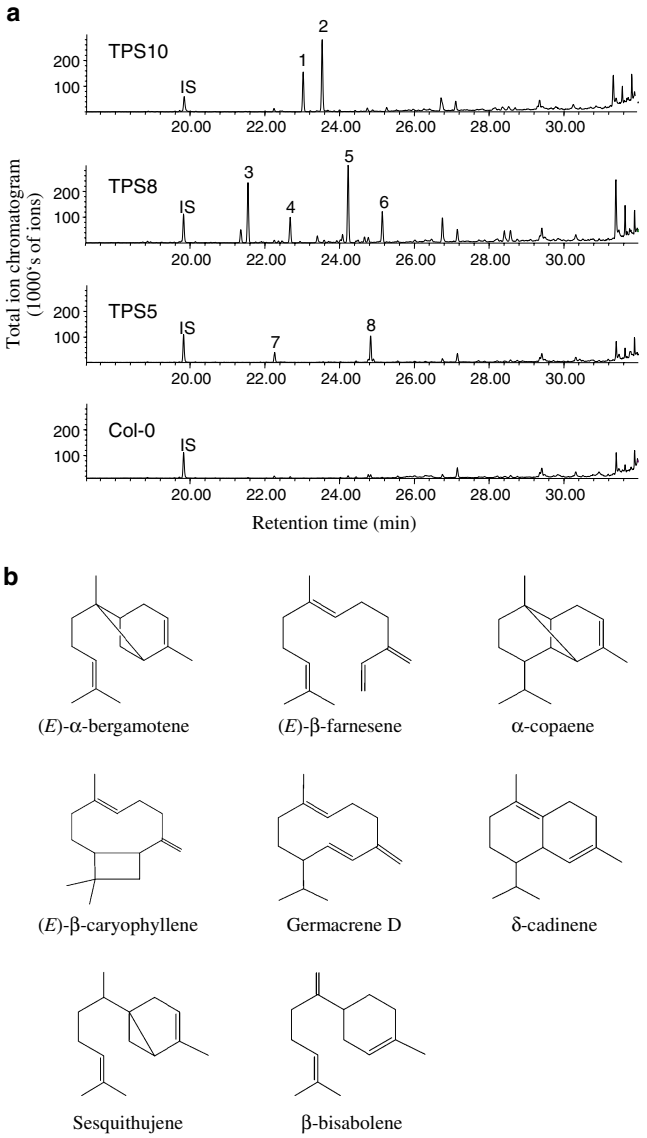

Fig. 1 **a** Volatile profile of *Arabidopsis thaliana* rosette stage plants transformed with *tps10*, *tps8*, and *tps5*, and of untransformed Col-0 plants. The main volatile compounds were identified as: 1. (*E*)-α-bergamotene; 2. (*E*)-β-farnesene; 3. α –copaene; 4. (*E*)-β-caryophyllene; 5. germacrene D; 6. δ-cadinene; 7. sesquithujene; 8. β-bisabolene. Their structures are shown in **b**. IS: internal standard

parasitoid's responses to the terpene blends are innate or learnt by association with an oviposition experience. It has been shown that *C. marginiventris* females can be attracted to different odors (among which is the odor of herbivore-induced maize) only after they had associated them to an oviposition experience (Hoballah and Turlings, 2005; Schnee et al., 2006). However, it is not known whether the parasitoids learn the whole blend or only some of its components, nor how specifically they learn the individual constituents. Finally, by using a third maize terpene blend, that of TPS5, we investigated whether the complexity of the mixture is an important variable in parasitoid attraction.

Methods and Materials

Generation of Transgenic Arabidopsis thaliana *Plants.* The generation of transgenic TPS10 (Schnee et al., 2006) and TPS8 (Fontana et al. unpublished data) plants has been described elsewhere. For TPS5 plants, the open reading frame (ORF) of *tps5* from *Zea mays* var. Delprim (*tps5-Del1*) was amplified from the pASK-IBA7 construct (Köllner et al., 2004b) with the primers forward (*tps5*fwd): 5′-ATGGCGTCTCCTCCAGCACATCG-3′ and reverse (*tps5*rvs): 5′-TCATTCGGGTATTGGCTCCACAAACAG-3′ and cloned into the pCR-TOPO vector (Invitrogen, Carlsbad, CA, USA) for sequencing. After sequence analysis, the 1665 bp ORF was re-amplified from the sequencing vector and cloned using Gateway technology (Karimi et al., 2002) into the plant expression vector pB2GW7 between the p35S promoter and the T35S terminator of the cauliflower mosaic virus. The resulting construct was introduced into the *Agrobacterium tumefaciens* strain GV3101, which was then used to transform *Arabidopsis thaliana* L. (ecotype Col-0) plants using the floral dip method (Clough and Bent, 1998) supplemented with vacuum infiltration. Since the construct had a *bar* selectable marker gene that confers resistance to the herbicide Basta, seeds from T_0 plants were screened for the transgene by applying Basta on soil-germinated young seedlings. To select for transgenic lines emitting the expected TPS5 volatile sesquiterpenes, headspace volatiles were collected from detached leaves of the Basta survivors with SPME (solid phase microextraction) and analyzed by GC-MS (see *Volatile Collection and Analysis* for details). Transformation was confirmed additionally by PCR analysis.

Plant and Insect Material A. thaliana plants overexpressing one of the maize sesquiterpene synthases TPS10, TPS8, or TPS5 (Schnee et al., 2006; Fontana et al. unpublished data), and wild-type (ecotype Col-0) plants were grown in 7 x 7 x 8 cm single pots on fertilized potting soil in a climate chamber at 21°C, 55% relative humidity, and 150 μmol s^{-1} m^{-2} photosynthetically active radiation (PAR) under short day conditions (8 h light day^{-1}) in order to retard flowering and maximize rosette size.

Maize plants var. Delprim were grown in a climate chamber at 23±2°C, 60% r.h., 16 h light day^{-1}, and 900 μmol s^{-1} m^{-2} PAR. Eggs of the Egyptian cotton armyworm, *Spodoptera littoralis* (Boisduval) (Lepidoptera: Noctuidae), were obtained from Syngenta rearing facilities (Stein, Switzerland). After emergence, larvae were reared on a wheatgerm-based artificial diet (also supplied by Syngenta) at room temperature. The solitary endoparasitoid *Cotesia marginiventris* (Cresson) (Hymenoptera: Braconidae) was reared as described in Turlings et al. (2004). Female and male adult parasitoids were kept together in plastic cages (30

x 30 x 30 cm) (MegaView Science Education Services Co. Ltd., Taiwan), at a ratio of approximately 2 : 1 in incubators at 25±1°C with 16 h light day^{-1} and supplied with moist cotton and honey. Mated, 2- to 5-d-old females were used in the olfactometer experiments.

Olfactometer Experiments The behavioral response of *C. marginiventris* females to the three maize sesquiterpene blends and their combinations was tested by using transgenic *A. thaliana* plants as odor sources in six-arm olfactometer experiments. The six-arm olfactometer (described in Turlings et al., 2004) was set with incoming air at 1.2 l min^{-1} per vessel. A portion of the air was pulled out from each vessel at 0.6 l min^{-1} through a volatile collection trap (see *Volatile Collection and Analysis*). Each of the six vessels either contained a plant as the odor source or was left empty. Purified, humidified air carried the volatile odors from the vessels to the corresponding arm of the olfactometer. When combinations of two or three terpene blends were tested, two or three *A. thaliana* plants were used as odor sources. The same number of plants was used in all the odor-carrying arms in order to have a comparable plant biomass in all the vessels. Plants used were all at the rosette stage, 4 to 6 wk-old. The transgenic plants were tested to confirm volatile emission prior to each experiment, and different confirmed individuals were chosen randomly for each experimental replicate (see *Volatile Collection and Analysis*).

Groups of 6 *C. marginiventris* females were released into the center of the olfactometer and were given 30 min to fly into one of the arms. Wasps that did not enter an arm within this time were considered as having made no choice. After the choice of the wasps had been recorded, the wasps were removed from the olfactometer. Each group of parasitoids tested was either naïve (with neither oviposition experience nor exposure to any of the tested odors) or experienced (for details on the number of releases per experience and experimental replicates, see Table 1). Oviposition experiences were given by placing a single female parasitoid in a glass enclosure that contained about 20 2nd- or 3rd-instar *S. littoralis* larvae and connected on one side to a glass vessel that contained a given odor source, which was either a transgenic *Arabidopsis* plant or a maize seedling. The wasps were allowed to oviposit in presence of the odor at least three times before they were removed from the enclosure. To induce volatile production in the maize seedling used for these experiments, plants were enclosed in a glass vial with a vented lid and one 3rd-instar *S. littoralis* caterpillar was allowed to feed overnight.

Every experiment was replicated 3 to 8 times. At the end of each replicate, all parts of the olfactometer were washed with water, acetone, and hexane, and the glass parts were dried in an oven at 250°C. In each replicate, 1 to 4 groups of 6 wasps with the same experience were released (Table 1). In total, four experiments were performed. The layout of the olfactometer for each experiment is schematically represented in Fig. 2.

Volatile Collection and Analysis All transgenic *A. thaliana* plants were screened for volatile production before being used in the olfactometer experiments. A leaf was detached from ca. 3-wk-old plants, put in a 1.5 ml glass vial, and incubated for about 20 min at 40°C with an SPME fiber (100 μm polydimethylsiloxane coating, Supelco, USA). The collected volatiles were then analyzed by GC-MS (GC: Hewlett-Packard 6890; carrier gas: He, 1 ml min^{-1}, splitless injection (injection T: 220°C), column: DB-5MS (5% diphenyl/95% dimethylsiloxane, 30 m x 0.25 mm x 0.25 μm film, J & W Scientific, Folsom, CA, USA), temperature program: 80°C to 180°C at 10°C min^{-1}, 180°C to 220°C at 100°C min^{-1}. MS: Hewlett-Packard 5973, quadrupole mass selective detector; transfer line T: 270°C; ionization potential: 70 eV; scan range: m/z 40–350).

During the second olfactometer experiment, volatiles were collected from the vessels in order to assess whether the quantity of volatiles affected the wasp

Table 1 Summary of details of the olfactometer experiments, including types of oviposition experience used for *Cotesia marginiventris* prior to experiment, number of releases per experience, number of experimental replicates, and total number of wasps used[a]

	Experiences					Releases per experience	Replicates of the experiment	Total number of wasps
	Naïve	TPS8	TPS10	TPS8 + TPS10	HI[b] maize			
Exp. 1	x	x				4	3	144
Exp. 2	x	x	x	x	x	1	8	240
Exp. 3			x			3 - 4	4	84
Exp. 4			x			5 - 6	7	216

[a] Six wasps were used in each release. Naïve wasps had no prior oviposition experience

[b] HI: Herbivore-induced

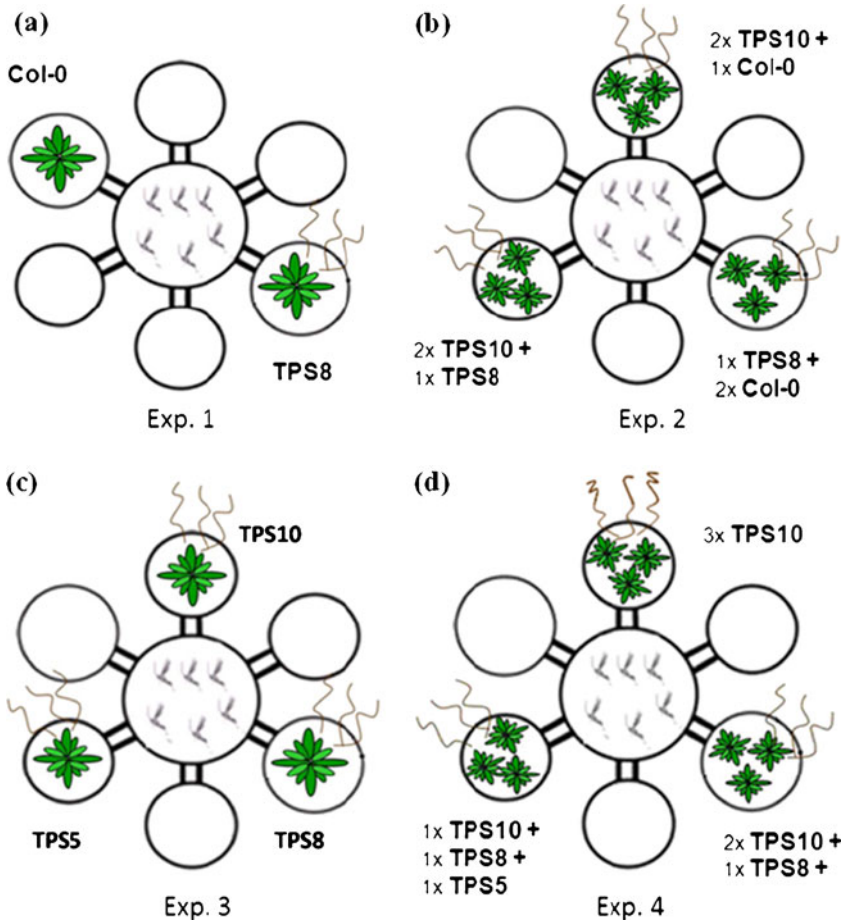

Fig. 2 Position of the odor sources in the olfactometer experiments (Experiment 1 **a**, Exp. 2 **b**, Exp. 3 **c**, Exp. 4**d**). The schematic plants represent *Arabidopsis thaliana* individuals, either transgenic or wild-type (ecotype Col-0)

responses. Odors were trapped with 25 mg Super-Q adsorbent (Alltech Associates, Inc., Deerfield, IL, USA), and eluted with 150 µl dichloromethane; 200 ng nonyl acetate were added as an internal standard. Volatiles were analyzed by GC-MS (GC: Agilent 6890 Series GC system G1530A, MS: Agilent 5973 Network Mass Selective Detector, electron impact mode, transfer line T: 230°C, ionization potential: 70 eV, scan range: m/z 33–280). The carrier gas was helium (1 ml min^{-1}). Samples were injected splitless at 230°C. We used an HP-1 column (Alltech Associates, polydimethylsiloxane, 30 m x 0.25 mm x 0.25 µm film), and the following temperature program: 40°C for 3 min, 40°C to 100°C at 8°C min^{-1}, 100°C to 200°C at 5°C min^{-1}, 5 min at 250°C. The relative quantity (%) of the sesquiterpenes was calculated based on their peak area relative to the peak area of the internal standard.

Statistical Analysis In order to analyze the influence of the odors tested and the experiences on the parasitoids' choices, a generalized linear model (GLM) with a log-link function and a quasipoisson error distribution was used (Turlings et al., 2004). "No choice" wasps were not included in the analyses. The model was fitted by maximum quasi-likelihood estimation, and its adequacy was assessed through likelihood ratio statistics and examination of residuals. Odor source and experience of the wasps were fitted to the model as fixed factors. We tested the interactions between the factors as well as the effect of the single factors on the wasps' choice. The effect of the odor was tested separately on naïve and experienced wasps in Exp. 1 and 2. The response of the wasps to the relative amounts of volatiles offered in Exp. 2 was assessed with the same GLM. All analyses were performed using the software package R (R Development Core Team (2008), R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. ISBN 3-900051-07-0,URL http://www.R-project.org).

Results

The Constitutively Produced Maize Sesquiterpene Blend Is Attractive to Experienced C. marginiventris *Parasitoids (Exp.1)* Experienced *C. marginiventris* females that had had a previous oviposition experience in the presence of TPS8 volatiles were more attracted by *A. thaliana* plants producing

TPS8 terpenes than by wild-type plants ($F_{1,22}$=14.00, P=0.001), while naïve parasitoids did not show a preference for either plant ($F_{1,22}$=0.01, P=0.915) (Fig. 3a, b). Both naïve and experienced wasps preferred arms containing a plant to empty arms (naïve: $F_{2,69}$=14.40, P<0.001, experienced: $F_{2,69}$=45.63, P<0.001). Overall, 49% of the parasitoids responded to the plant odors (i.e., they entered an arm), while 45% made no choice (Fig. 3c).

Experienced C. marginiventris *Females Prefer the Full Sesquiterpene Blend of an Herbivore-Induced Maize Plant Including Constitutive Volatiles (Exp.2)* Since experienced *C. marginiventris* were attracted to the constitutively released TPS8 volatiles of a maize plant, we tested whether this attraction is similar to that of herbivore-induced TPS10 volatiles (Schnee et al., 2006) and whether there is any interaction between the two terpene blends. The volatile blend of herbivore-damaged maize seedlings contains about twice as many herbivore-induced TPS10 volatiles as constitutive TPS8 compounds. To mimic these proportions, two TPS10-emitting plants were combined with one TPS8-expressing plant (Fig. 2b, Exp.2). This blend was compared to the volatiles of two TPS10 plants combined with one Col-0 plant and to the volatiles of one TPS8 plant with two Col-0 plants to simulate the ratio of herbivore-induced to constitutive volatiles naturally emitted by maize plants. The combination of TPS10 and TPS8 sesquiterpenes was preferred by experienced wasps over the TPS8 volatiles alone (t=−2.65, P=0.009), but not over the TPS10 volatiles (t=−1.51, P=0.13) (Fig. 4b). Experienced *C. marginiventris* preferentially oriented towards arms carrying plant odors than towards empty arms ($F_{1,190}$=38.93, P<0.001). Naïve wasps did not significantly prefer any of the odors offered ($F_{2,21}$=0.85, P=0.44) (Fig. 4a), but they chose arms carrying plant volatiles more frequently than empty arms ($F_{2,21}$=0.85, P=0.03). The different oviposition experiences had no influence on the parasitoids' choice ($F_{3,188}$=0.24, P=0.87). The wasps' responsiveness was low: 40% of the parasitoids chose a plant odor, while 51% made no choice (Fig. 4c). The relative amount of the volatiles collected from the plant-containing vessels did not influence the distribution of the wasps in the olfactometer ($F_{1,22}$=6*10^{-4}, P=0.98).

Experienced C. marginiventris *Females Do Not Discriminate Between Different Maize Sesquiterpene Blends (Exp.3)* We tested the hypothesis suggested by the previous experiment that the association of volatiles with oviposition may not be dependent on specific sesquiterpenes. The parasitoids preferred arms containing a plant to empty arms ($F_{1,82}$=9.23, P=0.003), but none of the sesquiterpene blends offered was preferred over the others ($F_{2,39}$=0.58, P=0.56) (Fig. 5a). Again, the responsiveness was low: 30% of the parasitoids chose a plant odor, while 61% made no choice (Fig. 5b). These results indicated that *C. marginiventris* did not associate specific sesquiterpenes with oviposition and chose any of the three blends for host finding.

Experienced C. marginiventris *Females Tended to Orient towards More Complex Sesquiterpene Blends (Exp.4)* Because specific sesquiterpenes were not recognized by *C. marginiventris* (Exp.3), and because the blend of TPS8 and TPS10 sesquiterpenes combined were more attractive than each separately (Exp. 2), we tested whether greater complexity of the blend may increase its attraction to the wasps. Parasitoids preferred arms containing a plant to empty arms ($F_{1,95}$=6.72, P=0.011) (Fig. 6b). Although there was no statistically significant preference for any of the blends offered, the wasps tended to orient towards the most complex blend (TPS8 + TPS10 + TPS5) ($F_{2,45}$=2.67, P=0.08) (Fig. 6a). Overall, 25% of the parasitoids responded to the plant odors, while 66% made no choice.

Discussion

Herbivore-induced plant volatiles have been frequently demonstrated to play a role in the attraction of herbivore

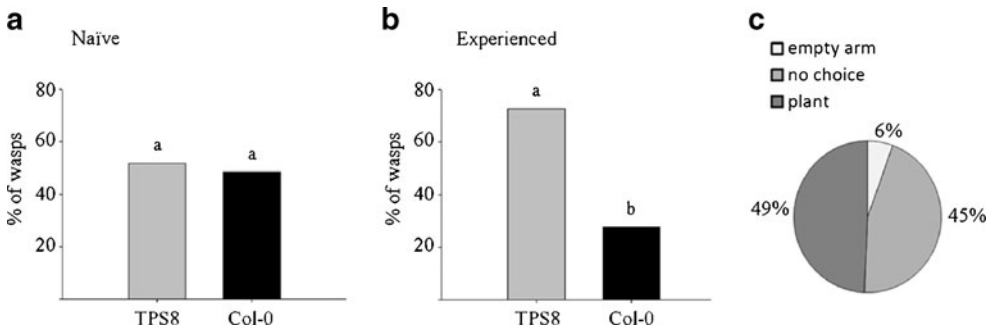

Fig. 3 Percentage of naïve **a** and experienced **b** *Cotesia marginiventris* females that were attracted to a terpene-emitting (TPS8) or a wild-type (Col-0) *Arabidopsis thaliana* plant in a six-arm olfactometer. Different letters represent a significant difference (P=0.001). Responsiveness of all the wasps tested is shown in **c**, where N=144=100%

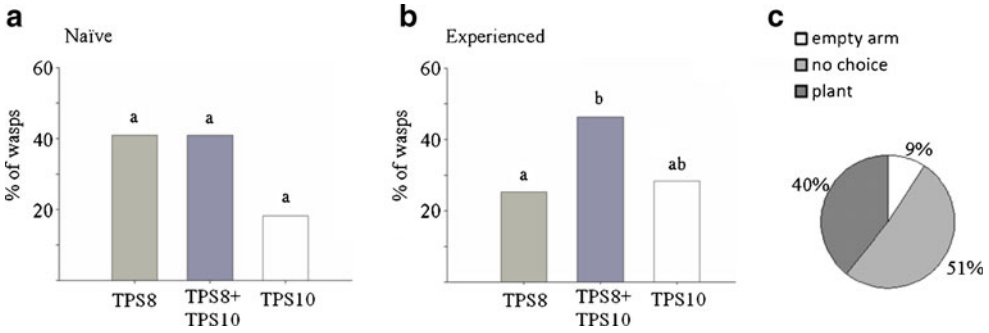

Fig. 4 Percentage of naïve **a** and experienced **b** *Cotesia marginiventris* females that were attracted to three maize sesquiterpene blends produced by transgenic *Arabidopsis thaliana* plants in six-arm olfactometer experiments. TPS8: sesquiterpene volatiles of an undamaged maize plant; TPS8 + TPS10: sesquiterpene volatiles of an herbivore-induced maize plant; TPS10: herbivore-induced sesquiterpenes of maize. Each transgenic line produces only a single blend; the mixture of TPS8 and TPS10 volatiles was obtained by combining TPS8- and TPS10-overexpressing plants. Different letters represent significant differences (P=0.009). Responsiveness of all the wasps tested is shown in **c**, where N=240=100%

enemies (Turlings et al., 1990; Takabayashi et al., 1991; Heil, 2008; Dicke, 2009). However, these studies usually do not take into account that enemies using herbivore-induced plant volatiles to search for their prey or hosts also come into contact with VOCs emitted by undamaged plant parts. A successful host finding strategy of an enemy might, therefore, involve both constitutive and herbivore-induced plant volatiles.

By utilizing *A. thaliana* plants genetically transformed with maize terpene synthases to emit blends of maize volatiles, we showed that females of *C. marginiventris*, a hymenopteran parasitoid that uses lepidopteran larvae as its hosts, can learn the constitutively released volatiles during an oviposition experience and be subsequently attracted to them. (Exp. 1, Fig. 3). Several other parasitoid species have also been shown to be attracted to odors from undamaged plants that support their hosts, including the aphid parasitoid *Aphidius funebris* Mackauer (Hymenoptera: Braconidae), which responded to uninfested *Centaurea nigra* L. (Asteraceae) (Pareja et al., 2007), and the lepidopteran parasitoids *Microplitis croceipes* and *Campoletis sonorensis*, which responded to cotton plant volatiles (Elzen et al., 1986, 1987). Here, we showed conclusively that specific maize sesquiterpene volatiles are involved in this attraction to undamaged plants.

In our experiments, experienced *C. marginiventris* females parasitoids were given a choice between terpene blends that reproduced: 1) the constitutive odor of an undamaged maize plant; 2) the odor produced by herbivore induction; or 3) the complete odor of an herbivore-infested plant, including both constitutive and induced volatiles. They showed a preference for the sesquiterpene blend that represented the combination of both constitutive and induced odors (Exp. 2, Fig. 4b). This shows that constitutively produced VOCs can act together with herbivore-induced VOCs to promote attraction of herbivore enemies. The constitutively emitted TPS8 terpenes may represent a background odor that indicates the general habitat of the host larvae. This background odor appears to reinforce the particular odor released by maize only upon herbivore feeding, thus enhancing parasitoid attraction. Such a positive

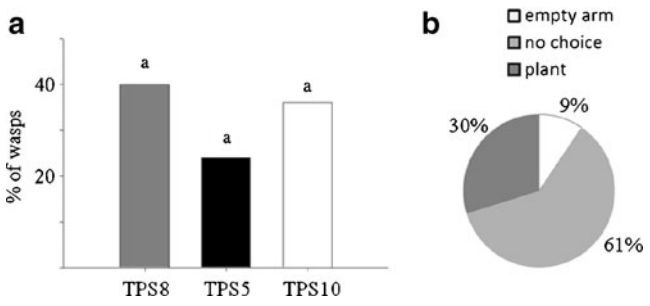

Fig. 5 Percentage of *Cotesia marginiventris* females that were attracted to sesquiterpene blends from maize produced by three lines of transgenic *Arabidopsis thaliana* plants in six-arm olfactometer experiments **a**. The terpene composition of the blends is detailed in Fig. 1. Responsiveness of all the wasps tested is shown in **b**, where N=240=100%

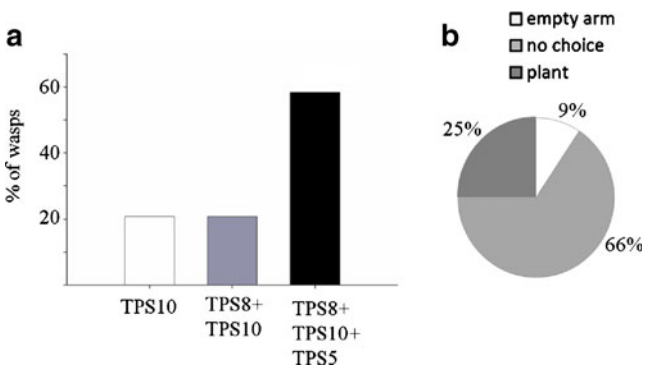

Fig. 6 Percentage of *Cotesia marginiventris* females that were attracted to sesquiterpene blends of increasing complexity in six-arm olfactometer experiments **a**. The odor sources were *Arabidopsis thaliana* plants each transformed with one maize sesquiterpene synthase gene (*tps8* or *tps10* or *tps5*). Plants from different transgenic lines were combined to give the combinations of odor blends. Responsiveness of all the wasps tested is shown in **b**, where N=96=100%

interaction of volatiles cues also has been described for *Leptopilina boulardi* (Barbotin, Carton & Kelner-Pillault) (Hymenoptera: Eucoilidae), a larval parasitoid of *Drosophila* species, which is attracted to the odors of pear and banana fruits (Couty et al., 1999). When this odor was provided together with damp filter papers impregnated with the smell of *Drosophila* flies, the parasitoids significantly preferred this combination to the smell of the flies alone. The importance of background odor for parasitoid host searching also has been highlighted by Mumm and Hilker (2005) in their study with the egg parasitoid *Closterocerus ruforum*, which did not respond to the signal of oviposition-induced pine twigs ((*E*)-β-farnesene) unless it was offered in combination with the odor of an uninfested twig. Another interesting interaction between odor blends has been reported by Fukushima and coworkers (2002), who found a synergistic effect in the attraction of conditioned *Cotesia kariyai* (Hymenoptera: Braconidae) parasitoids to a blend of four volatiles typically emitted after herbivory (geranyl acetate, (*E*)-β-caryophyllene, (*E*)-β-farnesene, and indole), and a non-specific blend made up of three GLVs, β-myrcene, and linalool. A limitation of this and other studies on volatiles lies in the authenticity of such partial plant volatile blends that are artificially constructed by mixing purified compounds, and may lack critical minor compounds. The use of transgenic *A. thaliana* plants transformed with TPS genes resulted in the formation of both major and minor components of the sesquiterpene blend, allowing a more accurate evaluation of its ecological function. Minor constitutents of volatile blends sometimes have been shown to play a disproportionate role in insect attraction (Leal, 2005, and references therein). In the present study, minor constituents other than sesquiterpenes could conceivably influence parasitoid attraction, but these did not differ among the *A. thaliana* lines tested (Suppl. Fig. 1).

The preference of experienced *C. marginiventris* females for the combination of two terpene blends observed in Experiment 2 also could be explained by the fact that more complex mixtures of terpenes are more attractive to these wasps. We tested, therefore, the effect of mixture complexity on *C. marginiventris* by giving females the choice between three terpene blends with an increasing number of components (Exp. 4). Here, the parasitoids tended to orient towards the most complex blend, suggesting that the number of compounds of a terpene mixture may play a role in attraction. Similar results have been obtained in field experiments where the number of insect herbivores attracted by a volatile blend was positively correlated with the number of chemicals present in the blend (Szendrei and Rodriguez-Saona, 2010). Complex volatile blends are known to play important roles in plant-insect interactions besides attraction of herbivore enemies. In a recent study, Riffell and coworkers investigated the perception and behavioral response of the moth *Manduca sexta* L. (Lepidoptera: Sphingidae) to the floral volatiles of the Sacred Datura (*Datura wrightii* (Regel), Solanaceae) (Riffell et al., 2009). Of the over 60 components of the floral scent, many of them terpenes, nine elicited a neural response in the moth, and, among these, four were monoterpenes (linalool, nerol, β-myrcene, and geraniol), and two were sesquiterpene hydrocarbons ((*E*)-β-caryophyllene and (*E,E*)-α-farnesene). Strikingly, these nine compounds were attractive to the moths only when offered as a mixture, but not when tested individually.

Theoretically, the preference of experienced *C. marginiventris* for the combination of two sesquiterpene blends observed in Experiment 2 also could be due to a higher total amount of volatiles, which leads to a stronger response. Previous studies indicate that the quantity of odors can be positively correlated to the attractiveness for different parasitoid species (Vaughn et al., 1996; Hoballah et al., 2002; Turlings et al., 2004; Kugimiya et al., 2010). However, in our work, the abundance of volatiles released in the olfactometer did not appear to influence the choice of the parasitoid (see *Results*, Exp. 2).

The parasitoid wasps used in our experiments did not prefer the TPS10 sesquiterpene mixture that they were trained on over the sesquiterpene mixtures formed by TPS8 and TPS5, although there are no major sesquiterpenes common to the three odors. This suggests that *C. marginiventris* may be attracted by the presence of sesquiterpenes in general, and does not distinguish among individual compounds. A study on *M. croceipes* investigated the ability of this egg parasitoid to distinguish among aliphatic alcohols differing in carbon chain-length and the position of functional groups (Meiners et al., 2002). The results suggested that a difference of at least two C atoms is necessary for wasps to make a choice between two aliphatic alcohols. It is possible that *C. marginiventris*, like *M. croceipes*, does not distinguish among mixtures of sesquiterpene hydrocarbons that all contain 15 carbon atoms, and, therefore, did not choose among the different blends offered, once they had learnt one of them.

The responsiveness of the parasitoids to the odors offered seemed to be low in our experiments, ranging from 25-49% (Figs. 3b, 4c, 5b, 6b). However, a responsiveness of *C. marginiventris* females of 42% was recorded previously by Turlings et al. (2004) in experiments with a six-arm olfactometer. An even lower responsiveness was found by Girling et al. (2006) in Y-tube olfactometer experiments with an aphid parasitoid (*Diaretiella rapae* (M'Intosh) (Hymenoptera: Aphiididae)) and *A. thaliana* plants. In this study, the percentages of parasitoids responding to the odors offered were as low as 22.5%. From this result, the authors concluded that the corresponding odors were not especially attractive to *D.*

rapae. On the other hand, Schnee et al. (2006) reported a responsiveness of 83% in olfactometer experiments with *C. marginiventris* and sesquiterpene-emitting TPS10 *A. thaliana* plants. Such a high responsiveness compared to the one we recorded could be due to the fact that the experiments were performed at different times of the year (Schnee et al. (2006) in spring, the experiments presented here in summer or in winter).

Studies on naïve *C. marginiventris* females that utilize the complete herbivore-induced volatiles of a maize plant demonstrated a responsiveness of up to 80% (D'Alessandro and Turlings, 2005). These high rates of attraction to the complete blend might be due to the fact that this contained one or more volatile compounds not present in our blends that may not have even been identified yet (D'Alessandro and Turlings, 2005; D'Alessandro et al., 2009). To fully understand the importance of volatile compounds in the host finding of *C. marginiventris*, bioassays should be carried out with additional constitutive host volatiles, such as monoterpenes and GLVs. Further tests with other parasitoids with different degrees of host specialization should give even more insight into the relative importance of constitutive vs. herbivore-induced compounds.

Acknowledgments We thank Andreas Weber and the gardeners of the MPICE for plant raising, Yves Borcard for parasitoid rearing, and Syngenta (Stein, Switzerland) for providing *S. littoralis* eggs and diet. We are grateful to Grit Kunert for suggestions on the experimental design, and to Sybille B. Unsicker for comments on earlier versions of the manuscript.

Abstract Herbivores can trigger a wide array of morphological and chemical changes in their host plants. Feeding by some insects induces a defensive hypersensitive response, a defense mechanism consisting of elevated H_2O_2 levels and tissue death at the site of herbivore feeding. The invasive hemlock woolly adelgid *Adelges tsugae* ('HWA') and elongate hemlock scale *Fiorinia externa* ('EHS') feed on eastern hemlocks; although both are sessile sap feeders, HWA causes more damage than EHS. The rapid rate of tree death following HWA infestation has led to the suggestion that feeding induces a hypersensitive response in hemlock trees. We assessed the potential for an herbivore-induced hypersensitive response in eastern hemlocks by measuring H_2O_2 levels in foliage from HWA-infested, EHS-infested, and uninfested trees. Needles with settled HWA or EHS had higher H_2O_2 levels than control needles, suggesting a localized hypersensitive plant response. Needles with no direct contact to settled HWA also had high H_2O_2 levels, suggesting that HWA infestation may induce a systemic defense response in eastern hemlocks. There was no similar systemic defensive response in the EHS treatment. Our results showed that two herbivores in the same feeding guild had dramatically different outcomes on the health of their shared host.

Introduction

The rapid expansion of global trade and transport links has been accompanied by a concomitant increase in the number of invasive species and the threat they pose to native ecosystems (Mooney and Cleland, 2001). As the number of biological invasions increases, the potential for interactions among invasive species will become more likely. Since invasive species tend to have high growth rates and population densities (Sakai et al., 2001), the likelihood and importance of these interactions is great (Denno et al., 1995). Such interactions are especially likely among specialist sessile herbivores that cannot emigrate in response to changes in host quality induced by competing insect species (Karban, 1989).

Herbivores can have differing effects on their host plants if one species, but not another, induces changes in plant physiology. Infestation by one herbivore may lead to the systemic induction of plant defenses and reduce the plant's susceptibility to subsequent invaders (Karban, 1990; Alborn et al., 1996; Bezemer et al., 2003). Some herbivores also are able to directly manipulate host plant metabolism and nitrogen allocation to their benefit, changes that can lead to the induction of systemic effects (Karban and Agrawal, 2002). Herbivores may be particularly harmful to their host if they are capable of inducing a pronounced hypersensitive response (HR). The HR is a plant defense response that increases reactive oxygen species, including hydrogen peroxide (H_2O_2), superoxide anions, and hydroxyl radical levels, and induces cell death in herbivore-damaged areas that isolates and starves invading organisms (Heath,

2000; Liu et al., 2010). Such localized tissue death usually is a response to sessile herbivores (Karban and Baldwin, 1997) and reduces the negative effects of insects such as balsam woolly adelgids, bark beetles, woodwasps, and gall midges (Fernandes, 1990; Ollerstam and Larsson, 2003). The hypersensitive response also defends plants against gall formation by isolating the galling insects (Fernandes and Negreiros, 2001).

The introduced hemlock woolly adelgid (*Adelges tsugae*; HWA) is causing mortality of eastern hemlocks along the east coast of North America (Orwig et al., 2002). A second invasive herbivore, the elongate hemlock scale (*Fiorinia externa*; EHS), also feeds on eastern hemlocks in North America (McClure, 1977). Although both species are sap-sucking insects that are considered pests, they have different impacts on their shared host (Preisser and Elkinton, 2008). In a multi-year experiment, Miller-Pierce et al. (2010) found that infestation with HWA, but not EHS, significantly decreased tree growth. While mature trees infested with HWA can die in as few as 4 years, mortality rarely occurs as a result of EHS infestation (McClure, 1980, 1991). The disproportionate hemlock mortality observed in response to HWA feeding has led to the hypothesis that HWA might have a systemic effect on the plant (Young et al., 1995), resulting in widespread tissue necrosis and tree mortality. We tested this hypothesis by measuring foliar H_2O_2, indicative of a hypersensitive response, in eastern hemlocks that were infested with HWA, EHS, or neither insect. Since plants often respond to sessile herbivores by mounting localized defenses (Fernandes, 1990), we expected both insects to induce a localized response at the site of infestation. We hypothesized that HWA settlement would induce a stronger HR in hemlock than EHS settlement, and that the HWA-induced HR would be detectable even in undamaged tissue (a 'systemic' response). Since a localized HR is marked by H_2O_2 exclusively surrounding the site of feeding, H_2O_2 accumulation in tissues not being directly fed upon would suggest the presence of a magnified HR in HWA-infested trees.

Methods and Materials

Our research took advantage of a pre-existing experimental manipulation intended to assess the long-term responses of hemlock trees to infestation with HWA or EHS (Miller-Pierce et al., 2010). While both projects sampled the same trees, our research question (assessment of an insect-induced hypersensitive response in hemlocks) differed substantially from those addressed in the initial research project (long-term changes in plant growth and C:N ratio in response to HWA and EHS infestation; Miller-Pierce et al., 2010).

Plant Material Hemlock saplings (1–1.5 m in height) were collected in April 2007 from the understory of a hemlock forest in Pelham, Massachusetts, USA. This area was outside the range of both HWA and EHS when the saplings were collected, and the saplings and surrounding trees were inspected prior to removal to ensure the absence of both insects. Saplings were transplanted into a field surrounded by a deer-proof fence at the University of Rhode Island's East Farm (Kingston, RI, USA). They were planted in a grid pattern and randomly assigned to each of 3 experimental treatments: HWA only, EHS only, or control (neither insect). Details of the insect inoculations are contained in Miller-Pierce et al. (2010); briefly, we used standard protocols (Butin et al., 2007) to inoculate saplings in the HWA and EHS treatments with the appropriate insect in May (for HWA) or June (for EHS) of every year from 2007 through 2010. From 2007 to 2008, trees in the HWA and EHS treatments had similar densities (2007–2008 mean: 0.97 and 0.93 insects/cm for HWA and EHS, respectively; Miller-Pierce et al., 2010), but in 2009 trees in the EHS treatment had higher densities (0.3 and 2.3 insects/cm for HWA and EHS, respectively; Miller-Pierce et al., 2010). To prevent contamination between treatments, each tree was caged during the time of year in which crawlers could be dispersed by wind.

In June 2010, we sampled foliage from 7 HWA-infested trees, 6 EHS-infested trees, and 8 uninfested control trees (21 total trees). We harvested four branches from each tree; each branch consisted of a single leader of new growth emerging from a ≥15 cm section of old growth. Each branch was bagged and returned to the lab where we recorded the number of HWA or EHS and the number of needles on the terminal 4 cm of new growth. All sampled branches in the insect treatments had settled HWA or EHS on the old growth. The spring generation of HWA had emerged, but had not yet settled on old growth. Because the new growth on each branch was produced after the first generation of HWA had emerged and begun to settle on old growth and prior to the emergence of EHS, there were no settled insects on any of the new growth; a careful examination of the new growth directly adjacent to the old growth on each branch confirmed that no insects had settled in this area.

Detection of H_2O_2 in Needles Detection of H_2O_2 involved a combination of chemical treatment and image analysis looking for a stain that is present if H_2O_2 is present in the needle. We removed the first two pairs of needles both above and below the base of new growth on each branch, giving 4 old-growth and 4 new-growth needles per branch. A DAB (1 mg ml^{-1} 3,3'-diaminobenzidine) solution was prepared following a protocol modified after Thordal-Christensen et al. (1997). The DAB was dissolved in DMSO (0.002% dimethyl sulfoxide) and then slowly added to water while stirring with a stir bar. Each needle was

placed in a separate 1.5 ml vial containing 1 ml of DAB-DMSO solution. We placed each vial in a bell jar and vacuum infiltrated each needle twice using Tween 20 as the surfactant (Katagiri et al., 2002). The vacuum was run to 26 in Hg and then left to run for 1 min. Following the second infiltration, the vials containing the needles were removed from the jar and allowed to sit in the DAB solution for 2 hr. To decolorize the needles and reveal the reddish-brown DAB polymer if H_2O_2 were present, we placed a cap with a small puncture on each vial and placed them in boiling ethanol (95%) for 10 min once a day for 3 d. Needles were stored in 95% ethanol.

Image Analysis We photographed treated needles using a PixeLink PL-A662 camera attached to an Olympus SZX12 microscope. Each digital image (1280×1020 pixels) was analyzed using Photoshop CS3 (Adobe; San Jose, CA, USA). In each needle, the number of stained pixels (indicative of H_2O_2 presence) was recorded and expressed as a percentage of the total needle area.

Statistical Analysis Response variables were needle area (in mm^2), the proportion of needle area that stained positive for the presence of H_2O_2, and needle density in the terminal 4 cm of new growth foliage. For both needle area and proportion of needle area stained, responses for the between-treatment analyses were calculated using the mean response of old- and new-growth foliage per tree for each treatment (21 replicates per foliage type, 42 total replicates). Because needle density was measured only on new growth foliage, there were 21 replicates in total for this variable. Data were square-root transformed when necessary to meet the assumptions of normality; variances were homogenous between treatments. We used ANOVA to test for the main effects of treatment, foliage age (old vs. new growth), and their interaction. Where appropriate, we performed means separation tests using Tukey's HSD.

Responses for the within-treatment analyses were calculated using the mean response of old- and new-growth foliage per branch per tree for each treatment (4 branches per tree, 28 replicates per foliage type in the HWA treatment, 24 replicates per foliage type in the EHS treatment). We used MANOVA to test for the main effects of insect density, foliage age, and tree, as well as an insect density*foliage age interaction. Statistical analyses were performed using JMP 6.0.2 (SAS Institute 2007).

Results

Between-Treatment Analyses Needles from HWA-infested trees had higher H_2O_2 levels than EHS and control treatments (Fig. 1a; $F_{2,36}=37.9$, $P<0.001$). In the HWA treatment, 25.2±2.30% (SE) of the needle area contained H_2O_2. Mean H_2O_2 levels in the EHS and control treatments were substantially lower (10.6±2.50% and 6.9±2.15% of total needle area, respectively).

Across all treatments, old-growth (infested) needles had higher H_20_2 levels than new-growth needles (18.5±2.44% and 9.4±1.91%, respectively; $F_{1,36}=30.9$, $P<0.001$). There was also a significant treatment*foliage age interaction ($F_{2,36}=3.34$, $P=0.047$). On old-growth foliage, both HWA and EHS showed an increase in H_2O_2 levels relative to the control (Tukey's HSD at $P=0.05$; Fig. 1a). On new-growth foliage, however, only trees in the HWA treatment showed increased H_2O_2 levels (Tukey's HSD at $P=0.05$; Fig. 1a).

Although there were no between-treatment differences in needle density ($F_{2,18}=0.33$, $P=0.72$), overall needle size differed between treatments (Fig. 1b; $F_{2,36}=4.03$, $P<0.026$). Needles in the control treatment were significantly larger than needles in the EHS treatment (13.52±0.61 mm^2 and 10.98±0.70 mm^2, respectively; Tukey's HSD at $P=0.05$). Needles in the HWA treatment averaged 11.81±0.65 mm^2 and did not differ from the control (Tukey's HSD at $P=0.05$).

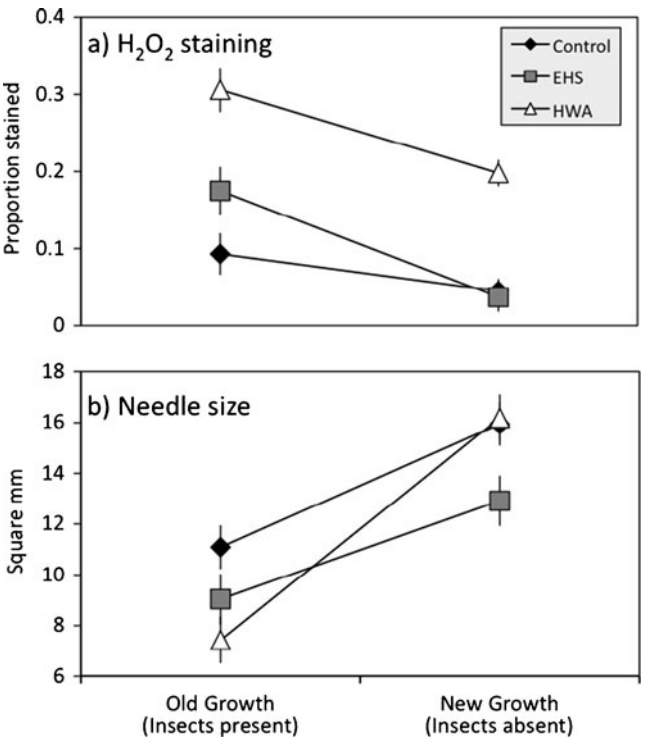

Fig. 1 Response of old-growth needles (herbivores present in hemlock woolly adelgid, 'HWA', and elongate hemlock scale, 'EHS', treatments) and new-growth needles (herbivores absent in all treatments) to infestation with HWA, EHS, or neither herbivore. Top panel (A): Proportion of needle area stained with DAB polymer, an indicator of H_2O_2. Bottom panel (B): Needle area (mm^2). Control treatment: Black diamonds, HWA present: White triangles, EHS present: Gray squares

Age had an effect on needle size ($F_{1,36}$=59.4, P<0.001). Across all treatments, old-growth needles were significantly smaller than new-growth needles (9.28±0.53 mm^2 and 15.16±0.53 mm^2, respectively). There was also a significant treatment*foliage age interaction ($F_{2,36}$=3.82, P=0.031; Fig. 1b). The proportional increase in needle size from old- to new-growth was similar in the control and EHS treatments, but not in the HWA treatment. Although old-growth needles in the HWA treatment were 33% smaller than old-growth control needles, new-growth needles in the HWA treatment were 1.5% larger than control new-growth needles (Fig. 1b).

Within-Treatment Analyses There was a positive correlation between HWA density and H_2O_2 levels ($F_{1,46}$=16.8, P<0.001; Fig. 2a). In contrast, there was no correlation between EHS density and H_2O_2 levels ($F_{1,39}$=0.56, P=0.46; Fig. 2b).

Although there was no correlation between HWA density and needle size ($F_{1,46}$=0.11, P=0.74), there was a positive correlation between EHS density and needle size ($F_{1,39}$=9.52, P=0.004). There was no relationship between insect density and needle density in either the HWA or EHS treatments (HWA: $F_{1,25}$=1.06, P=0.31; EHS: $F_{1,21}$=1.22, P=0.28).

Discussion

Our research showed that invasive herbivores with similar feeding modes can have very different effects on their shared host plant. Infestation by both hemlock woolly adelgid (HWA) and elongate hemlock scale (EHS) increased H_2O_2 levels relative to control hemlock needles, suggesting the presence of a localized hypersensitive response ('HR'; Fig. 1a). Although both insects induced a localized HR, needles with settled HWA at the base responded more strongly to insect settlement. After a year of HWA feeding, these old growth needles contained more H_2O_2 and were smaller than needles in the EHS or control treatments (Fig. 1b). The presence of HWA, but not EHS, also induced H_2O_2 accumulation in new growth needles that had no direct contact to feeding insects. Furthermore, HWA density on old growth needles was positively correlated with H_2O_2 accumulation in new growth needles (Fig. 2a), while EHS feeding was not (Fig. 2b). Since the HR is associated with cell death, the induction of a systemic hypersensitive response by HWA may partially explain why HWA causes more damage than EHS to eastern hemlocks.

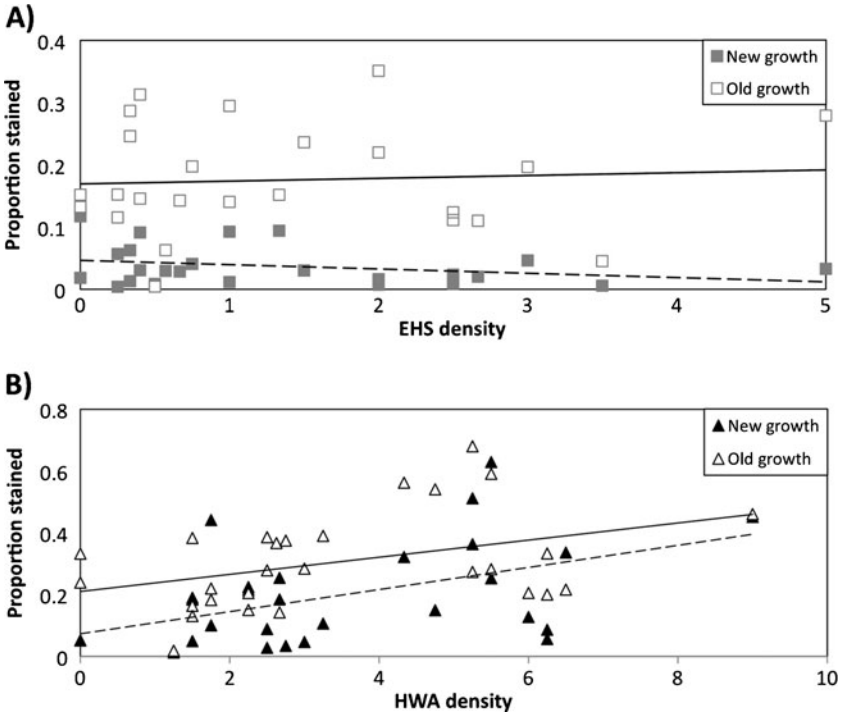

Fig. 2 Within-treatment correlation between settled insect density (either hemlock woolly adelgid, 'HWA', or elongate hemlock scale, 'EHS') on old-growth foliage and proportion of needle stained with DAB polymer. Top panel (A): Correlation between EHS densities on old-growth foliage and proportion of needle stained with DAB polymer. Old-growth needles: Open gray squares, New-growth needles: Closed gray squares. Old-growth correlation: Solid line ($F_{1,22}$=0.097, P=0.76), New-growth correlation: Dotted line ($F_{1,22}$=1.8, P=0.19). Bottom panel (B): Correlation between HWA densities on old-growth foliage and proportion stained with DAB polymer. Old-growth needles: Open black triangles, New-growth needles: Closed black triangles. Old-growth correlation: Solid line ($F_{1,26}$=4.83, P=0.37), New-growth correlation: Dotted line ($F_{1,26}$=7.91, P=0.009)

There are several possible explanations for the systemic effect of HWA settlement. Since measurements were made in old and new growth on the same branch, one possibility is that the H_2O_2 was produced in high quantities locally and spilled over into new growth foliage. The overproduction of defensive compounds could have been elicited by the mechanical damage caused by HWA stylet bundle insertion. This may be due to the slightly different feeding modes of the two insects. HWA settles on the petiole of the needle and feeds upon the xylem ray parenchyma cells, which function in nutrient storage (Young et al., 1995). In contrast, EHS settles on the underside of the needle and feeds upon mesophyll cells (McClure, 1980). Another possibility is that the defense compounds were elicited by some other factor related to HWA feeding (Young et al., 1995), as has been seen in several aphid species (Miles, 1999). Certain constituents in HWA saliva may be toxic at high levels of infestation, causing the hemlocks to initiate a defensive HR and produce large quantities of H_2O_2 that are carried into new growth tissues. Continued feeding by subsequent generations of HWA is common, as HWA has two generations while EHS has only one, and persistently high levels of H_2O_2 may lead to the suppression of bud formation after several years of HWA feeding (McClure, 1991).

The HWA-induced H_2O_2 also could have been produced in new growth needles *de novo* as a result of a magnified HR that extended even to tissues without settled herbivores. In order to be effective, a systemic response should provide systemic induced resistance to further herbivore attack. For example, Moore et al. (2003) found that increases in cell-wall peroxidase in *Rumex obtusifolius* reduce the amount of future herbivore damage by strengthening cell walls. A systemic hypersensitive response in response to pathogen infection and wounding has been found in several other plants (Alvarez et al., 1998; Orozco-Cardenas and Ryan, 1999), and Alvarez et al. (1998) suggested that the H_2O_2 was generated systemically and may function in induced immunity. Hemlocks mounting a successful systemic response could provide new growth needles with more protection from sessile herbivores. The widespread mortality of eastern hemlocks suggests, however, that this response does not provide adequate protection from HWA. Bonello et al. (2006) proposed that if an invader can persist despite local defenses, the plant will become increasingly stressed by the cost of defense and will become susceptible to future attack. Since high HWA densities induce a magnified HR in infested tissues, a defensive response that would otherwise be beneficial could become costly and lethal to the host plant (Bi and Felton, 1995).

Data on needle size also demonstrate that these herbivores also have different effects on plant morphology. Although old growth HWA needles were the smallest, new-growth needles on HWA-infested branches were as large as controls (Fig. 1b). EHS and control needle size increased at the same rate from old to new growth, while HWA needle size increased at a much greater rate. The increase in needle size could be a result of mobilization of plant nutrients away from stressed older needles and into new growth. A review by Trumble et al. (1993) outlines similar results in other plants, in which leaves remaining after herbivore defoliation become larger in length and weight. This hypothesis is supported by research exploring the amino acid profile of HWA- or EHS-infested vs. uninfested hemlocks that found higher amino acid levels in new-growth needles on HWA-infested trees relative to new-growth needles on EHS-infested trees (Gomez et al. unpublished data). Remobilization of nutrients away from herbivore feeding and the site of damage may be a strategy to tolerate insect infestation (Gómez et al., 2010). Because the summer generation of HWA feeds almost exclusively on new growth tissue, HWA may benefit from the production of these nutrient-rich new-growth needles. While additional research is necessary to determine the precise mechanism(s) underlying our findings, at a broader level the work illustrates that species-specific differences in herbivore feeding can substantially affect plant responses to biological invasions.

Abstract We synthesized 23 6-alkoxycoumarin derivatives, 20 of which are novel compounds. The structures of all compounds were confirmed by NMR, MS, and elemental analysis, and their antifeedant and termiticidal activities against *Coptotermes formosanus* Shiraki were examined. In a no-choice test, 6-(2-pentynyloxy)coumarin (**2v**), 6-(2-butynyloxy)coumarin (**2u**), 6-(2-octynyloxy) coumarin (**2w**), and 6-methoxycoumarin (**2a**), demonstrated high termiticidal activity at a concentration of 10 μmol. At a concentration of 5 μmol, 6-(2-butynyloxy)coumarin (**2u**) produced the highest mortality among the compounds tested. On the other hand, all of the 6-alkoxycoumarins showed antifeedant activity at both concentrations, except 6-octadecyloxycoumarin (**2j**) that was inactive at 5 μmol. Among the 23 compounds and the control, 6-ethoxycoumarin (**2b**), 6-isopropoxycoumarin (**2d**), and 6-isobutoxycoumarin (**2f**) exhibited the highest antifeedant activity with no mass loss (0.00%) at a concentration of 10 μmol. Our findings indicate that the presence of alkenyloxy and alkynyloxy groups was important for the termiticidal activity, while the incorporation of alkoxy groups with longer alkyl chains tended to reduce both the termiticidal and antifeedant activities. Furthermore, short chain alkoxy and arylalkoxy-substituted analogs showed good antifeedant activity, but methoxy groups on the benzene ring had a negative effect.

Key Words 6-alkoxycoumarins · *Coptotermes formosanus* Shiraki · 6-(2-pentynyloxy)coumarin · 6-isobutoxycoumarin · Antifeedant · Termiticidal

Introduction

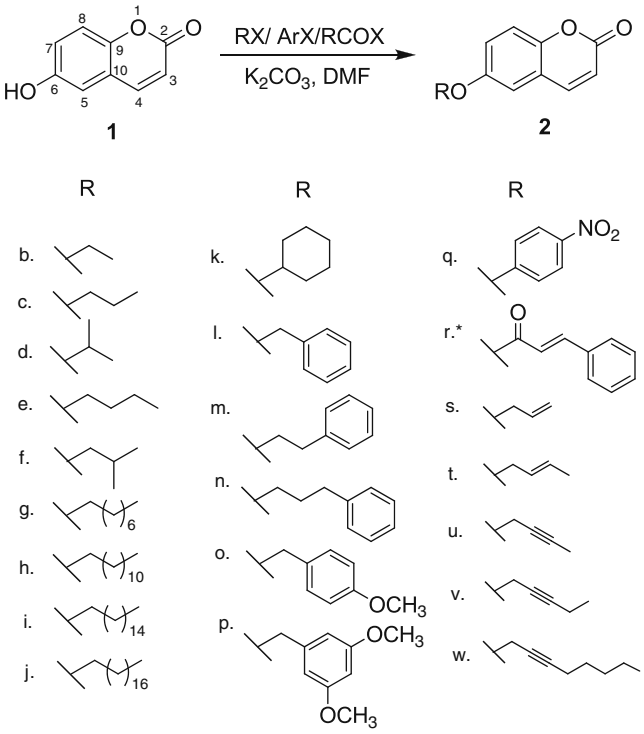
Coptotermes formosanus Shiraki is a subterranean termite responsible for major destruction of wooden materials. The diet of *C. formosanus* consists of anything that contains wood fiber, including residential and commercial structures and live plants (Meyer, 2005). Chemical treatments are the most important and widely used methods to reduce the infestation of termites. Several termiticides containing active ingredients, including bifenthrin, chlorfenapyr, cypermethrin, fipronil, imidacloprid, and permethrin are registered for termite control around the world under various brand names (Verma et al., 2009).

Environmental and health problems related to the use of synthetic insecticides have increased the need for less toxic and more environmentally friendly insect control substances. New methods for termite control are being developed continually by researchers. Plant-derived natural products, entomopathogenic fungi (Krutmuang and Mekchay, 2005; Mo et al., 2006), bacteria (Devi et al., 2007), nematodes (Weeks and Baker, 2004), physical barriers, and bait technology (Culliney and Grace, 2000; Evans and Gleeson, 2006; Verma et al., 2009) are some of the alternative methods. The use of botanicals as termiticides, termite

antifeedants, or termite repellents has been reported, and these include several quinones (plumbagin, isodiospyrin, and microphyllone) from *Diospyros sylvatica* (Ganapaty et al., 2004), flavonoids (castillen D and castillen E) from *Lonchocarpus castilloi* Standley (Reyes-Chilpa et al., 1995), limonoids (deacetylgedunin, gedunin, salanin, nimbandiol, azadiradione, and deacetylsalannin) from *Azadirachta indica* A. Juss. (Serit et al., 1992), and sesquiterpenes (sugikurojinols A and B) from the black heartwood of *Cryptomeria japonica* D. Don. (Arihara et al., 2004).

The relationship between chemical structure and antitermite activity for some of these active compounds has been investigated. For example, a study of latifolin and its derivatives suggested that the phenolic hydroxyl group at the C-5 position of the A ring is responsible for the termiticidal and antifeedant activities (Sekine et al., 2009). The termite antifeedant activity of some flavonoids (quercetin, taxifolin, and naringenin) also was influenced by the position of hydroxyl groups (Ohmura et al., 2000). Furthermore, Zhu et al. (2003) evaluated the repellency of eight valencenoid derivatives against *C. formosanus*, and they found that 1,10-dihydronootkatone was the most potent. The results showed that the ketone group at the 2-position of these valencenoid analogs was important for termite repellency. Recently, we confirmed the structure–activity relationship (SAR) of coumarin derivatives with antitermite activity (Adfa et al., 2010b). Coumarin and its derivatives were found to exhibit a broad spectrum of biological and pharmacological activities, such as molluscicidal (Schönberg and Latif, 1954), nematicidal (Takaishi et al., 2008), rodenticidal (Ishizuka et al., 2008), insecticidal, and antihelmintic properties (Soine, 1964). They also have exhibited anticoagulant, antibacterial, antioxidant, anti-inflammatory, and anti-cancer effects (Murray et al., 1982).

Our previous paper investigated the SAR of methoxy and hydroxy groups at C-6 and C-7 positions of the coumarin skeleton on termiticidal and antifeedant activities against *C. formosanus*. Scopoletin, isolated from *Protium javanicum* Burm. f. contains an OCH_3 and an OH group at C-6 and C-7 positions, respectively. Scopoletin exhibited the strongest termiticidal and antifeedant activities among the 10 compounds tested, followed by 6-methoxycoumarin, 6-hydroxycoumarin, and 7-hydroxycoumarin. The other compounds showed only weak or moderate activities. These results suggested that the methoxy or hydroxy groups at the C-6 and/or C-7 positions of the coumarin skeleton are important for termiticidal and antifeedant activities (Adfa et al., 2010b). To identify molecules with greater activity, we continued this study, investigating the effect of various substitutions on the oxygen at the C-6 position of the coumarin skeleton on antitermite activity. In this paper, we report the synthesis of 6-alkoxycoumarin analogs (**2a**–**2w**) and their antitermite properties against *C. formosanus*.



Methods and Materials

General Experimental Procedures ^{1}H and ^{13}C-NMR spectra were recorded on a JOEL ECA 600/400 spectrometer with tetramethylsilane (TMS) as an internal standard. Mass spectra were recorded using a JOEL JMS-700/GI mass spectrometer. Column chromatography was performed on a neutral silica gel (Silica Gel 60N, spherical, neutral, 40–50 μm) (KANTO Chemical Co., Inc.). Melting points were determined on a Yanagimoto micro melting-point apparatus. Elemental analyses were determined on a YANAKO MTA-620. All chemicals were purchased from Sigma-Aldrich and Tokyo Chemical Industry Co., Ltd.

Synthesis Procedure and Spectral Data of 6-Alkoxycoumarins and Related Analogs A mixture of 6-hydroxycoumarin (**1**) (30 mg, 0.19 mmol), alkyl, aryl, or acyl halide (0.38 mmol), and potassium carbonate (79 mg, 0.57 mmol) in DMF (5.0 ml) was stirred at 55–85°C for times ranging from 0.5 h to overnight (Table 1). The reaction mixture was extracted with ethyl acetate, and the combined extracts were washed with water. The organic layer was dried over sodium sulfate and evaporated to dryness. The residue then was purified by column chromatography on silica gel with *n*-hexane/ethyl acetate (7:3) to yield the products (**2b**–**2q**, **2s**–**2w**). Instead of K_2CO_3, Et_3N (79 μl, 0.57 mmol) and DMAP (23.2 mg, 0.19 mmol) were used for the preparation of **2r** at 80°C for 1 h (Scheme 1 and Table 1). 6-Methoxycoumarin (**2a**) was synthesized according to the previous report (Adfa et al., 2010b).

6-Ethoxycoumarin (**2b**), colorless crystals, mp. 108°C (97% yield): ^{1}H-NMR (600 MHz, $CDCl_3$): δ 1.44 (3H, t, *J*= 6.9 Hz, H-2'), 4.06 (2H, q, *J*=6.9 Hz, H-1'), 6.42 (1H, d, *J*= 9.6 Hz, H-3), 6.91 (1H, d, *J*=2.7 Hz, H-5), 7.10 (1H, dd, *J*= 8.9 and 2.7 Hz, H-7), 7.26 (1H, d, *J*=8.9 Hz, H-8), 7.65 (1H, d, *J*=9.6 Hz, H-4); ^{13}C-NMR (150 MHz, $CDCl_3$): δ 14.9 (C-2'), 64.3 (C-1'), 110.8 (C-5), 117.1 (C-3), 118.0 (C-8), 119.3 (C-10), 120.0 (C-7), 143.4 (C-4), 148.5 (C-9), 155.5 (C-6), 161.2 (C-2); FAB-MS m/z: 191 $[M+H]^+$ (matrix: mixture of dithiothreitol and dithioerythritol 3:1); Anal. Calcd for $C_{11}H_{10}O_3$: C, 69.49; H, 5.30. Found: C, 69.20; H, 5.56.

6-Propoxycoumarin (**2c**), colorless crystals, mp. 75°C (97% yield): ^{1}H-NMR (600 MHz, $CDCl_3$): δ 1.06 (3H, t, *J*=7.6 Hz, H-3'), 1.81–1.86 (2H, m, H-2'), 3.94 (2H, t, *J*= 6.9 Hz, H-1'), 6.42 (1H, d, *J*=9.6 Hz, H-3), 6.91 (1H, d, *J*= 2.8 Hz, H-5), 7.11 (1H, dd, *J*=8.9 and 2.8 Hz, H-7), 7.26 (1H, d, *J*=8.9 Hz, H-8), 7.65 (1H, d, *J*=9.6 Hz, H-4); ^{13}C-NMR (150 MHz, $CDCl_3$): δ 9.6 (C-3'), 21.6 (C-2'), 69.4 (C-1'), 109.9 (C-5), 116.1 (C-3), 116.9 (C-8), 118.3 (C-10), 119.1 (C-7), 142.4 (C-4), 147.4 (C-9), 154.8 (C-6), 160.2 (C-2); FAB-MS m/z: 205 $[M+H]^+$ (matrix: mixture of dithiothreitol and dithioerythritol 3:1); Anal. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92. Found: C, 70.85; H, 6.25.

Scheme 1 Synthesis of 6-alkoxycoumarins and related analogs (**2b**–**2w**)

6-Isopropoxycoumarin (**2d**), colorless crystals, mp. 57°C (88% yield): ^{1}H-NMR (600 MHz, $CDCl_3$): δ 1.36 (6H (2 CH_3), d, *J*=6.2 Hz, H-2' and H-3'), 4.52–4.58 (1H, m, H-1'), 6.42 (1H, d, *J*=9.6 Hz, H-3), 6.93 (1H, d, *J*=2.8 Hz, H-5), 7.09 (1H, dd, *J*=8.9 and 2.8 Hz, H-7), 7.25 (1H, d, *J*=8.9 Hz, H-8), 7.65 (1H, d, *J*=9.6 Hz, H-4); ^{13}C-NMR (150 MHz, $CDCl_3$): δ 20.0 (C-2' and C-3'), 71.1 (C-1'), 112.8 (C-5), 117.1 (C-3), 118.0 (C-8), 119.4 (C-10), 121.3 (C-7), 143.4 (C-4), 148.4 (C-9), 154.4 (C-6), 161.2 (C-2); FAB-MS m/z: 205 $[M+H]^+$(matrix: mixture of dithiothreitol and dithioerythritol 3:1); Anal. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92. Found: C, 70.42; H, 6.20.

6-Butoxycoumarin (**2e**), colorless crystals, mp. 99°C (99% yield): ^{1}H-NMR (600 MHz, $CDCl_3$): δ 0.99 (3H, t, *J*=7.6 Hz, H-4'), 1.48–1.54 (2H, m, H-3'), 1.79 (2H, quint., *J*=7.6 Hz, H-2'), 3.98 (2H, t, *J*=6.8 Hz, H-1'), 6.42 (1H, d, *J*=9.6 Hz, H-3), 6.91 (1H, d, *J*=2.8 Hz, H-5), 7.10 (1H, dd, *J*=8.9 and 2.8 Hz, H-7), 7.25 (1H, d, *J*=8.9 Hz, H-8),7.65 (1H, d, *J*=9.6 Hz, H-4); ^{13}C-NMR (150 MHz, $CDCl_3$): δ 13.9 (C-4'), 19.3 (C-3'), 31.3 (C-2'), 68.6 (C-1'), 110.8 (C-5), 117.1 (C-3), 118.0 (C-8), 119.3 (C-10), 120.1 (C-7), 143.4 (C-4), 148.4 (C-9), 155.8 (C-6), 161.2 (C-2); FAB-MS m/z: 219 $[M+H]^+$ (matrix: mixture of dithiothreitol and dithioerythritol 3:1); Anal. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47. Found: C, 71.67; H, 6.76.

6-Isobutoxycoumarin (**2f**), colorless crystals, mp. 46–47°C (88% yield): ^{1}H-NMR (600 MHz, $CDCl_3$): δ 1.04 (6H (2CH_3), d, *J*=6.8 Hz, H-3' and H-4'), 2.07–2.14 (1H, m, H-2'), 3.74 (2H, d, *J*=6.2 Hz, H-1'), 6.42 (1H, d, *J*=9.6 Hz, H-3), 6.91 (1H, d, *J*=2.8 Hz, H-5), 7.11 (1H, dd, *J*=8.9 and 2.8 Hz, H-7), 7.25 (1H, d, *J*=8.9 Hz, H-8), 7.65 (1H, d, *J*=9.6 Hz, H-4); ^{13}C-NMR (150 MHz, $CDCl_3$): δ 19.3 (C-3' and C-4'), 28.4 (C-2'), 75.2 (C-1'), 110.8 (C-5), 117.1 (C-8), 117.9 (C-3), 119.2 (C-10), 120.1 (C-7), 143.4 (C-4), 148.4 (C-9), 155.8 (C-6), 161.2 (C-2); Anal. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47. Found: C, 71.31; H, 6.63.

6-Octyloxycoumarin (**2g**), colorless crystals, mp. 60°C (98% yield): ^{1}H-NMR (400 MHz, $CDCl_3$): δ 0.89 (3H, t, *J*=6.9 Hz, H-8'), 1.19–1.41 (8H, br, H-4'–H-7'), 1.41–1.52 (2H, m, H-3'), 1.72–1.86 (2H, m, H-2'), 3.97 (2H, t, *J*=6.9 Hz, H-1'), 6.42 (1H, d, *J*=9.6 Hz, H-3), 6.91 (1H, d, *J*=2.8 Hz, H-5), 7.10 (1H, dd, *J*=8.9 and 2.8 Hz, H-7), 7.25 (1H, d, *J*=8.9 Hz, H-8), 7.65 (1H, d, *J*=9.6 Hz, H-4); ^{13}C-NMR (100 MHz, $CDCl_3$): δ 14.2 (C-8'), 22.7 (C-7'), 26.1 (C-3'), 29.26 (C-5'), 29.32 (C-4'), 29.42 (C-2'), 31.9 (C-6'), 68.8 (C-1'), 110.8 (C-5), 117.0 (C-3), 117.9 (C-8), 119.2 (C-10), 120.0 (C-7), 143.4 (C-4), 148.4 (C-9), 155.7 (C-6), 161.2 (C-2); FAB-MS m/z: 275 $[M+H]^+$(matrix: m-nitrobenzyl alcohol); HRFABMS m/z: 275.1629 $[M+H]^+$ (calcd for $C_{17}H_{23}O_3$, 275.1647, matrix: PEG 400); Anal.

Table 1 Reaction conditions and yields of 6-alkoxycoumarins and related analogs (**2b**–**2w**)

Entry	R	Reaction conditions	Yield (%) **2**
1.	Ethyl	55°C, overnight	97 (**2b**)
2.	*n*-Propyl	80°C, 8 hr	97 (**2c**)

Termites Workers and soldiers of *C. formosanus* Shiraki were obtained from a laboratory colony maintained at 28°C±2 and >85% Relative Humidity (RH) at the Deterioration Organisms Laboratory of the Research Institute for Sustainable Humanosphere (RISH), Kyoto University, Japan.

Termiticidal and Antifeedant Tests A no-choice test was employed for evaluating termiticidal and antifeedant activities (Adfa et al., 2010b). Each solution of the 6-substituted coumarin analogs **2a**–**2w** (5 μmol and 10 μmol) was dissolved in 0.05 ml chloroform and applied to paper discs (1.5 mm thick, 8 mm diam and average mass 30 mg, Advantec, Tokyo-Japan); the paper discs were dried overnight in a vacuum desiccator. Subsequently, each disc was placed on a plastic spacer in an acrylic resin cylinder with a plaster bottom (80 mm diam×60 mm in height), and 33 active termites (30 workers and three soldiers) were added to each cylinder. The cylinders were placed on a cotton sheet in a plastic tray and kept in a dark incubator at 28°C±2 and 80%±5 RH. Paper discs treated only with chloroform were used as a control. Three replications were performed for each sample.

Termite Bioassay Data Analysis The number of dead termites was counted daily for 2 weeks. Paper disc consumption by the termites was measured at the end of the test. Mass loss of the paper discs was determined by subtracting the vacuum-dried weight at the end of the test from that before the start of the test. Cumulative daily mortality and consumption (mean and standard deviation) were calculated from the three replicates of each treatment.

Statistical Analysis Tukey's multiple comparison test was used to evaluate differences in percent mortality and mass loss in antitermite activities. Results with $P<0.05$ were considered significant. Calculations were performed using statistical software (XLSTAT, Addinsoft, New York, USA).

Results and Discussion

Synthesis of 6-Alkoxycoumarins and Related Analogs 6-Methoxycoumarin (**2a**) was synthesized according to a previous report (Adfa et al., 2010b). The remaining 22 coumarin analogs (**2b**–**2w**) were synthesized from the commercially available 6-hydroxycoumarin (**1**) by treatment with various alkyl/aryl/acyl halides and potassium carbonate in DMF using different reaction conditions (Scheme 1, Table 1). The corresponding products were obtained in good to high yields (62–99%), with the exception of product **2k** that was acquired in moderate yield (41%). The preparation of **2r** failed under the standard conditions (K_2CO_3, DMF, 80°C). However, when Et_3N and DMAP were used instead of K_2CO_3, **2r** was obtained in 93% yield (Table 1). Of the analogs prepared and tested, 20 compounds are novel. Exceptions are 6-benzyloxycoumarin (**2l**) and 6-allyloxycoumarin (**2s**), which were reported earlier by Shah and Trivedi (1975), and Durst et al. (2007). All compounds were characterized by ^{1}H-NMR, ^{13}C-NMR, MS, and elemental analysis; additionally, the structure of compound **2l** was determined by X-ray crystallography (Adfa et al., 2010a). To summarize, we synthesized 23 compounds and tested them for antifeedant and termiticidal activities against *C. formosanus*.

Termiticidal Activity of 6-Alkoxycoumarins and Related Analogs Against C. formosanus Shiraki The mortality of *C. formosanus* exposed to 6-alkoxycoumarins and related analogs (**2a**–**2w**) was determined daily for two weeks. The results are summarized in Figs. 1 and 2. Among the 23 coumarin derivatives, eight compounds (**2a**, **2f**, **2m**, **2o**, **2s**, **2t**, **2u**, **2v**, and **2w**) demonstrated termite mortalities that were significantly higher than that of the control at concentrations of 5 and 10 μmol (Table 2). Compound (**2u**) 6-(2-Butynyloxy)coumarin showed the highest termite mortality (58.59%) at a concentration of 5 μmol (Fig. 1). At a concentration of 10 μmol, 6-(2-pentynyloxy)coumarin (**2v**) exhibited the strongest mortality (74.75%), followed consecutively by 6-(2-butynyloxy)coumarin (**2u**) (52.53%), 6-(2-octynyloxy)coumarin (**2w**) (44.44%), and 6-

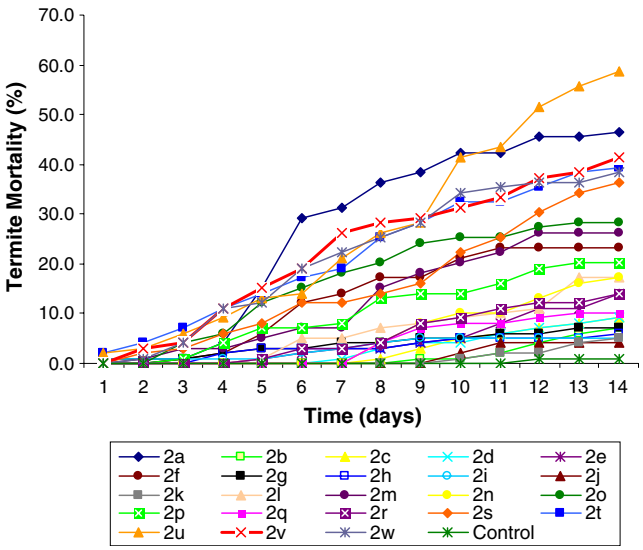

Fig. 1 Termite mortalities (%) of 6-alkoxycoumarins and related analogs (**2a**–**2w**) against *Coptotermes formosanus* Shiraki in no-choice test at concentration of 5 μmol. Each experiment was performed in triplicate. Thirty-three termites were used per replication and the data was averaged (N=3)

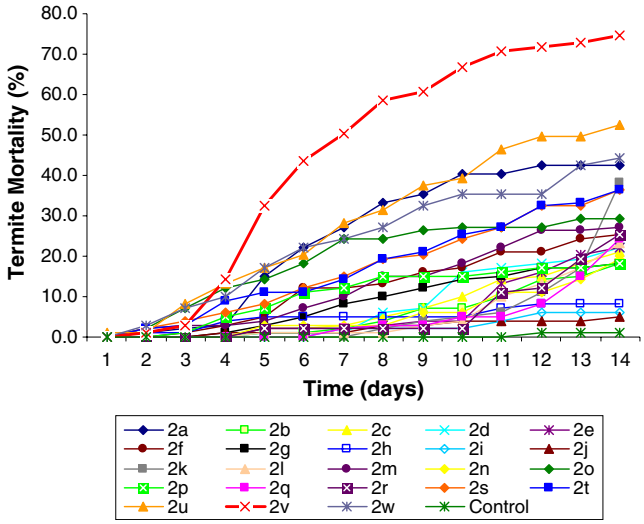

Fig. 2 Termite mortalities (%) of 6-alkoxycoumarins and related analogs (**2a**–**2w**) against *Coptotermes formosanus* Shiraki in no-choice test at concentration of 10 μmol. Each experiment was performed in triplicate. Thirty-three termites were used per replication and the data was averaged (N=3)

methoxycoumarin (**2a**) (42.42%). Termite mortality with **2v** at a concentration of 10 μmol was 1.8 times higher than that at 5 μmol, while the mortalities of **2a** and **2u** at 10 μmol showed a slight decrease compared to that at 5 μmol concentration, but the difference was not statistically significant. However, different patterns of mortality were observed; the mortality of **2v** at 10 μmol started to increase sharply after four days, while the mortalities of **2a** and **2u** showed a more steady increase (Fig. 2).

Four additional analogs, 6-Cyclohexyloxycoumarin (**2k**), 6-benzyloxycoumarin (**2l**), 6-(4-nitrophenoxy)coumarin (**2q**), and 6-cinnamoyloxycoumarin (**2r**) yielded termite mortalities that were significantly higher than that of the control at a concentration of 10 μmol. Interestingly, termite mortality with **2k** at 10 μmol increased sharply after 11 days and showed an eight-fold gain compared with the 5 μmol concentration (Fig. 2). The least active analogs were 6-ethoxycoumarin (**2b**), 6-propoxycoumarin (**2c**), 6-isopropoxycoumarin (**2d**), 6-butoxycoumarin (**2e**), 6-octyloxycoumarin (**2g**), 6-dodecyloxycoumarin (**2h**), 6-

Table 2 Statistical analysis of termiticidal activity of 6-alkoxycoumarin and related analogs

Compound	Mortalities of termite (%) after 2 weeks	
	[5 μmol]	[10 μmol]
6-Methoxycoumarin (**2a**)	$46.46\pm7.6^{b, c, d}$	$42.42\pm8.0^{b, c, d, e, f}$
6-Ethoxycoumarin (**2b**)	$7.07\pm4.6^{k, l, m, n, o}$	$18.18\pm3.0^{h, i, j, k, l, m, n, o}$
6-Propoxycoumarin (**2c**)	$9.09\pm3.0^{j, k, l, m, n, o}$	$21.21\pm3.0^{f, g, h, i, j, k, l, m, n, o}$

6-(2-Pentynyloxy)coumarin (**2v**)	$41.41\pm4.6^{b, c, d, e, f, g}$	74.75 ± 7.6^{a}
6-(2-Octynyloxy)coumarin (**2w**)	$38.38\pm9.7^{b, c, d, e, f, g, h, i}$	$44.44\pm3.5^{b, c, d, e}$
Control	0.01 ± 1.7^{o}	

Data are given as mean ± standard deviation of triplicate tests (N=3). Numbers followed by different letters (a–o) are significantly different at the level of $P<0.05$ according to Tukey's multiple comparison test

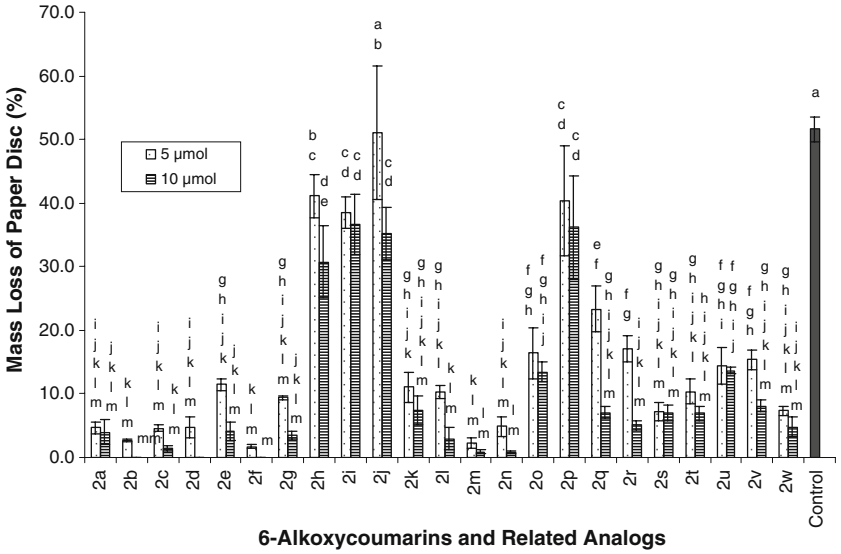

Fig. 3 Paper disc consumption by *Coptotermes formosanus* Shiraki after 14 d exposure to 6-alkoxycoumarins and related analogs (**2a**–**2w**) in no-choice test. Each experiment was performed in triplicate. Thirty-three termites were used per replication and the data were averaged (N=3). *Different letters* (a–m) indicate significant difference (Tukey's multiple comparison test; P<0.05). *Error bars* represent standard deviations

hexadecyloxycoumarin (**2i**), 6-octadecyloxycoumarin (**2j**), 6-(3-phenylpropoxy)coumarin (**2n**), and 6-(3,5-dimethoxybenzyloxy)coumarin (**2p**), which demonstrated no significant difference from the control at either concentration. In general, the presence of alkynoxy and alkenoxy groups was found to be important for the termiticidal activity. Furthermore, the existence of alkoxy groups with a longer alkyl chain tended to decrease the activity.

Antifeedant Activity of 6-Alkoxycoumarins and Related Analogs Against C. formosanus Shiraki Paper disc consumption by the termites after 14 days exposure to the 6-alkoxycoumarins and related analogs (**2a**–**2w**) was compared to that of the control, and the average mass losses for the 23 compounds are shown in Fig. 3. At both concentrations, all analogs showed antifeedant activity, with the exception of 6-octadecyloxycoumarin (**2j**) that had a 51.12% mass loss of the paper disc at a concentration of 5 µmol, essentially the same as that of the control. Considering both concentrations, this compound exhibited the lowest antifeedant activity with a higher average mass loss than that exhibited by other compounds. Compound (**2f**) 6-isobutoxycoumarin elicited the lowest average mass loss at a concentration of 5 µmol (1.65%), showing a significantly greater reduction in feeding activity compared to the control (51.61%), but no significant difference was observed between **2f** and 13 other compounds (**2a** 4.69%, **2b** 2.71%, **2c** 4.62%, **2d** 4.72%, **2e** 11.47%, **2g** 9.37%, **2k** 11.10%, **2l** 10.25%, **2m** 2.28%, **2n** 4.86%, **2s** 7.27%, **2t** 10.35%, and **2w** 7.35%) at the same concentration (Tukey's multiple comparison test). At a concentration of 10 µmol, 6-ethoxycoumarin (**2b**), 6-isopropoxycoumarin (**2d**), and 6-isobutoxycoumarin (**2f**) exhibited the strongest antifeedant activity with no mass loss (0.00%) of the paper disc. However, in the statistical analysis, no significant difference was observed between these analogs and 14 other compounds (**2a** 3.98%, **2c** 1.48%, **2e** 4.02%, **2g** 3.51%, **2k** 7.48%, **2l** 2.98%, **2m** 0.91%, **2n** 0.80%, **2q** 7.09%, **2r** 5.09%, **2s** 7.03%, **2t** 6.90%, **2v** 8.10%, and **2w** 4.81%). The results suggested that 6-alkoxycoumarins having a short alkyl chain (methyl–octyl) showed high antifeedant activity, while increasing the length of the alkyl chain (dodecyl, hexadecyl, and octadecyl) led to a sharp decrease in activity. The presence of arylalkoxy groups was important for antifeedant activity, but methoxy substitution on the benzene ring was a disadvantage. In addition, the existence of alkynoxy and alkenoxy led to analogs with good activity.

In summary, we synthesized and tested a number of 6-alkoxycoumarins and related analogs, and showed effective termiticidal and antifeedant activities against *C. formosanus*. SAR studies summarized the key features that are important for activities and demonstrated the potential of 6-alkoxycoumarin derivatives to be used as termite control agents.

Ecosystem, Location, and Climate Effects on Foliar Secondary Metabolites of Lodgepole Pine Populations from Central British Columbia

Abstract Lodgepole pines, *Pinus contorta* Douglas ex Louden var. *latifolia* Engelm. ex S. Watson, are encountering increased abiotic stress and pest activity due to recent increases in temperature and changes in precipitation throughout their range. This tree species counters these threats by producing secondary metabolites, including phenolics and terpenoids. We examined foliar levels of lignin, soluble phenolics, monoterpenoids, sesquiterpenoids, and diterpenoids in 12 stands in British Columbia, Canada. We used these data to assess associations among foliar secondary metabolite levels and ecosystem, geographic, and climatic variables. Regressions were also performed to observe which combinations of variables best explained secondary metabolite variance. Stands of *P. c. latifolia* in the Coastal Western Hemlock and Interior Cedar/Hemlock biogeoclimatic zones had consistently greater foliar levels of almost all measured secondary metabolites than did other stands. Lignin was present in greater amounts in Boreal White/Black Spruce ecosystem (i.e., northern) stands than in southern stands, suggesting a role for this metabolite in pine survival in the boreal forest. Attempts to develop regression models with geographic and climatic variables to explain foliar secondary metabolite levels resulted in multiple models with similar predictive capability. Since foliar secondary metabolite levels appeared to vary most between stand ecosystem types and not as much due to geographic and climatic variables, metabolic profiles appeared best matched to the stress levels within local environments. It is unknown if differences in secondary metabolite levels are the result of genetic adaptation or phenotypic plasticity, but results from this and other studies suggest that both are important. These results are interpreted in light of ongoing efforts to assist in the migration of certain populations of *P. c. latifolia* northward in an effort to counter predicted effects of climate change.

Key Words Climate change · Gas chromatography–mass spectrometry (GC-MS) · Lignin · Lodgepole pine · Monoterpenoid · Phenolics · *Pinus contorta latifolia* · Sesquiterpenoid · Diterpenoid

Introduction

Lodgepole pine, *Pinus contorta* Douglas ex Louden var. *latifolia* Engelm. ex S. Watson (http://www.itis.gov/), is a valuable and widespread species found throughout western North America, where it is widely planted as a part of sustainable forestry practice (Wu et al., 2005; Ying and Yanchuk, 2006). However, in recent years many plantations of *P. c. latifolia* throughout its range have been severely impacted by generally warmer temperatures (especially in winter) and localized changes in precipitation (Folke et al., 2004). In addition to climate adversely affecting tree physiology, and in turn productivity, there has been an increase in pest activity, including widespread mortality caused by the mountain pine beetle, *Dendroctonus ponderosae* Hopkins (Coleoptera: Scolytidae) (Walther et

al., 2002; Kurz et al., 2008; Bentz et al., 2010) and regionally important outbreaks of *Dothistroma* needle cast [causal agent: *Mycosphaerella pini* Rost. in Munk; anamorph *Dothistroma septospora* (Dorog.) Morelet] (Ascomycota: Mycosphaerellaceae) (Woods et al., 2005). It is hypothesized that in the future, climate change will continue and even intensify, which will further impact pine growth and result in more frequent pine pest and disease outbreaks (Coakley et al., 1999; Logan et al., 2003; Desprez-Loustau et al., 2007; Bentz et al., 2010).

To counter the potential negative effects of climate change, efforts have begun to move individuals from particular pine populations to areas whose future climates are predicted to be optimal for their growth in a process called assisted migration (O'Neill et al., 2008). Assisted migration involves moving pine populations to higher latitudinal or elevational sites because it is hypothesized that certain populations of trees are better-suited to areas which, although also warming, will remain cooler overall (Coakley et al., 1999; O'Neill et al., 2008; Marris, 2009).

It remains unclear what impacts the assisted migration of certain populations of *P. c. latifolia* into new areas will have on their ability to thrive in the near- and long-terms (Marris, 2009). Although attempts have been made to find suitable locations to minimize climate change effects on *P. c. latifolia* physiology (Cumming and Burton, 1996; Hamann and Wang, 2006; O'Neill et al., 2008), our understanding of this process is in its infancy (Wu et al., 2005; Wallis et al., 2010). Populations of *P. c. latifolia* that originated from different ecosystems, or that were far apart geographically, have been found to vary not only in growth and reproduction, but also in their susceptibility to diseases (Rehfeldt et al., 1999; Wu et al., 2005; Heineman et al., 2010; Wallis et al., 2010). Such distinct populations also were observed to vary in foliar secondary metabolite (SM) levels, at least when they were planted together at one seed orchard site (Wallis et al., 2010). Overall differences in the ability of populations of *P. c. latifolia* to synthesize SMs, such as phenolics and terpenoids, are likely to have led to observed variations in growth rates and susceptibility to pests, because such compounds have a variety of roles including photoprotection, relieving oxidative stress, reducing water stress, and protection from insect and pathogen pests (Keeling and Bohlmann, 2006; Seybold et al., 2006; Whitzell and Martin, 2008).

Populations of *P. c. latifolia* from lower latitudes and from warmer, wetter stands will need increased protection from biotic stresses, and therefore the possession of greater pest defense-associated SM levels (both phenolics and terpenoids) will confer fitness advantages (e.g., Franceschi et al., 2005; Wallis et al., 2008; Adams et al., 2009). In contrast, *P. c. latifolia* from northern, colder, and drier locales will gain a fitness advantage by putting more resources into primary metabolites, presumably at the cost of producing certain SMs, in order to deal with a shorter growing season and to outcompete neighboring plants for scarce resources (Siska et al., 2002; Andrew and Hughes, 2005; Adams et al., 2009).

However, other SM classes might play larger roles in conferring resistance to abiotic stresses than in their abilities to combat pests; for instance, *P. c. latifolia* from boreal forest locations may possess greater cell-wall thickening phenolics such as lignin that could confer fitness advantages in overcoming abiotic stresses such as extreme cold (Smallwood and Bowles, 2002; Wei et al., 2006). Levels of other SMs, in particularly flavonols, are positively associated with latitude presumably because they are involved in resisting abiotic stresses (Lätti et al., 2008; Stark et al., 2008; Martz et al., 2009, 2010). Day lengths, lowered temperatures, and UV exposure are all implicated in the relationship between latitude and levels of certain SMs (reviewed by Jaakola and Hohtola, 2010).

Therefore, levels of biotic and abiotic stresses imparted on populations can positively or negatively affect distinct groups of SMs, depending on the class of the compounds and the particular roles that they play in resistance to stress. The aim of our study was to quantify the differences in foliar SM levels among stands of naturally regenerating *P. c. latifolia* that should be exposed to a variety of abiotic and biotic stresses. We examined variations in SM levels—including total soluble phenolics, lignin, and terpenoids—in the foliage from 12 distinct stands of *P. c. latifolia*. Ecological, geographical, and climatic differences among these sites were examined to observe which variables might influence the levels of these compound classes. We hypothesized that associations among SM classes and ecological, geographic, or climatic variables will be due, in part, to the particular roles they play in countering abiotic or biotic stresses.

Methods and Materials

Stand Descriptions and Sampling A total of 12 mature stands of *P. c. latifolia* of natural origin were assessed across central British Columbia (Fig. 1). These stands were from a variety of habitats and climates comprising five distinct ecosystems as delineated by British Columbia's biogeoclimatic (BEC) zone system. They included the very cold boreal white and black spruce (BWBS) zone; the very wet Coastal Western Hemlock (CWH) zone; the high elevation Englemann Spruce/Subalpine Fir (ESSF) zone; the very wet Interior Cedar/Hemlock zone (ICH); and the widespread Sub-boreal Spruce (SBS) zone (Meidinger and Pojar, 1991). Climate data for each sampling site [mean summer (June through August), mean winter (December through February) and mean annual temperatures; and

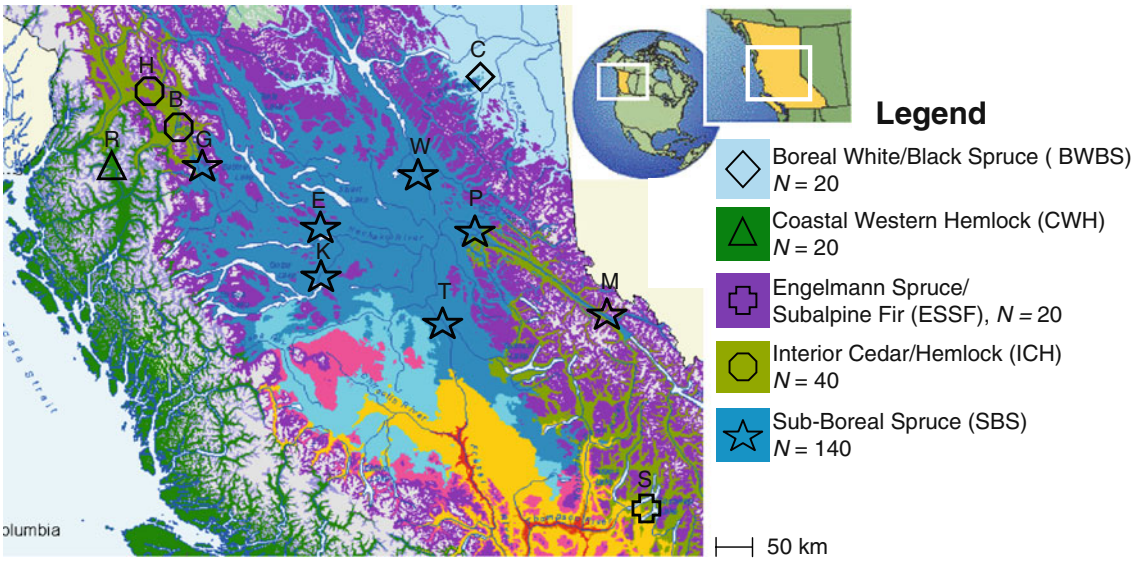

Fig. 1 Locations of populations of *Pinus contorta latifolia* in British Columbia, Canada identified by letter corresponding to site names in Table 1; and their British Columbia biogeoclimatic (BEC) classification and sample size. Map courtesy of the BC Ministry of Forests and Range (http://www.for.gov.bc.ca/hre/becweb/)

mean summer (June through August) and mean annual precipitation levels] were determined by using the Climate BC program, based upon measured temperature and precipitation data from 1961 to 1990 (Wang et al., 2006) (Table 1). Sampling occurred between June 15, and July 15, 2009, and at each stand the trees were in the same phenological stage (near the completion of needle expansion from newly-formed candles). At each site, approximately 5 g of apparently insect- and disease-free, second-year needles (i.e., those that were formed in 2008) were collected from three

Table 1 Coordinates and site characteristics for the *Pinus contorta latifolia* stands assessed for foliar secondary metabolites

randomly chosen branches from each of 20 naturally regenerating trees ranging from 15 to 25 year-old. The samples were immediately placed onto dry ice for transport to the lab, where they were stored at −20°C until processed for phytochemical analyses roughly 1 month later.

Phytochemical Analyses Needle samples were ground by mortar and pestle in liquid nitrogen, with 100 mg of ground tissue twice-extracted in 1 ml of methanol (Thermo-Fisher Scientific, Pittsburg, PA, USA) and another 100 mg of tissue twice-extracted in 1 ml of dichloromethane (methylene chloride) (Sigma-Aldrich, St. Louis, MO, USA) according to the protocols of Wallis et al. (2008). The methanol extracts were assessed for total phenolics by using the Folin-Ciocalteu reagent spectrophotometric method (with an instrument from Perkin-Elmer, Waltham, MA, USA) for quantifying soluble phenolics, and the pellet left behind following the methanol extraction was further processed to quantify total lignin (bound to the cell walls) according to the procedures of Wallis et al. (2008) with all reagents from Sigma-Aldrich. In brief, the pellets were washed once with 1 ml water, then 1 ml methanol, and finally 1 ml of petroleum ether and were allowed to dry overnight. To the pellet, 200 μl of 1 N NaOH were added, and this was left in a shaker at 40°C for 21 h, after which 200 μl of 1.5 M formic acid and 400 μl of methanol were added. The mixture was centrifuged at 10,000 x *g* for 5 min, and the supernatant removed. The pellet then was washed in 1 ml of water and re-suspended in 800 μl of 2 N HCl and 300 μl of thioglycolic (mercaptoacetic) acid heated at 86°C for 4 h. The tubes were spun down for 5 min at 10,000 x *g*, and the supernatant removed, with the pellet then twice-washed in 1 ml water. The pellet was then re-suspended in 1 ml of 0.5 M NaOH and left for 18 h on a shaker. Following centrifugation, the supernatant was transferred to a clean tube and the pellet re-suspended in 0.5 ml of 0.5 M NaOH. Following centrifugation, the supernatant was combined with that from the previous step to total a 1.5 ml of 0.5 M NaOH solution. To this, 300 μl of concentrated (12 N) HCl were added and allowed to stand at room at room temperature for 4 h. The solution was spun down for 5 min at 10,000 x *g*, and the supernatant discard. The pellet was re-suspended in 1 ml of 0.5 M NaOH, and read on a spectrophotometer (Perkin-Elmer) at 280 nm. Lignin concentrations in mg were determined by using a standard curve made from a dilution series of commercially available lignin standard from spruce (Sigma-Aldrich).

The dichloromethane extracts were analyzed for terpenoid content (monoterpenoids, sesquiterpenoids, and diterpenoids) with a Varian Model 3800 gas chromatograph with a flame-ionization detector and a split line to a Saturn 2200 Ion Trap MS-MS (Agilent, Palo Alto, CA, USA) and *n*-pentadecane (Sigma-Aldrich) as an internal standard (Wallis et al., 2010). The column was a 30 m×0.25 mm i.d.×0.25 μm film thickness Agilent Ultra 2.5% phenylmethylsiloxane capillary column; the carrier gas was helium running at a constant flow of 2.1 ml/min; the split/splitless injection port was in split mode (10:1 ratio) with the temperature set at 320°C; and the detector/transfer line temperatures were set at 320°C. The temperature program started with a hold of 2 min at 40°C; ramped at 10°C/min to 200°C; and finally ramped at 50°C/min to a final temperature of 300°C (with a 5 min final hold) (total run time of 28.20 min). All peak areas of identified terpenes were summed together with others in their class (monoterpenoids, sesquiterpenoids, or diterpenoids) to give an overall value for each terpenoid group. Compound identifications were based on retention time matching to known standards and matching to mass spectral libraries with reverse search indices higher than 850 (Wallis et al., 2008). Stereoisomers of certain compounds (e.g., α-pinene, β-pinene, and limonene) went unresolved, as this study stressed changes in total terpenoid group production (i.e., the regulation upstream of individual monoterpenes, sesquiterpenes, and diterpenes). The toxicity of terpenoids to pathogens is thought to not depend on the enantiomeric composition (Wallis et al., 2008). Putative diterpenoids, labeled in this work as unknown diterpenoids, were compounds whose matches to mass spectral libraries contained a typical diterpenoid skeleton of C_{20} and for which the top five library matches were different diterpenoids. However, for these putative diterpenoids no single compound exceeded the reverse search index threshold set at 850.

Statistical Analyses All statistical tests were performed with either SPSS ver. 17 (SPSS Inc., Chicago, IL, USA) or R ver. 2.10.0 (CRAN, Wirtschaftsuniversität Wien, Austria) at a threshold of $\alpha=0.05$. Normality was assessed by examining residual plots and histograms, and Levene's tests for variance heterogeneity were performed. Pearson's correlations were used to find associations between groups of foliar compounds. Univariate ANOVAs were used to find differences in phytochemistry between trees grown in different BEC zones. Tukey HSD tests were used to separate individual BEC zone means.

Coordinates were first converted from UTM to BC Albers, a metric that is continuous throughout British Columbia (http://geobc.gov.bc.ca) for all analyses that examined relationships between geographical variables and SM levels. Specifically, the BC Albers has an x-coordinate that represents longitude (with increasing numbers representing movement eastward) and a y-coordinate that represents latitude (with increasing numbers representing movement northward).

Pearson's correlations were used to examine potential relationships between geographic or climatic variables and

foliar SM levels. One analysis compared the mean levels of the SMs for each site with these variables, whereas another used the SM values for individual trees. The first analysis was performed to emphasize the geographic or climatic effects on a typical individual in the tree's population, whereas the latter emphasized effects on multiple individuals in the same stand of trees. This was also performed in part due to concerns over the large sample size (greater than 250 replicates overall) of SM levels potentially skewing these associations, considering that 12 estimates were made for each of the geographical and climatic variables. An additional analysis compared the levels of SMs from individual trees vs. geographic or climatic variables with data from the SBS zone only, as this zone was represented far more (7 times) than the other sites and is arguably the primary ecosystem type in which *P. c. latifolia* is found in British Columbia.

Linear regression analyses were performed to observe which combination of variables best explained the variance in foliar secondary metabolites. Using the "Rcmdr" package within R, a linear regression model for each SM group as explained by all the geographic and climatic variables was loaded. These models then underwent the "subset model selection…" application under Rcmdr's "Model" menu, which output a list of the variables included in the models that had the lowest Schwarz's Bayesian Information Criteria (BIC) values (with the lowest values representing the best models) (Schwarz, 1978). The strongest model matched that selected via Stepwise Regression Analysis based on BIC; however, the next two top models also were selected for comparison as they could not be dismissed due to their possessing similar BIC values (within ~2) to the top model (Burnham and Anderson, 2002). For additional evaluation, the Akaike Information Criteria (AIC) values also were assessed (Akaike, 1974). These regressions were performed on the mean SM levels at each site; on SM levels for all of the individual trees; and on the SM levels for all individual trees for the SBS zone alone.

Results

Secondary Metabolite Identities and Associations In this study, we assessed a total of 14 monoterpenoids (sabinene, α-pinene, camphene, β-pinene, β-myrcene, α-phellandrene, δ-3-carene, *p*-cymene, β-phellandrene, δ-2-carene, linalool, camphor, bornyl acetate, and verbanone), seven sesquiterpenoids (α-cubenene, α-copanene, aristolene, β-cadinene, τ-cadinol, germacrenol, and an unidentified sesquiterpenoid), and five diterpenoids (all of which were unable to be identified to specific compounds). We also assessed total phenolic (with Folin-Ciocalteu reagent) and total lignin content.

Foliar phenolic levels were significantly and positively associated with the foliar levels of all three groups of terpenoids; and sesquiterpenoid levels were positively associated with levels of both monoterpenoids and diterpenoids (Table 2). No other significant correlations were observed.

BEC Zone and Subspecies Effects on Foliar Secondary Metabolites Populations of *P. c. latifolia* from the Coastal Western Hemlock (CWH) and Interior Cedar Hemlock (ICH) zones had greater levels of soluble phenolics (41% to 45% more) than the Boreal White/Black Spruce (BWBS) zone (F=8.348, P<0.001, N=237) (Fig. 2a). Lignin levels were greater in the BWBS zone (11% to 22% more) than the SBS or Engelmann Spruce/Subalpine Fir (ESSF) zones, and trees from the ICH zone had greater lignin levels (14% more) than those in the ESSF zone (F=4.591, P=0.001, N=238). Total monoterpenoid levels were greater in *P. c. latifolia* from the ICH zone (72% to 242% more) than from any other zone (F=10.105, P<0.001, N=226) (Fig. 2b). Total sesquiterpenoid levels were greater in the CWH zone (60% to 147% more) than any other zone, and levels were greater in the ICH (38% more) and BWBS (37% more) zones than the SBS zone (F=38.467, P<0.001, N=233). Total diterpenoid levels were greater in the CWH population (39% to 857% more) than any other population, and diterpenoid levels were also greater in populations in the BWBS and ICH zones (93% to 588% more) than in the ESSF or SBS zones (F=38.763, P<0.001, N=224).

The foliar levels of almost every individual compound, with the exceptions of sabinene, β-pinene, and linalool, were significantly related to BEC zone (Table 3). Pines from the ICH zone possessed greater levels of camphene, δ-3-carene, and β-phellandrene than pines from the ESSF zone (F>4.088, P<0.010, N=233). Pines in the CWH zone had greater levels of α-cubenene, aristolene, β-cadinene,

* P<0.010; ** P<0.001

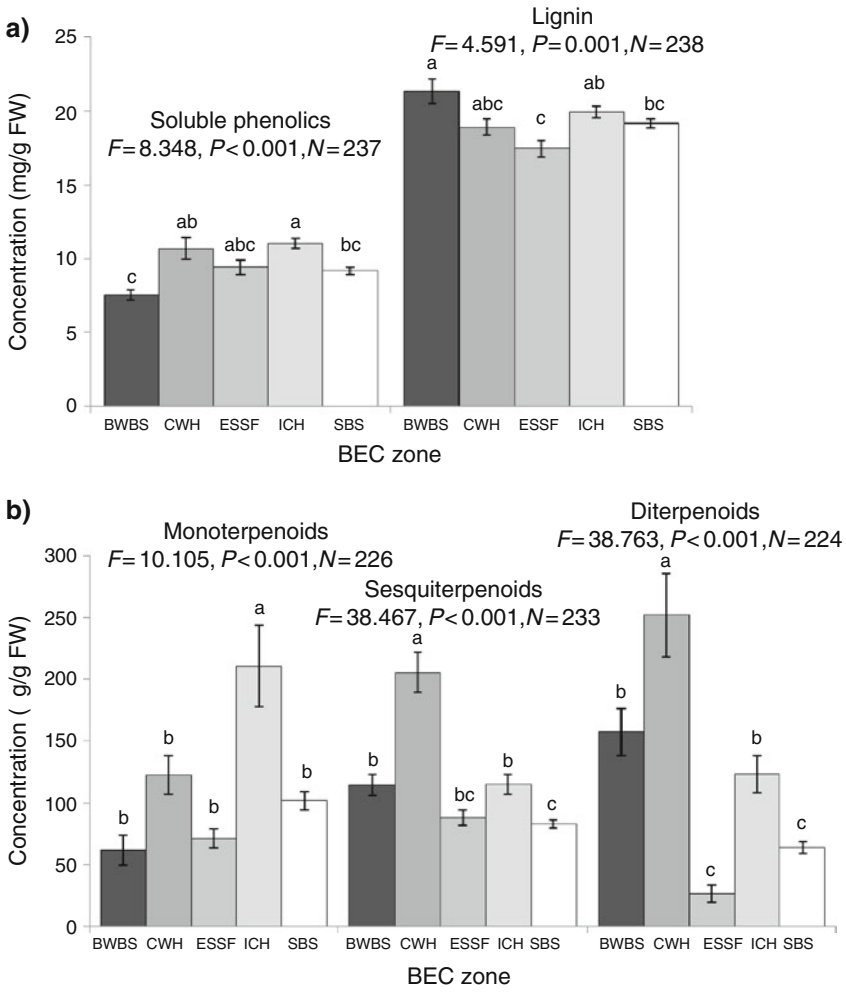

Fig. 2 Concentrations (mean ± s.e.) of **a** phenolic and **b** terpene secondary metabolites in the foliage of *Pinus contorta latifolia* collected from various British Columbia biogeoclimatic (BEC) zones. ANOVA statistics are given, and letters indicate significant differences by Tukey HSD tests. BEC zones are as follows: Boreal White/Black Spruce (BWBS); Coastal Western Hemlock (CWH); Engelmann Spruce/Subalpine Fir (ESSF); Interior Cedar Hemlock (ICH); and Sub-Boreal Spruce (SBS)

and germacrenol than those growing in either the ESSF, ICH, or SBS zones ($F \geq 5.247$, $P<0.001$, $N=233$). Pines growing in the BWBS zone possessed greater levels of the unidentified sesquiterpenoid than those growing in the ESSF or SBS zones ($F=5.355$, $P<0.001$, $N=233$). Pines growing in the CWH zone possessed greater levels of all five diterpenes than pines growing in the ESSF or SBS zones ($F \geq 4.766$, $P<0.001$, $N=233$).

Geographic and Climatic Variables and Secondary Metabolite Levels By using the mean compound levels from each site for the correlation analyses, foliar levels of phenolics were negatively associated with longitude (i.e., phenolic levels were lower in more easterly sites); levels of lignin were positively associated with latitude (i.e., lignin levels were higher in more northerly stands); levels of sesquiterpenoids were positively associated with winter temperature and annual precipitation; and levels of diterpenoids were negatively associated with longitude but positively associated with latitude and winter temperature (Table 4). No other significant correlations were observed.

Considering the foliar levels of SMs in each tree and not using site means for the correlation analyses, levels of phenolics were negatively associated with elevation, longitude, summer temperature, and summer precipitation but positively associated with latitude and winter temperature; levels of lignin were negatively associated with longitude, summer temperature, annual temperature, and annual precipitation but positively associated with latitude; levels of all terpenoid classes were negatively associated with elevation and longitude but positively associated with latitude, summer temperature (with the exception of the diterpenoids), winter temperature, annual temperature, and annual precipitation (with the exception of the monoterpenoids); and levels of monoterpenoids were negatively associated with summer precipitation, whereas levels of sesquiterpenoids and diterpenoids were positively associated with summer precipitation (Table 4). No other significant correlations were observed.

For trees in the SBS zone only, total phenolics were negatively associated with elevation, longitude, summer temperatures, annual temperature, summer precipitation,

and annual precipitation but positively associated with latitude; lignin levels were negatively associated with elevation, longitude, summer temperatures, annual temperatures, and summer precipitation but positively associated with latitude; monoterpenoid and sesquiterpenoid levels were positively associated with latitude; and diterpenoid levels were negatively associated with elevation, longitude, summer precipitation, and annual precipitation but positively associated with latitude (Table 4). No other significant correlations were observed.

Linear Regression Modeling to Explain Variance in Foliar Secondary Metabolite Levels Whereas the correlation analyses related individual climatic and geographic variables with the observed levels of the SMs, linear regressions were made to combine multiple factors together to explain the observed levels. Mean foliar phenolic levels at each site were best explained [by having the lowest Bayesian Information Criterion (BIC)] by longitude; lignin levels were best explained by elevation, mean annual temperature, and mean winter temperature; monoterpenoid levels were

Table 4 Pearson's correlations between geographic or climatic variables and mean compound levels per site or individual tree compound levels from an analysis of foliage metabolites from *Pinus contorta latifolia*

best explained by mean summer precipitation, mean summer temperature, and mean winter temperature; sesquiterpenoid levels were best explained elevation, longitude, mean annual precipitation, mean annual temperature, and mean summer precipitation; and diterpene levels were best explained by elevation, latitude, longitude, mean annual precipitation, and mean summer precipitation (Table 5).

By using the chemical levels found in foliage from individual trees and not using their site means for analyses, foliar soluble phenolic levels were best explained by longitude, elevation, and mean annual temperature; lignin levels were best explained by elevation, mean annual temperature, and mean winter temperature; monoterpenoid levels were best explained by mean summer precipitation, mean summer temperature, and mean winter temperature; sesquiterpenoid levels were best explained by longitude, elevation, mean annual precipitation, mean annual temperature, and mean summer temperature; and diterpenoids were best explained by longitude, latitude, elevation, mean annual precipitation, and mean summer temperature (Table 6).

By using the chemical levels found in foliage from individual trees from the SBS zone only, foliar soluble phenolic levels were best explained by latitude, elevation, and mean summer temperature; lignin levels were best explained by mean annual precipitation, mean annual temperature, and mean winter temperature; monoterpenoid levels were best explained by longitude and mean summer temperature; sesquiterpenoid levels were best explained by elevation and mean summer precipitation; and diterpenoids were best explained by longitude and elevation (Table 7).

It should be noted that in all cases the top three models for each variable had close BIC and AIC values, meaning that one model cannot be considered necessarily better than the others. Additional studies and data collection would be necessary to assess which of the top models would be best for explaining the levels of foliar SMs.

Discussion

Ecosystem type (represented by the BEC zone classifications), geographical location, and climate all significantly impacted at least some of the foliar secondary metabolite levels in the *P. c. latifolia* that were analyzed in this study. Thus, *P. c. latifolia* foliar SMs, which likely contribute to overall fitness, varied with ecosystem, locale, and climate.

BEC zones were associated with differential levels of almost every SM that we analyzed. Trees from the CWH and ICH zones often possessed greater foliar SM levels than trees from other zones, albeit significant differences varied depending on the compound. The CWH and ICH are both defined, in part, as rainforests

Increasing latitude represents movement from south to north, and increasing longitude represents movement from west to east.
* $P<0.050$; ** $P<0.010$; *** $P<0.001$.

(Meidinger and Pojar, 1991). These ecosystems likely allow *P. c. latifolia* to have a longer growing season and a climate where certain abiotic stresses (e.g., drought) are reduced. Both longer growing season and reduced stress could have resulted in additional resources for the pines to invest in their secondary metabolism (Herms and Mattson, 1992). Furthermore, these ecosystems could have been more favorable to pest development (Allen et al., 1996), which would, due to more frequent pest encounters, impose selective pressure on the lodgepole pines to produce more defense-associated compounds in their foliage (Wallis et al., 2010). This latter hypothesis could be overtly tested by attempting to find associations between foliar pest outbreaks and SMs, potentially with dendrochronological techniques to estimate historical pest outbreak frequency (Welsh et al., 2009). Regardless, it would appear that the need to counter biotic stresses in these ecosystems resulted in selection pressure leading to greater levels of defense-associated SMs, namely monoterpenoids for the Interior Cedar-Hemlock ecosystem and both sesquiterpenoids and diterpenoids for the Cedar-Western Hemlock ecosystem.

Precipitation likely had some influence on the measured levels of SMs because these compounds were extracted from 0.1 g of fresh and not dried material. However, the differences in terpenoid levels from the wettest sites would presumably be even greater than those from drier sites if samples were dried first, as wetter sites (i.e., those from the CWH and ICH) would likely have greater water content in their tissues.

Regardless of ecosystem type, stands in more northerly and westerly locations, and at lower elevations, were associated with higher foliar SM levels. These results do not support the hypothesis that more southerly stands would contain greater levels of SMs (Siska et al., 2002; Andrew and Hughes, 2005; Adams et al., 2009). However, in this study, northern, western, and lower elevation sites included some of the wettest and warmest sites, including the CWH and ICH zones. Indeed, prior studies observed that greater pest activity at lower elevations was associated with plants having increased levels of SMs (e.g., Hobbs and Partridge, 1979; Hengxiao et al., 1999; Heineman et al., 2010), and the CWH and ICH sites were at the lowest elevations of all the sites sampled.

In contrast to the other SMs, levels of lignin were highest in the boreal BWBS ecosystem type, whereas the other metabolites were often at the lowest levels in trees from that zone. Lignin is involved with cell wall thickening and strengthening, which contributes to cold temperature tolerance (Smallwood and Bowles, 2002; Wei et al., 2006). However, lignin was not associated with lower winter temperatures, so other selection pressures might be at play.

Increasing latitude represents movement from south to north, and increasing longitude represents movement from west to east.
* $P<0.050$; ** $P<0.010$; *** $P<0.001$.

When only the SBS *P. c. latifolia* populations were considered (because most pine plantations are found in that ecosystem type), increases in total soluble phenolics and lignin levels were associated with lower temperatures and rainfall averages, suggesting greater abiotic stress. By contrast, monoterpenoids and sesquiterpenoids were not associated with climatic variables at all, perhaps implying low variance in biological stresses that influence their production in the SBS zone. Increasing latitude was positively associated with the production of all SMs for trees in the SBS zone. Studies are needed to determine the specific factors that might explain this trend, such as increased summer day length, decreased growing season duration, or increases in cold temperature extremes that occur with higher latitude that imparts a selection pressure for greater SM production in pine populations.

Although we observed that geographic and climatic variables did affect foliar SM levels in *P. c. latifolia* populations, the physiological and genetic mechanisms behind these observations remain unclear. Our attempts to form testable regression models proved inconclusive, as the top models did not vary much according to their information criteria (both BIC and AIC values), likely because of the inter-relatedness between all of these variables. This also suggests that these geographic and extrapolated climatic variables are perhaps not the best explanatory variables to use for the levels of foliar SMs.

Future studies should attempt to correlate historic and current abiotic and biotic stress levels of stands of *P. c. latifolia* with their secondary metabolites. Associations with current stress levels would indicate that populations might have responded to local abiotic and biotic stresses by shifting SM production or responding via systemic induced responses (Herms and Mattson, 1992; Koricheva et al., 1998). Alternatively, associations with historical stress levels might reveal that different pine populations may have evolved to produce greater SM levels in response to selection pressures caused by adverse abiotic and biotic stressors (Wu et al., 1996; Hodkinson, 2005; Wallis et al., 2010).

Viewed in light of current efforts to assist the migration of *P. c. latifolia* populations from warmer, southerly areas, to colder, northerly areas (O'Neill et al., 2008), these results are not in and of themselves sufficient to suggest that such efforts are or are not worthwhile. However, these results reveal that variation exists between different populations of

P. c. latifolia, especially those in different broadly-defined ecosystem types. Previous studies have shown that when grown in the same location, pines originating from different stands and ecosystems still retain their variance in both SM levels and pest resistance (Wu et al., 1996, 2005; Wallis et al., 2010). Therefore, the variance in SM concentrations observed in pine populations in this study could be predicted to remain for at least one generation if trees undergo assisted migration.

Climate change is predicted to increase both biotic and abiotic stresses on pine populations. Bark beetle populations are the major cause of area wide mortality for *P. c. latifolia*, and these populations are predicted to increase regionally with climate change (Bentz et al., 2010). Coupled with changes in temperature and rainfall patterns, bark beetles could force pine ecosystems to higher latitudes and elevations (Bentz et al., 2010). In this study, terpenoid levels, and to some extent the soluble phenolics and lignin, were greater in ecosystems that were wetter and warmer (the CWH and ICH *versus* the SBS and ESSF), i.e., those likely facing greater biological stresses (Allen et al., 1996). Therefore, migrant pines from these populations would be expected to have a fitness advantage over native pines (i.e., trees whose ancestors originate from the same area) at higher latitude or elevation sites when predicted bark beetle, and possibly pathogen, outbreaks expand into those areas (Bentz et al., 2010). Hypothetically, migrant pines would possess a greater capacity to produce defense-associated compounds. These pines might also be more tolerant of certain abiotic stresses, such as increased temperature extremes and more frequent droughts. However, only longer-term monitoring of the variation of secondary metabolites in multiple stands can confirm if this is the case, or if the native pines might fare little better than migrant trees.

Acknowledgments The authors thank Nick Ukraintz, Alex Woods, Brian Aukema, Sam Barnes, and Rhiannon Montgomery for planning and technical help in executing this study. We also acknowledge the University of Northern British Columbia, the Forest Genetic Council of British Columbia, the British Columbia Ministry of Forests and Range, the Natural Science and Engineering Research Council of Canada, the Canada Research Chairs Program, the Canada Foundation for Innovation, and the British Columbia Knowledge Development Fund for funding and other support in conducting this research.

Abstract Egg parasitoids are able to find their hosts by exploiting their chemical footprints as host location cues. In nature, the apolar epicuticular wax layer of plants that consists of several classes of hydrocarbons serves as the substrate that retains these contact kairomones. However, experiments on chemical footprints generally have used filter paper as substrate to study insect behavior. Here, we explored the ability of *Trissolcus basalis* (Scelionidae) females to discriminate between footprint cues left by male and female *Nezara viridula* (Pentatomidae) on leaves of their host plant *Brassica oleracea* (broccoli). Furthermore, we analyzed the chemical composition of the outermost wax layer of broccoli leaves to evaluate the degree of overlap in insect and plant cuticular hydrocarbons that could lead to masking effects in the detection of footprint cues. Our results showed that *B. oleracea* epicuticular wax retains the chemical footprints of adult bugs and allows *T. basalis* females to differentiate hosts of different sex. Traces of female bugs elicited more extensive searching behavior in egg parasitoids than traces of males. The application of *n*-nonadecane, a compound specific to male *N. viridula*, on the tarsi of female bugs prevented parasitoid females from distinguishing between host male and host female footprints. Analyses of *B. oleracea* leaves revealed that epicuticular waxes were mainly composed of linear alkanes, ketones, and secondary alcohols. Alkanes were dominated by *n*-nonacosane (*n*C29) and *n*-hentriacontane (*n*C31), while male-specific *n*-nonadecane (*n*C19) was absent. The ecological significance of these results for parasitoid host location behavior is discussed.

Introduction

Insect parasitoids that attack and develop within non-feeding host stages, such as eggs or pupae, have evolved the ability to exploit chemical cues related to the adult stage. This behavior can help to overcome the so-called reliability-detectability dilemma (infochemical detour) (Vet and Dicke, 1992). In the case of hymenopteran egg parasitoids, an extensive body of literature describes how parasitoids can find patches where eggs have recently been deposited or where this is soon to occur, chiefly by exploring the semiochemicals produced by host adults (reviewed by Fatouros et al., 2008; Colazza et al., 2010). Within the host's habitat, volatile pheromones may be detected by female egg parasitoids to actively reach the mating sites of hosts (Lewis et al., 1982; Colazza et al., 1997; Boo and Yang, 2000; Conti et al., 2010) or to recognize mated female hosts ready to lay eggs. Such gravid females also may be used for phoretic transportation (Fatouros et al., 2008; Huigens et al., 2010). Contact kairomones left by mated female hosts allow egg parasitoids to locate recently laid eggs more efficiently (Colazza et al., 1999; Chabi-Olaye et al., 2001; Fatouros et al.,

2007). Furthermore, plants can modify the synthesis of organic defensive compounds as a consequence of the insect footprints (Bown et al., 2002).

From a tri-trophic perspective, chemical substances deposited by many insects while walking on a plant surface can mediate both intra- and interspecific relationships (Klomp, 1981; Colazza et al., 1999; Witjes and Eltz, 2009). The physicochemical characteristics of plant surfaces should, therefore, strongly influence these interactions, as the chemistry of the epicuticular wax components may affect how exogenous substances are adsorbed and released (Müller and Riederer, 2005). For example, the larval parasitoid *Cotesia marginiventris* (Cresson) (Hymenoptera: Braconidae) responds differently to the chemical footprints of its host *Spodoptera frugiperda* (J.E. Smith) (Lepidoptera: Noctuidae), when footprints that mainly consist of linear and monomethyl-branched alkanes are left on the leaf surface of either wild-type or *eceriferum* mutants of barley. The mutants were characterized by lower amounts of the main wax component hexacosanol and a high aldehyde fraction (Rostás et al., 2008; Rostás and Wölfling, 2009).

In recent years, the role of footprint cues deposited by true bugs (Hemiptera: Heteroptera) as an indirect host-related contact cue for scelionid egg parasitoids (Hymenoptera: Scelionidae) has been investigated (reviewed by Colazza et al., 2010). Extensive studies have been carried out in particular on the host-parasitoid association of *Nezara viridula* (L.) (Heteroptera: Pentatomidae) and *Trissolcus basalis* (Wollaston) (Hymenoptera: Scelionidae). In these experiments, the behavioral responses of the parasitoid were observed in arenas made of filter paper, which is an amorphous artificial substrate that does not interfere with parasitoid behaviors and/or the chemical properties of host cues (Colazza et al., 1999; Peri et al., 2006; Salerno et al., 2006). Under such conditions, *T. basalis* females show an initial motionless period of a few minutes (arrestment response) followed by locomotion and increased antennal movements while searching within the patch (motivated search). During the motivated search, wasp females adjust both turning rate (klinokinesis) and locomotion rate (orthokinesis) depending on the host's sex. The presence of contact kairomones eventually leads to a longer and more intensive exploration in an area contaminated by the host adult females, as the cues associated with this host sex are spatially and temporally closer to the host eggs (Colazza et al., 1999).

Under natural conditions, the interactions between *N. viridula* and *T. basalis* are influenced by the presence of plant surface waxes. Previous experiments demonstrated that the wasps responded to footprints from female *N. viridula* walking on *Vicia faba* L. plants only if the leaf's wax layer was intact, but were unable to detect host kairomones when the bugs have walked over mechanically dewaxed leaves (Colazza et al., 2009). Clearly, the physicochemical characteristics of the leaf surface can hamper the detectability of host footprints by wasp females, as active compounds could be part of the components that make up the plant's epicuticular wax surface. Recent observations of *T. basalis* behavior using filter paper arenas demonstrated that the linear alkane *n*-nonadecane (nC_{19}) is an active component among the cuticular hydrocarbons of *N. viridula* males that allows wasp females to distinguish between residues left by male or female bugs (Colazza et al., 2007). As linear alkanes are a major class of compounds in plant epicuticular waxes (Eigenbrode and Espelie, 1995; Müller and Riederer, 2005)—although alkanes with less than 21 carbon atoms don't seem to be widely present—possible masking effects by the alkanes present in the plant waxy background on *N. viridula* male-specific hydrocarbons need to be assessed.

In this study, we investigated the ability of *T. basalis* females to distinguish between the footprint cues left by male and female *N. viridula* on leaves of broccoli plants (*Brassica oleracea* L., var. Italica, cv. Marathon). Then, we evaluated the responses of female wasps to the male bug-specific hydrocarbon *n*-nonadecane. Finally, we studied the chemical composition of the broccoli leaf surface to evaluate its role in mediating the interactions between host footprints and female wasps and specifically to answer the question whether *n*-nonadecane was present or absent.

Methods and Materials

Plants In all experiments, broccoli plants grown from certified seed material (Esasem Spa, Casaleone -VR- Italy) were used. In experiment 1, plants were cultivated in 14-cm plastic pots with fertilized commercial potting soil (Trflor, HOCHMOOR) in a climate-controlled greenhouse of the Department of DEMETRA, University of Palermo, Italy from 08/2008 to 12/2008. In experiments 2 and 3, plants were grown in 9-cm-pots containing soil mixture ED 73, and kept in a growth chamber with a day/night cycle of 16:8 hr, 20°C temperature, and 60% relative humidity at the Department of Botany II, University of Würzburg, Germany.

Insects Colonies of *N. viridula* and *T. basalis* were established from material collected in the fields around Palermo, Italy, and were maintained in separate climate chambers at 26±1°C, approximately 60% R.H., and a photoperiod of 16:8 hr (L:D). Immatures and adults of *N. viridula* were reared in wooden cages (50×30×35 cm with 5-cm circular mesh-covered holes) and fed with seasonal fresh vegetables, and sunflower seeds. Mated adults of known age were available for the bioassays by keeping pairs of *N. viridula* in different cages, and checking daily until mating was assured. Females and males then were

separated and placed into different rearing cages. Egg masses of *N. viridula* were collected from the rearing cages on a daily basis and used to maintain both *N. viridula* and *T. basalis* colonies. Newly laid egg masses of *N. viridula* were individually exposed to 3–4 female wasps for about 3 d in 16-ml glass tubes. Then, parasitoids were removed and parasitized egg masses were held in the rearing room until adults emerged. Adults of *T. basalis* were fed with a 10% honey-water solution streaked on the inside surface of the glass tubes.

Experiment 1 The aim of this experiment was to determine whether female parasitoids were able to detect and discriminate the chemical footprints of male and female bugs on the surface of broccoli leaves. Four-wk-old plants with 5–6 fully expanded leaves were exposed to 2–3 *N. viridula* adults. The stink bugs were allowed to walk over the leaves and produce chemical footprints for about 30 min according to the method of Colazza et al. (2009). Plants not exposed to insects were used as controls. Male and female bugs were 8–10 d-old kept isolated for 3–4 d after mating. *Trissolcus basalis* females were 4 d-old, mated and naive with respect to both, oviposition experience and contact with host chemical traces. The day before the experiments were carried out, single wasps were isolated in 2-ml glass vials closed with a cotton plug. Parasitoids were fed with a drop of honey provided on the inside surface of the vials. Thirty to sixty min prior to the experiments, female wasps were transferred to the bioassay room to acclimatize. A single wasp was released in the center of an adaxial leaf surface by gently tapping on the vial. Wasps were scored either as "responding" if they immediately displayed the typical arrestment posture, i.e., remaining motionless with the antennae in contact with the leaf surface, or as "non-responding" where they did not show this posture after three trials. For responding females the time spent on the adaxial leaf surface was measured as "retention time" with a stopwatch. Each leaf was used for testing five wasp females. Thirty replicates were carried out for each treatment. All experiments were conducted at room temperature (20–25°C) and under natural daylight conditions between 9:00 a.m. and 2:00 p.m.

Experiment 2 In a series of bioassays we evaluated the effect of *n*-nonadecane (nC_{19}), the compound specific for male bugs, on the discriminatory behavior of female parasitoids. Females of *N. viridula* were immobilized by cooling the insects down at −20°C for 5 min. Then, three tarsi on one side of the insect body were treated with hexane (nC_6) or with 4 µl of the test alkanes (0.1% w/v in hexane), while the remaining three tarsi were left untreated. Tested alkanes were: *n*-nonadecane (*n*C19) (Fluka, 99.8% purity) to mimic footprints of male bugs, and *n*-eicosane (nC_{20}) (Sigma-S. Louis, MO, USA, 99% purity) a saturated hydrocarbon that is not present in adult *N. viridula* cuticle but was used as a control for any masking or modifying effects on host footprint detection by *T. basalis.* The pure solvent was applied as a second control. Female bugs retained normal activity 10–15 min after treatment, and then they were left to walk over the adaxial surface of a leaf disk (5 cm diam) cut out from a fully expanded broccoli leaf for 30 min. Finally, a female parasitoid was released in the center of the leaf disk and its behavior was scored as described in the previous experiment. Each leaf disk was used for testing five wasps. Thirty replicates were carried out for each treatment. All experiments were conducted between 9:00 a.m. and 2:00 p.m. at room temperature (20–25°C) and under natural daylight conditions.

Experiment 3 The compounds that constitute the epicuticular wax layer of broccoli leaves were assessed, in particular, to answer the question whether *n*-nonadecane was present. Leaf surfaces were prepared by mechanically removing the outermost wax layer, using the cryo-adhesive based method described by Riedel et al. (2003). Disks were cut out from broccoli leaves taken from 4-wk-old plants with 5–6 fully expanded leaves. Leaf disks were placed on an aluminum holder. Then, cylinders (inner diam: 1.4 cm) were centered on the leaf disks and filled with water, completely covering the surface of the disks. The whole apparatus was frozen in liquid nitrogen and the resulting ice blocks were taken off the leaf disks by lifting the cylinders, thereby stripping off the wax. The cylinder walls were rapidly warmed up thus allowing the ice blocks to slip out. The wax-holding ice blocks were immediately collected in a vial containing chloroform (4 ml) and water (4 ml). Preparations from 3 to 5 leaf disks from the same leaf were pooled and *n*-tetracontane (nC_{40}) was added as an internal standard. The two-phase system was heated to approximately 40°C in a water bath and agitated repeatedly. Then, the organic phase was removed and the aqueous phase was extracted × 3 with chloroform. All three chloroform fractions were combined. The wax extracts in chloroform were dried over Na_2SO_4 to eliminate all remaining water and were then filtered. Prior to gas chromatographic (GC) analysis, chloroform was evaporated from all samples under a gentle stream of N_2 while heating the sample-vials to 50°C. Then, all samples were treated with bis-*N,N*-(trimethylsilyl)-trifluoroacetamide in pyridine (BSTFA, Supelco, Sigma-Aldrich) (30 min at 70°C) to transform all hydroxyl-containing compounds to their corresponding trimethylsilyl (TMSi) derivatives. The qualitative composition was analyzed using a capillary GC (6890 N, Agilent Technologies, Santa Clara, CA, USA; column: 30 m×0.32 mm inner diam, Zebron ZB-1HT, d_f=0.1 µm, Phenomenex, Torrance, CA, USA) and mass spectrometric

detector (MSD 5973 N, Agilent Technologies, Santa Clara, CA, USA; 70 eV, m/z 50–650). Gas chromatography was carried out with cool-on-column injection at 50°C. Oven temperature was held at 50°C for 2 min, raised by 3°C min^{-1} to 320°C and held for 20 min at 320°C. Helium carrier gas inlet pressure was 50 kPa at injection, held for 5 min, raised by 3 kPa min^{-1} to 150 kPa and held at 150 kPa for 90 min. Wax components were identified by comparison of their mass spectra with those of authenticated standards and literature data. Quantification of wax compounds was accomplished by capillary GC (6850 N, Agilent Technologies, Santa Clara, CA, USA; same column as above) and flame ionization detection under the same gas chromatographic conditions as described above but with H_2 as carrier gas. The wax composition of six individual plants was analyzed.

Statistical Analysis The total numbers of "responding" and "non-responding" *T. basalis* females for each treatment were compared with Pearson's χ^2 test. Goodman's *post hoc* procedure was used for internal contrasts among different treatments. The wasp's resident time on leaves and leaf disks, recorded only from responding individuals, led to unequal numbers of replicates. Therefore, these unbalanced data were analyzed using one-way ANOVA with type III sums of squares for log-transformed data. Comparisons among means were made using Fisher's LSD *post hoc* tests. Statistical analyses were performed using XLSTAT add-in software for Excel.

Results

Experiment 1 Wasp responses to broccoli leaves were strongly affected by the presence or absence of host chemical footprints ($\chi_{(2)}^2$=32.76; P<0.001; Pearson's χ^2) (Fig. 1 a). On leaves contaminated with *N. viridula* footprints, about 75% of *T. basalis* females displayed the typical arrestment posture, while on non-contaminated leaves only ca. 13% responded. No statistical differences could be observed when comparing the responses of wasps towards male or female hosts. In contrast, the average leaf residence time of responding wasps was clearly influenced by the host's sex ($F_{(2,47)}$=6.38, P=0.002; ANOVA Type III Sum of Squares analysis) (Fig. 1 b). On average, responding wasps showed longer retention time on leaves when footprints originated from female rather than male *N. viridula*. No statistical difference in retention time was found between uncontaminated leaves and leaves contaminated with male footprints.

Experiment 2 About 80% of all parasitoids displayed the typical arrestment posture on encountering leaf disks treated with chemical footprints from *N. viridula* females. This response was irrespective of whether bug legs had been treated with *n*-nonadecane, *n*-eicosane, or hexane ($\chi_{(2)}^2$=0.53, P=0.76; Pearson's χ^2) (Fig. 2 a). In contrast, tarsal treatments significantly affected the retention time of the wasps exploring the treated leaf disks. Host footprints from females that had been treated with *n*-nonadecane induced parasitoids to search for a significantly shorter period than the footprints from bugs treated with *n*-eicosane or hexane ($F_{(2,68)}$=5.62, P<0.001; ANOVA Type III Sum of Squares analysis) (Fig. 2 b). The retention time of the latter two treatments was similar with no significant difference between them.

Experiment 3 The total amount of epicuticular waxes on the adaxial side of *Brassica* leaves averaged 11.60 μg cm^{-2}±

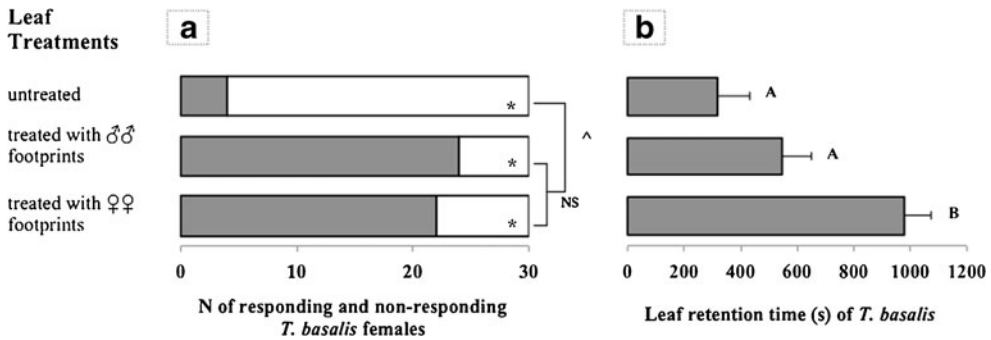

Fig. 1 Effects on the host sex discrimination ability of *Trissolcus basalis* females exploring the adaxial leaf surface of broccoli. Leaves were contaminated with chemical footprints laid by adult males and females of *Nezara viridula*. The number of tested wasp females was 30 for each treatment. **a** Bars indicate the number of the wasps that showed the arrestment response (responding, *grey bars*) and those that did not show this behavior (non-responding, *white bars*). Statistically significant differences are indicated with asterisks within treatments, and by carets between treatments. NS = not significant. Karl Pearson χ^2 test and Goodman's *post hoc* procedure. **b** Bars indicate mean values, whiskers are ± SE, of the leaf resident time of *T. basalis* females that responded to the different treatments. Bars followed by the same letters are not significantly different. One-way analysis of variance with type III sums of squares, followed by Fisher's LSD *post hoc* tests

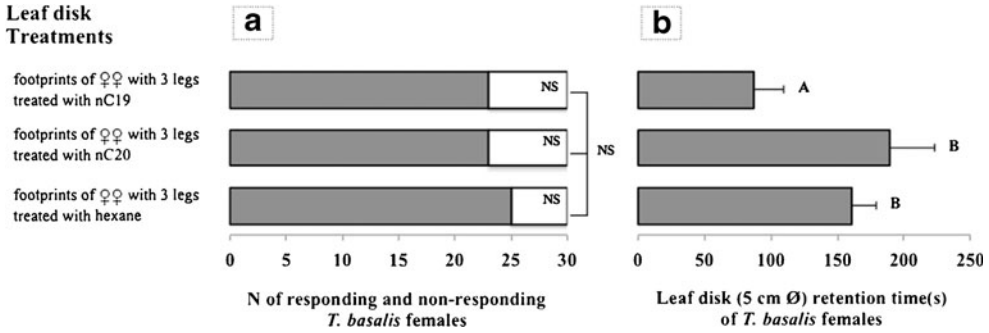

Fig. 2 Effects on the host sex discrimination ability of *Trissolcus basalis* females exploring leaf disks (5 cm Ø) of broccoli. Leaves were contaminated with chemical footprints of *N. viridula* females with legs treated with *n*-nonadecane, *n*-eicosane, and hexane, respectively. The number of tested wasp females was 30 for each treatment. **a** Bars indicate the number of wasps that showed the arrestment response (responding, *grey bars*) and those that did not show this behavior (non-responding, *white bars*). Statistically significant differences are indicated by asterisks within treatments, and by carets between treatments. NS = not significant. Pearson's χ^2 test and Goodman's *post hoc* procedure. **b** Bars indicate mean values, whiskers are ± SE, of the leaf resident time of *T. basalis* females that responded to the different treatments. Bars followed by the same letters are not significantly different. One-way analysis of variance with type III sums of squares, followed by Fisher's LSD *post hoc* tests

1.50 (mean ± SE). The mixture was composed mainly of linear hydrocarbons (38.70%), ketones (28.11%), and secondary alcohols (12.06%). Small amounts of esters (4.86%), primary alcohols (1.75%), aldehydes (1.56%), and traces of fatty acid esters and saturated and unsaturated fatty acids (less than 1%) were found. Within the class of linear hydrocarbons, *n*-nonacosane (nC_{29}) was the most abundant component, followed by *n*-hentriacontane (nC_{31}), while *n*-nonadecane was not present at the detection level in the extracts (Fig. 3).

Discussion

Here, we provide further evidence that broccoli epicuticular wax retains chemical footprints of adult *N. viridula* and show that these cues allow *T. basalis* females to distinguish between the sexes of their host. On encountering the chemical footprints of adult bugs, motivated egg parasitoids displayed a well-described arrestment response that was followed by extensive host searching behavior. More time was spent investigating leaves contaminated by female than

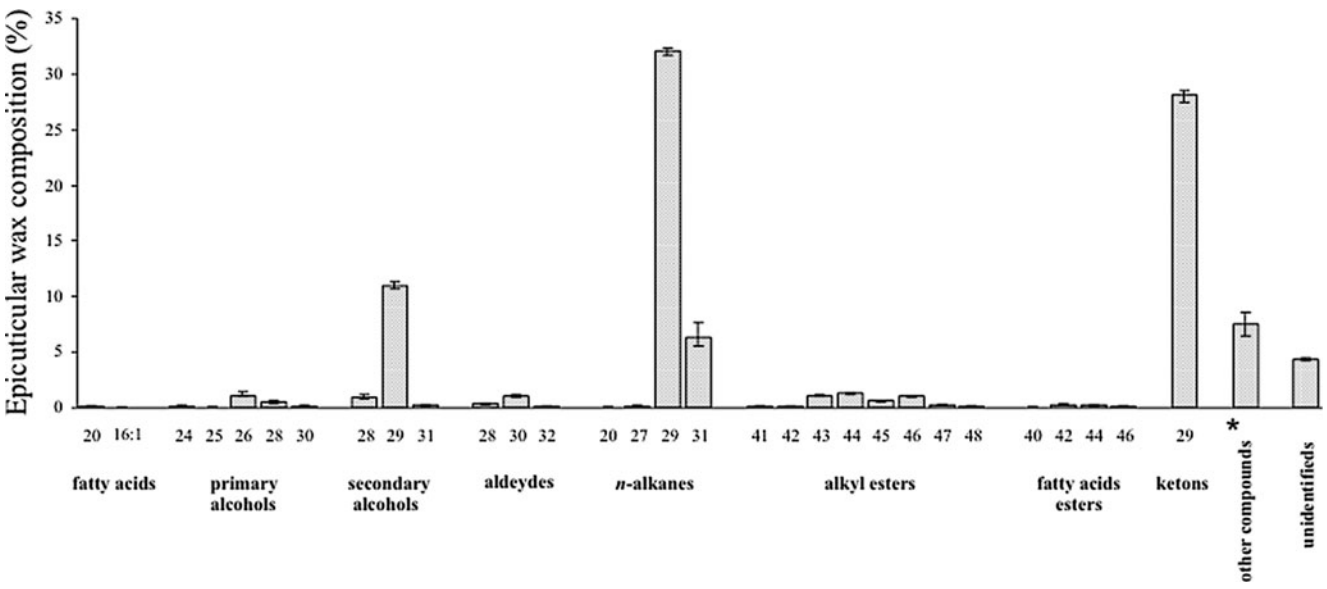

Fig. 3 Composition (%) of the outer epicuticular wax layer on the adaxial leaf surface of *Brassica oleracea* var. Italica cv. Marathon. Relative amounts of compounds are given as medians (*bars*) and 25th and 75th percentile (*whiskers*) (N=6). Compounds are listed according to chain lengths in the homologous series of aliphatic compound classes. *Compounds not separable in GC peaks

by male hosts or uncontaminated control leaves. By using an approach based on tarsal treatments of adult bugs, our results support previous experiments conducted on filter papers, which indicated that *n*-nonadecane (nC_{19}), a compound present only in *N. viridula* males, plays a role as a host sex recognition cue for wasp females. This conclusion can be drawn because treating the legs of female *N. viridula* with *n*-nonadecane resulted in footprints that apparently resembled male footprints. Female parasitoids were unabale to differentiate between male footprints and female footprints mimicking those of males. It remains to be investigated for how long *T. basalis* can detect the chemical footprints of its host. Studies on a larval parasitoid showed that the wasps recognize footprints from caterpillars for a period of at least 2 days (Rostás and Wölfling, 2009). This suggests that these kairomones can be retained for a relevant length of time and should help to improve the efficiency in finding a suitable host.

So far, the linear alkane *n*-nonadecane has been found in few pentatomid species (Aldrich, 1996; Durak and Kalender, 2007; Durak, 2008). In *N. viridula*, it is present only in adult males. It occurs in the sex pheromone blend where it represents about 7% of the total volatiles (Aldrich et al., 1987), and it constitutes about 3% of the amount of cuticle linear hydrocarbons (Colazza et al., 2007). Long-chain hydrocarbons are of high volatility, thus *n*-nonadecane from *N. viridula* can disperse into the environment as a component of the pheromone blend and adsorb onto plant surfaces at the time the adults touch the plants. Earlier experiments showed that both male volatile pheromone and male contact footprints stimulate wasp females. However, when compared, *T. basalis* clearly preferred the chemical footprints produced by host females (Colazza et al., 1999). Therefore, the presence of this linear alkane in different sources, i.e., in the pheromone glands and the cuticle of the male bug, and the similar responses of *T. basalis* females to pheromone and footprints, suggests a function for *n*-nonadecane as a compound to differentiate between host sexes. Linear hydrocarbons most likely are secreted from cuticle tissue to protect the insect from desiccation (Howard and Blomquist, 2005). However, whether *n*-nonadecane is passively dispersed as a component of the cuticular hydrocarbons or if it is released through active secretion from the pheromone glands, is as yet unknown.

All compound classes and homologues identified from the wax extracts of broccoli leaves are found commonly in plant waxes (Müller and Riederer, 2005). The wax mixture contained mainly linear hydrocarbons, ketones, and secondary alcohols. Linear hydrocarbons were dominated by *n*-nonacosane and *n*-hentriacontane, while *n*-nonadecane was absent. Based on the literature, *n*-nonadecane is not present in the epicuticular waxes of several of *N. viridula* host plants belonging to different families, such as Solanaceae, e.g., *Lycopersicum esculentum* (Zygadlo et al., 1994), *Solanum tuberosum* (Szafranek and Synak, 2006); Brassicaceae, e.g., *B. oleracea* (Baker, 1974; Hunsche et al., 2006; Purdy and Truter, 2010); Fabaceae, e.g., *Vicia faba* (Powell et al., 1999), *Glycine max* (Kim et al., 2007), *Phaseolus vulgaris* (Hunsche et al., 2006), and *Pisum sativum* (Gniwotta et al., 2005). Therefore, the absence of *n*-nonadecane among the hydrocarbons of epicuticular plant surfaces of these *N. viridula* host plants avoids possible masking effects and may enhance *T. basalis* host location.

Our study represents a starting point in elucidating the mechanisms by which egg parasitoids can distinguish host footprint compounds from the waxy background of the plant cuticle, but further studies are necessary to clarify the role that plant cuticular hydrocarbons play in the host finding process of parasitoids. Recent experiments indicate that footprints of *N. viridula* females also contain diglycerides and triglycerides of high molecular weight, and long-chain alcohols and fatty acids (Lo Giudice, 2009). On the various host plant species, these compounds can be retained to different degrees as a result of the absorptive properties of epicuticular waxes. As a consequence, the host recognition behavior of *T. basalis* females may vary among plants. Another interesting question that awaits better clarification is, whether *T. basalis* is not only able to recognize the adult host's sex but also the physiological state of the female or distinguish adults from immatures. Such capabilities were demonstrated in the related species *Trissolcus brochymenae* (Hymenoptera: *Scelionidae*) and its host *Murgantia histrionica* (Heteroptera: Pentatomidae). Salerno et al. (2009) found that footprints of mated female bugs elicited longer periods of host searching than kairomones from virgin bugs. However, as in most experiments, the chemical footprints were tested on filter paper substrate, while future studies on parasitoid-host interactions should take into account the great variety of plant-specific epicuticular wax chemistries and how they may potentially influence the perception of kairomones.

Acknowledgements We thank Mauro Lo Bue for assistance in the behavioral bioassays run at University of Palermo, Paolo Lucido for help in the collections of *N. viridula* from fields, Olga Frank for technical assistance with the GC analysis, and John Marris for constructive comments on the manuscript. The work was partially supported by the German DAAD and the Italian CRUI within the German-Italian bilateral program "VIGONI 2009".

Abstract Contact kairomones from the host mud dauber wasp *Trypoxylon politum* Say (Hymenoptera: Crabronidae) that mediate behavioral responses of its ectoparasitoid *Melittobia digitata* Dahms (Hymenoptera: Eulophidae) were investigated. Chemical residues from host by-products, the cocoon, and the meconium, induced arrestment behavior of macropterous female parasitoids, while those from the host stage attacked, i.e., the prepupa, did not. *Melittobia digitata* response to polar and apolar extracts of host by-products indicated kairomone(s) solubility mainly in hexane. GC and GC/MS analysis of cocoon and meconium apolar extracts revealed a mixture of linear carboxylic acids from C_6 to C_{18}, and both extracts contained almost identical compounds. When a reconstructed blend of host by-product carboxylic acids was tested, *M. digitata* females showed only a weak response, thus suggesting that other unidentified compounds present in small quantities also may be involved. *Melittobia digitata*'s response to contact kairomones was innate and not affected by previous host exposure experience. Our results provide evidence of contact kairomone exploitation in the genus *Melittobia*. The ecological significance of these findings in the host selection process of *M. digitata* is discussed.

Introduction

Insect parasitoids rely mainly on semiochemicals for location and recognition of hosts, and several studies have been published on the role played by various chemical cues in the host selection behavior of hymenopteran parasitoids (Godfray, 1994; Quicke, 1997; Vinson, 1998, 2010; Fatouros et al., 2008). Parasitoids, at the initial steps of the host location process, exploit mainly volatile cues (Group I cues sensu Vinson, 1998, 2010) since they can be perceived at long range distance, whereas slightly volatile cues or contact cues become progressively more important when parasitoids are in the close vicinity (Group II cues) or in contact (Group III cues) with the host (Vinson, 1998, 2010). Experience is particularly important in affecting the initial phases of host selection behavior, especially for generalist species, as experienced females have been reported to respond more efficiently to the host-plant complex than naive females (Drost et al., 1986; McAuslane et al., 1991). However, the role of experience may be important at all levels of the host selection process (i.e., time required to recognize and parasitize a host decreases as the parasitoid handles successive hosts) (Wajnberg, 1989; Segoli et al., 2009).

Wasps in the genus *Melittobia* are gregariously developing ectoparasitoids that frequently attack solitary wasps and bees, but also attack a wide range of hosts that represent several insect orders (González et al., 2004; Matthews et al., 2009). *Melittobia* wasps are sexually

dimorphic, and females are polymorphic (short winged and long winged) (González and Matthews, 2005, 2008; Matthews et al., 2009). Long-winged females, also called macropterous females, are the dispersal stage in all *Melittobia* species, while some non-dispersing short-winged females, also called brachypterous females, may be produced on high quality hosts. While several aspects of *Melittobia*'s behavioral ecology have been studied (reviewed in Matthews et al., 2009; Tanner et al., 2011), the chemical ecology of *Melittobia* species is poorly understood. The only such study (Cônsoli et al., 2002) elucidated the role of α- and β-*trans*-bergamotenes as the male-produced sex pheromone in *M. digitata* Dahms. Nonetheless, chemical cues are likely to be important in allelochemical communication of *Melittobia* too, as, for example, during the host location process. The antennae of *Melittobia* females possess numerous mechano- and chemo-receptors (Dahms, 1984; Imandeh et al., 2001), suggesting that chemical cues are important in *Melittobia* biology.

Macropterous females of *Melittobia* wasps appear to disperse randomly once out of their natal nest, but when close to host nests, little is known about cues that might direct them to parasitize a healthy host (González and Terán, 2001; Matthews et al., 2009). However, some progress has been made in understanding how *Melittobia* wasps locate their hosts (Silva-Torres et al., 2005a,b; Cusumano et al., 2010). Cusumano et al. (2010), working with *M. digitata*, suggest that once the mud dauber wasp host *Trypoxylon politum* Say (Hymenoptera: Crabronidae), is located the *Melittobia* female adopts a "sit and wait" strategy relying mainly on indirect host-related volatile cues. Females search for *T. politum* nests under construction, and once located, they enter the newly built cell and wait inside until the host becomes a prepupa, the stage attacked by the parasitoid. Before such transformation, the mature larva scrapes grains from the cell wall and glues them with saliva and the first released meconial fluids to build its cocoon, and once it is built, the larva releases the remainder of the meconium (Cooper, 1957; Cross et al., 1975; R.W. Matthews pers. comm.). The presence of the cocoon and the final release of meconium are indicators associated with host suitability (Cusumano et al., 2010).

Contact cues are important in host location, host recognition, and also in mate finding of parasitic wasps (Godfray, 1994; Fauvergue et al., 1995; Vinson, 1998; Colazza et al., 1999). The parasitoid response to contact cues usually consists of flight inhibition, an intense tapping of the substrate with its antennae, and a modification of the walking pattern characterized by a reduction in linear speed and an increase in turning rate (arrestment response) (Waage, 1978, 1979). Several host-produced stimuli act as contact cues, such as frass (Loke and Ashley, 1984; Takabayashi et al., 1985; Meiners et al., 1997), honeydew (Vinson et al., 1978; Gardner and Dixon, 1985; Mehrnejad and Copland, 2006), wing scales (Laing, 1937; Noldus and van Lenteren, 1985; Gardner and van Lenteren, 1986; Schmidt and Carter, 1992; Chabi-Olaye et al., 2001), footprints (Colazza et al., 1999; Borges et al., 2003; Conti et al., 2003; Rostás and Wölfling, 2009), and mandibular gland secretions (Waage, 1978).

Chemical investigations have revealed that both polar and non-polar compounds can be the biologically active substances responsible for eliciting wasps' arrestment behavior. For example, active compounds in honeydew are often water or polar solvent soluble (Vinson et al., 1978; Bouchard and Cloutier, 1984); water-soluble propriety can be important for parasitoids because of rain that can wash away honeydew from area where hosts are no longer available. In contrast, in the case of parasitoids that exploit contact cues produced by the walking traces of the host, kairomones often are hexane soluble, suggesting that cuticular lipids may be involved (Howard and Flinn, 1990; Colazza et al., 2007; Rostás and Wölfling, 2009). Due to similar solubility properties, such compounds can be adsorbed and retained on the wax surface of leaves, and thus, can be easily perceived by the searching parasitoid. The parasitoid's response to contact cues also can be affected by experience which modifies the innate response to contact stimuli (Peri et al., 2006).

In order to better clarify the role of contact chemical cues in the host-parasitoid system *Trypoxylon politum* Say - *Melittobia digitata* Dahms, a series of bioassays were developed to investigate: (1) if *M. digitata* exploits contact kairomones from the host prepupa and/or host by-products, the cocoon, and the meconium; (2) the solubility and the chemistry of the kairomones; and (3) if experience affects the parasitoid's response to contact cues.

Methods and Materials

Insect Cultures Parasitoid wasps of the species *Melittobia digitata* were reared on naked prepupae of *T. politum* from stock cultures maintained in the Entomology Research Laboratory of Texas A&M University's Department of Entomology. Wasp cultures were kept in an incubator at 25°C and 70% RH in total darkness. Only macropterous (long-winged) females less than 5 d-old were used in the experiments. Because of their age, and since they were taken directly from cultures previous to their use in the bioassays, the wasps were presumably mated. About 1 hr before bioassays, wasps were transferred individually to size 1 gelatine capsules (vol: 0.5 ml; diam: 6.63 mm) and tested only once.

Hosts Prepupae of *Trypoxylon politum* Say were obtained from nests collected in 2009 (HW 47, West of Bryan, Texas

N 30° 36′, W 96° 24′) and kept in a refrigerator (<12°C) to maintain the prepupae in diapause for eventual use as hosts of *Melittobia* wasps. Previous to use in these bioassays, every cocoon was opened gently at the subtruncate cap (Cross et al., 1975) making a small hole in order to check if each host prepupa was healthy and not parasitized.

Open Arena Preparation Bioassays with *M. digitata* females were conducted in an open arena consisting of a rectangular filter paper sheet (120×140 mm). At the center of the arena, a circle with 58 mm diam. (2,642 mm^2, about 15% of the entire arena) was treated with the stimuli, while the rest of the filter paper was left untreated. We performed bioassays by using a flat surface in order to avoid any possible bias due to physical cues, since shape has been also shown to have a role in the host acceptance of *M. digitata* (Cooperband and Vinson, 2000). Each arena was used for testing five female wasps; it was then discarded and replaced with a new one. For each different experiment, the following preparation procedure used for bioassays was performed:

(1) *In vivo prepupa, cocoon, and meconium*. *Trypoxylon politum* prepupae are found protected by cocoons inside cells of mud nests. Each cell chamber contains a single cocoon/host (Fig. 1). Collected hosts were divided into three parts and tested separately: 1) prepupa; 2) empty cocoon; 3) dried meconium originally released by the mature *T. politum* larvae, and easily scraped from the bottom and inside the cocoon. The portion of cocoon to which the meconium was in direct contact was discarded and not used in the experiments to avoid any possible contamination.

(2) *Hexane and acetone host-by product extracts*. Hexane and acetone extracts were prepared for the following host-by products and tested separately: a) five cocoons with meconium but without prepupae inside (cocoon + meconium); b) five cocoons with no prepupae inside and meconium scraped out. The bottom part of the cocoon that was directly in contact with the meconium was not used in order to avoid any possible contamination with chemicals located on the meconium surface (cocoon only); c) five dried meconium pieces scraped from cocoons (meconium only).

Since *in vivo* bioassays (see Results) indicated that the prepupa of *T. politum* did not elicit a response to *M. digitata* wasps, we did not test the prepupa extract.

The cocoon + meconium, cocoon only or meconium only were placed in a 15 ml-glass vial and extracted with 10 ml of hexane or acetone (Sigma-Aldrich) at 28°C for 2 hr. After removal of host by-products, the resulting extracts were evaporated under a gentle nitrogen stream and redissolved in 200 µl of hexane or acetone. After each extract was chemically analyzed, it was stored at −18°C until bioassayed.

(3) *Reconstructed Blend of Straight-chain Carboxylic Acids*. The wasps responded strongly to apolar extracts (see Results). Thus, we investigated only the chemical composition of hexane extracts. Additionally, since the parasitoid's responses to cocoon and meconium hexane extracts were similar, and because of the high chemical similarities among identified compounds of the cocoon and meconium (see results and Table 1), we decided to use a solution containing an average quantity of each compound present in the cocoon crude extracts. This was done by reconstructing the hexane extract with a mixture of standard carboxylic acids, normalizing the concentration of the carboxylic acids found in crude extract to oleic acid, the most abundant compound. The stock of chemicals was prepared as a hexane solution containing (in mg/l): $C_{18:1}$(1000), $C_{18:2}$(618), C_{18}(369), C_{16}(294), C_8(262), $C_{16:1}$(125), C_{14}(124), C_7(94), C_6(90), C_9(30), C_{12}(17), (Sigma-Aldrich) (numbers given in brackets: see Table 1). The working solution was obtained by using 10 ml stock solution and diluting it to 100 ml. The reconstructed blend was stored at −18°C until bioassayed.

Open Arena Bioassay A single parasitoid female was gently introduced inside the lid of a small Petri dish (diam=35 mm) that was placed with the open end over the center of the treated area of the arena, thereby allowing the wasp to acclimatize. After 1 min and verification that the wasp was in direct contact with the arena, the lid was removed and observations of the unrestrained wasps' behavior were recorded. Recording stopped when the wasp walked off of the arena or after 10 min. For each experiment, the following bioassay procedure was used.

(1) *In vivo prepupa, cocoon, and meconium.* Prepupae, empty cocoons, or only meconium (5 of each) were gently rubbed in the center of the filter paper for about 5 min in order to contaminate the area homogenously with chemicals. Plain filter paper arenas served as controls.

(2) *Hexane and acetone host-by product extracts.* Hexane and acetone extracts of the cocoon + meconium, cocoon only, meconium only were tested at doses of 5 insect equivalent (IE) by pipetting 200 µl extract onto the central area of the arena. The 5 IE dosage was applied by repetitive pipetting of about 50 µl solution, and allowing the solvent to evaporate between repetitions. Filter paper in which the central area was treated with 200 µl of hexane or acetone was used as a control. The solvent was left to evaporate completely (~5 min.) before observation started.

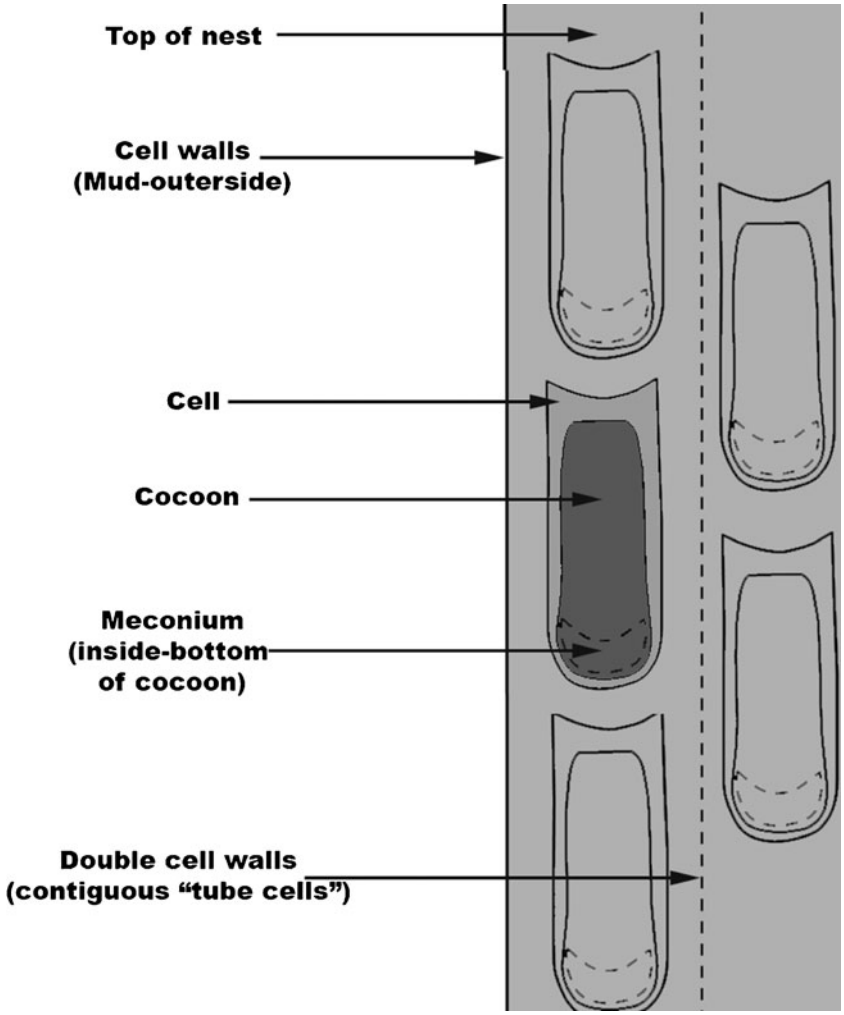

Fig. 1 Line drawing of *Trypoxylon politum* wasp mud nest showing the typical position of nest cells and the wasp cocoons inside. The dried meconium is shown inside the cocoons (in *broken lines*)

(3) *Reconstructed blend of straight-chain carboxylic acids*. Five IE of the reconstructed carboxylic acid blend of cocoon were tested by pipetting 20 µl of a hexane solution containing 0.1 mg/ml of the most abundant component ($C_{18:1}$) and proportional amounts of the minor components onto the treatment areas. Filter paper with the central area treated with 20 µl hexane served as control.

The walking pattern of *M. digitata* was observed using a video camera (EyeCom, PRO-9000) connected to a screen (Symphonic, 19-inch) in order to monitor the wasp away from the experimental arena and to avoid any possible disturbance effect of the observer on the behavior of the wasp. Meanwhile, data was digitalized and processed by using XBug, a video tracking and motion analysis system. The parameters computed by the system that best defined and described the parasitoid's behaviors were: (1) total residence time (sec); (2) average linear speed (mm/sec); (3) average angular speed (°/sec); (4) tortuosity index. This index ranges from 0 to 1, with 0 indicating a completely linear track, and 1 the maximum tortuosity. It was computed as follows: $T=1\text{-}mp/tl$; where T, tortuosity index; mp, maximum projection of the track over the generic line in the plan; and tl the total length of the track. All parameters were processed only for the central area and not for the total arena because we assumed that data from the treated area better characterized the behavior of the searching wasps stimulated by contact chemicals. To minimize cues from the room, the walls were painted black, and the experimental chamber was equipped with red fluorescent light (provided by 8, 40-W fluorescent bulbs covered with red tube guards) in order to keep visibility in the room in accordance to parameters previously established by González et al. (1985) and Matthews et al. (1985). For experiments (1) and (2), 25 replicates were performed, while for experiment (3), 40 replicates were performed. Experiments were carried out in a completely randomized design performing five replicates per experiment/day. The room was maintained at a temperature of 20°C and a RH of 60%. All bioassays were conducted from 10:00 to 12:00 and from 14:00 to 16:00.

Table 1 Mean amounts (± SE) of compounds identified from the cocoon and meconium of *Trypoxylon politum.* and their relative abundance (%)

Peak #	Compound[a]	Rt[b]	Amount (ng)		Relative abundance (%)		*t*-test[d]

[a] Carboxylic acids were first converted into methyl ester derivatives and then identified by comparison of retention times and mass spectra with authentic standards

[b] Rt retention time

[c] Hexane extracted compounds are equivalent to 1 meconium and 1 cocoon, respectively

[d] The amount of each carboxylic acid present in both cocoon and meconium hexane extracts was compared by using a *t*-test ($N=10$) *$P<0.05$; *ns* not significant; *ND* not detected

Gas Chromatography GC analyses were performed on a Hewlett Packard 6890 system with 7683 injector. One μl of each sample was injected onto a 0.32 mm×25 m SGE BP1 column in splitless mode. A temperature program of 50°C was set for 5 min., then 220°C at 10°/min. (5 min). Helium carrier gas at 20 psig was used. Ten samples in hexane of each type (cocoon and meconium) obtained as previously described in section (2) of the "open arena preparation procedure" were used for analysis. Mass spectral data were acquired on a Thermoelectron Trace GC2000 quadrupole GC-MS instrument. The attached GC unit was a Trace GC Ultra (Finnegan) equipped with a 0.25 mm×25 m SGE BP1 column operated at constant flow of 1 ml/min, using the same temperature gradient. Spectra were acquired in total ion current mode over a range of 40–500 amu with 70 eV electron impact ionization. Peak analysis was by comparison of acquired mass spectral data with that in the NIST 2001 libraries. Samples of all tentatively identified acids and of their methyl esters were purchased from Sigma-Aldrich chemical company, and retention time and mass spectra of these compounds were used for confirmation. Samples of acids then were prepared for bioassay. Due to poor peak symmetry of carboxylic acids, methyl ester derivatives were used for quantification. To obtain the methyl esters, 100 μl of crude insect derived extract for analysis, or 100 μl of a fatty acid mixture containing 1–10 μg fatty acids for standards were placed in a 2 ml HP screw cap vial, and 100 μl at 10% of BF3/MeOH were added to the vial, which was placed in heater block at 60° for 30 min., removing to shake well at 10 min. intervals. Then, 1 ml of water and 800 μl of hexane were added, shaking well and allowing layers to separate. The upper layer was removed carefully with a disposable pipette and filtered through anhydrous sodium sulfate, around 2 cm in a disposable pipette held in place by a small plug of Kimwipes, collecting the filtrate in a 2 ml crimp cap vial.

Detection Limits The limit of detection (LOD) of 1 ng/μl was determined by measuring progressively more dilute concentrations of the identified methyl esters until a signal-to-noise ratio of 3:1 was reached. Means and standard error for amounts of each compound in each sample type were calculated based on ten replicates (Table 1).

Effect of Experience To test if there was any influence of the experience elicited by exposing wasps to host by-products (cocoon or meconium) or to the host itself (prepupa) on the parasitoid's arrestment response, wasps less than 5 d-old were isolated together with the source of the stimulus into small glass vials (1 dram) with tight cotton stoppers and kept for 24 hr prior to bioassays; in the case of exposure to prepupa, *M. digitata* initiated host feeding and oviposition after 2–6 hr; such parasitoids were experienced with respect to oviposition. The response of cocoon-experienced wasps, meconium-experienced wasps, or prepupa-experienced wasps were tested subsequently on

filter paper arena contaminated, as *in vivo* bioassays, with contact chemicals of the cocoon, meconium, or prepupa, respectively. As controls, we used naïve females of the same age that were tested in arenas contaminated with chemicals of the cocoon, meconium, or prepupa, respectively, in order to make paired comparison between experienced and naïve wasps. For each set of bioassays 25 replicates were performed.

Statistical Analysis Data were not significantly different from a normal distribution (Shapiro-Wilk test $P=0.05$). Data from the *in vivo* bioassays, from host by-product extracts, and from reconstructed blends of carboxylic acids were analyzed by one-way ANOVA followed by Tukey's HSD *post hoc* test for comparisons between means. Comparisons between naïve and experienced female wasps were done by using a *t*-test. The amounts of each carboxylic acid extracted from cocoon and meconium also were compared by using a *t*-test. All statistical analyses were performed by using Statistica 6.0 for Windows (StatSoft Inc., Tulsa, OK, USA).

Results

For all experiments with control conditions, wasp residence time in the arena was short, and the tortuosity index was low. Control wasps spent little time in the central area, exploring at most only small sections of the arena's surface (Fig. 2a). With the different treatment conditions, in those experiments that elicited a behavioral response of wasps, there was increased residence time in the central treated area compared to controls. In general, wasps spent more time within the contaminated (treated) area and performed a more convoluted locomotion pattern, thus resulting in a more complete exploration of the arena (=arrestment response) characterized by a high tortuosity index. Females often were observed turning back to reenter the treated area after exceeding its boundaries (Fig. 2b).

In vivo Prepupa, Cocoon, and Meconium Residence time in the central area was higher in the arena contaminated with host by-products compared to those contaminated with either the host prepupa or the control ($F=10.59$; $df=3,96$; $P<0.001$) (Fig. 3a). In fact, no significant difference was found between time (mean ± SE) spent by wasps on the prepupa-contaminated arena (59.91±22.11 sec) and time spent on the control (27.21±6.40 sec). Linear speed was lower on patches contaminated by cocoon and by meconium compared to patches contaminated by prepupa or the control ($F=46.15$; $df=3,96$; $P<0.001$) (Fig. 3b). Higher values of angular speed of parasitoid were found in the arena contaminated by prepupa compared to those contaminated by host by-products or control ($F=21.23$; $df=3,96$; $P<0.001$)

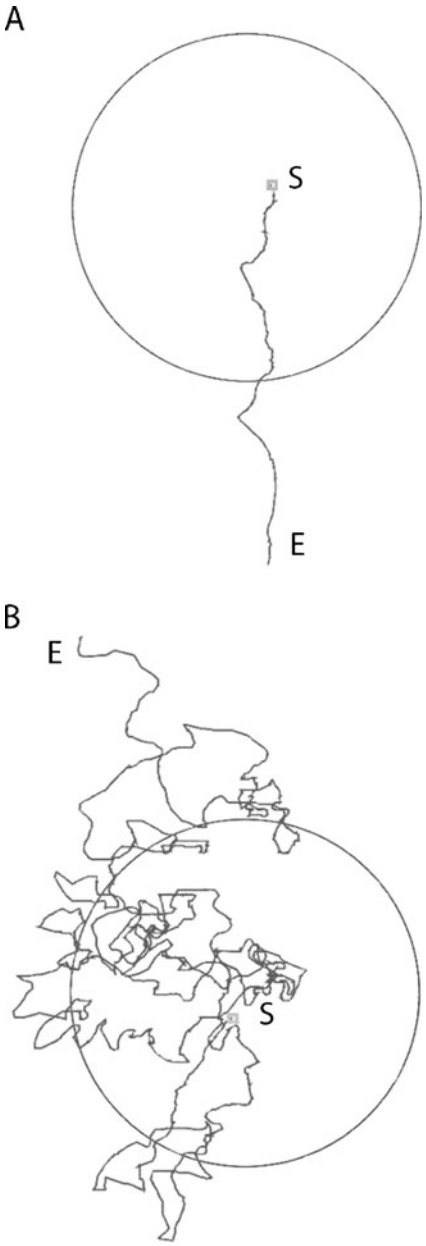

Fig. 2 Examples of two recorded paths (A+B) of *Melittobia digitata* in an open arena consisting of a rectangular filter paper sheet (120× 140 mm) (central circle area 58 mm diam.). **a** Untreated central area. **b** Central area rubbed with *Trypoxylon politum* cocoons. *S* start; *E* end

(Fig. 3c). Tortuosity was higher on the patches contaminated by host by-products compared with the control, and intermediate in those contaminated by prepupa ($F=30.12$; $df=3,96$; $P<0.001$) (Fig. 2d).

Hexane Host By-Product Extracts Residence time was higher in the arenas contaminated with cocoon + meconium extract, cocoon extract, and meconium extract compared to the control ($F=4.06$; $df=3,96$; $P=0.009$) (Fig. 4a). Linear speed was lower on patches contaminated with cocoon +

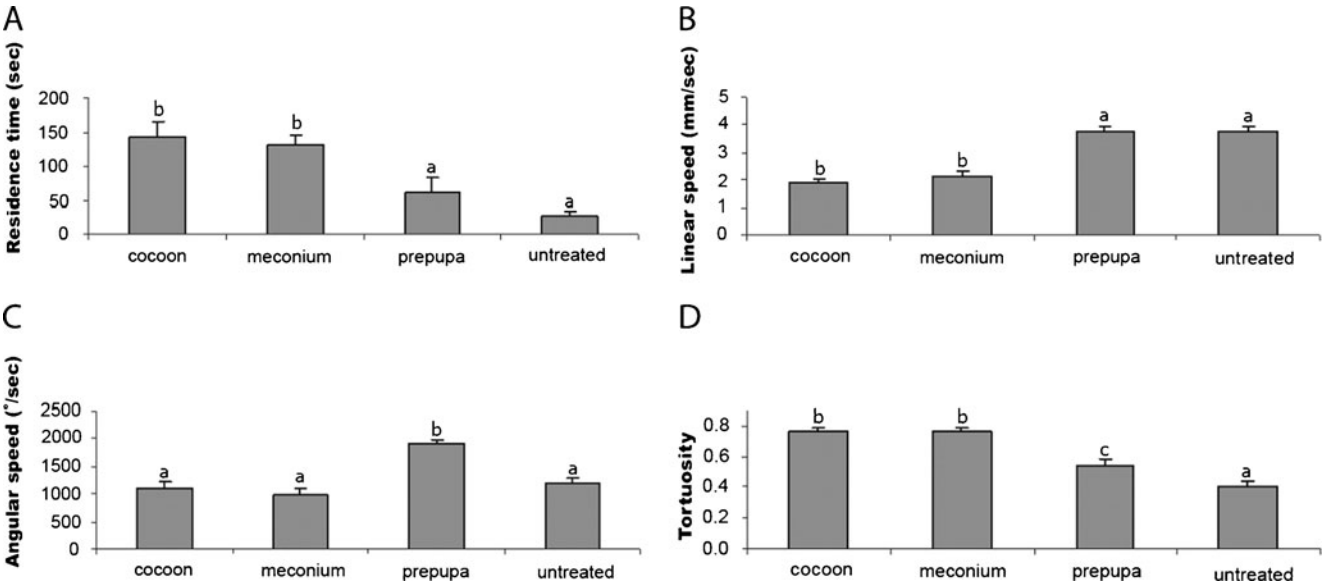

Fig. 3 Various measures (mean±SE) of *Melittobia digitata* responses to contact chemicals from rubbed cocoon, rubbed meconium, and rubbed prepupa of *Trypoxylon politum*. Untreated arena served as control. Columns with the same letter are not significantly different at $P<0.05$ (ANOVA, Tukey tests)

meconium extract compared to the other tested conditions or the control ($F=6.67$; $df=3,96$; $P<0.001$) (Fig. 4b). Higher values of angular speed of parasitoid were found in the arena contaminated by cocoon extract compared to the other tested conditions or control ($F=9.49$; $df=3,96$; $P<0.001$) (Fig. 4c). Tortuosity was higher within the patches contaminated by extract of cocoon + meconium, cocoon, and meconium compared to the control ($F=7.30$; $df=3,96$; $P<0.001$) (Fig. 4d).

Acetone Host By-Product Extracts Central area residence time was higher for arenas contaminated with cocoon + meconium extract compared to the other host by-product extracts or control ($F=5.96$; $df=3,96$; $P<0.001$) (Fig. $4a_1$). There were no significant differences in the linear speed of the parasitoid on host by products contaminated patches over the control ($F=2.05$; $df=3,96$; $P=0.112$) (Fig. $4b_1$). Higher values of the angular speed were found for arenas treated with extract of cocoon + meconium or cocoon compared to those contaminated by meconium extract or controls ($F=14.95$; $df=3,96$; $P<0.001$) (Fig. $4c_1$). Tortuosity was higher on the patches contaminated by extract of cocoon + meconium or cocoon compared to control ($F=8.92$; $df=3,96$; $P<0.001$) (Fig. $4d_1$). However, no statistically significant differences were found between cocoon extract and meconium extract nor between meconium extract and control (Fig. 4d).

Reconstructed Blend of Straight-chain Carboxylic Acids The mix of linear carboxylic acids (test) elicited a weak but significant response in terms of arena residence time compared to the control ($F=9.32$; $df=1,78$; $P=0.003$). In fact, time (mean ± SE) spent by the wasps on the test arenas was 76.72±13.77 sec, while the time spent on the control arenas was 32.29±4.81 sec.

Chemical Analyses Twelve detected compounds, all linear carboxylic acids, were identified in the host by-product hexane extracts of *T. politum*. The five most abundant compounds were octanoic (cocoon[c] = 8.7%; meconium [m] = 12.2%), palmitic (9.7%c; 8.5%m), linoleic (20.5%c; 22.5%m), oleic (33.1%c; 30.5%m),and stearic acid (12.2%c; 14.4%m) representing 84.2% and 88.1% of the total carboxylic extract of cocoon and meconium, respectively. Qualitative differences were found, since decanoic acid was only detected in small quantities from meconium extract, and quantitative differences also were found because, for all carboxylic acids, excluding myristic acid, the relative amount was significantly higher for meconium extract compared to the cocoon extract; however, the compounds were present in similar ratios (Table 1) (Fig. 5).

Effect of Experience Central arena residence time was not significantly influenced by exposure of wasps to host by-products (cocoon: $t=0.677$; $df=48$; $P=0.501$; meconium: $t=0.174$; $df=48$; $P=0.862$) nor to exposure to the host itself (prepupa: $t=-0.878$; $df=48$; $P=0.384$); even though experienced parasitoids increased the time (mean ± SE) spent on an arena contaminated by prepupa chemicals (naïve = 59.91±22.11 sec; experienced = 93.85±31.70 sec), no statistical differences were found between values of naïve vs. experienced wasps; similar values were found for the time

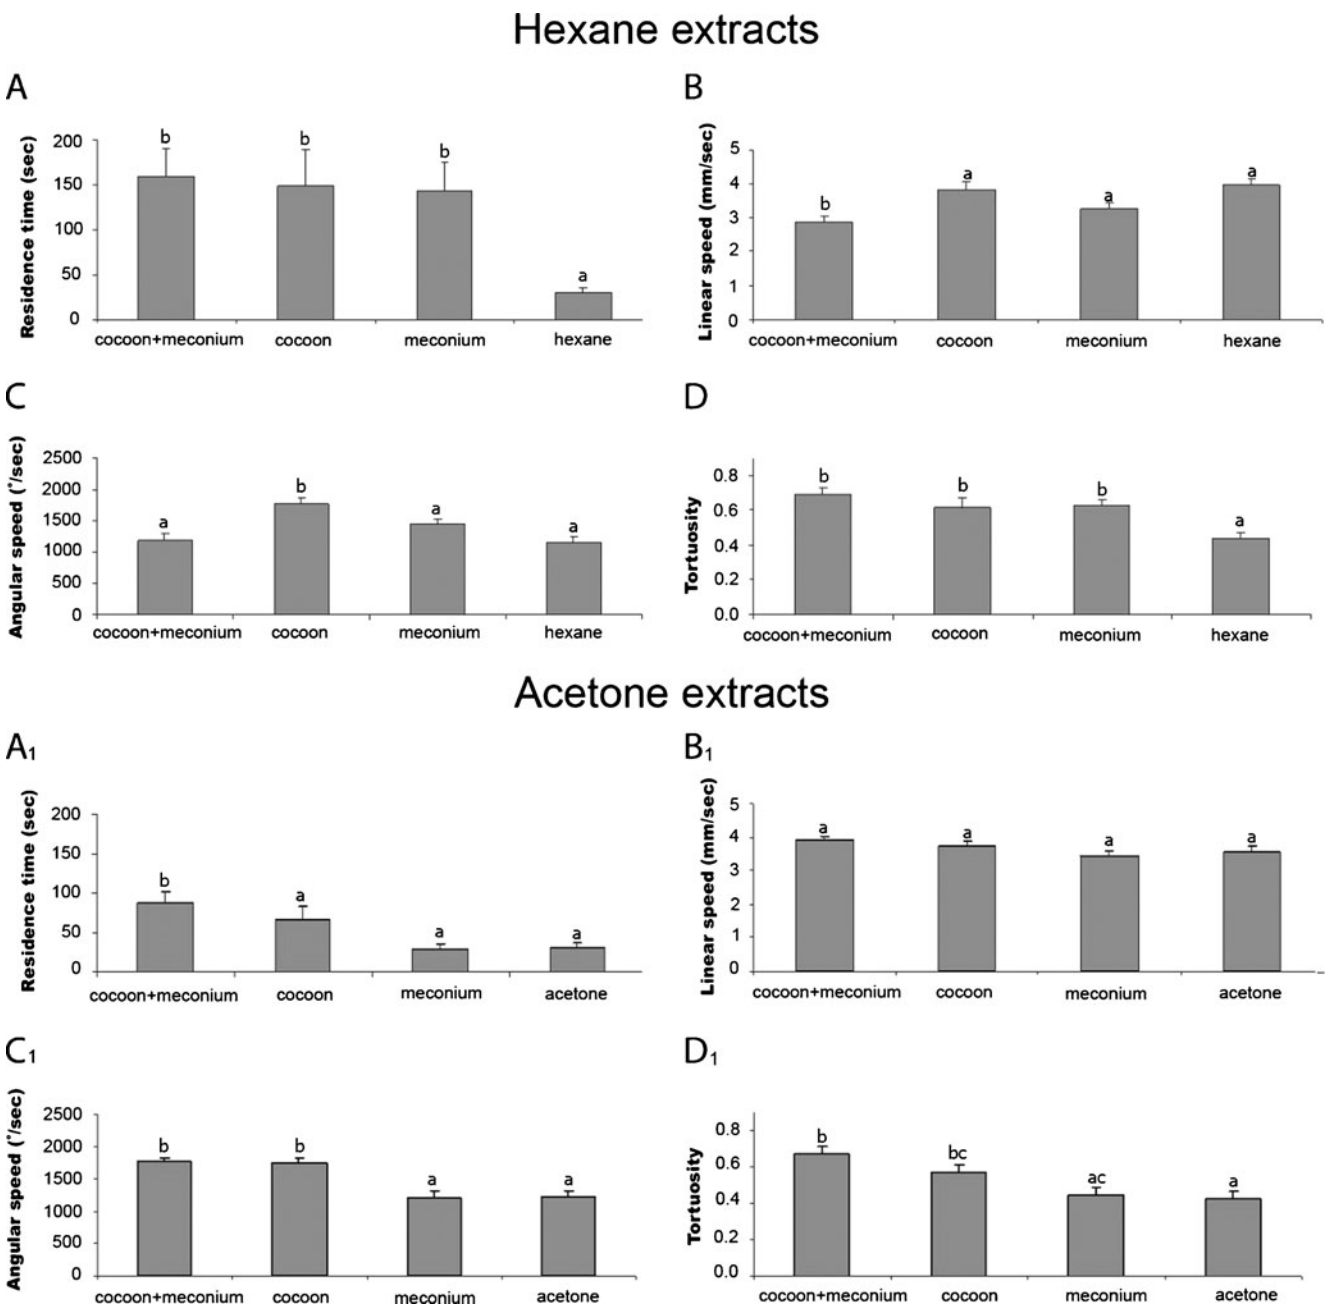

Fig. 4 Various measures of *Melittobia digitata* responses to hexane extracts (*above*) and acetone extracts (*below*) of cocoon + meconium, cocoon only, and meconium only of *Trypoxylon politum*. Arena treated with hexane or acetone served as control. Columns with the same letter are not significantly different at $P<0.05$ (ANOVA, Tukey tests)

spent by naïve and experienced wasps on patches contaminated with host by-products (cocoon: naïve = 143.86± 22.50 sec; experienced = 120.87±25.40 sec; meconium: naïve = 132.49±12.88 sec; experienced = 129.38±12.27 sec).

Discussion

The results of the *in vivo* bioassays showed clearly that *M. digitata* was arrested by contact kairomones from the host by-products (cocoon, meconium) providing the first evidence that contact cues are exploited by *Melittobia* wasps. Surprisingly, the host stage attacked, *T. politum* prepupa, did not induce the parasitoid to spend significantly more time in an arena treated with chemicals in their exocuticle when compared to the control. Contact chemicals located in the host cuticle are cues always associated with the host, but *M. digitata* seems not to exploit them during the host selection process. Such behavior may be explained by considering that the host selection process is divided into a

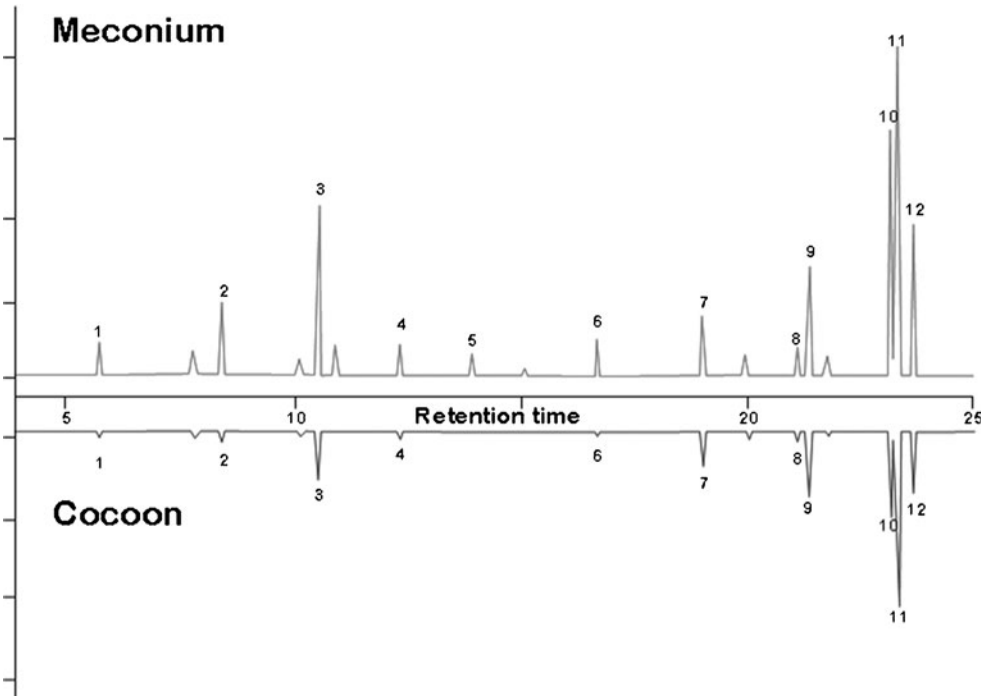

Fig. 5 Representative gas chromatograms of compounds extracted from cocoon and meconium of *Trypoxylon politum* with hexane. For peak identities, see Table 1; "Methods and Materials" describe analysis conditions

series of hierarchical steps in which each step is influenced by the previous one: the parasitoid, under natural condition, is expected to find a prepupa after having found a cocoon and contacted the meconium; hence, the lack of occurrence of the host by-product cues may explain the non-response to contact chemicals from the prepupa since cocoon and meconium are always associated with the presence of a suitable host. In addition, it also is possible that physical or tactile cues play an important role when parasitoids first contact a potential host as shown by Cooperband and Vinson (2000); chemical information could be secondary or redundant to physical cues.

The bioassays conducted with polar and non-polar extracts revealed that *M. digitata* responded strongly to hexane extract of cocoon + meconium, cocoon only, and meconium only, suggesting that the nature of the kairomones is mainly non-polar soluble. Since the response of the parasitoid was similar when the hexane extract of the cocoon or the hexane extract of the meconium was tested, we assume that contact kairomones of these host-by products share similarity. Indeed, the cocoon and the meconium have the same origin, and they are both produced by the mature larva just prior to its transformation to the prepupa (which is the suitable stage for parasitoid offspring development). GC and GC/MS analysis of cocoon and meconium extracts showed the presence of linear carboxylic acids (C_6–C_{18}). Cocoon and meconium extracts contained almost identical compounds in similar proportion (the most abundant compounds were: octanoic acid; hexadecanoic acid; (*Z*,*Z*)-9,12-octadecadienoic acid; (*Z*)-9-octadecenoic acid; octadecanoic acid).

Fatty acids are common compounds in nature that play roles in various ecological contexts, including the host location process of some parasitoids (Renou et al., 1992; Horikoshi et al., 1997). However, when the reconstructed blend of fatty acids was tested, *M. digitata* showed a weak response compared with the control; hence, even if carboxylic acids play a role, probably some other unidentified compounds present in small quantities are also involved. Many studies show that synthetic blends have only low activity when compared to the activity of crude extracts, thus supporting the presumed high complexity of contact kairomones. For example, the egg parasitoid *Trissolcus basalis* (Wollaston) weakly responded to a reconstructed blend of straight-chain hydrocarbons compared to hexane extracts of other host cuticular lipids (Colazza et al., 2007); the larval parasitoid *Cotesia marginiventris* Cresson weakly responded to reconstructed blends of linear *n*-alkenes compared with hexane extracts of the host larvae footprint and of the larval ventral cuticle (Rostás and Wölfling, 2009).

Melittobia digitata can successfully parasitize a large variety of hosts that belong to different insect orders. In general, the less specialized a parasitoid is, the more likely that experience can affect its behavior (Vet and Dicke, 1992). In our experiment, no difference was found between experienced and naïve wasps regardless if they were experienced on a cocoon, on meconium, or on prepupa. In the latter case, *M. digitata* was able to host feed and even oviposit on the host, resulting in rewards experienced by the wasps, which could act as strong reinforcing stimuli. We expected that prepupa-experienced wasps would spend significantly more time compared with naïve wasps when

tested on filter papers arena contaminated with contact cues of the prepupae. However, this did not occur. Unlike many other parasitoids that attack and parasitize multiple hosts, thereby gaining repeated oviposition experience, *Melittobia* females usually locate and parasitize (and/or superparasitize) only a single host; thus, prior host experience would not be selectively favored. Silva-Torres et al. (2005b) reared *M. digitata* on 3 different hosts: *T. politum*, *Sarcophaga bullata* (Parker), and *Megachile rotundata* (Fabricius), and found that the female's natal host did not influence host choice. This suggests that pre-imaginal experience is irrelevant for *M. digitata* wasps as well.

Cusumano et al. (2010) stressed the importance of volatile cues emitted by host by-products of *T. politum* in the host location process of *M. digitata* macropterous females. The results of our study indicate that once *M. digitata* is within the host cell, host acceptance is mediated by chemicals of low volatility that arise following host meconium release and cocoon construction.

Acknowledgements We thank Sherry Ellison whose help was invaluable to find, organize, and build devices and equipment for our research. Thanks also to Daniele Peri and Ezio Peri for their help in adapting the Xbug software for this research. We are indebted to Robert W. Matthews for valuable comments on the original manuscript.

New Sex Pheromone Blend for the Lightbrown Apple Moth, *Epiphyas postvittana*

Ashraf M. El-Sayed · Vanessa J. Mitchell · Lee-Anne M. Manning · David Max Suckling

Received: 5 February 2011 / Revised: 23 April 2011 / Accepted: 3 May 2011 / Published online: 15 May 2011
© Springer Science+Business Media, LLC 2011

Abstract The composition of the sex pheromone gland of the lightbrown apple moth, *Epiphyas postvittana* (Walker) was re-investigated. In addition to the two previously identified compounds, (*E*)-11-tetradecenyl acetate (E11-14Ac) and (*E,E*)-9,11-tetradecadienyl acetate (E9E11-14Ac), seven additional candidate pheromone compounds were identified: (*E*)-11-tetradecen-1-ol (E11-14OH), tetradecyl acetate, hexadecanal, (*E*)-11-hexadecenyl acetate (E11-16Ac), hexadecyl acetate, octadecanal, and octadecyl acetate. Gas chromatographic-electroantennographic detection analysis showed that only four (of the nine) compounds (E11-14OH, E11-14Ac, E9E11-14Ac, and E11-16Ac) elicited electrophysiological responses. When either E11-14OH or E11-16Ac were tested at various ratios in three-component blends with both E11-14Ac and E9E11-14Ac, no increase in trap catch was observed compared to that to the previously identified binary blend. However, when these two compounds (1% E11-14OH and 0.5% E11-16Ac) were both added to E11-14Ac and E9E11-14Ac, trap catch was roughly double that to the previously identified binary blend alone. The new four-component blend should be more sensitive for detecting this economically important insect, especially in low population areas (i.e., in newly invaded habitats). In addition, this new blend may enhance pheromone control of this pest, through approaches such as mating disruption, lure and kill, and mass trapping.

Key Words Lightbrown apple moth · *Epiphyas postvittana* · Sex pheromone · Pheromone identification · Monitoring and control · Lepidoptera · Tortricidae

Introduction

The lightbrown apple moth (LBAM), *Epiphyas postvittana* (Walker) (Lepidoptera: Tortricidae) is an important pest of horticulture in its native Australia and in introduced habitats of New Zealand, USA, and UK (Suckling and Brockerhoff, 2010). The endemic Australian genus, *Epiphyas*, contains approximately 60 species (Hitchcock, 2009). LBAM larvae typically feed on leaves and the fruit surface by webbing a leaf to a fruit to create a protected shelter (Lo et al., 2000). This causes unsightly blemishes on fruit and can lead to secondary disease development, causing rots, in crops such as grapes (Bailey et al., 1996). LBAM is known as a pest primarily of tree fruits, including apples, pears, citrus, peaches, nectarines, apricots, vines, and berryfruit, but also, to a lesser extent, of forestry, vegetable, and flower crops (Wearing et al., 1991). The sex pheromone of LBAM was initially identified as a two-component blend of (*E*)-11-tetradecenyl acetate (E11-14Ac) and (*E*,*E*)-9,11-tetradecadienyl acetate (E9E11-14Ac) (Bellas et al., 1983), in a ratio of 100:5, respectively. Further work on the sex pheromone (Foster and Roelofs, 1990) found tetradecyl acetate (14Ac) in glands at about 10% of the major component. However, Muggleston and Foster (1989) found no evidence for a behavioral role for this compound in wind tunnel assays.

During work on the quantification of the sex pheromone of this insect, as part of a study on fitness of irradiated insects, several additional potential pheromone compounds were found. Since most moth species use multi-components

blends for sexual communication (El-Sayed, 2011), we wondered whether any of these compounds were involved in male attraction? Therefore, we undertook to re-investigate the chemistry of the female sex pheromone gland comprehensively, and to field test any additional potential pheromone compounds identified. As result, we identified a new four-component blend that attracts more males than the previously identified binary blend. This identification is particularly timely, as LBAM continues to expand beyond its native habitat and was recently confirmed in the USA, Sweden, and other parts of Europe; this new blend could help in the eradication of, or management efforts for, this pest.

Methods and Materials

Insects A colony of LBAM was established and maintained at Mt Albert Research Centre (Auckland). The insects were sexed as pupae, with adult males allowed to emerge in isolation from females. Males and females were kept at 22± 2°C, 18:6 hr L:D, and were provided with water. All insects were 2–3 d old at time of testing.

Chemicals All compounds used as authentic standards in the chromatographic analyses or field trapping experiments were >97% pure by gas chromatographic (GC) analysis, and were stored at −80°C until used. Samples of E11-14Ac, E9E11-14Ac, (*E*)-11-tetradecen-1-ol (E11-14OH), hexadecanal (16Ald), (*E*)-11-hexadecenyl acetate (E11-16Ac), hexadecyl acetate (16Ac), and octadecyl acetate (18Ac) were purchased from Plant Research International, Wageningen, The Netherlands. Tetradecyl acetate (14Ac) was purchased from Bedoukian Research Inc., Connecticut, USA, and octadecanal (18Ald) was synthesized at Plant & Food Research. Each blend of synthetic compounds, in 200 µl of *n*-hexane GR (Merck Ltd, New Zealand), was applied to the large "well" of a red rubber septum (West Pharmaceutical Services, Kearney, NE, USA). The solvent was allowed to evaporate in a fume hood, and the septa were stored in heat-sealed foil bags at −20°C until ready for use in field trapping experiments.

Pheromone Gland Extraction The sex pheromone glands of 2 to 3-d-old calling females (>10 females) were removed during the first 2 hr of the scotophase and extracted in ca 20 µl of hexane for 5–10 min. Analysis of the gland extracts was performed by using gas chromatography-electroantennogram detection (GC-EAD) or gas chromatography–mass spectrometry (GC-MS) as described below. Quantification of each compound in the gland extract was conducted using an external standard method (Scott, 1995), with known amounts (0.1, 1.0, 10.0, and 100.0 ng) of each compound injected into the GC-MS. The results were subjected to linear regression analysis (SAS Institute Inc., 1998) to determine the relationship between amount of compound injected and peak area of the mass chromatogram.

GC-MS Analysis Gland extracts and synthetic chemicals were analyzed on a Saturn 2200 GC-MS (Varian Walnut Creek, CA, USA), using an ionization voltage of 70 eV and a mass range of 30 to 650, equipped with splitless injection and two capillary columns: a non-polar 30 m×0.25 mm i.d.× 0.5 µm, VF5-MS and a polar 30 m×0.25 mm i.d.×0.5 µm, VF23-MS (both Factor Four, Varian Inc, USA). For both columns, the oven was programmed from 80°C (held for 1 min.) to 240°C at 10°C min^{-1}. Compounds were identified by comparison of retention times and mass spectra with those of synthetic compounds.

GC-EAD Coupled GC-EAD analyses of gland extracts were conducted on a Varian 3800 GC equipped with a flame ionization detector (FID), a splitless injector, and a 30 m×0.25 mm i.d.×0.5 µm, VF5-MS capillary column. The oven temperature was programmed from 80°C (held for 1 min) to 220°C at 10°C.min^{-1}, and then held for 13 min. Helium was used as carrier gas. The column effluent was split 1:1 (by a Graph pack—3D/2 crosspiece splitter; Gerstel GmbH & Co, KG, Germany) between the FID and EAD apparatus. Antennal depolarization was detected by a high-resistance EAD Probe, Signal Interface Box, Type ID-02 and Intelligent Data Acquisition Controller, Type IDAC-02 (Syntech, Hilversum, The Netherlands). Antennae from 2 to 3-d-old males were excised at the base and attached to silver electrodes housed in saline-filled glass electrodes. Ten antennal preparations were used in the analyses.

Field Trapping Experiments

Optimization of the Ratio of E11-14OH and E11-16Ac The previously identified binary blend (Bellas et al., 1983) of E11-14Ac and E9E11-14Ac (0.1:0.005 mg) was supplemented with different amounts (0, 0.001, 0.002, and 0.005 mg) of either of the two EAD-active compounds, E11-14OH and E11-16Ac, and tested on rubber septa in the field using red delta traps, made of plastic corflute, with an adhesive-coated base (The New Zealand Institute for Plant & Food Research Ltd, Auckland) (Suckling and Shaw, 1992). An additional experiment was conducted to test lower amounts of E11-16Ac, using the two-component blend (E11-14Ac: E9E11-14Ac; 0.1: 0.005 mg) supplemented with varying amounts of E11-16Ac (0, 0.0001, 0.0005, and 0.001 mg). Traps baited with each of the pheromone blends were placed in five rows, with five replicates of each

treatment in a randomized block design. Traps were positioned 1.7 m above the ground in a tree, and were spaced 20 m apart in each row. Each treatment was assigned randomly to a tree within a row of trees. Septa were placed in the center of the sticky base. Sticky bases were replaced weekly during the experimental period. A trap with a blank lure was used as a control.

Other Multi-component Blends The attractiveness of the following blends was tested: a nine-component blend (E11-14OH, E11-14Ac, 14Ac, E9E11-14Ac, E11-16Ac, 16Ald, 16Ac, 18Ald, and 18Ac, in a ratio of 0.001, 0.1, 0.005, 0.005, 0.0005, 0.005, 0.005, 0.01, and 0.005 mg, respectively), a four-component blend (E11-14OH, E11-14Ac, E9E11-14Ac, E11-16Ac, in a ratio of 0.001, 0.1, 0.005, and 0.0005 mg, respectively), and the binary blend (E11-14Ac, E9E11-14Ac, in a ratio of 0.1 and 0.005 mg, respectively). Traps baited with a single, caged female were used as positive controls, and traps with a blank lure as negative controls.

A final experiment was conducted to eliminate non-attractive components of the blends, particularly saturated aldehydes, which were considered unlikely to be attractive because of the lack of electrophysiological responses. The following blends were tested: a seven-component blend lacking the two saturated aldehydes (E11-14OH, E11-14Ac, 14Ac, E9E11-14Ac, E11-16Ac, 16Ac, and 18Ac in a ratio of 0.001, 0.1, 0.005, 0.005, 0.0005, 0.005, and 0.005 mg, respectively), a six-component blend lacking the three saturated acetates (E11-14OH, E11-14Ac, E9E11-14Ac, E11-16Ac, 16Ald, and 18Ald in a ratio of 0.001, 0.1, 0.005, 0.0005, 0.005, and 0.01 mg respectively), a four-component blend lacking the saturated aldehydes and acetates (E11-14OH, E11-14Ac, E9E11-14Ac, E11-16Ac, in a ratio of 0.001, 0.1, 0.005, and 0.0005 mg, respectively), and the binary blend (E11-14Ac, E9E11-14Ac, in a ratio of 0.1 and 0.005 mg, respectively). A trap baited with a blank lure was used as a control. The experimental design and protocol of these last two experiments were identical to the other experiments, except that 14 replicates were used in the first experiment and 10 replicates in the second experiment.

Data Analysis

The effect of treatment on the mean number of LBAM males captured was tested using ANOVA (SAS Institute Inc., 1998), after variances were stabilized using the $\sqrt{x}$ transformation. Significantly different treatment means were identified *post-hoc*, using Fisher's Protected Least Significant Difference Test at the 5% level (SAS Institute Inc., 1998).

Results

Chemical Identification Chemical analyses of the pheromone gland extracts of female *E. postvittana* showed seven additional minor compounds that had a pheromone-type structure (Table 1). The first compound had the diagnostic ions *m/z* 55, 67, 81, 95, 109, and 123, and eluted earlier than the main pheromone compound on a non-polar column, suggesting that it was either a saturated aldehyde or monounsaturated alcohol or acetate. The lack of *m/z* 61 excluded the acetate functionality, suggesting that it would be either a saturated aldehyde or monounsaturated alcohol. The retention time and Kovat's retention indices (KI) of this compound matched E11-14OH on both polar and non-polar columns. Four of the new compounds had the diagnostic *m/z* 61, characteristic of acetates. Three of these compounds had the diagnostic *m/z* 69, 83, 97, 111, and 125, suggesting saturated acetates. Retention times and KIs of these compounds matched those of 14Ac, 16Ac, and 18Ac on both polar and non-polar columns. The fourth acetate had the diagnostic *m/z* 67, 81, 95, 109, 123, and 222, suggesting a monounsaturated 16-carbon acetate. Retention times and KIs of this compound matched E11-16Ac on both polar and non-polar columns. The final two structures had the diagnostic *m/z* 55, 67, 81, 95, 109, and 123, suggesting

Table 1 Normalized ratios and retention indices of the candidate pheromone compounds found in sex pheromone gland extract of female lightbrown apple moth, *Epiphyas postvittana*

Compound	ng/female[a]	Ratio (%)	Non Polar VF5-MS	Polar VF23-MS
(*E*)-11-tetradecen-1-ol	0.01	0.1	1,679	2,310
(*E*)-11-tetradecenyl acetate	9.18	100	1,804	2,254
Tetradecyl acetate	0.52	5.7	1,809	2,204
Hexadecanal	0.58	6.3	1,824	2,320
(*E*,*E*)-9,11-tetradecadienyl acetate	0.48	7.1	1,868	2,480
(*E*)-11-hexadecenyl acetate	0.05	0.7	1,999	2,466
Hexadecyl acetate	0.42	4.6	2,010	2,422
Octaadecanal	0.76	8.3	2,028	2,552
Octadecyl acetate	0.04	0.4	2,108	2,641

[a] $N=5$

they were either saturated aldehydes or monounsaturated alcohols. Retention times and KIs of these compounds matched 16Ald and 18Ald on both polar and non-polar columns.

GC-EAD Analysis Analysis of gland extracts by GC-EAD revealed that four compounds consistently elicited responses from male moth antennae. E11-14Ac elicited the strongest EAD response, followed by E9E11-14Ac, E11-14OH, and E11-16Ac (Fig. 1).

Optimization of the Ratio of E11-14OH and E11-16Ac The addition of 1, 2, or 5% E11-14OH to the two-component blend of E11-14Ac and E9E11-14Ac did not result in an increase in the number of LBAM males caught in the traps (Fig. 2). Similarly, the addition of 1, 2 or 5% E11-16Ac to the binary blend did not result in an increase in the number of LBAM males caught (Fig. 3, top). It was evident that the number of males caught declined as the amount of E11-16Ac increased (Fig. 3, top). Therefore, we conducted another experiment testing lower amounts of E11-16Ac (0. 0.1 or 0.5 or 1%). However, there was no difference in male catch at any of the ratios tested (Fig. 3, bottom).

Other Multi-component Blends In the first experiment that tested other multicomponent blends, there was an effect of blend on the number of males caught in the trap ($F_{5,78}$=9.8, P<0.001). The four-component blend caught the greatest number of males, with the mean catch greater than that of the binary blend (Fig. 4). No difference was observed between mean catch to the nine-component blend and that to the two-component blend. Caged females caught fewer males than the binary blend (Fig. 4). In the final experiment, traps baited with the three multi-component (4, 6, or 7) blends captured significantly more males than traps baited with the binary blend. There was no difference in trap catch among the 4, 6, or 7-component blends (Fig. 5), showing that the saturated aldehydes or acetates had no detectable effect on trap catch.

Discussion

Many moth species utilize multi-component pheromones for sexual communication. When species share common pheromone components, the composition of multi-component blends is critical for species specificity. As there are many species in the Australian genus *Epiphyas* (Hitchcock, 2009), with E11-14Ac and E9E11-14Ac found in a number of them (Horak et al., 1988), it is likely that multi-component blends are critical for ensuring specificity of response within the genus.

Analysis of LBAM sex pheromone gland extracts confirmed the presence of seven additional (E11-14Ac and E9E11-14Ac) compounds: two monounsaturated compounds (E11-14OH and E11-16Ac), three saturated acetates (14Ac, 16Ac, and 18Ac), and two saturated aldehydes (16Ald and 18Ald). Apart from 14Ac (Foster and Roelofs, 1990), this is the first report of the presence of these compounds in the sex pheromone gland of LBAM females. GC-EAD analysis demonstrated that, of these seven compounds, only E11-14OH and E11-16Ac elicited an EAD response. Field trapping studies identified a new four-component pheromone blend for LBAM, consisting of the two previously identified components, E11-14Ac and E9E11-14Ac, plus E11-14OH and E11-16Ac. This blend elicited roughly double the catch of males compared to that of traps baited with the previously identified binary blend. E11-14OH has been reported as a pheromone component of many tortricid moth species, for example, *Choristoneura orae* (Gray et al., 1984), and, *C. parallela* (Neal et al.,

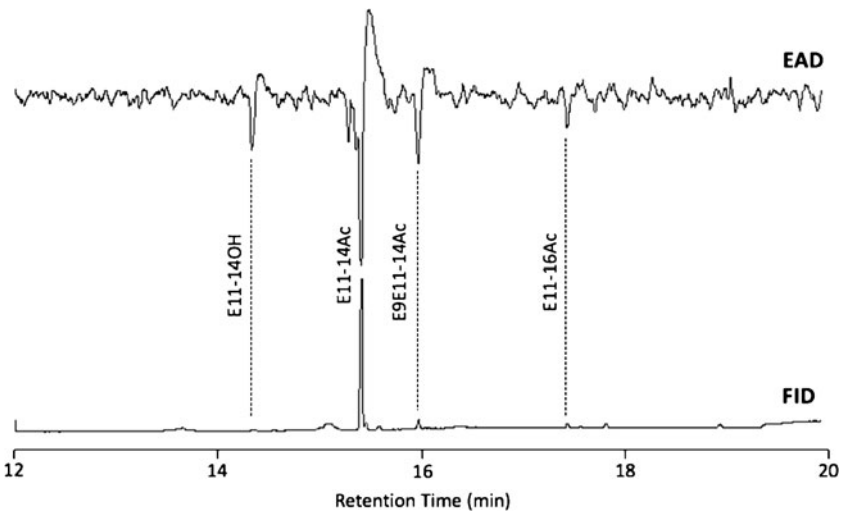

Fig. 1 Coupled gas chromatographic-electroantennographic detection responses of male *Epiphyas postvittana* to female pheromone gland extract. *EAD* electroantennogram detection; *FID* flame ionization detection; *E11-14OH* (*E*)-11-tetradecen-1-ol; *E11-14Ac* (*E*)-11-tetradecenyl acetate; *E9E11-14Ac* (*E*, *E*)-9, 11-tetradecadienyl acetate; *E11-16Ac* (*E*)-11-hexadecenyl acetate

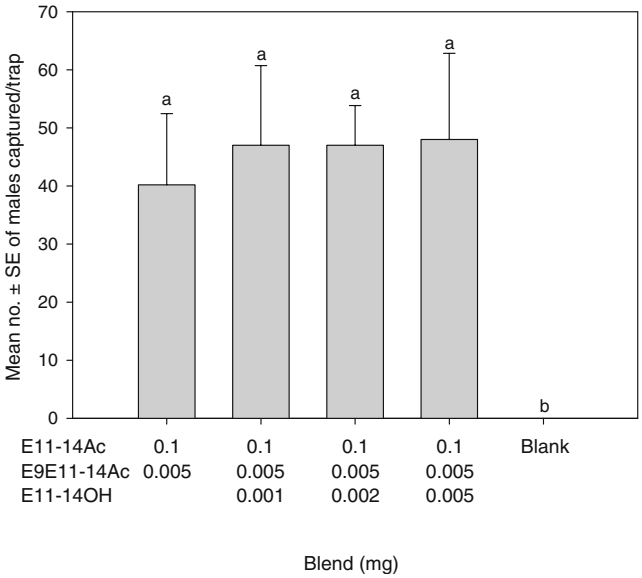

Fig. 2 Mean catch (± SE) of *Epiphyas postvittana* males caught in traps baited with a three-component blend containing a constant 0.1: 0.005 mg proportion of (*E*)-11-tetradecenyl acetate (E11-14Ac): (*E*, *E*)-9, 11-tetradecadienyl acetate (E9E11-14Ac) plus varying amounts of (*E*)-11-tetradecenol (E11-14OH). The experiment was conducted from 18 February 2010 to 4 March 2010 in apple orchards at Lincoln, New Zealand. A total of 911 male moths were captured. Treatments labeled with the same letter were not significantly different at $P<0.05$

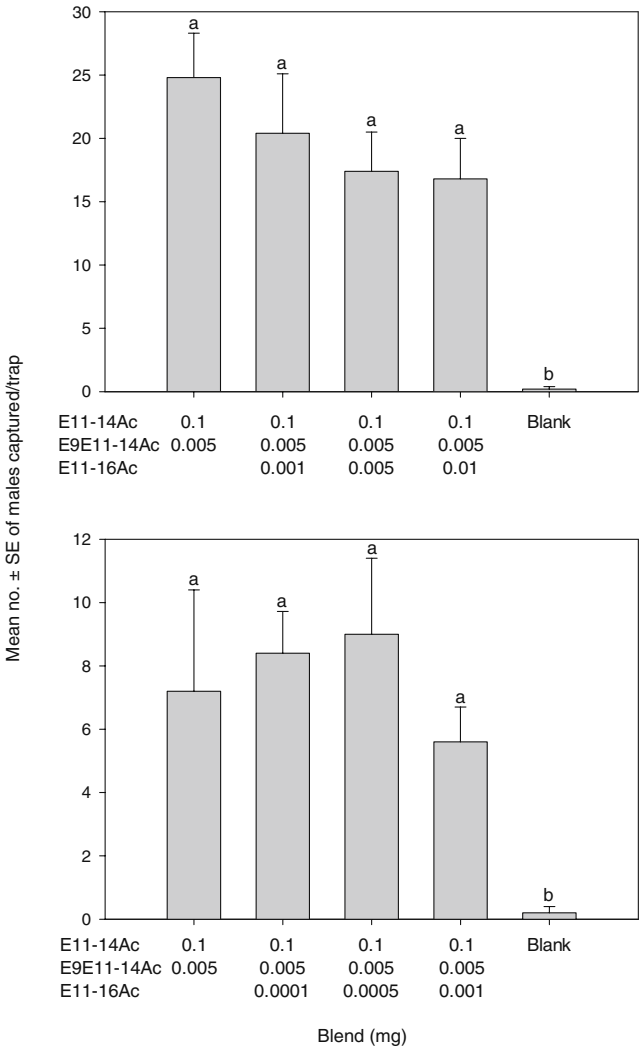

Fig. 3 Mean catch (± SE) of *Epiphyas postvittana* males in traps baited with a three-component blend containing a constant 0.1: 0.005 mg proportion of (*E*)-11-tetradecenyl acetate (E11-14Ac): (*E*, *E*)-9, 11-tetradecadienyl acetate (E9E11-14Ac) plus varying amounts of (*E*)-11-hexadecenyl acetate (E11-16Ac). The two experiments were conducted from 11 March 2010 to 12 April 2010 in apple orchards at Lincoln, New Zealand. A total of 556 male moths were captured. Treatments labeled with the same letter were not significantly different at $P<0.05$

1982). In contrast, E11-16Ac has not been reported previously as a sex pheromone component of tortricid moth species, but is commonly found in species of Crambidae, Noctuidae, and Saturniidae (El-Sayed, 2011).

The addition of the saturated aldehydes, 16Ald and 18Ald, or the saturated acetates, 14Ac, 16Ac, and 18Ac, to the new quaternary blend had no effect on male catch. Previous work had shown that the addition of different ratios of 14Ac to the binary blend did not enhance the number of males arriving at the odor source (Muggleston and Foster, 1989). In light of our work, this is not surprising, as 14Ac did not elicit an EAD response. The saturated acetates, 14Ac, 16Ac, and 18Ac, commonly are found in the sex pheromone glands of species of tortricid moths, and have been reported to be part of the sex pheromone blend in a few cases. In contrast, the two saturated aldehydes have not been reported to be sex pheromone components of a tortricid moth (El-Sayed, 2011).

Bellas et al. (1983) identified only E11-14Ac and E9E11-14Ac in the sex pheromone gland of female *E. postvittana*, and demonstrated that a 100:5 ratio was optimal for male attraction. The inability of these authors (Bellas et al., 1983) to identify the two new minor compounds reported here is likely due to improved sensitivity of today's GC-MS systems, and perhaps the lack of use of a GC-EAD.

In a study of sex pheromone gland content in LBAM females, the amount of E9E11-14Ac to E11-14Ac, varied from 2.2% to 11% (Muggleston and Foster, 1989). Male LBAM responded to a wide range of ratios of these two components, from 1:10 to 1:50 (Bellas et al., 1983). There could be similar variation in production of, and response to, the new components, as indicated by the fact that addition of different ratios of E11-14OH or E11-16Ac to the binary blend had little positive or negative effect on trap catch. In many species of moths, minor compounds invoke either a peak response to a tight ratio, or similar responses over a wide range of ratios. For example, in the European

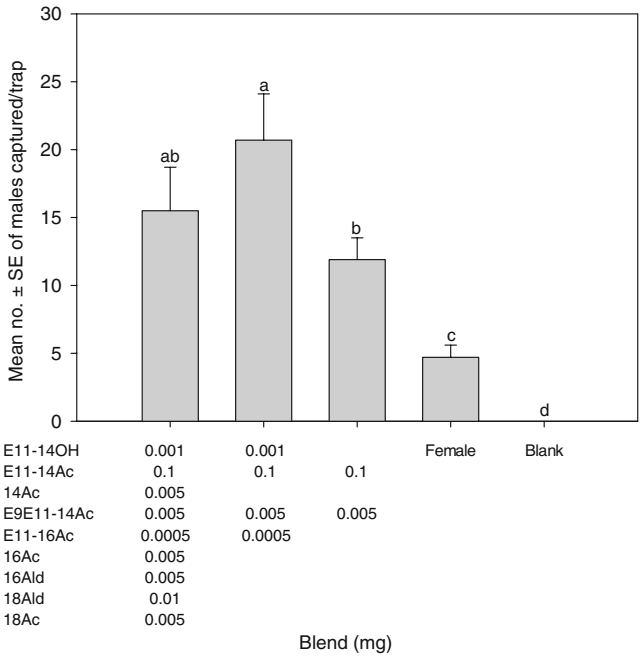

Fig. 4 Mean catch (± SE) of *Epiphyas postvittana* males in traps baited with four different pheromone blends: a nine-component blend with all compounds identified in the gland; a four-component blend with all compounds that elicited an electroantennographic response; and the previously identified binary blend. Caged virgin females were used as positive controls and blanks as negative controls. The experiment was conducted from 30 April 2010 to 15 May 2010 in apple orchards at Lincoln, New Zealand. A total of 744 male moths were captured. Treatments labeled with the same letter were not significantly different at $P<0.05$. E11-14OH = (*E*)-11-tetradecenol; E11-14Ac = (*E*)-11-tetradecenyl acetate; 14Ac = tetradecyl acetate; E9E11-14Ac = (*E*, *E*)-9, 11-tetradecadienyl acetate; E11-16Ac = (*E*)-11-hexadecenyl acetate; 16Ac = hexadecyl acetate; 16Ald = hexadecanal; 18Ald = octadecanal; 18Ac = octadecyl acetate

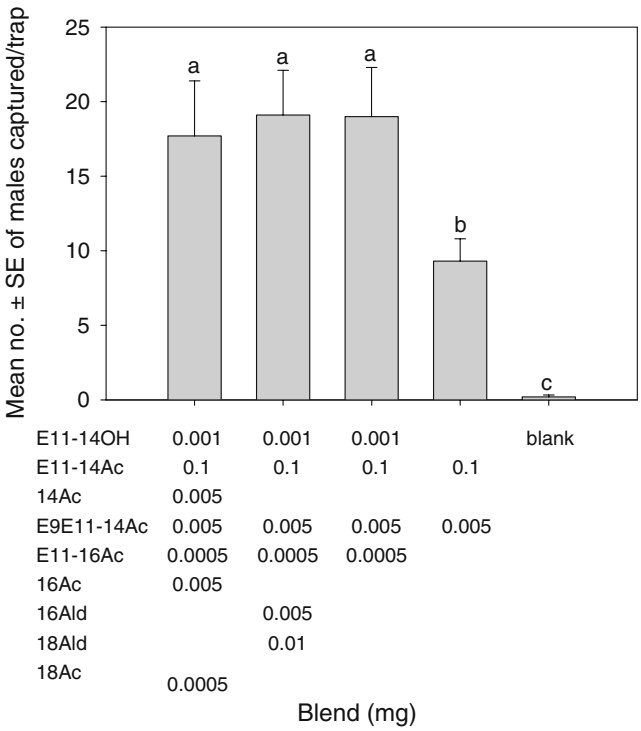

Fig. 5 Mean catch (± SE) of *Epiphyas postvittana* males in traps baited with four different pheromone blends: a seven-component blend containing all compounds identified in the gland except the saturated aldehydes; a six-component blend containing all compounds identified in the gland except the saturated acetates; a four-component blend containing all compounds that elicited an electroantennographic response; the previously identified binary blend; a blank was the negative control. The experiment was conducted from 11 to 25 May 2010 in apple orchards at Lincoln, New Zealand. A total of 659 male moths were captured. Treatments labeled with the same letter were not significantly different at $P<0.05$. E11-14OH = (*E*)-11-tetradecenol; E11-14Ac = (*E*)-11-tetradecenyl acetate; 14Ac = tetradecyl acetate; E9E11-14Ac = (*E*, *E*)-9, 11-tetradecadienyl acetate; E11-16Ac = (*E*)-11-hexadecenyl acetate; 16Ac = hexadecyl acetate; 16Ald = hexadecanal; 18Ald = octadecanal; 18Ac = octadecyl acetate

grapevine moth, *Lobesia botrana*, the two minor components, (*E*,*Z*)-7,9-dodecadienol and (*Z*)-9-dodecenyl acetate, elicited peak attraction at 5% and 1% amounts (of the major component), respectively (El-Sayed et al., 1999). In tortricid moths, such as *Grapholita molesta* (Baker et al., 1981; Linn and Roelofs, 1983), *Adoxophyes orana* (Guerin et al., 1986), *Cacoecimorpha pronubana* (Witzgall, 1990), and *Spilonota ocellana* (Witzgall et al., 1991), males responded to a wide range of ratios of the minor components.

Traps baited with our new blend caught more males than traps baited with caged virgins. Indeed, even the binary blend elicited greater trap catches than did caged females. In previous work, catches from traps baited with three females were similar to those from traps baited with rubber septa loaded with 105 μg of the binary blend (Suckling and Brockerhoff, 1999). The relatively low catch in traps baited with virgins in the current work could be due to the quality of the females used or to adverse weather and light conditions during the experiment, which could have caused females to release pheromone for restricted periods.

LBAM is a major pest of tree fruits, berryfruit, forestry, vegetable, and flower crops in New Zealand and Australia. Recently, this insect expanded its range to California, Sweden, and other parts in Europe. In the initial stages of invasion, the population density of a given invasive species is usually low and hard to detect. The availability of a more potent sex pheromone blend for LBAM should make it easier to detect this insect at low population densities. This may make an eradication strategy, using both mass trapping and lure and kill more feasible (El-Sayed et al., 2006, 2009). We anticipate that the improved pheromone blend will be a valuable tool in the eradication and pest management efforts against this pest.

The Level of Major Urinary Proteins is Socially Regulated in Wild *Mus musculus musculus*

Abstract Major urinary proteins (MUPs) are highly polymorphic proteins that have been shown to perform several important functions in the chemical communication of the house mouse, *Mus musculus*. Production of these proteins in C57Bl/6 females is cyclic, reaching the maximum just before the beginning of estrus. Social environment is an important factor that increases MUP production in both sexes. We examined responsiveness of MUP production to social stimuli in wild mice, *Mus musculus musculus*. The direction of change of MUP production in males depended on the sex of the stimulus animal. Males up-regulated MUP production when caged with a female, but down-regulated MUP production when caged with a male. Down-regulation was more pronounced in males that were defeated in a male–male encounter. Females responded to a male's presence with a decrease in MUP production. We conclude that social modulation of MUP production is specific and, in coordination with other mechanisms, facilitates adjustment of the animal's odor profile to different social contexts. Our results also suggest that in males, MUPs may play an important role in advertizing the male's quality to females. Furthermore, we highlight the importance of analyzing data corrected with creatinine, which show MUP production on the (post)translational level as well as raw data (non-corrected with creatinine), which represent actual concentrations of MUPs in the urine.

Introduction

Major urinary proteins (MUPs) are lipocalins that are excreted in substantial amounts in the urine of the house mouse, *Mus musculus* L. (Flower, 1996). In their internal binding pocket, they bind and transport diverse sets of volatile pheromone ligands (Bacchini et al., 1992; Robertson et al., 1993; Novotny et al., 1999). The key role of these proteins is the stabilization of mouse chemical signals by slowing down the evaporation of their pheromonal ligands. Hurst et al. (1998) proved that pheromones bound to MUPs are released more gradually and for a considerably longer period from a deposited scent mark, whereas free pheromones are, due to their high volatility, lost within a few hours.

However, MUPs have been shown to perform additional functions in intra-specific chemical communication. These functions are primarily facilitated by extreme MUP polymorphism, which has been observed in wild mice, principally in *Mus musculus domesticus* Rutty (Beynon and Hurst, 2003). Different individuals of this subspecies have been shown to express different combinations of alleles from the MUP gene cluster that is located on chromosome 4 and contains as many as 21 genes (Krauter et al., 1982; Stopkova et al., 2009). In populations of *M. m. domesticus* from Great Britain (Robertson et al., 1997) and Switzerland (Rusu et al., 2008), the combinatorial nature of MUP expression results in the occurrence of multiple distinct MUP profiles composed of different isoforms. Due to their high variability, genetic inheritance, and presumptive stability, these MUP profiles are suitable

candidates for the signalling of a variety of genetically determined characteristics such as kinship (Sherborne et al., 2007), gender (Armstrong et al., 2005), or heterozygosity (Thom et al., 2008). Moreover, the variability of MUP profiles in *M. m. domesticus* from Great Britain is so substantial that each individual possesses a unique MUP chemical signature that has been reported to be employed in identity recognition (Cheetham et al., 2007).

The diversity of MUP roles in chemical communication has been highlighted with the finding that male MUPs can directly induce, without their pheromonal ligands, a physiological or behavioral response in a recipient. In juvenile females, they accelerate the onset of puberty (Mucignat-Caretta et al., 1995), and in adult females that are held in crowded living conditions, they increase the amount of ova (Morè, 2006). MUPs also act directly in intrasexual communication where they trigger aggressive behavior between males (Chamero et al., 2007). Several results suggest that MUPs mediate their pheromonal effect through activation of an accessory olfactory pathway (Morè, 2006; Chamero et al., 2007).

There is complex and dynamic regulation of MUP production that employs genetic and epigenetic mechanisms and several hormones, including testosterone, growth hormone, and thyroxine (Knopf et al., 1983; Johnson et al., 1995; Roemer et al., 1997). Testosterone is known to be primarily responsible for the high levels of MUPs in males when compared to females (Wicks, 1941; Thung, 1956). In females, hormones may participate in the progression of the estrous cycle and influence the production of MUPs, thus inducing the fluctuation of MUP quantity in the course of the female reproductive cycle. This fluctuation with maximum MUP titer reached just at the beginning of estrus may be used to signal either directly or through the binding and release of MUP pheromonal ligands, a female's reproductive receptivity to potential mates (Stopka et al., 2007).

Stopka et al. (2007) showed that MUP production is up-regulated following an introduction of individuals of the opposite sex to singly caged C57BL/6 males and females. This increase of MUP quantity may reflect an enhanced need for communication in animals that are in social contact when compared to animals held in isolation. However, we hypothesized that the regulatory role of the social environment may be more specific. It would be advantageous for animals if MUP production is regulated differently in different social contexts, thus contributing to modulation in the production and release of an animals' chemical signal that should fulfill its roles in a variable social environment. Such social dependence has been reported, for example, for the MUP regulatory agent, testosterone, whose level is strongly affected by social interactions (Macrides et al., 1975; Van Oortmerssen et al., 1987; Oyegbile and Marler, 2005), and which in turn regulates production of several male pheromones known to enhance the attractiveness of a male and his urinary scent marks to females (Jemiolo et al., 1991; Ferkin et al., 1994; Zala et al., 2004).

Here, we explored the dependence of MUP quantity on different social conditions. Inbred mice, used in our previous study (Stopka et al., 2007), are descendants of excessive brother-sister breeding and exhibit atypical behavioral responses (Nevison et al., 2000; Lacey and Hurst, 2005). They express a limited number of MUPs that can substantially affect their roles in chemical communication (Nevison et al., 2003; Cheetham et al., 2009). Therefore, we decided to use wild, unrelated mice as experimental subjects. We examined the effects of cohabitation with individuals of the same or opposite sex on MUP quantity in the East-European house mouse, *Mus musculus musculus* L. Although past research has been focused primarily on *M. m. domesticus* and laboratory mice it has been shown that MUPs are also produced in high quantities in *M. m. musculus* (Sampsell and Held, 1985; Stopkova et al., 2007). The level of MUPs in males of this subspecies is even higher than in male *M. m. domesticus* (Stopkova et al., 2007). Moreover, a high level of sexual dimorphism indicates that the roles of MUPs in this subspecies may be different in males and females (Janotova and Stopka, 2009). Another aim of our study was to provide new information about MUP expression in *M. m. musculus*. We confirmed the modulatory effect of social environment on MUPs in *M. m. musculus*, and analyzed the variation of MUP production in males that were exposed to social stimuli from other males with respect to their competitive abilities.

Methods and Materials

Subjects of Study and Experimental Setup The mice (*Mus musculus musculus*, 30 males, 10 females) used were caught at different sites within the Czech Republic (Sedlecko [50º14′11.611″N, 12º57′28.763″E], Vintirov [50º14′3.795″, 12º43′16.715″E], Brandys [50º11′1.653″N, 14º39′49.804″E], Svetla Hora [50º2′52.555″N, 17º24′0.948″E], and Znojmo [48º50′48.596″N, 16º3′54.453″E]). Experiments were carried out in accordance with the European Communities' Council Directive of November 24, 1986 in the University Breeding Facility (Accreditation licence number: 1020/919/A/00). The experimental procedures were approved by the Czech Ministry of Agriculture (licence to P Stopka—No. CZU 514/01). Animals were kept on a 12:12 h light cycle with lights off at 1900 h. Water and food were provided *ad libitum*. We tested three experimental groups: females that were subjected to male stimuli (Females), males exposed to females (Males), and males exposed to other males (Male-

Male). All animals were adults and held in the laboratory for at least 1 mo before the beginning of the experiment. The experiment was divided into two parts, each lasting 10 d. In the first part (individual), all subjects were housed singly in cages containing clean bedding material (sawdust Lignocel 3/4, J. Rettenmaier & Söhne, Rosenberg, Germany). In the second part (social), subjects were paired and caged in compartmented enclosures, where they were separated from each other by a metal grid with circular openings (radius was 0.4 cm) allowing communication but suppressing direct contact. The experimental cages were supplied with fresh bedding at the beginning of the social part and were not cleaned until the end of the experiment (10 d). There were 10 pairs in each experimental group. In pairs, animals were unfamiliar to each other and captured from different sites. Males were paired with same-sex counterparts of similar weights.

Urine samples were collected every day for the duration of the experiment (both individual and social parts) in the beginning of the light phase by gentle bladder massage, and stored in polyethylene 1.5 ml Eppendorf tubes, and frozen at −20°C. All samples were analyzed within 1 mo from time of collection. We also checked the estrous stage of females daily. Vaginal smears were stained by using method of Pappenheim (1899) and analyzed under a light microscope.

The response of males in same-sex experimental pairs may be influenced by the social hierarchy, which should establish in the pair during the course of experiment. Therefore, after finishing the social part of the experiment, we allowed members of each pair to interact freely in a neutral arena for 5 min. In order to assess the social relationship between the males, we recorded the number and direction of attacks and submissive behavioral patterns such as crouching, freezing, or fleeing (Zielinski and Vandenbergh, 1993; D'Amato et al., 2001). When aggression escalated (the attacks from one male were continuous) or any of males showed visible wounds, the confrontation was interrupted immediately.

Protein Analysis Urinary proteins were separated by SDS-PAGE in the Mini-PROTEAN III Electrophoresis System (Bio-Rad Laboratories, Hercules, CA, USA) according to a modified protocol from Laemmli (1970). Samples were defrosted, stirred, and centrifuged for 5 min at 16000 x *g*. The volume of 0.1–0.2 μl of male and 0.2–0.4 μl of female urine, respectively, contains enough protein to ensure optimal separation and accurate quantification of bands. To avoid pipetting such small amounts, which can lead to inaccuracy, we diluted 1 μl of urine with 9 μl of distilled water and loaded an appropriate amount of this solution onto a 10% Tris-Glycine gel. Moreover, to exclude potential loading error, we added 1000 ng (2 μl) of carbonic anhydrase as a marker for SDS-PAGE (29 kDa, Sigma-Aldrich, St. Louis, MO, USA) to each sample.

Gels were stained with Coomassie® G-250 (SimplyBlueTM Safe Stain, Invitrogen Life Technologies, Paisley, UK). Gel images were acquired by using a GS-800 Calibrated Densitometer. Denaturing polyacrylamide gel electrophoresis used to separate urinary proteins gave a well-resolved band with an approximate size of 18 kDa. This band represents MUPs, as was confirmed by western blotting (data not shown) with Goat Anti-Mouse MUP serum (YN-GMMUP, Accurate Chemical & Scientific Corporation, Westbury, NY, USA) as a primary antibody.

The concentration of MUPs in urine samples was determined by volumetric analysis of bands on polyacrylamide gels in Quantity One 1-D Analysis Software (Bio-Rad Laboratories). The volume of each band was defined as the sum of intensities of the pixels inside a defined boundary. Mean background intensity was subtracted from the acquired values.

The concentration of urinary proteins depends greatly upon the volume of excreted urine. To eliminate variability in the data set attributable to different urine dilutions between samples, we measured creatinine concentration by using LKreatinin kit (BioVendor, Brno, CR) and calculated the dilution coefficient kdil=(1/Cref)*Ccreat, (where Cref is the reference creatinine concentration and Ccreat is creatinine concentration of each sample). The reference value was defined as the highest concentration of all measured creatinine concentrations. Corrected volumes were obtained by dividing each MUP volume by the dilution coefficient.

Data Analysis The absolute concentration of MUPs represented by creatinine non-corrected values is an important parameter that should be included in the analysis even though it changes as the urine mark dries. Therefore, we performed a statistical analysis on both sets of data, corrected by creatinine as well as non-corrected by creatinine. Creatinine-corrected data are referred to as MUP production, whereas data analyzed without creatinine correction are denoted as MUP concentration.

For analysis of social modulation, we used samples collected on d 1 of the 10 d individual part. From the social part, samples were collected 24 h after the animals were paired, which is based on our previous experience where we showed that 24 h was sufficient to trigger socially dependent changes in MUP production. To analyze the differences in MUP quantity between the sexes, Student's two tailed *t*-test was performed on the data from the individual experimental setup. These data also were used to examine individual variation. However, due to insufficient volume of some urinary samples, we could not perform a creatinine assay on all samples (none of the samples included in social modulation analysis belonged to these low-volume samples). Therefore, because of the incompleteness of creatinine corrected data, only creatinine non-corrected data (representing concentration) was used to

analyze individual variation in MUP quantity. Since there were big differences in MUP levels among individuals we calculated ratio scores by dividing the data obtained in the social experimental setup by the data from the individual experimental setup prior to statistical analysis of social modulation. The ratio scores were transformed to the natural logarithm scale to remove non-linearity. Statistical analyses were performed in STATISTICA 6.0 (StatSoft Inc., Tulsa, OK,USA 2001). We used *One-Way ANOVA* and *post-hoc* Tukey test to analyze individual differences and the effect of social treatment. The effect of social hierarchy on the responses of males in male-male pairs was tested by using *Repeated Measures ANOVA*. To assess changes in MUP quantity in females during the estrous cycle *Nested-Design ANOVA* was used. The results were considered significant at a critical level of $\alpha=0.05$.

Results

Sexual Dimorphism and Individual Differences Prior to analysis of samples from mice held under social conditions, we aimed to assess individual variability and the level of sexual dimorphism of MUP quantity in experimental animals. Big differences among individuals were revealed in males (*One-Way ANOVA*; $F_{(29,270)}=32.23$, $P<0.001$) and females ($F_{(9,90)}=18.13$, $P<0.001$; Fig. 1). For this reason, further analyses were conducted on the ratio scores of data from "individual" and "social" parts of the experiment (see Methods). The variability among different localities was tested with male samples because they represented all trapping sites. However, no differences among the five localities were observed (*One-Way ANOVA*; $F_{(4,25)}=0.74$; $P=0.57$). The level of sexual dimorphism was significant in both concentration ($t=-3.74$, $d.f.=38$, $P<0.001$; $\text{mean}_{(\text{females})}=5.1$ mg/ml, s.e.$=\pm1.97$; $\text{mean}_{(\text{males})}=33.2$ mg/ml, s.e.$=\pm4.5$) and production of MUPs ($t=-4.43$, $d.f.=38$, $P<0.001$; $\text{mean}_{(\text{females})}=9.1$ mg/ml, s.e.$=\pm3.65$; $\text{mean}_{(\text{males})}=80.5$ mg/ml, s.e.$=\pm12.61$).

Social Modulation Pairing of mice that were previously caged as individuals with same or different sex conspecifics resulted in a significant change of MUP production in all treatment groups (Fig. 2a). When we analyzed creatinine non-corrected data (representing MUP concentration), a significant change was only found in females that were exposed to the presence of a male. In the other two treatment groups, the confidence intervals overlapped with the zero line, which indicates that the effect of treatment was not significant (Fig. 2b).

Differences between groups were investigated by using *One-way ANOVA* followed by a *post-hoc* Tukey test. Differences in MUP production ($F_{(2,37)}=7.92$; $P=0.001$) and concentration ($F_{(2,37)}=6.58$; $P=0.004$) (Fig. 2) were significant, indicating that the groups reacted differently to the experimental treatment. Responses were dependent on the sex of both test and stimulus individual. Of the 10 test males, 8 showed up-regulation of MUP production when stimulated by the presence of a female. When a same-sex individual was introduced into the cage, down-regulation was observed (in 15 of the 20 males). Difference between the responses of the two male groups, Males (exposed to a female) and Male–Male, respectively, exposed to different sex conspecifics was significant (*Tukey*, $P=0.007$). On the level of concentration, the difference between the responses of these two groups was not signficant ($P>0.05$). Females (8 of 10) reacted to the male's presence with decrease in MUP quantity. The response of this group was significantly different from the response of males stimulated by a female in both MUP production (*Tukey*, $P=0.002$) and concentration (*Tukey*, $P=0.003$).

The analysis of behavioral patterns of freely interacting males performed after finishing the experiment revealed a clear asymmetry of agonistic interactions that shows that the social hierarchy was established in all male-male pairs. In each pair, we were able to identify a male who initiated most attacks (winner) and apparently dominated the other member of the pair who displayed frequent submissive behaviors (loser; see Methods). The median of number of attacks (NA) for winners was 13.5 (quartiles:11.2; 14). The median NA for losers was 1 (quartiles: 0.25; 1.75). In one case, the encounter had to be interrupted after 3 min to prevent serious injury because of continuous attacks (at least 20 attacks) from one male, who was then considered to be the winner. Males significantly down-regulated MUP production when presented with same sex conspecific (*repeated measures ANOVA* $F_{(1,18)}=6.86$; $P=0.017$). The category of male (winner and loser) was also a significant factor influencing males' response ($F_{(1,18)}=4.67$; $P=0.044$) showing that winners expressed more protein than losers. Combination of both factors, treatment and status, did not reveal any significant effect, indicating that both tested male categories responded to the treatment equally ($F_{(1,18)}=0.56$; $P=0.46$), i.e., with down-regulation (Fig. 3). However, when the concentration of MUPs was analyzed, no significant result was found ($F_{(1,18)}=3.58$; $P=0.075$).

The difference in results obtained for MUP concentration and MUP expression in males indicates that urine dilution had changed due to experimental treatment. To confirm this, we analyzed creatinine concentration in the urine of tested animals. Urine of loser males became more concentrated when compared to winners in which no change of urinary concentration was apparent ($F_{(1,18)}=5.02$; $P=0.038$; Fig. 4). Thus, losers lowered MUP level, but MUP concentration in the urine remained unchanged.

In our experiment, an incidence of estrus was approximately two times more frequent in the second part of the experiment

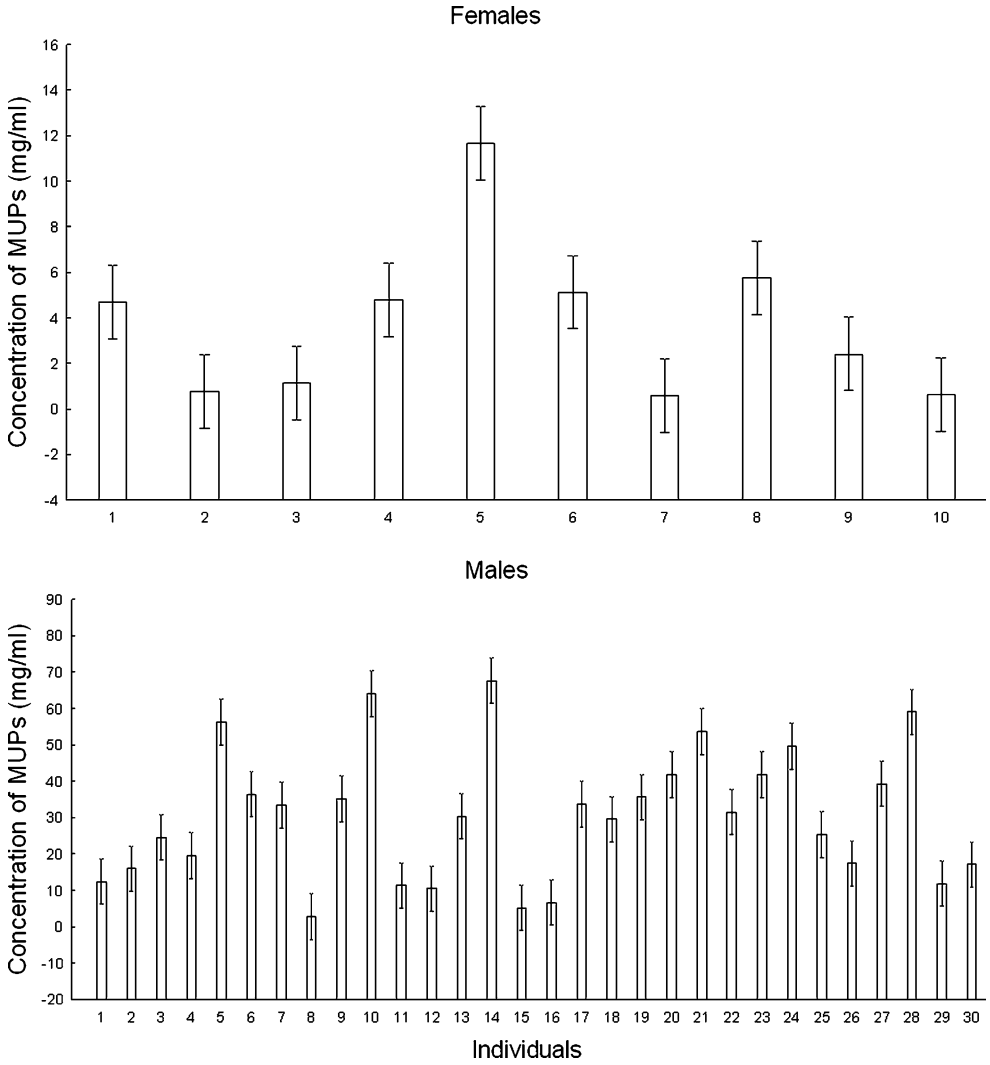

Fig. 1 Individual variation of major urinary protein concentration in male and female house mice, *Mus musculus musculus*. Bars represent 95% confidence intervals. $N_{(females)}=10$; $N_{(males)}=30$

(42 out of 100) when females were exposed to male stimuli than in the first, individual part (20 out of 100). In the social part, all females showed estrous cycling, while in the individual setup, three of females failed to display estrus. Because of it we did not assess fluctuation of MUP quantity in the course of the reproductive cycle in individually housed females. However, *Nested-design ANOVA* revealed that under social conditions, MUP production did not change significantly ($F_{(10,80)}=1.53$, $P=0.14$) during the estrous cycle.

Discussion

The variation of MUP production under individual and social housing conditions in laboratory mouse strain C57BL/6 has been reported by Stopka et al. (2007). Here, we extend this research result and provide evidence that this phenomenon is not restricted to laboratory mice but represents an intrinsic characteristic of MUP expression in a wild mouse species (*M. m. musculus*). Our results demonstrate that stimulation of an individual by the presence of conspecifics influences expression level of urinary MUPs, and that due to changes of urine dilution, this may not necessarily be manifested on the level of urinary MUP concentration. Moreover, we showed that the direction of MUP production change (i.e., either up- or down-regulation) differs according to the sex of both tested and stimulus animal. This indicates that observed variation of MUPs is not a nonspecific response that should solely ensure a sufficient strength of chemical signals in animals that have been isolated and subsequently subjected to social contact with conspecifics. Instead, it seems to be a specific response that facilitates a modification of the animal's urinary odor profile in different social conditions. The mechanism of this modification may be either direct, utilizing pheromonal potency of MUPs (Mucignat-Caretta et al., 1995; Morè, 2006; Chamero et al., 2007) or indirect, operating through modulation of ligand evaporation by MUPs (Marie et al., 2001; Veggerby et al., 2001).

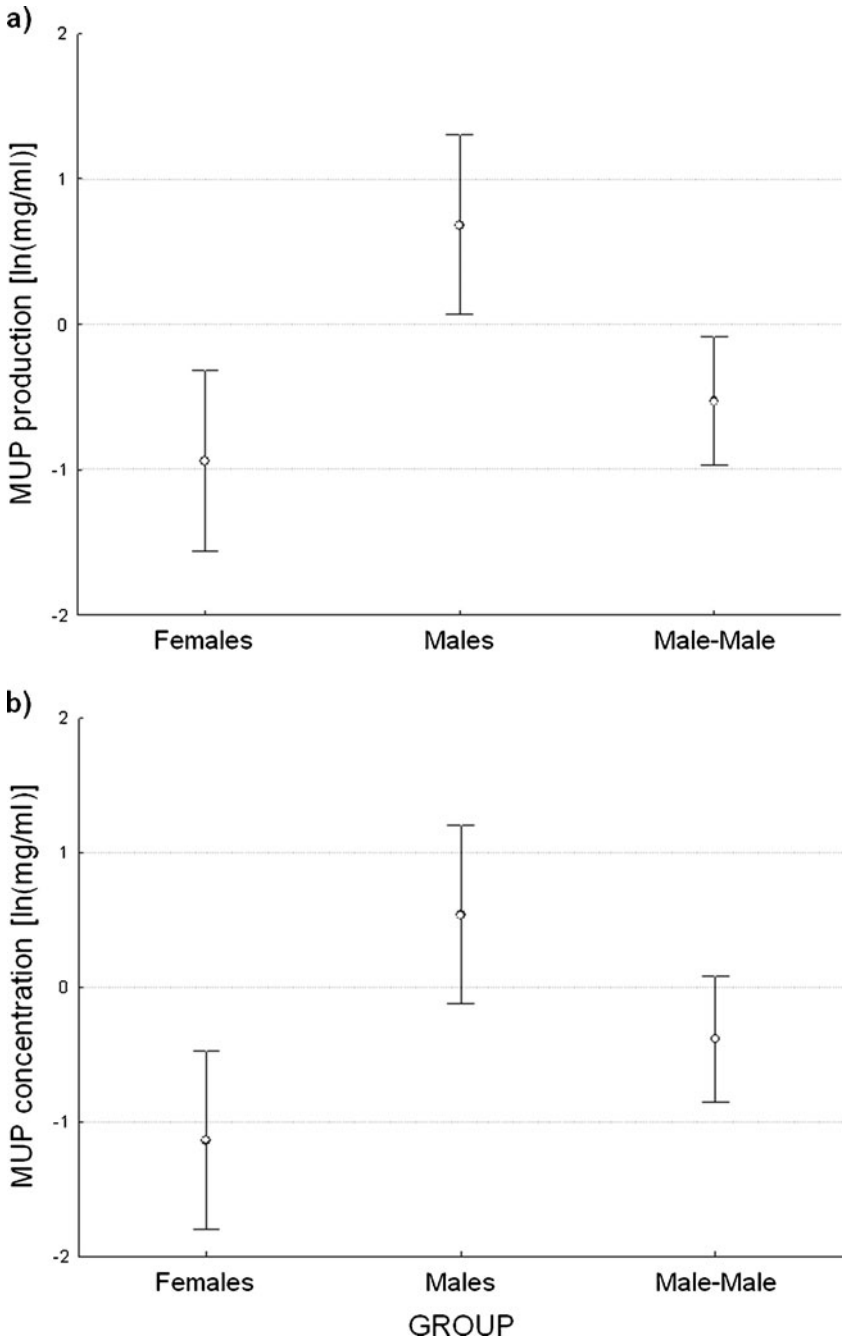

Fig. 2 Social modulation of major urinary protein (MUP) quantity in three groups of house mice, *Mus musculus musculus*: 1) females that were exposed to a male: Females, $N=10$; 2) males that were exposed to a female: Males, $N=10$; and 3) males that were exposed to another male: Male-Male, $N=10$. Values are expressed as a ratio of MUP quantity in social and individual experimental setup. The ratio was calculated by dividing the data obtained in the social experimental setup by the data from the individual experimental setup (S/I) due to big individual differences of MUP quantity. This ratio was transformed with the natural logarithm function. Dots represent means; bars represent 95% confidence intervals. Plot **a** demonstrates changes in MUP level (corrected with creatinine). The ratio S/I is in all three tested groups different from zero (confidence intervals do not overlap the zero line), which indicates that the animals respond significantly to the treatment. Positive values of the ratio S/I shows that Males up-regulated MUP level in social when compared to individual treatment while negative values obtained for the other two groups demonstrate that these animals down-regulated the production of MUPs. Plot **b** demonstrates change in MUP concentration (non-corrected with creatinine) where the only significant response gave Females (confidence intervals of the ratio S/I do not overlap zero line). Females lowered MUP concentration when exposed to males

Since the main aim of the study was to examine whether or not the fluctuation of MUP production due to social contact that is observed in laboratory mice, occurs and may play a role in chemical communication of wild-living mice, we used *M. m. musculus* trapped from different sites in the Czech Republic. Interestingly, not all animals in the study responded in the same way to social stimulation (see Results). Although it might be a result of random variation, factors may exist that were not fully controlled such as age, dietary conditions, or sexual experience, and that may be responsible for the distinct responses. This disadvantage that comes from using wild animals trapped as adults from their natural environment is, however, compensated by the fact that they experienced complex social conditions before housing in a laboratory, and thus, should display a full repertoire of social behavior.

The results show a high variability of MUP concentration among wild-living individuals that appears to be retained even after creatinine correction and, therefore, is not caused by changes in urine dilution but by different MUP production. Although sample size was rather low and the analysis thus has limited validity, it should be pointed out that we did not observe any difference of MUP variability among males from five different localities. Since

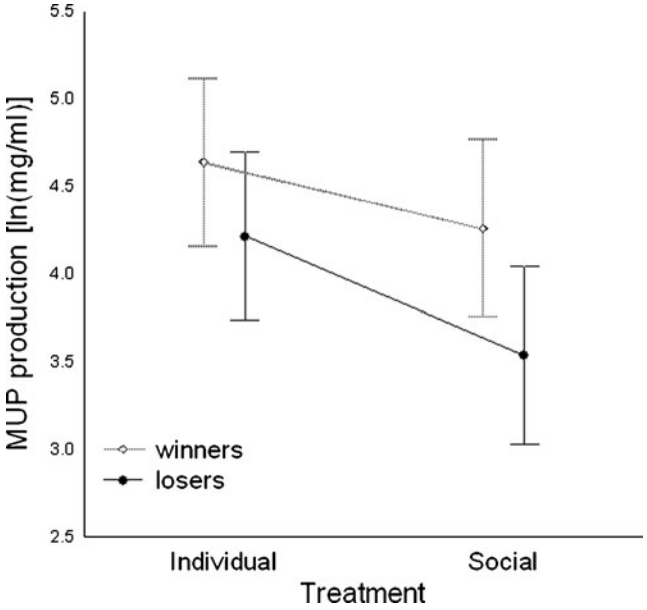

Fig. 3 Production of major urinary proteins (MUPs) in winner and loser male house mice, *Mus musculus musculus*. The data were transformed by using the natural logarithm function. Both male categories down-regulated the MUP level in social when compared to individual treatment. Repeated measures ANOVA revealed that the category of male (winner and loser) was also an important factor influencing males' response ($F_{(1,18)}$=4.67; P=0.044) showing that winners expressed more protein than losers $N_{(winner)}$=10; $N_{(loser)}$=10; bars represents 95% confidence intervals

there is still a lot of uncertainty about the mechanisms of the regulation of MUP production, it is difficult to suggest what genetic and regulatory factors underlie their individual quantitative variability and how they influence the properties of individuals' scent signals. Another interesting question is whether this characteristic of MUP production is specific for *M. m. musculus* or is common to other species and subspecies especially for *M. m. domesticus* in which the high qualitative variability has been demonstrated (Robertson et al., 1997).

Socially induced changes of MUP production that we observed may be mediated by common hormonal regulators. MUP expression is under the control of several hormones including testosterone (Wicks, 1941; Thung, 1956), the production of which is highly dependent on social conditions (Macrides et al., 1975; Van Oortmerssen et al., 1987; Oyegbile and Marler, 2005). Although from our experiments we are not able to define a direct regulatory agent responsible for the change of MUP expression level, testosterone is, in males, a probable candidate. Specifically, the up-regulation of MUP expression observed in males may be caused by an elevation of plasma testosterone that is known to be triggered by the introduction of a strange female to a male's homecage (Macrides et al., 1975). Interestingly, the scent marks of high testosterone males are more attractive for females than those of low testosterone males (Ferkin et al., 1994; Zala et al., 2004). This is presumably caused by increased production of male pheromones that act as female attractants (Jemiolo et al., 1985, 1991). Some of them are known to bind to MUPs (Bacchini et al., 1992; Novotny et al., 1999) and thus it is likely that up-regulation of MUPs contributes, directly or in coordination with the pheromonal ligands, to the enhancement of attractive properties of male chemical signals to females. Moreover, enhanced level of MUP expression may facilitate triggering ovulation in females, which has been demonstrated by Morè (2006).

Testosterone also may play a role in down-regulation of MUP production after male-male exposure which appeared

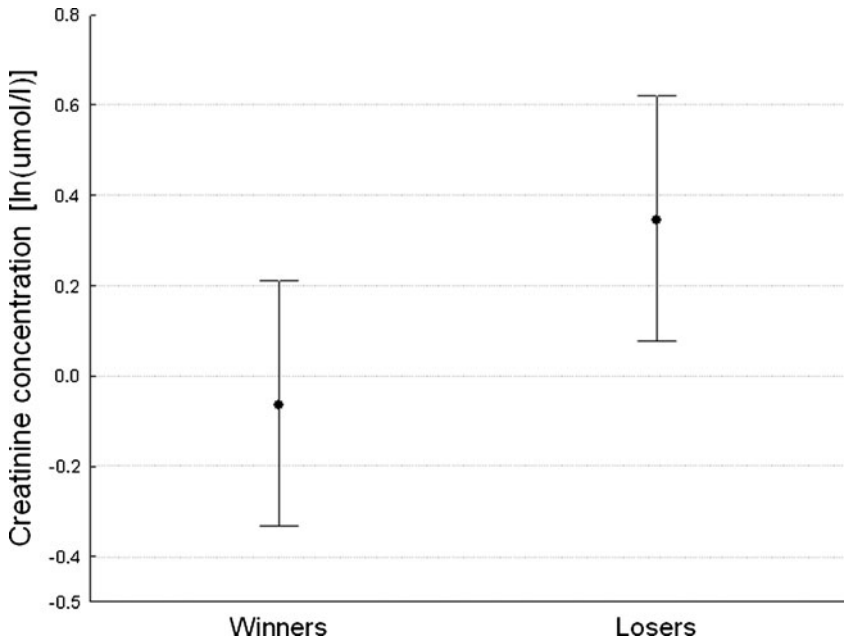

Fig. 4 Concentration of creatinine in winner and loser male house mice, *Mus musculus musculus*. Values are expressed as a ratio of creatinine quantity in social and individual experimental setup (S/I) and transformed with the natural logarithm function. Dots represent means; bars represent 95% confidence intervals. In social treatment losers significantly concentrated their urine which is demonstrated by the confidence intervals that do not overlap zero

to be more pronounced in those males that were defeated in intra-pair male-male encounters performed after the social part of experiment (Fig. 3) (Zielinski and Vandenbergh, 1993; Oyegbile and Marler, 2005). Moreover, in defeated males, an increased concentration of urinary creatinine was observed (Fig. 4), indicating that their urine was more concentrated than urine of winners. Interestingly, Drickamer (1995) reported a difference in urine production between dominant and subordinate males, with subordinates producing less urine than dominants. Although we did not measure the total excretion of urine, we suppose that higher concentration of urinary creatinine, which we observed in defeated males, might be caused by reduced urinary production. Since urine contains quite a few of aggression promoting molecules including MUPs (Novotny et al., 1990; Chamero et al., 2007), the lowering of its production and the reduction of overall scent marking in males of lower competitive abilities (Desjardins et al., 1973), reduces the probability of attack from a dominant male. In this context, it is noteworthy that the while concentration of creatinine in the urine of losers increased, concentration of MUPs remained unchanged due to down-regulation of their expression.

Surprisingly, female mice responded to male's presence with down-regulation of MUP expression and with reduction of MUP concentration in urine. This is in contradiction to the results of a previous study where C57BL/6 females up-regulated MUPs in the same experimental setup (Stopka et al., 2007). Since territory owners are known to be aggressive towards intruders of both sexes and thus a contact with a strange male represents a potentially dangerous situation for wild females (Rowe and Redfern, 1969; Hurst, 1990; Munclinger and Frynta, 2000), one possible explanation for our observation is that down-regulation of MUP expression is a consequence of stress response. Inbred mice C57Bl/6 that are genetically identical and have been demonstrated to show impaired ability to discriminate among members of the same laboratory strain (Nevison et al., 2003), might fail to show this response because they did not recognize a stimulus C57BL/6 male as a stranger (Nevison et al., 2000).

It is, however conceivable that quantitative changes of MUPs, molecules that are actively involved in mouse chemical communication, may have functional significance and influence responses of conspecifics to a female. For example, an earlier study suggested that inbred females may use MUPs to advertise their reproductive conditions to males (Stopka et al., 2007). However, in wild females exposed to a male presence, we did not find any evidence of fluctuation of MUP quantity in the course of the estrous cycle, which may indicate that the response was triggered more by unfamiliarity of a male than by the fact that it may be a potential mate. Therefore, more specific behavioral experiments have to be performed to elucidate a prospective role of MUPs in stabilization of social unit or in mate choice in wild house mice.

To reliably assess the quantity of proteins in urinary samples that may be diluted differently among individuals, the creatinine to protein ratio that corresponds to the (post) translational level of expression usually is calculated (Beynon and Hurst, 2003). However, in this study, we also analyzed data that were non-corrected with creatinine, thus reflecting an absolute concentration of MUPs in the urine. Considering these data, we were able to detect a difference in urine dilution between the winner and loser males. Our data support the work of Drickamer (1995), who showed that decreased production of urine is a mechanism that contributes to the maintenance of the characteristic pattern of urination in submissive males (Desjardins et al., 1973). The volume of urine produced influences the number of territorial marks that an individual can make, and the amount of protein deposited in the urine mark is dependent on both the production of protein and the volume of the mark. Therefore, the strength of the signal in the scent marks from two males with similar level of MUP expression but with different urine dilution may differ. For this reason, the concentration of MUPs should not be omitted from the analysis whenever the quantity of MUPs is being assessed.

We elected to use a densitometric analysis that permitted us to measure the amount of a particular protein in a mixture instead of the Bradford protein assay (Bradford, 1976), which determines the total concentration of all proteins in a sample. As standard for the densitometric analysis, we chose carbonic anhydrase (molecular weight of 29 kDa), which is only slightly higher than that of MUPs.. Carbonic anhydrase contains a comparable amount of dye binding sites to MUPs, in contrast to the frequently used bovine serum albumin standard (60 kDa). The use of the latter standard may result in underestimation of the MUP concentration.

The results of this study further our knowledge of MUPs in that it shows a plasticity of their expression in different social contexts. This plasticity is supposedly mediated by the hormonal regulation, primarily by testosterone. In wild females, however, the regulatory role of testosterone and other hormonal agents remains uncertain. Studies that have examined hormonal regulation of MUPs to date, are, unfortunately of limited value because they usually tested laboratory or even hormone-deficient mice and treated them with unnaturally high hormone levels (Knopf et al., 1983; Johnson et al., 1995). Therefore, to get better insight into the roles of MUPs, there is need to characterize ultimate as well as proximate factors that modulate MUP expression in wild animals under more natural conditions.

Another significant result of this study shows that expression change of MUPs in males depend on the sex

of the animal introduced into a male's cage. The up-regulation that was observed in response to females indicates that for males, MUPs may be more important in communication between, rather than within, sexes. Given the overall cost of scent-marking and production of high amounts of protein and volatile pheromones, it can be hypothesized that scent marks are honest displays of males' quality (Penn and Potts, 1998; Gosling and Roberts, 2001). MUPs may, therefore, play a role in the process of mate choice by increasing the attractive properties of a male's scent marks and advertising his fitness to females.

Our study was performed on the Eastern European subspecies of the house mouse (*M. m. musculus*), which differs slightly in several aspects from *M. m. domesticus*. These include behavioral (Christophe and Baudoin, 1998; Smadja and Ganem, 2002), morphological (Boursot et al., 1993) differences as well as the specific level of MUP expression (Stopkova et al., 2007). Whether they differ also in the function of MUPs in chemical communication is unclear (Janotova and Stopka, 2009). Therefore, we emphasize that further studies in *M. m. domesticus* are needed to determine to what extent our findings are applicable to this subspecies.

Abstract P450 enzymes are known for catalyzing hydroxylation reactions of non-activated C-H bonds. For example, $P450_{cam}$ from *Pseudomonas putida* oxidizes (1*R*)-(+)-camphor to 5-*exo*-hydroxy camphor and further to 5-ketocamphor. This hydroxylation reaction proceeds via a catalytic cycle in which the reduction of dioxygen (O_2) is coupled to the oxidation of the substrate. We have observed that under conditions of low oxygen, *P. putida* and isolated $P450_{cam}$ reduce camphor to borneol. We characterized the formation of borneol under conditions of low oxygen or when the catalytic cycle is shunted by artificial oxidants like *m*-chloro perbenzoic acid, cumene hydroperoxide, etc. We also tested the toxicity of camphor and borneol with *P. putida* and *Escherichia coli*. We have found that in *P. putida* borneol is less toxic than camphor, whereas in *E. coli* borneol is more toxic than camphor. We discuss a potental ecological advantage of the camphor reduction reaction for *P. putida*.

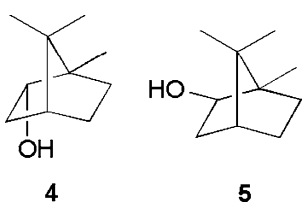
Introduction

Cytochrome $P450_{cam}$ (CYP101) is a heme monoxygenase (Sligar et al., 1974; Sono et al., 1996) isolated from the soil bacterium *Pseudomonas putida* (Davydov et al., 2001), which utilizes camphor as a carbon source. $P450_{cam}$ is known to catalyze the hydroxylation of camphor (**1**) to 5-*exo*-hydroxycamphor (**2**) (Sibbesen et al., 1996; Altun et al., 2007) and further to 5-ketocamphor (**3**) (Auclair et al., 2001). $P450_{cam}$ needs two electron transfer proteins, putidaredoxin (PdX) and putidaredoxin reductase (PdR) (Katagiri et al., 1968) for its catalytic activity (Lipscomb et al., 1976; Pochapsky et al., 2003). The catalytic cycle of the enzyme has evolved to couple the highly favorable reduction of O_2 to the unfavorable oxidation of the hydrocarbon substrate. A key intermediate in the catalytic cycle, the iron-oxo species (Fe(IV)=O), is supposed to be the most reactive species (Makris et al., 2006), and also is believed to form via a shunt pathway (Schunemann et al., 2004; Newcomb et al., 2006) when artificial oxidants such as iodosobenzene, cumene hydro-peroxide (Chefson and Auclair, 2006), or *meta*-chloro perbenzoic acid (*m*-CPBA) are used (Egawa et al., 1994).

Some *P. putida* contain a plasmid (the CAM plasmid) that encodes a degradation pathway for the monoterpene (1*R*)-(+)-camphor (Aramaki et al., 1993). The first step in that pathway is the oxidation of camphor at position 5 (Gould et al., 1981). This step is catalyzed by the $P450_{cam}$ complex with its redox partners PdR and PdX (Gunsalus and Sligar, 1976; Shimada et al., 2001). We identified 5-*exo*-hydroxycamphor (**2**) and 5-ketocamphor (**3**) (Scheme 1) in enzymatic assays performed with the purified proteins isolated from *P. putida* (Rojubally, 2007).

Here, we describe the identification of a third product borneol (**4**) from assays involving the peroxide shunt and



Scheme 1 The hydroxylation reaction of camphor. formation of 5-*exo*-hydroxy camphor and 5-Ketocamphor

for assays conducted under regular catalytic conditions. This finding is surprising, because borneol, a reduction product of camphor, is formed under conditions that are not considered to be reducing. Also surprisingly, isoborneol (**5**) was not detected (Scheme 2). We have found that cytochrome $P450_{cam}$ produces borneol, and we describe the conditions under which it forms *in vivo* and *in vitro*. We also compared the toxicity of camphor and borneol against strain ATCC 17453 of *P. putida* (containing the cam plasmid) and against *Escherichia coli*, a bacterium that lacks cytochrome P450 (Cryle et al., 2003). Our results suggest that the formation of borneol from camphor may confer an advantage to *P. putida*.

Methods and Materials

General Methods and Chemicals Experimental procedures and full spectroscopic details are available for all compounds in the Supplementary Data section. All solvents were distilled prior to use. Reduced nicotine adenine dinucleotide (NADH), dithiothreitol (DTT), lysozyme, DNase, RNase, Vitamin B_1, riboflavin, δ-aminolevulinic acid, hydrogen peroxide (used for assays), protease inhibitors leupeptin, aprotinin, and 4-(2-aminoethyl)-benzenesulfonyl fluoride were purchased from Sigma-Aldrich (Oakville, ON, Canada); dimethyl sulfoxide (DMSO, 99.9% chemical purity) from Caledon Laboratories Ltd (Georgetown, ON, Canada). Reagent grade 1-indanone was purchased from Eastman Co. (Kingsport, TN, USA) and used without further purification. *m*-Chloro perbenzoic acid (≤77% c.p.) was purchased from Sigma-Aldrich; purified by known methods (Aggarwal et al., 1998), and used for assays. Other shunting agents, cumene hydro-peroxide (CHP), sodium periodate ($NaIO_4$), and sodium hypochlorite (bleach) were used as received. Gas chromatography was performed on a Hewlett Packard 5890 GC (Avondale, PA, USA) equipped with a flame ionization detector and a 30 m×0.25 mm i.d.×0.25 μm film thickness SPB-5 column (Supelco, Bellefonte, PA, USA). The instrument was programmed as follows: 80°C (5 min), 10°C/min to 200°C (4 min), 50°C/min to 250°C (20 min); head pressure 15 psi; total flow through the column was 1.7 ml/min with injector and detector temperatures set at 250°C. Enantiomers of borneol and isoborneol were separated on a 30 m×0.25 mm i.d.×0.25 μm film thickness CycloSil B column (J & W Scientific, Folsom, CA, USA), with the column oven programmed isothermally at 120°C and a head pressure 15 psi. Gas chromatography-mass spectrometry (GC-MS) was carried out on a Varian Saturn 2000 MS (Mississauga, ON, Canada) equipped with the identical SPB-5 column (Supelco), and the column was programmed as follows: 45°C (0.5 min), 7°C/min to 120°C (1 min), 50°C/min to 260°C (3 min) with injector and transfer line temperatures set at 220°C and 260°C, respectively. Electron impact spectra were obtained at an emission current of 30 μA, scanning from 50 to 365 amu, with ion storage (SIS mode) 49–375, trap temperature 170°C and transfer line 250°C. For sensitivity measurements, electron impact spectra were obtained with ion storage (SIS mode) 90–170.

UV/Vis spectra were obtained on a Cary 300 Bio UV-visible double beam instrument (Mississauga, ON, Canada). NADH utilization rates and hydrogen peroxide formation were measured on a thermostatted Hach DR/4000 U spectrophotometer (Mississauga, ON, Canada). The dissolved oxygen in the aerated and poorly aerated cultures was determined by an Orion DO meter (model 850) (Beverly, MA, USA). Activity assays were carried out at 22°C. Electrophoresis was performed on polyacrylamide gels (14%, 29:1) with 0.5% sodium dodecyl sulfate (SDS-PAGE). Samples were reduced by treatment with DTT (31 mg/ml) before loading on gels. Gels were stained with Coomasie Brilliant Blue R (Sigma). Samples were sonicated in a Branson Ultrasonic sonicator (Danbury, CT, USA). Centrifugations were carried out with a Beckmann Avanti J-26 XPI centrifuge (Mississauga, ON, Canada), equipped with a JLA 8.1000 rotor.

Scheme 2 Borneol (**4**), one possible reduction product of camphor, and isoborneol (**5**). borneol is formed in *P.Putida* but not isoborneol

The buffers used were: lysis (20 mM phosphate buffer (K^+), pH 7.4 with 1 mM camphor; T-100 (50 mM Tris, 100 mM KCl, pH 7.4); and T-400 (50 mM Tris, 400 mM KCl, pH 7.4). Substrate-free P450 was prepared by passing the substrate-bound enzyme over a Sephadex G-10 column equilibrated with 100 mM MOPS (pH 7.0) (Gunsalus and Wagner, 1978). The concentration of the substrate-free P450 was calculated by the ε_{417}=104 mM^{-1} cm^{-1}. GC-MS analysis of the chloroform extract of the substrate-free P450 confirmed that less than 2% of the camphor was bound to P450.

(1R)-(+)-Camphor Purification (1*R*)-(+)-Camphor (Sigma-Aldrich) contained ~5% borneol as confirmed by GC-MS in comparison with authentic borneol (Sigma). The camphor was recrystallized from ethanol/water and then purified on silica gel with a hexane:ethyl acetate gradient [from 1:0 (30 fractions, 8 ml) to 99:1 (5 fractions), to 4:1 (8 fractions)]. The (1*R*)-(+)-camphor was chemically pure (GC-MS). Mass spectrum (EI): *m/z* (% of base peak) 153 (M+1, 6), 152 ($M^{\cdot+}$, 8), 137(7), 108 (66), 95 (100), 69 (15), 67 (55), and 55 (28) and CI (isobutene): *m/z* (% of base peak) 153 (M+1, 100), 137 (2), 135 (6), 108 (10), 95 (3), 81 (10), 69 (12), and 67 (20). Other products, 5-ketocamphor and 5-*exo*-hydroxy camphor were synthesized by known methods (Dauben et al., 1956; Darby et al., 1979) and were characterized by nuclear magnetic resonance spectroscopy (NMR) and GC-MS.

Nuclear Magnetic Resonance Spectroscopy (NMR) The proton and the carbon nuclear magnetic resonance spectra were run on a Varian 500 MHz instrument (Varian Inc., Palo Alto, CA). The chemical shifts (δ) for all compounds are listed in parts per million with NMR solvent ($CDCl_3$) as an internal reference. The coupling constants (*J*) are listed in Hertz (Hz).

Protein Production (from P. putida) and the Purification Steps $P450_{cam}$, PdR, and PdX were isolated from *P. putida* (ATCC 17453) according to the protocol reported by (Gunsalus and Wagner, 1978). *Pseudomonas putida* were grown in nutrient broth (Gibco) containing 0.5 mg/ml of (1*R*)-(+)-camphor with shaking (250 rpm) to A_{600}=0.9–1.0. Cells from 2 l of culture were lysed in 50 ml of 20 mM potassium phosphate, pH 7.4, 1 mM camphor. Cells were suspended in 10 mM in EDTA (pH 7.4). Then, lysozyme (100 mg/l) and camphor (1 mM in ethanol) were added and stirred for 30 min at 4°C. The suspension was sonicated with 50% duty cycle for 10 min and brought to 10 mM in $MgSO_4$. DNase (2 mg, Sigma) and RNase (10 mg, Sigma) were added and stirred for 30 min at 4°C. The lysate was sonicated for 5 min and homogenized in a tissue homogenizer with a Teflon pestle. The homogenized cells were harvested by centrifugation (7000×*g*, 30 min), and dialyzed with frequent changes of 20 mM potassium phosphate (pH 7.4) containing 1 mM camphor for further purification by ammonium sulfate precipitation. The dialyzed lysate of *P. putida* was subjected to a 20% ammonium sulfate cut to remove the cell debris. The 20% supernatant was carried forward to 55% ammonium sulfate saturation to isolate the proteins. All three proteins were isolated together in the above step. Proteins were further purified by column chromatography (DE-52 column with a linear gradient of buffer T-100 to T-400 containing 1 mM camphor and 1 mM β-mercaptoethanol at 1 ml/min). Fractions with high absorbances at A_{392} (in the case of P450), A_{454} (in the case of PdR), and A_{325} (in the case of PdX) were pooled, and checked by SDS-PAGE before proceeding with gel-filtration chromatography. The collected fractions were concentrated in an Amicon ultrafiltration cell equipped with a 10 kDa membrane (Millipore Corporation, Billerica, MA, USA), and the concentrate (containing P450, PdR, and PdX) was loaded onto a S-100 column, eluted with T-100 buffer, 1 mM sucrose, and 1 mM camphor at 1 ml/min. The three proteins could not be separated, and the selected fractions containing A_{280}/A_{392}<7.0, A_{280}/A_{454}<9, A_{280}/A_{325}<4.0 were analyzed by SDS-PAGE for molecular weight determination and taken for assays.

In vivo Assays with P. putida To monitor product formation under aerated and non-aerated conditions, *in vivo* assays were performed with *P. putida* cultures. Culture assays were performed in 500 ml Erlenmeyer flasks. A dense culture (A_{590}=0.9) was treated with 100 mg of camphor delivered in dimethyl sulfoxide (DMSO). Cultures were monitored by removing 1 ml of culture, adding 0.2 ml of saturated NaCl solution, and extracting with 1 ml of chloroform. The organic layer was dried over Na_2SO_4 and analyzed by GC-MS. Aerated conditions (dissolved oxygen was measured to be 11 mg/l) were obtained in small flasks (250 ml) by shaking at ~250 rpm, whereas poorly aerated conditions (dissolved oxygen was measured to be 2 mg/l) were obtained in 10 ml tubes with very slow shaking (50 rpm).

To monitor the conversion of camphor to metabolites by the induction of P450 under aerated and non-aerated conditions, *P. putida* ATCC 17453 strain was grown for seven generations in two replicates without camphor. Aliquots (20 μl) of the 7th generation cultures (both aerated and non-aerated) were inoculated into 100 ml of nutrient broth medium in a 250 ml flask. This 8th generation of log phase culture was treated with 0.77 g of camphor delivered in DMSO, and the absorbances at 280, 392, and 410 nM were recorded at 0 min (immediately after adding camphor), 5, 30, 60, 120, 180, 240 min, and 8 h under both aerated and non-aerated conditions. At every time point, the sample was centrifuged to collect the

pellet and the supernatant. Supernatants from the different time points were extracted with $CHCl_3$/indanone (7.2 μM) for the extraction of the product(s) and the substrate. Indanone was our internal standard for the quantification of products by GC-MS. A second extraction of the aqueous phase with 0.7 ml of $CHCl_3$/indanone followed. The combined organic layers were dried over $MgSO_4$ and analyzed by GC-MS.

In vitro Assays with Isolated $P450_{cam}$, PdR, and PdX Complex In vitro enzymatic assays were performed in 2 ml of 50 mM phosphate buffer (100 mM K^+) (pH 7.4). The buffer was sparged with charcoal filtered air/oxygen or argon (both Sigma-Aldrich) prior to use. Concentrations of ferric P450 (with camphor), PdR, and PdX were determined by their extinction coefficients ε_{392}=104 mM^{-1} cm^{-1}, ε_{454}= 10.0 mM^{-1} cm^{-1}, and ε_{325}=15.6 mM^{-1} cm^{-1} (Gunsalus and Wagner, 1978). The reaction mixture contained 1.5 μM $P450_{cam}$, 2.5 μM PdR, 5 μM PdX, and the substrate camphor (2.5 mM). NADH consumption was initiated by the addition of 2.5 μl NADH stock (200 mM) and monitored for 10 min at 340 nm. The experiment was performed in four replicates, and three controls were run in parallel with the treatments: 1) blank: without enzyme but all other reactants added; 2) enzyme and the substrate added to the buffer without NADH; and 3) NADH and the enzyme added without camphor. The reaction was stopped by the addition of 1 ml $CHCl_3$/indanone (7.2 μM) for the extraction of the product(s) and the substrate. Indanone was our internal standard to quantify products by GC-MS. A second extraction of the aqueous phase with 0.7 ml of $CHCl_3$/ indanone followed. The combined organic layers were dried over $MgSO_4$ and analyzed by GC-MS.

In assays involving *m*-CPBA as a shunt agent for the catalytic cycle, the reaction mixture contained 1.5 μM $P450_{cam}$, *m*-CPBA (1 mM), and substrate camphor (1 mM). The experiment was performed in four replicates, and three controls were run in parallel with the treatments: 1) blank: without enzyme but all other reactants added; 2) enzyme and the substrate added to the buffer without *m*-CPBA; and 3) *m*-CPBA and the enzyme added without camphor. The reaction mixture was incubated for 15 min at 22°C and extracted in the same way as above. The dried organic layers were analyzed by GC-MS.

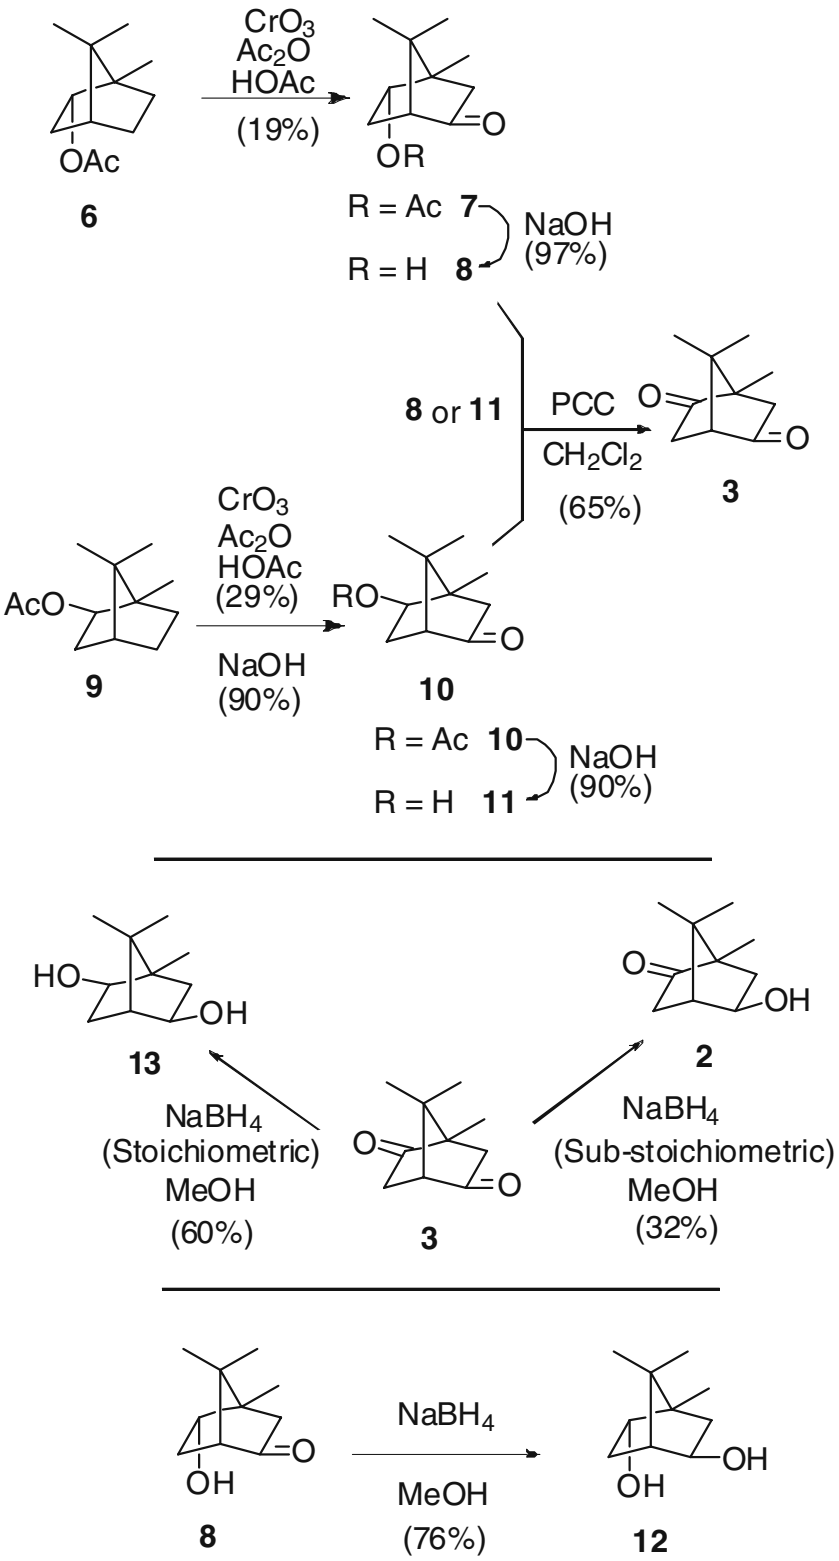
In assays involving borneol as the substrate and *m*-CPBA as a shunt agent for the catalytic cycle, the reaction mixture contained 2 μM $P450_{cam}$, *m*-CPBA (1 mM), and substrate (1 mM). The experiment was performed in four replicates, and three controls were run in parallel with the treatments: 1) blank: without enzyme but all other reactants added; 2) enzyme and the substrate added to the buffer without *m*-CPBA; and 3) *m*-CPBA and the enzyme added without borneol. The reaction mixture was incubated for 30 min at 22°C and extracted in the same way as above. The dried organic layers were analyzed by GC-MS.

Toxicity Assays of Tetracycline, DMSO, Camphor, and Borneol against P. putida and E. coli Cultures of the strains ATCC 17453 of *P. putida* and XL-1-blue of *E. coli* were grown overnight, and used to inoculate 2×250 ml growing cultures, which were grown at 300 rpm with good aeration until an O.D. of 0.1 was reached. An aliquot (5 ml) of each of these cultures was transferred separately to Falcon tubes in three replicates, to each of which either camphor, borneol, or tetracycline was added to a final concentration of 1 mM. Dimethyl sulfoxide (DMSO), the solvent used for preparing stocks, also was used as one of the controls. Cultures were grown for 1 hr and incubated overnight at 4°C. They were diluted 10^3×, 10^4×, 10^5×, 10^6×, 10^8× in three replicates and then plated on non-antibiotic LB-agar plates in two replicates (20 and 50 μl) and were incubated overnight at 27°C. Colonies were counted after overnight incubation. The toxicities of camphor and borneol to the two strains were assessed by measuring the reduction of cell density [colony forming units (CFU)/ml]. To obtain CFU/ml, colonies were grown on agar plates and the numbers of colonies were divided by the volume plated. This, when divided by the dilution factor, gives the CFU/ml in the original sample. We compared *P. putida* with the Cam plasmid to *E. coli*, a species of bacterium known to not contain any P450 genes (Cryle et al., 2003). A comparison of the relative toxicity between borneol and camphor on *E. coli* was determined by a one-way ANOVA test (Vander Waerden test) with JMP starter software (Cary, NC, USA) with significance determined at α=0.05. The distribution of the data was checked with JMP software, and the normal hypothesis was rejected. Therefore, a non-parametric method was used for the analysis. Tukey-Kramer pairwise comparisons were performed to test the effects of camphor and borneol relative to DMSO; Wilcoxon and Vander Waerden comparisons were used to test the effects of camphor and borneol directly.

IC_{50} Experiments with Camphor and Borneol Against E. coli Two growing cultures (250 ml each) were inoculated with an overnight grown culture of XL-1-blue of *E. coli* and then grown at 300 rpm with good aeration until a O.D. of 0.1 was reached. An aliquot (5 ml) of this culture was transferred to Falcon tubes to which either borneol or camphor was added in varying concentrations. The final concentrations of these compounds ranged from 0.5 nM to 1 μM. Dimethyl sulfoxide (DMSO), the solvent used for preparing stocks, also was used as one of the controls. Cultures were grown for 1 hr and incubated overnight at 4°C. They were diluted 10^4× and 10^5× in three replicates and then plated on non-antibiotic LB-agar plates in two replicates (20 and 50 μl) and

incubated overnight at 37°C. The concentration of colony forming units (CFU/ml) was calculated the next day, depending on the number of colonies. The IC_{50} was calculated by graphing CFU/ml vs. the logarithm of concentration of compounds (Vrzal et al., 2010).

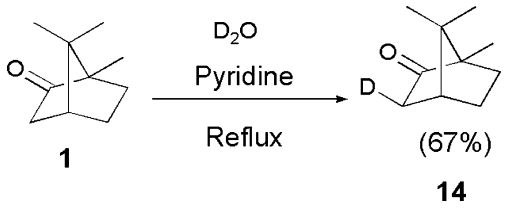
Synthesis of Standards The synthesis of 5-*exo*-hydroxycamphor (**2**) was initiated from commercially available borneol (**4**) or from racemic isoborneol (**5**) (Scheme 2). Either borneol was transformed into its acetate (**6**), and oxidation with chromium trioxide in acetic anhydride and acetic acid afforded the intermediates (**8**) or (**11**). The oxidation of compounds **8** and **11**, with pyridinium chlorochromate (PCC), afforded 5-ketocamphor (**3**). The selective reduction of 5-ketocamphor (**3**) with sodium borohydride yielded 5-*exo*-hydroxycamphor (**2**). 5-*exo*-Hydroxyisoborneol (**13**) was obtained as a major product from the complete reduction of 5-ketocamphor (**3**) or (**11**), and 5-*exo*-hydroxyborneol (**12**) was obtained by the reduction of (**8**) (Scheme 3). To monitor the bioconversion of camphor *in vivo* and *in vitro* by *P. putida* enzymes, deuterated camphor (3-D_1-camphor) **14** was synthesized (Scheme 4) from camphor **1** with D_2O in the presence of pyridine. The method for complete syntheses of all these compounds with its characterization is provided in the Supplementary Data.



Results

Analysis of Products Formed in Pseudomonas putida Culture with (1R)-(+)-Camphor During in vivo Assays with Purified $P450_{cam}$ System *In vivo* production of the metabolites from an induced *P. putida* culture was monitored by extracting samples with chloroform and analyzing them by GC-MS. Under aerated conditions, 5-*exo*-hydroxycamphor (**2**) and 5-ketocamphor (**3**) were obtained as reported by Gould et al. (1981). In addition to **2** and **3**, 5-*exo* hydroxyborneol (**12**) and borneol (**4**) were detected (Fig. 1). In the poorly aerated system, borneol (**4**) was detected in the early stage of the reaction, its quantity gradually peaked around 4 hr, and then decreased, whereas 5-*exo*-hydroxyborneol (**12**), the other reduction product, formed at a later stage in the metabolic pathway (Fig. 2a). 5-Ketocamphor (**3**) formed only after 5 hr of incubation, whereas 5-*exo*-hydroxy camphor (**2**) was not detected in the poorly aerated system (Fig. 2a). In the non-aerated system, the quantity of borneol (**4**) increased steadily and did not appear to be bioconverted any further. The oxidation products, 5-*exo*-hydroxycamphor (**2**) and 5-ketocamphor (**3**), were present at low levels in the non-aerated system (Fig. 2b).

In vivo production of borneol and 5-ketocamphor was monitored under aerated and non-aerated conditions in growing *P. putida* cultures that had been treated with camphor. The quantities of borneol under both aerated and non-aerated conditions increased in the first 3 hr and then reached a plateau (Fig. 3). To prove that these products were obtained from camphor, deuterated camphor (3-D_1-camphor) **14** was synthesized (Scheme 4) from camphor **1**. (refer to Supplemental Data for complete synthesis). When 3-D_1-camphor **14** was added to a growing culture of *P. putida* and under oxidizing conditions, deuterated 5-ketocamphor was detected. Borneol detected under poorly aerated conditions was identified by chiral stationary phase GC-FID with a retention time of 29.8 min and compared to the retention times of two products of sodium borohydride reduced (1*R*)-(+)-camphor, borneol (**4**), and isoborneol (**5**). Isoborneol (**5**), eluted from the cycloSyl B column with a retention time of 25.8 min. This confirms that borneol is the only reduction product detected in the *P. putida* culture (Rojubally, 2007).



In vitro Assays with the Isolated $P450_{cam}$, PdR, and PdX Complex To determine whether $P450_{cam}$ is involved in the formation of **2**, **3**, and **4**, experiments were performed with purified, isolated $P450_{cam}$ and its redox partners, obtained from *P. putida* induced with camphor. The first unexpected result was that these proteins cannot be separated during the purification process but instead form a ternary complex. We, therefore, used this ternary complex in our *in vitro* assays.

Under oxygenated conditions, (when the assay buffer was sparged with oxygen or air), the enzyme complex catalyzed the oxidation of camphor to 5-ketocamphor (as the major product) and reduction to borneol (minor product) (Table 1). When there was insufficient oxygen for the catalysis (when the assay buffer was sparged with argon), surprisingly, borneol formed and 5-ketocamphor was not detected. Under these conditions, when the enzymatic pathway was shunted in the presence of *m*-CPBA and cofactor NADH was added, the amount of 5-ketocamphor formed was the same as that of borneol. In this assay, the concentration of 5-ketocamphor formed was less when compared to the oxygenated conditions. When hydrogen peroxide was used in place of *m*-CPBA under similar conditions, 5-ketocamphor was not detected and less borneol was formed (Table 1). In the absence of cofactor in the above mentioned conditions and when *m*-CPBA was used as a shunt agent, 5-ketocamphor was not detected and surprisingly more borneol was formed than with H_2O_2. This illustrates that the cofactor NADH is not responsible for the borneol formation. Further evidence that NADH is not the source of electrons was obtained when NADD was added to the assay reaction mixture that contained the substrate camphor and the enzyme, and

Scheme 3 Synthesis of 5-*exo*-hydroxy camphor (**2**), 5-ketocamphor (**3**) and 5-exo-hydroxy borneol standards

deuterated borneol was not detected under GC-MS in comparison with its synthetic standard (Rojubally, 2007) (Data not shown). Hydrogen peroxide, when added to the system, appears to be inhibitory, giving lower amounts of borneol. Taken together, these observations suggest that borneol forms under conditions when the bacteria begin to be stressed by low oxygen levels, but are still metabolizing camphor.

Scheme 4 Formation of 3-D_1-camphor (**14**) from camphor (**1**)

Enzymatic Assays Involving Borneol as the Substrate The enzymatic assays involving borneol as the substrate were conducted under shunt conditions and the products formed were monitored by GC-MS. We demonstrated the conversion of borneol to camphor and further to 5-*exo*-hydroxycamphor, which shows that this formation of borneol is a reversible reaction. The concentration of camphor was 33± 1.6 nmol/min/μmol P450, and 5-*exo*-hydroxycamphor was 50±1.6 nmol/min/μmol P450. This illustrates that *P. putida* can convert borneol back to camphor.

Toxicity Assays for Camphor and Borneol To test for a potential adaptive value for the conversion of camphor to borneol, we compared the relative toxicities of camphor, borneol, and tetracycline on *P. putida* and on *E. coli*. The ANOVA on mean cell densities for each species revealed an effect of treatment (*P. putida*: P=0.006 and F=4.40; *E. coli*: P< 0.001 and F=8.63). Tukey-Kramer pairwise comparisons of the toxicity of the substrates to *P. putida* revealed no significant differences in cell densities following monoterpene treatment relative to DMSO, suggesting that neither camphor nor borneol were toxic to *P. putida* (Fig. 4a) (DMSO/camphor pair, P=0.393; DMSO/borneol pair, P=0.981; and camphor/borneol pair, P=0.629). In contrast, treatment with tetracycline did cause a reduction in cell density relative to DMSO (Fig. 4a) (DMSO/

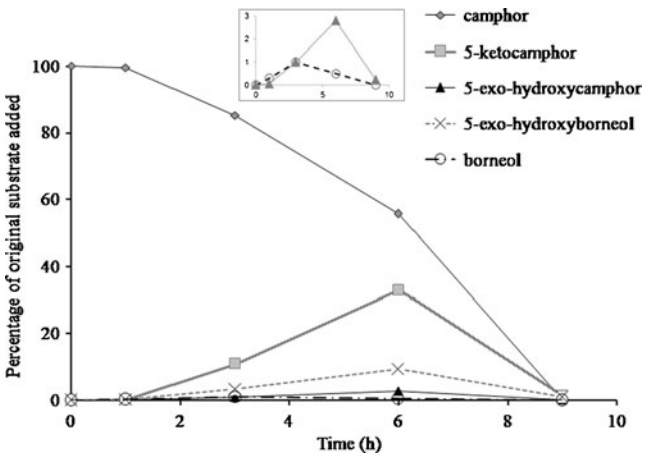


Fig. 1 Time course of relative quantities of metabolites measured from an induced culture of *Pseudomonas putida* under aerated conditions. The figure in the inset shows the time course for 5-*exo*-hydroxy camphor and borneol

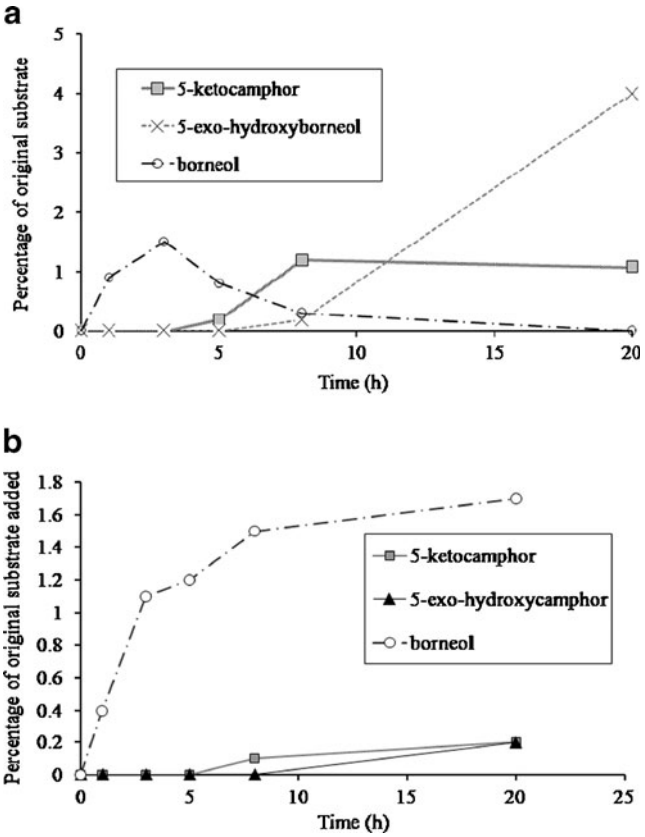

Fig. 2 Time course of relative quantities of metabolites measured from an induced culture of *Pseudomonas putida* under poorly-aerated (**a**) and non-aerated (**b**) conditions

tetracycline pair, P=0.007; camphor/tetracycline pair, P= 0.320; and borneol/tetracycline pair, P=0.022). Wilcoxon and Vander Waerden tests revealed that camphor was more toxic than borneol to *P. putida* (Fig. 4a) (P=0.025, N=3). Tukey-Kramer pairwise comparisons of the toxicity of the substrates to *E. coli* revealed that camphor, borneol, and tetracycline were all toxic to *E. coli* relative to DMSO (Fig. 4b) (DMSO/camphor pair, P<0.001; DMSO/borneol pair, P<0.001; DMSO/tetracycline pair, P<0.001; camphor/borneol pair, P=1.0; camphor/tetracycline pair, P=1.0; and borneol/tetracycline pair, P=1.0). Wilcoxon and Vander Waerden comparisons revealed that while both monoterpenes were toxic to *E. coli*, borneol was more toxic than camphor (P=0.035, N=3). In addition to this, the IC_{50} of borneol with growing cultures of *E. coli* ranged from 14.3 to 20 nM, whereas the IC_{50} of camphor ranged from 19 to 42 nM (Fig. 5).

Discussion

Hydroxylation of camphor is catalyzed by the $P450_{cam}$ complex with its redox partners PdR and PdX (Gunsalus

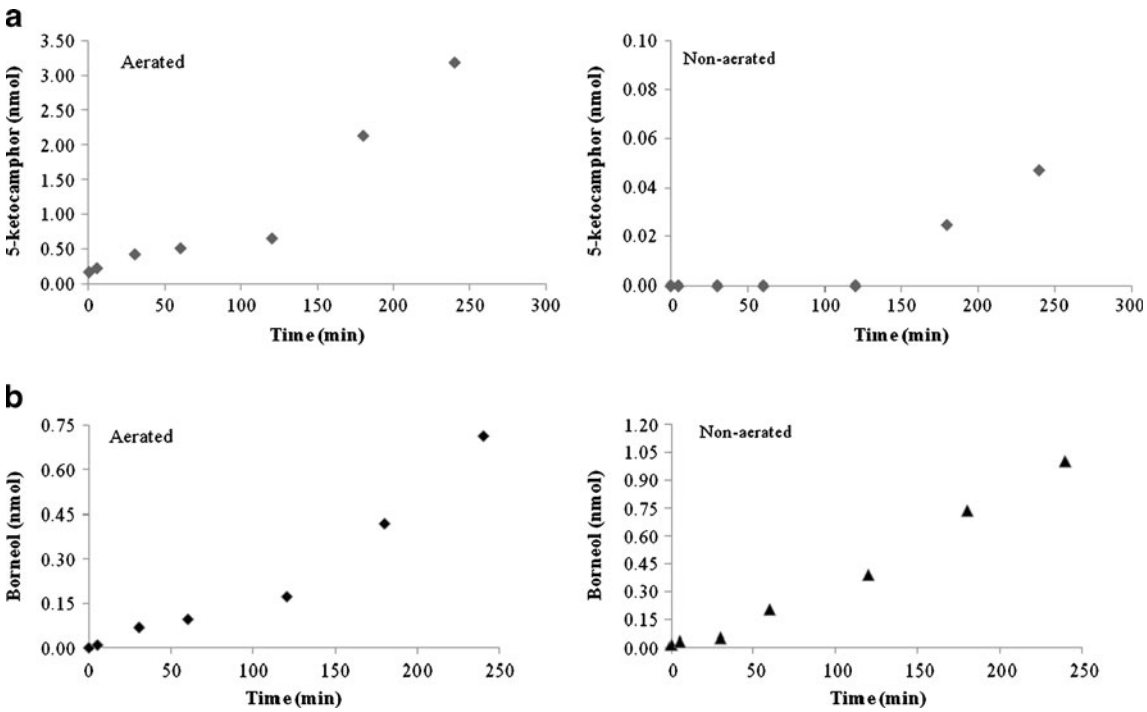

Fig. 3 Time course of quantities of 5-ketocamphor (**a**) and borneol (**b**) from an induced culture of *Pseudomonas putida* under aerated and non-aerated conditions

and Sligar, 1976; Shimada et al., 2001). The P450 reduces O_2 with electrons from NADH and incorporates one oxygen atom into product (Guengerich and MacDonald, 1990). Here, we observed that, in addition to the known camphor oxidation products 5-*exo*-hydroxycamphor (**2**) and 5-ketocamphor (**3**), a reduction product, borneol (**4**),

forms during $P450_{cam}$ catalysis. The distribution of products appears to be dependent on the reaction conditions. Under well oxygenated conditions, 5-ketocamphor (**3**) is the major product, whereas under poorly aerated conditions borneol (**4**) is the major product. One way in which borneol could form is via reduction of the 2-keto group of camphor with NADH. Two observations conflict with this hypothesis. First, the formation of borneol also can occur in the absence of NADH, when shunting agents are used instead of O_2 as the oxidant. Second, NADH appears not to be necessary for borneol formation, as addition of NADD does not result in deuterated borneol (Rojubally, 2007).

Previous studies may have missed the formation of borneol, because various camphor-derived compounds that elute after camphor like borneol, isoborneol, and 5-*exo*-hydroxycamphor elute closely on non-polar GC columns typically used for this analysis. Furthermore, the mass spectra of the oxygenated bornyl-based monoterpenes (**1**, **2**, **3**, **4,** and **5**) are similar, because of a strong tendency to fragment to ions with *m/z* of 108, 95, 81, and 67. From studies with ^{17}O- labeled camphor, we know that none of these ions contain oxygen (Prasad et al., 2011). The products of camphor oxidation and the reduction product, borneol were detected in the early stages of metabolism, up to ~6 hr of culture. Further metabolism of borneol to 5-*exo*-hydroxy borneol (**12**) was observed in the non-aerated conditions, which suggests that the reduction to borneol and its further hydroxylation to (**12**) occurs in the intact bacterium. To test for a potential adaptive value for this reaction, we compared the relative toxicity of camphor and borneol on *P. putida* and on *E. coli.* This experiment suggested that camphor is toxic to both *E. coli* and *P. putida*, whereas borneol is more toxic than camphor to *E. coli*. Therefore, formation of borneol may confer an advantage to strains of *P. putida* that metabolize camphor and are competing with other bacteria that do not metabolize camphor. Under conditions of low oxygen, borneol forms from camphor, and this compound is less toxic than camphor itself to *P. putida* but more toxic to P450-free bacteria such as *E. coli*.

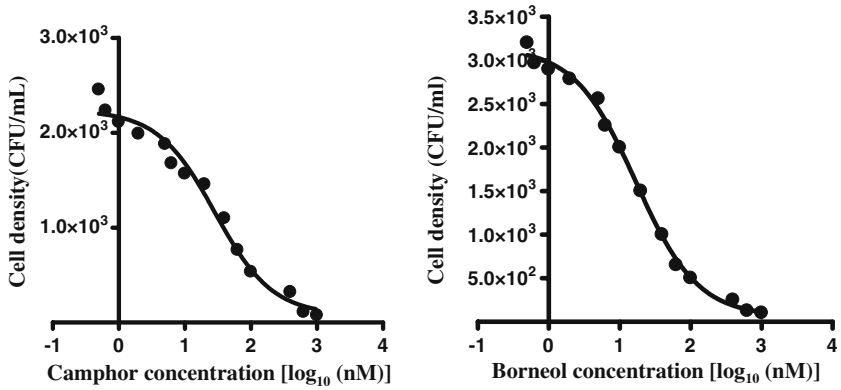

Fig. 5 IC50 experiments on *Escherichia coli* with varying concentrations of camphor and borneol

We are not aware whether *E. coli* and *P. putida* compete with each other ecologically.[1] We know that *P. putida*, for example, exists in soil and in sink sludge (Shen and Wang, 1995) (from where the camphor metabolizing strain of *P. putida* was originally isolated). *Escherichia coli* is a widespread enteric bacterium, but also can exist outside of vertebrate organisms (in soil or in water), as some past tragic incidents with drinking water in rural areas have demonstrated (Winfield and Groisman, 2003).

Bacterial P450's have been widely studied in the past for their ecological functions in the detoxification of both natural and artificial toxicants. For example, P450 BM3 from *Bacillus megaterium* hydroxylates fatty acids, fatty amides, and alcohols at the ω-1, ω-2, or ω-3 positions, making them less amphiphilic (Narhi and Fulco, 1986). P450 isolated from the actinomycete *Nonomuraea recticatena IFO 14525*, catalyzes the hydroxylation of oleanolic acid, a toxic triterpene (Kinoshita et al., 1999). P450s from members of the order *Actinomycetales* catalyze pentachlorophenol dehalogenation and the degradation of sulphonylurea herbicides (Munro and Lindsay, 1996).

In summary, we have identified the reduction product borneol by using the substrate camphor and purified *P. putida* proteins. We plan to perform experiments with the recombinant proteins expressed in *E. coli*. The source of electrons for this reduction reaction and our proposed mechanism for the reduction mechanism will be reported in the near future.

Acknowledgments This work was supported by NSERC (Discovery grant No. 222923-05). We thank the Chem 381 class (Spring 2006) for help in isolating products from *P. putida*. B. Prasad performed experiments with the purified $P450_{cam}$ system, with camphor/borneol toxicity, the IC_{50} experiments and wrote the paper. A. Rojubally performed the standard syntheses and time course experiments with *P. putida*. E. Plettner designed and planned the project.

COMMENTARY

New Synthesis—Back to the Future: New Approaches and Directions in Chemical Studies of Coevolution

Lee A. Dyer

Published online: 9 June 2011
© Springer Science+Business Media, LLC 2011

The concept of an arms race between herbivores and plants, associated with increases in diversity of plant secondary compounds, has long provided an appealing theoretical framework for evolutionary biologists pondering adaptive radiations, and has been a stimulus for studies of chemical ecology. While publications on coevolution are steadily increasing in ecology and evolutionary biology, such studies have stagnated in chemical ecology, even though modern chemical techniques have made it easier to examine coevolutionary predictions for phytochemical diversification. An example of what can be accomplished is illustrated by Kursar et al. (2009), who documented considerable divergence in effective antiherbivore defenses of the tropical plant genus *Inga*, indicating that an arms race between plants and herbivores caused rapid, divergent trait evolution. Interestingly, closely related *Inga* species that occur together in tropical forests also have distinct defensive profiles driven by tritrophic interactions. Thus, diffuse multitrophic coevolutionary interactions, mediated in part by plant chemistry, help structure diverse communities, allowing for high alpha diversity for *Inga*.

The study of *Inga* and related studies on *Quercus*, *Piper*, and *Bursera* utilize modern approaches to natural history, ecology, phylogenetics, and chemistry, and indicate that the time is ripe for chemical ecologists to return to coevolution as a unifying research theme. For natural products chemistry, synthesis and complex mixture analysis have improved dramatically (Hoye and Sizova 2009) with advances in MS sources, including electrospray ionization, matrix-assisted laser desorption ionization, and atmospheric pressure chemical ionization. These approaches permit rapid elucidation of a broad array of compounds in a taxon of interest, which is necessary for testing causes and consequences of increases of chemical diversity. Such input from chemists can synergize with advances in molecular ecology. For example, new sequencing technologies present the opportunity to generate high resolution population genomic data that can be used to test the hypothesis that host plant affiliations are associated with distinct chemical profiles and population genetic differentiation.

How will these new technologies contribute to understanding chemical mediation of coevolution? The answer includes a long list of theoretical advances, but here I provide two examples of exciting research directions.

First, a major problem with any approach to studying insect-plant coevolution is that there is a bias towards examining individual plant compounds and their effects on the physiology of herbivores and their predators. Redundancy in plant defenses has long been appreciated, and common effects such as synergy obfuscate results from traditional mechanistic tests of coevolutionary hypotheses. For example, in numerous coevolutionary studies, the failure to demonstrate negative correlations in performance on hosts with different defensive compounds or to demonstrate defensive efficacies of secondary metabolites could easily be due to the fact that compounds do not function in isolation. It is quite possible that phytochemical synergy is the rule rather than the exception, even for putatively induced defenses, and we need new initiatives of chemical ecological research that aim to test for defensive efficacy of suites of compounds or cross-host tradeoffs for different synergistic mixtures.

Second, any new approach to studying coevolution must acknowledge that plants and parasites interact within complex food webs. Thus, it makes sense to examine the phylogenetic histories and ecological interactions of both the hosts and the parasites of focal herbivores. Forister and Feldman (2011) take this approach when they present the concept of a "phylogenetic cascade," in which diversification at one trophic level affects two or more other levels, resulting in a shared evolutionary history across a food chain. Classic coevolutionary hypotheses are a subset of the phylogenetic cascades framework, and chemistry can play a major role in these interactions, as evidenced from numerous ecological studies that demonstrate strong indirect trophic effects of variation in plant chemistry. If future research on chemical mediation of coevolution is considered within synergistic or phylogenetic cascades contexts, by utilizing the latest technological advances, our understanding of diversity of animals, plants, and secondary metabolites should improve dramatically.

Differential Levels of Stress Proteins (HSPs) in Male and Female *Daphnia magna* in Response to Thermal Stress: A Consequence of Sex-Related Behavioral Differences?

Andrzej Mikulski · Piotr Bernatowicz · Małgorzata Grzesiuk · Małgorzata Kloc · Joanna Pijanowska

Received: 10 February 2011 / Revised: 5 May 2011 / Accepted: 12 May 2011 / Published online: 26 May 2011

Abstract In two independent experiments, we compared: (1) water depth selection (and accompanying temperature selection) by male and female *Daphnia magna* under different kinds of environmental stress, including the presence of filamentous cyanobacteria, the risk of predation from fish, and the presence of toxic compounds; and (2) sex-dependent production of heat shock proteins (HSP60, 70, and 90) in response to a sudden change in temperature. Male *D. magna* selected deep water strata, which offer a relatively stable environment, and thereby avoided the threat of predation and the presence of toxic compounds in surface waters. Correlated with this behavior, males reduce their molecular defenses against stress, such as the production of heat shock proteins (HSPs), and do not maintain the physiological machinery that triggers an increase in HSP levels in response to stress. In contrast, female *D. magna* actively select habitats that offer optimal conditions for growth and production of offspring. Consequently, females are exposed to variable environmental conditions that may be associated with increased stress. To permit survival in these different habitats, *D. magna* females require molecular mechanisms to protect their cells from rapid changes in stress levels. Thus, they maintain high constitutive levels of the heat shock proteins from HSP 60, 70, and 90 families, and they have the potential to further enhance the production of the majority of these proteins under stress conditions. The results of this study indicate that the separate habitats selected by male and female *D. magna* result in different patterns of HSP production, leading us to hypothesize that that male and female *Daphnia magna* adopt different strategies to maximize the fitness of the species.

Introduction

In many species, differences between males and females are not restricted to the morphology of sexual structures involved in mating or fertilization (Andersson, 1994). Individuals of each sex possess unique adaptations to maximize fitness. Under favorable environmental conditions, most water fleas, *Daphnia* spp. (Cladocera, Daphniidae) reproduce parthenogenetically. When conditions become adverse, *Daphnia* females produce resting eggs and deposit them into a special carapace structure called the ephippium. For successful hatching, resting eggs require fertilization before storage in the ephippium (Hobæk and Larsson, 1990; Pijanowska and Stolpe, 1996; Shurin and Dodson, 1997; Gyllström and Hansson, 2004).

The optimal strategy of female *Daphnia* involves a trade-off between the necessity to assimilate enough energy to grow and produce offspring, and the avoidance of environmental risks (e.g., predation or toxicity). The impact

of majority of stress factors is associated with surface water. Harmful chemicals that reach the lake in summer remain in the epilimnion (surface, warm water stratum). Even when these stresses reach the hypolimnion (deep, cold, and dark water stratum), their influence on organisms is limited due to low temperature (Cairns et al., 1975). Risk from predaceous fish that rely on vision to locate their prey, strongly depends on light and, as a consequence, is constrained to the upper strata. Because of the high temperatures and the abundance of food, epilimnetic conditions allow rapid growth (Wetzel, 2001). The necessity of avoiding the most dangerous locations at the surface and, at the same time, maximizing growth and reproduction has promoted the evolution of vertical migration behavior in *Daphnia* (e.g., Dawidowicz and Loose, 1992). Unlike females, males do not need to attain a large size or gather as much energy for reproduction. Their fitness depends on the number of females they fertilize during their lifetime. Therefore, their main goal is continued survival. We hypothesize that male *Daphnia magna* Straus should remain deeper in the water column than females, where they experience lower temperatures and food concentrations, but avoid predation by fish and adverse factors like cyanobacteria or toxins that are more prevalent in surface waters. Such male behavior has been described in *Daphnia galeata* by Spaak and Boersma (2001), who explained the inter-sexual differences in migratory behavior as a strategy to avoid inbreeding.

One of the main consequences of vertical migration in stratified lakes is exposure to rapid changes in temperature. For example, *D. magna* migrating twice a day – from the epilimnion to the hypolimnion and back – can experience a temperature gradient of 10-15°C. The reaction to thermal shock at the cellular level involves the expression of heat shock (or stress) proteins (HSPs) that protect cell structures against thermal stress (Jolly and Morimoto, 2000).

A change in the level of HSPs is one of the most widely recognized molecular responses to stress in pro- and eukaryotic organisms (Lindquist and Craig, 1988; Mager and de Kruijff, 1995; Jolly and Morimoto, 2000). HSPs were first discovered in *Drosophila busckii* following exposure to high temperature (Ritossa, 1962). They are divided into several groups (families) of different molecular weights (kDa): e.g., HSP100, HSP90, HSP70, HSP60, HSP40, and small proteins. HSP60s control modifications of newly synthesized proteins, repair damaged ones, and prevent peptides from accumulating (Jolly and Morimoto, 2000; Pockley, 2003). HSP70s are the most important molecular chaperones permanently active in the cell. In cooperation with other proteins, they are responsible for cellular homeostasis under non-stress conditions. Moreover, they play a vital role in stress tolerance and survival under adverse conditions. HSP70s also act to reduce accumulation of peptide aggregates, but if this does happen they can dissolve aggregates. HSP70s also promote the correct folding of newly synthesized proteins (Mayer and Bukau, 2005). HSP90s play a major role in stress tolerance. They act to remove proteins with incorrect structure, and by mediating proper folding under stress conditions, they prevent the accumulation of peptide aggregates. They also regulate the activity of other proteins (e.g., kinases) and stabilize the cytoskeleton (Csermely et al., 1998).

The induction of HSPs in *Daphnia* sp. was first described as a reaction to arsenic stress (Chen et al., 1999). Few studies have examined changes in HSP levels in response to biotic factors such as predation risk (Pijanowska and Kloc, 2004; Pauwels et al., 2005) and parasite infection (Pauwels et al., 2007). We recently have observed enhanced production of HSP60, HSP70, and HSP90 in heat-shocked *D. magna* (Mikulski et al., 2009). If the amplitude of migration of *D. magna* females is indeed broader than that of males, there are likely to be sex-related differences in the molecular response of HSPs to changes in temperature experienced by these animals.

The primary aim of this study was to examine whether depth (temperature) selection by *D. magna* in response to different kind of stress [the presence of cyanobacteria, fish, and polychlorinated biphenyls (PCBs) and their various combinations] differs between males and females. A second aim was to determine whether male and female *Daphnia* differ in the constitutive level of stress proteins and their production in response to changing temperature.

Methods and Materials

Two experiments were conducted on genetically identical individuals of a *D. magna* clone originating from Binnensee, a shallow coastal lake in northwestern Germany. To avoid any maternal effect, *D. magna* were cultured in 0.8 l of medium in glass jars (20 animals per jar) at 20°C under a summer photoperiod (16:8 hL:D) for several generations before the experiment. The experimental medium was lake water that had been aerated for a few weeks and filtered through a 0.2 μm capsule filter. Animals were fed green algae, *Scenedesmus obliquus*, at the non-limiting concentration of 1 mg C/l (Lampert, 1987), and the experimental medium was changed daily. Neonates from the second clutch were used for further breeding.

In the first experiment, differences in depth selection between *D. magna* males and females exposed to different kinds of stress were recorded. The stresses tested were the presence of filamentous cyanobacteria, the threat of fish predation, and the presence of toxic compounds, all of which are more severe in surface waters (reviewed by Mengel and Clarck, 1988). Moreover, all of these factors

are known to influence depth selection by cladocerans (Bernatowicz and Pijanowska, 2010). In the second experiment, the levels of HSPs were quantified in male and female *D. magna* exposed to thermal stress as a surrogate for depth selection.

Depth Selection of Males and Females A single cohort of *D. magna* neonates from the pre-experimental culture was transferred to several 0.8 l glass jars (20 animals of unknown sex per jar) and cultured at 20°C under a summer photoperiod (16:8 hL:D) for 6 d after birth. The animals were fed green algae, *Scenedesmus obliquus*, at 1 mg C/l, and the growth medium was changed daily.

On the seventh day, after all animals had reached maturity, some were selected for further experiments and transferred (3 females or 5 males per tube) to flow-through tubes (60 cm long, 1 cm diam) placed in a water bath, with surface waters heated to 22°C and bottom waters cooled to 9°C, and illuminated from above. This system, known as a "plankton organ," is widely used for studies on the diel vertical migration behavior of *Daphnia* (see Dawidowicz and Loose, 1992). The temperature gradient (Fig. 1) was stable throughout the experiment in all tubes. The specific stress factors then were applied, in four replicates (tubes) each, to both females and males: (1) the toxic cyanobacterium, *Cylindrospermopsis raciborskii* (Cy), from a laboratory culture added to the standard medium at a concentration of 1 mg C/l; (2) fish-conditioned (Fi) medium prepared by using water in which crucian carp, *Carassius carassius*, had been held for 24 h (1 fish per 10 l water); (3) toxic polychlorinated biphenyls PCB 52; and (4) PCB 153 added at a concentration of 10 μg/l. In the control treatment, standard medium containing only the *Scenedesmus obliquus* food was used. In addition to these single stressor treatments, 7 different combinations of these stress factors also were applied (see Fig. 2). The flow-through system ensured even distribution of food and chemicals in all tubes.

The depth of each animal in each tube was recorded at noon, for 2 d. From these data, the temperature experienced by individuals at particular depths was extrapolated (based on data shown in Fig. 1). The data were analyzed by using two-way nested ANOVA (with tube effect nested in treatment and sex as independent variables). Based on the mean temperature experienced by animals in the separate treatments, Levene's test of homogeneity of variance (Levene, 1960) was applied to compare the variability of temperature-depth selection between males and females exposed to the experimental factors.

Analysis of HSP Levels in Males and Females A single cohort of *D. magna* neonates from the pre-experimental culture was transferred to several 0.8 l glass jars (20 animals of unknown sex per jar) and cultured at 20°C under constant dim light until first reproduction. Animals were

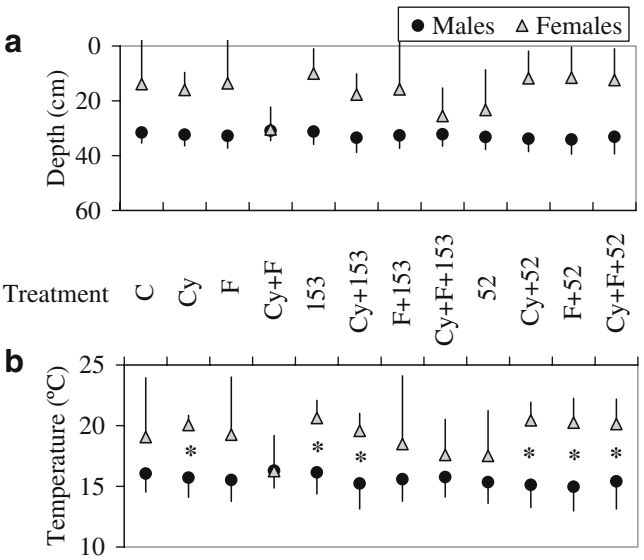

Fig. 2 The effect of different stress factors on **a** depth and **b** temperature selection (mean ± s.d.) by *Daphnia magna* males and females. C–control; Cy–cyanobacteria, *Cylindrospermopsis raciborskii*; F–fish, crucian carp, *Carassius carassius*; 153–toxic polychlorinated biphenyl (PCB)153; and 52–PCB52. * $P<0.05$ (significant difference between sexes in temperature selection within the same treatment; Tukey test, $N=4$)

fed green algae, *Scenedesmus obliquus*, at a concentration of 1 mg C/l and the growth medium was changed daily. After reaching maturity, animals were transferred to twelve glass jars (each treatment replicated three times) containing 200 ml medium (5 females or 15 males per jar). The combined mass of 5 females was approximately equal to that of 15 males, so the total mass of animals in each jar was roughly equivalent. After 24 h, half of the medium was removed from each jar. The same medium was immediately pumped back into 6 control jars (3 with males, 3 with females), while the other 6 jars were filled with hot medium to produce a 10°C increase in the water temperature within a few seconds. These jars were transferred to a 30°C water bath for 1 h. The range of temperature change was selected based on Mikulski et al. (2009). The thermal gradient set in this experiment (and the resulting thermal shock experienced by the animals) was more severe than in those conducted previously. Our unpublished data show that coping with even milder temperature gradients, e.g., crossing the thermocline (from 20°C at the surface to 15°C at the preferable depth), generates significant costs for female *D. magna* in terms of their life history and through enhanced production of HSPs. In this experiment, the severity of the thermal stress was increased to highlight the impairment of HSP production in males.

After this period of incubation at 30°C, the jars were removed from the water bath and slowly (over about 20 min) cooled to 20°C. Six h after the start of the heat treatment, the *D. magna* from each jar were collected, immediately dried on a sieve, and then transferred to 1.5 ml microcentrifuge tubes and homogenized in 75 μl of RIPA buffer (0.15 M NaCl, 1% deoxycholate Na salt, 1% Triton X-100, 0.1% SDS, 0.01 M Tris-HCl, pH 7.2) containing Complete protease inhibitors (Roche, Basel, Switzerland, Cat. No. 11836153001). The homogenates were centrifuged for 1 min at 13.4 rcf, and 10 μl aliquots of each supernatant were used to measure protein concentration with a DC Protein Assay (Bio-Rad, Berkeley, CA, USA, Cat. No. 500–0001) to ensure equal protein loading.

The remaining supernatants were transferred to fresh microcentrifuge tubes, and an equal volume of SDS-PAGE loading buffer (Sigma-Aldrich, St. Louis, MO, USA, Cat. No. L4390) was added. After boiling for 5 min, samples containing equivalent amounts of protein (30 μg) were separated by electrophoresis on 25% SDS-polyacrylamide gels, and HSPs were immunodetected by western blotting with four different primary antibodies made by Stressgen (Victoria, British Columbia, Canada): Anti-Hsp60 (Stressgen, Cat. No. SPA-805 and Cat. No. SPA-807), Anti-Hsp70 (Stressgen, Cat. No. SPA-812) and Anti-Hsp90 (Stressgen, Cat. No. SPA-846). The blots then were incubated with alkaline phosphatase-conjugated secondary antibody (Anti-Rabbit IgG - Stressgen, Cat. No. 611–1502), and positive immunoreaction was identified by a color reaction with SIGMAFAST™ BCIP/NBT substrate (Sigma-Aldrich, Cat. No. B5655).

The processed blots were examined with a Bio-Rad Gel-Doc system, and the intensity of immunostained bands was determined by using Quantity One analysis software (Bio-Rad, Cat. No #170-9600).

The relative amounts of the individual HSPs in each sample were calculated as a percentage of the intensity of the corresponding HSP bands in a thermally stressed human HeLa cell positive control sample (Stressgen, Cat. No LYC-HL101) run alongside the test samples. Data were analyzed by using the ANOVA model and *post-hoc* Tukey test with Statistica (StatSoft, Tulsa, OK, USA).

The Anti-Hsp60 and Anti-Hsp70 antibodies revealed multiple immunoreactive protein bands of different molecular weights. These bands were treated as separate proteins, as described by Mikulski et al. (2009).

Results

Generally, the stress factors (toxic cyanobacteria, presence of fish, toxic polychlorinated biphenyls, or combinations of these cues) (ANOVA: $F_{(11,\ 288)}=2.24$, $P=0.013$) and sex (ANOVA: $F_{(1,\ 288)}=207.99$, $P<0.001$) influenced depth (temperature) selection of *D. magna* (Fig. 2). Males occupied colder (deeper) water strata than females (Tukey test: $P<0.001$). There was a strong interaction between sex and treatment effects (ANOVA: $F_{(11,\ 288)}=2.24$, $P<0.001$). The different types of environmental stress resulted in higher variability of depth (and temperature) selection in *D. magna* females than in males (Fig. 2; Table 1; Levene's test: $F_{(1,22)}=11.25$, $P=0.003$). Thus, males did not change their depth (temperature), but females varied their depth according to the nature of the environmental stress.

The pattern of production of different HSPs detected in *D. magna* (Mikulski et al., 2009) depended on the sex of the animal (Table 2, Fig. 3), and apart from the 79-kDa

protein, the level of all HSPs was significantly higher in females than in males (Fig. 4). The level of the majority of HSPs (50 kDa, 55 kDa, 73–74 kDa, and 92 kDa) also was dependent on temperature (Table 2, Figs. 3 and 4). However, a significant increase in the level of these HSPs in response to raised temperature was only observed in females (see Fig. 3). There was a significant interaction between the effect of thermal shock and the effect of sex on the level of three HSPs: 50 kDa, 55 kDa, and 73–74 kDa (Table 2 and Fig. 3).

Discussion

According to our hypothesis, depth-temperature selection is more dependent on environmental stress in *D. magna* females than in males (Fig. 2). To achieve reproductive success, females must grow and assimilate sufficient energy. Therefore, they undertake vertical migration and adjust their depth according to the availability of food and the level of environmental stress (Dawidowicz and Loose, 1992). In contrast, the fitness of adult males seems to be poorly correlated with assimilation rate; rather, it would be expected to depend on their longevity, which is related more to safety than growth rate (Roff, 1992). Albeit smaller than females, size of males renders them susceptible to fish predation (e. g., Eggers, 1982). Therefore, males assimilate less energy and grow more slowly while staying in deeper water (poor in food but thermally stable), waiting for the appearance of receptive females. Since *D. magna* females are exposed to greater variability in environmental (including thermal) conditions than males, their molecular anti-stress machinery should be adequately developed.

We found that *D. magna* females maintain generally higher levels of HSPs than males (Fig. 4). Furthermore, a

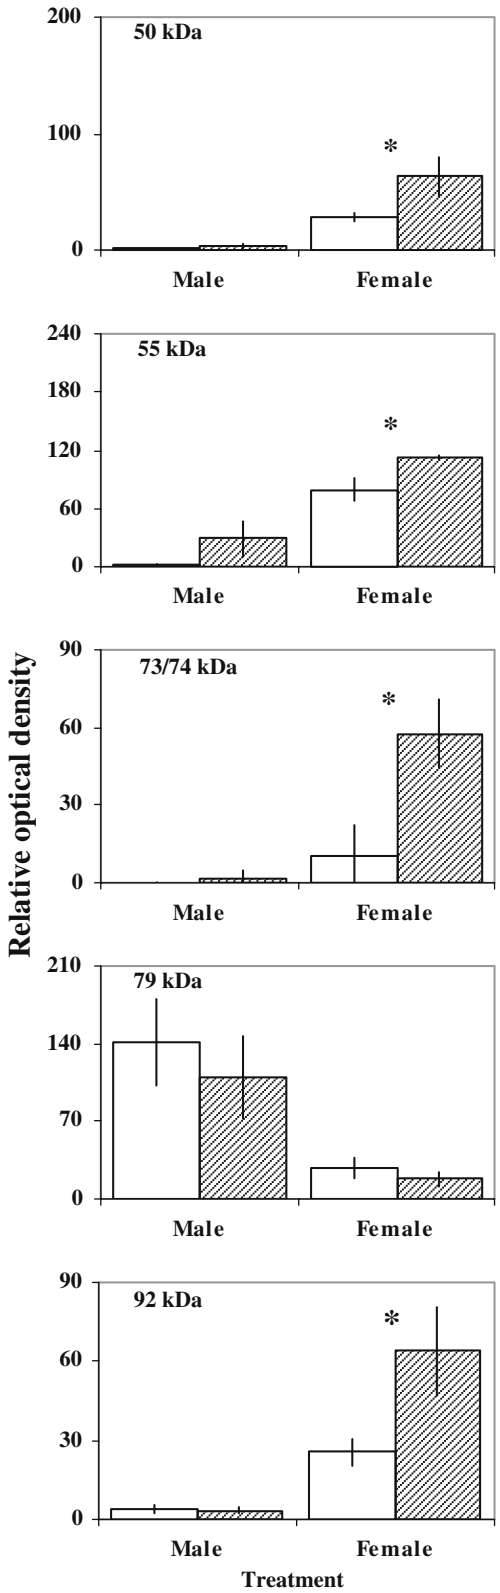

Fig. 4 The relative amounts (mean ± s.d.) of different HSPs expressed in control (white bars) and heat-shocked (shaded bars) male and female *Daphnia magna*. Optical density is expressed as a percentage of the density of the respective HSP bands in a thermally stressed human HeLa cell positive control sample run on the same gel; * $P<0.05$ (significant effect of heat shock on protein level, Tukey test, $N=3$)

significant increase in the level of these HSPs in response to thermal stress was observed solely in females (this inter-sex difference is supported by the significant interaction between the effect of thermal shock and the effect of sex on the level of the majority of heat shock proteins). Apparently, females that perform diel vertical migrations protect themselves against various stress factors associated with surface waters by maintaining a constitutively high level of HSPs and by greater responsiveness to temperature change. The only exception was HSP 79 kDa, which showed the opposite pattern, being more abundant in males than in females. It has been suggested that HSP 79 kDa represents a post-translational modification of HSP 73–74 kDa (Jolly and Morimoto, 2000). The intriguing physiological role of HSP70 in aquatic invertebrates is not well characterized. Higher levels of HSP70 in males compared with females previously have been described in *Drosophila,* although this apparently is not associated with greater survival in males (Dahlgaard et al., 1998). Only more detailed statistical analysis revealed a positive association between HSP70 level and survival after the induction of thermotolerance.

The results of our study show that behavioral and molecular defenses against environmental stress may be interrelated. *Daphnia magna* males can avoid dangers associated with surface waters by selecting the safe and stable (albeit cold with scarce food resources) environment of deep water strata. They may thus save energy by abandoning the expression of molecular defenses against stress. In contrast, *D. magna* females actively select an environment that is optimal for growth and reproduction, and, in consequence, are exposed to a broader range of environmental conditions that will unavoidably include stresses. For survival in these habitats, they require molecular mechanisms to protect their cells from adverse environmental conditions and rapid changes in stress levels. We have shown that these two strategies are adopted by genetically identical individuals of the same clone (sex in *D. magna* is environmentally determined; reviewed by Eads et al. 2008). The choice of both a behavioral strategy (migrating in the water column or permanently residing at certain depths) and a molecular strategy (e.g., activation of an inducible molecular anti-stress system) can thus constitute novel elements of phenotypic plasticity.

Although it is unwise to over-interpret the identification of these apparently linked defense mechanisms in a single clone (different genotypes are known to exhibit different stress responses), our study represents the first comprehen-

sive analysis of sex-related differences in the levels of stress proteins in *D. magna* in an ecological and evolutionary context.

Abstract The red alga *Gracilaria chilensis* is commercially farmed for the production of agar hydrocolloids, but some susceptible algae in farms suffer from intense epiphyte growth. We investigated the induced chemical defense response of *G. chilensis* against epiphytes and demonstrated that an extract of an epiphyte-challenged alga can trigger a defense response. The hormonally active metabolites were purified by RP-HPLC. Treatment with the extract or the purified fraction changed the chemical profile of the alga and increased resistance against epiphyte spores. Semi-quantitative RT-PCR and enzyme assays demonstrated that this metabolic response occurs after an increase in lipoxygenase and phospholipase A2 activity. Although this suggests the involvement of regulatory oxylipins, neither jasmonic acid nor the algal metabolite prostaglandin E2 triggers comparable defense responses.

Introduction

For at least two decades, from 1980–2000, cultivation of the marine red alga *Gracilaria chilensis* for the production of agar hydrocolloids was a major asset of Chilean aquaculture. More than 300 farming operations were established across the country, with annual yields of over 120,000 wet metric tons (Buschmann et al., 2001). However, the decade 2000–2010 was marked by a dramatic decline in farming operations due to a combination of negative economical and biological factors. The main nuisance to farmers is the widespread occurrence of

infections by algal epiphytes, which negatively affect the crop growth rate, lead to biomass losses due to increased drag, and result in products with lower economic value. In this context, we initiated a study to understand the biological and biochemical basis of the interactions between *Gracilaria chilensis* and its main epiphytic pests.

Resistance against epibionts could be mediated by either structural or chemical means, with both mechanisms interfering with the settling and penetration of spores (Wikstrom and Pavia, 2004; Nylund and Pavia, 2005; Paul et al., 2006). Direct morphological comparison and ultrastructural investigations of resistant and susceptible *G. chilensis* isolates revealed that resistance against epiphytes is not linked to any structural properties (Leonardi et al., 2006). Either constitutive or induced chemical defense is the most likely basis for resistance. Algae may store toxins or other adverse compounds and rely on the action of these constitutive defense metabolites (Paul et al., 2006; Nylund et al., 2010). If predation risk or pathogen pressure is highly variable, dynamic defenses may evolve that rely on the recognition of a challenge and a subsequent metabolic response (Pohnert, 2004; Weinberger, 2007).

Wound-activated defense is based on the rapid transformation of stored metabolites after tissue disruption, and results in reactive products that act with a very short delay (Pohnert, 2004). Recently, we found that *G. chilensis* reacts to tissue damage like that which occurs upon attack by certain epiphytes (Leonardi et al., 2006) with the release of hydroxylated and dihydroxylated fatty acids (Lion et al., 2006). If administered in artificial substrates in naturally occurring concentrations, these metabolites significantly inhibit the settlement of epiphyte spores. The biosynthetic pathway for these defense metabolites involves both the release of arachidonic acid from phospholipids and its subsequent oxidation to 8-hydroxyeicosapentaenoic acid (8-HETE), and the direct release of 7,8-dihydroxyeicosapentaenoic acid (7,8-diHETE) from galactolipids (Lion et al., 2006).

Induced defenses rely on signals from an attacker with the subsequent production of defense metabolites, a strategy that is well documented in higher plants (Baldwin, 1998; Howe and Jander, 2008). The mechanistic details of induced defenses in algae are different from higher plants (Gaquerel et al., 2007). Most of the research on induced defenses of algae has focused on herbivore-induced chemical defense (Pavia and Toth, 2000; Pohnert, 2004; Molis et al., 2006), but dynamic defensive processes also can be induced under the influence of endo- or epiphytes (Potin et al., 2002; Weinberger et al., 2002; Bouarab et al., 2004; Weinberger, 2007). We report here that, in addition to a wound-activated defense, an induced process is stimulated in *G. chilensis* by epiphyte attack. We found that immunity can be triggered by exposing *G. chilensis* to hormonally active metabolites prior to inoculation with epiphyte spores, and that the response needs several days for the full defensive potential to build up.

Methods and Materials

Algal Culture Unialgal *G. chilensis* C.J. Bird, McLachlan & E.C. Oliveira strains CR14 and CS7 (maintained in the culture collection at U. Catholica, Santiago, Chile), originating from an intensive mariculture farm at Caldera (Chile), were cultivated at 15°C and under a photon flux density of 40–50 $\mu mol \cdot m^{-2} \cdot s^{-1}$ (D12:L12) in 500 ml glass flasks containing SFC medium (Correa and McLachlan, 1991). The medium was changed weekly. Fertile fragments of *Acrochaetium sp.* and *Sahlingia subintegra* were isolated from infected thalli of *G. chilensis* collected at Caldera, Chile. Unialgal cultures of the epiphytes were maintained actively growing and reproducing by using standard culture conditions in enriched modified seawater medium SFC with 2 mM $NaNO_3$ and 100 μM NaH_2PO_4 but without Tris, Na_2SiO_3, or Mo, and with only 0.02 pM Co.

Preparation and Fractionation of Active Extracts A total of 1.2 kg wet weight of frozen *G. chilensis* that was previously exposed to epiphytes and subsequently cleaned mechanically to remove epiphytes was brought to room temperature, homogenized in artificial seawater with an ultra Turrax, and extracted three times with 1 L of CH_2Cl_2. Tissue disruption in seawater leads to elevated oxylipin levels (Lion et al., 2006). The organic phases were combined, filtered, and concentrated to about 200 ml. Excess water was removed by freezing and subsequently by drying over Na_2SO_4, and the remaining CH_2Cl_2 was removed in vacuum.

Fractionation of the crude CH_2Cl_2 extract was done by HPLC using a preparative Gilson 321 pump connected to a Gilson 115 UV-detector. Separation was achieved with a Merck LiChroCart 250-10 Purosphere RP-18 cartridge. A gradient of water (A) and acetonitrile (B) (0 min 100% A, 25 min 100% B, 30 min 100% B at a flow rate of 6 ml min^{-1}) was used for elution. Fractions corresponding to 0–40%, 41–60%, 61–80%, and 81–100% acetonitrile were collected, and the acetonitrile was removed by rotary evaporation. The remaining water was removed by freeze drying, and the resulting residue was dissolved in ethanol for further bioassays.

Monitoring Metabolic Responses Gracilaria chilensis plantlets that were about 10 cm in length were cultured at a plant density of 50 $g L^{-1}$ in Petri dishes on a shaker using culture conditions as described above. Plantlets were treated with solutions of the crude dichloromethane extract, the

respective HPLC fractions, 7,8-di-HETE, prostaglandin E2 (Sigma-Aldrich, Seelze, Germany), methyl jasmonate (Givaudan, Vernier, Swizerland), linolenic acid (Sigma-Aldrich), coronalone (Schuler et al., 2004), or pure EtOH (control). Stock solutions (10 mg ml^{-1} ethanol) were prepared with all samples except the HPLC fractions, for which the final concentrations were adjusted to give a concentration equivalent to 10 mg ml^{-1} of the crude extract used for separation. The final concentrations in the medium were adjusted to 100 μg ml^{-1} or the amount of the HPLC fraction that was obtained from 100 μg ml^{-1} crude extract. After incubation (18 h), the algal biomass was transferred to fresh medium and cultured for an additional 48 h. Samples for chemical analysis were frozen in liquid nitrogen and stored at −80°C until further work-up as described below.

Analytical Procedures For metabolic profiling, *G. chilensis* samples were frozen in liquid nitrogen, spiked with 1 mg ml^{-1} phenyldodecanoic acid in ethanol as an internal standard (400 μl g^{-1} alga), ground with mortar and pestle, and immediately extracted with methanol (10 ml g^{-1} alga). The extracts were concentrated under vacuum, redissolved in methanol (400 μL g^{-1} alga), centrifuged, and submitted to analytical HPLC-MS analysis on an Agilent series 1100 HPLC equipped with a RP18 normal phase column GROM-SIL 120 ODS3 CP, 125×2 mm, and a DAD detector connected to a Finnigan LCQ with an ESI interface (Thermo Finnigan, Manchester, UK). A gradient with 0.5% aqueous acetic acid (A) and acetonitrile (B) (0 min 50% A, 30 min 100% B, 35 min 100% B at a flow rate of 0.2 ml min^{-1}) was used for separation. Spectra were recorded in the positive mode, needle voltage 4 kV, capillary temperature 120°C.

Bioassays Precultivated apical fragments (1 cm long) of *G. chilensis* from two different isolates were placed in beakers with 60 ml SFC medium, and were treated with 10 μg ml^{-1} of dichloromethane extract, HPLC fractions in ethanol at 1 mg ml^{-1}, or solvent controls. Incubation times were 18 h or 18 h followed by a second incubation of 54 h in 60 ml fresh SFC medium without extract. After treatment, the fragments were rinsed, transferred to 60 ml of fresh SFC medium, and 20 fertile *Acrochaetium sp* thalli and a 2× 2 cm glass slide were added in order to quantify spore settlement on *G. chilensis* in comparison with the inert support. Settlement of epiphytic spores was recorded under a light microscope 48 h after the start of the co-culturing. Spores were counted on 1 cm transects of the alga and on identical transects of the control glass slide. For each replicate, 3 transects were counted. For each isolate, 5 independent replicates consisting of treatments and control were run. In all of the experiments, spore settlement did not differ between the two isolates ($P>0.5$), and thus the results were pooled and the 10 replicates statistically evaluated.

Native Polyacrylamide Gel Electrophoresis For protein extraction, ground samples of *G. chilensis* were incubated at 4°C for 60 min in 1 ml g^{-1} of extraction buffer (50 mM Tris–HCl, pH 9.5, 500 mM potassium chloride and 10 mM β-mercaptoethanol). Protein concentrations were determined according to the method of Bradford (Bradford, 1976). Crude protein extracts (80 μg of total protein per lane) were separated by polyacrylamide gel electrophoresis (PAGE) on 12% native polyacrylamide gels. Lipoxygenase (LOX) activity was stained with o-dianisidine (Delumen and Kazeniac, 1976) using Na-pyrophosphate buffer (0.1 M, pH 7.95) containing 1 mM KCN instead of Na-acetate buffer. The intensities of bands appearing in the presence of 2 mM arachidonic acid or linoleic acid were quantified by image analysis, using the SigmaScan Pro 5.0 software package (SPSS Inc., Chicago, IL, USA).

Putative LOX Gene Expression Semi-quantitative reverse transcriptase polymerase chain reaction (RT-PCR) was used to analyze gene expression. RNA was isolated from *G. chilensis* that was ground in liquid nitrogen using the plant RNeasy kit (Qiagen, Hilden, Germany). To design homologous primers for RT-PCR of LOX transcripts, the amplification and cloning of a putative lipoxygenase (LOX) cDNA fragment from *G. chilensis* was undertaken using degenerate primers designed from available sequences of *Porphyra purpurea* [GenBank accession number U08842 (Liu and Reith, 1994)] and *Porphyra yezoensis* [Kazusa accession number AU186969 (Asamizu et al., 2003)] and from conserved sections of a putative LOX coding region selected in an unpublished EST database from *Gracilaria tenuistipitata* (Jonas Collén, personal communication). The two primers used were 5'-GATAAGGTTGGCGTGCAAGCA-3' and 5'-GTTTGGGACGTAGGACAAGTA-3'. The 740 bp RT-PCR product was cloned into the pGEM-T vector (Promega, Madison, WI) and sequenced (GenBank accession number JF896804). RNA from *G. chilensis* treated with dichloromethane extract for 0, 6, and 24 h was pooled and amplified in a RT-PCR reaction. Three independent replicates were examined. Subunit I of cytochrome c oxidase (COX, GenBank accession number EF434915, forward: 5'-AAGTCACTCTGGTGGTGC-3' and reverse: 5'-GTATC-TACATCAAGACCTAC-3') was used as control. Reactions were carried out in a final volume of 25 μl of the following reaction mix: 1 μL cDNA, 1× GoTaq Reaction Buffer (2.5 mM $MgCl_2$) (Promega) with 0.2 mM dNTP, 1.25 units of GoTaq DNA polymerase (Promega) and 0.2 μM gene-specific primers (Eurogentec, Seraing, Belgium). PCR was performed on a GenAmp PCR System 2700 (Applied Biosystems Foster City, LA, USA). The cycling program for PCR was: initial denaturation 5 min at 95°C, 25 to 30 cycles of 15 s at 95°C, 30 s at 50°C, and 45 s at 72°C, and

final elongation for 3 min at 72°C. For each gene, 5 µl of PCR product were loaded on a 1.8% agarose electrophoresis gel and run at 100 V for 30 min before incubation with ethidium bromide (0.07 µg ml^{-1}). Images were obtained using Biovision 1000/26 M (Vilber Lourmat, Marne-la-Vallée, France), and one representative image of each replicate was selected for quantification. The expression levels were determined by quantifying the gel bands using ImageQuant TL software (Molecular Dynamics, GE Healthcare, Piscataway, NJ, USA). The relative changes in expression among genes were calculated as x-fold changes to the appropriate control treatments.

Quantification of PLA_2-activity Aliquots of protein extract containing 100 µg crude protein were diluted with protein extraction buffer to a volume of 500 µl. The fluorescent probe PED6 (Molecular Probes, Leiden, The Netherlands) was added from a stock solution in ethanol to a final concentration of 4 µg ml^{-1} PED6 and 0.4% ethanol. The mixture was incubated on a shaker for exactly 10 min at room temperature and in darkness. Enzymatic decomposition of PED6 was stopped by addition of 500 µl chloroform/acetic acid (200:1 *v/v*, pH 2.6). For extraction of the released fluorescent label (BODIPY® FL C_5), the mixture was incubated for 10 min on a shaker. After separation of phases, the organic phase was evaporated under reduced pressure at room temperature, and the residue was taken up in 250 µl ethanol. The fluorescence of 100 µl of the resulting extract was observed with a Wallac Victor^2 (Perkin Elmer, Courtaboeuf, France) plate fluorimeter (excitation wave length: 485 nm, emission wave length: 535 nm). The background fluorescence was examined in parallel experiments without the addition of PED6, and proved to be close to zero, due to the two step extraction in aqueous buffer and in chloroform, which eliminates all potentially interfering pigments.

Statistical Analysis Data were analyzed with the Statistica 7.0 software (Statsoft Inc., Tulsa, OK, USA). Data distributions were tested for normality and heteroscedasticity using the Shapiro-Wilk test ($P<0.05$) and Levene's test ($P<0.05$), respectively. The Student *t*-test ($P<0.05$) was used for comparisons among pairs of treatments, while 2-way-ANOVA ($P<0.05$) and the Tukey-*posthoc* test ($P<0.05$) were employed where interactive effects of treatment and incubation time had to be analyzed.

Results and Discussion

Field and laboratory studies suggested that resistance of *G. chilensis* towards epiphytic algae is dynamically regulated (Lion et al., 2006). We initiated a mechanistic study to look for mechanisms of dynamic defense responses in this alga. While an immediate production of defensive metabolites in *G. chilensis* is based on rapid enzymatic reactions that are triggered by wounding (Lion et al., 2006), induced defenses require more time and a complex cascade of signaling events that includes hormonal regulation of metabolic responses (Pohnert, 2004; Devoto and Turner, 2005; Conrath et al., 2006). To search for underlying principles of regulation in the induced defense of *G. chilensis* we assayed extracts derived from field samples of epiphyte-stressed algae for hormonal activity. Treatment of *G. chilensis* with a crude lipophilic extract from epiphyte-challenged conspecific algae induced a significant metabolic response (Fig. 1). In contrast, the aqueous extract from the same individuals was inactive (data not shown). Concentrations as low as 1 µg ml^{-1} of the CH_2Cl_2-extract of *G. chilensis* triggered an increase of 8-hydroxyeicosatetraenoic acid (8-HETE) and 7,8-dihydroxyeicosatetraenoic acid (7,8-di-HETE), two metabolites previously identified as involved in the activated defense of this alga against epiphytes (Lion et al., 2006). In addition, unidentified metabolites that were not found in unchallenged algae or wounded tissue were induced (Fig. 1). This demonstrates that the dichloromethane fraction triggers the production of secondary metabolites, and thus might contain a hormone involved in the up-regulation of pathways required to produce defense metabolites. Because we cannot culture epiphyte-free algae, we cannot conclude whether or not the production or the respective hormone(s) is induced by epiphytes. Future studies are required to clarify how this activity is regulated upon challenge of the alga.

Separation of the active extract by preparative HPLC yielded four fractions, and the less polar ones were tested. Only the fraction of medium polarity induced the production of secondary metabolites (Fig. 1). Neither the more polar nor the more nonpolar fraction triggered any metabolic response. We concluded there was activity associated with one specific metabolite or a group of metabolites with a narrow distribution of polarities (Fig. 1).

To gain further insight into the inducing metabolite(s) we evaluated the activity of candidate molecules identified in the active HPLC fraction of the *G. chilensis* extract, and also of known plant hormones. Treatments with 7,8-di-HETE and prostaglandin E2 did not change the metabolic profile of the algae. While 7,8-di-HETE is a specific metabolite found only in *G. chilensis*, prostaglandin E2 is a mammalian hormone that also occurs in several *Gracilaria spp.* including *G. chilensis* (Fusetani and Hashimoto, 1984). In addition, we tested methyl jasmonate, a plant hormone that was not detected in *G. chilensis* but was active in the red alga *Chondrus crispus* (Farmer and Ryan, 1990; Bouarab et al., 2004); coronalone, a synthetic analogue of jasmonic acid that is also hormonally active in plants (Schüler et al. 2004); and linolenic acid, the biosynthetic precursor of jasmonic acid. None of these potential hormones or hormone

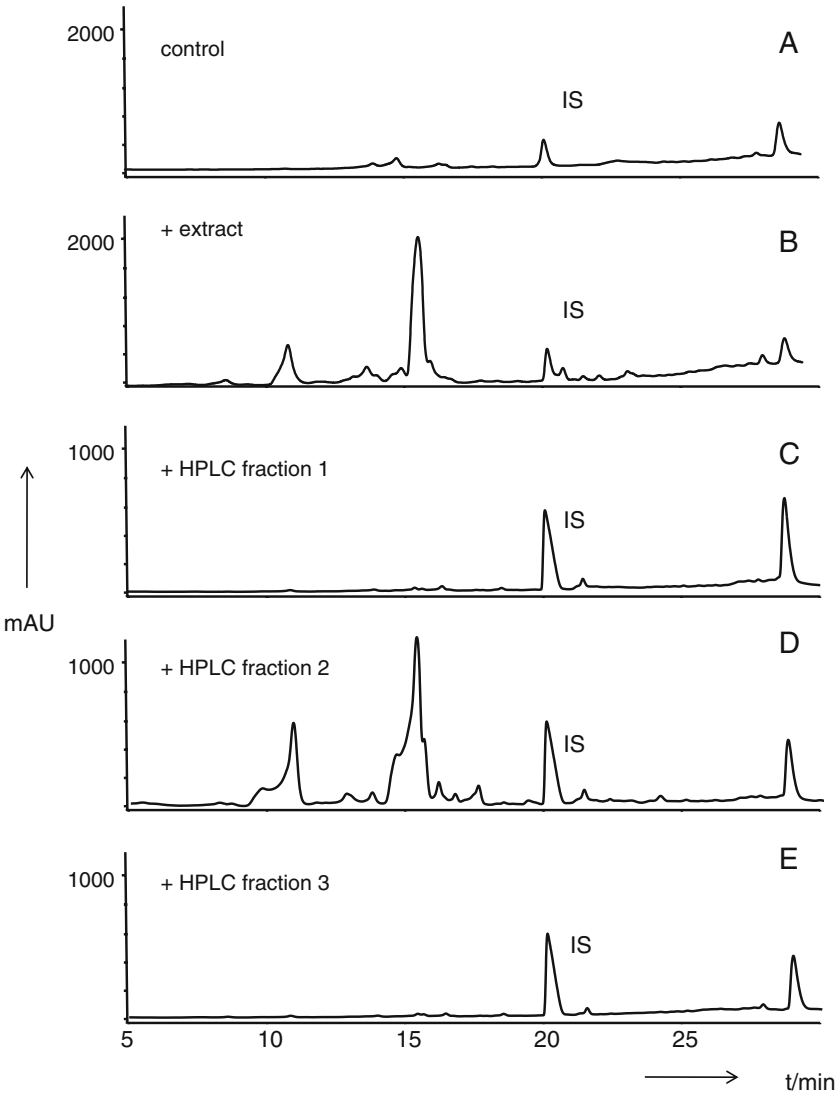

Fig. 1 Elicitation of the formation of oxylipins in *Gracilaria chilensis*. **a** Ethanol (control). **b** Crude dichloromethane extract (1 μg ml^{-1} in ethanol). The major peak at the retention time 11 min corresponds to 7,8-di-HETE and at 15.8 min to 8-HETE. **c**–**e** Fractions obtained by preparative RP-HPLC of the dichloromethane extract. Fractions eluted at 40–60% CH_3CN (**c**); 61–80% CH_3CN (**d**); 81–100% CH_3CN (**e**). The UV-trace at 254 nm is shown. Chromatograms were referenced in comparison to the internal standard (IS) phenyldocecenoic acid (retention time 20.5 min). Note the different scales of A, B and C-E

precursors triggered any detectable metabolic response in *G. chilensis* (data not shown). Concentrations of the plant hormones and coronalone that were tested exceeded those required to induce metabolic responses in higher plants and algae by about 5 to 50 fold, thus leading us to conclude that lack of activity was not a consequence of low concentration of the potential inducers (Bouarab et al., 2004; Schüler et al. 2004). The chemical nature of the active algal compound(s), which co-elutes with dihydroxylated C20 fatty acids in RP-HPLC, thus, remains unknown.

To determine whether the metabolic reaction observed after treatment with the crude, hormonally-active fraction is linked to an induced defense, we developed a bioassay in which settlement of epiphyte spores on induced and uninduced *G. chilensis* was monitored. In this assay, *G. chilensis* was incubated with fertile spores that were releasing *Acrochaetium sp.* thalli, and after defined time spans, the number of settled epiphyte spores on the algae were compared to the number of spores on a comparable

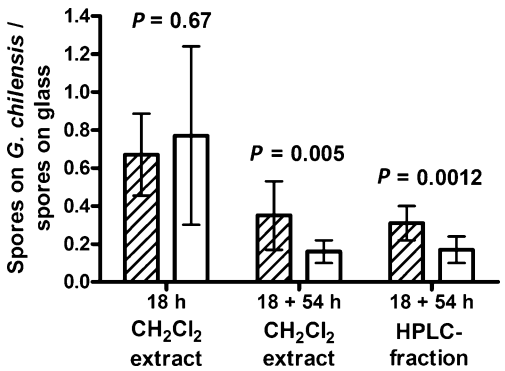

Fig. 2 Resistance of *Gracilaria chilensis* against spore settlement of the epiphyte *Acrochaetium* after different times of treatment with crude (10 μg ml^{-1}) or fractionated (corresponding to 10 μg ml^{-1} crude extract) CH_2Cl_2 extract in ethanol (*white bars*) or with ethanol only (*hatched bars*). Mean +/− standard deviation, N=10 (P values are indicated above bars)

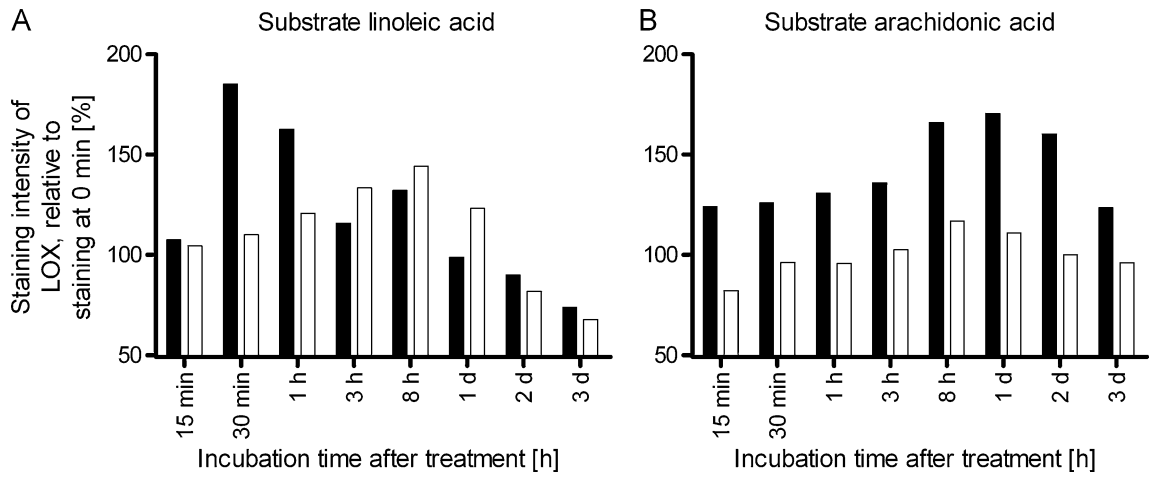

Fig. 3 Induction of lipoxygenase-type activity in *Gracilaria chilensis*. The activity was determined in native PAGE gels using 2 mM arachidonic acid or linoleic acid as a substrate. The protein extracts from algae that had been exposed to ethanol containing (*black bars*) or not containing (*white bars*) crude CH_2Cl_2-extract of *G. chilensis* for the times indicated

transect of a glass slide. This method allows normalization of the assays without the need to co-incubate treated and untreated *G. chilensis*, which could result in cross talk between the algae. Pre-treatment with the active extract for 18 h followed by a 54 h period in which the algae were allowed to develop metabolic reactions in pure culture medium resulted in a significantly reduced number of settled spores on the *G. chilensis* surface compared to algae that were treated with the solvent alone (P=0.005)(Fig. 2). The medium polarity HPLC fraction that induced a metabolic response also triggered a significant (P=0.001) reduction in the number of settled spores (Fig. 2). Resistance was observed only if an initial 18 h treatment with the active fraction was followed by a 54 h incubation period. Shorter incubations did not increase resistance. Results obtained with two different isolates of *G. chilensis* were statistically indistinguishable. Comparison of the uninduced isolates as controls also revealed no difference (P=0.63) in spore settlement. This significant response demonstrates clearly that a defense reaction against epiphyte spores can be triggered by algal compounds. Since shorter times of pre-incubation did not result in any significant biological response, it is likely that a slow up-regulation in defense genes is required for the establishment of the resistance. Comparable slow responses are known from the induced chemical defense of both plants and algae (Toth and Pavia, 2000; De Vos et al., 2005). It is important to note that the observed induced response is not a general defense against epiphytes, since parallel infection experiments with the red alga *Sahlingia subintegra* did not reveal any increased resistance (data not shown).

Recent work in algal chemical ecology suggests that induced defenses are widely distributed among seaweeds (Coleman et al., 2007; Weinberger, 2007; Molis et al., 2008; Rohde and Wahl, 2008). Nevertheless, besides studies on the activity of oxylipins from *Chondrus crispus,* little information about the nature of the involved signals is available (Bouarab et al., 2004; Gaquerel et al., 2007). Several hormones from a wide range of phyla from mammals to plants belong to the class of oxylipins. Since our HPLC fractionation of the crude extract also pointed

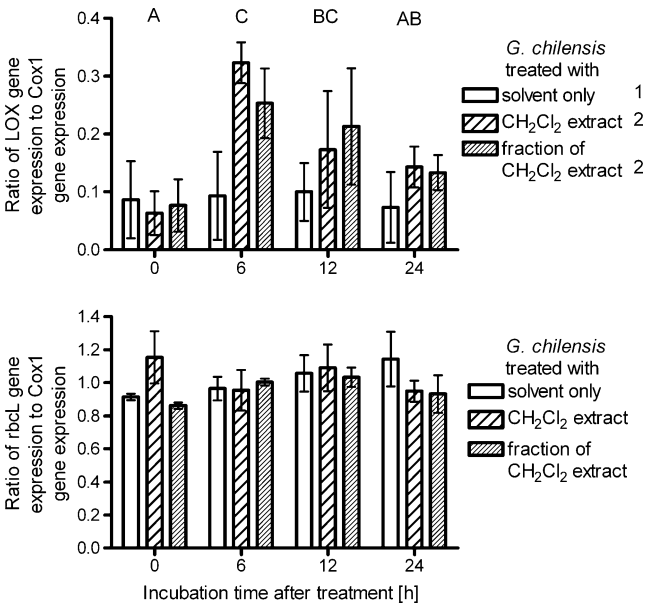

Fig. 4 Expression of a putative lipoxygenase gene in *Gracilaria chilensis* after treatment with dichloromethane extract. RNA from *G. chilensis* treated with solvent (control), with the dichloromethane extract or with fractions . Expression of LOX, the large subunit of ribulose-bisphosphate carboxylase (rbcL), or cytochrome c oxidase (COX) was quantified by semi-quantitative RT-PCRMean +/− standard deviation, N=3. Different capitals and different numbers indicate incubation times and treatments, respectively, that are significantly different (Tukey-test, P<0.05)

towards an active fraction that co-elutes with major C20-oxylipins from *G. chilensis*, such as 7,8-di-HETE, we decided to investigate the activity of key enzymes involved in the formation of these metabolites.

In-gel activity staining revealed that crude protein extracts of *G. chilensis* had lipoxygenase-activity towards linoleic and arachidonic acid (Fig. 3). Treatment of *G. chilensis* with dichloromethane-extract increased the algal capacity to oxidize linoleic acid within 30 min to 1 h after exposure (Fig. 3). The ability to oxidize arachidonic acid increased within 15 min of exposure, and was most substantially visible 8 h to 2 d after exposure (Fig. 3). The activity was insensitive to KCN, and was, therefore, not attributed to peroxidases or other heme proteins. but to lipoxygenases (Manchenko, 1994). Over the entire assay period, the up-regulation of linolenic acid LOX activity was not significant ($P>0.5$). When linoleic acid was used as substrate, only a weakly stained band was detected, although a relatively large amount of crude protein was loaded (80 μg per lane). The expression of a linolenic acid lipoxygenase was stronger in *C. crispus*, where more intense staining and two additional isoforms were detected on electrophoretic gels when only 30 μg protein were loaded (Bouarab et al., 2004). When arachidonic acid was used as the substrate during the gel staining procedure, a single stained band was detected accompanied by changes in arachidonic acid LOX activity upon challenge with the active extract ($P<0.001$). The stained band had a retention factor similar to the band observed after treatment with linoleic acid. However, the transformations were not catalyzed by the same enzyme because there were clear differences in the time courses of fatty acid hydroperoxide formation (Fig. 3). While induction with the dichloromethane extract resulted in a maximally increased arachidonic acid LOX activity after 24 h, linoleic acid was preferentially acted on after 30 min. The delayed metabolic response observed after the treatment with the extract is in accord with the delayed defense response in our bioassays. Such orchestrated expression of different lipoxygenases often is observed in higher plants, where oxylipins also play

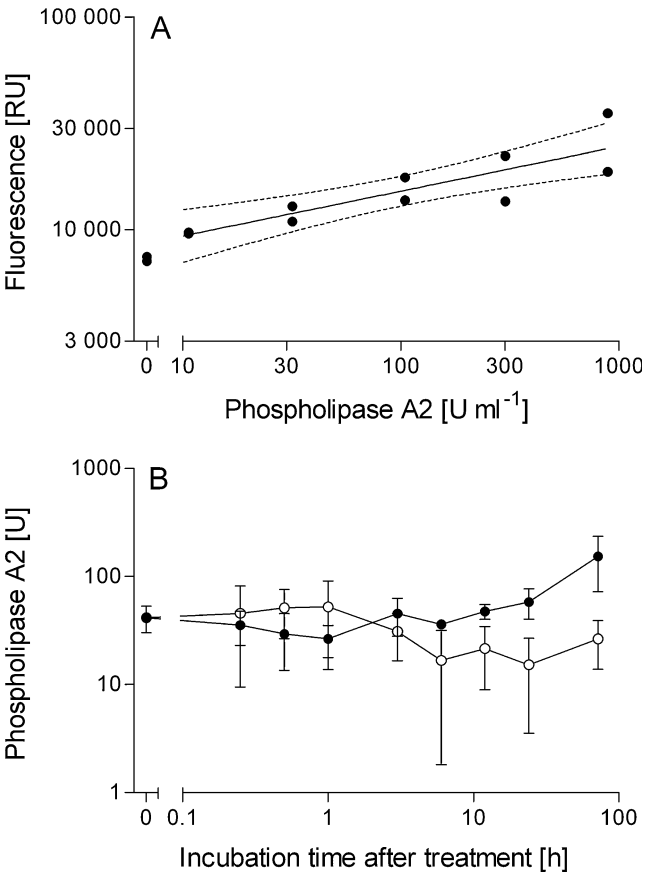

Fig. 5 Induction of phospholipase A2 in *Gracilaria chilensis*. **a** Calibration: Incubation of PED6 with increasing amounts of phospholipase A2 in 500 μl protein extraction buffer ($r^2=0.7366$, $P=0.002$ the dotted lines represent 95% confidence intervals). Averages of two replicates, bars represent minimum and maximum response

key roles in quick wound-activated and in slower induced defense reactions (Halitschke et al., 2000; Truman et al., 2007; Bonaventure and Baldwin, 2010).

The design of a set of primers based on an EST clone from a cDNA library of the red alga *Gracilaria tenuistipitata* (P. Nyvall, J. Collén et al., unpublished) allowed the cloning of a partial cDNA fragment from *G. chilensis*. This 764 bp fragment exhibited significant similarity to plant and animal LOX as well as to a putative red algal LOX (Supplemental Information). The corresponding amino acid sequence was 43% identical to the putative LOX from *Porphyra purpurea* (GenBank™ accession no. AAA61791). Sequence analysis shows that some of the residues that are involved in iron-ligand binding in all LOX (Prigge et al., 1997) are present in the partial sequence. Conserved sequences include the central histidine-rich region around His-510 and His-515 in the *P. purpurea* sequence, whereas the other residues including a distal histidine (His-638) and an asparagine (Asn-642) are missing in the partial fragment. The partial cDNA clone shared 87.4%, 52.2% and 50.6% similarity with the LOX cDNAs of *G. tenuistipitata* (J. Collén, pers. comm.), *Porphyra purpurea* (Liu and Reith, 1994), and *P. yezoensis* (Asamizu et al., 2003). The translated sequence also contained two determinants for substrate and regiospecificity (Sloane et al., 1991; Borngraber et al., 1996) as well as a generally conserved domain in lipoxygenases (Marchler-Bauer et al., 2005).

Expression of lipoxygenases was monitored by using semi-quantitative RT-PCR. A pronounced transcription of lipogygenase relative to cytochrome oxidase 1 was observed in *G. chilensis* after treatment with either the CH_2Cl_2 extract or the medium polar HPLC fraction (two-way-ANOVA and Tukey-test, $P<0.05$, Fig. 4, Table 1A). There were no changes in the expression of ribulose bisphosphate carboxylase relative to cytochrome oxidase 1 in the same samples, thus indicating a specific LOX upregulation (two-way-ANOVA and Tukey-test, $P>0.05$, Fig. 4). The effect was maximal after 6 h and still significant after 12 h, a delay that corresponds to the observed kinetics of the arachidonic acid LOX activity (Fig. 3). Only two-way ANOVA (Table 1B), but not the Tukey-test ($P<0.05$) detected a significant interaction of treatment and incubation time. The detected mRNA, therefore, probably encodes the enzyme that acts on arachidonic acid. To what extent the enzyme has a role in the direct synthesis of defensive oxylipins (Lion et al., 2006) vs. the production of regulatory active oxylipins can only be concluded indirectly. Since a further delay in the induced defense response is observed it might be more likely that LOX is involved in the triggering of further defensive metabolic reactions, also a well known phenomenon in higher plants.

Other enzymes that are crucial for the production of oxylipins are lipases. These enzymes release free unsaturated fatty acids, which are the substrates for LOX. They often are involved in the regulation of defense reactions in algae (Lion et al., 2006) and higher plants (Roy et al., 1995; Kallenbach et al., 2010). Treatment of *G. chilensis* with the dichloromethane extract also increased PLA_2 activity. In protein extraction buffer, enzyme activity could be quantified by the concentration-dependent release of fluorescent BODIPY FL C_5 from the phospholipase substrate PED6 (Fig. 5). Algae treated with dichlormethane extract for 6 h to 3 d had more activity than untreated plants (2-way-ANOVA, $P=0.03$). The strongest upregulation was observed after 3 d, when treated plants exhibited 5.8 times more PLA_2-activity than untreated plants. From the data on enzyme activity, we conclude that induction results after 6 h in an increased liberation of fatty acids from phospholipids, which probably fuel the lipoxygenase that is increasingly expressed after 8 h. To fully develop the defense potential the alga, however, requires additional time, since a response in the bioassay is delayed for another 48 h.

In summary, we provide evidence for an induced chemical defense mechanism of *G. chilensis* against epiphytes. This can be triggered by a hormonally active fraction of the *G. chilensis* extract, thereby supporting a general role of hormones in the induced defense of the alga. In addition, candidate genes and enzyme activities, commonly associated with an oxylipin based hormonal regulation of metabolic processes, are triggered by the addition of the active fraction. Further work will focus on the structural elucidation of the actual hormone and on an examination of how this hormone is regulated in response to biotic stress.

Acknowledgements The study was financed by the European Commission INCO-DEV Programme (contribution of the joint research effort INCO-EPIFIGHT ICA4-CT-2001-10021), and by a European Community—Research Infrastructure Action grant (ASSEMBLE agreement no. 227799) given to FW. GP acknowledges funding of the VolkswagenFoundation within the framework of a Lichtenberg Professorship. We also thank Jonas Collén and Pi Nyvall for sharing unpublished data of an EST sequence from *Gracilaria tenuistipitata*.

Searching for Major Urinary Proteins (MUPs) as Chemosignals in Urine of Subterranean Rodents

Abstract Chemosensory information mediates behavior in many rodent genera. Major Urinary Proteins (MUPs) facilitate chemical communication in some species of mice. We sought to demonstrate the importance of MUPs in chemosignaling across a range of rodent genera that live in different habitats and social structures. We analyzed urine from three subterranean rodent genera from different continents, and with diverse social systems: eusocial Zambian mole-rats (*Fukomys*), solitary Israeli blind mole rats (*Spalax*), and social Chilean coruros (*Spalacopus*). 2D gel electrophoresis revealed low levels of protein, with sequences similar to aphrodisin, in *Fukomys* mole-rat urine, but no MUPs in urine of any of the studied species. Previous research demonstrated that subjects from the tested genera responded differentially to odors indicating transmission of individuality, family/colony or population, species, and reproductive state in secretions and excretions of conspecifics. This extends, to subterranean rodents, the evidence that rodent species can successfully transmit and receive chemosignals without the necessity of MUPs.

Key Words Aphrodisin · Lipocalin · Major urinary proteins · Subterranean rodents · Mole-rat · Coruro · *Fukomys* · *Spalacopus* · *Spalax*

Introduction

Rodents depend on chemical secretions and excretions to communicate everything of social importance: their individual identity, sex, age, health, reproductive and social status, etc. (Brown and MacDonald, 1985). There is abundant behavioral evidence (reviewed, e.g., in Todrank and Heth, 2003) of adaptive responses in a broad range of rodent species to individual genotypes and changing biological states expressed in rodent semiochemicals. The processes underlying transmission of these complex, largely volatile, semiochemicals remain enigmatic. In particular, in rodent urine it is unclear to what extent urinary proteins are involved. Major Urinary Proteins (MUPs), with or without their bound ligands, are conduits of chemosignals in house mice (e.g., Beynon and Hurst, 2003, 2004; Cheetham et al., 2007), but studies of MUPs in wild rodents are scarce.

MUPs are expressed in the liver, filtered by the kidneys, and excreted in the urine, at quantities constituting up to 99% of protein content in adult male house mice (Humphries et al., 1999). The β-strands of lipocalins form a hydrophobic pocket in which small, volatile and non-polar molecules can be bound (Lücke et al., 1999; Cavaggioni and Mucignat-Caretta, 2000). MUPs have

Electronic supplementary material The online version of this article (doi:10.1007/s10886-011-9971-y) contains supplementary material, which is available to authorized users.

mass ranges of approximately 19 kDa (Robertson et al., 2007). Aphrodisin, another member of the lipocalin superfamily, with a mass of approximately 17 kDa (Henzel et al., 1988), originally was identified in the vaginal discharge of hamsters (Singer et al., 1986, 1987), but also has been found at low concentrations in the urine of hamsters (*Phodopus roborovskii*) and bank voles (*Myodes glareolus*) of both sexes (Beynon et al., 2008), along with three other aphrodisin-like odor-binding proteins (Stopková et al., 2010).

Because initial studies showed high polymorphism in MUPs (Robertson et al., 1996), it was concluded that variants in proportions of particular MUPs contribute inherently to signaling individuality in urine scent marks (Hurst et al., 2001). Findings from a few studies seem to support direct involvement of MUPs in conveying identity, species, and biological state (e.g., Mucignat-Caretta et al., 1995; Beynon et al., 2002; Nevison et al., 2003; Martìnez-Ricòs et al., 2007), while findings from other studies have suggested an indirect role of MUPs through active ligand binding or ligand/MUP-complexes (e.g., Novotny et al., 1999; Novotny, 2003; Peele et al., 2003).

Investigating the prevalence and modulation of MUPs across Rodentia could broaden the understanding of the function of MUPs in chemical communication. We hypothesized that if MUPs serve a central function in rodent chemical communication, they will be present, in abundance, across a broad spectrum of species, irrespective of habitat or social structure. Thus, in this study we looked for MUPs in urine samples from species that respond differentially to urine and bodily secretions of conspecifics (Todrank and Heth, 1996; Heth and Todrank, 2000; Heth et al., 2004; Hagemeyer and Begall, 2006; Hagemeyer, 2010), and which belong to three different subterranean genera, representing different rodent families and diverse social systems: eusocial Zambian mole-rats (*Fukomys*), solitary Israeli blind mole rats (*Spalax*), and social Chilean coruros (*Spalacopus*).

Methods and Materials

Animals We analyzed urine from 63 animals, representing three genera of subterranean rodents, for comparison with urine from C57BL/6 laboratory mice (Table 1). Eusocial Zambian *Fukomys* mole-rats (*Fukomys anselli*, *F. kafuensis*, and their hybrids, *F. anselli* x *F. kafuensis*) live in large families, consisting of a single reproductive pair and their philopatric offspring (cf., Begall and Burda, 1998; Burda et al., 2000). Israeli *Spalax ehrenbergi* blind mole rats (*S. galili, S. golani, S. carmeli*, and *S. judaei*) live solitarily in tunnel territories (Nevo et al., 2001). Social Chilean *Spalacopus cyanus* coruros live in harems (Begall et al., 1999).

Coruros (N=6 males, N=2 females) and *Fukomys* mole-rats (N=7 males, N=9 females), either wild-captured or laboratory-bred, were kept in an animal room at the Department of General Zoology in Essen (Germany), under a natural daylight cycle at room temperature (20–25°C) in glass terrariums of varying size (depending on colony size), with a floor consisting of a 5 cm layer of horticultural peat. They were provided with a diet of fresh carrots, potatoes, and apples, supplemented weekly with lettuce and cereals. The *Spalax* blind mole rats (N=16 males, N=9 females) were captured in the field and kept in the Institute of Evolution at the University of Haifa. Each of the 4 species was kept in a separate room under a 14:10 hr light:dark cycle with constant temperature (21±1°C) and relative humidity (70±5%). The animals were kept individually in plastic cages (30×40×25 cm) and were provided carrots

Table 1 Sample sizes, sex, age class, origin, and number of specimens with MUP/lipocalin-bands in SDS-PAGE

Species	Sample size	Sex		Continent (country)	Specimens with bands
		m	f		
Fukomys anselli (Bathyergidae)	2 kings, 3 queens, 7 non-reproductives	4	8	Africa (Zambia)	12
F. kafuensis (Bathyergidae)	1 king, 1 queen, 4 non-reproductives	2	4	Africa (Zambia)	6
F. anselli x *F. kaufensis* (Bathyergidae)	3 kings, 3 queens, 5 non-reproductives	7	4	Africa (Zambia)	11

Total	63 adults	32	21		

m males; *f* females

and potatoes *ad libitum*. Subterranean rodents do not drink free water, but get it from their food.

Laboratory mice (N=9 males, N=10 females), used as a reference species for the analysis, were kept under standard laboratory conditions at the Chair of Zoology of the Charles University in Prague, and provided water and commercial mouse pellets *ad libitum*.

Urine Collection Urine of *Fukomys* mole-rats was collected by picking up an animal by its back, gently, and putting a 1.5 ml Eppendorf-tube under the urogenital region. In rare instances when an animal did not urinate within 1 min, it was put into a clean bucket and allowed to urinate. Immediately after urination, the urine was transferred by pipette into an Eppendorf tube. This latter method was used with the coruros, as they seldom urinated when picked up. Urine samples were centrifuged at 8,000 rpm for 8 sec, and the supernatant transferred into a sterile Eppendorf tube. Following this procedure, urine samples were frozen at −80°C until analysis. Urine from *Spalax* mole rats was collected by picking up an animal and massaging the hind quarters until it urinated into a sterile plastic cup (from which the urine was transferred to sterile Eppendorf tubes and frozen at −80°C for shipment to Prague). Urine from mice was obtained by gently massaging the abdomen of an animal until it urinated into a 1.5 ml Eppendorf tube, which was placed immediately at −20°C.

Bradford Test and Creatinine Determination Total protein concentration in urine was measured by the Bradford method, using bovine serum albumin at known concentrations to create a standard curve (R^2>0.98) (Quick Start™ Bradford Protein Assay; BioRad Laboratories, Hercules, CA, USA).

To take different urine concentrations into account, the total protein concentration of each sample was corrected for creatinine (Cr) concentration. Creatinine is a breakdown product of tissue proteins, usually formed in muscles. For each sample, the Cr concentration was determined using the Jaffe reaction. The freshly prepared picric reagent (4 units sodium hydroxide, 1 unit picric acid) was incubated for 15 min. at room temperature in darkness (Bio Vender Lab., Brno, Czech Republic). In a 1 ml cuvette, 50 µl of standard, water (blank), or sample, were mixed and measured spectrophotometrically, at 492 nm, after 30 and 90 sec. We used the following formula to calculate the molar Cr concentration:

$$C_{creatinine} = \frac{C_{st} \cdot \left(\Delta A_{sample} - \Delta A_{blank}\right)}{\Delta A_{standard} - \Delta A_{blank}} [\mu\text{mol/l}]$$

C_{st} = concentration of standard (337 µmol/l, 0.038 mg/ml), A = absorbance, and delta A = (A after 90 sec-A after 30 sec). Results are presented as mg protein/mg Cr.

SDS-PAGE (Sodium Dodecylsulfate-Polyacrylamide-Gel-Electrophoresis) Urinary proteins were precipitated by pipetting 100 µl urine into 500 µl acetone, and then centrifugation at 14,000 g for 5 min. After this, samples were dissolved in 15 µl sample buffer [3.55 ml H_2O, 1.25 ml 0.5 M Tris/HCl (pH 6.8), 2.5 ml glycerol, 2.0 ml 10% SDS, 0.2 ml 0.5% bromphenol blue]. We used a modified protocol, based on that of Laemmli (1970). Samples were applied to 4–15% and 4–20% SDS-PAGE discontinuous gradient gels (precast-gel, BioRad Laboratories, Hercules, CA, USA), and run at 50 V for 20 min., followed by 80 V for 120 min, using a mini-gel apparatus (Mini-PROTEAN II Electrophoresis System, BioRad Laboratories, Hercules, CA, USA). Gels were stained with Coomassie® G-250 (SimpleBlue™ Safe Stain, Invitrogen Life Technologies, Paisles, UK) for 1 hr and destained with deionized water. Prestained molecular weight standards (see above) were run with each set of samples. As an internal MUP standard, we used 1 µl natural urine (i.e., not precipitated with acetone before SDS-PAGE) from a male mouse, that was loaded into 10 µl of sample buffer. Images were collected with a GS-800 Calibrated Densitometer (BioRad Laboratories, Hercules, CA, USA). Quantity One 1D Analysis Software (BioRad Laboratories, Hercules, CA, USA) was used for the densitometry analysis. The intensity of the MUP band from the mouse, relative to protein bands from the subterranean rodents, was calculated by the average optical density (OD) of MUP divided by average OD of all protein bands. The average OD of MUP also was divided by the average OD of the ~22.5 kDa protein bands of the subterranean rodents.

Urine from all rodents was tested by SDS-PAGE to assess the presence of proteins in the mass range of MUPs (or lipocalins) (Table 1). Samples from animals with such proteins were analyzed further by 2D gel electrophoresis.

2D Gel Electrophoresis - IEF (Isoelectric Focusing) Isoelectric focusing was performed on the urine specimens with the most concentrated bands in SDS PAGE, using the BioRad Protean® IEF Cell. Because the amount of protein in the samples was low, it was necessary to concentrate the urine before analysis. First, 800 µl of urine were centrifuged at 15,000 g for 10 min. Urine samples were fractionated in 300–400 µl aliquots, which were transferred into a Millipore-column (5 kDa, Ultrafree-MC) and spun at 15,000 g for 20 min. Samples were washed and centrifuged again at the same speed for 20 min., several times with a 1:4 times diluted PBS-buffer, until the stock solution was reduced to 50–100 µl. From this stock solution, 15 µl were precipitated in 250 µl acetone. Then, 7 cm IPG-strips (pH range 3.9–5.1 and 3–10, BioRad Laboratories, Hercules, CA, USA) were dissolved in 120 µl rehydration buffer (4.2 g urea, 1.5 g thiourea, 0.2 g CHAPS, 200 µl of 1 M

DTT, 10 μl of 0.5% bromphenol blue, 1 ml of 100x ampholytes pH 3–10; Bio-Lyte, BioRad Laboratoires, Hercules, CA, USA, in 10 ml distilled water). The strips were allowed to rehydrate passively overnight at 4°C. The program for focusing was as follows: 1 hr at 50 V, 25 μA per strip at 15°C, and a voltage limit of 4,000 V. Focusing was finished after 16,000 Vhr. Equilibration was done with 4 ml of two SDS equilibration buffers for 15 min. The first buffer contained 6 M urea, 0.375 M Tris pH 8.8, 2% SDS, 20% gycerol, 2.5% DDT. The second had the same components, but DDT was replaced by 2.5% iodoacetamide. The IPG strip was placed onto a 2nd dimension SDS-PAGE. An 8 μl sample molecular weight standard (Sigma-7-Ladder, BioRad Laboratories, Hercules, CA, USA) ran simultaneously with each set of samples.

MALDI–TOF-MS/MS (Matrix-Assisted-Laser-Desorption-Ionization – Time-of-Flight – Tandem-Mass-Spectrometry) For mass spectrometric analysis, proteins were isolated from pooled urine samples and concentrated by acetone precipitation. From each sample, 200 μg of protein were resuspended in 200 μl IEF rehydration buffer and applied on IPG strip (11 cm, pH 3–10; BioRad Laboratories, Hercules, CA, USA). Second dimension was carried out, as described above, on pre-cast gels (BioRad Laboratories, Hercules, CA, USA) stained with Coomassie® G-250. The major spot, with a molecular weight around 20 kDa, was excised from the gel and subjected to trypsin digestion. The gel spot was washed twice with 100 μl of 50 mM ammonium bicarbonate buffer in 50% acetonitrile and allowed to dry. Five ng of trypsin (Promega), in 10 μl of 50 mM ammonium bicarbonate and 10 μl of 97% ^{18}O water, were added, and the samples were incubated overnight at 37°C. Tryptic peptides were extracted with 1% trifluoric acid in 30% acetonitrile. A drop of extract was placed on the MALDI target plate and allowed to dry, and then covered with 2 mg/ml of α-cyano-hydroxycinnamic acid solution in 80% acetonitrile.

Tryptic peptides for *de novo* analysis were separated on PepMap 100 C18 RP column (3 μm particle size, 15 cm long, 75 μm internal diam; Dionex) with a gradient of 5% (v/v) acetonitrile, 0.1% (v/v) trifluoroacetic acid to 80% (v/v) acetonitrile, 0.1% (v/v) trifluoroacetic acid, using an Ultimate 3000 HPLC system coupled to a Probot microfraction collector (Dionex). Matrix solution (2 mg/ml α-cyano-hydroxycinnamic acid in 80% acetonitrile) was added in the ratio 1:3.

MS spectra were obtained using a 4800 Plus MALDI TOF/TOF analyzer (Applied Biosystems/MDS Sciex) equipped with a Nd: YAG laser (355 nm, firing rate 200 Hz). MS/MS was performed with 1 kV collision energy and an operating pressure in the collision cell of 10^{-6} Torr. Spectra were interpreted manually using double peaks formed by $^{16}O/^{18}O$ to distinguish y-ion series. The series of b-ions was matched to corresponding y-ion series by subtraction of y-ion mass from parent ion mass.

Statistical Analyses We used the *Kruskal Wallis one-way ANOVA* for independent samples to compare mean total urinary protein concentrations (Bradford test) across animals of different genera, because the data were not normally distributed (*Kolmogorov-Smirnov test*). The *Mann-Whitney U-test* for independent samples was used to compare mean total urinary protein concentrations (Bradford test) for males and females. All statistical analyses were performed with SPSS 15. Means are given as $\bar{x} \pm SD$.

Results

Bradford Test The mean total urinary protein concentration for the experimental animals was 0.45±1.09 SD mg/mg Cr, with no differences (except for mice) between males and females [tested separately for each genus: *Mann-Whitney U-test* (*Fukomys*: U=132.0, P=0.90; *Spalax*: U=31.0, P=0.23, *Spalacopus*: U=10.0, P=0.37, mice: U=7.0, P< 0.01)], and with comparable values at the genus level (*Kruskal Wallis one-way ANOVA*, χ^2=3.168, P=0.205) (Fig. 1). The urinary protein concentration of mice (12.4± 4.4 SD mg/mg Cr) was higher than that of the subterranean species (*Kruskal Wallis one-way ANOVA*, χ^2=49.62, P< 0.001) (Fig. 1). In contrast to the generally low values found for the subterranean rodents, there were three

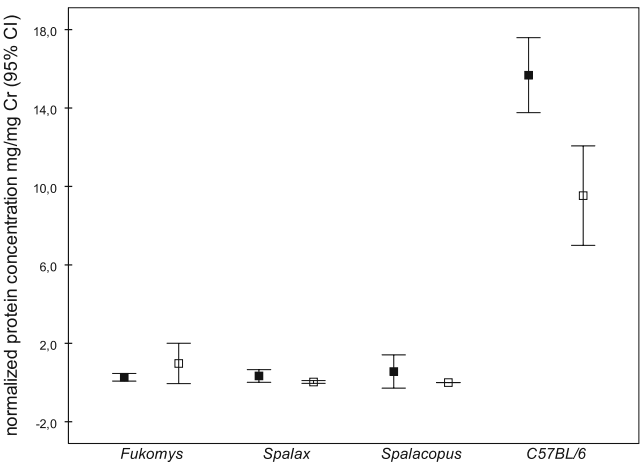

Fig. 1 Normalized total urinary protein concentration (mg/mg Cr) of both sexes of *Fukomys* (N=17 males, 16 females), *Spalax* (N=16 males, 6 females), *Spalacopus* (N=8 males, 4 females), and C57BL/6-mice (N=9 males, 10 females). Filled squares represent means of males, open squares females, with error bars signifying confidence intervals. Cr=creatinine

reproductively active *Fukomys* females (queens) with high total protein concentrations (individual #3: 2.7 mg/mg Cr, individual #12: 2.4 mg/mg Cr, and individual #17: 7.3 mg/mg Cr). The higher concentrations in these samples also were conspicuous in SDS-PAGE (Fig. 2).

SDS-PAGE In the qualitative SDS-PAGE analysis of urine samples of the three subterranean genera under study, only *Fukomys* showed one or two consistent bands (approximately ~22.5 kDa) (Fig. 2). In *Spalax*, only the samples of two males (out of 25 animals) had one band of approximately ~19–20 kDa (Fig. 3). None of the *Spalacopus* specimens revealed a band in the MUPs or lipocalin mass range (cf. Table 1).

Given that all *Fukomys* individuals showed a band in the MUPs mass range, we analyzed their SDS-PAGE pattern in order to investigate polymorphisms related to species, sex, or reproductive status (e.g., queens vs. non-reproductive daughters). No protein mass polymorphisms could be detected for *Fukomys* by this method. Band patterns, in the range of 22–23 kDa, consisted mainly of two bands (23 out of 31 samples); all other animals showed a pattern of one band (8 out of 31) (Fig. 2).

2D Gel Electrophoresis The most concentrated *Fukomys* samples came from two males (numbers 11 and 14), and these, along with those of two females (numbers 4 and 22; Fig. 2), were used for 2D gel electrophoresis. The only samples from *Spalax* that contained detectable amounts of protein were samples 5 and 7 (Fig. 3). A sample from a male mouse was used as a reference. The short range 2D PAGE (isoelectric point: pI=3.9–5.1) showed similarity only between spot 1 of the mouse and spots 5 and 6 of *Fukomys* (#11 m). They differed slightly (about 3 kDa) in mass, and the pI also was different (Fig. 4). None of the spots could be detected in the three other *Fukomys* specimens (e.g., #1 m, Fig. 4).

In the broad-range 2D PAGE (pI=3–10), two spots (spot 1 and 2) of the tested *Fukomys* specimen (#11 m) were nearly congruent to spots 1 and 2 of the mouse, although they differed slightly in both parameters: mass by approximately 1–3 kDa and pI (broad range not shown here, c.f., Fig. 4). The other two spots of the mouse did not correlate with the spots found in *Fukomys* urine samples.

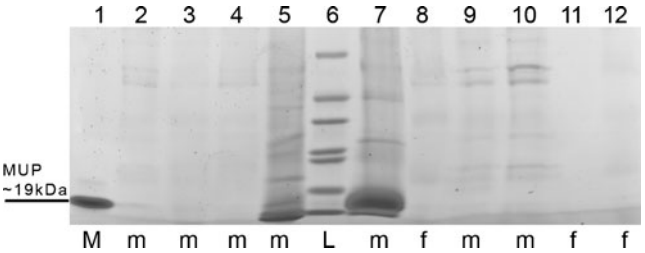

Fig. 3 SDS-PAGE of urine of males (m) and females (f) of *Spalax ehrenbergi* species complex. Sigma-7-ladder (L) and C57BL/6-mouse (M) as internal (qualitative) standard. Where major urinary proteins (MUPs) are expected is given

Of the two tested *Spalax* individuals, spot 3 of animal #7 m had the same range in both parameters as the *Fukomys* and mouse specimens (Fig. 5). None of the other numerous spots of this individual, nor any of the spots of individual #5, exhibited similar characteristics to the spots of the mouse or those of *Fukomys*.

A trend emerged in *Fukomys*: spot 1 was approximately similar to the mouse, although slightly different in mass (20–21 kDa) and pI; spot 2 existed in two male *Fukomys* individuals (#11 and #14); spot 3 in male #11, #14, and one queen (#4); the characteristics of spot 4 for males #11 and #14 were similar to the mouse. In sum, those three spots may be typical for *Fukomys* mole-rats. Both spots that, more or less, fit the pattern of the mouse were detected in just one out of four *Fukomys* specimens.

MALDI–TOF-MS/MS Peptide mass fingerprints were matched against a sequence database to identify the proteins present in the 20 kDa spot of the 2D-PAGE gel of *Fukomys*. No significant hits were obtained based on peptide masses. Subsequent *de novo* sequencing revealed the sequence of the peptide, which showed high similarity to the sequence of hamster aphrodisin (GI:1168469, BLAST, Basic Local Alignment Tool, www.ncbi.nlm.nih.gov/blast). The fragment differs from the corresponding aphrodisin sequence by four amino acid residues: YJAADNVEKJEEGGELR (where J is Leu or Ile, and K is Lys or Gln residue). Changes are indicated in grey.

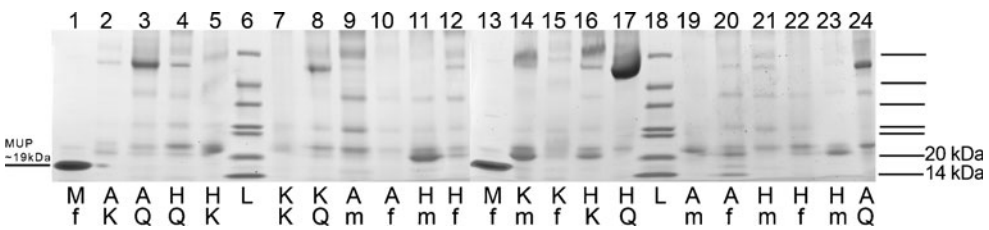

Fig. 2 SDS-PAGE (precast 4–15%) of urine from non-reproductive males (m), non-reproductive females (f), reproductive males (K, kings) and reproductive females (Q, queens) of *Fukomys anselli* (A), *F. kafuensis* (K) and their hybrids (H). Migration from top to bottom. Sigma-7-ladder (L) and C57BL/6-mouse (M) as internal (qualitative) standard. Where major urinary proteins (MUPs) are expected is given

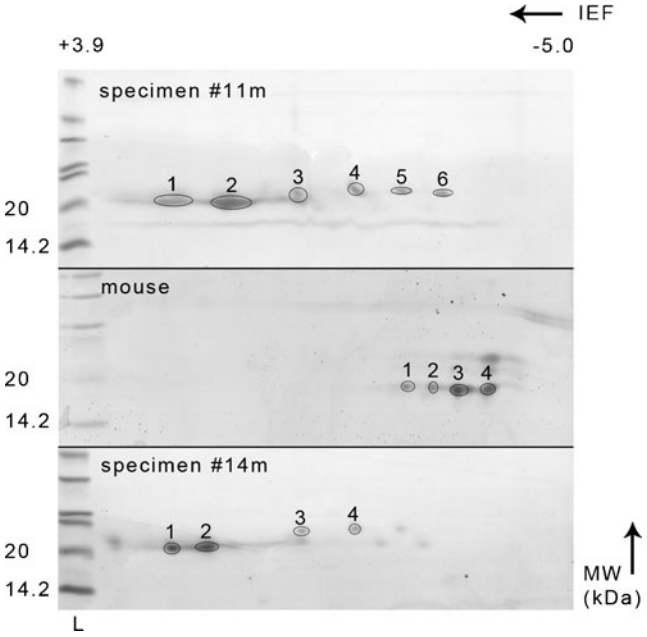

Fig. 4 2D PAGE of urine from two male *Fukomys* individuals and a mouse. Isoelectric focusing (IEF) was conducted with low range strips, with the isoelectric point (pI) ranging from 3.9 to 5.1. Sigma-7-ladder (L). The specimen number refers to the lane number in Fig. 2

Discussion

The biochemical analyses indicated the absence of MUPs in urine of the three tested rodent genera. No urinary protein in the mass range of ~20 kDa could be detected in *S. cyanus*. Of the 25 individuals tested from the four species of the *S. ehrenbergi* superspecies, one individual (#5) showed an SDS-PAGE band in the range of ~14 kDa, while another individual (#7) showed one band in the ~18 kDa range. These bands could be expanded through 2D gel electrophoresis to reveal two spots (~11 and ~14 kDa) in the first individual, and several spots, ranging from ~11 to ~20 kDa, in the second individual. High urinary protein excretion can be an indication of proteinuria (e.g., Rustom et al., 1998; Ghiggeri et al., 2004). Although there were no overt signs of illness at the time this individual's urine was collected, this mole rat may have been ill, particularly as 23 other *Spalax* samples showed no protein bands. In all the *Fukomys* samples, one or two bands in the mass-range of ~22–23 kDa were identified, but there was no indication of mass polymorphism according to species, sex, or reproductive status. 2D gel electrophoresis further demonstrated in one *Fukomys* male, two spots with similar charges to those of the mouse (pI 4.4–4.9 and pI 5.0–5.4), although they had a different mass range (~20 and ~22 kDa vs. ~19 and 19.5 kDa). The typical spot pattern in *Fukomys* consisted of three spots that were in the range of pI 4.05–4.57 with a mass of ~20–23 kDa.

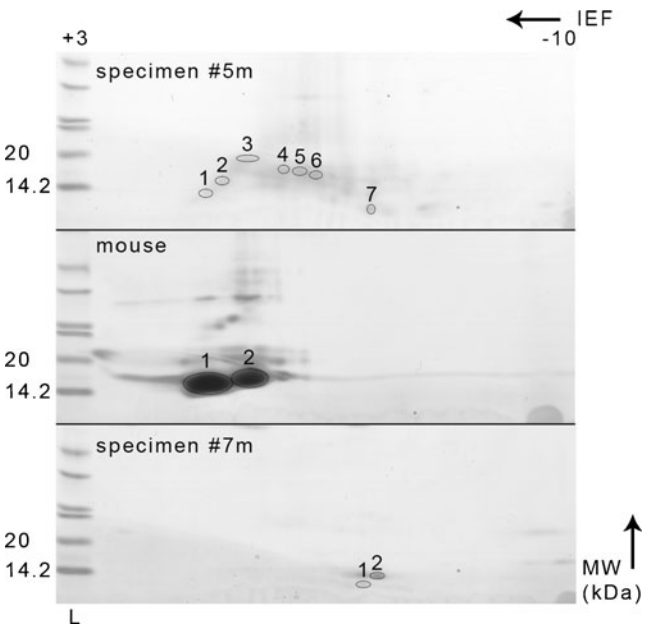

Fig. 5 2D PAGE of urine from two male *Spalax carmeli* and a mouse. Isoelectric focussing (IEF) was conducted with broad range strips, with the isoelectric point (pI) ranging from 3 to 10. Sigma-7-ladder (L). The specimen number refers to the lane number in Fig. 3

Although the urinary proteins of *Fukomys* were somewhat similar to the mouse in mass and charge, Bradford analysis revealed very low mean total urinary protein concentrations in *Fukomys*; protein concentrations were 19 times lower in *Fukomys* than in the mouse, and 27 times lower when all analyzed urine samples were considered. Although subterranean rodents do not drink free water, they consume enough water from their food to produce large amounts of urine, along with substantial calcium and magnesium carbonates, suggested to be a means of reducing CO_2 in the hypercapnic subterranean environment (Haim et al., 1985). This might explain the low protein concentrations. Total urinary protein concentrations were sufficiently low in both sexes of the subterranean species, in comparison with the mouse, so it is unlikely that urinary proteins play more than a trivial role, if any, in chemical communication in these species.

According to the average OD, the MUP band of the mouse is substantially more concentrated than all protein bands of *Fukomys*. The discrepancy, between this and the Bradford measures of total urine protein (see above), may be because proteins respond differently in OD measurements. Nevertheless, both types of data (Bradford and SDS-PAGE) demonstrate substantial differences in the amount of urinary proteins in the mouse compared to *Fukomys*. Whereas, the urinary proteins of mice are 99% MUPs, only one quarter of *Fukomys* urinary proteins is represented by the ~22.5 kDa band (mean ratio of the average OD all bands/~22.5 kDa). MALDI-TOF analysis identified the ~22–23 kDa band of *Fukomys* as comparable to aphrodisin, rather than a MUP-type lipocalin, confirming that none of

the subterranean rodent genera investigated, produce MUPs in their urine.

Interpreting these unexpected findings in the context of the behavioral evidence about how these subterranean rodents respond to urine odors, as well as in the context of findings about MUPs in other rodent species, could provide insight into a broad understanding of the processes underlying transmission of semiochemicals in rodents. All the rodent species analyzed here discriminate between individuals on the basis of odors in urine or urogenital and/or ventral secretions that may also include some urine (in *Spalax*, Todrank and Heth, 1996; Heth and Todrank, 2000; in *Fukomys*, Heth et al., 2004; and in *Spalacopus cyanus*, Hagemeyer and Begall, 2006). Studies, published while our study was underway, also noted that MUPs could not convey individual identity in species in which there was no polymorphism in MUPs, as in *Mus macedonicus* (Robertson et al., 2007), nor in species in which the patterns of urinary lipocalins across individuals were "remarkably consistent", as in *M. spretus*, as well as wild-caught rats, *Rattus norvegicus*, and the Roborovski hamster, *Phodopus roborovskii* (Beynon et al., 2008).

In species lacking polymorphism in MUPs, it is still possible to posit a role for MUPs in transmitting information about reproductive readiness or dominance status by variations in the concentration of MUPs (Beynon et al., 2008). However, in species lacking MUPs altogether, like the rodent species in the present study, there must be another mechanism for disseminating information about status and identity. This must be true for any rodent species, irrespective of ecotope, such as the wood mouse, *Apodemus sylvaticus* (family Muridae), which lacks urinary proteins in the 18–20 kDa range typical of lipocalins (Stopka, unpublished data). Although the behavioral research on the species in this study focused primarily on aspects of individual identity and responses to genetic similarity/difference, *Fukomys* and *Spalax* both responded to distinctions in urine that are indicative, for example, of reproductive state (Heth et al., 1996; Hagemeyer, 2010). It is clear that communication of information about reproductive status is accomplished in *Spalax*, despite their lack of both MUPs and aphrodisin. Additional research would be necessary to determine what role, if any, the trace amounts of aphrodisin found in *Fukomys* urine serves. Demonstrating a role for the aphrodisin-like odor-binding proteins found in bank voles (Stopková et al., 2010) would also contribute to a more thorough understanding of the extent to which urinary proteins influence chemical communication in rodents.

Chemical communication of both individual identity and biological state is so essential in the life of rodents that the fundamental mechanisms of chemosignaling have probably been conserved, despite adaptation to different ecotopes and social structures. Because rodent species lacking MUPs or polymorphic MUPs respond adaptively to chemosignals conveying information about individuality, species, and biological state, the basic process underlying transmission of this information cannot rely universally on MUPs. Indeed, a recent study characterizing MUP genes and pseudo-genes in a wide array of placental mammals, from rodents to horses, found extensive MUP gene polymorphism only in *M. musculus*, and moderate polymorphism only in *Rattus norvegicus* (Logan et al., 2008), suggesting that the separate expansion of the MUP gene cluster in *Mus* and *Rattus* may be atypical among mammals. It is, therefore, conceivable that the use of MUPs in mice with polymorphic MUPs is a secondary process that augments the primary process of conveying identity or status directly, perhaps by extending the availability of the semiochemicals in urine. If there is a universal process that transmits semiochemicals from sender to receiver across Rodentia, then the search for such a process must continue, because MUPs are not sufficiently prevalent to accomplish this task.

Polar Metabolites Synergize the Activity of Prostaglandin $F_{2\alpha}$ in a Species-Specific Hormonal Sex Pheromone Released by Ovulated Common Carp

Hangkyo Lim · Peter W. Sorensen

Received: 17 January 2011 / Revised: 18 May 2011 / Accepted: 24 May 2011 / Published online: 7 June 2011

Abstract Many species of teleost fish detect and release F prostaglandins (PGFs), but the specific identities of these compounds and how they function as species-specific pheromones have yet to be resolved. This study addressed these questions in the common carp. An initial set of experiments established that mature male common carp were attracted to chemicals released by ovulated conspecifics, whereas the odor of female goldfish, a close relative, was less attractive. Tests of fractionated holding water from ovulated carp revealed that only the non-polar fraction was attractive on its own. Mass spectrometry and immunoassay next demonstrated that the non-polar fraction contained large quantities of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), 15keto-prostaglandin$F_{2\alpha}$, and 13,14-dihydro-15keto-prostaglandin $F_{2\alpha}$ (100 g fish released over 1 μg of all 3 PGFs per h at a ratio of 1.0: 1.7: 0.7). Ovulated goldfish released the same three PGFs but at a slightly greater rate and in a different ratio. Tests of synthetic mixtures of these PGFs revealed that the carp-specific mixture attracted male carp but was no better than the goldfish-specific mixture or $PGF_{2\alpha}$ alone and that $PGF_{2\alpha}$ was just as attractive as mixture of all three PGFs. A final set of attraction tests revealed that although $PGF_{2\alpha}$ could explain all of the activity of the non-polar portion of female carp holding water, it could not explain the entire activity of female water but that a mixture of PGFs and the polar fraction could. We conclude that ovulated female carp release a multi-component sex pheromone complex that is comprised of $PGF_{2\alpha}$ and unknown species-specific polar compound(s) that synergize the activity of the former. The pheromone also might be useful in controlling this invasive species. The observation that a fish hormonal sex pheromone incorporates bodily metabolites in addition to relatively common hormonal products demonstrates a mechanism by which species specificity may be conferred to this common type of sex pheromone.

Key Words Common carp · *Cyprinus carpio* · Electrospray ion mass spectrometry (ESI-MS/MS) · Enzyme-linked immunosorbent assay (ELISA) · Goldfish · Hormonal pheromone · Invasive species · Mass spectrometry (MS) · Pheromone complex · Species-identifying pheromone

Introduction

Fish rely on sex pheromones to mediate various aspects of their reproductive biology, and many of these appear to be at least partially comprised of hormones and their derivatives and are known as 'hormonal pheromones' (Stacey and Sorensen, 2009). Sex pheromones released by recently-ovulated females are some of the best understood hormonal pheromones. They often appear to contain F prostaglandins (PGFs), which also are known to serve as endocrine mediators of ovulation and female spawning behavior (Sorensen and Goetz, 1993; Stacey and Sorensen, 2009). The seemingly common use of PGFs as pheromones is supported by much physiological and behavioral evidence, but proof of their precise identities and function within ovulated female odor remains to be elucidated. Thus, while approximately a dozen electrophysiological studies of olfactory function in a variety of fishes have shown that they detect prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and two of its metabolites with acute sensitivity and specificity, evidence

e-mail: soren003@umn.edu

of PGF release comes from only a few species and relies entirely upon either immunoassays (whose interpretation can be complicated by antibody specificity), or HPLC (whose interpretation can be complicated by co-elution of related structures) (Sorensen and Goetz, 1993; Sorensen et al., 1995; Stacey and Sorensen, 2009). Further, while laboratory studies have consistently shown PGFs to stimulate arousal and /or attraction in males of those species that detect them (see Stacey and Sorensen, 2009), responses have not yet been compared to those elicited by ovulated female odor to see if they are identical. Thus, the specific identities, amounts, and functions of PGFs released by ovulated fishes are not established.

Because the identity of pheromonal PGFs is unresolved, questions about whether and how they might account for pheromone specificity also persist. Complicating this situation is the fact that it is not yet clear whether the odors (pheromones) of ovulated females are always species-specific or why. Thus, while approximately a dozen species of fish have been shown to release odors with species-specific actions when ovulated (Sorensen and Stacey, 1999), a few species appear to release cue(s) that are not species-specific (ex. McLennan and Ryan, 1997) (hence, our usage of the seemingly redundant term "species-specific pheromone"). The precise significance of these observations is difficult to ascertain because no study has yet attempted to link directly the release of any particular compounds including PGFs to pheromonal specificity to test whether/ how they might explain either the full activity or the apparent specificity of the odor of ovulated fish. Curiously, only three PGFs ($PGF_{2\alpha}$, 15keto-prostaglandin $F_{2\alpha}$ [15K-$PGF_{2\alpha}$], and 13,14-dihydro-15keto-prostaglandin $F_{2\alpha}$ [dh15K-$PGF_{2\alpha}$]) have been shown to have pheromonal function to date (see Sorensen and Stacey, 1999; Stacey and Sorensen, 2009).

There are at least four, non-mutually exclusive ways that these seemingly common hormonal products might explain the apparent species-specificity of ovulated pheromones. One possibility is that female fish release and male fish detect highly prescribed and distinctive mixtures of these PGFs (Sorensen et al., 1998). Although the finding that goldfish, *Carassius auratus,* possess multiple olfactory receptors for PGFs adds credence to this hypothesis (Sorensen et al., 1988), its relevance to pheromonal specificity has not been tested. Another possibility is that some female fish may release novel PGFs that have not yet been discovered. A third possibility is that PGFs do not themselves convey species information but rather this information is conveyed by metabolic compounds released along with them. The finding that juvenile fish of a variety of species discern species identity by using an odor that includes both polar and non-polar components (Sisler and Sorensen, 2008) supports this possibility (Levesque et al., 2011), but it has not been tested in mature, sexually-active adults. Fourth, it is possible that hormonal pheromones themselves are not always species-specific, and that this information is instead conveyed by contextual information such as visual appearance and temporal patterning of pheromone release (Sorensen and Stacey, 1999). The finding that female goldfish release PGFs in highly regulated urinary pulses supports this possibility (Appelt and Sorensen, 2007). Direct tests of the potency of ovulated female odor and the various components it contains are lacking for any fish and now are needed to distinguish among these possibilities.

The common carp, *Cyprinus carpio,* (hereafter 'carp'), is a good model to test these questions. It is a close relative of the goldfish and is one of the only species for which detailed information exists on prostaglandin release, detection, and response (Sorensen and Goetz, 1993; Kobayashi et al., 2002). To date, lessons learned from the goldfish have proven applicable to many fishes, although distressingly few species have been studied, and few exhibit radically different reproductive strategies (Stacey and Sorensen, 2009). Interestingly, although the goldfish and carp have strikingly similar behaviors, endocrine systems, and olfactory sensitivities to PGFs (Irvine and Sorensen, 1993; Sorensen and Stacey, 2004), they do not commonly hybridize, suggesting they employ some type of species isolating mechanism (Sorensen et al., 1992; Hänfling et al., 2005). Because both male goldfish and carp suffer from severe reductions in spawning activity if their olfactory systems are occluded (Stacey and Kyle, 1983; Lim and Sorensen, unpublished results), it is likely that female pheromones are involved with this process. The carp is an invasive species (Weber and Brown, 2009) and complete identification of its sex pheromones would be useful in its detection and control (Sorensen and Stacey, 2004).

The overarching goal of the present study was to investigate whether the carp uses a $PGF_{2\alpha}$-based female-derived sex pheromone to encode species specificity at the time of ovulation and spawning. Four questions were addressed: (1) Do ovulated female common carp release a sex pheromone? (2) If so, is this pheromone species specific? (3) Do PGFs play a dominant and/or exclusive role in this pheromone? and (4) Are the ratios of PGFs released by different species of fishes important to pheromone function?

Methods and Materials

Study Design The study investigated the role of PGFs in the female carp pheromone in four sets of experiments whose designs were based on each other's findings. Experiments employed an attraction assay that used circular

mazes that we have used before (see section below). Each experiment tested a single treatment (odor), and the results of related sets of experiments were then compared to each other and a control to answer questions about the identity and role of PGFs. Several follow-up experiments tested odors of special interest against each other in 'head-to-head' tests to determine their relative potencies. Odor fractionation/purification employed reverse-phase C18 resin, which is known to separate aqueous polar and non-polar structures (see Levesque et al., 2011) while both mass spectrometry/mass spectrometry (MS/MS) and enzyme-linked immunosorbent assays (ELISA) were used to analyze for the presence of PGFs in both carp and goldfish waters. This combination of techniques permitted cross-validation.

Question 1. Do Ovulated Carp Release a Sex Pheromone that Attracts Males? First, we determined whether ovulated carp release a sex pheromone by testing the behavioral responses of male carp to holding water from ovulated carp, holding water from non-ovulated female carp, and blank well water (control). The holding waters for these experiments were created by placing ≈200 g of ovulated or non-ovulated fish (typically 3 fish) into plastic containers containing 10-l of aerated 20°C well water for 1 h following established protocols (Sisler and Sorensen, 2008; Levesque et al., 2011). Matching controls for each experiment were created in the same manner without fish. Ovulation was induced by injecting females with hormones (0.5 ml Ovaprim/kg body weight, Syndel Inc., Vancouver, Canada) 12 h in advance of when they were needed (typically 2000 h). Ovulated fish were collected the next morning [0800 h; approximately 4 h after ovulation and at a time that steroidal pre-ovulatory pheromone levels would have been very low (Scott and Sorensen, 1994)], rinsed in well water to further minimize any possibility of including pre-ovulatory pheromones (Stacey and Sorensen, 2009), and then incubated. Control females were treated in the same manner except they were injected with saline and thus did not ovulate. All fish were handled carefully using well-rinsed nets and placed into clean containers with well water for holding water collection.

Question 2. Is the Pheromone Species-Specific? Having established the ovulated carp release an attractant, we tested the specificity of this attractant by describing the behavioral responses of male carp to ovulated carp holding water, ovulated goldfish holding water, and then to a choice of the two. A well water control was also tested. Responses of male goldfish to a choice of carp and goldfish waters were evaluated in a fifth experiment. Protocols for odor collection and testing followed those used to answer question 1 except that water samples were collected in advance and frozen until needed when they were thawed in a 20°C water bath. Pilot tests established that freezing/thawing did not affect the attractiveness of ovulated carp water [male carp offered a choice of fresh and previously frozen ovulated carp water did not distinguish between them (relative attraction value was 1.8±0.7%; N=3)].

Question 3. Do Known PGFs Play a Dominant Role in the Female Odor (the Entire Pheromone)? This question was addressed in a step-wise fashion by several subsets of experiments that addressed the importance of the non-polar fraction (which we already knew to contain all PGFs (Eom et al., 2009; Sorensen, unpublished data), the identity of the PGFs found in the non-polar fraction, the relative importance of the identified PGFs in this fraction, and finally the importance of PGFs in the entire odor. For the first subset of experiments, 1-l samples of ovulated carp holding water or well water control were passed through activated reverse phase C18 columns (Sep-Pak, Waters Inc, Milford, MA, USA), eluted with 5 ml of methanol (Sigma-Aldrich, St. Louis, MO, USA), dried under a stream of nitrogen, reconstituted in 100 µl of methanol, and dissolved in 1-l of well water for testing. Meanwhile, the filtrate (i.e., the polar fraction) was collected and tested directly. Ovulated carp holding water and a blank well water control also were tested on their own as controls. Pilot studies confirmed that treating water with C18 columns had no effect on carp behavior (relative attraction value was 0.8±0.4%; N=2). For the second subset of experiments, we analyzed the PGF content of C18 extracts of 5 ovulated carp and 3 ovulated goldfish holding waters by using both MS/MS and ELISA (see section below) on all samples. Next, we tested the importance of these PGFs in the non-polar fraction by creating a carp-specific mixture of PGFs using synthesized $PGF_{2\alpha}$, 15K-$PGF_{2\alpha}$, dh15K-$PGF_{2\alpha}$ (purity >98%; Cayman Chemical, Ann Arbor, MI, USA), and then tested this mixture on its own, and then against the non-polar fraction from ovulated carp water. Awell water control was also tested as part of this subset of experiments. Lastly, in a fourth subset of experiments, we determined the importance of these PGFs within the entire pheromone by testing the mixture of $PGF_{2\alpha}$, 15K-$PGF_{2\alpha}$, and dh15K-$PGF_{2\alpha}$ against thawed ovulated carp holding water, and then adding it to filtrate and testing this complete mixture against ovulated water.

Question 4. Is the Specific Ratio of PGFs Found in Female Holding Water (the 'Entire' Pheromone) Important to its Activity? Although the previous set of experiments found PGFs to be important, they did not address the possible role that mixtures of PGFs might play in specificity. This was addressed by three additional subsets of experiments. First, we tested the activity of each PGF by testing each at a concentration of 2×10^{-10} Molar (M), the lowest concentration measured in holding water, and then at 6×10^{-10} M, a concentration equal to the sum of all three

PGFs. Control experiments that tested well water control were included in each of these sets of experiments. Second, to test whether the PGF ratio might convey species-specific information, we evaluated the mixture of the PGFs found in ovulated carp water against a mixture of the PGFs found in ovulated goldfish water in a head-to-head test. A final experiment assayed the carp-specific mixture of PGFs (6×10^{-10} M) and against $PGF_{2\alpha}$ (2×10^{-10} M), the only component found to be active on its own.

Experimental Fish Carp and comet variety goldfish were purchased from fish farms (Osage Catfisheries, MO, USA and Hunting Creek Fisheries, PA, USA, respectively) and shipped to the university where males and females were held into different 1000-l flow-through circular tanks supplied with 20°C well water at a rate of 10-l/min. All fish were fed a mixture of flake fish food (Aquatic Eco-Systems, Apopka, FL, USA) and frozen brine shrimp (San Francisco Bay Brand, Newark, CA, USA) every day while being maintained on a 16:8 h (L:D) photoperiod. The goldfish were sexually mature when they arrived, but the common carp had to be raised to maturity (this took 1 yr) and sorted by sex after they matured (based on body shape and sperm production). The day prior to testing, male fish were 'primed' (placed into a state of moderate sexual arousal) by placing them into 100-l tanks that contained 10^{-10} M 17α,20β-dihydroxy-4-pregnen-3-one (Sigma-Aldrich, St. Louis, MO, USA), the major component of the pre-ovulatory steroidal pheromone. Previous studies have shown that this pheromone greatly enhances behavioral responsiveness to the odor of prostaglandins (deFraipont and Sorensen, 1993; Lim and Sorensen, unpublished results). Males were selected randomly for all experiments and re-used up to 3 times after being given at least a month to recover in separate holding tanks to minimize any chance that previous experience might affect results. At the time of testing, male common carp were spermiated (i.e., they released sperm when squeezed), had an average weight of 89.7±10.3 g, and an approximate gonadosomatic index (GSI =gonad weight/whole body weight × 100%) of 6.3±0.8% (mean ± standard error). Female carp had mature eggs, weighed 100.5±11.9 g, and had an approximate GSI of 11.5 ±2.1%. Female goldfish had an average weight of 41.3± 7.1 g and GSI of 12.8±3.4%. Gonadosomatic indices were determined by euthanizing 4 fish at the conclusion of experiments using 0.1% MS222 following the institutional animal use and care protocol.

The Attraction Assay The attractiveness of test odors to male carp was evaluated by using a protocol based on one that we have used before (Maniak et al., 2000; Rolen et al., 2003; Sisler and Sorensen, 2008; Levesque et al., 2011). In this assay, the distribution of groups of fish is observed in darkened circular mazes, each of which has two arms and a central, drained, neutral area (Fig. 1). Test and control odors are added to one side arm and/or the other arm following a pre-test period. We use groups because carp are social and behave more naturally when tested in this manner. For this study, each experiment was repeated 10 times using different groups of male fish, each of which was considered an independent trial. Trials commenced by placing groups of 5 primed males into a circular maze tank after which incoming water was turned off and they were allowed to acclimate for 1 h. This was then followed by a 15-min pre-test period during which time well water control was added to both test areas of the maze, after which an odor was pumped into the one test area while well water control (or in the case of head-to-head tests, another odor) was pumped into the other side for another 15-min for the test-period. Test odors were added to the test area with the fewest carp during the pre-test, and were introduced (10 ml/min) via small plastic tubes connected to air-stones which promoted mixing. Dye tests demonstrated that odors were diluted about 10 fold within a distance of 10 cm from the point of introduction, and did not cross between test areas for 15-min. Mazes were covered by black curtains and illuminated by two overhead infrared lights (Vitek, Taipei, Taiwan) and dim (5W) incandescent lights while low light cameras (Bosch Security Systems, Germany) were positioned overhead and connected to a monitor and a DVD recorder.

Each trial was analyzed independently by reviewing DVDs. To accomplish this, the number of carp observed in the test area of the maze was counted at 15-sec intervals during the pre-test period and then the test period (the individual identities of fish were not noted). The numbers

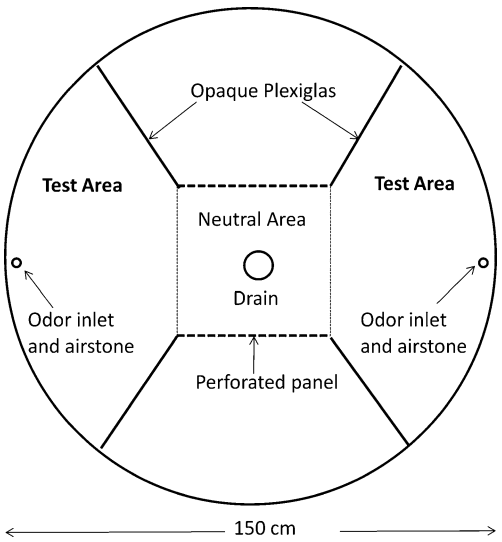

Fig. 1 A schematic drawing of the two-choice maze used to test behavioral responses of primed male common carp, *Cyprinus carpio*. Fine dashed lines mark the borders between test and neutral areas. The maze was filled to a depth of 20cm

of fish seen were summed for each period, and divided by 300 [the total possible score (i.e., 5 fish × 60 15-sec time periods)] to yield percent time that all fish spent in the experimental side during each period. Pre-test values were subtracted from test values for each trial to yield 'relative attraction', a measure of change in time spent in the test area during odor addition. The use of relative attraction served to normalize the data and remove any possible side bias. An average value for relative attraction next was calculated for all 10 trials of each experiment and differences between treatments (test odors) compared by using one-way ANOVAs (SigmaStat, Ashburn, VA, USA). If significance was indicated ($P<0.05$, $P<0.01$, or $P<0.001$), individual values were compared to each other and the blank control using a Holm-Sidek adjustment (Aickin and Gensler, 1996). In addition to these analyses, values for blank control also were tested against zero using *t*-tests to confirm a lack of maze bias. Head-to-head experiments were evaluated independently by comparing relative attraction values with *t*-tests (SigmaStat, Ashburn, VA, USA) after confirming normality with a Kolmogorov-Smirnov test (Sigmastat).

Biochemical Analysis of PGFs Goldfish and carp samples were analyzed by using a combination of electrospray negative ion mass spectrometry (ESI-MS/MS) and ELISA. We used both techniques on both species because neither technique could be fully definitive on its own. In particular, while the immunoassays we employed were highly specific, the possibility that as yet unidentified PGFs might be interfering with measurements could not be ruled out. Additionally, ESI-MS/MS cannot differentiate between $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$ as they have identical molecular weights and fragment in similar manners. Thus, we used both techniques to cross-check each other's findings.

For ESI-MS/MS, 5 µl aliquots of C18 extracts of carp and goldfish holding waters were injected into an ion trap mass spectrometer (LCQ-1, ThermoScientific, Waltham, MA, USA) equipped with an electrospray ionization source [ion trap was operated in the negative ion mode with a spray voltage of 5 kV; sheath gas was 99% pure nitrogen at 60 psi; sheath fluid was 50:50 20 mM triethylamine: acetonitrile (v/v)]. Ionization patterns were compared with standards of $PGF_{2\alpha}$, 15K-$PGF_{2\alpha}$, and dh15K-$PGF_{2\alpha}$, the three PGFs previously described in ovulated fish extracts (Sorensen et al., 1988, unpublished). For quantification, standards (Cayman Chemical, Ann Arbor, MI, USA) were made up in blank holding water at concentrations ranging from 3.5–175.5 ng/l and then extracted with activated C18 columns to produce a calibration curve that corrected for possible matrix effects and extraction efficiencies (Fine et al., 2006). Daughter ions of *m/z* 291, 309, 317, and 335 were monitored to quantify $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$, and *m/z* 315 and 333 for 15K-$PGF_{2\alpha}$.

To analyze by immunoassay we used duplicate samples and commercially available kits for $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$ (15K-$PGF_{2\alpha}$ was not re-analyzed because MS/ MS was deemed to give distinctive reliable measurements). For $PGF_{2\alpha}$, we used an antisera that reacted 100% with $PGF_{2\alpha}$, 90% with $PGF_{1\alpha}$, <4% with thromboxane B2 and 6-keto-$PGF_{1\alpha}$, and <1% with 2,3-dinor-6-keto-$PGF_{1\alpha}$, 11b-$PGF_{2\alpha}$, 8-iso-$PGF_{2\alpha}$, and 15K-$PGF_{2\alpha}$, dh15K-$PGF_{2\alpha}$ (Neogen, www.neogen.com, catalog #404710). To analyze for dh15K-$PGF_{2\alpha}$, we used an antisera that reacted 100% with dh15K-$PGF_{2\alpha}$, and less than 1% with $PGF_{2\alpha}$, 15-keto-dihydro-PGE_2, and 15K-$PGF_{2\alpha}$ (Neogen, www.neogen.com, catalog #404610). For each ELISA test, the eluate was dried down under nitrogen and re-suspended in the buffer supplied with the kits. Samples were then run in duplicate along with 8-point standards and blanks (0–1 ng/ml). Most samples had to be run several times after diluting them 10–1,000 times to produce values that fell on the 8-point calibration curve. Final ELISA results were confirmed by adding the values generated by the ELISAs for both $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$ and then comparing them with the value generated by ESI-MS/MS by *t*-test.

Results

Analyses of pre-test data found neither a side bias in any of our mazes nor any effect of adding blank control ($P>0.05$; $N=25$ for all 4 sets of experiments). Our first set of experiments found that primed male carp were attracted to ovulated carp holding water ($P<0.001$ vs. control), but not to the well water control ($P>0.05$) nor to non-ovulated female carp holding water ($P>0.05$; Fig. 2a). Our second set of experiments confirmed the behavioral potency of ovulated water and showed that responses to this cue were species-specific; although ovulated goldfish holding water was attractive ($P<0.05$), paired comparisons showed it to be less so than ovulated carp water ($P<0.05$). Further, when the two stimuli were compared directly in head-to-head tests, the ovulated carp odor was preferred ($P<0.001$; Fig. 2b). Tests with male goldfish showed that they too preferred ovulated goldfish water to that of carp (mean relative attraction=14.5%±1.7; $P<0.001$; $N=10$).

Experiments designed to answer question 3 found that while the polar fraction (filtrate) was not attractive to male carp when tested against the control ($P>0.05$), the non-polar fraction (eluate) was ($P<0.001$) (Fig. 3). Analysis of the non-polar eluate of female carp and goldfish water by ESI-MS/MS found negative ions with *m/z* ratios of 291, 309, 317, and 335, which corresponded to both $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$ (their profiles were identical) and *m/z* ratios of 315 and 333, which corresponded to 15K-$PGF_{2\alpha}$ (Fig. 4)

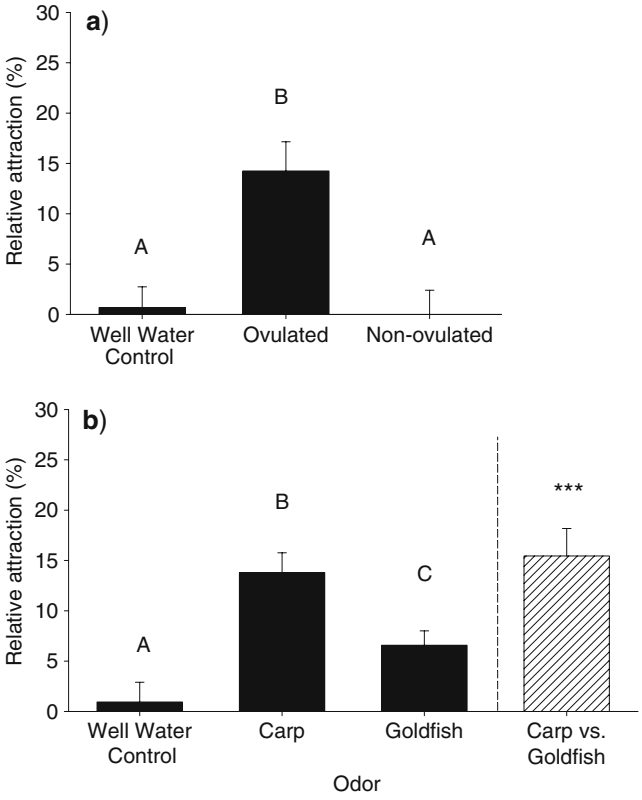

Fig. 2 Responses (mean relative attraction ± standard error) of primed male carp, *Cyprinus carpio*, to: **a** Blank well water control, holding waters of ovulated and non-ovulated female carp; **b** Blank control, holding water of ovulated carp, and holding water of ovulated goldfish, *Carassius auratus*. Stimuli were tested against appropriate matching controls (see text). The test of blank water control was not significant ($P>0.05$). Treatment groups with different letters are significantly different from each other ($P<0.01$). ***$P<0.001$ (head-to-head test of the holding water of ovulated carp versus the holding water of ovulated goldfish using male carp)

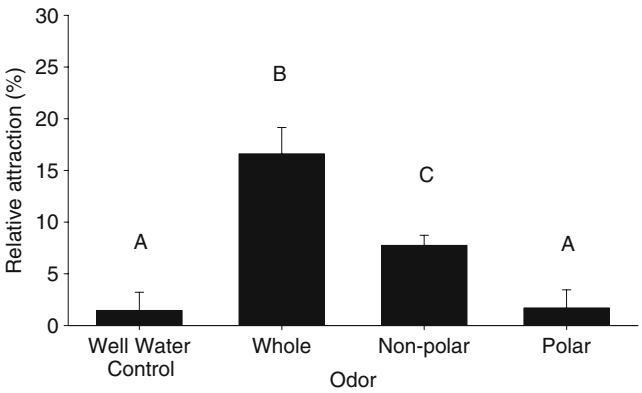

Fig. 3 Responses (mean relative attraction ± standard error) of primed male carp, *Cyprinus carpio*, to blank control, the holding water of ovulated carp ('Whole'), the reverse phase C18 column chromatography eluate ('Non-polar'), and C18 filtrate ('Polar') fractions of ovulated carp water. Samples were tested against appropriate controls (see text). Treatment groups with different letters are significantly different ($P<0.01$)

in each. Quantification of $PGF_{2\alpha}$ / dh15K-$PGF_{2\alpha}$, and 15K-$PGF_{2\alpha}$ using their parent ions (*m/z* 353 and 351, respectively) produced linear calibration curves ($R^2=0.94$; $R^2=0.92$). The latter was used to calculate 15K-$PGF_{2\alpha}$ release rates, which ranged from less than 0.1 ng/g body weight/h for non-ovulated carp to nearly 9.0 ng/g/h for ovulated goldfish (Table 1). Immunoassay further suggested that these species released similar quantities of $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$, although female goldfish released greater quantities of dh15K-$PGF_{2\alpha}$ (Table 1). When summed, the quantities of $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$ measured by ELISA were not different from the total values measured by ESI-MS/MS for both products ($P>0.05$), confirming the ELISA results. Relatively high variation in the specific values of individual PGFs released by individual carp and goldfish was evident (Table 1).

Behavioral tests of the carp-specific mixture of $PGF_{2\alpha}$:15K-$PGF_{2\alpha}$: dh15K-$PGF_{2\alpha}$ found it to be attractive when tested against well water control ($P<0.001$) and equivalent in potency to the eluate ($P>0.05$), suggesting it could explain all activity in the non-polar fraction (Fig. 5a). However, when the PGF mixture was tested against whole ovulated carp water, it was less potent than the latter ($P<0.001$), and when added to the filtrate (polar fraction), the potency of the PGF / filtrate mixture was equivalent to that of ovulated carp water (Fig. 5b). Experiments conducted to address our fourth question about PGF ratios showed that of the three PGFs, only $PGF_{2\alpha}$ was attractive ($P<0.05$) at a concentration 2×10^{-10} M ($P<0.001$; Fig. 6a). It was also the only PGF that was active at 6×10^{-10} M ($P<0.001$; Fig. 6b).

Table 1 Mean release rates[a] of three F prostaglandins by common carp, *Cyprinus carpio*, and goldfish, *Carassius auratus*

Fish	$PGF_{2\alpha}$	15K-$PGF_{2\alpha}$	dh15K-$PGF_{2\alpha}$	Ratio
Non-ovulated carp	0.05±0.02	0.05±0.03	0.04±0.03	1.0: 1.0: 1.0
Ovulated carp	3.43±0.82	5.67±1.02	2.27±0.39	1.0: 1.7: 0.7
Ovulated goldfish	7.57±1.50	8.70±1.05	16.76±1.67	1.0: 1.1: 2.2

[a] Table entries are in ng/g fish weight/h ± standard error

Subsequent head-to-head tests between the carp PGF mixture and the goldfish PGF mixture, and later against $PGF_{2\alpha}$ alone, found them all to be equipotent (relative attraction=1.7± 3.6% and −0.9±1.1%, respectively; $P>0.05$).

PGF concentrations were matched. ***$P<0.001$

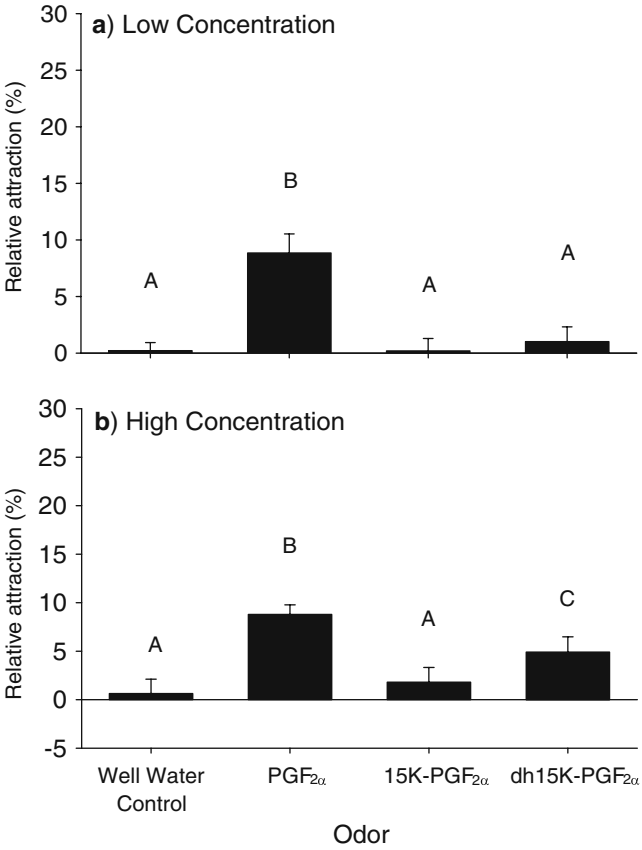

Fig. 6 Responses (mean relative attraction ± standard error) of primed male carp, *Cyprinus carpio*, to the three individual PGFs against well water containing methanol carrier only at: **a** 2×10^{-10} M (the approximate concentrations of each found in ovulated water); and **b** 6×10^{-10} M. Control values did not differ from zero ($P>0.05$). Treatment groups with different letters are significantly different from each other ($P<0.001$)

Discussion

This study is the first to describe the identity and role of PGFs in a pheromone released by an ovulated fish in a definitive manner. It also is the first to describe pheromone release by the common carp, an important model for pheromone function and a damaging invasive species with economic importance. Although we found that $PGF_{2\alpha}$ plays a critical role in the ovulated carp pheromone, we also found that the PGF ratios are seemingly unimportant to the attractive properties of this pheromone and that the activity of $PGF_{2\alpha}$ is synergized by as yet unidentified polar compounds. The latter compounds also may contribute to the species-specific character of this cue, but this has yet to be demonstrated. Because a mixture of different types of compounds is required for the ovulated carp sex pheromone to be fully active, we consider it to be a 'complex.' Further, we hypothesize that the carp has evolved to recognize mature conspecifics by using mixtures of bodily metabolites and relatively common hormonal products such as

PGFs, and that this ability may be shared by other fishes. If so, this could explain the apparent specificity of many (although not necessarily all) hormonal sex pheromones. Additional support for this possibility is found in the observation that male goldfish do not respond to PGFs if they are added to holding water of juvenile blue gourami (*Trichogaster trichopertus*) (Sorensen et al., 2000) and that juvenile goldfish, like mature male carp, are attracted to both polar and non-polar fractions of body washings released by juvenile conspecifics (Levesque et al., 2011). Direct tests of the importance of fish body odors on the perception of hormonal cues and their specificity are now needed to prove this hypothesis.

This study establishes the common carp as an important model for understanding PGF pheromone function while contributing to our understanding of the goldfish. Irvine and Sorensen (1993) showed that the carp and goldfish olfactory systems are acutely and specifically sensitive to $PGF_{2\alpha}$ and two of its metabolites. The present study found that these products are also released in significant quantities by both species, although in slightly different ratios, and that they drive behavioral responses in males of both species. Interestingly, only $PGF_{2\alpha}$ appears to function as an attractant for male carp, even though males also detect 15K-$PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$. There was no indication that unknown PGFs (or other non-polar compounds) contribute to the mixture. Although our study did not directly test whether ovulated carp odor and $PGF_{2\alpha}$ might also stimulate swimming activity and endocrine activity as noted in goldfish (Stacey and Sorensen, 2009), re-review of our data suggested that $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$ also stimulated swimming activity so we assayed a range of behavioral activities. Although attraction of male goldfish to PGFs has not yet been assayed, they have been shown to become strongly aroused by all three PGFs (Sorensen et al., 1986, 1988, 1989). Thus, PGF function may differ slightly between these species.

Somewhat surprisingly, this study appears to show that the ratios of PGFs released and detected by carp have little bearing on pheromone response in carp. This may make some sense because our studies and those of Ogata et al. (1994) both show PGF release rate and composition to vary greatly and to involve multiple release pathways (Sorensen et al., 1995), which would blur the ratio profiles that fish normally encounter. Additionally, although poorly understood PGF production rates and profiles may change during the course of spawning because of their apparent reliance on the presence of ovulated eggs in the reproductive tract that would change during the course of spawning (Stacey and Sorensen, 2009). The possibility that PGF ratio may influence responses other than attraction (e.g., endocrine responses) is nevertheless untested and warrants attention, both because electrophysiological recording suggests that the goldfish olfactory system has some (albeit limited) ability to discern between them (Sorensen et al., 1988) and because goldfish appear to become more aroused by mixtures of PGFs (Sorensen et al., 1989). The seemingly low importance of PGF release profile contrasts with the situation with the steroidal pre-ovulatory pheromone in goldfish where ratios strongly modulate signal strength; however, the steroids that comprise this cue are released in a highly prescribed temporal sequence that spans many hours, and olfactory sensitivity to them is extraordinarily specific (Scott and Sorensen, 1994; Stacey and Sorensen, 2009). To date, steroid ratio also has not been linked to species-specificity. Many insects are extremely sensitive to small changes in the ratios of pheromonal products but these are produced and released in species-specific ratios from highly specialized glands that apparently evolved and are used for communication alone (Sorensen et al., 1998; Cardé and Haynes, 2004; Derby and Sorensen, 2008). There may be functional relevance to a water-borne sex signal in fish that relies on chemically–unrelated metabolites to convey signal specificity, especially if the main hormonal component ($PGF_{2\alpha}$) is relatively common and there is considerable variation in the means by which it is produced, metabolized, and released.

The failure of male carp to distinguish between PGFs and the non-polar fraction of ovulated carp holding water, together with their preference for holding water (containing both non-polar and polar constituents), suggests that we have isolated all relevant PGs and that their activity is in fact synergized by non-hormonal polar products. Previous studies of the metabolism of radiolabeled $PGF_{2\alpha}$ in goldfish do not support the possibility that the polar products are metabolites of $PGF_{2\alpha}$ (Sorensen et al., 1995, unpublished). We hypothesize that the polar products may be amino acids, which are known to both be released by fish and detected with high sensitivity (Hara, 1994). It is interesting that these unknown polar products were not attractive to sexually active males on their own, suggesting that they provide contextual information whose use may vary with the maturation state of the receiver. These complexes may be used by all life history stages of fish, and their hormonal composition may change with maturational state. Interestingly, recent studies of half a dozen species of fish have now shown that juveniles can discern species identity of other juveniles (Sisler and Sorensen, 2008) and that common polar metabolites make a contribution to this odor complex, which also cannot contain sex hormone products (Levesque et al., 2011). It is conceivable that the same sets of polar compound(s) synergize the activity of the ovulated sex pheromone and convey species information in both juveniles and adults. Thus, species-identity may commonly be conveyed by

complex mixtures of hormonal and non-hormonal (polar) products in fish whose olfactory systems also appear capable of discerning complex olfactory information (Sorensen et al., 1998). Clearly, additional study of the pheromones used by other, more distantly related species is needed to resolve this issue.

The PGF release data collected by this study appear to be the first definitive data on prostaglandin release by a fish. While other studies have employed immunoassay or HPLC, which can be inaccurate, this study used a combination of ESI-MS/MS and immunoassay to both accurately identify the released compounds and quantify their release rates. The masses we identified are both distinctive for PGFs and the values generated for $PGF_{2\alpha}$ and dh15K-$PGF_{2\alpha}$ did not differ from those measured by ELISA, giving us a high level of confidence in our findings. Values previously measured in ovulated goldfish by using radioimmunoassay (Sorensen et al., 1988, 1995) are in fundamental agreement with those generated here, although a bit lower. However, previous studies have used different sized fishes with different numbers of eggs, and we still do not know the precise source of PGFs in fish. Nevertheless, the $PGF_{2\alpha}$ release rates for female carp were adequate to explain $PGF_{2\alpha}$'s behavioral activity in the mazes, given that the carp's olfactory detection threshold for this compound falls between 10^{-10} M and 10^{-11} M (Irvine and Sorensen, 1993; Lim, unpublished data). Notably, release rates of all three PGFs were about 100 times higher by ovulated than non-ovulated carp, making PGFs an excellent and reliable indicator of sexual activity for males. It seems likely that $PGF_{2\alpha}$ is mostly released in the urine of carp as in the goldfish (Appelt and Sorensen, 2007) and that this may enhance their effects in the wild.

In summary, this study establishes that the ovulated common carp, like many fish, release a PGF-based sex pheromone that is both potent and species-specific. Interestingly, although the female carp releases three PGFs, only $PGF_{2\alpha}$ is behaviorally active, and its activity is synergized by unidentified polar metabolites. If other fish also use pheromonal complexes it would explain how combinations of relatively common hormonal products can serve as species-specific pheromones. Research is now needed to identify these complex signals, elucidate their complete function, determine if they are used by other fish species, and to develop them for use as attractants to attract and remove the invasive carp, for which few control measures presently exist.

Acknowledgments This study was funded by the Invasive Animals Cooperative Research Centre (Canberra, Australia) and the Minnesota Agricultural Experiment Station. Both Gas Chromatography and an Electronic Nose Reflect Chemical Polymorphism of Juniper Shrubs Browsed or Avoided by Sheep

Abstract Chemical polymorphism may contribute to variation in browsing damage by mammalian herbivores. Earlier, we demonstrated that essential oil concentration in juniper, *Juniperus communis*, was negatively associated with herbivore browsing. The aim of the present study was to characterize the volatile chemical composition of browsed and non-browsed *J. communis*. By using either gas chromatography with flame ionization detection (GC-FID) or an electronic nose device, we could separate sheep-browsed or non-browsed juniper shrubs by their essential oil pattern and complex odor matrix. The main components of the essential oil from *J. communis* were monoterpenes. We distinguished three chemotypes, dominated either by α-pinene, sabinene, or δ-3-carene. Shrubs belonging to the α-pinene- or sabinene-dominated groups were browsed, whereas all individuals with the δ-3-carene chemotype were unused by the local herbivores. The electronic nose also separated the browsed and non-browsed shrubs indicating that their odor matrix could guide sheep browsing. Responses of sheep could integrate the post-ingestive effects of plant secondary metabolites with sensory experience that stems from odor–phytotoxin interactions. Chemotype diversity could increase the survival rate in the present population of *J. communis* as certain shrubs could benefit from relatively better chemical protection against the herbivores.

Key Words Chemical polymorphism · Chemotype · δ-3-carene · Electronic nose · Essential oil · *Juniperus communis* · Gas chromatography-flame ionization detection (GC-FID) · Odor · *Ovis aries* · α-pinene · Sheep

Introduction

Almost all plants produce secondary metabolites for their chemical defense against herbivores (Freeland and Janzen, 1974; Miller et al., 2005). The quantity and composition of plant secondary metabolites (PSMs) are key factors in plant chemical defense (Villalba and Provenza, 2005), as well as herbivore sensitivity and their coping capacity against toxins (Freeland and Janzen, 1974; Miller et al., 2005; Iason and Villalba, 2006). Plants that contain higher toxin concentrations benefit from relatively high biochemical protection against herbivores (Bryant et al., 1985) or belong to a relatively new and specific PSM polymorphism (Linhart and Thompson, 1999; Provenza et al., 2003). Chemical polymorphism can be manifested in chemotypes, which represent individuals with similar chemical metabolite composition and are usually designated by their main component (Schmidt et al., 2004).

In general, essential oils have strong antibacterial and antifungal effects (e.g., Angioni et al., 2003; Filipowicz et al., 2003). Such oils are repellents for insects such as moths (Rocchini et al., 2000) and beetles (Wibe et al., 1998). Feeding on big sagebrush, *Artemisia tridentata*, which is

high in terpenes, inhibits the cellulolytic activity of rumen microbes (Nagy and Tengerdy, 1968), and accordingly in high volumes it is toxic for ruminants (Schwartz et al., 1980a). Reduced food intake has been associated with plant items containing relatively high essential oil yield in the interaction of mule deer, *Odocoileus hemionus*, with different juniper species (*Juniperus deppeana, J. osteosperma, J. scopulorum*) (Schwartz et al., 1980b) or Spanish goats, *Capra bircus* with two juniper species (*J. ashei, J. pinchotti*) (Riddle et al., 1996).

The ability to discriminate among foods is critical for herbivore survival in an environment abundant in poisonous plants (Provenza et al., 1998). Herbivores must avoid or decrease PSM toxicity (e.g., Provenza, 1995; Dearing et al., 2000; Duncan et al., 2006; Rogosic et al., 2007) and may use the senses of smell and sight before feeding to prevent harmful consequences (Provenza et al., 1992; Provenza, 1996). Domestic sheep, *Ovis aries*, were able to avoid food items treated with common monoterpenes and discriminate them by their odor (Narjisse et al., 1996), and the same was observed in female red deer, *Cervus elaphus* (Elliott and Loudon, 1987). Augner and his colleagues (1998) observed that lambs preferred a weaker flavored food, because the more flavored food was associated with a higher toxin level.

Essential oils, such as the commonly produced PSM group of aromatic plants, are complex natural mixtures (Bakkali et al., 2008). Each component in an essential oil mixture could have a different kind of specific biochemical (toxicological) impact on herbivores (Nagy and Tengerdy, 1968) dependent on its molecule structure and/or its special functional group. Moreover, these components may produce either synergistic or antagonistic interactions with each other (Aparicio et al., 1996; Vokou et al., 2003) influencing the toxicity of the whole mixture. Furthermore, essential oil content shows high diversity with habitat and season (Riddle et al., 1996; Vourc'h et al., 2001; Gomez et al., 2003; Markó et al., 2008) and is also variable among individuals of a particular species (Miller et al., 2005).

Odor or flavor patterns can be measured by electronic sensory systems. Such devices, also called electronic noses, are rapid, objective, and reliable analytical tools for the detection and characterization of volatile and/or odorous compounds (El Barbri et al., 2008). An electronic nose is a detector that contains an array of different sensors and software processing sensor data without reference to the exact chemical composition. Until now, electronic noses have been used to detect and identify volatile compounds (Maricou et al., 1998), and to classify the complex aromatic features of herbs (Novák et al., 2001; Baby et al., 2005; Seregély and Novák, 2005). Their use is widespread in the food and beverage industry (Pearce, 1997b), as well as in quality monitoring (Hobbs et al., 1995; Hogben et al., 2004). The perception of different chemicals also may induce the same taste (Legin et al., 2003) or flavor (Cleland et al., 2002). As browsing animals are not likely to respond to individual chemical components but rather to differences in odor or taste patterns, one would expect a functional similarity in the odor mixture discrimination by an electronic nose and the herbivore (Pearce, 1997a).

Recently, Markó et al. (2008) found that both the concentration of PSMs and specific compounds of the essential oil may play a role in selective browsing damage. The main goal of this study was the characterization of the volatile chemical composition of the common juniper, *Juniperus communis* L., either browsed or non-browsed by sheep. First, we tried to separate the essential oil of differently browsed shrub groups by gas chromatography (GC) to see if browsing was affected by the essential oil composition. Second, we classified the differently browsed shrub groups with an electronic nose reflecting the odor matrix. Third, we compared the odor matrix with the pattern of essential oil composition. Finally, we investigated which terpenoids best reflected the odor matrix.

Methods and Materials

Sampling and Extraction of Essential Oils The samples originated from the juniper forest of the Kiskunság National Park central Hungary, near the area of Orgovány (46°47′30″N; 19°27′34″E). Heavily browsed (N=9) and non-browsed (N=9) shrubs of *J. communis* were chosen, and all plant material was collected at late winter. The sampling procedure was detailed in Markó et al. (2008). The size (height 2–2.5 m) and sex (female) of the sampled shrubs were similar, reducing the possible impact of these factors. The terminal 10–15 cm of foliage was clipped from several branches from ground level to a height of 2 m. Samples were 100–120 g of foliage after removal of berries. Plant material was gathered in plastic bags that were placed immediately in a cooler (5°C), until they were oven dried at 37±3°C (Memmert U-type oven). For the extraction of oil yield, the method of water-distillation with a Clevenger-apparatus described by Pharmacopoea Hungarica (Végh, 1986) was used. The content of essential oil was calculated as percentage of the dry mass.

Gas Chromatography The main chemical compounds of essential oils were analyzed by using a Shimadzu 14B GC equipped with a FID detector and SE-30 capillary column (30 m×0.25 mm, and 0.25 mm film thickness). The carrier gas was nitrogen (1 ml/min), and the split ratio was 75/1. The temperature of the oven was programmed as follows: 110°C for 3 min, up to 220°C at 8°C/min (5 min), 21.75 min analysis time, injector temperature was 220°C

and detector temperature was 250°C. Data were analyzed by using the Shimadzu Class VP Chromatography Data System (Shimadzu, Kyoto, Japan) software. Relative percentage of the oil constituent was calculated from the GC (FID) peak areas as percent of the total area by using the area normalization method (Novák et al., 2001, 2003). The identification of compounds was performed by peak enrichment with GC-standards from Carl Roth (Karlsruhe, Germany).

Electronic Nose Analysis Electronic nose determinations were performed with an NST 3320 instrument (Applied Sensor, Linköping, Sweden), with a built-in headspace autosampler for 12 samples, a detector unit containing 22 different sensors, and software for collecting and processing data from the sensors. The NST 3320 is equipped with 10 MOSFET (metal oxide semiconductor field effect transistor) sensors, 12 MOS (metal oxide semiconductor) sensors, and a humidity sensor for measuring relative humidity. Ambient air filtered through a drying column with silica gel and a combined moisture/hydrocarbon filter was used as a clean reference gas for the sensors. The gas flow rate of the dynamic sampling was set to 60 ml/min. The filtered gas flow to the sensors, and into the headspace of the samples at the same time, finally left the instrument into the ambient air.

The stand-by temperature, at which the samples were kept until their incubation phase, was set to 20°C (5 min). The analysis was started with the incubation at 40°C (5 min). The baseline phase of the measurement cycle timing was set to 10 sec, the sample phase to 30 sec, the recovery phase of the sensors to 260 sec, and the flush time of the gas lines to 60 sec. The total cycle time per sample was 5 min. Signal parameters were collected as follows: "baseline" for 5 sec, "on derivative" (derivative of the sensor signal during adsorption) for 4 sec and "on integral" (integral of the sensor signal during adsorption) for 10 sec, "response" for 5 sec, "off derivative" (derivative of the sensor signal during desorption) for 4 sec and "off integral" (integral of the sensor signal during desorption) for 10 sec. Sample amount and temperature conditions for the electronic nose analysis were optimized before the actual quality evaluations in the storage test.

We used 0.7 g of fresh juniper twigs from the same shrubs as described above for the GC-FID analysis. After removing the berries, twigs were crushed and put into the labeled vials, which were sealed with a Teflon-coated butyl septum and a screw cap. Electronic nose measurement was conducted at the Department of Refrigeration and Livestock Products Technology, Corvinus University of Budapest. The parallel analysis of samples collected from the same juniper shrubs allowed us to compare the results of the GC and the electronic nose analysis.

Statistical Analyses

Multivariate Statistical Analyses For the evaluation of the electronic nose sensor signal response of the sensor array, principal component analysis (PCA) was performed. The 22 sensor values were reduced to three principal components. Also, PCA was performed using the data set composed of all the essential oil samples transformed into centered and reduced variables (correlation method, varimax rotation). Selected variables consisted of absolute amounts of the identified compounds in the essential oil samples. The PCA is sensitive to rare or missing values, so the components less than 1% of the total samples were excluded from the analysis. The volume of each component was calculated from its relative ratio to the essential oil yield of each shrub. The use of absolute concentrations rather than relative amounts demonstrates that such calculations are not a statistical artifact of compositional data. In this way, we corrected for the total essential oil yield, which it is more realistic in sheep-juniper interactions.

Factor analysis was used to determine the main variables for each PC of the essential components. The scores from the PCA were inserted to the factor analysis. The first three factor loadings were included based on the eigenvalues (cumulative variance 85.07% in GC-FID).

General Linear Mixed Model After PCA, we used general linear mixed models (GLMM) to investigate the relationship between browsing status and the first three PCs of the electronic nose. Browsing status was a dependent variable and showed binomial distribution, while the PCs were used as covariates. We used GLMM to investigate the relationship between browsing status of the juniper shrubs and the first three PCs from GC-FID analysis. Browsing status was a dependent variable and showed a binomial distribution, while the PCs were included as covariates in the model.

In all GLMM models, we employed a stepwise analysis with a backward deletion procedure, removing insignificant effects from the model one by one in decreasing order of statistical significance and re-entering the removed variables to the final model to obtain relevant statistics. Statistica package (version 8.0, StatSoft, Inc. 2004, Tulsa, OK, USA) was used for all statistical analyses.

Results

Classification by Essential Oil Patterns We extracted essential oils from *J. communis* and identified their components (Table 1). The PCA distinguished the individual plants based on their browsed level with high power (85.07%) in the first three PCs, which are presented on

Table 1 Composition of the essential oils of the three chemotypes of *Juniperus communis* from Hungary

Components	Chemotype								
	δ-3-carene (*N*=4)			Sabinene (*N*=13)			α-pinene (*N*=1)		
	Mean (μl)	± SD	CI	Mean (μl)	± SD	CI	Mean (μl)	± SD	CI
α-Pinene	41.36	±5.61	3.18–20.93	46.33	±37.78	27.1–62.38	81.63		
Sabinene	0			121.20	±92.03	66–151.93	3.04		
δ-3-Carene	239.9	±117.64	66.65–438.66	3.54	±2.45	1.76–4.05	0		
β-Myrcene	24.16	±9.49	5.38–35.39	13.70	±8.47	6.08–13.99	3.77		
γ-Terpinene	20.28	±4.31	2.44–16.09	14.68	±6.42	4.61–10.61	21.05		
Borneol	21.65	±8.51	4.82–31.74	14.68	±8.57	6.15–14.15	0		
cis-Nerolidol	0			1.80	±2.62	1.89–4.34	0		
trans-Neroidol	9.04	±6.13	3.48–22.89	7.90	±6.31	4.53–10.42	1.95		
γ-Muurolene	0			3.74	±5.11	3.67–8.44	0		
Total volume of the essential oil	431.06	±170.06	96.34–634.09	283.36	±162.92	116.83–268.95	121.65		

Columns contain the mean values, standard deviations (SD) and confidence intervals (CI) of each chemotypes, which were calculated from the given sample size (*N*). The rows contain the main essential oil components

scatter plots with each other (Fig. 1b). The correlation plot of PC 2 and PC 3, and plot of PC 2 and PC 3 showed well classified groups. The scores of browsed shrubs were more aggregated than the values for the non-browsed junipers, similarly to the electronic nose classification. Furthermore, if we compare the scatter plots of the two patterns (Fig. 1a and b), we find the essential oil PCs less aggregated than the dots from the electronic nose analysis.

The GLMM analysis (Table 2) supports the PCA classification of the essential oil pattern. The PC 2, PC 3 and their interaction were significantly important in discrimination of the juniper individuals, while PC 1 was not significant in the model.

Factor Analyses of Gas Chromatography After PCA, reduction factor analyses was used to see which essential oil components belonged to each PC (Table 4). The first factor (PC 1) included almost all monoterpene components, e.g., β-myrcene, γ-terpinene, and borneol, whereas the dominant monoterpenes, such as α-pinene, sabinene, and δ-3-carene, composed the third factor (PC 3). The second factor (PC 2) grouped all the sesquiterpenes. The essential oil components showed that their retention times were close to each other. The retention time is reflected by the structure and weight of each molecule.

Sensory Classification by the Odor Matrix We measured the odor pattern of browsed and non-browsed *J. communis* by using an electronic nose apparatus; the sensor values were analyzed with PCA; the first three principal component (PC) scores were displayed in a scatter plot (Fig. 1a). Based on their browsed status, we could classify the odor patterns with high power (77.1%). The scatter plots between PC 1 and PC 3, and between PC 1 and PC 2 express the plant use best. These plots show that the browsed groups were well demarcated from the non-browsed groups, although there were three browsed individuals (numbers 2, 5, and 6) that seemed more similar to the non-browsed groups than to the browsed ones. The plots of PC 2 and PC 3 showed less determinant differences among the groups. Furthermore, the correlation plots showed that scores of browsed juniper individuals were more aggregated than the non-browsed junipers.

The GLMM analysis (Table 3) supported the PCA classification. Every PC was significantly important in the discrimination of the juniper individuals, and none of the interactions was significant in the model.

Discussion

We investigated the essential oil pattern of previously sheep-browsed and non-browsed *J. communis* and found that both the electronic-nose (e-nose) and GC separated the two groups. By using the e-nose, we also found that the juniper shrubs contained significantly different odor patterns depending on their browsed status. For studying the relationship between browsed status and essential oil patterns, we reduced the number of components by PCA. The factor analysis suggested that browsed and non-browsed shrubs differed in their mono- and sesquiterpene

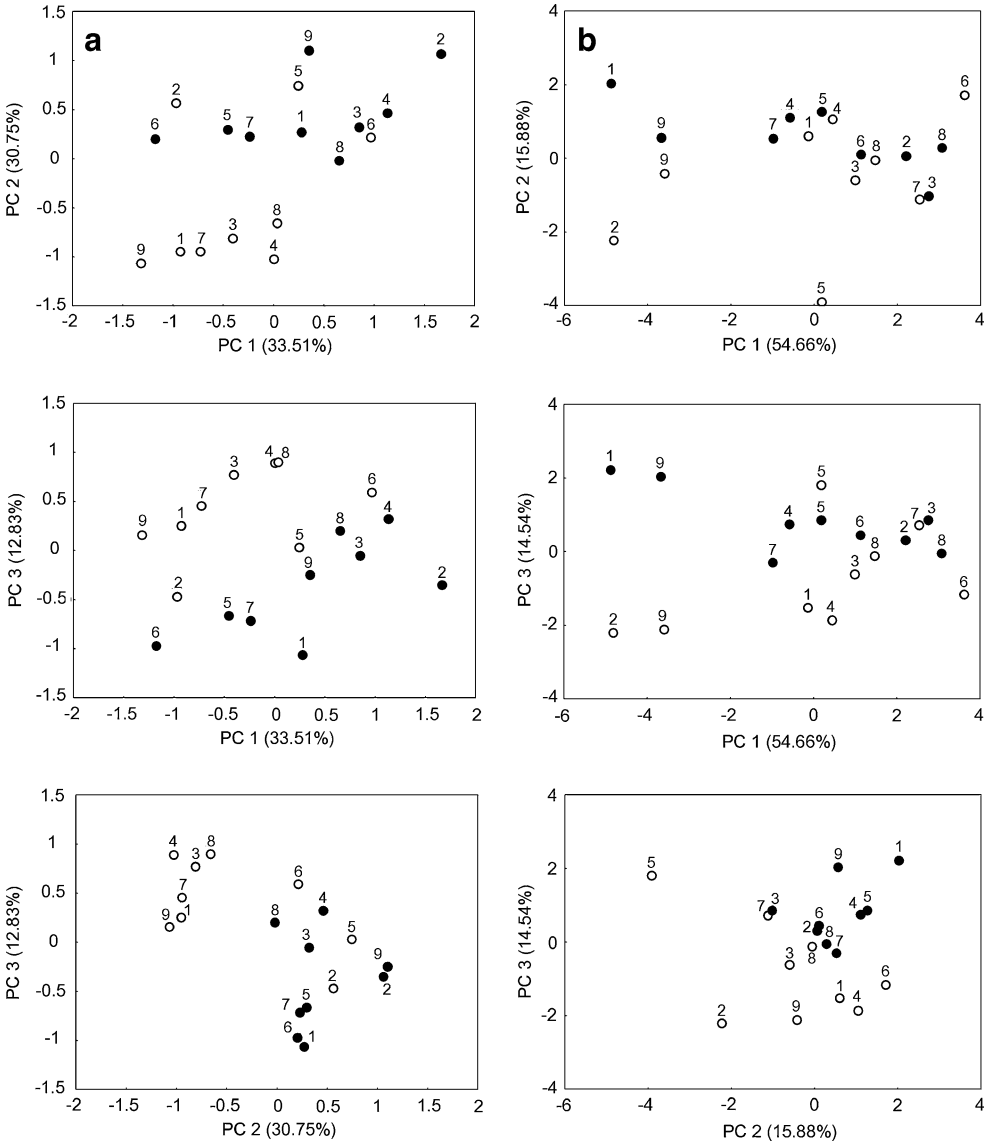

Fig. 1 Scatter plots of principal components (PC) showing the electronic-nose (**a**) and GC (**b**) discrimination of the juniper shrubs, *Juniperus communis*. The lines enclose the browsed (*empty circles*) and non-browsed (*full circles*) individuals, respectively; labels describe samples. The cumulative power of electronic-nose was 77.1% for the first three factors, whereas it was 85.1% for the GC. The browsed groups were well demarcated from the non-browsed groups, but some browsed shrubs (ID: 2, 5, 6) showed non-browsed odor characteristics in both classification methods

ratios (see Table 4). We distinguished three different chemotypes, dominated by α-pinene, sabinene, and δ-3-carene, respectively, in our juniper population. All shrubs belonging to the α-pinene were browsed, whereas all δ-3-carene chemotype individuals were unused by the local herbivores. Shrubs containing elevated levels of sabinene were mixed in their browsed status. However, the δ-3-carene chemotype has been reported for Scots pine, *Pinus sylvestris* L. (Thoss et al., 2007), but to our knowledge this

Table 2 *F*-statistics of GLMM analyses of gas-chromatography

The components are quoted by their retention order of GC analysis. The most important factors are indicated by stars (*) in each essential oil component

is the first study to identify uncommonly high amount of this monoterpene in *J. communis*.

The observed juniper population was rich in monoterpenes (Markó et al., 2008) similarly to other stands of this species (e.g., Adams and Pandey, 2003; Butkiene et al., 2004). The factor analysis of the essential oil pattern determined by GC resulted in three factors: F1 contained monoterpenes with medium retention times; F2 contained sesquiterpenes; whereas F3 was related to dominant monoterpenes. The relative importance of the dominant monoterpenes and the sesquiterpenes differed significantly between the two browsed statuses (Table 1). The first group included almost all monoterpene components, the second group incorporated all identified sesquiterpenes, while the dominant monoterpenes, such as α-pinene, sabinene, and δ-3-carene, composed the third group. Essential oil mixtures can show high terpenoid diversity containing 20–60 different components at quite different concentrations (Bakkali et al., 2008) and quite different toxicities (Oh et al., 1967), so grouping the components to find common patterns seems to be necessary to understand their effect in reducing herbivory.

Juniperus communis exhibits chemical polymorphism with geographical variation (Adams et al., 2003). A Swedish population showed high amounts of α-pinene, with moderate amounts of β-pinene, myrcene, limonene, δ-3-carene, and β-phellandrene, and low amounts of sabinene (Adams, 1998). Sabinene-type and α-pinene-type junipers have been described for Poland (Filipowicz et al., 2009) and Lithuania (Butkiene et al., 2007, 2009). The δ-3-carene has been described in many other juniper species (Adams, 1998; Angioni et al., 2003) and also in pines (Rocchini et al., 2000; Hiltunen and Laakso, 1995). PSMs, such as δ-3-carene, could be effective toxins, having a relatively unique molecular structure, because herbivores hardly ever cope with it. Despite these widely existing chemicals among conifers, plants might use them in their defense systems. The oil of *J. communis* with high carene content is effective against bacteria and fungi species (Angioni et al., 2003), and the same effect has been observed in insects (Rocchini et al., 2000; Almquist et al., 2006). δ-3-Carene has shown strong inhibition on the rumen microbial activity in sheep (Oh et al., 1967).

PSM production and composition are well studied in conifers. Among conifer taxons, terpenoid biosynthesis shows high similarity and the genetic regulation also is known (Trapp and Croteau, 2001; Fäldt et al., 2003). Terpene production and the relative amounts are genetically determined and expressed through specific enzymes, monoterpene synthetases (Huber et al., 2004; Martin et al., 2004). Thoss and colleagues (2007) found two different chemotypes, either δ-3-carene or α-pinene dominated, for *P. sylvestris*. They also found δ-3-carene production to be negatively associated with α-pinene concentration. The same biochemical trade-off between δ-3-carene and α-pinene was found in *J. communis* (Orav et al., 1997), similar to junipers of the chemotype in the present study. The δ-3-carene concentration is under strong genetic control (Hiltunen, 1975; Yazdani et al., 1982; Kinloch et al., 1986). In *Pinus taeida* L., variation in content of all major monoterpenes except α-pinene, such as β-pinene, myrcene, limonene, and β-phellandrene, seems to be controlled by two alleles at a single locus (Squillace et al., 1980).

In the present study, browsed and non-browsed juniper shrubs contained different odor patterns. We found that every δ-3-carene chemotype shrub was untouched. This chemotype contains a special essential oil composition pattern, which could be more aversive or toxic to sheep than the other chemotypes, such as α-pinene or sabinene. Chemical quality

of the essential oil can be linked to its unique odor matrix (Novák et al., 2001). We also should note that some browsed junipers (shrub ID: 2, 5, 6, see Fig. 1a) showed non-browsed odor characteristics. Supposing that the discrimination ability of sheep and our electronic nose is similar, there are two alternative hypotheses to explain this category overlap: browsing of junipers could be based on complex odor pattern recognition and selection, or avoidance of one specific component. Neurological bases of mammalian olfaction enabling pattern recognition are well known (Buck and Axel, 1991; Vosshall et al., 2000), and their importance in sheep also has been demonstrated (Lledo et al., 2005). Such similarity in the categorization of junipers by sheep and electronic nose suggests that discrimination in both sheep browsing and in the electronic nose analysis may have common bases.

The sensing ability of sheep is crucial for avoiding unpalatable or poisonous plants and for survival (Provenza et al., 1998). Unpalatable food plants often have strong or unpleasant odors and/or taste (Eisner and Grant, 1981). Sheep are able to discriminate different kind of aromatic food items, containing volatile compounds. In an aversion learning study, Augner et al. (1998) found that they preferred weaker flavors over strong ones, because the animals learned to associate the flavor with toxicity and avoided the conditioned flavor depending on its concentration. Narjisse et al. (1996) reported that sheep exposed to the aroma of a monoterpene mixture during feeding discriminated against feed associated with the terpene mixture. Other ruminants also are able to discriminate odors on the basis of the quality of their food. Red deer rejected a pelleted diet while being exposed to the odor of widespread monoterpenes, including α-pinene (Elliott and Loudon, 1987). Monoterpenes also have been shown to be related to shrub use by goats (Riddle et al., 1996). Estell et al. (1998) found that the negative influences of specific monoterpene (α-pinene and camphor) concentrations on pellet consumption could explain differential herbivory of individual tarbush plants.

Herbivores may have different kinds of effective, non-exclusive mechanisms to avoid poisoning. We propose several alternative explanations for the avoidance of δ-3-carene chemotype individuals. The first may be that sheep food choice is conservative, thus the new chemical variant could be an unfamiliar food option for them. As Van Tien and his colleagues (1999) demonstrated, sheep readily eat foods with a familiar odor, but if an unfamiliar food is presented, the animals show aversion. The second explanation could be that the δ-3-carene dominated individuals are relatively new phenotypic variants among junipers in our stand. Therefore, herbivores have not yet developed defense mechanisms to cope with this special and potent toxin mixture. The chemical polymorphism in the studied juniper population might indicate an ongoing adaptation against local herbivory (Markó et al., 2008), because it might provide relatively higher protection against local herbivores unique in consuming junipers.

Varying enantiomeric composition of certain monoterpenoids could be a third alternative explanation for the relationship of differential browsing and odor characteristics. Several studies have proven the importance of enantiomers on the effect of odors (Friedman and Miller, 1971; Leitereg et al., 1971; Laska et al., 1999) or their influence on other biological activities (Norin, 1996; Wibe et al., 1998; Filipowicz et al., 2003). Enantiomeric composition of monoterpenes has been investigated in *J. communis*, and α-pinene, sabinene, and myrcene were found as the most varied components (Ochocka et al., 1997). In other juniper populations, δ-3-carene occurred almost entirely as the (+)-enantiomer, whereas the enantiomeric composition of other monoterpenes was highly variable (Hiltunen and Laakso, 1995; Filipowicz et al., 2006). The same pattern was found in *P. sylvestris*, where large differences were found in the enantiomeric ratios among monoterpenes, but in δ-3-carene only the (+)-enantiomer was detected (Sjödin et al., 1996).

Nutrients and PSMs do not act in isolation in determining the level of herbivory (Villalba and Provenza, 2005). Partial preferences for certain plant species have been attributed to the inability of herbivores to discriminate among related plant species (Illius et al., 1999), limited perception (Berec, 2000), attempts to meet nutritional needs (Westoby, 1978), or reducing intake of poisonous food (Freeland and Janzen, 1974). The emerging evidence that integrates biochemical interplay between plant species and browsers suggests that varied diets result from the experience with nutrients and toxins (Provenza, 1995; Provenza et al., 2003). Responses of herbivores integrate the post-ingestive effects of PSMs with sensory experience that results in odor–nutrient–phytotoxin interactions.

Acknowledgments We are grateful to Zsolt Seregély for his contribution to the electronic nose measuring. We are also grateful to our referees for their useful comments. We thank Robyn Elisabeth Hudson for her linguistic revision on previous versions of the manuscript. We also thank the Kiskunság National Park for the support of our field surveys. During the manuscript preparation GM was supported by TÁMOP-4.2.1./B-09/1-KMR-2010-0005.

Abstract Earlier work has shown that adult male *Prionus californicus* Motschulsky (Coleoptera: Cerambycidae) are attracted to the female-produced compound (3*R*,5*S*)-3,5-dimethyldodecanoic acid, and to a synthetic mixture of the four stereoisomers of 3,5-dimethyldodecanoic acid. Here, we report the results of field trials that tested whether or not three structurally related compounds (methyl 3,5-dimethyldodecanoate, 3,5-dimethyltridecanoic acid, and 3,5-dimethylpentadecanoic acid), present in extracts of virgin females, are attractive, and whether or not they influence attraction to 3,5-dimethyldodecanoic acid. In a trial with single components, only traps baited with the acid or its methyl ester captured more beetles than did control traps; catches to the acid were five times higher than to the methyl ester. Another trial, excluding 3,5-dimethyldodecanoic acid, confirmed the activity of the methyl ester. Finally, addition of the three compounds to 3,5-dimethyldodecanoic acid, in the ratio found in extracts from female beetles, gave a catch similar to that of traps baited with 3,5-dimethyldodecanoic acid alone. Consequently, the function of these minor compounds remains undetermined.

Key Words Prioninae · Pest management · Pheromone · (3*R*,5*S*)-3,5-dimethyldodecanoic acid · Coleoptera · Cerambycidae

Introduction

A number of insects including the herald moth, *Scoliopteryx libatrix* L, and the peach twig borer, *Anarsia lineatella* Zeller, produce novel, branched alkanes, alkenes, and alcohols (Francke et al., 2000; Schlamp et al., 2005). Adult females of the cerambycid beetle *Prionus californicus* Motschulsky produce a volatile sex pheromone, (3*R*,5*S*)-3,5-dimethyldodecanoic acid, to which males are strongly attracted, and which has potential as a management tool (Rodstein et al., 2009, 2011; Maki et al., 2011). Males responded as strongly to a synthetic mixture of the four stereoisomers of 3,5-dimethyldodecanoic acid as they did to the natural enantiomer, indicating that the unnatural stereoisomers were not inhibitory (Rodstein et al., 2011). Antennae of male *P. californicus* responded most strongly to 3,5-dimethydodecanoic acid in coupled gas chromatography-electroantennography (GC-EAD) studies, and also responded to three other compounds, the methyl ester of 3,5-dimethyldodecanoic acid and the homologs 3,5-dimethyltridecanoic acid and 3,5-dimethylpentadecanoic acid, that were present in solid phase microextraction (SPME) wipe samples of ovipositors

(Rodstein et al., 2009). Here, we report field trials testing these compounds.

Methods and Materials

Field sites were commercial hop yards in Canyon Co., ID, USA, which were infested with *P. californicus*. We used pitfall traps made of polypropylene buckets (19 l, 38 cm tall×30 cm diam.) fitted with aluminum funnels (model 2815B, BioQuip, Rancho Dominguez, CA, USA). Traps were buried between rows of hop plants, with tops of funnels flush with the soil surface, at least 27 m from the margins of hop yards. We conducted three independent bioassays at different times during 3–15 July 2009 (max. air temp: 28–36°C; average wind speed: 2.4–15.5 $km.h^{-1}$; 0.18 cm of precipitation on 15 July).

In Bioassay 1, we compared the attractiveness of the four individual compounds. Compounds were synthesized non-stereoselectively as mixtures of all four possible stereoisomers in approximately equal proportions (≥90% chemical purity), using the methods of Rodstein et al. (2009), and described in the online Supplementary Information. Lures were clear, low-density, polyethylene press-seal bags (Bagette model 14770, 5.1×7.6 cm, 0.05 mm wall thickness, Cousin Corp., Largo, FL, USA), with 10 mg of synthetic compounds, diluted to 100 µl in hexane (HPLC grade, Chromasolv®, Sigma-Aldrich, St. Louis, MO, USA), or 100 µl hexane alone (controls). Lures were attached to the wire bucket handles, which had been modified to remain upright. Treatments were randomly assigned to traps, positioned 18 m apart in each of three commercial hop yards, which were at least 0.4 km apart. The bioassay was repeated for another 3 d in two of the hop yards, re-randomizing treatments daily, to yield nine replicates. Each morning we recorded the number of male *P. californicus* trapped during a night. Differences between treatments in the number of beetles caught were tested with the nonparametric Friedman's test (blocked by day and hop yard; Proc Freq with CMH option; SAS Institute, 2001). We tested differences between pairs of means with the REGWQ means separation test to control maximum experiment-wise error rates (SAS Institute, 2001).

Because 3,5-dimethyldodecanoic acid could affect attraction of males by the other compounds, either positively (by attracting beetles into the vicinity of traps) or negatively (by competing against the other compounds), we compared the activity of 3,5-dimethyldodecanoate, 3,5-dimethyltridecanoic acid, and 3,5-dimethylpentadecanoic acid, in the absence of 3,5-dimethyldodecanoic acid, in Bioassay 2. We used the same methods and hop yards as in Bioassay 1. The bioassay was replicated in two hop yards over 4 d, re-randomizing treatments daily, to yield eight replicates. Data were analyzed as above, excluding one replicate that caught no beetles.

In Bioassay 3, we compared the activity of 3,5-dimethyldodecanoic acid alone vs. a blend of all four compounds that approximated their proportions in extracts of ovipositors (Rodstein et al., 2009). For the latter treatment, lures were loaded with 100 µl of a stock solution of 100 mg of 3,5-dimethyldodecanoic acid, 2.4 mg of methyl 3,5-dimethyldodecanoate, 36 mg of 3,5-dimethyltridecanoic acid, and 133 mg of 3,5-dimethylpentadecanoic acid, diluted to 1 ml in hexane. We used the methods described above, replicating the experiment in four commercial hop yards (including two used in the other bioassays). Treatments were re-randomized daily for 3 days and on a 4th day in one yard, yielding 13 replicates. Differences between treatments in catches of male *P. californicus* were tested with a paired *t*-test, after the normality of data was confirmed using the Shapiro-Wilk test for normality (SAS Institute, 2001). We present means ± 1 SE throughout.

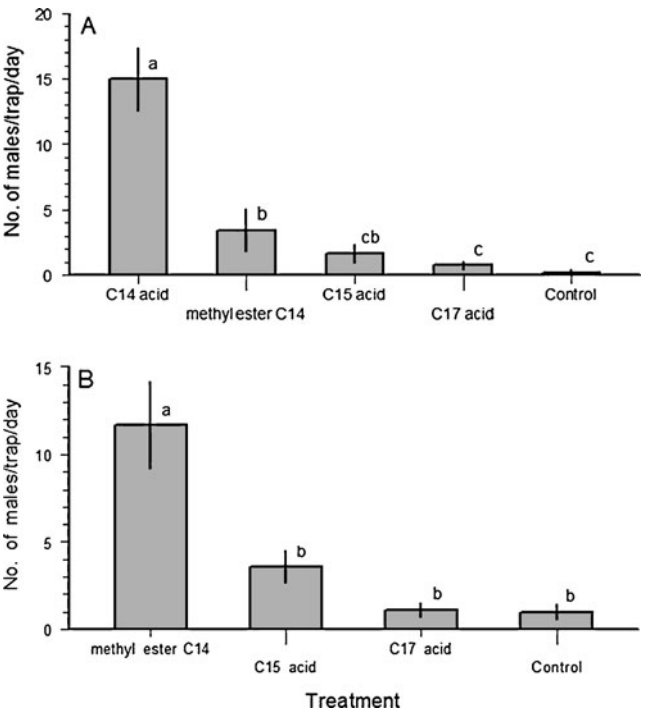

Fig. 1 Mean (± 1 SEM) numbers of male *Prionus californicus* captured by traps baited with various compounds (as mixtures of stereoisomers) that are released by females: **A**) Bioassay 1, **B**) Bioassay 2. Compounds tested were: 3,5-dimethyldodecanoic acid (C14 acid), methyl 3,5-dimethyldodecanoate (methyl ester C14), 3,5-dimethyltridecanoic acid (C15 acid), and 3,5-dimethylpentadecanoic acid (C17 acid). Control traps had lures of hexane only. Bars with the same letters are not different (REGWQ means-separation test) at $P<0.05$

Results and Discussion

No female *Prionus californicus* were captured in any bioassay. In Bioassay 1, only traps baited with 3,5-dimethyldodecanoic acid or its methyl ester captured more male *P. californicus* than did controls. Traps baited with the acid captured more than five times as many beetles as those baited with the methyl ester (Fig. 1A; Friedman's $Q_{4,45}$= 27.9, P<0.001). The activity of the methyl ester, in the absence of 3,5-dimethyldodecanoic acid, was confirmed in Bioassay 2 (Fig. 1B; Friedman's $Q_{3,28}$=115.1, P<0.002). These results suggest that the methyl ester is moderately attractive to male beetles, consistent with a stronger antennal response in GC-EAD analyses to that compound, relative to homologs of the acid (Rodstein et al., 2009).

Despite the activity of the methyl ester when tested alone, the reconstructed blend of components that mimicked the ovipositor extracts was no more attractive to males than 3,5-dimethyldodecanoic acid alone (means: 8.3±1.9 and 9.0±2.1 males/trap/day, respectively; not different, paired t-test P= 0.45). Although it is possible that one or more of the pure stereoisomers of these analogs might affect attraction to 3,5-dimethyldodecanoic acid, this seems unlikely, as any antagonistic effect from a particular stereoisomer would likely be manifested despite the presence of its stereoisomers. Similarly, it is unlikely that any synergistic effect from a particular stereoisomer would exactly cancel out effects by one or more of the other stereoisomers.

That possible minor components have no apparent effect on attraction of beetles to 3,5-dimethyldodecanoic acid, coupled with the fact that the unnatural stereoisomers of (3*R*,5*S*)-3,5-dimethyldodecanoic acid have no effect on its activity (Rodstein et al., 2011), will simplify development of the pheromone for management of *P. californicus*.

Acknowledgments We thank Brenda Nelson for technical assistance, and the growers of the Idaho Hop Commission for access to study sites. Signal Honesty through Differential Quantity in the Female-Produced Sex Pheromone of the Moth *Heliothis virescens*

Stephen P. Foster · Chris P. Johnson

Received: 1 March 2011 / Revised: 12 May 2011 / Accepted: 7 June 2011 / Published online: 18 June 2011

Abstract Over the last 50 years, female-produced sex pheromones of moths have been subjected to intensive study. Most work has focused on their role in mate recognition, and little on any role they may have in mate assessment. This is largely because it has been assumed that female, rather than male, moths are "choosy", and invest larger amounts of carbon in eggs than in pheromone. Recently, we found that pheromone production in the moth *Heliothis virescens* depended on hemolymph trehalose concentration, and that sugar-stressed females produced less pheromone than unstressed ones. In this paper, we demonstrate, for the first time in moths, that a female-produced pheromone signal can allow *H. virescens* males to assess sugar resources (quality) of a female. This signal honesty is based on quantitative, rather than qualitative (component ratio), differences in pheromone, produced and released by sugar-stressed and unstressed females. Increasing marginal cost of pheromone production, as sugar resources are depleted, may ensure signal honesty.

Introduction

Chemical signals can be used to recognize mates or, more profoundly, to choose a mate based on fitness benefits the signal receiver may obtain from mating (Johansson and Jones, 2007). A key principle of the latter is that the signal should honestly represent the differential quality of the signaler, allowing a receiver to choose a mate to maximize his/her fitness (Hausken and Hirshleifer, 2004). Most work on pheromone mating signals has focused on their role in recognition, although examples (reviewed in Johansson and Jones, 2007) in which they enable mate assessment are known. This work on mate assessment in mating signals typically has focused on female assessment of male quality (e.g., Iyengar et al., 2001; Lassance and Löfstedt, 2009) because, in sexual selection theory, females are generally considered the "choosy" sex, investing more resources in reproduction than do males (Trivers, 1972). However, mate assessment by males is known in animals (Bonduriansky, 2001), and in insects it is known to occur through assessment of female size (e.g., Rhainds et al., 1995; Van Dongen et al., 1998), which typically correlates with fecundity (e.g., Xu and Wang, 2009).

Female-produced sex pheromones of moths are legendary for specificity and potency at minute concentrations (Wyatt, 2003). In most moth species, individual isolated females release sex pheromone that attracts conspecific males. The chemistry of, and perception and behavioral responses of males to, these signals have been studied intensively (Witzgall et al., 2010) within the context of mate recognition (Johansson and Jones, 2007). While a number of studies have shown that male moths can discriminate among females, based on pheromone compo-

nent ratios (e.g., Collins and Cardé, 1989; Allison and Cardé, 2008), none has shown that male discrimination of signals among females has fitness consequences.

Recently, we found that pheromone production in mated and virgin females of the polyandrous moth, *Heliothis virescens* (Fabricius) (Lepidoptera: Noctuidae), depended on feeding status (Foster, 2009; Foster and Johnson, 2010). Adults of this species, like many other Lepidoptera, feed on plant nectar (Ramaswamy et al., 1997; Wäckers et al., 2007). Sugar feeding resulted in an increase in hemolymph trehalose concentration (HTC) that, in turn, caused increases in pheromone and fatty acid precursors. This effect occurred only in sugar-stressed females (i.e., with low HTC; Foster, 2009), caused by prolonged starvation or mating, the latter lowering HTC through increased oocyte maturation (Ramaswamy et al., 1997; O'Brien et al. 2000).

As nectar feeding causes large increases in fecundity of females of *H. virescens* (Ramaswamy et al., 1997), and in Lepidoptera in general (Wäckers et al., 2007), we hypothesized that quantitative pheromone differences between sugar-replete and sugar-stressed females may be perceived by males, and thus might honestly signal female quality. In this manuscript, we demonstrate, for the first time, that the sex pheromone produced by a female moth acts as an honest signal of female quality (sugar resources) and potential fitness benefits to males. This honesty is conveyed quantitatively (amount) rather than qualitatively (component ratios).

Methods and Materials

Insects Insects were from a colony originally supplied by Dr W.L. Roelofs (Cornell University, Geneva, NY, USA). Larvae were reared on a wheat germ-casein diet at 25°C under a 16:8 h L:D photoperiod. After pupation, insects were sexed, and females and males kept in separate incubators under the same conditions as larvae.

Adult females, 4–5 per container, were given either 10% sucrose solution or water, on cotton wool, to feed. The liquid was changed daily. Mated females were obtained by placing 1-d-old virgins with an excess of virgin males (2-3-d-old). Females that mated were placed in a container with their previous food (sugar or water) and used 2 d after mating (when 3-d-old). Sugar-stressed virgins were obtained by allowing females to feed on water for 4 or 5 d (Foster and Johnson, 2010). Younger virgins (1- or 3-d-old), fed on water or sugar, were used as unstressed controls.

Pheromone Analyses The pheromone gland of a female was dissected at one of three times in the scotophase: beginning (0–0.5 h), mid (3.75–4.25 h), and end (7.5–8 h). The gland was extracted in 10 µl *n*-heptane, with 50 ng of (*E*)-11-tetradecenal as internal standard, for at least 3 h at ambient temperature before analysis by gas chromatography–mass spectrometry (GC-MS) on a Hewlett-Packard 5890–5972 system, fitted with a 30 m×0.25 mm i.d. ZB-Wax column (Phenomenex, Torrance, CA, USA). The GC oven was programmed from 80–180 at 15°C/min, following a delay of 1 min, and then to 200 at 3°C/min. Samples were injected splitlessly, with helium as carrier gas at 1 ml/min. Mostly, only the titer of the major pheromone component, (*Z*)-11-hexadecenal (Z11-16:Ald; Roelofs et al., 1974), was measured, as all *de novo* fatty acids and derived compounds are influenced by sugar feeding (Foster and Johnson, 2010). However, ratios of Z11-16:Ald: (*Z*)-9-tetradecenal (Z9-14:Ald), together capable of eliciting male flight (Vetter and Baker, 1983), were measured for 5-d-old virgins, to preclude the possibility that differences in male responses were caused by changes in female blend ratios. The identities of the two pheromone components was confirmed by comparison of their retention times and mass spectra with those of synthetic standards available in the laboratory.

Pheromone was collected from two 4-d-old virgins (either sugar- or water-fed) in a 200 ml glass cylinder with inlet and exhaust ports. Activated charcoal-purified air was pushed through the cylinder at 160 ml/min, and volatiles were collected on 150 mg of Tenax GC (60–80 mesh; Alltech Assoc., Deerfield, IL, USA) packed between two plugs of glass wool in a Pasteur pipette. The adsorbent was conditioned at 220°C for at least 1 h under nitrogen flow. Pheromone was collected for three periods: 0–2 h, 2–4 h, and 4–6 h of the scotophase. After collection, 50 ng of E11-14:Ald were placed on the glass wool, and chemicals eluted with 1.3 ml of *n*-hexane. The solvent was evaporated to 20 µl using nitrogen, and pheromone determined by GC-MS.

The MS was operated in the selected-ion mode, recording *m/z* 192 (E11-14:Ald and Z9-14:Ald) and 220 (Z11-16:Ald). Pheromone quantity or ratio was determined by integration of peak areas, with *m/z* intensities calibrated by standard solutions. In the text and figures, pheromone quantity is the amount of Z11-16:Ald.

Mating Frequencies and Times The propensity of sugar- and water-fed females (virgin and mated) to mate was determined in confined conditions. A single female and male (virgin, 1-2-d-old) were placed in a 150 ml container (Solo Cup Co., Urbana, IL, USA) 1 h before the onset of the scotophase. Pairs were observed every 15 min, over the next 9 h or until all had copulated. The time that copulation commenced was recorded.

Male Responses to Females The ability of sugar- or water-fed females (virgin or mated) to elicit male upwind flight was tested in a wind tunnel. Just prior to the scotophase,

females were placed individually in 30 ml containers (Solo Cup Co.), with nylon mesh lids and bases. A 0.45 m diam× 1.3 m long cylindrical wind tunnel, constructed from clear acrylic, was used. Smoothed air was pushed through the tunnel, by a fan, at 30 cm/sec. The tunnel floor was a 20 cm-wide white laminate sheet, with random 7.5 cm diam black circles for visual orientation, and was illuminated to 2 lux by six overhead, voltage-regulated tungsten lamps. An exhaust fan removed pheromone from the room.

Insects were tested at two times: from 0.5–2.5 h (early) and from 3–5 h (mid) of the scotophase. These periods were used because, peak sexual activity occurs at mid-scotophase (Heath et al., 1991), and because of the potential mating benefit for females by attracting males earlier in the scotophase. We tested 22 to 41 females for each treatment, alternating sugar- and water-fed females. This allowed us to reduce any problem of female variability, as well as compare proportions of females that elicited a full response (touch) from at least one male. We tested 3 males to each female, roughly over a 5 min period. Female *H. virescens* call continuously for multiple periods, each of up to an hour, throughout the scotophase (Ramaswamy, 1990). Therefore, we likely tested a female either when she was calling or not calling.

A female was placed on a 15-cm high stand, at the upwind end of the tunnel, so that the mesh ends of the container were in line with the airflow. Females acclimated for 3 min in the tunnel, before a male was released at the downwind end. The response of a male was recorded as: (1) whether or not it fanned wings ("activation") within 3 min of being in the tunnel, (2) whether or not it exhibited sustained flight upwind, orienting to a female ("upwind flight"), and (3) whether or not it contacted the female's container ("touch").

Statistical Analyses Experiments were conducted as paired blocks of sugar- and water-fed females, of a particular age and mating status. For pheromone analyses, sugar- and water-fed females, of a given age and photoperiodic time, were compared by ANOVA, after first confirming normality and heteroscedasity. For the bioassays, the various proportions (copulation, flight responses, females that elicited at least one male to "touch") of sugar- and water-fed females were compared using likelihood ratio *chi-square* tests. Mean times of copulation commencement were compared by ANOVA, after confirming normality and heteroscedasity.

Results

Pheromone Analyses Sugar- and water-fed 1-d-old virgins had similar pheromone titers (beginning $F_{1,26}=0.82$, $P=0.37$; mid $F_{1,20}=1.53$, $P=0.23$; end $F_{1,22}=1.74$, $P=0.20$) at each of the three scotophase times (Fig. 1a). Sugar- and water-fed 3-d-old virgins had similar titers at mid ($F_{1,27}=0.30$, $P=0.59$) and end scotophase ($F_{1,30}=1.80$, $P=0.19$), but sugar-fed females had greater ($F_{1,32}=9.95$, $P=0.004$) titers than water-fed ones at the beginning (Fig. 1b). Five-d-old sugar-fed virgins had greater pheromone titers at each of the three periods throughout the scotophase (beginning $F_{1,28}=5.11$, $P=0.032$; mid $F_{1,26}=23.9$, $P<0.001$; end $F_{1,32}=4.27$, $P=0.047$) than did water-fed females (Fig. 1c). Sugar-fed mated females had greater titers than water-fed ones, at the beginning ($F_{1,27}=4.35$, $P=0.047$) and middle ($F_{1,31}=4.93$, $P=0.034$), but not the end ($F_{1,28}=0.81$; $P=0.35$), of the scotophase. Overall, regardless of age and feeding status, titers increased from beginning to mid, and declined by the end of scotophase.

There was no difference ($F_{1,33}=1.37$; $P=0.25$) in mean ratio of Z11-16:Ald: Z9-14:Ald produced by 5-d-old sugar- (mean=100: 4.22±0.49; $N=17$) and water-fed (mean=100: 5.03±0.48; $N=18$) virgins.

Pheromone amount released by 4-d-old virgins was greater for sugar- than water-fed females, for each period (0–2 h $F_{1,18}=6.27$, $P=0.022$; 2–4 h $F_{1,19}=4.45$, $P=0.048$; 235 4–6 h $F_{1,16}=7.76$; $P=0.013$) (Fig. 2). Pheromone amount released, increased through the scotophase for both types of females.

Mating Frequencies and Times For 3-d-old virgin ($\chi^2=1.30$, $P=0.26$), 5-d-old virgin ($\chi^2=0.93$, $P=0.33$) and mated ($\chi^2=2.24$, $P=0.14$) females, there were no differences between the respective proportions of sugar- and water-fed females that mated (Fig. 3). The mean time that copulation commenced was similar for sugar- and water-fed females for 3-d-old virgins, 5-d-old virgins and mated females, with most copulations occurring between the hour preceding onset and the second hour of scotophase (Fig. 3).

Male Responses to Caged Females Activation (early $\chi^2=2.15$, $P=0.34$; mid $\chi^2=0.20$, $P=0.65$), upwind flight (early $\chi^2=1.25$, $P=0.54$; mid $\chi^2=0.12$, $P=0.73$); and touch (early $\chi^2=1.06$, $P=0.59$; mid $\chi^2=0.26$, $P=0.61$) responses of males were similar to sugar- and water-fed 3-d-old virgins, at both periods of the scotophase (Fig. 4a). Very high, and similar, proportions of sugar- or water-fed females elicited touch from at least one male at both early ($\chi^2=0.17$, $P=0.68$) and mid ($\chi^2=1.46$, $P=0.23$) scotophase (Fig. 4a).

Greater proportions of males activated (early $\chi^2=19.5$ $P<0.001$; mid $\chi^2=14.9$, $P<0.001$), flew upwind (early $\chi^2=18.6$ $P<0.001$; mid $\chi^2=29.9$, $P<0.001$); and touched (early $\chi^2=13.5$ $P<0.001$; mid $\chi^2=25.9$, $P<0.001$) cages containing 5-d-old sugar-fed virgins than cages containing 5-d-old water-fed virgins, at both time periods (Fig. 4b). The proportion of females that elicited touch from at least one

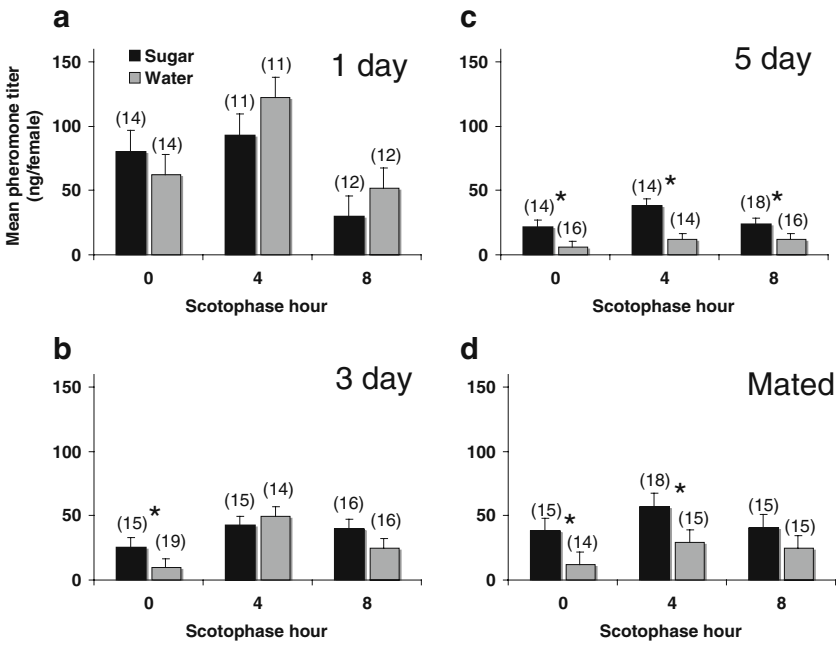

Fig. 1 Mean sex pheromone titers, at different scotophase times, of female *Heliothis virescens* fed on either 10% sucrose or water: **a** 1-d-old virgins, **b** 3-d-old virgins, **c** 5-d-old virgins, and **d** 3-d-old mated females. An asterisk above a pair of titers shows means that are different at $P<0.05$ (ANOVA). Ns are in parentheses

male was greater for sugar- than water-fed females, at both early ($\chi^2=8.35$, $P=0.004$) and mid ($\chi^2=15.5$, $P<0.001$) scotophase (Fig. 4b).

Sugar-fed, mated females elicited greater upwind flight (early $\chi^2=10.5$, $P=0.001$; mid $\chi^2=6.03$, $P=0.011$); and touch ($\chi^2=9.84$, $P=0.002$; mid $\chi^2=8.55$, $P=0.004$) responses from males than did water-fed, mated females, at both times. Activation was similar ($\chi^2=0.33$, $P=0.56$) to both female types at early, but greater ($\chi^2=7.41$, $P=0.007$) to sugar-fed females at mid-scotophase. The proportions of cages containing mated females touched by at least one male were similar ($\chi^2=0.26$, $P=0.61$) for both types (sugar- or water-fed) at early, and greater ($\chi^2=4.53$, $P=0.033$) for sugar-fed females at mid-scotophase.

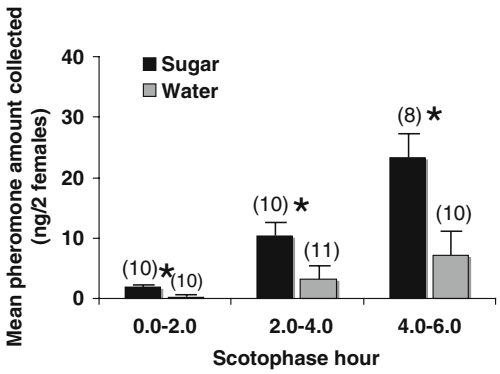

Fig. 2 Mean amount of sex pheromone released by 4-d-old virgin *Heliothis virescens* females, fed on either 10% sucrose or water, collected at different periods of the scotophase. An asterisk above a pair of titers shows means that are different at $P<0.05$ (ANOVA). Ns are in parentheses

Discussion

Honest signals for mate assessment must convey information to the receiver about the quality of a signaler, thereby enabling reliable differentiation of high quality signalers from low quality ones (Johansson and Jones, 2007). Signal honesty is thought to be maintained by increasing signal cost to signalers that can least afford it (Zahavi, 1977; Grafen, 1990). Here, we demonstrated that pheromone production and release by *H. virescens* sugar-replete females was greater than that by sugar-stressed females, and that greater proportions of males responded to the sugar-replete females than to the stressed ones. Our data do not allow us to distinguish between whether this quantitative difference is a function of different amounts released, or different intermittencies between release (calling), although the pheromone titer and male response data suggest the former is more likely. This quantitative difference in pheromone signal is related to female quality, with sugar-replete female *H. virescens* producing many more eggs than sugar-stressed ones (Ramaswamy et al., 1997). Thus, males benefit by distinguishing between females based on pheromone quantity. Moreover, sugar-replete females are likely to benefit from releasing more pheromone by increasing their chance of obtaining mates, particularly by competing more successfully for males earlier in the scotophase. As mating delays cause decreased fecundity in moths (e.g., Jiménez-Pérez and Wang, 2003), the benefit of mating earlier can be substantial for both sexes. Increased likelihood of further mating is important for mated females as, in polyandrous species such as *H.*

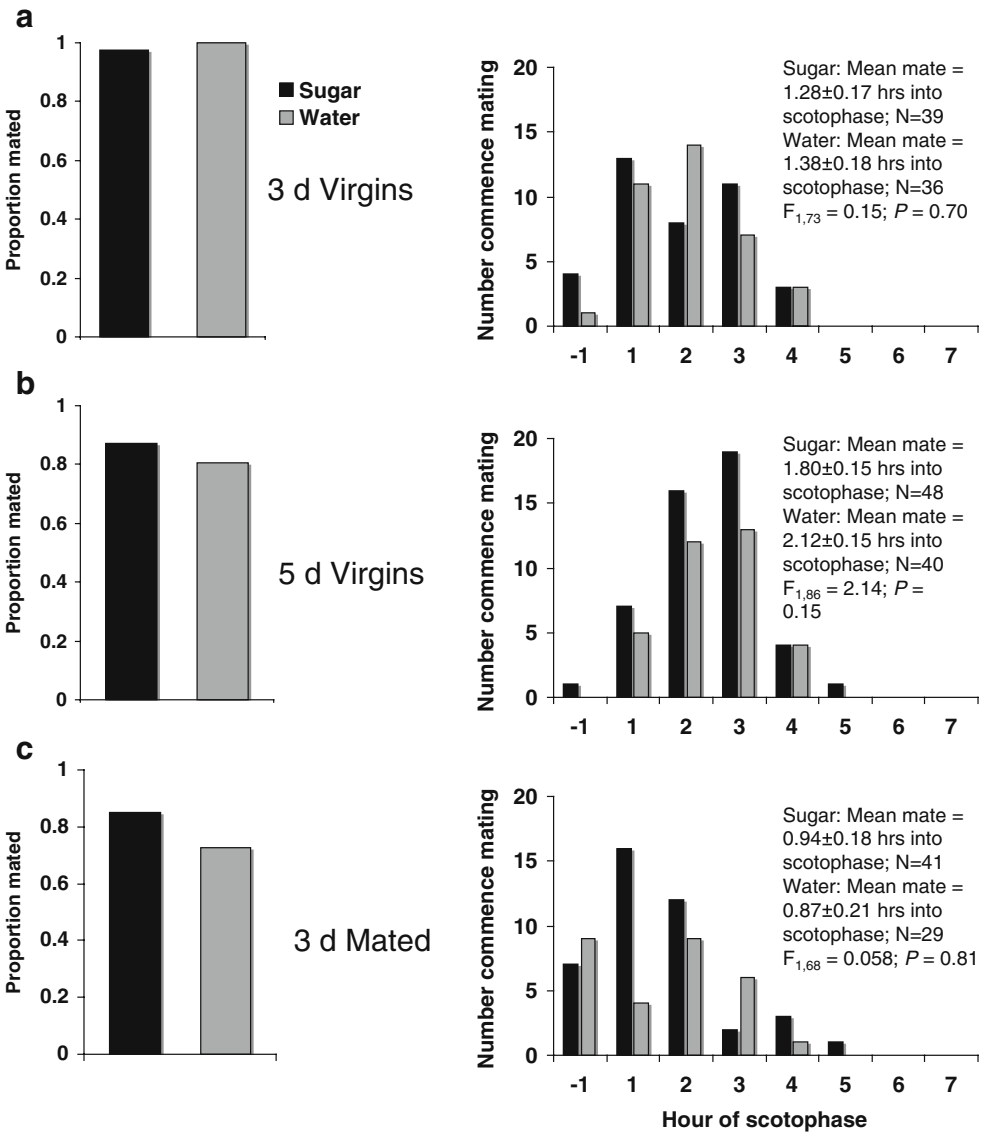

Fig. 3 Proportions and periodicities of *Heliothis virescens* copulations. Females were fed on either 10% sucrose or water: **a** 3-d-old virgins, **b** 5-d-old virgins, **c** 3-d-old mated females. There were no differences in proportions of, or mean times commencing, copulation between sugar- and water-fed females for each female category

virescens (Lamunyon, 2000), multiple mating causes greater fecundity (Torres-Vila et al., 2004). Therefore, the sex pheromone produced by female *H. virescens* is an honest signal for male assessment of a female's quality.

The relationship between pheromone quantity and fecundity is robust because pheromone and egg production share a common metabolite: adult sugar (O'Brien et al. 2000; Foster, 2009). We found no differences in pheromone quantity or male responses, with feeding status of young virgins, because these females, regardless of feeding status, have high HTC (Foster, 2009; Foster and Johnson, 2010); only when sugar-stressed (from mating, prolonged starvation) is the effect on pheromone manifest.

The possibility of male mate assessment based on female-produced moth sex pheromones has been proposed previously (Allison and Cardé, 2006, 2008) for the almond moth. Age-related changes in component ratios and female fecundity, led the authors to propose that males could assess female age and reproductive value through pheromone ratios (Allison and Cardé, 2008). However, almond moth females are considered mostly monandrous (McNamara et al., 2008) and, therefore, age-related mate selection would be effective only if high proportions of old females were unmated, which is unlikely. Males may also be capable of assessing the mating status of females through differences in female chemical signals (Thomas, 2011). For monandrous moth species, such as the almond moth, this is somewhat trivial, as sex pheromone production is probably permanently shut down in mated females (e.g., Foster, 1993). In contrast, in polyandrous species such as *H. virescens* (Lamunyon, 2000), sex pheromone production continues after mating, as shown in Fig. 1. In *H. virescens*, the effect of mating on pheromone production is governed largely by feeding status (HTC), with sugar-replete mated females having fairly similar pheromone titers to comparable virgins (Foster, 2009). Thus, males may be unable to

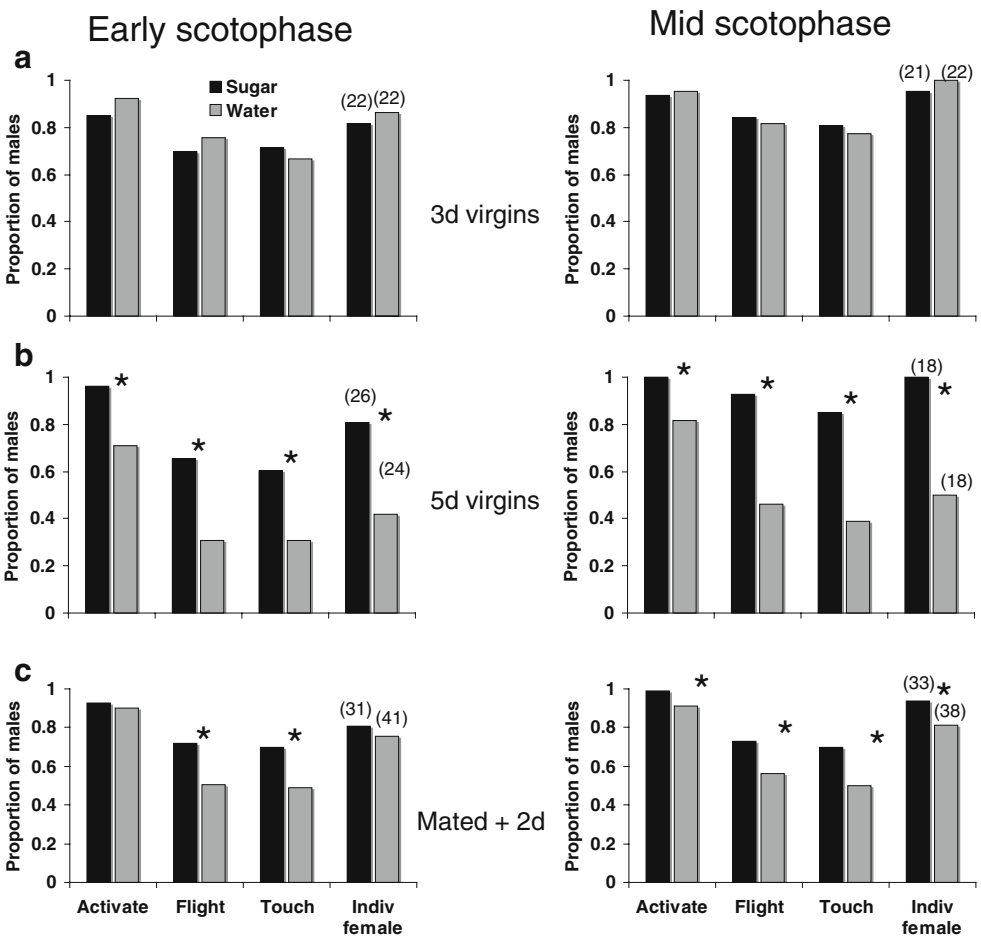

Fig. 4 Flight responses of male *Heliothis virescens* to individual females fed on 10% sucrose or water. **a** 3-d-old virgin, **b** 5-d-old virgin, **c** 3-d-old mated females. Trials were run at early (0.5–2.5 h after onset) and mid-scotophase (3–5 h after onset). Activate=wing fanning; Flight=sustained, oriented upwind flight; Touch=touched the container housing a female. The proportions of individual (Indiv) females that elicited at least one male to Touch are given. An asterisk above a pair of responses, indicates proportions that are different at $P<0.05$ (likelihood ratio chi-square tests). The numbers of females tested are given above the Indiv female bars (multiply by 3 for the total males flown per treatment)

differentiate sugar-replete mated females from virgins, on the basis of quantity of pheromone released alone.

Our behavioral studies showed that differential responses of males to the different female types were evident only over long distance, via pheromone quantity released. At close distance in *H. virescens*, hair pencil compounds are thought to mediate acceptance of males by females (Hillier and Vickers, 2004). Our confined experiment showed that female receptivity to copulation was unaffected by sugar stress, both in terms of mating proportions and latency to mate. Both bioassays were no-choice, because we felt this represented the natural situation better, in which isolated females release pheromone that distant males either respond to or not, rather than males assessing pheromone plumes of different females in close proximity to each other. Allison and Cardé (2008) also concluded that a no-choice situation was probably more natural for testing male mate assessment in the almond moth.

Previous work (Foster, 2009; Foster and Johnson, 2010) examined the effect of sugar stress at peak pheromone production in *H. virescens*. In this paper, we found that sugar stress impacts pheromone production and release throughout the scotophase. The patterns of production and release were similar for both female types, regardless of sugar stress, with peak release occurring after peak pheromone titer at mid-scotophase. While a similar relationship between peak titer and release has been found in other moths (e.g., Heath et al., 1991; Bäckman et al., 1997), our bioassays showed that most females attract and copulate with males much earlier in the scotophase than the peak release time. This suggests that female *H. virescens* produce and release pheromone in a martingale strategy, with increasing quantities released, the longer the female remains unmated through the scotophase, thereby increasing the chance of eventually attracting a male. This suggests that pheromone production may actually be a cost to a female, especially as after mating its production and release typically ceases (i.e., is conserved), at least for the remainder of the sexually active period (Raina, 1989; Foster, 1993). Pheromone production in female moths has been regarded as of little cost (Svensson, 1996), because small amounts of carbon are invested in pheromone compared to in eggs. Moreover, as both pheromone and egg production are adversely affected when females are sugar stressed, it is possible that pheromone production has a marginal cost, that impacts increasingly on fitness as a female's sugar resources are depleted. This marginal cost may be the increased signal cost, to signalers that can least

afford it, that maintains signal honesty (Zahavi, 1977; Grafen, 1990).

Further work is needed to test whether this phenomenon of male mate assessment through female pheromone quantity, based on female sugar resources, influences mate selection in the field, as well as expanding this work to other species of moths so as to establish whether it is a widespread phenomenon.

Acknowledgments This work was supported by a North Dakota Agricultural Experiment Station Hatch grant.

Secondary Metabolites Released by The Burying Beetle *Nicrophorus vespilloides*: Chemical Analyses and Possible Ecological Functions

Thomas Degenkolb · Rolf-Alexander Düring · Andreas Vilcinskas

Abstract Burying beetles of the genus *Nicrophorus* localize small vertebrate carcasses by emitted volatiles. The carcass that serves as reproduction and breeding site is buried in the soil by the beetles. Biparental care for offspring includes both preservation of the carrion and its preparation as diet and nursery. Buried carcasses show no signs of microbial decay, and those experimentally treated with *Nicrophorus* secretions are known to grow fewer bacteria and fungi. In order to investigate the chemical composition of these secretions, we used GC-MS for analysis of methanolic extracts of anal and oral secretions released by adult *N. vespilloides*. Furthermore, we analyzed the headspace of adult *N. vespilloides* by SPME-GC-MS and searched for compounds with known antimicrobial activity. We identified 34 compounds in the headspace, and anal and oral secretions, 26 of which occurred consistently. We discuss the ecological relevance of these compounds with respect to both their antimicrobial activity and ecological relevance.

Introduction

Members of the coleopteran taxon Silphidae are commonly referred to as carrion beetles. Currently, the most prominent genus, *Nicrophorus*[1] (subfamily Nicrophorinae), comprises 68 species of burying or sexton beetles (Sikes, 2008), which are unique in their behavior of searching for small vertebrate carcasses, preferably of small rodents or birds, that are subsequently buried to be used as a reproduction site. This behavior was investigated in the pioneering study by Pukowski (1933) who provided the first detailed description of *Nicrophorus* ecology. She described the remarkable biparental care of this taxon for the offspring, which involves *i*) providing the offspring with intestinal content during the first 4–5 d of larval development, *ii*) defending larvae against predators, and *iii*) immediate repair of a destroyed brood chamber. In contrast, silphids outside the genus *Nicrophorus* do not bury or prepare a carcass. Their larvae develop externally by feeding on the carcass and maggots (Sikes, 2008).

[1] The genus was first described as *Nicrophorus* by Fabricius in 1775. It appears that the same name was used by Fabricius several times subsequently. By contrast, the etymologically more meaningful name *Necrophorus* (gr.: 'corpse carrier') describes a habit characteristic for this genus. Nevertheless, assuming *Nicrophorus* to be an incorrect transliteration, a change to *Necrophorus* would lead to a violation of the priority rule (Herman, 1964). Thus, the name *Necrophorus* must no longer be considered valid (Herman, 1964; Peck and Miller, 1982). Despite this, the latter spelling was still predominant in literature until the early 1990s.

Members of the genus *Nicrophorus* are able to locate a deceased animal within 1 d after its death, being attracted from a distance of up to several km (Kalinová et al., 2009). Carrion is located by chemoreceptors on the antennal club. Recent investigations have demonstrated that both *N. vespilloides* and *N. vespillo* are lured by several sulfur-containing organic volatiles, above all dimethylsulfide (DMS), dimethyldisulfide (DMDS), and trimethyltrisulfide (DMTS) (Kalinová et al., 2009). When a carcass has been located by a burying beetle, it is first checked for its size and properties (i.e., degree of decomposition). After acceptance of a carcass, the beetle defends this resource against intra- and interspecific competitors. The carcass is subsequently buried by a single *Nicrophorus* sp. pair that first removes the underlying soil and then moves the carrion down a slope into a cave. The spherical bottom of this brood chamber is termed 'crypt'. Hairs or feathers of the carrion are mechanically removed, and a 'brood ball' is formed. According to Pukowski (1933), the latter is impregnated with the beetle's feces and anal secretion. Larval development is accelerated and complete within seven days.

During the past three decades, research mainly has focused on aspects of *Nicrophorus* behavioral and reproductive ecology (Eggert et al., 1998; Scott, 1998; Meierhofer et al., 1999; Müller et al., 2007), along with the question of how phoretic mites (Mesostigmata: Parasitidae) such as *Poecilochirus carabi*, *P. necrophori*, and *P. subterraneus* affect *Nicrophorus* biology (Schwarz and Müller, 1992; Schwarz and Koulianos, 1998; Grossman and Smith 2008). By contrast, chemical ecology has barely been pursued for silphids in the past, although chemical signaling in beetles (Francke and Dettner, 2005) and chemical defense of insects (Laurent et al., 2005) have been major areas of research for more than six decades.

The few studies devoted to chemical ecology of Silphidae include analysis of the anal defensive spray of the red-lined carrion beetle *Necrodes surinamensis* (Eisner et al., 1986), the neutral fraction of which consists of three terpene alcohols: lavendulol, and two cyclopentanoids, (−)-α- and (−)-β-necrodol (Roach et al., 1990). From anal secretions of *Silpha americana* (Meinwald et al., 1985) and *S. novaboracensis*, several defensive steroids (pregnane derivatives) have been identified (Meinwald et al., 1987). More recent work on nest mate recognition (Müller et al., 2003) by *Nicrophorus* has addressed the role of polyunsaturated cuticular hydrocarbon patterns for discrimination between breeding partners and conspecific intruders (Steiger et al., 2007, 2008, 2009; Scott et al., 2008).

The process of burying has been shown to prevent infestation of a carcass by dipteran larvae (Suzuki, 2000). Furthermore, a carcass buried by *Nicrophorus* sp. shows hardly any sign of microbial decay, although it is completely buried in the soil (Pukowski, 1933). Burying beetles regularly come into close contact with high loads of carrion-associated gram-positive and gram-negative aerobic and (facultatively) anaerobic bacteria (Solter et al., 1989; Berdela et al., 1994). Consequently, burying beetles must avoid uncontrolled bacterial and fungal decomposition of the carrion (Scott, 1998). A digestive phospholipase A_2 (PLA_2) is present in the oral secretion of the North American species *N. marginatus*, but absent in the midgut. It has been hypothesized that this enzyme contributes to preservation of the carcass by attacking bacterial membranes (Rana et al., 1997). In a study on *N. quadripunctatus*, Suzuki (2001) demonstrated the importance of parental pre-treatment that effectively reduces fungal growth on carcasses. Observations by Rozen et al. (2008) led to the conclusion that *N. vespilloides*, whenever possible, tends to avoid breeding in carcasses that display advanced putrefaction. If impossible, extended parental care before and after larval hatching is applied that limits the negative effects of carcass decay induced by microorganisms.

Studies of the anal and oral fluids of seven North American *Nicrophorus* species have revealed that oral secretions from *N. marginatus*, *N. obscurus*, *N. americanus*, *N. tomentosus*, and *N. orbicollis* show antimicrobial activity, whereas the anal secretion is antimicrobially active only in the latter two species (Hoback et al., 2004). The lack of antimicrobial activity in the *N. pustulatus* fluids is attributed to the brood-parasitic behavior of this species, which uses carcasses that have already been pre-treated with antimicrobial fluids by other *Nicrophori.* However, the lack of antimicrobials in *N. carolinus* fluids has not been explained satisfactorily and recently was reconsidered (Jacques et al., 2009). So far, the anal and oral secretions of *Nicrophorus* are known to display pronase and heat stability (Hoback et al., 2004), however, their antimicrobially active compounds are unknown.

Here, we chemically analyzed extracts of anal and oral secretions of *N. vespilloides* by GC-MS. Furthermore, we studied the headspace of adult beetles by SPME-GC-MS.

Methods and Materials

Origin of Beetles Parasite-free *N. vespilloides* males and females were provided by Josef K. Müller and Wolf Haberer (Department of Evolutionary Biology and Ecology, Faculty of Biology, University of Freiburg, Germany). The method of obtaining a culture of 'foster parents' free of mites and nematodes has been described in detail by Eggert et al. (1998). Groups of up to 6 adults of the same sex were kept in transparent plastic containers (100×100×65 mm; Famos-Westmark, Lennestadt-Elspe, Germany), two-thirds filled with soil (Fruhstorfer Erde®, type T, structure 1b; distributed by Hawita Group GmbH, Vechta, Germany), in

a 20°C constant temperature room under a 16/8 h photoperiod. Each beetle was fed one freshly decapitated mealworm twice a week.

Rearing of Beetles Reproduction in *Nicrophorus* species is induced easily by providing a male-female pair with a suitable mouse carcass. Mice which have been deep-frozen immediately after killing were obtained from the Department of Medical Microbiology, University of Giessen, Germany. Approximately 4 h before darkness, when beetles typically start searching for carrion, a mouse which had been thawed for 8 h was placed on top of the soil surface, and a pair of beetles was added. Parents were removed 5 d after hatching of the larvae. Containers were transferred to darkness after 3rd instars appeared on top of the soil surface for pupation.

Sampling To minimize possible influences of inconsistent diet on the composition of the secretions analyzed, only sexually mature, non-breeding beetles that had been fed exclusively on mealworms (*Tenebrio molitor*) were used. Mealworms were reared in the same 20°C constant temperature room under a 16/8 h photoperiod in transparent plastic containers (Geo Medium, Ferplast S.p.A., Vicenza, Italy) and fed exclusively on oat flakes (C. Hahne Mühlenwerke GmbH & Co. KG, Löhne, Germany). All beetles analyzed were at least 3 wk-old. The day the young beetle left the pupal chamber was considered d 1 of the adult stage. Only larvae experienced a mouse-based diet during biparental care, whereas adults were fed mealworms in order to avoid contamination of the analyzed secretions with carcass-derived compounds.

Headspace Sampling by SPME For analysis of VOC's emitted by adult *N. vespilloides*, one individual beetle was transferred carefully into a 20 ml amber GC vial with screw cap and septum (CS—Chromatographie Service, Langerwehe, Germany) by using flexible forceps. This vial was placed in the autosampler of a CTC Combi Pal unit that was subsequently agitated for 3 min at room temperature, thus inducing the beetle to regurgitate or to secrete anal fluid. The headspace subsequently was absorbed for 3 min onto a solid-phase micro-extraction fiber (SPME, coating polydimethylsiloxane [PDMS], Supelco, Bellefonte, PA, USA), then desorbed for 3.5 min, and finally analyzed by gas chromatography-mass spectrometry (GC-MS).

Sampling of Anal and Oral Secretions For analysis of anal and oral fluids, the respective secretions from 5–15 beetles were sampled into a 150 µl glass insert placed in a 1.5 ml HPLC vial with screw cap (CS—Chromatographie Service, Langerwehe, Germany). Samples of each sex were collected separately. Oral fluid was released when gently placing the beetle's head into the wide opening of the insert, whereas anal fluid was obtained by gently pressing the beetle's abdominal tip into the opening of the insert. All vials were kept on crushed ice during sampling. Each sample was mixed with 50 µl of methanol, vortexed for 3 min, and placed back on ice. After sedimentation, the supernatant was transferred into the glass insert of an amber GC vial (CS—Chromatographie Service, Langerwehe, Germany) and analyzed by direct-inlet GC/MS. Animals were transferred back into the container immediately after sampling, and each beetle was provided with a freshly decapitated mealworm.

GC/MS Analysis—General Analyses were performed on a Varian CP 3800 gas chromatograph with a CTC Combi Pal unit coupled to a Varian Saturn 2000 EI mass spectrometer (Varian, Darmstadt, Germany). The system was equipped with a Varian VF-XMS column/precolumn combination (30 m×0.25 mm, df=0.25 µm). Helium was used as carrier gas at a flow rate of 1.0 ml/min. EI mass spectra were recorded with an ionization voltage of 70 eV in the mass range of m/z 35–450. Total analysis time was 30 min. Data analysis was performed by the Saturn GC/MS Workstation 5.52 software, including the 2006 NIST/EPA/NIH Mass Spectral Library. Tentative compound identifications by the NIST Library were verified by analyzing retention time and EI fragmentation patterns of commercial standard samples purchased from Sigma-Aldrich-Fluka (Steinheim, Germany). 2-Acetamido-2-deoxy-D-mannolactone was obtained from Carbosynth Ltd. (Compton, Berkshire, UK). Whenever possible, positional isomers such as isoquinoline vs. quinoline as well as *o*- and *m*- vs. *p*-cresol were included to unambiguously confirm our identification. Only those peaks displaying a signal-to-noise ratio≥3 were considered for interpretation. All reference substances (*trans*-geranylacetone, phenol, *o*-, *m*-, and *p*-cresol, indole, benzaldehyde, phenylethyl alcohol [= 2-phenylethanol], isobutyric acid, *n*-butyric acid, isovaleric [3-methylbutyric] acid, (±)-2-methylbutyric acid, *n*-valeric acid, *N,N'*-dimethyl urea, benzoic acid, 2-piperidone [= δ-valerolactam], *N*-methylpiperidine, 1-methyl-2-pyrrolidinone, caprylic acid [= *n*-octanoic acid], pelargonic acid [= *n*-nonanoic acid], 2-phenylacetic acid, quinoline, isoquinoline, 3-phenylpropionic acid, 2-acetamido-2-deoxy-D-mannolactone, capric acid [= *n*-decanoic acid], *m*- and *p*-hydroxybenzyl alcohol, 2-, 3- [= skatole], 5-, 6-, and 7-methylindole, *p*-hydroxybenzoic acid methyl ester [= methylparaben], 2-indolinone [= oxindole], *N*-(2-phenylethyl)-acetamide, *m*- and *p*-hydroxybenzoic acid, *m*-and *p*-hydroxyphenylacetic acid, lauric acid [= *n*-dodecanoic acid], methylmyristate, myristic acid, methylpalmitate, palmitic acid, methylstearate, oleic acid, and stearic acid) and organic solvents were of GC/MS or LC/MS quality (purity usually≥99%). Water for SPME headspace GC/MS was

purified by a Millipore Q system (Millipore, Schwalbach, Germany) providing a conductance of 18.2 MΩ/cm.

GC/MS Analysis of Headspace Samples Conditions were as follows: injector, initial temperature 50°C, ramped at 200° C/min, final temperature 270°C, hold for 10 min, splitless mode; column oven, initial temperature 50°C, ramped at 10°C/min, final temperature 250°C, hold for 6 min. Reference standards (1 mg of solids, 1 µl of liquids, or dilutions thereof) were suspended in 10 ml of water and sampled at 60°C instead of room temperature.

GC/MS Analysis of Anal and Oral Fluids Conditions were as follows: injector, initial temperature 50°C, hold for 0.1 min, ramped at 200°C/min, final temperature 250°C, hold for 10 min, splitless mode; column oven, initial temperature 50° C, hold for 2.6 min, ramped at 10°C/min, final temperature 250°C, hold for 7.4 min. Reference standards (1 mg of solids, 1 µl of liquids) were dissolved in 4 ml of methanol; if required, diluted in methanol and analyzed.

Results

Both oral and anal secretions of *N. vespilloides* are of dark brown color and exhibit a characteristic odor. The bouquet of the latter is pungently putrefactive, suggesting the dominance of phenolic (phenol, *p*-cresol) and amine (indole) components. The scent of the former, however, is less penetrating, suggesting the presence of fatty acids. These differences were confirmed by the acidity of the respective samples: native anal secretions had pH 9, whereas oral secretions had pH 5–6, thus confirming data from Hoback et al. (2004).

The volume of secretion released by each beetle varied considerably. Thus, a number of minor components, although detectable in trace amounts, could not be considered for analysis in each sample. All metabolites in our study were identified by comparison of EI-MS fragmentation patterns, and were numbered consecutively according to their order of appearance in this Results section.

SPME-GC/MS Analysis—Headspace Analysis of Adult N. vespilloides (Fig. 1, Table 1) Headspace samples were obtained from 14 individual beetles (7 of each sex). As living beetles are assumed to simultaneously secrete both anal and oral fluids into the GC vial, volatiles found in the headspace may originate from either secretion. Ethyl-4-methyl heptanoate, previously described as a male-produced pheromone of *N. vespilloides* (Haberer et al., 2008), was not detected in our samples. No qualitative differences were observed between total ion current

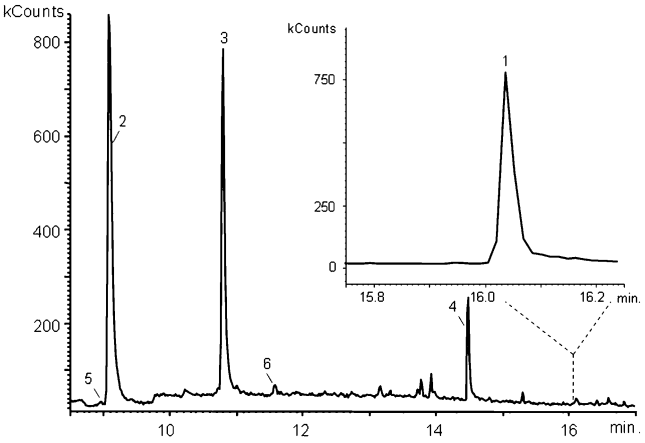

Fig. 1 GC-MS total ion current chromatogram of *Nicrophorus vespilloides* headspace. The sample was collected from one living female beetle. The position of (*E*)-geranylacetone (**1**) produced by calling sexually mature males is indicated in the insert

chromatograms of male and female beetles, except for the presence or absence of (*E*)-6,10-dimethyl-5,9-undecadien-2-one ('*trans*-geranylacetone': **1**), which is released by sexually mature males (Haberer et al., 2008).

Three major compounds were detected in the headspace of adults: phenol (**2**), *p*-cresol (**3**), and indole (**4**). In addition, small amounts of benzaldehyde (**5**) and 2-phenylethyl alcohol (**6**) were frequently detected. The presence of (**2**) and (**4**) in anal secretions of *N. vespilloides* recently has been reported by Haberer et al. (2010).

GC/MS Analysis of the Anal Secretion of N. vespilloides (Fig. 2, Table 1) Four samples, 2 of each sex, were analyzed. Samples were pooled from 5 and 10 males, as well as from 10 and 15 females, respectively. The pattern of low-molecular metabolites found in anal secretions was remarkably diverse, consisting of short-, medium-, and long-chain fatty acids, phenols, aromatic carboxylic acids, aldehydes, alcohols, amines, and amides. The following metabolites, listed in ascending order by retention time, were identified unambiguously (Fig. 2): isobutyric (2-methylpropionic, **7**), *n*-butyric (**8**), isovaleric (= 3-methylbutyric, **9**), (±)-2-methylbutyric acid (**10**),[2] *n*-valeric acid (**11**), benzaldehyde (**5**), phenol (**2**), *p*-cresol (**3**), *N,N'*-dimethyl urea (**12**), 2-phenylethyl alcohol (**6**), benzoic acid (**13**), 2-piperidone (= δ-valerolactam, **14**), pelargonic acid (= *n*-nonanoic acid, **15**), 2-phenylacetic acid (**16**), quinoline (**17**), indole (**4**), 3-phenylpropionic acid (**18**), 2-acetamido-2-deoxy-D-mannolactone (**19**), *m*- or *p*-hydroxybenzyl alcohol (**20**), skatole (= 3-methylindole, **21**), *p*-hydroxybenzoic acid methyl ester (= methylparaben, **22**), 2-indolinone (= oxindole, **23**), *N*-(2-phenylethyl)-acetamide (**24**),

[2] (+)- and (−)-2-methylbutyric acid could not be separated under the GC conditions applied.

Table 1 Possible contribution of individual metabolites detected to the carcass-preserving effect of *Nicrophorus vespilloides* secretions

Metabolite (**No.**) name		Origin	Produced by male(♂)/female(♀)	Consistency of occurrence[*1] [%]	Presumed biological significance for *N. vespilloides* (References)
(**1**)	*(E)*-geranylacetone	(?)	♂	57 (♂)	male-produced, significance unknown (Haberer et al., 2008)
(**2**)	phenol	H/A	♂/♀	100 (H) 100 (A)	insect repellent, antibacterial and antifungal disinfectant (Duffey et al., 1977; Goddard and McCue, 2001)
(**3**)	*p*-cresol	H/A	♂/♀	86 (H) 100 (A)	invertebate repellent (Duffield et al., 1977); antibacterial and antifungal disinfectant (Lüllmann et al., 2006)
(**4**)	indole	H/A/O	♂/♀	100 (H) 100 (A) 100 (O)	insect repellent (Duffield et al., 1977); antibacterial, antifungal (Devi et al., 2010)
(**5**)	benzaldehyde	H/A	♂/♀	21 (H) 25 (A)	deterrent to invertebrate predators (Duffey et al., 1977; Kelley and Schilling, 1998)
(**6**)	2-phenylethyl alcohol	H/A	♂/♀	50 (H) 50 (A)	broad-spectrum antibacterial (Ali et al., 2001)
(**7**)	isobutyric acid	A	♀	25	antimicrobial (Stratford and Eklund, 2003); contribution to the spread- and penetration-enhancing ability of long-chain fatty acids (Roach, et al., 1990); repellent to insect predators (Dettner and Reissenweber, 1991)
(**8**)	*n*-butyric acid	A/O	♂/♀	75(A) 100(O)

(**14**)	2-piperidone	A/O	♂/♀	100	(?)[*2]
(**15**)	pelargonic acid	A/O	♂/♀	100	antimicrobial (Stratford and Eklund, 2003)
(**16**)	phenylacetic acid	A/O	♂/♀	100	antibacterial, antifungal (do Nascimento et al., 1996; Hwang et al., 2001; Kim et al., 2004; Mendonça et al., 2009)
(**17**)	quinoline	A/O	♂/♀	100	antiseptic (Frerichs et al., 1930)
(**18**)	3-phenyl-propionic acid	A/O	♂/♀	50 (A) 100 (O)	antibacterial, antifungal (Dettner and Schwinger, 1980; Narayana et al., 2007)
(**19**)	2-acetamido-2-deoxy-D-mannolactone	A/O	♂/♀	50 (A) 100 (O)	(?)
(**20**)	*m*-/*p*-hydroxy-benzyl alcohol	A	♀	25	antioxidant, radical-scavenging (Dhiman et al., 2009)
(**21**)	skatole	A	♀	25	repellent to vertebrate and invertebrate predators (Blum et al., 1973; Duffield et al., 1977)
(**22**)	*p*-hydroxy-benzoic acid methyl ester	A	♀	25	E 218: broadly antimicrobial (Schildknecht, 1970; Classen and Dettner, 1983; Stratford and Eklund, 2003)
(**23**)	2-indolinone	A	♂/♀	50	(?)
(**24**)	*N*-(2-phenyl-ethyl)acetamide	A	♂/♀	75	(?)[*3]
(**25**)	*p*-hydroxy-benzoic acid	A	♀	25	antibacterial (Huberman et al., 2007); anti-*Candida albicans* (Ata et al., 2011)
(**26**)	*p*-hydroxy-phenylacetic acid	A	♀	25	antibacterial (Huberman et al., 2007)
(**27**)	methylmyristate	A/O	♂/♀	100	spread- and penetration-enhancement of antimicrobial and repellent metabolites (Roach et al., 1990); insect repellent (Henderson and Jeanne, 1989)
(**28**)	myristic acid	A/O	♂/♀	100	
(**29**)	methylpalmitate	A/O	♂/♀	100	
(**30**)	palmitic acid	A/O	♂/♀	100	
(**31**)	methylstearate	A/O	♂/♀	100	

Table 1 (continued)

Metabolite (**No.**) name		Origin	Produced by male(♂)/female(♀)	Consistency of occurrence[*1] [%]	Presumed biological significance for *N. vespilloides* (References)
(**32**)	oleic acid	A/O	♂/♀	100	insect repellent (Eisner et al., 1996; Dani et al., 1996); 'necromone' (Rollo et al., 1994)
(**33**)	stearic acid	A/O	♂/♀	100	see (**28**)–(**32**); 'necromone' (Rollo et al., 1994)
(**34**)	caprylic acid	O	♂/♀	100	antimicrobial (Stratford and Eklund, 2003)

n. d.—not detected, *i. e.*, metabolite not present or signal-to-noise-ratio below the 3:1 threshold; H—headspace (N=14=100%); A—anal secretion (N=4=100%); O—oral secretion (N=2=100%); (?)—biological significance for *N. vespilloides* remains unresolved. [*1]—a metabolite is defined consistent if it is present in ≥ 50% of the samples analyzed. [*2]—recently isolated as an end product of the L-amino acid oxidase escaping present in the ink of sea hares (*Aplysia californica*: Kamio et al., 2009), [*3]—frequently isolated as a biologically inactive by-product of antibiotic fermentations (Asolkar et al., 2002; Maskey et al., 2003).

p-hydroxybenzoic acid (**25**), *p*-hydroxyphenylacetic acid (**26**), methylmyristate (**27**), myristic acid (**28**), methylpalmitate (**29**), palmitic acid (**30**), methylstearate (**31**), oleic acid (**32**), and stearic acid (**33**).

GC/MS Analysis of the Oral Secretion of N. vespilloides (data not shown) Two samples, 1 of each sex, were analyzed. Samples were pooled from 5 males and 15 females, respectively. The chromatogram was dominated by (**28**), (**30**), (**32**), and (**33**) whereas (**9**), (**10**), caprylic (*n*-octanoic acid, **34**), (**13**), (**14**), and (**15**) were present in minor amounts.

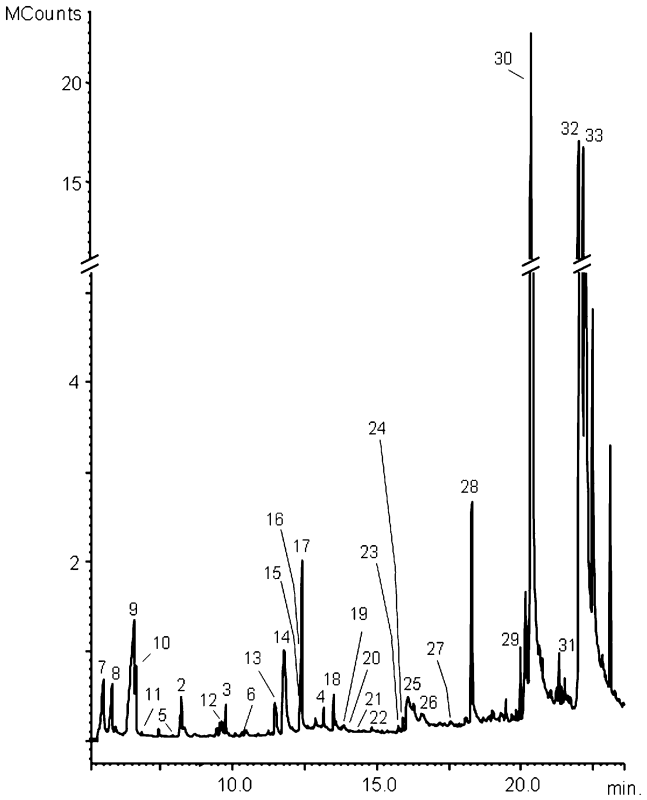

Fig. 2 GC-MS total ion current chromatogram of *Nicrophorus vespilloides* anal secretion. The sample was collected from 15 female beetles

Neutral (**19**) and amine components, (**17**) and (**4**), were detected in traces, only.

Discussion

Metabolic Origin of Compounds Detected in Nicrophorus Secretions The majority of the metabolites detected originate from amino acid catabolism. The detected short-chain volatile fatty acids (VFA's) have been previously reported as derived from amino acid precursors. A study by Elsden and Hilton (1978) on *Clostridium* sp. revealed that strains that were able to oxidize valine to isobutyric acid (**7**) also oxidized leucine to isovaleric (= 3-methylbutyric) acid (**9**) and isoleucine to 2-methylbutyric (**10**) acid. Depending on the species tested, threonine served as a precursor of propionic, *n*-butyric (**8**), or *n*-valeric acid (**11**). Further studies on the end products of fermentation of aromatic amino acids by clostridia revealed that phenylalanine served as the precursor of either phenylacetic or phenylpropionic acid (Elsden et al., 1976), whereas tyrosine yielded *p*-hydroxyphenylacetic acid (**26**), phenol (**2**), and *p*-cresol (**3**). Tyrosine and phenylalanine also have been discussed as precursors of phenol (**2**), and *p*-cresol (**3**), benzoic acid (**13**), and *p*-hydroxybenzoic acid. Deamination of tryptophan leads to the formation of skatole (**21**) at low pH values, whereas high pH values favor the production of indole (**4**) (Le et al., 2005; Swann et al., 2010). 2-Piperidone (= δ-valerolactam, **14**) previously has been shown to originate from lysine degradation *via* cadaverine, 1-piperideine, and subsequent cyclization of 5-aminopentanoic acid (Callery and Geelhaar 1984). The C_{14}-, C_{16}-, and C_{18}-fatty acids and their corresponding methyl esters (**27**–**33**) may originate from the activity of lipolytic enzymes such as phospholipase A_2 (Uscian et al., 1995; Rana et al., 1997; Nor Aliza and Stanley 1998).

The structures of the metabolites found indicate that a highly diverse, as yet uninvestigated community of microbial symbionts is likely to contribute to their biosynthesis in *N.*

vespilloides. So far, *N. tomentosus* is the only species of burying beetles whose microbial flora in the midgut, hindgut, and hemolymph has been partly characterized (Solter et al., 1989; Berdela et al., 1994).

Putative Ecological Function of Metabolites Detected in Nicrophorus Secretions The high microbial load and the high viscosity of the secretions prevented us from testing the antimicrobial activity of our small, volatile samples, which could not be effectively sterilized. Possible contributions of the 34 individual metabolites identified in this study to the carcass-preserving effect *N. vespilloides* are compiled in Table 1. Most of the substances found have been reported previously as products of putrefaction (Dekeirsschieter et al., 2009; Swann et al., 2010); however, many also exhibit a pronounced anti-putrefactive, antimicrobial activity. Given that a breeding couple of *N. vespilloides* regularly and repeatedly impregnates the carcass in the crypt (Pukowski, 1933), we hypothesize that burying beetles are able to positively regulate the microbial colonization of carrion. Most of the primary and secondary metabolites found in the headspace and secretions of adult *N. vespilloides* might serve this ecological function.

Occurrence of Compounds in Other Taxa and Their Dependence on the Physiological State of the Beetle Overall, most of the primary and secondary metabolites we found are widespread amongst invertebrate taxa (Table 2): A total of 68 species are known in the taxon *Nicrophorus*, but hydrolytic enzymes such as phospholipase A_2 have so far been shown only in *N. marginatus* (Rana et al., 1997). The presence of such an enzyme in anal and oral secretions of *N. vespilloides* might provide free fatty acids, as detected in our samples. To further elucidate the pattern of secondary metabolites responsible for preservation of carcasses, anal and oral secretions could be extracted by less polar GC-compatible solvents and analyzed with or without further derivatization. Furthermore, anal and oral secretions should be investigated by state-of-the-art HPLC/MS-MS methods.

The composition of anal and oral secretion might vary with the physiological state of the beetle. Studies (Müller et al., 2003; Steiger et al., 2007, 2008, 2009) have shown that the cuticular hydrocarbon profile of *N. vespolloides* varies between breeding and non-breeding mates. Similarly, the monoterpenoid (*E*)-methylgeranate is emitted only by breeding *N. vespolloides,* not by non-breeding beetles (Haberer et al., 2010). Furthermore, the pattern of metabolites present in breeding *N. vespilloides* could change in the course of time during parental care. As diet previously has been shown to influence the antimicrobial properties of oral secretions in *N. carolinus* and *N. marginatus* (Jacques et al., 2009), the metabolite pattern of beetles feeding on a rodent carcass might be different from that of beetles feeding on freshly decapitated mealworms. Finally, studies on the microbial flora found in secretions of *Nicrophorus vespilloides* should be considered as a future point of interest in order to gain further insight into the biosynthesis and decomposition of small metabolites.

In summary, we report for the first time a detailed analysis of secondary metabolites secreted by *N. vespilloides.* These metabolites could contribute both to defense against competitors and to chemical preservation of carcasses used for reproduction and as a diet for offspring. So far, our knowledge of secondary metabolites of *Nicrophorus* sp. remains fragmentary and additional research is needed for basic understanding of chemical carcass preservation by burying beetles.

Acknowledgements The support of this study by the Erwin-Stein-Foundation (Giessen, Germany) through a grant to Thomas Degenkolb is gratefully acknowledged. The study was supported by the Hessian Ministry for Science and Art by a grant from the LOEWE-Research Focus AmbiProbe to Rolf-Alexander Düring and Andreas Vilcinskas. We are indebted to Josef K. Müller and Wolf Haberer (University of Freiburg, Germany) for providing parasite-free *Nicrophorus vespilloides*. Trinad Chakraborty (University of Giessen, Germany) provided mouse carcasses. The comments of Monika Wimmer-Röll and Dirk Preuß (both from University of Giessen), and Hartmut Laatsch (University of Göttingen) improved the quality of our manuscript. This work would not have been possible without the technical assistance of Janusz Czynski (University of Giessen). We thank Rod Snowdon (University of Giessen) for language editing of the manuscript.

Abstract Aulacoscelinae beetles have an ancient relationship with cycads (Cycadophyta: Zamiaceae), which contain highly toxic azoxyglycoside (AZG) compounds. How these "primitive" leaf beetles deal with such host-derived compounds remains largely unknown. Collections were made of adult *Aulacoscelis appendiculata* from *Zamia* cf. *elegantissima* in Panama, *A. vogti* from *Dioon edule* in Mexico, and *Janbechynea paradoxa* from *Zamia boliviana* in Bolivia. Total AZG levels were quantified in both cycad leaves and adult beetles by high performance liquid chromatography (HPLC). On average, cycad leaves contained between 0.5–0.8% AZG (frozen weight, FW), while adult beetles feeding on the same leaves contained even higher levels of the compounds (average 0.9–1.5% FW). High AZG levels were isolated from reflex bleeding secreted at the leg joints when beetles were disturbed. Nuclear magnetic resonance and mass spectroscopy identified two AZGs, cycasin and macrozamin, in the reflex bleeding; this is the first account of potentially plant-derived compounds in secretions of the Aulacoscelinae. These data as well as the basal phylogenetic position of the Aulacoscelinae suggest that sequestration of plant secondary metabolites appeared early in leaf beetle evolution.

Key Words Aulacoscelinae · *Aulacoscelis* · Azoxyglycosides · Chrysomelidae · Coleoptera · *Dioon* · *Janbechynea* · Reflex bleeding · *Zamia* · Zamiaceae

Introduction

One of the least understood plant-insect interactions is that between cycads and aposematic herbivorous beetles in the subfamily Aulacoscelinae (Chrysomelidae *sensu lato*), a basal lineage of leaf beetles closely associated with the neotropical cycad family Zamiaceae (Cycadophyta: Gymnosperm) (Windsor et al., 1999; Santiago-Blay, 2004). Cycads contain toxic azoxyglycosides (AZGs); herbivore defense compounds that have the common aglycone, methylazoxymethanol (MAM) (Bowers and Larin, 1989). The two most common cycad AZGs, cycasin and macrozamin (the β-glucoside and β-primeveroside of MAM, respectively), are found in the seeds and leaves of all cycad genera (De Luca et al., 1980; Yagi, 2004). These glycosylated storage forms are non-toxic but upon herbivory, endogenous plant or gut-associated enzymes cleave AZGs to the aglycone, which readily reacts with nucleic acids resulting in potentially mutagenic changes (Kobayashi and Matsumoto, 1965; Laqueur and Spatz, 1968; Schneider et al., 2002). Sequestration of AZGs from the host plant has been observed in a number of cycad-specialist herbivores. The larvae of the hairstreak butterfly (*Eumaeus atala florida* Poey, Lycaenidae: Lepidoptera) and of the

arctiid moth (*Seirarctia echo* Abbot and Smith, Arctiidae: Lepidoptera) feed on the leaves of *Zamia floridana* A.DC. In both herbivore species, the sequestered cycasin is retained in the adult stage where it is concentrated in the wings and abdomen (Teas, 1967; Rothschild et al., 1986). High β-glycosidase activity in the gut of the arctiid moth suggests that free MAM is re-glycosylated to restore cycasin after sequestration. Cycasin in *E. atala* deters ant predators and, probably, vertebrate predators as well (Bowers and Larin, 1989). The pollinating weevil of *Zamia furfuraceae* L. fil., *Rhopalotria mollis* Sharp (Belidae: Coleoptera), also sequesters cycasin from the male cones (Schneider et al., 2002).

Reflex bleeding refers to hemolymph-related secretions that are often associated with defensive posturing in many insect species. Aulacosceline adults exhibit a reflex bleeding mechanism similar to that observed in the Meloideae (Coleoptera) where upon disturbance of the insect, a droplet of hemolymph is exposed through the joints of the tibia and femur (Carrel and Eisner, 1974). The droplet is reabsorbed when the disturbance ceases. The purpose of this study was to determine whether AZG compounds are sequestered and secreted by cycad-feeding Aulacoscelinae leaf beetles.

Methods and Materials

Natural History Observations and Sample Collection Adult aulacosceline leaf beetles were collected from their respective cycad host plants by using a sweep net at three study sites: Huasteca Potosina, Mexico (May–September), Chagres National Park, Panama (May), and Potrerillos del Guenda, Bolivia (November) between 2008 to 2010. *Janbechynea paradoxa* Monrós and *Aulacoscelis appendiculata* Cox & Windsor suddenly appeared in large numbers as voracious feeders on the new leaves of *Zamia boliviana* (Brongn.) A.DC. in Bolivia and on *Zamia* cf. *elegantissima* Schutzman, Vovides and Adams in Panama, respectively. *Aulacoscelis vogtii* Monrós was observed in smaller numbers on *Dioon edule* Lindl. leaves during the rainy season in Mexico. Undamaged fully grown leaflets were collected and immediately frozen at −20°C until analysis. Adult beetles were removed from their host plants and the head, thorax, abdomen, and legs were manually separated using forceps. Three to four individuals of each species were pooled and frozen at −20°C for AZG analysis. Reflex bleeding was collected from live adults by gently holding the beetles with tweezers and transferring the droplets collected from the femur-tibia joints to filter paper by using capillary tubes. Beetle hemolymph was collected by centrifuging decapitated insects. The hemolymph and filter paper containing reflex bleeding were frozen at −20°C until extraction.

Azoxyglycoside Extraction and High Performance Liquid Chromatography Analysis Insect and leaf tissues were weighed and ground in 1 ml of chilled 70% ethanol. Homogenates were centrifuged at 13,000 rpm for 5 min, and the supernatant was split into subsamples; the first was used to measure basal levels of MAM and the second allowed measurement of AZGs through MAM equivalents. To measure AZG equivalents, the second subsample was diluted in sodium acetate buffer (pH 5.0) containing 0.27 U (enzyme unit) of β−glucosidase (Sigma) and incubated overnight in the dark at room temperature. Samples were syringe-filtered for HPLC analysis. Separation was achieved on a Cyano column (Varian Microsorb MV 100–5 CN, 150×4.6 mm) using a gradient from 75% methanol to 25% methanol in 10 min at a flow rate of 1.2 ml/min (Yagi, 2004). Peaks were monitored by a photodiode array detector at 215 nm. MAM standards were prepared by incubating commercially available MAM acetate (National Cancer Institute) in Tris–HCl buffer (final concentration 1 mg/ml, pH 8.0) with 36.9 U of esterase enzyme (Sigma) for 1 h at 25°C and used to generate a standard curve.

NMR and MS of Reflex Bleeding To identify the AZGs present in the reflex bleeding of *Janbechynea paradoxa*, four samples were pooled (approx. 10 μl), extracted in 50% methanol, and purified by HPLC. The concentrated sample was dried in a rotary evaporator and re-suspended in deuterated water for proton nuclear magnetic resonance analysis using a Bruker 300 MHz and accurate mass was obtained by sodium electrospray ionization ($[M+Na]^+$) MS/MS using an Agilent LS/MSD TOF mass spectrometer.

Results

Natural History Observations Little is known about the lifecycle of Aulacoscelinae beetles, except that the adults appear suddenly and for a brief period feed voraciously on the younger leaves of their cycad host plants during the onset of the rainy season (Windsor et al., 1999). Their long, sharp mandibles pierce the epidermis releasing plant juices that are then ingested. Mating occurs while the females are feeding.

Plant and Insect Azoxyglycoside Content The leaf AZG content of three Zamiaceae species ranged from 0.5–0.8% frozen weight (FW) on average (Table 1). *Dioon edule* showed the highest values (0.8%). For adult Aulacoscelinae beetles, the AZG content was higher, ranging from 0.9–1.5% FW. Trace amounts of AZGs were detected in the adult beetle head, thorax, abdomen, legs, and hemolymph.

Table 1 Azoxyglycoside content of adult Aulacoscelinae species and their respective host cycads

Azoxyglycosides in Adult Beetle Reflex Bleeding In response to disturbance, adult beetles secreted a droplet of reflex bleeding from the joint between the tibia and the femur. The color of the secretion ranged from clear to yellow and had a penetrating smell. The droplet was produced from any set of legs but usually was a localized response from the leg nearest the region of the body being held. Reflex bleeding (approx. 1.2 μl) was observed in all three Aulacoscelinae: *Aulacoscelis appendiculata, Aulacoscelis vogtii*, and *Janbechynea paradoxa.* Proton magnetic resonance spectra of secretions from *J. paradoxa* confirm that the reflex bleeding contained AZGs with diagnostic signals observed at 5.11, 4.03, and from 3.1 to 3.8 ppm (Fig. 1A). Mass spectroscopy identified a mixture of compounds with masses of 275.08, 286.09, 309.2, 337.06, and 437.14 *m/z*, indicating that the major component of the sample is cycasin (275.08603 *m/z*) with minor levels of macrozamin (437.14246 *m/z*) (Fig. 1B).

Discussion

Our observations suggest that toxic AZGs sequestered from the host plant may be part of the aulacosceline beetle defenses as they are exuded by the adult in response to disturbance (Fig. 1). Given the rarity of this class of compound in nature, it is likely that their abundance in insect herbivores reflects leaf chemistry as proposed by Schneider et al. (2002). Beetles were collected on specific plant species, and their sequestered AZG content is comparable to that of the host; however, in one of the field sites, Huasteca Potosina Mexico, another Zamiaceae species, *Ceratozamia mexicana,* grows near the *Dioon edule* population where insects were collected and might serve as an alternative AZG source for *Aulacoscelis vogtii.* The presence of both cycasin and macrozamin in the reflex bleeding suggests that these compounds are taken directly from the gut to the hemolymph through an active transport mechanism. A less likely possibility is that the sugar moiety is removed from AZG by glycosidases releasing toxic MAM that moves freely into the hemolymph, and then is re-glycosylated to form cycasin as proposed for *S. echo* caterpillars (Teas, 1967). Further research is being conducted to determine how Aucaloscelinae species accumulate these compounds and if they are capable of *in situ* synthesis.

As the strong smell of the secretion cannot be attributed to the AZGs, other plant- or insect-derived chemicals might also be part of the aulacosceline defense system. For example, AZGs are not the only compounds known to protect cycads against herbivores. The non-protein amino acid β-*N*-methylamino-L-alanine (BMAA) has the capacity to degenerate neural systems, and is found in several cycad tissues (Seawright et al., 1990). BMAA also could be part of the Aulacoscelinae defensive secretions, but this was not addressed in our study.

In an earlier review on defensive glands and secretions in the Chrysomelidae, Deroe and Pasteels (1982) lamented the lack of information available regarding Aulacoscelinae defense mechanisms. The authors proposed that for insects that do not have defensive glands associated with the surface of their elytra and pronotum as seen for other leaf beetle families, hemolymph-associated reflex bleeding may be an alternate defense mechanism. Here, we report that the Aulacoscelinae do not possess defensive glands in their elytra or pronotum but, in fact, reflexively bleed when disturbed. These secretions contain unusual AZG compounds also found in their host plants. The Aulacoscelinae is a sparse lineage of gymnosperm-associated herbivores, diverging alongside ancestors of the plant-feeding beetle superfamilies Chrysomeloidea and Cerambycoidea (Cox and Windsor, 1999). Putative Aulacoscelinae fossils date back to the Jurassic and earliest Cretaceous (Medvedev, 1968; Zhang, 2004). Therefore, the identification of plant-related secondary metabolites in Aulacoscelinae tissues and reflex bleeding opens the possibility that the ability to sequester plant-derived toxins may have appeared early in leaf beetle evolution, perhaps even predating the appearance of angiosperms.

Abstract The cotton aphid, *Aphis gossypii* (Homoptera: Aphididae), is increasing in importance as a pest worldwide since the introduction of Bt-cotton, which controls lepidopteran but not homopteran pests. The chemical ecology of interactions between cotton, *Gossypium hirsutum* (Malvaceae), *A. gossypii*, and the predatory lacewing *Chrysoperla lucasina* (Neuroptera: Chrysopidae), was investigated with a view to providing new pest management strategies. Behavioral tests using a four-arm (Pettersson) olfactometer showed that alate *A. gossypii* spent significantly more time in the presence of odor from uninfested cotton seedlings compared to clean air, but significantly less time in the presence of odor from *A. gossypii* infested plants. *A. gossypii* also spent significantly more time in the presence of headspace samples of volatile organic compounds (VOCs) obtained from uninfested cotton seedlings, but significantly less time with those from *A. gossypii* infested plants. VOCs from uninfested and *A. gossypii* infested cotton seedlings were analyzed by gas chromatography (GC) and coupled GC-mass spectrometry (GC-MS), leading to the identification of (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), methyl salicylate, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT), which were produced in larger amounts from *A. gossypii* infested plants compared to uninfested plants. In behavioral tests, *A. gossypii* spent significantly more time in the control (solvent) arms when presented with a synthetic blend of these four compounds, with and without the presence of VOCs from uninfested cotton. Coupled GC-electroantennogram (EAG) recordings with the lacewing *C. lucasina* showed significant antennal responses to VOCs from *A. gossypii* infested cotton, suggesting they have a role in indirect defense and indicating a likely behavioral role for these compounds for the predator as well as the aphid.

Introduction

Cotton, *Gossypium hirsutum* (Malvaceae), is a major fiber crop grown in over 100 countries. The earliest cultivation of cotton in the Americas occurred in Mexico 8,000 years ago (Wendel and Albert, 1992; Seelan et al., 1997), while for Asia, cotton cultivation was reported in India as far back as the Indus valley civilization, 7,000 years ago (Stein, 2001). The largest producers of cotton are China and India, with annual production of about 30 million bales and 24 million bales, respectively, in 2010 (http://www.cotton.org/econ/cropinfo/cropdata/rankings.cfm); most of this production is consumed by their own textile industries.

The primary route to the control of insect pests of cotton crops involves the use of synthetic chemical pesticides. To reduce reliance on pesticide usage, genetically modified cotton was introduced, which involved expression of genetic material associated with toxin production derived from *Bacillus thuringiensis* (Bt). After the introduction of Bt cotton, initial reports suggested that there was substantial reduction in the use of pesticides for control of bollworms (Qaim and De Janvry, 2005, Wu et al., 2008) without altering the status of sucking pests. However, recent reports show a surge in populations of sucking pests, including mirid bugs (Lu et al., 2010) and stink bugs (Willrich et al., 2004a, b, c; Siebert et al., 2005; Reay-Jones et al., 2010), with a steady increase in the use of pesticides (Anon., 2010). Several insecticides such as carbofuran, aldrin, and, more recently, thiamethoxam (Kharbouti and Allen, 2000) are reported to be effective. However, negative effects on non-targets in crop ecosystems and a perceived negative environmental impact have been reported, together with resistance to insecticides (Kerns and Gaylor, 1992; Herron et al., 2001; Herron and Wilson, 2010). A number of alternative pest control practices, such as habitat management (Landis et al., 2000), inundative release of predatory lacewings, *C. rufilabris* (Rosenheim and Wilhoit, 1993), and use of nucleopolyhedrovirus (Xia, 1997) have been tried in the past, but have failed to make much impact against the target due to poor efficacy, limited availability, high cost, and low adoptability.

The cotton aphid, *Aphis gossypii* Glover (Homoptera: Aphididae), is a major sucking pest on a global scale, having a wide host range and attacking many economically important crops (Kerns and Gaylor, 1992). Apart from direct damage, it is a vector of many viral diseases such as P (PRSV-P) and W (PRSV-W) strains of Papaya Ringspot Virus, Watermelon Mosaic Virus 2 (WMV-2), Cucumber Mosaic Virus (CMV), Celery Mosaic Virus (Francki et al., 1979), and Zucchini Yellow Mosaic Virus (ZYMV) (Blua and Perring, 1992). Direct damage and virus transmission are caused by the sucking behavior, mainly on the underside of leaf surfaces. Infested leaves often become cupped downwards and may appear wrinkled. Heavy infestations on some hosts may result in wilting, while young plants may have reduced or stunted growth. The aphids produce copious amounts of honeydew, which serves as a medium for sooty mould. This blackens the leaf and decreases photosynthetic activity (Elmer and Brawner, 1975). Adult *A. gossypii* generally are wingless, but a high population density induces the production of winged (alate) individuals that will migrate to new food sources.

To overcome problems associated with insecticide use in *A. gossypii* control, natural plant resistance, compatible with other more eco-friendly pest management practices (Biswas and Singh, 1998), has been investigated. Marker-assisted selection offers a means to increase the efficiency of incorporating aphid resistance in new plant varieties, but although some effort has been directed towards melon crops (Klingler et al., 2001), for cotton no progress has been reported. Furthermore, breeding approaches have been slow and difficult to achieve by traditional selection, and the availability of pest resistant cultivars to the farming community in India is unlikely in the foreseeable future. Another option is to exploit natural plant defense pathways, including the production of volatile semiochemicals (behavior-modifying chemicals) on insect herbivory (Bruce and Pickett, 2007). These volatile organic compounds (VOCs) attract parasitic and predatory insects that are natural enemies of the herbivores. They also may induce defense responses in neighboring plants (Pickett and Poppy, 2001). Although considerable attention has recently been directed towards plant/insect interactions in agricultural crops, relatively little has been done on the chemical ecology of cotton and associated sucking insect pests such as *A. gossypii*.

Currently, insecticides are the only available and widely used measure for controlling *A. gossypii*; because of the global rise in problems associated with sucking pests on cotton during recent years (Lu et al., 2010; Anon., 2010), more sustainable strategies are required. Lacewings (Neuroptera: Chrysopidae) are major aphid predators (Canard, 2001), and some widely distributed species such as green lacewings within the genus *Chrysopa* have been evaluated as biological control agents (Koczor et al., 2010). Here, we studied the chemical ecology of interactions between cotton and *A. gossypii* and, to provide evidence that *A. gossypii* induced defense can be detected at the next trophic level, we used adult predatory lacewings, *Chrysoperla lucasina* Lacroix (Neuroptera: Chrysopidae), as a model natural enemy.

Methods and Materials

Insect and Plant Material Aphids, *A. gossypii*, were reared on cotton, *G. hirsutum* cv. Linda, in an insectary (20°C; 16:8 h L:D regime) at Rothamsted Research, Harpenden,

Hertfordshire, UK. Cotton seedlings required for rearing *A. gossypii*, headspace collection and behavioral tests were grown under controlled conditions (25°C; 16:8 h L:D regime) in 15 modules or "cells" per standard seed tray, 2 seeds per cell. At the 2 weeks stage, trays were transferred into a growth room (25°C; 16:8 h L:D regime), where they were illuminated from above by fluorescent lights positioned 60 cm above bench height. Lacewings, *C. lucasina*, were obtained as adults from Koppert B.V., The Netherlands, and maintained in cages at 20°C, 16:8 h L:D, prior to use in coupled GC-electrophysiology.

VOC Collection Air entrainment (also referred to as dynamic headspace collection) was carried out following standard procedures (Webster et al., 2008) using 3-wk-old cotton plants. Seeds were planted singly in 13 cm plastic pots inside a growth chamber (25°C, 16:8 L:D). For each headspace collection, a seedling was enclosed in a glass vessel (22 cm high × 10 cm internal diam), open at the bottom, and with two collection ports at the top (one for inlet of air and the other for outlet). The bottom was closed without pressure around the plant stem, using two semicircular aluminum plates with a hole in the center to accommodate the stem. The plates were clipped to a flange on the open end of the glass vessel. Air, purified by passage through an activated charcoal filter (BDH, 10–14 mesh, 50 g), was pumped into the vessel through the inlet port at 700 ml/min (flow rate was controlled by a needle valve and measured by a flow meter). Air was drawn out at 600 ml/min through 50 mg Porapak Q (Alltech Associates, Carnforth, Lancashire, UK) in a 5 mm diam glass tube The differences in flow rates created a slight positive pressure to ensure that unfiltered air did not enter the system, thus removing the need for an airtight seal around the stem. All connections were made with polytetrafluoroethylene (PTFE) tubing (Alltech Associates) with brass ferrules and fittings (North London Valve, London, UK) and closed with PTFE tape (Gibbs and Dandy, Luton, UK). Glassware, metal plates, and other equipment were washed with aqueous Teepol detergent (Herts County Supplies, Herts, UK), acetone, and distilled water, and then baked overnight at 180°C. Porapak Q filled tubes were conditioned before use by washing with redistilled diethyl ether (1 ml) and heating inside an oven (132°C) under a stream of nitrogen for a minimum of 2 hr. Once conditioned, Porapak Q tubes were closed with Swagelok cap fittings and left to cool at ambient temperature prior to use. VOCs were collected on Porapak Q tubes inserted into the collection port on the top of the vessel and were subsequently eluted with 750 µl of freshly distilled diethyl ether.

VOCs were obtained from infested (100 *A. gossypii* per plant) and uninfested cotton seedlings. Aphids were released and allowed to settle for 1 hr before entrainments began. Plants were entrained for a total of 5 days, with the tubes being changed at 24 hr periods. Samples were combined prior to use in behavioral, electrophysiological, and chemical analytical studies, and were stored at −20°C until required for use. For electrophysiological studies with *C. lucasina*, the headspace sample of *A. gossypii* infested cotton was concentrated to *ca.* 50 µl under a gentle stream of nitrogen prior to use.

Four-Arm Olfactometer Bioassay Bioassays were conducted in a controlled environment room (22±2°C, 40% RH) fitted with an extraction fan. A Perspex olfactometer, having four glass arms and a central space connecting all the arms (10 cm diam, 14 cm arm long), was kept on a small stand. The central area of the top portion of the olfactometer contained a hole into which alate (winged) *A. gossypii* were introduced, and which was connected to a low pressure air pump. The olfactometer was set up in a cage (60 × 60 × 76 cm) comprising a steel frame covered with black cardboard paper to avoid external visual cues. Uniform illumination was provided by two fluorescent light tubes (70 W Luminux) positioned approximately 45 cm above the olfactometer. A charcoal-filtered airstream (200 ml/min) was supplied to the central space of the olfactometer using an electric pump. Adult winged aphids were collected from rearing cages in a separate insectary room and starved for 2 hr before each trial. Each aphid was exposed to the test samples for 16 min, and every 2 min the position of the olfactometer was rotated by 180°. The time spent by *A. gossypii* in the different arms of the olfactometer was recorded using a software programme (OLFA: F. Nazzi, Udine, Italy).

Several series of bioassays were conducted. Ten replicates were done for each sample. In the first series, the responses of *A. gossypii* to odor from *A. gossypii* infested and uninfested 3-wk-old cotton seedlings were studied, as were responses to VOCs obtained from the headspace above *A. gossypii* infested and uninfested seedlings. In the second series, the response was studied of *A. gossypii* to a synthetic blend of *A. gossypii* induced compounds (identification described later) [(*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), methyl salicylate, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT)] and individual compounds, all at the levels found in the *A. gossypii* infested VOC sample. The doses used in the first and second series were equivalent to the amount emitted by one cotton seedling over 19.8 min. The blend also was tested in combination with the VOCs collected from uninfested cotton seedlings. For the third series, individual compounds were tested at a single dose (1 µg), either alone or in combination with the VOCs collected from uninfested cotton seedlings. In all series, the treatment sample (10 µl) was added to a filter paper, and the solvent was allowed to evaporate over 30 sec prior to placement in

a single arm, while the three control arms contained a piece of filter paper with 10 µl of control solvent (diethyl ether or hexane for VOC sample and synthetic blend, respectively). Treatments were offered to insects for the duration of each assay (16 min). Treatments were replaced with fresh material between replicates. Data were analyzed using a paired *t*-test (one tail) with statistical software (Genstat Version 11, VSN International Ltd.) after ensuring that data were normally distributed.

GC Analysis Samples of VOCs (4 µl) were analyzed on an Agilent 6890 GC equipped with a cool on-column injector, flame ionization detector (FID) and a non-polar HP-1 bonded phase fused silica capillary column (50 m × 0.32 mm i.d., film thickness 0.52 µm). The oven temperature was maintained at 30°C for 1 min, programmed at 5°C min/min to 150°C, and held for 0.1 min, then 10°C min/min, then 10°C min/min to 230°C. The carrier gas was hydrogen. Data were analyzed using HP Chemstation software. Quantification of VOCs was performed using a single point external standard quantification method using authentic samples of standards (Skelton et al., 2010).

Electrophysiology Lacewings, *Chrysoperla lucasina*, were obtained as adults from Koppert B.V., The Netherlands, and maintained at 20°C, 16 hr day length, prior to use. Electroantennogram (EAG) recordings were made using Ag-AgCl glass electrodes filled with a saline solution (composition as in Maddrell 1969, but without glucose:7.55 g/l sodium chloride, 0.64 g/l potassium chloride, 0.22 g/l calcium chloride, 1.73 g/l magnesium chloride, 0.86 g/l sodium bicarbonate, 0.61 g/l sodium orthophosphate). An antenna from a female lacewing was excised, its tip removed to ensure a good contact, and then suspended between the two electrodes. The signals were passed through a high impedance amplifier (UN-06, Syntech, Hilversum, The Netherlands) and analyzed with a customized software package (Syntech).

Coupled Gas Chromatography-Electroantennography (GC-EAG) The coupled GC-electrophysiology system, in which the effluent from the GC column is simultaneously directed to the antennal preparation and the GC detector, has been described previously (Wadhams, 1990). The effluent from the transfer line to the antenna was delivered into a purified airstream (1 l/min) flowing continuously over the preparation. Separation of the VOCs was achieved on an AI 93 GC equipped with a cold on-column injector and an FID. The GC column was 50 m × 0.32 mm i.d. HP-1. The oven temperature was maintained at 30°C for 2 min and then programmed at 15°/min to 250°C. The carrier gas was helium. The outputs from the EAG amplifier and the FID were monitored simultaneously and analyzed using the Syntech software package. FID peaks were assumed to be EAG active if they elicited responses on three or more preparations.

GC-MS Analysis Coupled GC-MS analysis of volatile extracts was performed using a fused silica capillary column (50 m × 0.32 mm i.d., film thickness 0.52 µm, DB-1), attached to a cool on–column injector, which was directly coupled to a magnetic sector mass spectrometer (Autospec Ultima, Fisons Instruments, Manchester, UK). Ionization was by electron impact (70 eV, source temperature 250°C). Helium was the carrier gas. The oven temperature was maintained at 30°C for 5 min, and then programmed at 5°C/min to 250°C. Tentative identifications were made by comparison of spectra with mass spectral databases (NIST 2005). Identifications were confirmed by peak enhancement on GC using authentic compounds (Pickett, 1990).

Chemicals Porapak Q (80/100 mesh) was purchased from Alltech (PA, USA). Diethyl ether (purris.) was purchased from Sigma Aldrich. Hexane (95% pesticide residue) was purchased from Fisher Scientific (Loughborough, Leicestershire, UK). Both solvents were distilled prior to use. (*Z*)-3-Hexenyl acetate and methyl salicylate were purchased from Sigma Aldrich (Steinheim, Germany). (*E*)-4,8-Dimethyl-1,3,7-nonatriene (DMNT) (>98%) and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) (>98%) were synthesized from geraniol and (*E,E*)-farnesol, respectively, by oxidation to the corresponding aldehyde followed by Wittig methylenation (Leopold, 1990).

Results

Olfactometry Experiments—Series 1 Alate (winged) *A. gossypii* spent more time ($P<0.001$) in the presence of odor from intact cotton seedlings compared to clean air (Fig. 1), and less time ($P<0.01$) in the presence of odor from *A. gossypii* infested cotton seedlings (Fig. 1) compared to clean air. *A. gossypii* also spent more time ($P<0.05$) in the presence of VOCs collected from intact cotton plants, but less time ($P<0.01$) in the presence of VOCs from *A. gossypii* infested seedlings, compared to solvent controls (Fig. 1).

VOC Analysis GC and coupled GC-MS analysis of headspace collections from 3-wk-old intact and *A. gossypii* infested cotton seedlings revealed an increase in the production of (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), methyl salicylate, and (*E,E*)-

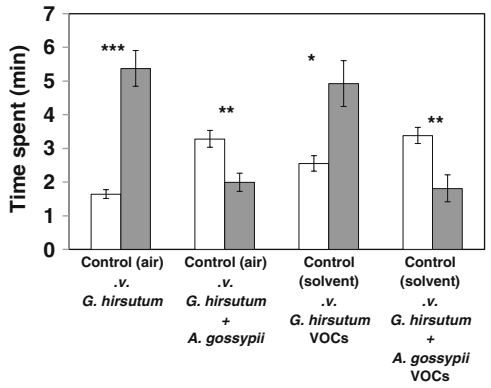

Fig. 1 Response in a four-arm olfactometer of the cotton aphid, *Aphis gossypii*, to odor from above *A. gossypii* infested or intact cotton (*Gossypium hirsutum*) plants, and VOCs obtained by air entrainment. Data are expressed as the mean (± SE) time (min) spent in treatment and control arms, and were analyzed by using a paired *t*-test (one tail) with statistical software (Genstat Version 11, VSN International Ltd.) after ensuring that data were normally distributed. * $P<0.05$; ** $P<0.01$; *** $P<0.001$. □ Control. ■ Treatment

4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) in *A. gossypii* infested plants compared to uninfested plants (Fig. 2). Using a single point external standard quantification method with authentic samples of standards, the concentrations of *(Z)*-3-hexenyl acetate, DMNT, methyl salicylate, and TMTT in the *A. gossypii* infested sample

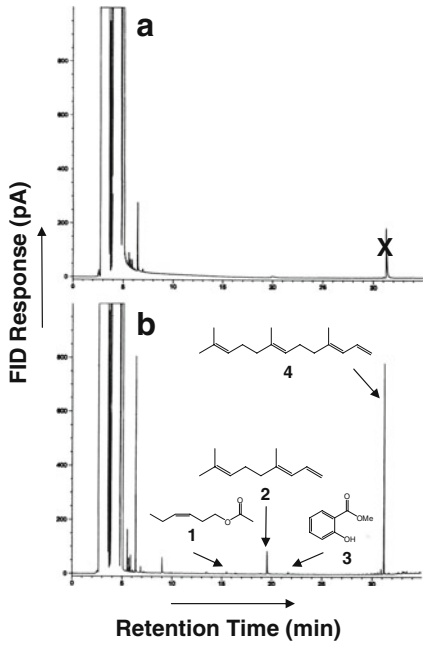

Fig. 2 Gas chromatography analysis of VOC samples collected from (**a**) uninfested and (**b**) *Aphis gossypii* infested cotton (*Gossypium hirsutum*) plants: *1* = (*Z*)-3-hexenyl acetate, *2* = (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), *3* = methyl salicylate, and *4* = (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT). X = column bleed

were determined to be 0.34, 4.12, 0.33, and 14.62 ng/µl, respectively. Based on the weight of sampled plant material and the duration of entrainments, emission rates for the four compounds were calculated to be 3.54, 42.92, 3.44, and 152.29 ng/g/h, respectively.

Olfactometry Experiments—Series 2 A. gossypii spent more time ($P<0.05$) in the control arms when presented with a synthetic blend of (*Z*)-3-hexenyl acetate, DMNT, methyl salicylate, and TMTT, prepared and tested at the same dose and ratio as found in *A. gossypii* infested cotton seedlings (Fig. 3a). *A. gossypii* also spent more time ($P<0.05$) in the control arms when presented with the VOCs from intact cotton in the presence of the four component blend (Fig. 3a). When (*Z*)-3-hexenyl acetate, methyl salicylate, and TMTT

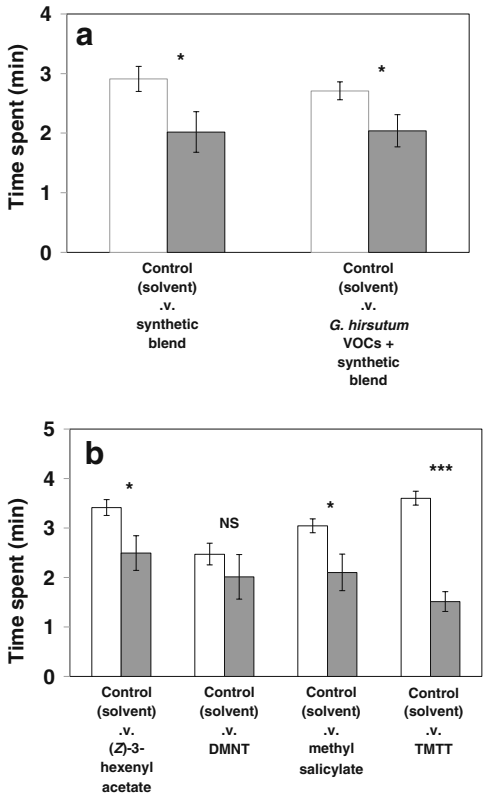

Fig. 3 Response in a four-arm olfactometer of the cotton aphid, *Aphis gossypii*, to (**a**) a synthetic blend of *Aphis gossypii*-induced compounds from cotton [(*Z*)-3-hexenyl acetate, DMNT, methyl salicylate, and TMTT] and a VOC sample collected from intact cotton in combination with the synthetic blend, and (**b**) to individual synthetic compounds. In all experiments, the synthetic compounds were tested at the levels found in *A. gossypii* infested cotton (0.34, 4.12, 0.33, and 14.62 ng μl^{-1} for (*Z*)-3-hexenyl acetate, DMNT, methyl salicylate, and TMTT, respectively). Data are expressed as the mean (± SE) time (min) spent in treatment and control arms, and were analyzed using a paired *t*-test (one tail) with statistical software (Genstat Version 11, VSN International Ltd.) after ensuring that data were normally distributed. * $P<0.05$; *** $P<0.001$. □ Control. ■ Treatment

were presented individually at doses found in the *A. gossypii* infested sample, *A. gossypii* spent more time in the control arms [Fig. 3b; (*Z*)-3-hexenyl acetate ($P<0.05$); methyl salicylate ($P<0.05$); TMTT ($P<0.001$)]. No significant difference was observed in the time spent between control and treatment arms when DMNT was tested.

Olfactometry Experiments—Series 3 When (*Z*)-3-hexenyl acetate, methyl salicylate, and TMTT were presented individually at a 1 μg dose, *A. gossypii* spent more time in the control arms [Fig. 4; $P<0.01$ for (*Z*)-3-hexenyl acetate; $P<0.001$ for methyl salicylate; $P<0.01$ for TMTT]. No significant difference was observed in the time spent when DMNT was tested. Similarly, addition of (*Z*)-3-hexenyl acetate, methyl salicylate, and TMTT individually to VOCs collected from uninfested cotton at a 1 μg dose resulted in *A. gossypii* spending more time in the control arms [Fig. 4b, $P<0.01$ for (*Z*)-3-hexenyl acetate; $P<0.001$ for methyl salicylate; and $P<0.05$ for TMTT]. There was no significant difference in the time spent by *A. gosspyii* between the control arms and the VOCs from uninfested cotton in the presence of DMNT.

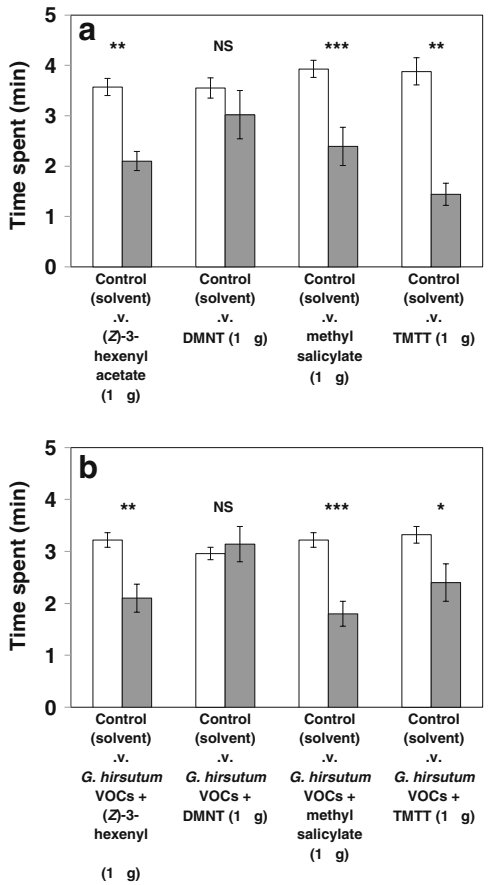

Fig. 4 Response in a four-arm olfactometer of the cotton aphid, *Aphis gossypii*, to (**a**) synthetic compounds tested alone (1 μg), and (**b**) a VOC sample collected from intact cotton (*Gossypium hirsutum*) plants in combination with individual synthetic compounds (1 μg). Data are expressed as the mean (± SE) time (min) spent in treatment and control arms, and were analyzed by using a paired *t*-test (one tail) with statistical software (Genstat Version 11, VSN International Ltd.) after ensuring that data were normally distributed. * $P<0.05$; ** $P<0.01$; *** $P<0.001$; *NS* no significant difference. □ Control. ■ Treatment

Coupled GC-Electrophysiology Coupled GC-EAG analysis using the antennae of female *C. lucasina* revealed the perception of a number of compounds in the *A. gossypii* infested cotton VOC sample (Fig. 5). These included methyl salicylate, DMNT, and TMTT, but no significant response to (*Z*)-3-hexenyl acetate was observed in these experiments. Electrophysiological responses to several other peaks were demonstrated, with compounds tentatively identified as 6-methyl-5-hepten-2-one, (*Z*)-4,8-dimethyl-1,3,7-nonatriene, octanal, nonanal, decanal, 3-methylhexane, *n*-heptane, methylcyclohexane, α-pinene, and an ethylbenzaldehyde isomer (stereochemistry undefined).

Discussion

To our knowledge, this is the first study of the chemical ecology underlying interactions between cotton and the cotton aphid, *A. gossypii*, and the induction of defense VOCs following *A. gossypii* infestation. Olfactometer data confirmed that *A. gossypii* was attracted to the odors from uninfested cotton plants but was repelled by odors from *A. gossypii* infested plants. Furthermore, *A. gossypii* was attracted to VOCs collected from uninfested cotton but repelled by those from *A. gossypii* infested cotton, and also was repelled by three synthetic VOCs identified as being induced by *A. gossypii* infestation, i.e., (*Z*)-3-hexenyl acetate, methyl salicylate, and TMTT. No effect was observed for DMNT, i.e., the lower molecular weight homologue of TMTT, which was also induced on aphid infestation. Induction of defense compounds in cotton on herbivory by beet armyworms (*Spodoptera* spp.) and whiteflies has been reported previously (Loughrin et al., 1994; McCall et al., 1994; Rose et al., 1996; Rodriguez-Saona et al., 2003; Rose and Tumlinson, 2005), and include three of the defense VOCs reported in this study, i.e., the green leaf volatile compound (*Z*)-3-hexenyl acetate, and the homoisoprenoid compounds DMNT and TMTT. In our study, methyl salicylate was emitted by *A. gossypii* infested cotton, but no emission of sesquiterpenes was detected. This emission pattern by *A. gossypii* infested cotton implies an herbivore specific response, i.e., a response to an aphid (sucking) pest. The emission of methyl salicylate in this study is similar to that seen for aphid damaged soybean (Zhu and Park, 2005).

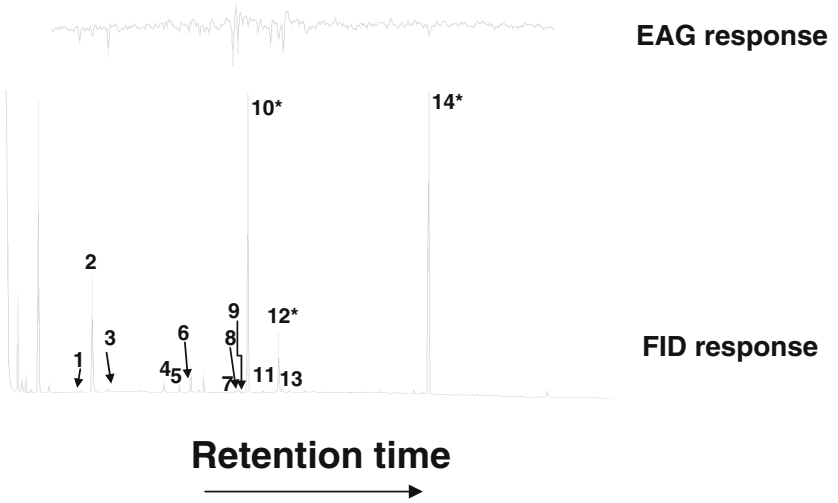

Fig. 5 Typical coupled GC-EAG analysis showing antennal response of female lacewings, *Chrysoperla lucasina,* to the headspace sample from *Aphis gossypii* infested cotton (*Gossypium hirsutum*) plants. Upper trace, response of antenna; lower trace, FID response. GC peaks identified as: *1* = 3-methylhexane; *2* = *n*-heptane; *3* = methylcyclohexane; *4* = α-pinene; *5* = 6-methyl-5-hepten-2-one; *6* = octanal; *7* = linalool oxide (furan); *8* = nonanal; *9* = (*Z*)-4,8-dimethyl-1,3,7-nonatriene; *10* = (*E*)-4,8-dimethyl-1,3,7-nonatriene; *11* = 2, 3 or 4-ethylbenzaldehyde; *12* = methyl salicylate; *13* = decanal; *14* = (*E, E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. *Identifications confirmed by GC peak enhancement using authentic standards

Blends and ratios of VOCs are important in insect olfaction (Bruce et al., 2005), and the VOC blend released by *A. gossypii* is likely to be important for modifying aphid natural enemy behavior, as seen for other aphid/plant interactions (Du et al., 1998). The profile of induced VOCs also may vary, based on age/stage of the plant (Zhu and Park, 2005), along with the type of cultivar studied. Thus, selection of cultivar specific traits such as the production of induced defense VOCs is an important point to be considered for future cultivar development in relation to biological control. Furthermore, studies have shown that induced defense VOCs have the ability to prime neighboring plants for enhanced defense, including one of the induced VOCs in this study, i.e., (*Z*)-3-hexenyl acetate (Frost et al., 2008). Further studies are planned to investigate the potential for induced cotton VOCs to prime neighboring plants for defense against future biotic (herbivore or pathogen) attack.

VOC production in crop plants, e.g., maize, is induced by elicitors originating from herbivores (Alborn et al., 1997; Frey et al., 2000). Furthermore, VOC production is linked to transcription of terpene synthase genes, which are involved in the biosynthesis of sesquiterpenes, and of which several have been isolated and characterized (Degenhardt et al., 2009). Production of the homosesquiterpene compound TMTT in *Arabidopsis thaliana* involves *TPS04/GES*, a geranyllinalool synthase (Herde et al., 2008), and CYP82G1, a cytochrome P450 monoxygenase, the latter reported as being responsible for the oxidative cleavage of geranyllinalool (Lee et al., 2010). However, other genes may be involved, including other cytochromes P450, e.g., CYP81D11 (Matthes et al., 2011). Production of methyl salicylate is under the control of salicylate methyltransferase (SMAT) in tobacco (Ross et al., 1999) and the *bsmt1* gene in *A. thaliana* (Snoeren et al., 2010). Further studies at the molecular level are required to establish the molecular basis of VOC production in cotton.

The EAG active compounds (*Z*)-3-hexenyl acetate, methyl salicylate, and TMTT all interfered with the attraction of *A. gossypii* to VOCs from uninfested cotton. Roles for these three compounds in the chemical ecology of plant/aphid/natural enemy interactions have been reported previously. Hardie et al. (1994) demonstrated that methyl salicylate stimulates olfactory cells in the primary rhinaria of the black bean aphid, *A. fabae.* In behavioral studies employing a linear track olfactometer, this compound was repellent to *A. fabae* and also inhibited attraction to VOCs from the host plant, broad bean, *Vicia faba.* Methyl salicylate also is released from soybean, *Glycine max*, following herbivory by the soybean aphid, *A. glycines*, and is shown to be electrophysiologically active for seven-spot ladybirds, *Coccinella septempunctata* (Zhu and Park, 2005). Thus, release of methyl salicylate by cotton on damage by aphid pests may be a well-defined strategy that attracts predators. Application of methyl salicylate in wheat fields reduced aphid populations by at least by 30–40% when used as a slow release formulation (Pettersson et al., 1994). Increased biological control activity with methyl salicylate has been reported in hop yards and grape blocks (James et al., 2005, Zhu and Park, 2005). *Aphis fabae* is repelled by (*Z*)-3-hexenyl acetate and TMTT (Webster et al., 2010), in line with the present findings, and the latter is

attractive for aphid parasitoids (Bruce et al., 2008) and stink bug parasitoids (Moraes et al., 2009) following its emission from plants exposed to the plant activator *cis*-jasmone. Although the presence of specific olfactory receptors for TMTT has been demonstrated for an aphid parasitoid, *Aphidius ervi* (Bruce et al., 2008), to our knowledge, this paper is the first to report evidence of antennal perception of this plant stress compound in an aphid predatory species.

Coupled GC-electrophysiology with *C. lucasina* revealed the presence of other electrophysiologically active compounds for which no discernable difference in levels between uninfested and *A. gossypii* infested samples could be detected by GC analysis (data not shown). These included 6-methyl-5-hepten-2-one, which has been shown in other studies to be an important host derived semiochemical for *A. gossypii* (da Costa et al., 2011), while octanal and decanal have been shown to be host derived semiochemicals for *A. fabae* (Webster et al., 2010). Investigations into the behavioral roles of the EAG active compounds other than those used in behavioral studies, i.e., 6-methyl-5-hepten-2-one, (*Z*)-4,8-dimethyl-1,3,7-nonatriene, octanal, nonanal, decanal, 3-methylhexane, *n*-heptane, methylcyclohexane, α-pinene, and an ethylbenzaldehyde isomer (Fig. 5), were beyond the scope of this study, but will form part of ongoing investigations, both in the laboratory and in the field.

In summary, this study has demonstrated the role and identity of volatile semiochemicals released by cotton upon infestation by the aphid *A. gossypii* and olfactory detection of the defense compounds by predatory *Chrysoperla* spp. lacewings. While the manipulation of beneficial insects by using field deployment of volatile semiochemicals has been investigated extensively in various crop scenarios, the application of synthetic blends can be costly and inefficient due to the high cost of semiochemical production, coupled with the instability and high volatility of semiochemicals under field conditions. Production of defense semiochemicals in cotton for protection against *A. gossypii* could be achieved in a cheaper and more sustainable manner by using "smart" resistant cotton varieties, through activation and priming of defense by small lipophilic molecule plant activators such as *cis*-jasmone (Birkett et al., 2000; Bruce et al., 2003; Moraes et al., 2009), or even by developing cotton varieties that have been genetically transformed to produce these defense semiochemicals upon exposure to *cis*-jasmone (Bruce et al., 2008; Matthes et al., 2010). Further studies are underway to investigate the potential for activation of defense in cotton.

Production of Induced Volatiles by *Datura wrightii* in Response to Damage by Insects: Effect of Herbivore Species and Time

Abstract Natural enemies of herbivorous insects utilize numerous chemical cues to locate and identify their prey. Among these, volatile plant compounds produced after attack by herbivores may play a significant role (hereafter herbivore-induced plant volatiles or HIPVs). One unresolved question is whether the composition of the volatile cue blends induced by different herbivore species differ consistently enough to indicate not only that the plants are damaged by herbivores but also the identity of the herbivore species causing the damage. We studied HIPV production in the undomesticated plant species *Datura wrightii* in the laboratory when damaged by either of two leaf-chewing herbivore species, *Lema daturaphila* or *Manduca sexta*, or when damaged by *L. daturaphila* and the piercing-sucking bug, *Tupiocoris notatus*, or both *L. daturaphila* and *T. notatus,* for 24 hr. HIPV production was monitored 1 d before induction, the day of induction, and for 7 d after induction. In all experiments, both the quantities and composition of the HIPV blends varied with the time since induction as different components reached peak production at different times after induction. HIPV blends did not differ consistently with the herbivore species causing the damage. For plants damaged by both *L. daturaphila* and *T. notatus*, greater amounts of HIPVs were produced than by plants damaged by either species alone, but the amounts did not differ from that predicted as the sum from damage inflicted by each herbivore species independently. The HIPVs of *D. wrightii* are a general rather than specific indicator of damage by herbivores. Because generalist predators are the most abundant natural enemies in this system, general cues of herbivore damage may be all that are required to facilitate the discovery by predators of plants damaged by any of several suitable prey species.

Key Words Induced defense · HIPVs · Tritrophic interactions · Specificity · *Datura wrightii* · *Lema daturaphila* · *Tupiocoris notatus* · *Manduca sexta*

Introduction

Odors of plants can serve as cues to attract natural enemies of the insect herbivores attacking those plants (Vinson, 1976, 1981; Nordlund et al., 1988; Allison and Hare, 2009). These odors may be comprised of hundreds of compounds (Dudareva et al., 2006), many of which are released only by plants after they have been damaged by herbivores (Elzen et al., 1983; Dicke and Sabelis, 1988; Turlings et al., 1991; Tumlinson et al., 1992). One unresolved question in the production of these herbivore-induced plant volatiles (HIPVs) is whether different herbivore species induce consistently different or specific blends, and how specific a blend must be in order to be recognized by the species of natural enemies that effectively suppress the plant's herbivores.

Congenitally fixed responses to herbivore-specific cues were predicted for cases involving extreme specialization by natural enemies on particular herbivore species which themselves are specialized on a particular species of plant, whereas progressively greater levels of learned responses

on the part of the natural enemies were predicted for less extreme levels of specialization (Vet and Dicke, 1992; Faeth, 1994). Similarly, specialist natural enemies were predicted to utilize specific cues from their host/prey complex, whereas generalists were predicted to utilize general cues released by all of their different host/prey complexes (Steidle and van Loon, 2003). Although simple predictions may be reasonable for relatively simple trophic chains, especially for plants attacked by a single herbivore species that itself has only one resident species of natural enemy, predictions that concern the responses of plants become more difficult if plants are attacked by a community of generalist and specialist herbivores, themselves attacked by numerous species of natural enemies differing in host specificity.

In some cases, attack by single vs. multiple herbivore species may result in statistically significantly different HIPV blends (Shiojiri et al., 2001; Delphia et al., 2007; De Boer et al., 2008), whereas in other systems, plants infested with multiple herbivore species simply emit a greater quantity of the same volatiles than plants damaged by single herbivore species (Moayeri et al., 2007). In still other systems, damage by one herbivore species may suppress the HIPV response normally induced by other species (Zhang et al., 2009). Therefore, the consequences of infestation of plants by more than one species of herbivore are difficult to predict, and depend upon such factors as the particular combination of plant species, herbivore species, and species of natural enemy (Hare, 2011).

Another controversy in this area focuses upon whether the HIPV blend produced by plants in response to damage by herbivores is anything more than a simple response to mechanical injury. In most studies, damage by herbivores elicits HIPV blends containing a greater range of compounds and in greater concentrations than mechanical damage. Mechanical damage that is most similar to damage by herbivores, both as to the mechanism of damage as well as its duration, elicits HIPV blends most similar to those elicited by natural herbivores (Mithofer et al., 2005; Connor et al., 2007). Plant species may differ in how closely their volatile profiles induced by mechanical damage resemble those induced by herbivore damage, however (Maffei et al., 2007). Even for plant species in which the volatile blends are similar in response either to mechanical or herbivore damage, differences in plant responses can be seen at the molecular level (Bricchi et al., 2010).

Variation in the total quantity of HIPVs as well as the relative proportions of components may vary with plant genotype (Hare, 2007; Schuman et al., 2009), the environmental conditions under which plants are grown (Gouinguene and Turlings, 2002; Kigathi et al., 2009), and the amount of time following damage (Turlings et al., 1998; Kunert et al., 2002). Variation in composition also may be a function of the amount of damage (Gouinguene et al., 2003; Delphia et al., 2007). Such variation raises important questions as to whether any aspect of the HIPV blends of plants induced by different herbivore species may be sufficient to reveal reliably the identities of the herbivores (Turlings et al., 1995; Turlings and Wäckers, 2004; Webster et al., 2010).

When damaged by its primary herbivore, the chrysomelid beetle *Lema daturaphila*, plants of the undomesticated plant species, *Datura wrightii* produce an array of at least 17 compounds, most of which are sesquiterpenes (Hare, 2007, 2010). In a laboratory study, total production of volatiles increased 3.9 to 16.2 times among genetic lines of *D. wrightii* after insect damage. The most abundant compound was (*E*)-β-caryophyllene, which comprised from 17 to 59% of the volatiles from insect-damaged plants, depending upon genetic line. Other relatively abundant HIPV compounds included (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, (*E,E*)-4,8,12-trimethyl-1,3,7,11- tridecatetraene (hereafter TMTT), (*E*)-4,8-dimethyl-1,3,7- nonatriene (hereafter DMNT), and β-selinene, most of which are commonly induced by herbivores in other plant species (Arimura et al., 2005). The array of compounds emitted by young plants induced in the field was similar (Hare, 2010; Hare and Sun, 2011).

Within southern California populations, *D. wrightii* exhibits two leaf trichome phenotypes, and aspects of the ecology and genetics of the trichome dimorphism have been described elsewhere (van Dam and Hare, 1998; van Dam et al., 1999). The 'velvety' phenotype is densely covered by short, non-glandular trichomes and feels velvety to the touch, whereas the 'sticky' phenotype is less densely covered with glandular trichomes that secrete esters of glucose and aliphatic acids, and these leaves feel sticky to the touch. The trichome phenotype is governed by a single locus and is inherited in a Mendelian fashion; the allele for the sticky phenotype is dominant over that of the velvety phenotype (van Dam et al., 1999).

The herbivore community that attacks *D. wrightii* in southern California is relatively simple, being comprised of some 5–10 species depending upon season and location, but the herbivore community varies with trichome phenotype (Elle and Hare, 2000; Hare and Elle, 2002). The most abundant herbivore species overall is *L. daturaphila*, a folivore whose larval and adult stages damage sticky and velvety plants similarly throughout the growing season. Another potentially more damaging insect herbivore, because of its greater rate of food consumption (Bronstein et al., 2006), is the tobacco hornworm, *Manduca sexta*. This species is more constrained seasonally in its abundance on *D. wrightii,* but it is more abundant on velvety than sticky plants (Elle and Hare, 2000; Hare and Elle, 2002).

The most abundant herbivore on sticky plants is the mirid bug, *Tupiocoris notatus*. It utilizes the sugar esters produced by the glandular trichomes of the sticky phenotype of *D. wrightii* as feeding and oviposition stimulants, but *T. notatus* can survive and reproduce on velvety plants if given no choice (van Dam and Hare, 1998). Although the effect of *T. notatus* on HIPV production of *D. wrightii* has not yet been studied, the omnivorous heteropteran predator, *Geocoris pallens*, is attracted to plants of *Nicotiana attenuata* damaged either by *T. notatus* or *Manduca* spp. (Kessler and Baldwin, 2004). On the other hand, damage by *T. notatus* also can suppress some of the jasmonate-mediated responses to other insects in other plant species (Heidel and Baldwin, 2004), which suggests that the HIPV blend induced by *T. notatus* in combination with *L. daturaphila* may differ from the HIPV blend induced by *L. daturaphila* alone.

A number of natural enemies that differ in host range are associated with these herbivore species. In a comprehensive survey of the parasitoids and predators of *M. sexta* on *D. wrightii* in Arizona, more than 40 natural enemies were identified, including 34 insect predators and parasitoids from 8 different orders and 14 species of spiders from 4 different families (Mira and Bernays, 2002). Less intensive sampling of the natural enemies associated with *D. wrightii* in California found many of the same generalist predators, including species of *Nabis* and *Chrysoperla* (Gassmann and Hare, 2005), although the most abundant predator in California was *G. pallens*, a species not reported from the survey in Arizona. Like several other generalist predators, *G. pallens* exhibited lower rates of predation of *L. daturaphila* and *T. notatus* when the herbivores were on sticky plants than when on velvety plants in the greenhouse (Gassmann and Hare, 2005). This predator also inflicted greater levels of mortality of young larvae of *L. daturaphila* on young *D. wrightii* plants when plants either were damaged by *L. daturaphila* or treated with MeJA compared to undamaged or untreated plants. The increase in predation was especially pronounced on the velvety genotype (Hare and Sun, 2011). In field experiments, predation of eggs of *L. daturaphila* by *G. pallens* increased with increasing total HIPV production in the early part of the season, when predators were colonizing plants, but predation rates did not vary with the variation in the composition of the HIPV blend produced by different genetic lines of *D. wrightii* (Hare and Sun, 2011). Common parasitoids of *M. sexta* in California include the generalists, *Hyposoter exiguae* and *Trichogramma* spp. (Oatman et al., 1983). Only two parasitoids of *L. daturaphila* are observed occasionally in southern California, *Conura delumbis* (Hymenoptera: Chalcidae) and *Myiopharus infernalis* (Diptera: Tachinidae). Both of these utilize other coleopteran hosts as well (Arnaud, 1978; Burks, 1979).

Our overall goals were to compare the quantities and compositions of HIPV blends induced by the three predominant herbivores of *D. wrightii* in southern California, the chewing herbivores *L. daturaphila* and *M. sexta*, and the piercing-sucking herbivore, *T. notatus,* when these insects were feeding on two relatively highly inducible lines of *D. wrightii*. We asked if the blends differed consistently among inducers to indicate the possible identity of the herbivore causing the damage. The paucity of specialized natural enemies of the herbivores of *D. wrightii* compared to the abundance of generalist predators also suggested that there may be reduced opportunities for the evolution of herbivore-specific HIPV blends in *D. wrightii.* We also asked if the quantities and composition of HIPV blends induced by plants infested by both *T. notatus* and *L. daturaphila* differed from the blends induced by each species alone. Both the total quantity as well as the composition of blends induced by each herbivore treatment were subjected to multivariate analysis and compared over a period from 1 d prior to induction until 7 d after induction.

Methods and Materials

Two experiments were carried out using similar, though not identical designs. The first compared the HIPVs induced over time by *L. daturaphila* and *M. sexta,* whereas the second compared the HIPVs induced by *T. notatus* and *L. daturaphila* when each damaged plants alone or in combination.

Plants Fifth-generation backcross progeny of the highly inducible MVV6 and MVV8 lines (Hare, 2007) were used in both experiments. These lines were established by backcrossing heterozygous sticky progeny to their original velvety pollen parent. Because the genotypes of the progeny of these backcrosses can be only heterozygous or homozygous recessive, then trichome phenotype maps directly to genotype. The expected ratio of adult heterozygous sticky to homozygous recessive velvety sibs within each of the lines is 1:1, and sibs within families are expected to be at least 98.4% similar after five generations of backcrossing. Plants were grown in a greenhouse equipped with high-pressure sodium lamps providing supplemental illumination for 14 hr/d so that mid day light intensities averaged 1250±39 μmol m^{-2} s^{-1} PAR illumination (N=5 readings) at plant height. Greenhouse temperatures ranged between 15° and 35°C. Plants were maintained under these conditions for ca. 2–4 mo until they had produced 6–8 true leaves (first experiment) or 10–12 leaves (second experiment). The first experiment was performed using younger trichome-undifferentiated plants

because prior research showed no difference in HIPV blends between sticky and velvety plants when induced by *L. daturaphila* (Hare, 2007). The effect of trichome genotype was of more interest with regard to the HIPVs induced by *T. notatus*, so the second experiment utilized older plants for which trichome differentiation had been completed (van Dam et al., 1999).

Collection of Volatiles Volatiles were collected nondestructively from intact plants in a growth room 14:10 photophase: scotophase, 26°C day and 20°C night temperatures with light intensity of 293 (± 29 SE, n=5) μmol m^{-2} s^{-1} PAR illumination at plant height. Aeration chambers were made from polyester cooking bags (unprinted 45×55 cm bags, Terinex, Bedford, England) as described earlier (Hare, 2007).

An aeration chamber was placed over a whole plant, excluding senescing leaves, and secured with a twist-tie around the stem. Intake and exhaust flow rates were regulated with flow meters (Aalborg, Orangeburg, NY, USA). PTFE tubing was used upstream of the adsorbent trap and PVC tubing was used downstream. Compressed air, filtered through activated charcoal, flowed into the bag at 600 ml/min. Periodic collections of volatiles from an empty bag showed that the charcoal filter removed all potentially interfering volatile compounds. Air was exhausted from the bag through an adsorbent trap at the same rate using house vacuum. HIPVs were collected on traps made of glass tubing and filled with Super-Q (25 mg, Alltech, State College, PA, USA). At the termination of the aeration, traps were wrapped in aluminum foil, labeled, and stored at −20°C for extraction later that day.

For the first experiment, 6 plants were assigned to each of two herbivore damage treatments, and 1 plant was assigned to a 'no induction' control treatment within each trial. Control plants were included simply to ensure that plants were not induced by mechanical handling. The greater allocation of replicates to insect-damage treatments reflect the higher priority placed upon comparing the HIPV blends induced by the two different herbivore species than on comparing either to uninduced controls. The whole experiment was repeated five times. One plant in one trial was damaged during the course of the experiment and deleted, leaving a total of 64 experimental plants. For the second experiment, 4 plants, 2 sticky and 2 velvety were assigned to damage by *T. notatus* alone, *L. daturaphila* alone, or both, whereas 1 plant of each trichome genotype was assigned to a 'no induction' treatment (control) within each trial of 14 plants. This experiment also was repeated five times, but 3 plants were damaged during handling and so were deleted from the experiment leaving a total of 67 plants.

Induction Treatments For plants to be induced by *L. daturaphila,* groups of four fourth (last) instar larvae of *L. daturaphila* per leaf were placed on each of three leaves, and larvae were allowed to feed for 24 hr. The youngest full-sized leaf, plus the one above and the one below, were chosen, and larvae were confined to their leaf by a small organdy leaf cage. For the plants to be induced by *M. sexta*, one newly-molted third instar *M. sexta* per leaf was placed on each of three leaves of similar age, as above, and these larvae also were confined to their leaf with a small leaf cage. These numbers and developmental stages of the two insect species were chosen on the basis of preliminary experiments (not shown) to cause similar levels of damage. In the second experiment, for plants to be induced by *T. notatus,* plants were infested with 50 nymphs and adults of *T. notatus*, two pairs of adult *L. daturaphila*, or both 50 *T. notatus* individuals and two pairs of adult *L. daturaphila*, and these insects also were allowed to feed on plants for 24 hr. A single 24-hr-damage-period was chosen to facilitate the calculations of the rate of HIPV emission per unit of remaining plant tissue over time. Although it might have been more realistic to leave insects on the plants until they had ceased feeding, this would have caused an artificial reduction in HIPV production by these plants over time due to the smaller quantities of leaf tissue available to emit HIPVs on each day of the 8-d-observation period.

Preliminary experiments showed little difference in HIPV quantities induced by 25, 50, or 100 *T. notatus* per plant, and the middle density of *L. daturaphila* was chosen to minimize leaf tissue losses during the experiment. The treatment with both herbivore species was designed to compare directly the quality and composition of blends induced by both herbivore species with the HIPV blends elicited by the same numbers of each herbivore species alone. In prior experiments, both adults and larvae of *L. daturaphila* induced the production of similar groups of HIPVs. In total, plants were aerated continuously for 9 d, including the day before induction, the day of induction, and then daily aerations for 7 d following induction, and traps were changed every 24 hr.

At the end of the experiment, all aerated leaves were removed from the plant, and the leaves damaged by *L. daturaphila* or *M. sexta* were scanned and digitized to determine the amount of leaf area removed using the Scion Imaging Software for Windows ver. A.4.0.3.2, (Scion Corp., Frederick, MD, USA). Because of the piercing-sucking feeding mode of *T. notatus,* no attempt was made to quantify damage caused by this insect. After scanning, all aerated leaves were dried (80°C for 48 hr) and weighed to determine total aerated leaf dry mass. Plant growth was slight over the course of the experiment and was ignored in determining total aerated leaf dry mass.

Volatiles Analysis Volatiles were eluted from the traps with 150 μl of CH_2Cl_2 containing 4 ng/μl of 1-bromoheptane

(Sigma-Aldrich) as an internal standard into autosampler vials with 250 μl glass inserts, and vials were sealed with crimp caps and PTFE-lined rubber septa. Samples were analyzed by gas-liquid chromatography largely as described in Hare (2007) except that a shorter column (DB-5, 30 m, 0.25 mm ID, 0.25 μm film thickness, J & W Scientific, Folsom, CA, USA) and an autoinjector (Hewlett-Packard 7673) were used. To confirm identifications, selected samples were analyzed with a Hewlett-Packard 6890 gas chromatograph coupled to a Hewlett-Packard 5973 mass selective detector, and the mass spectra and retention times of compounds were matched with those of authentic standards as described in Hare (2007). Peaks were quantified in units of ng g^{-1} leaf (dry wt.) hr^{-1} using Agilent ChemStation® software based on comparison of the peak height of each HIPV component with that of the internal standard.

Statistical Analyses We performed an exploratory principal components analysis (PCA) using PROC PRINCOMP of SAS (SAS Institute, 2008). The covariance matrix of $\log_{10}$ –transformed quantities of the individual HIPVS from induced plants was used to calculate a smaller number of uncorrelated components that were linear, independent combinations of the original variables. The factor loadings show how much each of the original variables contributes to each new component, and factor scores for the new components can be calculated for each original observation. This allows one to examine the composition of the blend as a whole instead of as an *ad hoc* combination of individual, potentially correlated variables. A repeated measures analysis of covariance on these factor scores (PCA-ANCOVA) was used in the experiment comparing the HIPV blends induced by *M.* sexta with *L. daturaphila* to detect significant variation in the composition of the blends induced by the different herbivore species. The analysis was performed using PROC MIXED of SAS that included: 1) insect species, aeration day, and their interaction as fixed effects; 2) block as a random effect; 3) percent leaf area removed as a covariate; and 4) the individual plant as the repeated subject effect over the 9 d of aeration. The results from PCA then guided analyses of individual compounds to explore changes in the composition of the HIPV blend with herbivore species or over time. Where significant interactions were obtained, then they were decomposed by using the SLICE option of PROC MIXED. Similar repeated-measures analyses were performed on the data from the experiment by comparing HIPV blends from plants damaged by *L. daturaphila, T. notatus,* or both except 1) there was no need to include defoliation level as a covariate, and 2) the effect of trichome genotype and all interactions with trichome genotype were included as fixed effects.

To test for nonadditive effects on the total HIPV production of both *L. daturaphila* and *T. notatus* feeding simultaneously on *D. wrightii*, we calculated the expected HIPV production of plants damaged by each herbivore species alone for each sampling day and block. These expected values were calculated after pooling plants from both trichome genotypes because HIPV production did not differ between trichome genotypes (see Results). The observed HIPV production of plants damaged by both herbivore species simultaneously was compared to these expected values, and the deviation from the expected value was calculated by subtraction. The deviations were not amenable to parametric statistical analysis because they did not meet the assumption of normally-distributed errors and homogeneity of variances, and no common transformation rectified these problems. We, therefore, utilized a non-parametric method of analysis. The frequencies of plants producing greater or lesser quantities of HIPVs than predicted was analyzed by a replicated goodness-of fit *G*-test (Sokal and Rohlf, 1995) replicated over each sampling day. Under the null hypothesis of additive effects of the two herbivore species on HIPV production, the frequencies of plants producing greater quantities of HIPVs than predicted would not differ significantly from the frequencies of plants producing less HIPVs than predicted; synergism would be consistent with a significantly greater number of plants producing higher quantities of HIPVs than predicted, and antagonism would be consistent with a significantly greater number of plants producing lower quantities of HIPVs than predicted. Data for the pretreatment aeration were not included in this analysis.

Results

Lema and Manduca A preliminary analysis of total HIPV production showed that HIPV production was low and did not differ among plants assigned to the various experimental treatments on the day prior to induction ($F_{2, 57}$=0.74, P=0.48, Fig. 1a). HIPV production of control plants did not differ among days ($F_{8, 535}$=0.81, P=0.59), whereas that of the herbivore-damaged plants did differ over time ($F_{8, 535}$=13.49, P<0.001 for plants induced by *L. daturaphila* and $F_{8, 535}$= 12.38, P<0.001 for plants induced by *M. sexta*). Highest average total HIPV production of 279±70 ng HIPVs g^{-1} hr^{-1} occurred in the plants damaged by *L. daturaphila* 1 d after induction (Fig. 1a). Because the control plants remained uninduced through the experiment, they were deleted to simplify subsequent analyses of potential differences in the HIPV quantities and blends induced by the two different herbivore species. Mean leaf area removed by *L. daturaphila* was 10.1±1.0 cm^2, or 20.0±2.5% of the available leaf area.

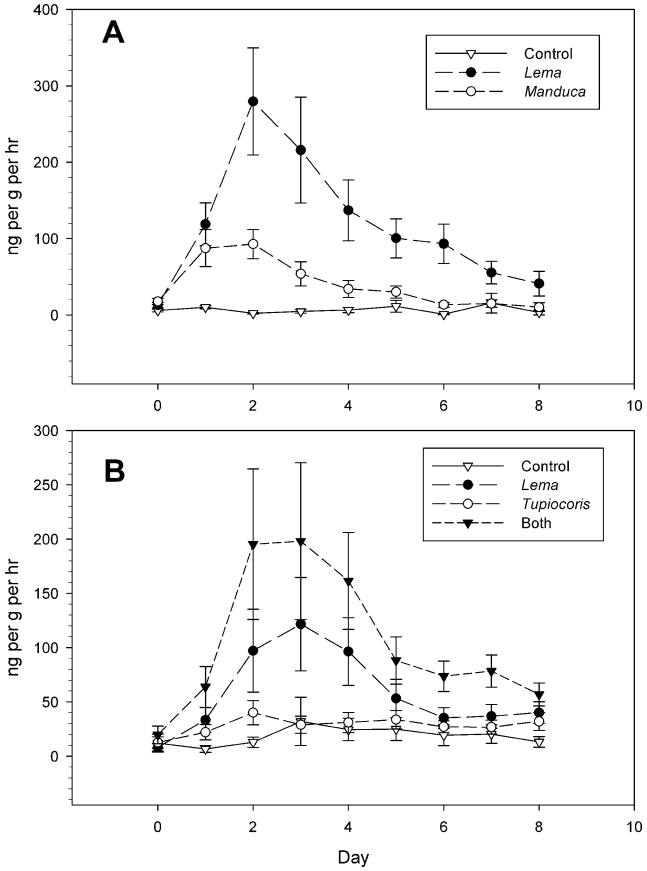

Fig. 1 Mean (± s.e.) total HIPVs by day and herbivory treatment for plants damaged for 24 hr between Day 0 and Day 1. Plot **a**: plants damaged by 12 fourth-instar *Lema daturaphila* or three third-instar *Manduca sexta* larvae; plot **b**: plants damaged by four *Lema daturaphila* adults, 50 adults and nymphs of *Tupiocoris notatus*, or the same numbers of both insect species simultaneously

Mean leaf area removed by *M. sexta* was less than expected based upon the preliminary experiment (5.9± 1.0 cm^2 or 10.1±1.3% of available leaf area), but the distributions of leaf area removed by the two insect species overlapped, with a maximum leaf area removed of 46% for *L. daturaphila* and 31.5% for *M. sexta*. In general, the group of HIPVs obtained was similar to those reported in a previous laboratory study (Hare, 2007). Abundant HIPVs included (*E*)-β-ocimene, (*E*)-β-caryophyllene, (*E,E*)-α-farnesene, (*Z*)-3-hexenyl acetate, and DMNT. Other components included limonene, linalool, an isomer of bergamotene, α-humulene, β-selinene, nerolidol, TMTT, and methyl salicylate (MeSA).

Results of the PCA analysis on HIPVs showed that the first component (PC 1) accounted for 63% of the total variation and PC 2 accounted for an additional 12%. PC 3 accounted for 5.5% and the remaining PCs accounted for progressively smaller percentages of the total variance and will not be considered further. All original variables had positive loadings on PC1, thus indicating that this component is largely a "general production" factor much like a "general size" factor in morphological studies (Fig. 2a). The highest loadings were for DMNT, TMTT, (*E,E*)-α-farnesene, (*E*)-β-ocimene, (*Z*)-3-hexenyl acetate, and (*E*)-β-caryophyllene (Fig. 2a). PC 2 is an index of the composition of the blend and contrasted the abundance of TMTT with DMNT, and to a lesser extent, TMTT with (*E,E*)-α-farnesene, (*E*)-β-ocimene, (*Z*)-3-hexenyl acetate, and (*E*)-β-caryophyllene. Most of the rest of the components had factor loadings near zero on PC 2 (Fig. 2b). PC 3 independently contrasts plants producing relatively high levels of (*E*)-β-caryophyllene with plants producing relatively high levels of MeSA, (*Z*)-3-hexenyl acetate, and DMNT (Fig. 2b).

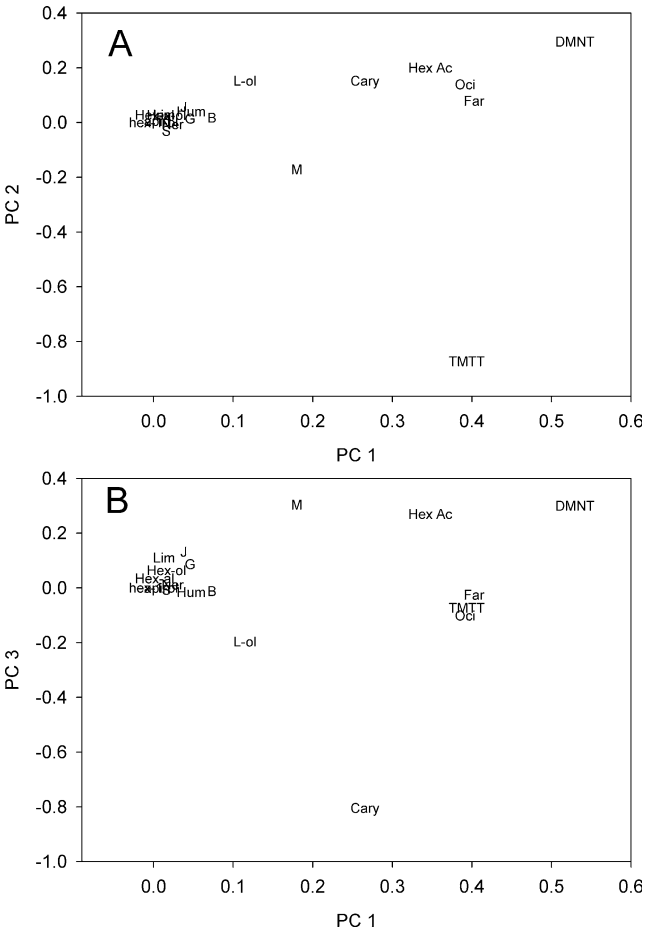

Fig. 2 Factor loadings for individual compounds for plants damaged either by larvae of *Lema daturaphila* or *Manduca sexta* for plants damaged for 24 hr between Day 0 and Day 1 as in Fig. 1a. Plot **a**: PC1 and PC 2; plot **b**: PC1 and PC 3. Chemical abbreviations: Cary: (*E*)-β-caryophyllene; DMNT: (*E*)-4,8-dimethyl-1,3,7-nonatriene; Far: (*E,E*)-α-farnesene; Hex Ac: (*Z*)-3-hexenyl acetate; Oci: (*E*)-β-ocimene; Lol: linalool; M: methyl salicylate; TMTT: (*E*)-4-8,12-trimethyl-1,3,7,11-tridecatetraene. Overlapping near the origin: Hum: α-humulene; J: jasmone; Lim: limonene; Ner: nerolidol Hex-al: *trans*-2 hexenal; Hex-ol: *cis*-3-hexen-1-ol; Hex-1-ol: *trans* 2-hexen-1-ol; apin: α-pinene B: α-bergamotene; G: geranyl acetone S: β-selinene

Scores for PC 1 increased with increasing defoliation (test of covariate, $F_{1,\ 506}$=7.87, P=0.005). There were no differences overall in the factor scores for PC 1 between the two induction treatments ($F_{\ 1,\ 506}$=0.00, P=0.97) after correcting for differences in defoliation, but there was significant variation in factor scores over time ($F_{8,\ 506}$=19.14). Scores for PC 1 also differed significantly due to the day by treatment interaction ($F_{\ 8,\ 506}$=3.82, P=0.002, Fig. 3a). Decomposing this interaction showed that PC 1 scores differed between induction treatments starting on the day after damage and continued to differ 6 d after insects were removed (all $P\leq$0.005). During this time period, plants induced by *M. sexta* had significantly lower scores for PC 1 than plants induced by *L. daturaphila*, even after correcting for the differences in defoliation; per unit leaf area removed, *M. sexta* induced a lower production of HIPVs than did *L. daturaphila*.

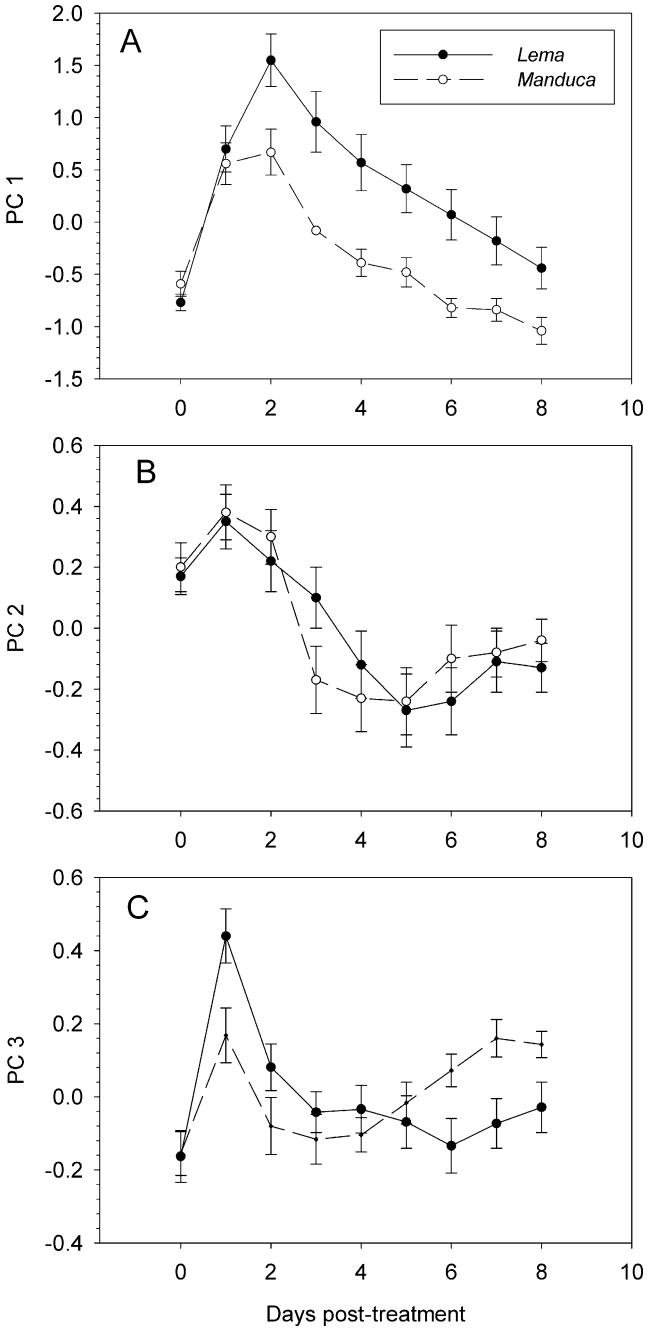

Fig. 3 Mean (± standard error) factor scores for principal components 1–3 for plants damaged either by larvae of *Lema daturaphila* or *Manduca sexta* for 24 hr between Day 0 and Day 1 as in Fig. 1a

ANCOVA on the scores for PC 2 showed significant variation among days ($F_{8,\ 506}$=9.95, P<0.001, Fig. 3b) and was due to the day by treatment interaction ($F_{8,\ 506}$=3.36, P<0.001) but not among induction treatments overall ($F_{1,\ 506}$=1.34, P=0.25). Scores for PC 2 were independent of the level of defoliation (test of covariate, $F_{1,\ 506}$=1.33, P=0.25). In general, plants produced blends relatively richer in HIPVs that loaded positively on PC 2 during the day of damage. Afterward, they produced blends relatively richer in HIPVs that loaded negatively on PC 2, principally TMTT, during the remainder of the experiment (Fig. 3b). Although the day by treatment interaction was statistically significant overall, on no day did the scores for PC 2 differ significantly among induction treatments. The closest difference to statistical significance occurred 3 d after induction (P= 0.074), in which the blend from plants induced by *L. daturaphila* was marginally richer in compounds with positive scores for PC 2 compared to plants induced by *M. sexta*.

ANCOVA on the factor scores for PC 3 also showed statistically significant variation over days ($F_{8,\ 506}$=9.79, P<0.001, Fig. 3c), and the day by treatment interaction ($F_{8,\ 506}$=4.33, P<0.001). There was no overall variation in PC scores between herbivore species ($F_{1,\ 506}$=0.00, P=0.99) but scores for PC 3 declined significantly with percent defoliation (test of covariate, $F_{1,\ 506}$=7.23, P=0.007). Apparently higher levels of damage were associated with higher proportions of (*E*)-β-caryophyllene and lower concentrations of most other compounds. Decomposing the day by treatment interaction showed that treatments differed only on the day of induction and the day following (P=0.003 and 0.03, respectively, Fig. 3c).

The individual compounds that contributed to the differences in PC 2 and PC 3 over time were revealed by comparing the temporal pattern of HIPV emission for the six compounds with the greatest absolute value for factor loadings on PC 2 and PC 3. For (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene DMNT, (*E*)-β-caryophyllene, and (*E,E*)-α-farnesene, peak concentrations were reached 1 d after herbivores were removed, and HIPV concentration declined regularly over the next 6 d (Fig. 4). By contrast, concentrations of TMTT persisted at near peak concentration for 3 d after insects were removed before declining. The persistence of TMTT during the middle of the observation period, while other HIPVs declined, accounted for the

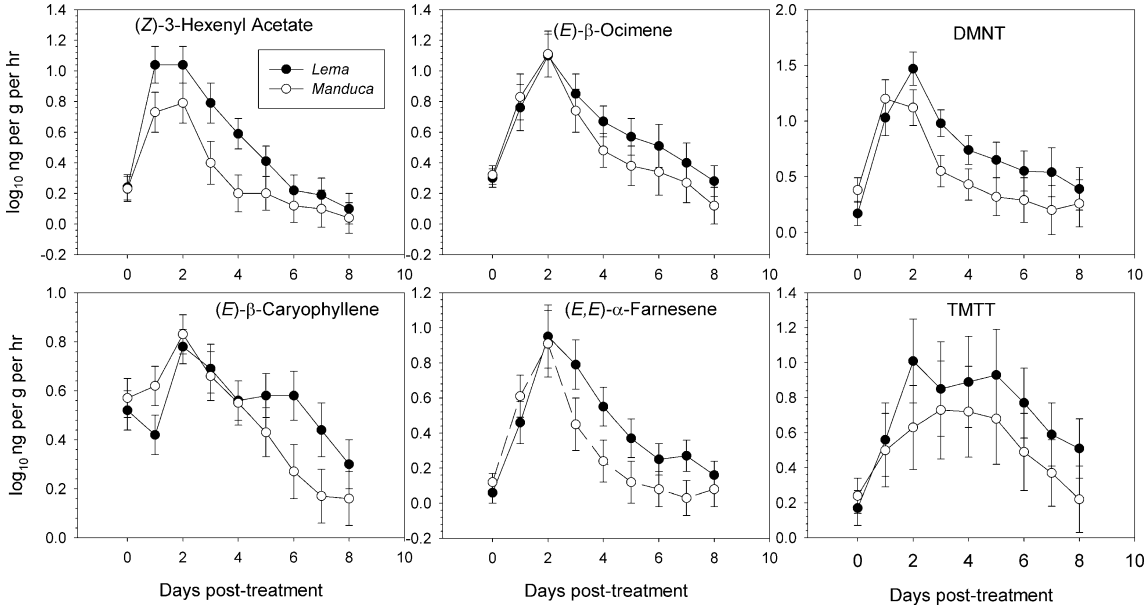

Fig. 4 Production of (*Z*)-3-hexenyl acetate, DMNT, (*E*)-β-ocimene, (*E*)-β caryophyllene, (*E,E*)-α-farnesene, and TMTT for plants damaged by *Lema daturaphila* or *Manduca sexta* for 24 hr between Day 0 and Day 1 as in Fig. 1a. Mean (± standard errors) in ng g^{-1} (dry wt.) leaf hr^{-1} are shown

change, with the composition of the blend becoming relatively richer in components loading negatively on PC 2 (i.e., TMTT) over time. The temporal pattern of variation in PC 3 is best reflected in the temporal pattern of variation in (*Z*)-3-hexenyl acetate (Fig. 4).

Lema, Tupiocoris, and Both A preliminary analysis on total HIPV production showed, once again, that HIPV production did not differ among plants to be assigned to the various experiments prior to induction ($F_{3,\ 58}$=0.51, *P*=0.67, Fig. 1b). HIPV production of control plants again did not differ among days ($F_{8,\ 545}$=0.70, *P*=0.69) but that for the other three treatments did differ among days (all $P \leq 0.02$). Highest average HIPV production of 198±72 ng HIPVs g^{-1} hr^{-1} occurred in the plants damaged by both *L. daturaphila* and *T. notatus*, 1 d after all insects were removed (Fig. 1b). Because the control plants also remained uninduced through the course of this experiment, they were removed from subsequent analyses to simplify the comparison of HIPVs produced by the different herbivore treatments. Mean leaf area removed by *L. daturaphila* was 5.06±0.9 cm^2, or 5.80±0.66% of available leaf tissue and did not differ between plants attacked by *L. daturaphila* or by *L. daturaphila* and *T. notatus*. In this experiment, the variation in total HIPV production was independent of the variation in herbivore damage ($F_{1,\ 330}$=0.96, *P*=0.33), probably because of the more consistent level of feeding compared to the first experiment, and there was no need to use defoliation as a covariate in subsequent analyses.

Results of the PCA analysis on HIPVs from insect-damaged plants showed that the first component (PC 1) accounted for 49% of the total variance, and PC 2 accounted for an additional 14.5%. PC 3 accounted for 10% of the total variance; the remaining principal components accounted for less than 10% each of the remaining variance and will not be considered in detail. All original variables except nerolidol had positive loadings on PC 1. The most abundant compounds were generally similar to those in the experiment comparing damage by *L. daturaphila* and *M. sexta* (Fig. 5a). In this experiment, PC 2 largely contrasted the abundance of (*E*)-β-caryophyllene with most of the rest of the HIPVs (Fig. 5a), and PC 3 independently contrasts plants producing high levels of TMTT with plants producing higher DMNT and (*Z*)-3-hexenyl acetate (Fig. 5b).

An analysis of variance on the factor scores for PC 1 showed significant differences among induction treatments overall ($F_{2,\ 445}$=11.06, *P*<0.001), over time ($F_{8,\ 445}$= 16.58, *P*<0.001), and scores for PC 1 also differed significantly due to the day by treatment interaction ($F_{16,\ 445}$=1.85, *P*<0.001, Fig. 6a). Scores for PC 1 did not differ significantly due to trichome genotype or any interactions involving trichome genotype (all $P \geq 0.16$). Decomposing the day by treatment interaction showed that PC 1 scores did not differ before insect damage ($F_{2,\ 445}$=0.81, *P*=0.45) but did differ among induction treatments starting the day of damage and continued to differ through the end of the experiment (all $P \leq 0.05$). On all days, plants damaged by both *Lema* and *Tupiocoris* emitted more HIPVs than did

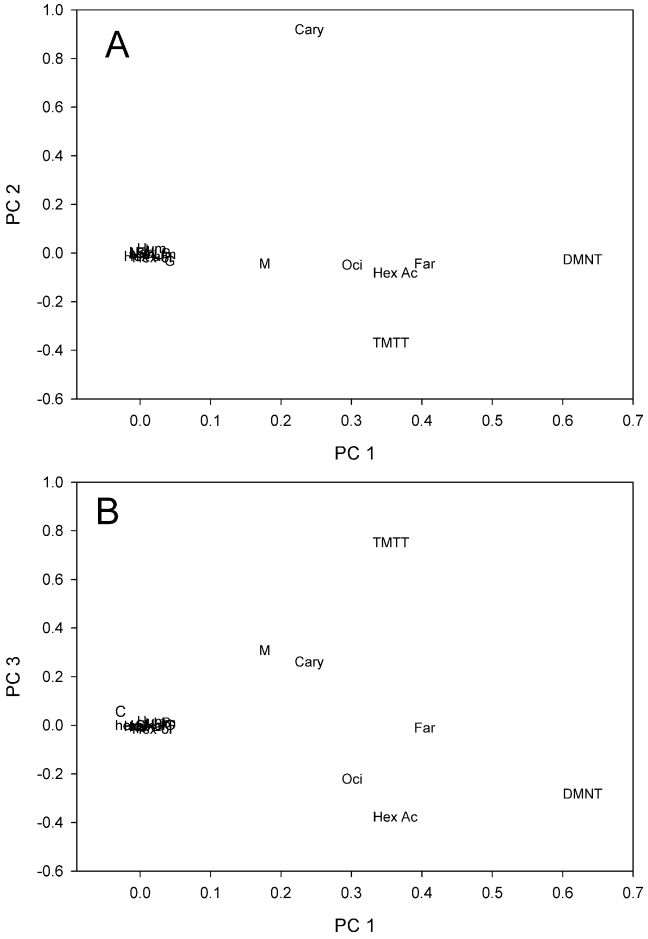

Fig. 5 Factor loadings for individual compounds for plants damaged by *Lema daturaphila, Tupiocoris notatus*, or both insect species simultaneously as in Fig. 1b. Plot **a**: PC1 and PC 2; plot **b**: PC1 and PC 3. Chemical abbreviations are as in Fig. 2

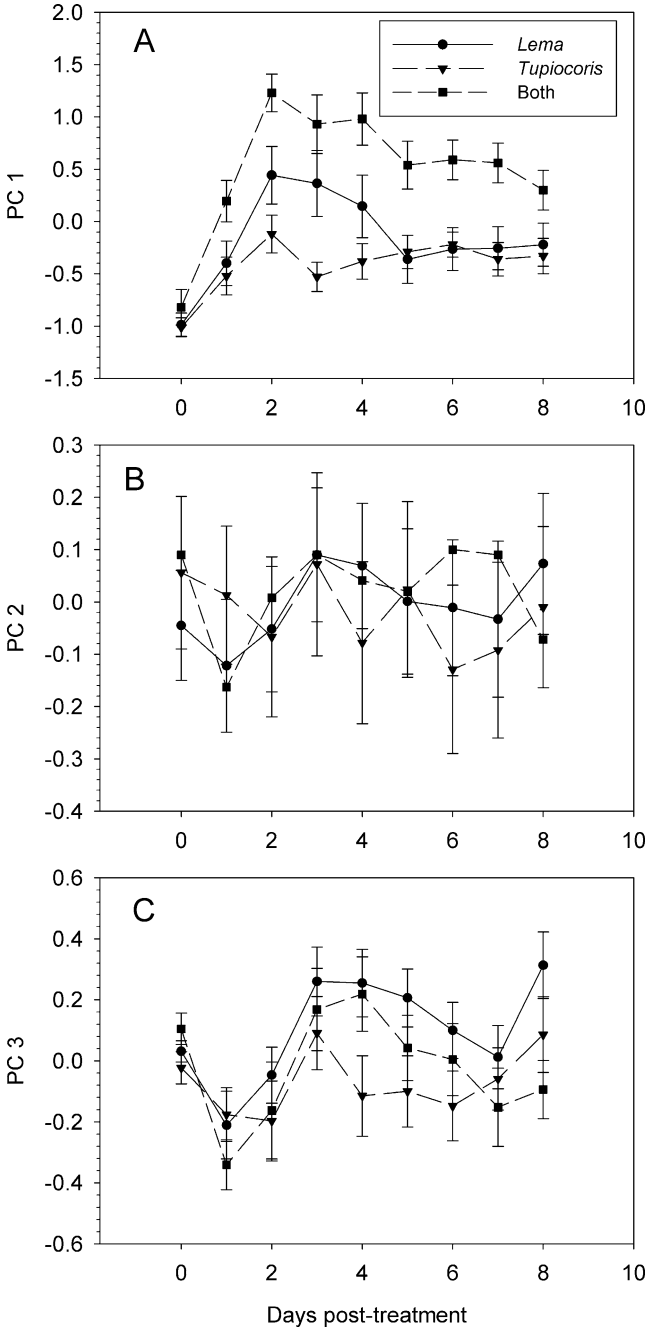

Fig. 6 Mean (± standard error) factor scores for principal components 1–3 for plants damaged either by *Lema daturaphila, Tupiocoris notatus,* or both insect species simultaneously as in Fig. 1b, for 24 hr between Day 0 and Day 1

plants damaged by either alone, and for all but the last 4 d, plants damaged by *Lema* emitted greater quantities of HIPVs than plants damaged by *Tupiocoris* (Fig. 6a).

For the plants damaged by both herbivores, the nonparametric analysis showed that the increased emission of plants damaged did not differ significantly from the null hypothesis of additive effects of damage by each herbivore species individually. Over the 160 observations in the full experiment (4 plants per block infested with both *L. daturaphila* and *T. notatus*, 5 blocks, and 8 d of observations), in 86 cases, plants produced lower total HIPV quantities than expected and in 74 cases they produced higher HIPV quantities than expected. These frequencies did not differ from the expected distribution of 80:80 (G_1=0.901, P=0.34). There also was no heterogeneity in the frequency distributions on different days (G_7=4.359, P=0.74).

ANOVA on the scores for PC 2, one index of the composition of the HIPV blend, showed no significant variation over time, treatment, or the time by treatment interaction (all $P \geq 0.14$, Fig. 6b). The scores for PC 3 differed over time ($F_{8,\ 445}$=8.54, P<0.001) and due to the day by treatment interaction ($F_{16,\ 445}$=1.94, P=0.016). Scores for PC 3 did not differ overall due to treatment (P=0.19), nor due to trichome genotype (P=0.15), nor due to any interaction including trichome genotype (all $P \geq 0.15$, Fig. 6c). Decomposing the day by treatment interaction showed that scores for PC 3 differed significantly only on

the last day of the experiment ($F_{2, 445}$=4.21, P=0.016). The largest difference was between plants damaged by *L. daturaphila* and plants damaged by both herbivores.

Individual Components The differences in PC 2 and PC 3 over time were revealed by comparing the temporal pattern of HIPV emission for the same 6 compounds as in Experiment # 1, but the temporal dynamics differed somewhat between the experiments. For (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, and DMNT, the highest concentrations were seen on the day after herbivores had been removed, as was the case in the first experiment. Also similar to the first experiment, peak concentrations of TMTT were somewhat delayed. In contrast to the first experiment, peak concentrations of (*E*)-β-caryophyllene and (*E,E*)-α-farnesene were not reached on the 1st d after insects were removed, but one to 2 d later, depending upon treatment (Fig. 7).

In summary, induction of plants by both *L. daturaphila* and *T. notatus* caused a greater emission of HIPVs than induction of plants by either herbivore species alone, but the increased emissions did not differ significantly from that predicted as the sum of the effects of each herbivore species' damage individually. There was no evidence that the differences in modes of feeding by *T. notatus* and *L. daturaphila* resulted in blends of different composition. The greatest source of variation overall was that due to the number of days since damage. The blends never differed consistently due to the differences in trichome genotype.

Discussion

The composition of HIPV blends from *D. wrightii* induced by feeding damage from *M. sexta* and *L. daturaphila,* or *L. daturaphila* and *T. notatus*, either alone or in combination, varied substantially with the number of days since damage, but there was no evidence that the HIPV blends characteristically and consistently differed between species of herbivore. Most of the induced monoterpenes [e.g., (*E*)-β-ocimene) and sesquiterpenes (e.g., (*E,E)*-α-farnesene, (*E*)-β-caryophyllene] reached peak emission rates within 1–3 d after the termination of plant damage, then declined over the next 4–6 d. In contrast, concentrations of the 16-carbon homosesquiterpene, TMTT, rose more slowly and persisted longer than the major mono- and sesquiterpenes. As a result, the HIPV blends became richer in TMTT in all treatments as the time since damage increased.

Temporal variation in HIPV production has been noted before in other systems. Commonly, C_6 green leaf volatiles are emitted from damaged leaves almost immediately after induction, and the emission of other compounds begins some time later. The amount of time between the emission of green leaf volatiles and other compounds varies among plant species. For example, Turlings et al. (1998) found significant temporal variation in the production of HIPVs in maize over a period of only 12 hr. In cotton, however, inducible terpene production peaked about a day after insect damage was terminated (Loughrin et al., 1994). In Brussels sprouts, 3 d of damage by 100 first- or second-instar caterpillars of *Pieris brassicae* was necessary to

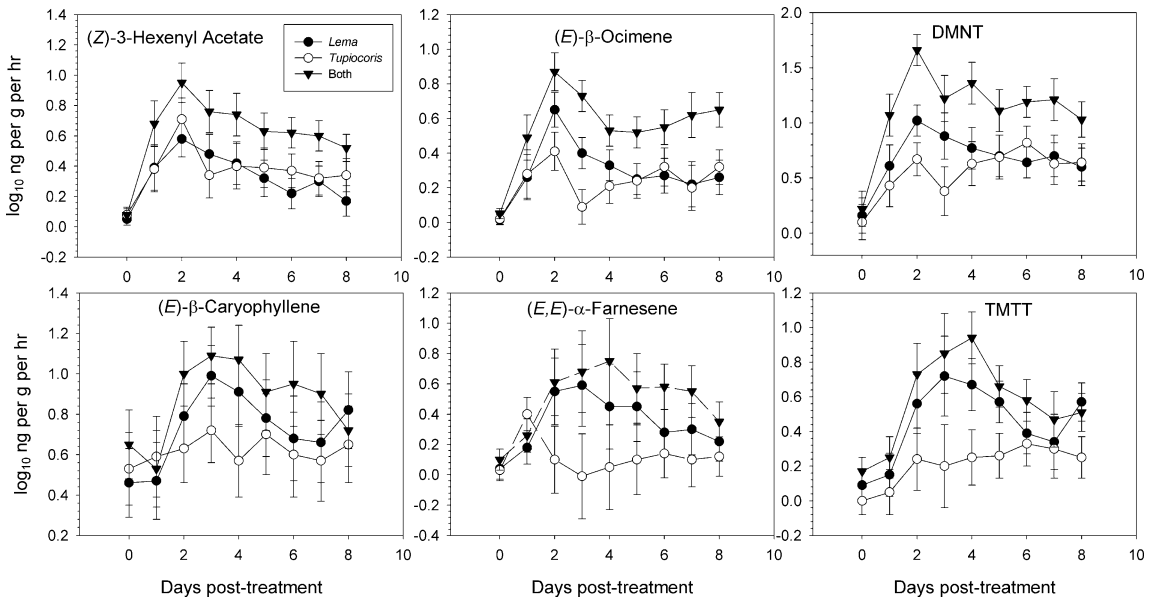

Fig. 7 Production of (*Z*)-3-hexenyl acetate, DMNT, (*E*)-β-ocimene, (*E*)-β caryophyllene, (*E,E*)-α-farnesene, and TMTT for plants damaged by *Lema daturaphila, Tupiocoris notatus*, or both insect species simultaneously as in Fig. 1b, for 24 hr between Day 0 and Day 1. Mean (± standard errors) in ng g^{-1} (dry wt.) leaf hr^{-1} are shown

induce sufficient HIPV production to attract its parasitoid *Cotesia glomerata*, and this response persisted for a day after insect herbivory ceased (Mattiacci et al., 2001). Similarly in *Brassica oleraceae,* plants subjected to 24 hr of herbivory or treated with JA remained attractive to parasitoids for 3 d after insects were removed and 5 d after JA treatment (Bruinsma et al., 2009).

Not only may total quantities vary temporally, but the production of individual components may follow independent time courses as well. In maize, DMNT was one of the first compounds produced, and the sesquiterpenes (*E*)-β-caryophyllene and (*E*)-β-farnesene were produced relatively later (Turlings et al., 1998). In tomato, TMTT and several terpenoids were induced within 3 hr of damage by *M. sexta,* but MeSA was not emitted until the 2nd d after damage (Farag and Pare, 2002). Different proportions of classes of volatile compounds also are emitted over a period from 1–37 hr in *Nicotiana attenuata*, with hexenyl esters predominating in the first 13 hr after damage and terpenoids in later time periods (Gaquerel et al., 2009).

Interestingly, different genotypes of plant species may exhibit different temporal profiles of HIPV emission; in one cultivar of maize, indole was emitted as early as DMNT, but in another, its peak emission was delayed to about the same time as the sesquiterpenes (Turlings et al., 1998). Thus, there are numerous precedents from other systems for the temporal variation seen in *D. wrightii*, not only in the total quantities of HIPVs, but also in the composition of the HIPV blends elicited by a single inducer. Such results suggest that the synthesis of different classes of compounds is regulated on different time scales following damage within species, but temporal pattern of regulation also can vary among species or genotypes within species.

Although the initiation of HIPV production in *D. wrightii* began on the day of damage and peaked 1–2 d later, the production of induced volatiles persisted for nearly a week. Such long relaxation times seen here and in other systems (Bruinsma et al., 2009) may complicate the efficient use of HIPVs as indicators of herbivores on plants because the HIPVs may be providing false information about the presence of actively-feeding herbivores (Puente et al., 2008a,b). One possible solution to this problem would be if the blend changed sufficiently over time that natural enemies could discriminate old damage from current damage. The solitary specialist parasitoid, *Cotesia vestalis*, for example, can make such discrimination on the basis of plant breakdown products that are emitted during herbivory but not after. The discrimination is imprecise because wasps still are attracted to plants with old damage when offered plants with old damage and plants with no damage (Kugimiya et al., 2010). The context-dependent nature of the responses of this parasitoid suggests that if there were natural selection on plants for the production of honest cues, then selection should favor the rapid cessation of HIPV emission when herbivores are no longer on those plants, rather than the continued emission of a blend of a different composition.

These experiments with *D. wrightii* in the laboratory, like most other laboratory experiments, greatly simplify how plants are attacked in nature. Under natural conditions, individual *D. wrightii* plants occur in patches that persist for several years (Hare and Elle, 2004). Plants quickly become colonized by overwintering adults of *L. daturaphila*, *T. notatus*, and other herbivores in the early spring, then suffer chronic herbivory throughout the growing season (Elle and Hare, 2000; Hare and Elle, 2002; Hare, 2010). Commonly, plants are infested with multiple life stages of *L. daturaphila* and other herbivorous insects throughout the season. It, therefore, is possible that damage inflicted by a single herbivore species for only a single day, as in this laboratory study, exaggerates the potential change in HIPVs over time compared to plants that are attacked under more natural conditions in the field.

Velvety plants infested with *T. notatus* were included in our experiments even though such infestations rarely occur in the field. We chose to include both trichome genotypes in order to avoid confounding herbivore species with trichome genotype when comparing the HIPV blends of sticky plants infested with *T. notatus* and *L. daturaphila* with velvety plants infested only with *L. daturaphila*¸ as is usually the case in the field. Despite the ability of feeding by *T. notatus* to suppress some jasmonate-mediated responses in other plant species (Heidel and Baldwin, 2004), we found no persistent differences in the HIPV production and composition of either plant genotype when infested with the combination of *T. notatus* and *L. daturaphila* compared to plants infested by *L. daturaphila* alone. One of our initial motivations to study the HIPV production of *D. wrightii* was to determine if predators like *G. pallens* might be able to recognize and avoid sticky plants, on which they are less effective predators (Gassmann and Hare, 2005). This might be possible if 1) the two trichome genotypes differed intrinsically in HIPV production, or 2) if the HIPV production of sticky plants was altered from that of velvety plants by the presence of *T. notatus* on sticky plants. Taken together with previous research (Hare, 2007), it appears that the HIPV blends of *D. wrightii* do not vary among trichome genotypes either intrinsically or when the trichome genotypes are attacked by *L. daturaphila* or *L. daturaphila* in combination with *T. notatus*. Moreover, sticky and velvety plants in the field do not differ in the composition of their HIPV blends even though the sticky plants were attacked by *T. notatus* in combination with *L. daturaphila*, whereas only the velvety plants were attacked by the latter species (Hare, 2010).

In systems in which HIPV blends are observed to vary with the inducing herbivore species, it may be a consequence of additional elicitors being associated with particular herbivores (Bruinsma et al., 2009; Peiffer and Felton, 2009). The evidence here suggests that there may be little difference in the response of *D. wrightii* to elicitors from different herbivore species, for there were no consistent, statistically different blends induced by the different herbivore species or combinations of species in the two experiments. Even if there were differences not detectable by the instrumentation, the biological significance of such differences may be slight, especially with regard to generalist predators like *G. pallens* that utilize all three herbivore species locally as prey. This conclusion is strengthened by the results of field experiments in other systems that show that predation rates of *G. pallens* can be increased when plant volatiles are augmented simply with a single HIPV component (James, 2003; Halitschke et al., 2008), suggesting that the precise composition of HIPV blends may be of less importance for *G. pallens* than for other natural enemies.

In summary, our original goals were to determine if three herbivores of *D. wrightii* produced HIPV blends that might differ consistently to possibly indicate the identity of the herbivore causing the damage. This was not the case. We also asked if simultaneous attack of plants by *T. notatus* and *L. daturaphila* might induce HIPV blends that differed qualitatively from those elicited by each insect alone and this also was not the case. The blends did not differ significantly and consistently in composition, rather, simultaneous damage by *T. notatus* and *L. daturaphila* simply elevated in an additive manner the HIPV production of plants with both herbivores over that induced by each species independently. Because the HIPV blends did not differ significantly among herbivore species or between trichome types for any combination of herbivores tested, this suggests that HIPV production by *D. wrightii* is more likely a general than specific indicator of damage by herbivores (Kessler and Baldwin, 2001). The absence of abundant specialist natural enemies of *M. sexta, L. daturaphila,* or *T. notatus* that might differentially respond to herbivore-specific HIPV blends may limit the potential for evolution of such herbivore-specific HIPV blends in *D. wrightii*.

Abstract The ability to cope with plant defense chemicals differs between specialist and generalist species. In this study, we examined the effects of the concentration of the two main iridoid glycosides (IGs) in *Plantago lanceolata*, aucubin and catalpol, on the performance of a specialist and two generalist herbivores and their respective endoparasitoids. Development of the specialist herbivore *Melitaea cinxia* was unaffected by the total leaf IG concentration in its host plant. By contrast, the generalist herbivores *Spodoptera exigua* and *Chrysodeixis chalcites* showed delayed larval and pupal development on plant genotypes with high leaf IG concentrations, respectively. This result is in line with the idea that specialist herbivores are better adapted to allelochemicals in host plants on which they are specialized. *Melitaea cinxia* experienced less post-diapause larval and pupal mortality on its local Finnish *P. lanceolata* than on Dutch genotypes. This could not be explained by differences in IG profiles, suggesting that *M. cinxia* has adapted in response to attributes of its local host plants other than to IG chemistry. Development of the specialist parasitoid *Cotesia melitaearum* was unaffected by IG variation in the diet of its host *M. cinxia,* a response that was concordant with that of its host. By contrast, the development time responses of the generalist parasitoids *Hyposoter didymator* and *Cotesia marginiventris* differed from those of their generalist hosts, *S. exigua* and *C. chalcites*. While their hosts developed slowly on high-IG genotypes, development time of *H. didymator* was unaffected. *Cotesia marginiventris* actually developed faster on hosts fed high-IG genotypes, although they then had short adult longevity. The faster development of *C. marginiventris* on hosts that ate high-IG genotypes is in line with the "immunocompromized host" hypothesis, emphasizing the potential negative effects of toxic allelochemicals on the host's immune response.

Key Words Chemical defense · *Chrysodeixis chalcites* · *Cotesia marginiventris* · *Cotesia melitaearum* · *Hyposoter didymator* · Immunocompromised host · Iridoid glycosides · *Melitaea cinxia* · Multitrophic interactions · *Spodoptera exigua*

Introduction

Plants have evolved a wide array of direct defenses against herbivores and diseases. Direct defenses include morphological traits (Cooper and Owen-Smith, 1986), and chemical toxins, repellents, or digestibility reducers (Fraenkel, 1959; Ehrlich and Raven, 1964). These defenses not only affect the performance of herbivores

but also can have positive or negative effects on natural enemies of herbivores. Positive effects of chemical defense in the herbivore's diet on natural enemies can arise in several ways. For instance, allelochemicals may slow down the growth rate of the herbivore, extending the time window during which the herbivore is vulnerable to parasitism or predation by its natural enemies (Clancy and Price, 1987). Toxic allelochemicals also may weaken host immune responses, making them more susceptible to parasitation or predation (Nappi, 1975; Smilanich et al., 2009). On the other hand, allelochemicals can have negative effects on the growth, development, or survival of predators and parasitoids (Gunasena et al., 1990; Paradise and Stamp, 1993; Harvey et al., 2007b). For instance, hosts may actively sequester these compounds in their haemolymph where they can again function as defense (Bowers, 1980, 1981; Camara, 1997b; Nishida, 2002).

The ability of herbivores to cope with plant allelochemicals varies among species that differ in their dietary range. Polyphagous species (generalists) feed on many species in a range of plant families (Bowers and Puttick, 1988; Agrawal, 2000). Even though many herbivores are polyphagous at the species level, they are not necessarily so at the population or individual level since species can be comprised of populations or individuals that are specialized on a few or even a single food plant (Singer, 2008). Some studies support the idea that detoxification systems of generalists are capable of accepting a more structurally diverse array of compounds than those of specialists (Li et al., 2004) at the expense of a less efficient detoxification of individual compounds (Johnson, 1999). Oligophagous species (specialists) often are physiologically adapted to the nutritional and secondary chemistry of particular plant species (Renwick et al., 2001; Cornell and Hawkins, 2003). They may use the allelochemicals to which they have adapted as host-finding cues and feeding stimulants (Rhoades, 1979; Bowers, 1981). A number of specialist herbivores sequester these substances as defense against their own natural enemies (Bowers, 1981), which requires physiological or morphological adaptations to prevent autotoxicity (Duffey, 1980).

The division between generalists and specialists also can be made for predators and parasitoids of herbivores. Allelochemicals present in herbivores, or in the diet of an herbivore, can reduce the performance of generalist predators and parasitoids (e.g., Duffey et al., 1986; Gunasena et al., 1990). Generalist parasitoids may attack a wide range of herbivorous host species that feed on plants with different defensive chemistry. These parasitoids may suffer during development if their hosts are able to sequester or accumulate plant derived compounds, to which they are not adapted (Barbosa, 1988; Barbosa et al., 1991; Harvey et al., 2005). In contrast, specialized natural enemies, such as many endoparasitoid wasps, are restricted to attacking only one or a few related host species, which generally feed on closely related plants (Godfray, 1994; Quicke, 1997). These parasitoids may be adapted to the limited set of chemicals to which they are exposed (Harvey et al., 2005), allowing them to use hosts that sequester specific plant chemical defenses (Barbosa et al., 1986; Sznajder and Harvey, 2003; Harvey et al., 2007a,b).

The types and concentrations of defensive substances found in plant tissues vary greatly among plant species as well as among individuals of the same species (Denno and McClure, 1983; Nieminen et al., 2003). In this study, we used genotypes of ribwort plantain [*Plantago lanceolata* L. (Plantaginaceae)] that differ in constitutive concentrations of two iridoid glycosides (IGs), aucubin and catalpol, to study the effects of allelochemical variation on specialist and generalist herbivore-parasitoid associations. Iridoid glycosides are monoterpenoids. Aucubin is the biosynthetic precursor of catalpol (Damtoft et al., 1983). The concentrations of IGs in *P. lanceolata* show large natural variation among individuals, and within individuals over time (Bowers and Stamp, 1992; Darrow and Bowers, 1997; Barton, 2007). Aucubin, and to a greater extent catalpol, are toxic or deterrent to generalists (Puttick and Bowers, 1988; Bowers, 1991). At the same time, these compounds serve as feeding and oviposition stimulants for some specialist herbivores (Bowers, 1984; Pereyra and Bowers, 1988; Nieminen et al., 2003; Reudler Talsma et al., 2008). Larvae and adults of the specialist butterflies *Melitaea cinxia* (Lepidoptera: Nymphalidae) and *Junonia coenia* (Lepidoptera: Nymphalidae) sequester aucubin and catalpol (Bowers and Collinge, 1992; Suomi et al., 2001, 2003). Larvae of *J. coenia* do this more efficiently than polyphagous insect herbivores (Lampert and Bowers, 2010), and they sequester catalpol more efficiently than aucubin (Bowers and Collinge, 1992). The latter is also observed for larvae of *M. cinxia* and *Parasemia plantaginis* (Lepidoptera: Arctiidae) (Reudler Talsma, unpublished). Only few studies have assessed the effect of these compounds on preference or performance of parasitoids, using dipteran (Mallampalli et al., 1996) or hymenopteran parasitoids (Nieminen et al., 2003; Harvey et al., 2005; Lampert et al., 2010). Our study extends that of Harvey et al. (2005) by including two generalist herbivores, each with two generalist parasitoids, to investigate whether effects of IG are consistent across these generalist systems, and compares them with a specialist system. Moreover, we include a series of plant genotypes that span a wide range of mean IG concentrations in order to gain quantitative insight into associations between plant IGs and insect development parameters.

We address the following questions: (1) Is the performance of herbivores and their parasitoids affected

by the concentrations of the iridoid glycosides aucubin and catalpol in *P. lanceolata*? (2) Are there consistent differences in the effect of plant iridoid glycosides on the performance of specialist vs. generalist herbivores and parasitoids?

Methods and Material

Plants

Plantago lanceolata is a perennial plant with a worldwide distribution (Sagar and Harper, 1964). In natural populations, IG levels range from undetectable to ca. 12% of the plant dry weight (Bowers et al., 1992; Fajer et al., 1992). There generally is no correlation between IG concentrations (aucubin or catalpol) and tissue nutrient concentrations (Marak et al., 2000; Reudler Talsma, 2007). Plants used for our experiments came from two sources. Thirteen genotypes, used in all experiments, were derived from an artificial selection experiment in which lines were selected for high and low leaf IG concentrations for four generations, originating from Dutch *P. lanceolata* (Marak et al., 2000). These genotypes, each originating from a different half-sib family, were clonally propagated (Wu and Antonovics, 1975) in order to generate sufficient leaf material of each genotype. For experiments involving the specialist butterfly *M. cinxia* and its specialist endoparasitoid *Cotesia melitaearum,* (Hymenoptera: Braconidae), we augmented this set of genotypes with three additional genotypes from the selection experiment, and ten genotypes collected from Åland, Finland [where the insects originated (see below)]. We tested the effects of quantitative variation in allelochemicals in the plants on the development of six different insect species: two generalist herbivores, two generalist endoparasitoids reared on each of these generalist herbivores, and a specialist herbivore and its specialist endoparasitoid.

Herbivores

Generalists The beet armyworm, *Spodoptera exigua* (Lepidoptera: Noctuidae), is polyphagous, and a serious pest of many crops worldwide. Females lay several clusters of 50–100 eggs that hatch within 2–3 d. The larvae normally have five instars (the first three are gregarious), and the entire life cycle is about 4–5 weeks with several generations per year (Wilson, 1934; Tingle and Mitchell, 1977). Cultures of *S. exigua* were established from eggs originating from a laboratory culture maintained on artificial diet at the Department of Virology at Wageningen University, the Netherlands.

The golden twin spot, *Chrysodeixis chalcites* (Lepidoptera: Noctuidae) is native to Central and Southern Europe, the Canary Islands, and Africa. Like *S. exigua*, it is a polyphagous crop pest. Eggs are laid singly or in small groups and hatch in 4–9 d. The larvae normally complete 6 instars and the entire life cycle is completed in about 5–7 weeks (Goodey, 1991). *Chrysodeixis chalcites* cultures were established from individuals collected from a garden in Nijmegen, the Netherlands.

Cultures of both *S. exigua* and *C. chalcites* were kept as caterpillars in plastic Petri dishes on artificial diet (Elzinga, 2002) at 25°C and 16:8 h L:D. When caterpillars were in their final instar, they were placed in plastic containers (15×10×10 cm) with diet and vermiculite into which they pupated. In order to get larvae for the experiment, adult moths were placed in a cage (40×50×65 cm) in a climate room at 25°C, 55% RH and 16:8 h L:D with honey water (1:1) and one *P. lanceolata* plant, that both noctuid species readily accepted for oviposition. Newly hatched caterpillars were collected from this cage and reared in Petri dishes (8 cm) on artificial diet until they reached their 3rd instar, after which they were used in the performance studies. The early growth on artificial diet was done in order to have sufficient numbers of caterpillars for the experiments, as their 1st instars survive better on artificial diet than on *P. lanceolata* diet (personal observation). Note that since the artificial diet contains no IGs, the effect of IG on larval and parasitoid performance is limited to what was ingested as later instars.

Specialist The Glanville fritillary butterfly, *M. cinxia,* inhabits open grasslands in parts of Europe and temperate Asia. It has one generation per year in most of its range. A female lays several large egg clusters (150–200) on plants in the genera *Plantago* and *Veronica* (Plantaginaceae) (Kuussaari et al., 2004). Larvae spin a communal web and feed gregariously throughout most of their development. Higher levels of IGs in the diet can increase the rate of development (Harvey et al., 2005; Saastamoinen et al., 2007). Furthermore, IGs are sequestered by the larvae (Suomi et al., 2001, 2003), and plants with higher IG levels are preferred for oviposition (Nieminen et al., 2003; Reudler Talsma et al., 2008). *Melitaea cinxia* caterpillars used for these experiments were the offspring of laboratory reared butterflies from Åland, SW Finland. The caterpillars were fed field collected *P. lanceolata* leaves until their 3rd instar when they were used for the experiment. Note that since rearing of *M. cinxia* on specific plant genotypes did not start until they reached their 3rd instar, assessment of effects of IG concentration on larval and parasitoid performance is limited to what was ingested as later instars.

Parasitoids

Generalists Hyposoter didymator (Thunberg, 1822) (Hymenoptera: Ichneumonidae) is a generalist solitary endoparasi-

toid of caterpillars of many species in the large Lepidoptera family Noctuidae (Bar et al., 1979; Ingram, 1981; Vinson, 1990; Figueiredo et al., 2000; Schneider et al., 2003). This species is a tissue feeder, so the developing wasp larva consumes the entire host. *Hyposoter didymator* adults were obtained from a laboratory colony that was started in 1993 with wasps collected from parasitized *Spodoptera littoralis* in the Cordoba, Spain. For 4 years, they were reared on *S. frugiperda* in the Laboratoire de Pathologie Comparée at INRA UMII, Saint-Christol-lèz-Alés, France. Adults used in the experiment were reared on *S. exigua*. In order to extend longevity of the adult wasps, they were kept at 10°C and 16:8 h L:D.

Cotesia marginiventris (Cresson, 1865) (Hymenoptera: Braconidae) also is a generalist solitary endoparasitoid that attacks Noctuidae (Krombein et al., 1979). As other *Cotesia*, the larva feeds primarily on host haemolymph and fat body during its development, and it does not consume the entire host (Sznajder and Harvey, 2003). *Cotesia marginiventris* were obtained from a colony maintained at Nijmegen University, The Netherlands, where they were reared on *S. exigua.* Adults were kept at 10°C and 16:8 h L:D and were constantly provided with honey and water.

Specialist Cotesia melitaearum agg. is a complex of cryptic species specialized on *Melitaea* or *Euphydryas* butterflies (Kankare and Shaw, 2004). The species of *C. melitaearum* agg. used in this study is restricted to the host *M. cinxia* (Kankare et al., 2005). The adult female parasitoid lays broods of 1–40 eggs (depending on host size) in all instars of *M. cinxia* larvae. We used *C. melitaearum* from Åland, SW Finland, where the wasp has 2–3 generations per year (Lei et al., 1997). For the experiment, laboratory reared *M. cinxia* caterpillars were put on potted plants that were placed in natural populations in Åland, where they were parasitized by naturally occurring *C. melitaearum.*

Experimental Design

Generalists Third instars of the two generalist herbivores, *S. exigua* and *C. chalcites,* were randomly assigned to one of three treatments: unparasitized (control), parasitized by *C. marginiventris*, or parasitized by *H. didymator.* For parasitism, a 3rd instar caterpillar was offered to a female parasitoid, and oviposition was observed as a single insertion of the ovipositor. Although the parasitoids attack all larval instars of *S. exigua* and *C. chalcites*, previous studies have shown that *H. didymator* has the highest reproductive success when it parasitizes 3rd instar hosts (Reudler Talsma et al., 2007). For each *P. lanceolata* genotype, 16–20 parasitized and 16–20 unparasitized caterpillars of each herbivore species were reared individually on freshly excised leaves in Petri dishes (55 mm diam) in a growth cabinet at 25°C, 16:8 h L:D and 70% RH. The total number of larvae included in the experiment was 451. Leaves were refreshed every day. This was done using young to intermediate-aged leaves from at least five different plant individuals per genotype. Leaves were collected and then pooled per genotype and distributed across the larvae assigned to that genotype. Due to insufficient leaf production by some of the genotypes, not all genotypes were represented in every treatment combination. Emerged adults (both butterflies and parasitoids) were provided with water and kept at 25°C, 16:8 h L:D; 70% RH. The following fitness correlates were recorded for the unparasitized caterpillars: larval development time (the number of days from the 3rd instar, when the experiment started, until pupation), pupal development time, pupal mass, pupal survival until adulthood, adult mass, and adult longevity. The same parameters were recorded for the parasitoids, except that larval development time was recorded from the day of parasitism until the larva emerged from the host, and pupal development time was the number of days between larval emergence and adult wasp eclosion. Pupal mass of parasitoids includes the silk of the cocoon.

Specialist The experiments with the specialist *M. cinxia* and its parasitoid *C. melitaearum* were undertaken in the field to allow for natural parasitism. Gregarious larval groups of *M. cinxia* were placed on intact potted plants in field locations where the parasitoid *C. melitaearum* is known to occur. Before putting the larvae on the plant, they were fed fresh leaves collected from *P. lanceolata* in the field. Groups of forty 3rd-instar caterpillars were placed onto single potted plants of 26 different genotypes of *P. lanceolata* (16 originating from the Netherlands, including the 13 genotypes used in the generalist experiments, and 10 originating from Åland, Finland). Five replicate plants of Dutch genotypes and three replicate plants of Finnish genotypes were used. Three plants were lost, so in total we used 107 plants and 4,280 caterpillars. Each pot was covered by a mesh cloth that prevented the caterpillars from escaping, but which allowed *C. melitaearum* to enter. Caterpillars were left in the field for 3 weeks, during which time their host plant was replaced with the same genotype if it was defoliated. After 3 weeks, all caterpillars had molted to their 5th (diapause) instar. The 2,728 recovered caterpillars then were removed from the plants, and a random subsample of caterpillars from each plant (1,501 in total) was placed in a separate plastic container in a root cellar in Åland, where the larvae spent the winter in diapause. The following spring their diapause was broken and the larvae were fed fresh leaves from the same genotype on which

they had fed the previous summer. Caterpillars were reared until pupation after the 7th larval instar, or larval parasitoid emergence. Post-diapause, the same parameters were measured as in the experiment with the generalists, except that larval development time was determined as the number of days between the breaking of diapauses, and emergence; adult longevity was not measured. Additionally we measured the survival of the larvae until diapause, and the number that survived overwintering. Because the hosts were parasitized naturally, rather than under visual observation in the laboratory, only a small fraction of the larvae was found to be parasitized (the natural rate of parasitism is low) (van Nouhuys and Punju, 2010). This approach allowed us to compare both the performance parameters and the rate of parasitism of larvae on the different genotypes of *P. lanceolata.*

Chemical Analyses

Collection of Leaf Material In the experiments with generalist herbivores and parasitoids, one mixed leaf sample per genotype was collected at three 4 weeks intervals, for analysis of leaf IG concentrations. The first two time points were during the growth period of the larvae. IG estimates from these two time points were averaged per genotype and used in tests of associations with insect performance parameters. Measurements from the third time point were used only to check for consistency of genotype differences over a longer time period. Each leaf sample consisted of the young and intermediate-aged leaves of at least 5 plants of the same genotype, as in the feeding trials. For the experiments with the *specialist* herbivore and parasitoid, leaves were sampled both pre- and post-diapause. From each plant, the 3rd and 4th fully grown leaf was collected before putting the pre-diapause caterpillars on them in the field. When a plant was completely defoliated and replaced by another of the same genotype, we also took the 3rd and 4th fully grown leaf from the second plant, and averaged their IG levels. Concentrations then were averaged per genotype and used in analyses of parasitism and survival until the breaking of diapause. After diapause, we took two subsamples of the leaves that were fed to the caterpillars per genotype, one early and one late during the remaining ca. 6 weeks development time of *M. cinxia*. The averages of these concentrations per genotype were then used to test for associations with post-diapause performance parameters.

Leaf IG Analysis These methods follow Marak et al. (2003). In brief, all leaves were freeze dried and ground to a fine powder with a ball mill (Retsch, type MM 301, Retsch GmbH and Co., Haan, Germany). Finely ground dry material from the leaves (25 mg) was extracted in 10 ml of 70% MeOH and was shaken overnight (15°C/100RPM). The crude extract was filtered through Whatman #4 filter paper and the filtrate was diluted ten times with Milli-Q water. Concentrations of the IGs aucubin and catalpol were analyzed by HPLC using a Bio-Lc (Dionex, Sunnyvale, USA) equipped with a GP40 gradient pump, a Carbopac PA 1 guard (4×50 mm) and analytical column (4×250 mm), and an ED40 electrochemical detector for pulsed amperimetric detection (PAD). NaOH (1M) and Milli-Q water were used as eluents (10:90%, 1 ml/min). Retention times were 3.25 min and 4.40 min for aucubin and catalpol, respectively. Concentrations were analyzed using Chromeleon version 6.60 (Dionex Corp., Sunneyval, USA). A standard concentration series of aucubin and catalpol of 0.25, 0.5, 1.0, 2.0, 4.0 and 8.0 ppm was used for calibration.

Statistical Analysis

For the 13 plant genotypes that were included in both the generalist and specialist performance trials, we used ANOVA to analyze differences in IG between plant genotypes, between experiments (greenhouse-grown plants for generalists, field-grown plants for specialists), and their interaction. IG values were square-root transformed to meet assumptions of normality. In addition we used ANOVA to test whether there were differences in leaf IG concentrations between Dutch (artificially selected) and Finnish (collected from the wild) genotypes among the field grown plants.

Pearson correlations were used to test for associations between mean values for development parameters of the insects on the different plant genotypes and the mean IG concentration of those genotypes. The latter were based on the leaf samples collected during the corresponding experiment (greenhouse, field pre-diapause, or field post-diapause). For the generalist species, we analyzed larval and pupal development time, pupal and adult weight, and adult longevity. For the specialist,s the last two parameters were not measured. In addition, logistic regression was used to test whether mean larval and pupal survival on plant genotypes was affected by mean genotype IG concentration and whether parasitism of *M. cinxia* larvae by *C. melitaearum* was affected by mean genotype IG concentration. Since Dutch and Finnish genotypes appeared to differ in their IG profiles (catalpol and catalpol-to-total IG ratio, see results), we used ANCOVA to test whether genotype mean performance of specialists differed between genotypes from Finnish and Dutch origin, and whether effects of genotype origin were still significant if genotype mean catalpol or the ratio of catalpol to the total IG concentration [catalpol/(aucubin+catalpol)] were included as a covariate. All

statistical analyses were performed using SPSS for Windows Release 16.0.2.

Results

Iridoid Glycoside Variation Among Plant Genotypes

Genotype mean leaf IG concentrations of the 13 Dutch genotypes that were included in all performance studies varied circa six-fold, ranging from 1.28±0.21 to 7.35±0.90 (% leaf dry weight ± SE). The differences in leaf IG concentration among this set of genotypes were highly significant ($F[12,102]$=11.03, P<0.001). The same was true for the constituent components aucubin ($F[12,102]$=10.61, P<0.001) and catalpol ($F[12,102]$=15.47, P<0.001) that showed ranges of among-genotype variation similar to those observed for total IG concentration. IG concentrations were lower in the greenhouse-grown plants (generalist performance study, Fig. 1a, ranging from 0.83±0.09 to 6.41±1.02) ($F[1,102]$=13.16, P<0.001) than in field-grown plants (specialist performance study, Fig. 1b, ranging from 1.47±0.26 to 8.63±0.26), but the ranking of the genotypes was maintained under both conditions (interaction $F[12,102]$=1.10, P=0.36). Mean leaf IG concentrations of the additional genotypes used in the specialist performance study all fell within the range of the 13 genotypes that were shared between the experiments.

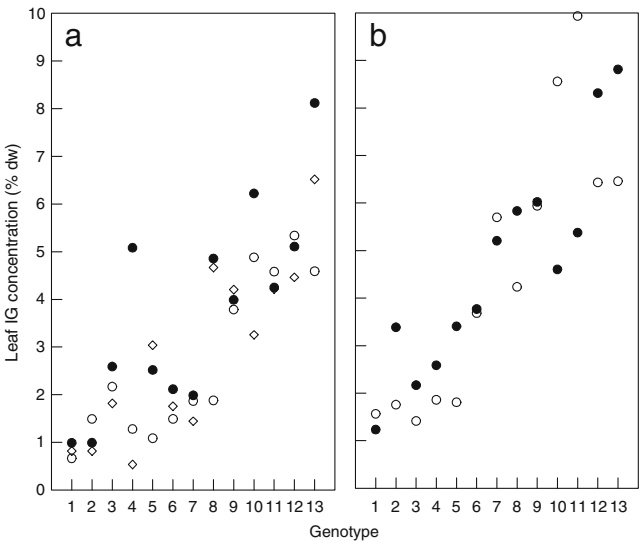

Fig. 1 Within- and between genotype variation in leaf iridoid glycoside (IG) concentrations in 13 *Plantago lanceolata* genotypes, ranked according to increasing genotype mean IG. (**a**) IG values from mixed leaf samples of each genotype taken at 4-wk intervals, two times during (*circles*) and one time after (*diamond*) the generalist feeding trials. (**b**) Mean values per genotype from samples taken before (*open circles*) and after diapause of specialists (*closed circles*), 10 months later

The mean IG values of the Finnish genotypes did not differ from the Dutch ones ($F[1,24]$=0.24, P=0.63), but they contained more catalpol (2.01±0.28 vs. 1.09±0.28, $F[1,24]$=9.82, P=0.004), resulting in a higher contribution of catalpol to the total IG level in Finnish (41.9%) than in the Dutch genotypes (31.7%). Since variation in IG concentrations between genotypes was large compared to the temporal variation within genotypes at the scale of weeks (Fig. 1a) or even months (Fig. 1b), and since the ranking of genotypes with respect to their leaf IG concentrations was fairly consistent over time (Fig. 1a and b), we are confident that even though we did not intensively sample IGs during larval development, the genotype mean IG values that we used provide a reasonable estimate of differences in IG levels experienced by the insects during the experiment.

Effects of Iridoid Glycosides on Specialist and Generalist Herbivores

Generalists Larvae of the generalist herbivore *C. chalcites* developed slowly on plant genotypes with high IG concentrations (Table 1). For instance, an increase in the IG concentration from 1% to 6%, the range spanned by the genotypes, caused a 20.0% (4.2 day) delay in larval development time (Fig. 2a). Development of the other generalist herbivore, *S. exigua,* also was slower on genotypes with higher IG concentrations, but in this species it was the pupal development that was delayed (Table 1). An increase in the average IG concentration from 1% to 6% of leaf dry weight caused a 9.9% (0.82 day) delay in pupal development (Fig. 2b). Adult longevity of *S. exigua* also was negatively affected by high leaf IG concentrations in its diet (Fig. 3a; r=−0.642, P=0.03). An increase in IG concentration from 1% to 6% of leaf dry weight reduced longevity by 59% (5.5 days). Adult longevity of the other generalist herbivore, *C. chalcites,* was independent of the concentration of IG in its diet (r=−0.102, P=0.77). Pupal weight, pupal survival, and adult weight of the generalist herbivores were unaffected by the leaf IG concentrations in their diet. This does not mean that these parameters were not affected by host plant genotype. For instance, pupal mass was strongly affected by host plant genotype in both *C. chalcites* ($F[10,88]$=12.81, P<0.001) and *S. exigua* ($F[12,90]$=3.94, P<0.001), but apparently these effects were not mediated by differences in the concentrations of IGs in these plant genotypes.

Specialist Roughly half (51.6%) of the caterpillars of the specialist *M. cinxia* from the 26 genotypes in the field and that had been randomly selected for further study survived diapause over winter. This is on par with the natural rate of overwintering survival (van Nouhuys et al., 2003). Their

Table 1 Correlations between mean leaf concentrations of iridoid glycosides and mean performance (larval development time, cocoon weight and pupal development time) of insect herbivores and their parasitoids on genotypes of *Plantago lanceolata*

Herbivore	Parasitoid	*N*	Larval development time	Cocoon weight	*N*	Pupal development time

*$P<0.10$; **$P<0.05$

probability of survival was significantly lower when they originated from plant genotypes with high levels of catalpol before diapause (Fig. 4A, logistic regression, *Wald* $\chi^2[1]=8.23$, $P=0.004$). An increase in leaf catalpol concentration from 0.5% to 3.0%, the range encompassed by the genotypes, was associated with a decrease in survival from 59% to 37%. Survival of diapausing larvae was lower when they had been raised on Finnish (Fig. 4a, open symbols) than on Dutch genotypes (Fig. 4a, closed symbols) before diapause (*Wald* $\chi^2[1]=4.50$, $P=0.03$). This difference could be explained by the higher catalpol concentrations in Finnish genotypes: effect of genotype origin (Finnish vs. Dutch) was no longer significant in a multiple logistic regression in which both genotype origin and genotype mean catalpol concentration were entered, whereas the latter effect was still significant. None of the post-diapause developmental parameters of *M. cinxia* were significantly associated with post-diapause levels of IGs in the herbivore's diet (Table 1), except for a faster development of post-diapause larvae on genotypes with a higher catalpol-to-total IG ratio ($r=-0.504$, $P=0.02$). Consequently, post-diapause larval development of *M. cinxia* was

Note the square-root scale of the X-axis

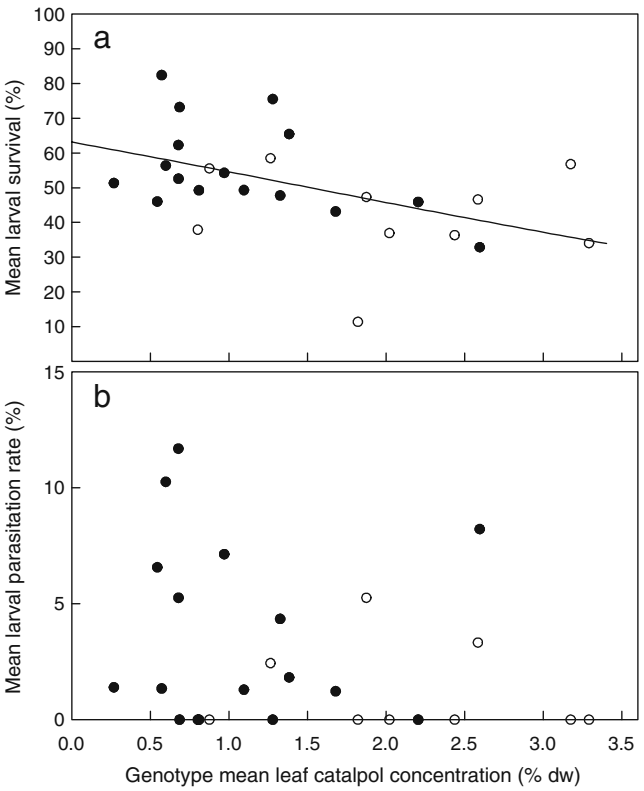

Fig. 4 (**a**) Mean survival of diapausing larvae of the specialist herbivore *Melitaea cinxia* and (**b**) Mean parasitism rate of *M. cinxia* by *Cotesia melitaearum* as a function of genotype mean leaf catalpol concentration in the food plant *Plantago lanceolata*. *Closed circles*: Dutch plant genotypes; *open circles*: Finnish plant genotypes. *Lines* are fitted values from logistic regressions based on data from all genotypes

faster on Finnish genotypes, that on average had a high catalpol-to-total IG ratio, than on Dutch genotypes (46.0±1.8 vs. 38.9±1.9 days, $F[1,20]=5.50$, $P=0.03$).

Additional analyses confirmed that the differences in post-diapause larval development time on Finnish vs. Dutch genotypes could be partly explained by differences in their IG profiles: when catalpol-to-total IG ratio was entered as a covariate in analyses of genotype origin (Finnish vs. Dutch) on larval development time, the significant effect of catalpol-to-total IG concentration remained ($F[1,19]=6.16$, $P=0.02$), whereas genotype origin (Finnish vs. Dutch) could explain only little additional variation ($F[1,19]=3.36$, $P=0.08$). This was not the case for post-diapause survival of *M. cinxia* larvae on Finnish vs. Dutch genotypes. Post-diapause survival until pupation was three times higher on Finnish than on Dutch genotypes (15.6 vs. 5.0%, logistic regression, *Wald* $\chi^2[1]=9.10$, $P=0.003$), and was independent of their IG profiles ($P>0.6$). Moreover, the probability of pupal survival to adulthood was four times higher on Finnish than on Dutch genotypes (56.0 vs. 12.9%, logistic regression, *Wald* $\chi^2[1]=17.39$, $P<0.001$), also independent of their IG profiles ($P>0.3$). The greater survival to adulthood by Finnish pupae was not mediated by pupal mass, which did not differ between individuals raised on Finnish vs. Dutch genotypes (148 vs. 140 mg, $F[1,20]=0.76$, $P=0.39$).

Effects of Iridoid Glycosides on the Generalist and Specialist Parasitoids

Generalists Overall, associations between plant IGs and development time of the generalist parasitoids were not concordant with those observed for their hosts. Larvae of the parasitoid *C. marginiventris* developed faster on *C. chalcites* (Fig. 2c), and their pupae developed faster on *S. exigua* (Fig. 2d) when these herbivores had been feeding on genotypes with high IG concentrations (Table 1). An increase in IG concentration from 1% to 6% of leaf dry weight was accompanied by advancement in larval and pupal development by 19% on these hosts, (1.9 and 1.1 days, respectively). Effects on longevity were more concordant between hosts and parasitoids. In accordance with its host *S. exigua*, adult longevity of *C. marginiventris* decreased with higher IG concentrations in the diet of this host (Fig. 3b; $r=-0.580$, $P=0.04$). An increase in IG concentration from 1% to 6% of leaf dry weight reduced longevity by 51% (7.2 days). Adult longevity of the other generalist parasitoid, *H. didymator,* also on average decreased

with increasing IG concentration in the diet of its host *S. exigua* (Fig. 3C), but too few parasitoids on this host survived until adulthood to allow meaningful tests of significance. None of the other developmental parameters of *H. didymator* were significantly affected by IG concentration (Table 1, Fig. 2e,f).

Some of the developmental parameters were not associated with the total concentration of IGs in the plant genotypes on which hosts were raised but only with the specific compounds aucubin or catalpol. Survival of *C. marginiventris* pupae to adulthood decreased with the concentration of catalpol in the plant genotypes fed to its host on *S. exigua* (logistic regression, *Wald* $\chi^2[1]$=5.60, P=0.02). An increase in catalpol from 0.3% to 1.8% of leaf dry weight, the range encompassed by the genotypes, more than doubled the mortality of *C. marginiventris* pupae, from 14.5% to 31.8%. No such effects were observed for aucubin (*Wald* $\chi^2[1]$=0.41, P=0.52). Pupal mass of *H. didymator* decreased with increasing ratio of catalpol-to-total IG in the plant genotypes fed to its host *C. chalcites* (r=−0.827, P=0.002) on *C. chalcites*. The reduction in pupal mass of this parasitoid observed on the other host, *S. exigua*, was not statistically significant (r=−0.766, P=0.076).

Specialist On 15 of the 26 plant genotypes that were placed into natural host populations in the field, at least one *M. cinxia* caterpillar was parasitized by *C. melitaearum*. In total, 3.2% of the caterpillars were parasitized, with a mean secondary brood size of 2.1 parasitoids per parasitized caterpillar. This is a normal rate of parasitism of pre-diapause *M. cinxia* larvae by *C. melitaearum* in Åland (Lei et al., 1997). The parasitism rate was not significantly affected by the level of IGs in the plant genotypes that hosts had been feeding on before diapause. The parasitism rate on average decreased with the concentration of catalpol in the genotypes on which *M. cinxia* had been raised (Fig. 4b), but this pattern was not statistically significant (logistic regression, *Wald* $\chi^2[1]$=1.70, P=0.19). Accordingly, the parasitism rate was on average lower on Finnish (1.05%) genotypes (that had relatively high catalpol concentrations) than on Dutch genotypes (3.93%), but this difference was also not statistically significant (logistic regression, *Wald* $\chi^2[1]$=2.81, P=0.09). None of the post-diapause developmental parameters of *C. melitaearum* were significantly associated with post-diapause levels of IGs in the herbivore's diet.

Discussion

Our study supports findings from earlier studies showing that the development of generalist and specialist insect herbivores and their parasitoids is often strongly associated with intra- or inter-specific variation in concentrations of secondary plant compounds (e.g., Barbosa, 1988; Barbosa et al., 1991; Adler et al., 1995; Harvey et al., 2005, 2007a; reviewed by Ode, 2006). Our results show that the strength and direction of such associations may not only differ between generalists and specialists but also between trophic levels: responses in development time to plant allelochemical variation differed between herbivores and their associated parasitoids.

Herbivores Larval development of the generalist herbivore *C. chalcites* and pupal development of the generalist herbivore *S. exigua* were significantly delayed on plant genotypes with high levels of IGs. This increases their development time, potentially decreasing the intrinsic rate of increase at the population level. It also may increase their window of susceptibility to natural enemies, as in the 'slow-growth high-mortality' hypothesis (Clancy and Price, 1987), which states that herbivores are potentially more vulnerable to larval and pupal parasitoids, pathogens, and predators when they feed on host plants with high levels of allelochemicals that extend their development time. Our results confirm those of earlier studies (Biere et al., 2004) showing that development time of *S. exigua* is prolonged on *P. lanceolata* genotypes selected for high leaf IG concentrations, but the results contrast with studies of Harvey et al. (2005) in which *S. exigua* only suffered reduced pupal weight on high-IG genotypes. Apparently, the stage and specific parameters at which negative associations between host IG and development are expressed can vary even within a single system. In the current experiment, feeding on high-IG genotypes was not associated with reduced pupal or adult weight of the generalist herbivores, traits, which are generally correlated with fecundity (Leather, 1988; Klingenberg and Spence, 1997; Saastamoinen, 2007). Only longevity of adult *S. exigua*, another trait that may be associated with fecundity, was reduced on high-IG plant genotypes. Interestingly, both *C. chalcites* and *S. exigua* showed large variation in pupal and adult mass on different plant genotypes, which was unrelated to differences in IGs among these genotypes. Apparently, traits other than IGs varied among these genotypes, and played a role in determining pupal and adult mass of the generalist insect herbivores.

With respect to associations between IGs and development time, the results for the specialist herbivore *M. cinxia* contrast with those for the two generalist herbivores. Whereas development time of the generalists was delayed on plant genotypes with high total leaf IG concentrations, that of *M. cinxia* was not. Development time of this specialist only responded to variation in the profile, not the total concentration, of leaf IGs; larvae developed more quickly on genotypes with high catalpol-to-total IG ratios.

Contrasts between specialist and generalist herbivores in their development time responses to the total leaf IG concentration in their hosts have been observed previously. Harvey et al. (2005) found that *M. cinxia* caterpillars developed faster on high-IG than on low-IG genotypes (see also Saastamoinen et al., 2007), whereas development time of the generalist *S. exigua* was unaffected by IG variation among genotypes. It is unclear why in our study the development time of this generalist was longer on high-IG genotypes than in the study of Harvey et al. (2005). One reason might be that we used a wider range of IG variation among genotype means (0.8–6.4% dw) than was encompassed by the two lines used by Harvey et al. (2005) (0.6 vs. 3.0% dw). However, what these studies have in common is the observation that on high-IG plants the development of the specialist is either less delayed (our study), or even more advanced (Harvey et al., 2005) compared to that of generalist herbivores. Similar observations have been made for other allelochemicals. For instance, pyrrolizidine alkaloids (PAs) commonly impact generalist herbivores, even though the strength of their effect may differ strongly among generalist species (Macel et al., 2005), but not specialists (Macel et al., 2002). These results support the general notion that specialized mono- or oligophagous herbivores are often better able to cope with allelochemicals in the host on which they are specialized than polyphagous herbivores, at least in terms of their development rate.

Our results correspond well with results from artificial diet studies with IGs (e.g., Bowers and Puttick, 1988; Puttick and Bowers, 1988; Mallampalli et al., 1996). These studies have shown that addition of aucubin and catalpol to artificial diet strongly reduces larval growth rates, at least during the early stages of growth, of the generalist caterpillars *Lymantria dispar* and *Spodoptera eridania*, but can increase larval growth rate of the specialist *Junonia coenia* (Bowers and Puttick, 1988), even though this specialist generally experiences slightly lower feeding efficiency on high- compared to low-IG artificial diets (Camara, 1997a; Smilanich et al., 2009).

Artificial diet studies provide more direct evidence for causal links between IGs and insect development than our correlative studies based on plant genotypes that differ in IGs, because traits that covary with IGs in the plant might affect insect performance as well. We tried to minimize such associations by using a core set of genotypes derived from artificial selection lines that had been subjected to four generations of selection for low and high leaf IG concentrations (Marak et al., 2000). During selection, pre-existing associations are generally broken up, unless they are caused by pleiotropy or very close linkage. Indeed, analysis of a subset of plants from the 13 genotypes that were used in all experiments of the current study revealed that among-genotype correlations between concentrations of leaf IGs and concentrations of leaf nutrients, which are also important determinants of development of insect herbivores, were non-significant (Pearson correlation coefficients between IGs and N: r=+0.31, P=0.31; P: r=+0.26, P=0.39; K: r=+0.34, P=0.26, J. H. Reudler, unpublished results). This suggests that our results probably have not been confounded with effects of co-varying levels of primary metabolites.

The large differences in post-diapause development of the specialist herbivore *M. cinxia* on the Finnish and Dutch *P. lanceolata* genotypes however, does illustrate the importance of other plant traits, in addition to IGs, in governing the interactions between *P. lanceolata* and its insect herbivores. Developmental success of *M. cinxia* was much higher on their local, Finnish, genotypes than on the Dutch genotypes: they developed faster and showed higher larval and pupal survival on the local genotypes. Finnish genotypes had consistently higher levels of catalpol than Dutch genotypes, a difference that was reflected in higher ratios of catalpol to the total amount of IGs. To our surprise, only the faster development of post-diapause *M. cinxia* larvae on Finnish than on Dutch genotypes could be (partly) explained by the differences in their IG profiles. Differences in IG profiles between Finnish and Dutch genotypes could not explain the large differences in post-diapause larval and pupal survival of *M. cinxia* on these genotypes. This suggests that *M. cinxia* has adapted to feeding on its local hosts at least partly in response to attributes other than their IG chemistry. Adaptation of insect herbivores to their local host plants is common, though not ubiquitous (Kaltz and Shykoff, 1998; Ballabeni et al., 2003; Greischar and Koskella, 2007), and the traits that underlie local adaptation may involve many aspects other than those involved in allelochemical-based interactions (e.g., Zovi et al., 2008).

Parasitoids The performance of the two generalist parasitoids on the generalist herbivores was associated strongly with the leaf IG concentrations in the plant genotypes on which these hosts were raised. In contrast to earlier studies (Mallampalli et al., 1996; Harvey et al., 2005), the magnitude and even direction of the correlations between IGs and performance of the parasitoids did not follow that of the hosts. Notably, whereas both of the generalist herbivores developed slowly on plant genotypes with high IG concentrations, the parasitoid *C. marginiventris* actually developed faster on both host species when they were reared on high-IG genotypes. The faster development of *C. marginiventris* on hosts that suffered from feeding on high-IG plants is surprising, since negative effects of the ingestion of toxic allelochemicals on the performance and quality of herbivores often have been observed to vertically transfer to higher trophic levels (Campbell and Duffey, 1979; Barbosa et al.,

1986, 1991; Harvey et al., 2007a; Lampert et al., 2008), especially in interactions where hosts sequester toxic allelochemicals (part of the "nasty host" hypothesis; Gauld et al., 1992, Lampert et al., 2010). One possible explanation for the faster growth of *C. marginiventris* on these hosts is that higher levels of allelochemicals in the host diet weaken the host immune system, as observed for *J. coenia* feeding on high-IG artificial diets (Smilanich et al., 2009), thus allowing the developing parasitoids to reallocate metabolic energy from immunosuppression to development (Kraaijeveld and Godfray, 1997; Ojala et al., 2005), the "immunocompromized host" effect. This hypothesis remains to be confirmed for the species studied here. Associations between adult longevity and host IGs were more concordant between herbivores and parasitoids. Longevity of adult *S. exigua* was significantly reduced on high-IG genotypes and so was that of *C. marginiventris,* when raised on this host. Similarly, longevity of both adult *C. chalcites* and its parasitoids was not affected by leaf IG concentration in the host's diet.

The effect of IGs in the diet of the generalist herbivores on the performance of their parasitoids strongly differed between the two parasitoid species. A high concentration of IGs in the diet of both host species resulted in faster development of *C. marginiventris,* despite slower development of its hosts, but did not affect the development of *H. didymator.* This illustrates that even when we consider interactions with a specific group of parasitoids, such as generalist endo-koinobionts, effects of IGs in the diet of an herbivore on interactions with its parasitoids cannot be generalized. Part of the difference between parasitoid species may be due to their different feeding modes. *Cotesia marginiventris* is a haemolymph feeder whereas *H. didymator* feeds on tissue. Haemolymph feeders may be less constrained by host growth rate than tissue feeders that have to consume their host before being able to emerge (Harvey et al., 2000; Harvey and Strand, 2002). Previous studies similarly found that the related tissue feeder *Hyposoter horticola* more closely followed developmental responses of the host *M. cinxia* to IG variation than the haemolymph feeder *C. melitaearum* (Harvey et al., 2005).

In contrast to the generalist parasitoids, development of the specialist parasitoid *C. melitaearum* did not vary with the IG levels in the plant genotypes on which its host *M. cinxia* was reared, in agreement with the results of Harvey et al. (2005). Nieminen et al. (2003) found that in natural populations, the rate of parasitism of *M. cinxia* by *C. melitaearum* decreased with the concentration of catalpol in the *P. lanceolata.* Although we found the same trend in our experiment, the decrease was not statistically significant, perhaps due to small sample size. Effects of host plant IGs on parasitism rates could result from two different processes. First, adult parasitoids may avoid ovipositing into host larvae feeding on high-IG plants. Second, development of immature parasitoids may be less successful on hosts feeding on high IG plants. For instance, whereas field parasitism of the Catalpa sphinx moth (*Ceratomia catalpa*), a species that sequesters IGs (Bowers, 2003), by the parasitoid *Cotesia congregata* appears to be independent of caterpillar IG concentrations, survival of this parasitoid is slightly lower on high-IG caterpillars (Lampert et al., 2010). *Melitaea cinxia* also is known to sequester IGs (Suomi et al. 2001, 2003) and development of *C. melitaearum* larvae on high-IG caterpillars may be less successful if the negative effects due to the vertical transfer of these toxic allelochemicals (the "nasty host" effects) more than outweigh any positive effects due to decreased immunocompetence of the host (the "immunocompromized host" effect). Interestingly, in contrast to *J. coenia*, that is immunocompromized when feeding on high-IG diets (Smilanich et al., 2009), Laurentz (2010) found no evidence for a decreased immune function in *M. cinxia*. In fact, *M. cinxia* showed higher levels of encapsulation of artificial implants when reared on plants with high levels of catalpol.

In summary, we found that development time of the specialist herbivore was less negatively impacted by high-IG genotypes than that of both of the generalists, supporting the idea that specialist herbivores are better adapted to allelochemicals in their hosts than are generalist herbivores. We also found that generalist parasitoids developed faster on hosts feeding on high-IG genotypes whereas the specialist parasitoid was not strongly impacted by the IG concentration in the diet of its host, which could reflect differences in the effects of IGs on immunocompetence on the different hosts that they parasitized. Our study, therefore, shows that associations between IG concentrations in *P. lanceolata* and development of its associated insect herbivores and parasitoids are species-specific.

Abstract We investigated endogenous plant hormones and needle growth in *Pinus tabulaeformis* plants grown in open-top chambers and exposed to ambient or elevated concentrations of carbon dioxide (CO_2) and/or ozone (O_3). Exposure to elevated CO_2 for 100 days significantly increased the change in fresh needle weight, indole-3-acetic acid (IAA), isopentenyl-adenosine (iPA), and dihydrozeatin riboside (DHZR) content. Abscisic acid (ABA) content decreased, and no effect was observed on zeatin riboside (ZR) content or changes in needle dry weight. The ratios of IAA/ABA and total cytokinins (CKs)/ABA $(ZR + DHZR + iPA/ABA)$ were increased. Elevated O_3 significantly decreased IAA and ZR, and decreased the ratios of IAA/ABA and CKs/ABA. Ozone treatment increased ABA content but did not change iPA or DHZR content or change fresh or dry needle weights. The combination treatment significantly increased ABA content and the IAA/ABA ratio but decreased the total CKs/ABA ratio and had no effect on CKs or IAA content or change in fresh and dry needle weights. The results indicate that elevated CO_2 ameliorated the effects of elevated O_3 on tree growth.

Key Words Ozone · Elevated CO_2 · Elevated O_3 · Endogenous plant hormones · Needle growth

Introduction

Levels of the greenhouse gases carbon dioxide (CO_2) and ozone (O_3) in the atmosphere are increasing because of human activities. Atmospheric CO_2 concentration has increased from 280 ppm in pre-industrial times to 379 ppm in 2010 and is predicted to at least double by the end of this century (IPCC, 2007). Anthropogenic emissions of O_3 precursors have increased significantly in China, in contrast to the small changes in North America and significant decreases in Europe (Streets and Waldhoff, 2000). Such changes in the atmospheric environment are expected to affect the growth and development of plants (Darbah et al., 2008; Riikonen et al., 2008). Plant hormones mediate plant responses to environment and plant development, and they communicate environmental conditions to the entire plant. Different parts of the plant are programmed to respond to hormonal levels by changing gene expression, thus increasing the chances that the individual will survive the changed environment (Winwood et al., 2007).

Leaf growth is often enhanced following exposure to elevated CO_2 (Taylor et al., 2003; Riikonen et al., 2004; reviewed in Lindroth, 2010). Li et al. (2002) and Teng et al. (2006) demonstrated that indole-3-acetic acid (IAA) levels increase under elevated CO_2. It is well known that IAA is important for cell division, elongation, and apical dominance (del Pozo et al., 2005; Mockaitis and Estelle, 2008) and that it promotes cell wall extensibility by inducing expression of expansin genes (Caderas et al., 2000; Greenwood et al., 2006). In *Populus* spp., the increase in leaf area expansion rate by elevated CO_2 was associated with increased cell wall

extensibility and increased activity of the cell wall-loosening enzyme (Ferris et al., 2001).

Natural cytokinins (CKs) induce cell division and shoot formation (Miller et al., 1955; Skoog and Miller, 1957), increase sink strength (Richmond and Lang, 1969), and delay senescence (Gan and Amasino, 1995). Dihydrozeatin (DHZ), isopentenyladenine (iPA) and zeatin (Z) are the predominant CKs found in higher plants. The free bases and their ribosides [dihydrozeatin riboside (DHZR), isopentenyladenine riboside (iPAR), and zeatin riboside (ZR)] are thought to be the biologically active forms of the CKs. The auxin-CKs hypothesis predicts that CKs, together with auxin, play an essential role in plant morphogenesis, influencing the formation of roots and shoots and their relative growth rates (Skoog and Miller, 1957). Some evidence indicates that accelerated growth and development observed under elevated CO_2 is accompanied by a corresponding increase in CKs concentrations (Li et al., 2002; Teng et al., 2006), while the slowed growth and development observed under elevated O_3 is accompanied by a decrease in CKs concentrations (Winwood et al., 2007). The role of CKs as retardants of leaf senescence under stress conditions has been documented both when exogenously supplied (Wingler et al., 1998) and in transgenic plants with elevated endogenous CKs levels (Gan and Amasino, 1995; Jordi et al., 2000).

Abscisic acid (ABA) regulates diverse plant processes, including growth and development under non-stress conditions, and plays a pivotal role in abiotic stress tolerance (Chinnusamy et al., 2008). Recently, evidence has been found for a role in community succession (Zhao et al., 2011). ABA is generally classified as a hormone with growth-inhibiting activity, but Cheng et al. (2002) reported a growth-promoting role for ABA in controlling fertility, vegetative growth, and organ and body size in the absence of stress conditions. These contrasting roles could be explained if ABA activates growth at low concentrations but inhibits growth at high concentrations (Cheng et al., 2002). ABA levels can change in response to environmental conditions. For example, ABA levels increase in response to elevated O_3 in *Pinus cembra* needles (Bianco and Dalstein, 1999) and decrease in response to elevated CO_2 in *Mokara yellow* and *Arabidopsis thaliana* leaves (Li et al., 2002; Teng et al., 2006).

In this study, hormone levels were determined in the needles of *P. tabulaeformis* grown under elevated CO_2, O_3, or CO_2 and O_3. We hypothesized that elevated CO_2 might increase the growth-promoting hormones and decrease the growth-inhibiting hormones in the needles of *P. tabulaeformis*, while elevated O_3 might have opposite effects. Furthermore, we hypothesized that when both CO_2 and O_3 were elevated, the CO_2 might ameliorate the negative effects of elevated O_3 on growth.

Methods and Materials

Experimental Site The experiment was conducted at the Shenyang Arboretum at the Chinese Academy of Science, located in the populated area of Shenyang, China (41°46′N, 123°26′E). The average annual temperature is 7.4°C, while the average temperatures in January and July are −12.6°C and 27.5°C, respectively. The highest temperature was 38.3°C, the lowest temperature was −32.3°C, and the average annual precipitation is 755.4 mm in this area.

Plant Material Four–yr-old Chinese pine (*Pinus tabulaeformis*) saplings (about 0.7–1.0 m high), all from a single maternal plant, were purchased from a local nursery. All saplings were planted in open-top chambers (OTCs), 20 saplings per chamber. The soil was loamy, and supplemental fertilizer was provided to ensure that saplings were not nutrient-limited. Rainfall was occasionally supplemented to minimize water stress.

Experimental Design The factorial design of 12 OTCs (diam 4 m, height 3 m, with 4 m distance between neighboring OTCs) containing 3 OTCs with ambient air, 3 with elevated CO_2, 3 with elevated O_3, and 3 with the combination of elevated CO_2 and O_3 treatment was randomized in four blocks. Pure CO_2 was injected into the chambers from cylinders 24 h per day. Ozone was produced by electrode discharge (O_3 generator, model GP-5J, Jiangsu Xinghua Environmental Protection Science and Technology Limited Company, Taixing, China) from bottled oxygen and added to the OTCs 9 h per day (08:00–17:00). The CO_2 and O_3 concentrations in the chambers were monitored with a CO_2 infrared transducer (eSENSE-D; SenseAir, Delsbo, Sweden) and an O_3 transducer (S-900; Aeroqual, Auckland, New Zealand). Mean temperature was approximately 25°C (max. 35.7°C; min. 11.4°C), and mean relative air humidity was 50.2% in the OTCs.

Experimental Treatment For 100 d from 17 June to 27 September 2007, saplings in the OTCs were exposed to control (ambient CO_2, 350 μmol mol^{-1} and ambient O_3, 55 nmol mol^{-1}, designated AA), elevated CO_2 (CO_2, 700 μmol mol^{-1} and ambient O_3, designated EC), elevated O_3 (ambient CO_2 and O_3, 80 nmol mol^{-1}, designated EO), and the combination treatment (CO_2 and O_3, 700 μmol mol^{-1} and 80 nmol mol^{-1}, respectively, designated EC+EO). For each OTC, one fascicle (two needles) was randomly taken from the stem apex of every sapling on June 16 (before fumigation) and on September 27 (after 100 d of fumigation). Needles collected on day zero and needles collected on d 100 of fumigation were each pooled to obtain two samples per chamber for analysis of fresh and dry weight (dried at 70°C for 48 h). Samples (1.0 g) were collected from each OTC

before fumigation and on days 20, 40, 60, 80, and 100 of fumigation washed in distilled water, frozen in liquid nitrogen, and stored at −70°C for subsequent hormone analyses.

Hormone Determination The frozen samples (1.0 g) were powdered in liquid nitrogen and extracted at 4°C for 16 h in the dark with 80% (*v*/*v*) cold methanol containing 1 mM butylated hydroxytoluene as an antioxidant, and centrifuged at 16,000 × *g* for 15 min at 4°C. The residues were re-suspended in the same ice-cold extraction solution at 4°C for 1 h and recentrifuged. The supernatants were combined, passed through Chromosep C18 columns (C18 Sep-Park Cartridge, Waters, Millford, MA, USA), dried under N_2, and dissolved in 2 ml phosphate-buffered saline (PBS) containing 0.1% (*v*/*v*) Tween 20 and 0.1% (*w*/*v*) gelatin (pH 7.5) for analysis by an enzyme-linked immunosorbent assay (ELISA) following methods described in previous publications (Yang et al., 2001; Teng et al., 2006). The mouse monoclonal antibodies against the hormones, and Igg-linked horseradish peroxidase, were produced at the Phytohormones Research Institute (China Agricultural University, Beijing, China). Each antibody had high immunoreactivity and showed low cross reactivity with other hormones.

Statistical Analysis All hormone measurements were performed on extracts of plant tissue from each chamber, and these independent measurements were averaged to obtain a chamber mean for each sample date. Chambers corresponding to AA, EC, EO, and EC+EO were considered statistical replicates (N=3). Two-way ANOVA was carried out using the SPSS statistical software package (SPSS Inc., Chicago, IL, USA) for all sets of data at each sampling day. The values presented are the means of all measurements, and comparisons of means were determined through LSD test.

Results

Changes in Growth under Elevated CO_2 and/or O_3 In this experiment, the increase in fresh mass (per needle) during the exposure period from day 1 to day 100 was larger under elevated CO_2 compared to AA control (P<0.05), but the increase in dry mass showed no significant change. Elevated O_3 and the combination treatment had no significant effect on the increases in fresh and dry masses (Table 1).

Changes in Endogenous CKs under Elevated CO_2 and/or O_3 Elevated CO_2 or the combination treatment did not induce any significant change in ZR content compared with the AA control, but elevated O_3 decreased ZR content at days 20 and 80 (P<0.05) (Fig. 1a).

Table 1 Effects of elevated CO_2 (EC), elevated O_3 (EO) and elevated CO_2+O_3 (EC+EO) on increase in needle mass of *Pinus tabulaeformis* from June 16 (before fumigation) to September 27 (after 100 days of fumigation). Different letters between treatments indicate significant difference at P<0.05

Treatment	Increase in fresh weight per needle (g)	Increase in dry weight per needle (g)
AA	0.221±0.0114a	0.107±0.0135ab
EC	0.277±0.0138b	0.115±0.0116b
EO	0.194±0.0131a	0.086±0.0125a
EC+EO	0.226±0.0144a	0.094±0.0128ab

From day 20 to day 80, elevated CO_2 increased DHZR content (P<0.05 at day 20, 60, and P<0.01 at day 40, 80), while from day 40 to day 80, O_3 fumigation increased DHZR content in the needles compared with the AA control (P<0.05 at day 60 and P<0.01 at day 40, 80). DHZR content during the combination treatment was not significantly different from the AA control (Fig. 1b).

Under elevated CO_2, iPA content was higher at day 20 (P<0.05) and 80 (P<0.01), while elevated O_3 decreased iPA content only on day 100 (P<0.05). Compared with the AA control, the combination treatment induced no significant change in the iPA content (Fig. 1c).

Changes in Endogenous IAA and ABA under Elevated CO_2 and/or O_3 IAA content was higher under elevated CO_2 than in the AA control (P<0.01). No significant change was observed under elevated O_3 (except at day 80) or under the combination treatment throughout the experiment (Fig. 1d). Elevated CO_2 decreased ABA content (P<0.05 at days 20 and 80), while elevated O_3 and the combination treatment increased ABA content (P<0.01 at days 20 and 60) (Fig. 1e).

Changes in Hormone Ratios under Elevated CO_2 and/or O_3 Elevated CO_2 significantly increased the ratios of IAA/ABA and total CKs/ABA $[(ZR + DHZR + iPA)/ABA]$ relative to the AA control. The ratios were lower under elevated O_3 (Fig. 2a, b). The combination treatment significantly increased the IAA/ABA ratio and significantly decreased the CKs/ABA ratio, but the changes were not as large as those obtained with the single treatments.

Discussion

Hormones act as signals that can stimulate or inhibit growth and regulate developmental programs in plants (Fosket, 1994). We showed that elevated CO_2 and elevated O_3 have opposite effects on plant growth. Generally, elevated CO_2

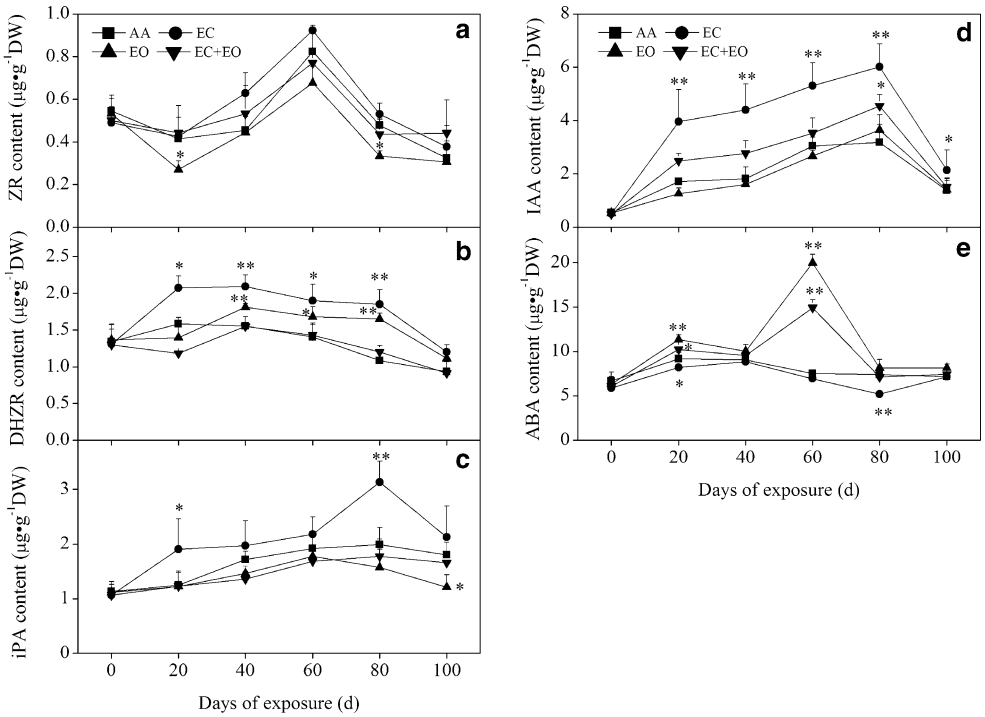

Fig. 1 Effects of ambient (*AA*), elevated CO_2 (*EC*), elevated O_3 (*EO*) and elevated CO_2+O_3 (*EC*+*EO*) on ZR (**a**), DHZR (**b**), iPA (**c**), IAA (**d**) and ABA (**e**) in *Pinus tabulaeformis* needles. Data are means of three independent open-top chambers (±SD). Significant differences from the AA control are indicated with asterisks: * $P<0.05$; ** $P<0.01$

increased the accumulation of growth-promoting hormones (IAA, CKs), and elevated O_3 increased the accumulation of the growth-inhibiting hormone ABA. The combination of elevated CO_2 and elevated O_3 had a little effect on hormone levels.

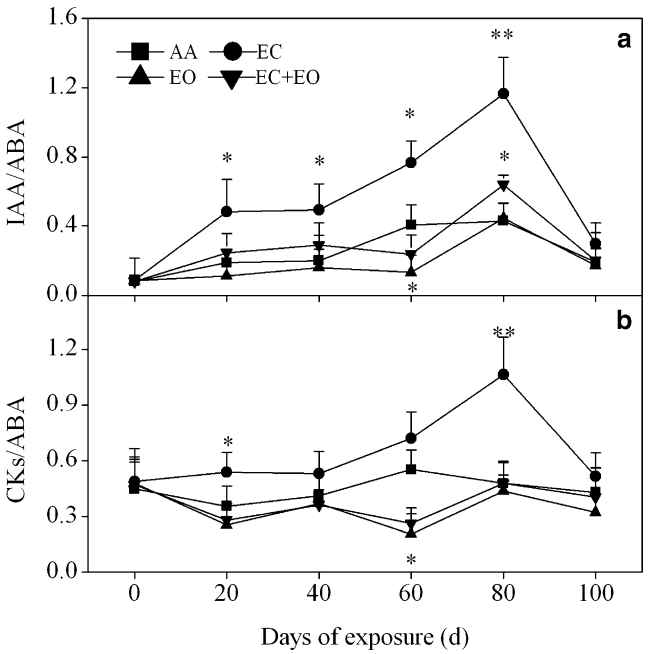

Fig. 2 Effects of ambient (*AA*), elevated CO_2 (*EC*), elevated O_3 (*EO*) and elevated CO_2+O_3 (*EC*+*EO*) on hormonal ratios IAA/ABA (**a**) and CKs/ABA (**b**) in *Pinus tabulaeformis* needles. Data are means of three independent open-top chambers (±SD). Significant differences from the AA control are indicated with asterisks: * $P<0.05$; ** $P<0.01$

Many researchers have reported that elevated CO_2 accelerates the net assimilation rate and enhances plant growth (King et al., 2005; Zheng et al., 2010). In contrast to the beneficial effects of elevated CO_2, O_3 is generally detrimental to plant growth and metabolism (Darbah et al., 2008; Lindroth, 2010; Noormets et al., 2010; Pinto et al., 2010). In our experiment, the change in fresh weight (per needle) was significantly increased by elevated CO_2. The change in fresh and dry weight (per needle) was slightly reduced by elevated O_3 compared with control although the change did not reach statistical significance. Cell division and expansion are controlled by a complex network of factors, including phytohormones that respond to environmental cues (Nishimura et al., 2004; Tsukaya, 2006). Taylor et al. (2003) suggested that the effects of elevated CO_2 on the cell cycle are likely to involve an interaction between plant hormones and carbon status. Accelerated *Arabidopsis thaliana* growth and development under elevated CO_2 could in part be attributed to increased foliar concentrations of plant hormones (Teng et al., 2006). We also observed that elevated CO_2 increased the levels of growth-promoting hormones (IAA, ZR, DHZR, and iPA). Therefore, we propose that elevated CO_2 levels may enhance plant growth by increasing hormone concentrations. Furthermore, we found that exposure to elevated O_3 levels decreased IAA content, which in turn may have inhibited plant growth. Somewhat lower needle growth rate accompanied lower concentrations of some hormones (IAA, ZR, and iPA) under elevated O_3.

The data presented here demonstrate that elevated CO_2 was associated with an increase in iPA and DHZR content,

which are likely responsible for the increase in growth and photosynthesis, as reported by other groups (Ookawa et al., 2004). Exogenous CKs application has been shown to attenuate the deleterious effects of O_3, perhaps because CKs may act as radical scavengers, protecting plant tissue from damage by O_3 (Pauls and Thompson, 1982). Our results show that under elevated O_3 there was an increase in DHZR content but no changes in iPA and ZR content. We speculate that the increase in DHZR content might enhance antioxidant capability to alleviate the oxidative stress of elevated O_3.

ABA traditionally has been considered an inhibitor of growth (Zhang and Davies, 1990) while other roles of ABA are less well defined. In the present study, we found that ABA content decreased under elevated CO_2 and increased under elevated O_3, and this change may be related to the corresponding increase or decrease in growth of *P. tabulaeformis*.

Plant growth and development is not governed by a single hormone but by the interaction of several. For example, Bettini et al. (2010) reported that a lower IAA/ABA ratio in the rolC-transgenic tomato can lead to reduced vegetative growth. A relationship between shoot development and the ratio of these two hormones was observed in lemon scions, in which a vigorous rootstock had a higher IAA/ABA ratio in the new shoots (Noda et al., 2000). We noted a relationship between increased vegetative growth and elevated IAA/ABA ratio and CKs/ABA ratio under elevated CO_2. In contrast, the IAA/ABA ratio is lower when plants are stressed (Zhang et al., 2008), consistent with our observations under elevated O_3 levels.

Little is known about the effect of simultaneously elevated CO_2 and O_3 on hormone levels. Our results indicate that EC+EO increased both the growth-promoting hormone IAA and the growth-inhibiting hormone ABA. It is well known that phytohormone metabolism is dependent on the supply of carbohydrates (Taiz and Zeiger, 2002). Under the combination of elevated CO_2 and O_3, more substrate and energy are required to prevent or repair injury (Paoletti and Grulke, 2005). Indeed, the level of the CKs that can enhance cell growth and development showed no change, but ABA, which can enhance plant resistance, was increased. The increase in IAA content induced by EC+EO may be related to increased CO_2 amelioration, but the mechanism behind these responses is still unclear.

In summary, our results show that elevating atmospheric CO_2 concentration alone enhances the growth of *P. tabulaeformis*. There is no growth enhancement when O_3 concentration is elevated, and there are reductions in IAA and CKs content and an increase in ABA content. There was no significant effect of the combined treatment with elevated CO_2 and elevated O_3 on hormone levels, probably because the elevated O_3 reduced the growth-promoting effects of elevated CO_2 or because elevated CO_2 counteracted the negative impact of elevated O_3.

Abstract Plants release secondary metabolites into the soil that change the chemical environment around them. Exogenous abscisic acid (ABA) is an important allelochemical whose role in successional trajectories has not been examined. We hypothesized that ABA can accumulate in the soil through successional processes and have an influence on forest dynamics. To this end, we investigated the distribution of ABA in forest communities from early to late successional stages and the response of dominant species to the gradient of ABA concentrations in three types of forests from northern to southern China. Concentrations of ABA in the soils of three forest types increased from early to late successional stages. Pioneer species' litters had the lowest ABA content, and their seed germination and seedling early growth were the most sensitive to the inhibitory effect of ABA. Mid- and late-successional species had a much higher ABA content in fallen leaves than pioneer species, and their seed germination and seedling early growth were inhibited by higher concentrations of ABA than pioneers. Late-successional species showed little response to the highest ABA concentration, possibly due to their large seed size. The results suggest that ABA accumulates in the soil as community succession proceeds. Sensitivity to ABA in the early stages, associated with other characteristics, may result in pioneer species losing their advantage in competition with late-successional species in an increasingly high ABA concentration environment, and being replaced by ABA-tolerant, late-successional species.

Introduction

Ecological succession is the result of interactions between vegetation and environmental factors and it is determined by multiple processes. Previous studies of community succession have identified numerous mechanisms that govern vegetation dynamics. These include physical factors [e.g., climatic (Kröpelin et al., 2008)], changes in soil moisture and nutrition (Gao et al., 2003), light interception (Facelli and Pickett, 1991b), and biological factors such as interactions between plants, life-history characteristics, seed predation (Facelli, 1994), and herbivory (Wilby and Brown, 2001). Studies have identified the importance of allelopathy in forest renewal and species composition (Rietveld et al., 1983; Fernandez et al., 2006), and some authors contend

that the replacement of plant species during succession is partly due to allelopathic mechanisms (Rice, 1972; Reigosa et al., 1999). Phytotoxins, released by leaching, root exudates, volatilization, or litter decomposition, can affect seed germination (Ruprecht et al., 2008), seedling establishment (Bosy and Reader, 1995), and plant growth and distribution (Rice, 1972). Biochemical interactions differ in their strength and may differentially affect the competitive vigor of dominant and subordinate species (Ruprecht et al., 2008). Hence, to understand these interactions and the potential influence of dominant species on ecosystem processes, it is necessary to identify those plant species in a community with significant allelopathic effects on other species (Anderson et al., 1978). Similarly, it is important to reveal the differential susceptibility of community constituents to these toxins (Wardle et al., 1993).

We previously assessed the allelopathic potentials of a series of dominant woody species in different successional stages on other dominant species in a subtropical forest on Dinghu Mountain, South China. We found that the litter and soils beneath individuals of *Castanopsis chinensis*, one of the dominant tree species in the mid-successional stage, have substantial inhibitory effects on seed germination of pioneer species as well as on conspecifics, but little impact on late-successional species (Zhao et al., unpublished results). This suggests that the allelopathic effect of this tree may affect vegetation succession by accelerating early-successional species decay and late-successional species establishment. We isolated the allelopathic chemicals in *C. chinensis* and confirmed that abscisic acid (ABA) is the major growth inhibitor (Zhao et al., unpublished results).

The phytohormone ABA regulates various aspects of the physiological and developmental processes of plants, such as seed maturation, dormancy, and germination (Leung and Giraudat, 1998), as well as plants' responses to biotic and abiotic stresses (Finkelstein et al., 2002). Studies have identified ABA as an allelopahtic chemical (Buta and Spaulding, 1989; Tseng et al., 2003). ABA synthesized by plants can enter the environment through litter leachate, trunk sap, and radicle exudation, and is common in higher plants. Nanogram quantities of ABA were sufficient to cause inhibition on tall fescue seed germination and seedling early growth (Buta and Spaulding, 1989), indicating its importance as a plant growth regulator. Thus, this compound has the potential to have an influence on vegetation composition and dynamics. The objectives of this work were: (i) to investigate the behavior of ABA in the process of community succession; (ii) to reveal the response of dominant species from different successional stages to environmental ABA; and (iii) to attempt to clarify the role of ABA in community succession.

Methods and Materials

Study Site We conducted our experiment in three forest types in three different national nature reserves in China (map in Supplementary Fig. S1): (i) Boreal mixed forest on Changbai Mountain (41°31′–42°28′N, 127°09′–128°55′E) in the southeast of the Jilin province in northeastern China. Here, there were three plots arranged along an elevation gradient from 700–800 m above sea level. The study area is dominated by a cool temperate continental climate with four clearly defined seasons and a monsoon influence. The mean annual temperature ranges from 0.9°–3.9°C., and the mean annual precipitation ranges from 700–800 mm. The zonal soils are dark brown forest soils. The primary stage of succession at this site consists of *Betula platyphylla* + *Populus davidiana*, while the middle stage is mainly represented by *B. platyphylla* + *P. davidiana* + *Pinus koraiensis*. The climax stage typically consists of *P. koraiensis*. (ii) Evergreen broadleaf forest on Tianmu Mountain (30°18′–30°25′N, 119°24′–119°28′E) in the northwest of the Zhejiang province, the northern subtropical area of eastern China. At this site, there were four plots arranged along an elevation gradient from 300–750 m above sea level. This area is influenced by a monsoonal climate and a high altitude with steep slopes, heavy rainstorms in the spring and fall, and a large range of snowfall in winter. The mean annual temperature ranges from 8.8°–14.8°C., and the mean annual precipitation ranges from 1390–1870 mm. The zonal soils are comprised of red soils (below 600 m a.s.l.), yellow soils (600–1,200 m a.s.l.), and brown yellow soils (above 1,200 m a.s.l.). The pioneer vegetation is dominated by *Pinus massoniana*, the early mid-successional stage is conifer-broadleaf mixture forest characterized by *P. massoniana* + *Schima superba*, the later mid-successional stage is mixed broadleaf forest with *S. superba* + *Cyclobalanopsis gracilis* + *Castanopsis sclerophylla* + *Castanopsis eyrei*, and the mature forest consists of *C. gracilis* + *C. sclerophylla* + *C. eyrei*. (iii) Evergreen broadleaf forest on Dinghu Mountain (23°09′–23°12′N, 112°30′–112°34′E) in the central part of the Guangdong Province in southern China. Here, there were four plots arranged along an elevation gradient from 150–300 m above sea level. The region is characterized by a typical south subtropical monsoon climate, with annual average precipitation of 1927 mm, of which nearly 80% falls in the warm humid season (April–September) and 20% in the cool dry season (October–March). The mean annual temperature is 20.9°C and the relative humidity is 80%. The soils, with serious natural acidification and a pH of 4.1–4.9, are classified as hydration lateritic. There are four types of natural vegetation communities in this forest representing a sequence of successional stages from pioneer to climax. The sequence begins with a conifer (*P. massoniana*, the same species found

on Tianmu Mountain), followed by a conifer-broadleaf mixture (with *P. massoniana* + *Castanopsis chinensis* + *S. superba*), then an evergreen broadleaf forest (with *Ca. chinensis* + *S. superba* + *Castanopsis fissa*), and finally the climax stage is mesophytic forest (with *Ca. chinensis* + *C. fissa* + *Cryptocarya concinna* + *Crvptocarya chinensis*).

Plant Material We selected 12 dominant species from different successional stages in the 3 forests (Table 1). The seeds and leaf litter of the dominant species were collected randomly. There were 10 trees of each species selected for leaf litter collection. Seeds were stored at 4°C until use, and fallen leaves were oven-dried at 40°C for 48 h and then stored at room temperature until use. Ten surface soil samples (at 2–4 cm depth) of all successional phases were collected randomly by a handle soil collecting tool; macroscopic stones, litters, roots, and other organic debris were removed. Each soil sample was mixed and separated into two parts. One part was oven-dried at 105°C to a stable weight to measure moisture content, and the other part was stored at −20°C until used to measure ABA content (storage at this temperature minimizes any microbial activity and prevents ABA decomposition). The soils of Changbai Mountain were collected in May, and the soils of Tianmu Mountain and Dinghu Mountain were collected in April, the seasons of highest seed germination.

ABA Quantification ABA content in the leaf litter and soils was measured by using an immunoassay, according to the method described by Pelèse et al. (1989) and modified by Hocher et al. (1991). Samples (0.5 g dry weight) were crushed and extracted for 60 h at 4°C in darkness in 5 ml of aqueous methanol (80%) containing 40 mg l^{-1} BHT as antioxidant. Sample purification was achieved by filtration of the methanolic extracts through a 0.2 μm pore size filter connected with a C_{18} Sep-Pack cartridge (Waters, Milford, MA, USA), which was eluted with 80% aqueous methanol. Extracts then were reduced to dryness by nitrogen evaporation and re-dissolved with a phosphate buffer prior to ELISA quantification.

Bioassay Based on the soil ABA concentration data, and taking into account the lower biological activity of artificial ABA compared to natural ABA, we used a series of ABA concentrations to test the response of seed germination and seedling early growth of selected seeds. The 250 ml conical flasks were filled with 100 ml of 0.9% agar culture medium and sterilized at 120°C for 0.5 h, then filled with 100 μg/ml of ABA solution (Sigma Co. USA) to create cultures containing 0, 0.5, 1.0, 2.0, 4.0, or 8.0 μg/ml of ABA when the temperature of the culture medium fell to about 50°C. Thirty surface-sterilized and germination-accelerated seeds were sown on the culture medium and cultivated in a dark room at 25°C. Three replicates were processed. Seedlings were harvested 7–15 d after seeds germinated, and seed germination and total length of roots and shoots were calculated. Percent inhibition (I) of seed germination was calculated by using the following formula (Chung et al., 2001):

$$\mathrm{I}(\%) = [1-(\text{growth parameter in a treatment}/\text{growth parameter in control})] \times 100$$

Statistical Analysis Differences among means of successional series in ABA concentration and bioassays were analyzed with one-way ANOVA LSD tests. Differences among means of ABA content in litter in Changbai Mountain were analyzed using an independent-samples *t*-test (2-tailed). The relationships between seed mass and the inhibitory effect of ABA were analyzed by Pearson Correlation Coefficients. Statistical analyses were per-

Table 1 Selected dominant species in each of the three forests, their seed mass and successional status

Stations	Location	Species	Seed mass (mg)	Successional status
Changbai	42°24′N, 128°05′E	*Betula platyphylla*	0.1	early
		Pinus koraiensis	547.9	late

formed in SPSS 13.0 for Windows at a significance level of $P<0.05$.

Results

ABA Contents in Leaf Litters The contents of ABA in different plant species' fallen leaves were dramatically different from one another. In Changbai Mountain, the mean content of ABA in the leaf litter of *B. platyphylla* was 1.81 μg/g dw (dry weight), while in the late-successional species (*P. koraiensis*), it was 5.52 μg/g dw, significantly higher than in the pioneer species ($P<0.001$, independent-samples *t*-test). In Tianmu Mountain, the mean content of ABA in the leaf litter of *P. massoniana* was 3.11 μg/g dw compared to 9.66, 4.28, and 16.17 μg/g dw in three mid-successional species (*S. superba, C. gracilis*, and *C. sclerophylla*, respectively), and 13.36 μg/g dw in *C. eyrei*. In Dinghu Mountain, the mean content of ABA in the leaf litter of *P. massoniana* was 3.30 μg/g dw, while the two mid-successional species (*Ca. chinensis* and *C. fissa*) were 11.19 and 4.39 μg/g dw, respectively. The mean content of ABA in two late-successional species (*C. concinna* and *Cr. chinensis*) were measured as 6.06 and 33.67 μg/g dw, respectively (Fig. 1).

In all three forest ecosystems, the early-successional species had the lowest ABA content in their leaf litter. The mid- and late-successional species had significantly more ABA in their leaf litter than did pioneer species, which implies that there is more ABA released into the soil in the middle and late phases of forest succession than in the early phase.

ABA Content in Soils The content of ABA in dry soil increased in all three types of forest as succession progressed. As a micro molecular organic compound, ABA dissolved in soil solution and its concentration also depended on soil moisture. Therefore the concentration of ABA in soil solution also increased with the process of succession, but not universally.

In Changbai Mountain, the mean content of ABA in the soil was 83.69 ng/g dw for the early successional phase, 98.65 ng/g dw for the middle phase, and 121.14 ng/g dw for the late phase (Fig. 2a). The mean concentration of ABA in soil solution was 127.93 ng/ml, 267.48 ng/ml, and 199.11 ng/ml, respectively, for the early, middle, and late successional stages (Fig. 2d). In Tianmu Mountain, the mean content of ABA in the soil increased from 100.1 ng/g dw in the early phase to 210.4 ng/g dw in the early mid-successional phase and to 270.1 ng/g dw in the later mid-successional phase, and to 382.4 ng/g dw in the late-successional phase (Fig. 2b). Accordingly, the mean concentration of ABA in the soil solution increased from 350.38 ng/ml in the early phase to 625.56 ng/ml in the early mid-successional phase and 694.04 ng/ml in the late mid-successional phase, and to 1684.15 ng/ml in the late-successional phase (Fig. 2e). In Dinghu Mountain, the mean ABA content in the soil was 122.0 ng/g dw, 218.5 ng/g dw, 336.6 ng/g dw, and 440.7 ng/g dw in the early, early mid-successional, later mid-successional, and late-successional stages, respectively (Fig. 2c). The mean ABA concentration

(**a**) Species from Changbai Mountain; (**b**) Species from Tianmu Mountain; (**c**) Species from Dinghu Mountain. Error bars are +/− SE. Means with different letters are significantly different at a significance level of $P<0.05$ (independent-samples *t*-test in Changbai Mountain and one-way ANOVA LSD tests in Tianmu and Dinghu Mountain)

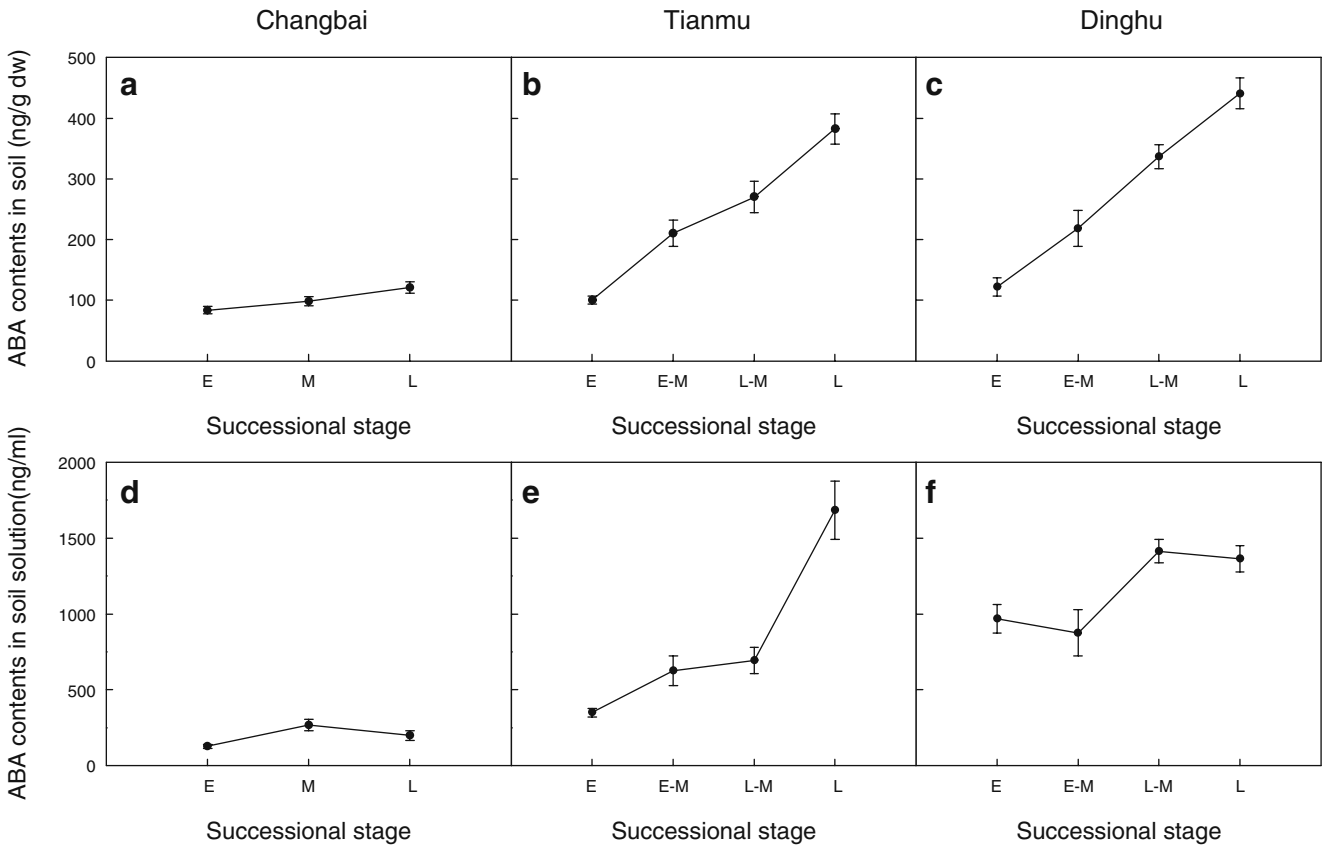

Fig. 2 ABA contents in soil and ABA concentration in soil solution in different successional phases in three forest types. Error bars are +/− SE. The letters below the horizontal axis indicate the successional phases (E, early; E-M, early-middle; M, middle; L-M, late-middle; L, late). (**a**)ABA content in soil in Changbai Mountain; (**b**)ABA content in soil in Tianmu Mountain; (**c**) ABA content in soil in Dinghu Mountain; (**d**) ABA concentration in soil solution in Changbai Mountain; (**e**)ABA concentration in soil solution in Tianmu Mountain; (f)ABA concentration in soil solution in Dinghu Mountain

in the soil solution was 968.74 ng/ml, 875.24 ng/ml, 1413.97 ng/ml, and 1363.80 ng/ml from the early through late successional stages (Fig. 2f).

The northern forest soils had the lowest ABA concentrations of all three forests, in accordance with the observation that species from northern forests have the lowest ABA concentrations in their leaf litter.

It is possible that some of the ABA in the soil may have partially decomposed before being assayed, although we froze the soil samples to minimize this loss. In addition, small amounts of ABA may have been lost in the process of extraction and purification, so the tested concentrations of ABA in the soil are likely even somewhat lower than natural concentrations in field.

Bioassay Seed germination and early seedling growth of pioneer, mid- and late-successional species showed different responses to ABA exposure. ABA had stronger negative effects on pioneer species than on mid- and late-successional species (for detailed dates see Supplementary Table S1 and S2). In the Changbai Mountain forest, seed germination and early seedling growth of *B. platyphylla* was inhibited by ABA at all concentration levels. In contrast, *P. koraiensis* was inhibited only at the highest concentration (8.0 μg/ml) and was influenced only slightly at low concentrations (Fig. 3a and b). In the soil solution, ABA concentrations ranged from 127.93 ng/ml to 267.48 ng/ml. As artificial ABA has less biological activity than natural ABA, this concentration approaches the lowest concentration (0.5 μg/ml) that we tested. At this concentration, ABA had no influence on the late-successional species (*P. koraiensis*) but had an inhibitive effect on pioneer species (*B. platyphylla*). In the Tianmu Mountain forest, the inhibitory effect of ABA on pioneer species was substantially higher than on all other mid- and late-successional species except *S. superba*, which showed higher sensitivity to ABA than pioneer species. The late-successional species *C. eyrei* was affected the least of all five tested species at high concentrations (4.0 and 8.0 μg/ml) (Fig. 3c and d). The mean ABA concentration in soil solution in the early successional stage was 350.38 ng/ml, approaching the lowest ABA concentration cultures. The pioneer species (*P. massoniana*) and one of the mid-

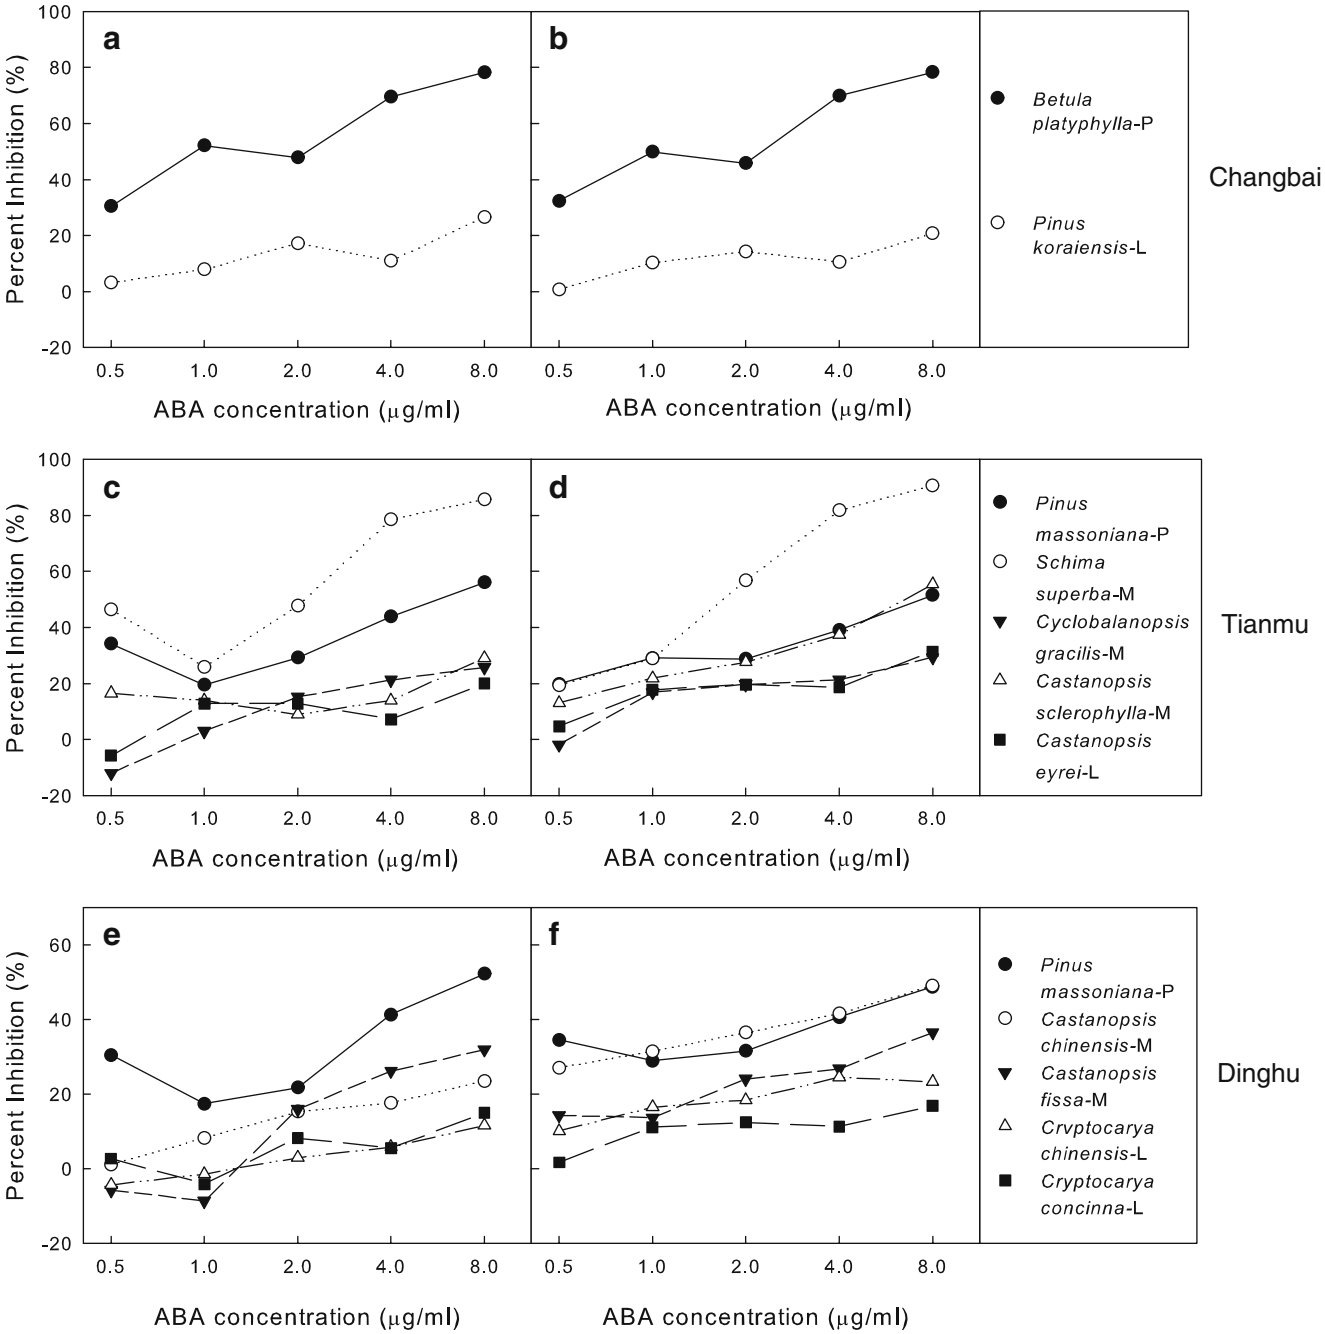

Fig. 3 Inhibitory effects of ABA on the seed germination and early seedling growth of dominant species in three forests. (**a**) Seed germination and (**b**) seedling growth on Changbai Mountain. (**c**) Seed germination and (**d**) seedling growth on Tianmu Mountain. (**e**) Seed germination and (**f**) seedling growth on Dinghu Mountain. P = pioneer species; M = midsuccessional species; L = late-succesional species

successional species (*S. superba*) were inhibited at this concentration, but mid- and late-successional species were influenced only slightly. In mid- and late-successional stages, ABA concentrations in the soil solution increased, and pioneer and mid-successional species were more inhibited; the late-successional species also was inhibited but to a lesser degree than the other species.

In the Dinghu Mountain forest, seed germination of *P. massoniana*, an early-successional species, showed the strongest suppression by ABA at all concentrations. Mid-successional species had the same response to ABA at low concentrations (0.5 and 1.0 μg/ml) as late-successional species, but had a more negative response at high concentrations (>2.0 μg/ml). The seed germination and

early seedling growth of late-successional species at Dinghu Mountain were least inhibited of the three forests, and had no significant response to ABA at any concentration level (Fig. 3e and f). In the soil solutions, ABA concentrations approached 1.0 μg/ml in early-successional stage forests and 2.0 μg/ml in late-successional stage forests. Pioneer and some mid-successional species were inhibited at all successional stages, but the other mid- and all late-successional species were not influenced in the early stage and were only slightly inhibited in later stages.

There was a significant negative correlation between seed mass and inhibition of ABA on seed germination ($P<0.01$ at all concentrations) and early seedling growth ($P<0.05$ at all concentrations) in all 12 species tested, indicating that small seeds are more sensitive to the inhibitory effects of ABA than large seeds. Additionally, inhibition of seed germination by ABA was more closely related to seed mass than early seedling growth, which indicates that the process of seed germination under ABA suppression is reflected by seed mass.

Discussion

Plant litter can alter the physical and chemical environment of a community and affect the probability of germination and establishment of plants (Facelli and Pickett 1991a; Bartha, 2001). The negative effects of litter on seedling recruitment have been recorded in many species (Goldberg and Werner, 1983; Facelli and Kerrigan, 1996; Foster, 1999; Vellend et al., 2000). During the process of succession, litter fall increases with increasing age of vegetation (Jensen and Gutekunst, 2003; Ostertag et al., 2008). Species from different successional stages may respond differently to litter cover. Monk and Gabrielson (1985) found that pioneer species were more affected by litter than late successional species. Multiple mechanisms, including light interception (Facelli and Pickett, 1991a, b; Jensen and Gutekunst, 2003), reduction of the amplitude of temperature (Grime et al., 1981), mechanical effects (Bosy and Reader, 1995), and facilitation of seed predators (Facelli, 1994) may be involved in the effects of litter on seed germination and seedling establishment. Allelochemicals leached from litter also have been considered as one of the mechanisms of succession (Facelli and Pickett, 1991a, b; Ganade and Brown, 2002). In this study, we found a very high concentration of ABA in forest leaf litter, which may be one of the reasons that litter has an important suppression effect on plant establishment. The concentration of ABA in grass leachates of tall fescue and straw had previously been measured at 390 ng/g fw (Buta and Spaulding, 1989). ABA concentrations in the leaf litter of the 12 species tested here were much higher than those previously recorded. ABA content also had been reported to vary greatly between fresh and dry leaves. A 10-fold increase in ABA levels had been observed in grass after one day of desiccation (Buta and Spaulding, 1989). Therefore, it is not unusual that the fallen leaves measured here had such high ABA concentrations.

During the course of succession, leaf traits such as leaf area, matter content, and chemical composition change as forest plant community composition and plant life form dominance change (Cortez et al., 2007). Most theories of plant herbivory predict that late-successional species produce greater amounts of chemical defense compounds for protection from desiccation, herbivory, and parasitism (e.g., Coley et al., 1985). Our results show that late-successional species produce more ABA in their fallen leaves than early-successional species. This could alter the chemical environment of the community and help later-successional species gain a competitive advantage over early-successional species by inhibiting the germination and growth of early-succesional species. In this way, ABA may serve as a chemical weapon of interspecific competition.

Leaf litter is the main source of ABA in the soil. As community succession progresses, both litter production and the amount of ABA in the litter increase. However, decomposition by soil microorganisms also increases with succession. Therefore, the true ABA concentration is a balance between ABA loss and retention in the soil; overall, the concentration increases as succession progresses. In maize, 10 nM (2.64 ng/ml) of ABA has been found to have an inhibitory effect on root elongation (Pilet and Saucy, 1987). In our study, the concentrations of ABA in the soil were much higher than levels shown previously to have inhibitory effects on plant species.

Soil is an important factor that influences plant community composition, and soil abiotic and biotic factors play key roles in plant community dynamics. Kardol et al. (2006) observed negative plant–soil feedback for early-successional plant species, neutral feedback for mid-successional species, and positive feedback for late-successional species. Many secondary compounds accumulate in soil organic matter (e.g., Koegel-Knabner et al., 1991; Northup et al., 1998; Hattenschwiler and Vitousek, 2000) and alter the chemical environment of the community. The accumulation of ABA in soil represents one possible chemical factor associated with community succession. The changed soil environment likely will directly inhibit some plant species while facilitating others, and ultimately influence community composition and vegetation succession.

Seed germination and early seedling growth are perhaps the most vulnerable stages in the life cycle of many plant species (Hester et al., 1991), and the suppression of

seedling recruitment can have serious consequences for population viability and species diversity (Tilman, 1993). ABA has been widely documented as an inhibitor of seed germination and early seedling growth in many species (Amaral et al., 2008), although its inhibitory effect varies among species (Buta and Spaulding, 1989; Tseng et al., 2003). In this study, the inhibitory strength of ABA depended on the successional stage at which the species occurred. ABA strongly inhibits both seed germination and the early growth of seedlings of pioneer species, but has little impact on mid- and late-successional species. This difference among species can change the competitive relationship between early- and late-successional species.

The mature stages of the life cycles of pioneer and late-successional species also may have different responses to the inhibitory effects of ABA, but this is not addressed in this paper. Tolerance of higher ABA concentrations in the initial stages of the life cycle would give late-successional species an additional advantage compared to pioneers. In the process of succession, increasing ABA concentrations in the soil as well as simultaneous changes among other physical and biological factors could cause pioneer species to lose their competitive advantage and be replaced by later-successional species.

ABA also can have a promotive effect on seed germination and plant growth when applied at low concentrations, a phenomenon known as hormesis (Mowha and Jackson, 1976, Chobot and Hadacek, 2009). In this study, seed germination of *C. gracilis, C. eyrei, C. fissa*, and *Cr. chinensis* were slightly stimulated by low concentrations of ABA. This implies that toxic levels of ABA for pioneer species may actually be favorable for late-successional species.

Early successional species often have a lower seed mass than late-successional plants (Jensen and Schrautzer, 1999; Jensen and Gutekunst, 2003), and this also was observed in this study. Seed size is a key feature for the regeneration of plants and affects both competitive and colonizing abilities of the species (Turnball et al., 1999; Jensen and Gutekunst, 2003). Large seed size correlates with higher amounts of nutrient storage, and large initial size has been shown to be an advantage for germination and establishment under shaded conditions and beneath litter layers (Venable and Brown, 1988; Leishman and Westoby, 1994; Jensen and Gutekunst, 2003). In our study, large seeds tolerated the inhibitory effect of ABA better than small seeds. Small seeds have little nutrient storage and must synthesize them through photosynthesis to provide for early growth. We hypothesize that ABA can inhibit the synthetic system to regulate seed germination and early seedling growth. Small seeds cannot gain nutrients in the presence of ABA and are thus inhibited. Conversely, nutrient storage in large seeds may help them pass this ABA-sensitive stage of life cycle. This theory explains why large seeds can germinate and grow well under thick litter and in soils with high ABA concentrations. Of course, the mechanism of large seeds' ability to tolerate high ABA levels needs investigation.

Our findings indicate that ABA accumulates in the soil during plant community succession and changes the chemical environment of the community. Increasing ABA concentrations in soil, associated with other community and species features, likely suppress the establishment of early-successional species and indirectly facilitate subsequent species, which, over time, leads to plant community succession. This finding has probable significance for forest management and ecological restoration.

Multiple deterministic and stochastic processes determine plant succession, and the detailed prediction of successional trajectories remains elusive. For example, although our results can help to explain why pioneer species are replaced by late-successional species, they do not explain why late-successional species can invade an established pioneer community. Our work, however, provides important initial research on the importance of ABA in community succession, and highlights the need for more research to be done in this area. We still lack an understanding of the effects of ABA in soil solutions over a longer time period, and additional sources of ABA, including plant root and stem radial flow, need to be detailed. ABA may influence not only seed germination and seedling growth, but also affect plant growth and interspecies relationships beyond the seed stage. Thus, the role of ABA accumulation in plant succession merits further investigation.

Abstract Despite a large number of studies on herbivore-induced plant volatiles (HIPVs), little is known about which specific compounds are used by natural enemies to locate prey- or host- infested plants. In addition, the role of HIPVs in attracting natural enemies has been restricted largely to agricultural systems. Differences in volatile blends emitted by cultivars and plants that originate from wild populations may be attributed to potentially contrasting selection regimes: natural selection among the wild types and artificial selection among cultivars. A more realistic understanding of these interactions in a broader ecological and evolutionary framework should include studies that involve insect herbivores, parasitoids, and wild plants on which they naturally interact in the field. We compared the attractiveness of HIPVs emitted by wild and cultivated cabbage to the parasitoid *Cotesia rubecula,* and determined the chemical composition of the HIPV blends to elucidate which compounds are involved in parasitoid attraction. Wild and cultivated cabbage differed significantly in their volatile emissions. *Cotesia rubecula* was differentially attracted to the wild cabbage populations and preferred wild over cultivated cabbage. Isothiocyanates, which were only emitted by the wild cabbages, may be the key components that explain the preference for wild over cultivated cabbage, whereas terpenes may be important for the differential attraction among the wild populations. Volatile analysis revealed that parasitoid attraction cannot be explained by simple linear relationships. Our results suggest that unraveling which compound(s) are innately attractive to parasitoids of cabbage pests should include wild Brassicaceae.

Introduction

The study of the factors that underpin rules governing the assembly, structure, and function of ecological communities is complicated by the fact that natural systems generally are characterized by a complex array of structural and chemical heterogeneity. This heterogeneity poses a profound challenge in the exploitation of resources by consumers (herbivores and their natural enemies). Individuals that use information enabling them to exploit resources will enjoy fitness benefits (e.g., Vet and Dicke 1992). Plants are known to emit volatile blends that provide information about the plant's identity, and can provide consumers with reliable information about the presence of a plant that might be a source of food (for herbivores), hosts (for parasitoids), or prey (for predators). However, as volatile signals do not always reveal which prey or host is feeding on the emitting plant and are released in a heterogeneous background, there will be variation in how this information is utilized by organisms throughout the food chain.

The functional and ecological importance of herbivore-induced plant volatiles (HIPVs) that are utilized by predators and parasitoids of herbivorous arthropods has received considerable attention over the past 25 years (e.g., Sabelis and Van de Baan 1983; Dicke et al. 1990; Turlings et al. 1995; De Moraes et al. 1998; Dicke and Baldwin 2010). However, despite the large number of papers on this topic, little is known about which specific plant compounds or mixtures of compounds are used by natural enemies to locate prey- or host- infested plants. Many studies with parasitoids of herbivorous arthropods have shown that experienced female wasps, i.e., wasps that have been in contact with hosts or the food plant of the host, are able to discriminate between volatile blends emitted by undamaged and herbivore-damaged plants, and that they prefer the latter (reviewed by Steidle and van Loon 2003; Turlings and Wäckers 2004; Allison and Hare 2009).

Study of the importance of specific HIPVs in natural enemy attraction traditionally has focused on terpenes, fatty acid derivatives (especially those produced by the lipoxygenase pathway), and products from the phenylalanine lyase (PAL) pathway (Ozawa et al. 2000; Schnee et al. 2006; Shiojiri et al. 2006a; Halitschke et al. 2008; Zhang et al. 2009). For example, specific terpenes attract natural enemies of arthropod herbivores when offered individually (Dicke et al. 1990; Rasmann et al. 2005) and are perceived by receptors in the antennae (Smid et al. 2002; Gouinguene et al. 2005). However, Mumm et al. (2008) showed that treatment of cabbage plants with fosmidomycin, an inhibitor of the biosynthesis of certain monoterpenes, did not affect the behavior of *Cotesia glomerata*. This throws doubt on the role of these monoterpenes as parasitoid attractants in this cabbage-parasitoid interaction.

Research on HIPVs and their role in host searching behavior of parasitoids has been driven largely by the potential for insect parasitoids as biological control agents of insect pests. Consequently, these studies often are restricted to cultivated plant species (Berenbaum and Zangerl 2008). However, artificial selection for specific plant traits has often not only changed the appearance of cultivated plants compared to their wild conspecifics, but also their chemistry. For example, wild cabbage *Brassica oleracea* populations, which grow naturally along the Atlantic coastline of western Europe, contain significantly higher levels of glucosinolates than cultivated cabbage (Harvey et al. 2007; Gols et al. 2008a). Glucosinolates (hereafter GS) are secondary plant compounds that play an important role in defense against insect herbivores and pathogens (Rask et al. 2000). However, the effect of domestication on the volatile profiles of plants has been little studied. For example, it is not known if HIPVs emitted by cultivated plants are similar to those emitted by wild conspecifics or whether natural enemies are equally attracted to HIPVs produced by cultivated and wild conspecifics. Given that insect predators and parasitoids have evolved in natural communities, this is a major gap in our knowledge. Köllner et al. (2008) have shown that a terpene synthase (TPS23) is involved in the production of (*E*)-β-caryophyllene, an HIPV that attracts natural enemies of a maize herbivore (Rasmann et al. 2005; Köllner et al. 2008). This gene is expressed in European maize lines as well as in its closest wild relative teosinte, but not in most American cultivated maize varieties (Köllner et al. 2008). This finding suggests that, in addition to plant traits that affect herbivory directly, volatile emissions that can be used by an herbivore's natural enemies also may differ between cultivated and natural conspecific plants.

Here, we compared the chemistry and attractiveness of HIPV blends emitted by plants originating from three wild cabbage (*Brassica oleracea* L, Brassicaceae, Fig. 1) populations, which differ dramatically in their levels of secondary plant metabolites (Gols et al. 2008b). Consequently, we expected variation in volatile secondary metabolites in response to herbivory, which in turn would differentially attract a parasitoid specialized on hosts feeding on brassicaceous plants. In addition, we compared the attractiveness of HIPV blends emitted by wild and cultivated cabbage to investigate the effect of domestication on parasitoid attraction. Our results are discussed in the context of the phenology of multitrophic interactions in natural communities, an aspect that is often ignored in studies of plant-insect interactions. We argue that studies examining the role of HIPVs on host searching behavior in parasitoids should explore more biologically and ecologically realistic interactions that involve herbivores and their parasitoids on wild food plants, on which these multitrophic interactions initially evolved.

Fig. 1 Wild *Brassica oleracea* growing naturally along the south coast of Dorset, England

Methods and Materials

Plants Seeds of *Brassica oleracea* were collected from several plants (>15) in three wild cabbage populations growing within 20 km of each other on chalk cliffs along the south coast of England, near Swanage in Dorset. These wild cabbage populations generally are regarded as the native wild form of cultivated cabbage (Wichmann et al. 2008). The three wild populations were located at sites known as 'Old Harry' ('OH', 50°38′N, 1°55′E), 'Kimmeridge' ('KIM', 50° 35′N, 2°03′E), and 'Winspit' ('WIN', 50°36′N, 2°07′E). The cultivar used in the experiment was a Brussels sprout variety (*B. oleracea* gemmifera) cv. Cyrus (CYR hereafter) and differs quantitatively and qualitatively in GS chemistry compared to the three wild cabbage populations (Gols et al. 2008b). Seeds were germinated and seedlings transferred to 1.5-l pots filled with potting soil ('Lentse potgrond #4'). Plants were grown in a greenhouse at 20–30°C, 40–80% r.h., and a photoperiod of at least 16 hr. Plants were watered daily. When plants were 4-wk-old, they were fertilized once a week with Kristallon blauw (N: P: K: micro nutrients as 19: 6: 20: 4) at 2.5 mg ml^{-1}, which was applied to the soil. Plants were 6-wk-old when they were used in experiments.

Insects The herbivore *Pieris rapae* L (Lepidoptera: Pieridae) and its specialist parasitoid *Cotesia rubecula* Marshall (Hymenoptera: Braconidae) are native to the Palearctic realm. In the Netherlands, *P. rapae* has three generations per year. In spring and early summer, the larvae feed mainly on GS-containing wild brassicaceous plant species (Fig. 2), whereas in late summer and autumn, cultivated species also may become important food plants. In this study, the herbivore and the parasitoid were collected originally from a Brussels sprouts field in the vicinity of Wageningen, The Netherlands. Insects were maintained in climate-controlled rooms at 20–24°C, 60% r.h., and a photoperiod of 16:8 h L:D. They were reared on cultivated CYR plants for at least 5 generations. Parasitized hosts were reared on CYR plants until the parasitoids had completed their immature development and egressed from the host. At this point, parasitoid cocoons were collected and transferred to a clean insect cage until adult emergence. Adult wasps were provided with honey as an energy source. In the flight bioassay, we used mated females that were 4–5-d-old and that had had no previous experience with hosts and are referred to as being 'naïve'. Wasps were used only once in the experiments.

To induce the plants, we used first instar (L1) *P. rapae* larvae, which were obtained from the insect culture.

Attraction of C. Rubecula to Volatiles Emitted by Wild and Cultivated Cabbage Experiment 1 – Herbivore-induced wild cabbage plants. The flight response of female *C. rubecula* to plants infested with *P. rapae* was tested in a tent-like structure (330×175×280 cm) made out of white nylon sheets, which was placed in a greenhouse (22–25°C, 50–70% r.h.). The greenhouse was continuously ventilated, which created a turbulent air current inside the tent. Previous studies have reported that 24 hr of caterpillar feeding results in the production of HIPV (Geervliet et al. 1997; Bruinsma et al. 2009). Each plant was infested with

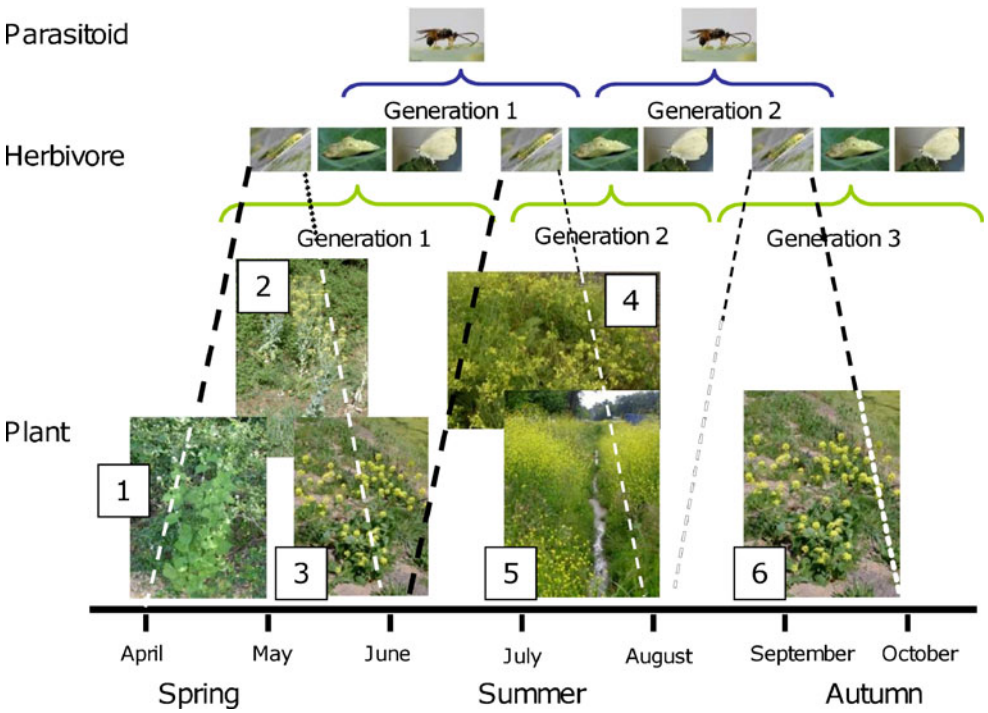

Fig. 2 Phenology of various wild food plants of *Pieris rapae* and occurrence of different generations of this herbivore and its specialist parasitoid *Cotesia rubecula* in the Netherlands. (1) *Alliaria petiolata*, (2) *Brassica napus*, (3) *Sinapis arvensis* (1st generation), (4) *Raphanus raphanistrum*, (5) *Brassica nigra*, (6) *S. arvensis* (2nd generation)

15 L1 *P. rapae* larvae divided over 3 leaves 20–24 hr prior to the bioassay.

We tested whether female wasps were equally attracted to plants of the 3 wild *B. oleracea* populations. Three host-infested plants, one from each cabbage population, were placed in a triangle 1 m apart. *Cotesia rubecula* females were collected from the insect cage in glass vials that were closed with cotton wool. These vials with single wasps then were placed in the center of the set-up, and the cotton wool was removed. Since the wasps did not leave the vial immediately, up to 5 vials were placed on the table simultaneously. Wasps were allowed to fly freely within the tent. As soon as a wasp landed on one of the three plants, it was collected, and the plant's identity was recorded. If some of the wasps that were initially released had not alighted on one of the plants within 30 min, they were excluded from the analysis. The response level, i.e., the proportion of wasps that alighted on a plant out of the total of wasps released, varied between 70 and 95%. A total of 30 responsive wasps were recorded for each combination of 3 plants. Based on visual inspection, each plant in a tested combination of plants had received similar amounts of herbivore damage. To control for any bias caused by the position of the plants, individual plants were rotated one position after 10 wasps had landed. The bioassay was repeated 14 times with newly prepared plants over 5 weeks.

Experiment 2 – Herbivore-induced plants: cultivated vs. wild cabbage. Here, we tested whether female *C. rubecula* were equally attracted to the Brussels sprout cultivar (CYR) compared to one of the wild cabbage populations (OH). Plant individuals were infested with 15 L1 *P. rapae* larvae divided over 3 leaves 20–24 hr prior to the bioassay. Two host-infested plants, one CYR and one OH plant were placed at opposite ends of the table (1 m apart) in the tent. Single wasps were released in vials half-way between the two plants. Observations were similar to the previous experiment. A total of 12 responsive wasps were recorded for each combination of two plants. To control for any positional bias, the positions of the plants were switched after 6 wasps had landed on the plants. The bioassay was repeated 15 times with newly prepared plants over 5 weeks.

Experiment 3 – Jasmonic acid (JA)-induced wild cabbage plants. The production of HIPVs is regulated by at least three signal-transduction pathways, the jasmonic acid (JA), the salicylic acid (SA), and the ethylene pathway (reviewed by Arimura et al. 2009). Biosynthesis of volatiles induced by biting-chewing insect herbivores depends mainly on the JA pathway (Reymond et al. 2004; De Vos et al. 2005). Exogenous JA-treatment often is used to mimic the effects of feeding by biting-chewing insects (Dicke et al. 1999; Thaler 1999; Bruinsma et al. 2009; Zhang et al. 2009). Here, we compared JA-treated plants from the 3 wild populations to investigate whether differential attraction to HIPV as observed in experiment 1 can be explained by differences in volatile emissions, whose biosynthesis is dependent on JA signalling.

Plants were sprayed with 15 ml of 1 mM JA (± jasmonic acid Sigma-Aldrich >97% purity) in a 0.2% Tween 80 (Merck) aqueous solution 20–24 hr prior to experiments. Control plants were sprayed with 15 ml of 0.2% Tween 80 in water. When plants were treated with JA, few wasps (<20%) initiated flying in the set-up that was used in the previous two experiments. Therefore, the flight response of *C. rubecula* was recorded in a wind tunnel (details in Geervliet et al. 1994), because a previous study showed that the wasps do respond to JA-treated cabbage plants in this device (Bruinsma et al. 2009). The wind tunnel conditions were set at 24±2°C, 60–70% r.h., and a wind speed of 20 cm s^{-1}. First, we investigated whether JA-treated OH plants attract more wasps than control OH plants. To investigate whether plants from the three wild populations are equally attractive to *C. rubecula* when treated with JA, three pair-wise comparisons were made, OH-WIN, OH-KIM, and WIN-KIM, as the wind tunnel only allows for dual-choice comparisons. Up to 5 vials with single wasps were placed in a horizontal glass cylinder on a 10-cm high socket positioned 60 cm downwind from the two plants. Recordings were similar to the previous experiments. Wasps that had not alighted on one of the plants within 15 min were removed and excluded from the analysis. Additional wasps were released until a total of 12 wasps had made a choice. The response level of the females in the wind tunnel varied between 60 and 90%. The position of the plants was switched after 6 wasps had made a choice. Each plant combination was tested eight times with newly prepared plants over 6 weeks.

Headspace Analysis of Herbivore Infested Plants: Collection of Volatiles Volatiles were collected from individual host-infested plants (N=5 or 6) from each of the four *B. oleracea* lines used in the bioassays. Plants were induced similarly as in the flight bioassays, i.e., plant individuals were infested with 15 L1 *P. rapae* larvae divided over 3 leaves 20–24 hr prior to volatile collection An entire host-infested plant, including soil, which was contained in aluminum foil, was transferred to a clean 35-l glass collection container. Pressurized air was filtered over silica gel, molecular sieves (4 Å, Sigma, St Louis MO, USA) and activated charcoal before entering the sampling container. Prior to sampling, the container was purged for 1 hr at 10 l/h. Subsequently, headspace volatiles were trapped on 90 mg Tenax TA for 4 hr at a flow of approximately 40 ml/min. Volatiles were also collected (N=2) from a collection container containing a piece of aluminum foil with water. Volatile compounds detected in these control samples were excluded from the data obtained for the plant samples.

Collected volatiles were released from the Tenax traps by heating in a thermodesorption cold trap unit (Markes, UK) at 200°C for 10 min and flushing with a He flow of 30 ml/min. Released compounds were cryofocused in a coldtrap at a temperature of −10°C. Volatiles were injected in splitless mode into the RTX-5 Silms GC column (Restec, 30 m×0.32 mm ID, 0.33 μm film thickness) by heating of the cold trap to 270°C. After an initial column temperature of 40°C for 2 min, the temperature was raised to 90°C at 3°C/min, then to 165°C at 2°C/min, and subsequently to 250°C at 15°C/min. The column was directly coupled to the ion source of a Finnigan quadrupole mass spectrometer, which was operating in the 70 eV EI ionization mode and scanning from mass 33 to 300 at 3 scans/sec. Collected volatiles were separated and identified using GS/MS (gas chromatography combined with mass spectrometry). Compounds were tentatively identified by comparison of the mass spectra with those in the NIST 2002 (version 2a) and Wiley 7 edition spectral libraries and by checking the retention indices. For identification and quantification, we used AMDIS version 2.1 (Automated Mass spectral Deconvolution & Identification Software). Compounds were quantified by measuring peak areas of the total ion fractions of the integrated signal. Peak areas were divided by above-ground fresh weight of plant tissue, which was determined immediately after trapping.

Statistical Analysis To determine whether *C. rubecula* females were differentially attracted to the three wild cabbage populations, we conducted a *G*-test for independence on wasp counts in the replicated three-way choice bioassays. The results for the replicate tests were homogeneous, so a *G-test* (goodness of fit) was conducted on the pooled data (H_0 = the three populations are equally attractive). A similar approach was used for the dual choice bioassays.

First, we determined whether population preferences could be explained by abundance patterns of individual volatile compounds. Each of the volatiles produced by the three wild populations was subjected to Kruskal-Wallis non-parametric one-way ANOVA. For the CYR-OH comparison, *Mann–Whitney U* tests were used. For each of the compounds for which the population effect was significant, we determined whether the emissions quantities ranked according to the landing preference. In a second approach, we used multivariate statistics (Principle Components Analysis = PCA) to reveal: (1) which volatile compounds are important for the separation of the three wild cabbage populations; (2) which are important for the separation of the OH and WIN plants; and (3) which are important for the separation of the wild OH and cultivated CYR plants. PLS-DA (Projection to Latent Structures Discriminant Analysis) is a projection method that separates groups of observations by rotating the PCA's such that a maximum separation among classes, here *B. oleracea* populations, is obtained (Eriksson et al. 2006). To achieve this, a Y-data matrix of dummy variables is included, which assigns a sample to its respective class, here population. The PLS-DA extension of the SIMCA P+ 12.0 software program (Umetrics AB, Umeå, Sweden) used for this analysis approximates the point 'swarm' in X (matrix with volatile compounds) and Y in PLS components in such a way that maximum covariation between the components in X and Y is achieved. The results of the analysis are visualized in score plots, which reveal the sample structure according to the model components, and loading plots, which display the contribution of the variables to these components, as well as the relationships among the variables. The program's cross validation procedure evaluates the significance of each additional component (starting with none) by comparing the goodness of fit (R^2) and the predictive value (Q^2) of the extended model with that of the reduced model. In a second PLS-DA analysis, those compounds were eliminated that contributed little to the separation of the samples belonging to different populations based on the variable importance on projection values (VIP values). Variables with VIP values greater than 1 are most influential to the model (Eriksson et al. 2006). Per sample, amounts of the individual volatile compounds were measured as peak areas divided by fresh mass (g) of aboveground plant tissues. In the analysis, those volatile compounds were included that were present in at least three of the samples in one of the populations. Based on their biosynthetic pathways, the substances found in volatile plant emissions in response to herbivory can be classified into terpenes, fatty acid derivatives, phenylpropanoids, benzenoids, and various nitrogen and sulfur containing products (Dudareva et al. 2004). Here, we also included the total amounts of alcohols, esters, aldehydes, ketones, sulfides, terpenes, and nitrogen-containing volatiles, as variables in the analyses. Data were log-transformed, mean-centered, and scaled to unit variance before they were subjected to the analysis.

Results

Attraction of C. rubecula to Caterpillar-Induced Volatiles Emitted by Wild and Cultivated Cabbage Plants (Experiments 1 and 2) The results for the flight bioassays in experiment 1 and 2 were homogenous (wild cabbage populations: $\chi 2$=25.2, *df*=26, *P*=0.51; OH vs. CYR plants: $\chi 2$=0.94, *df*=14, *P*=0.95). *Cotesia rubecula* females were differentially attracted to the plants of the three wild populations ($\chi 2$=7.04, *df*=2, *P*=0.03, Fig. 3), and OH plants were significantly more attractive to the parasitoids than

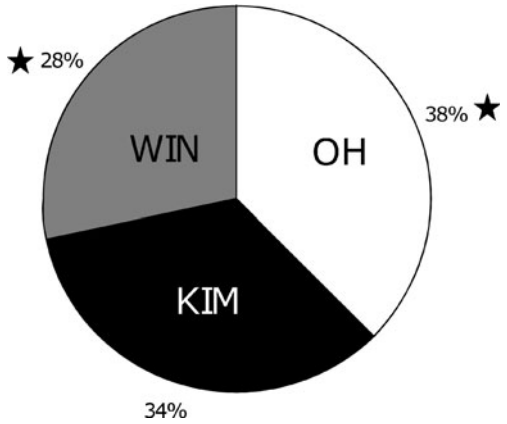

Fig. 3 Landing preference of *Cotesia rubecula* in a three-way comparison of wild host-infested *Brassica oleracea* plants originating from three wild populations (OH, KIM, and WIN) in Dorset, UK. Pie parts represent the average percentages of 14 bioassays performed in a tent set-up. In each bioassay 30 landing preferences were recorded (in total 420 wasps were released). The asterisks indicate populations for which the wasp preference was higher or lower than the expected preference of 1/3 (*G-test* for goodness of fit)

WIN plants (Fig. 3). Despite their rearing history on CYR plants, *C. rubecula* females preferred to alight on OH over CYR plants ($\chi 2=9.67$, $df=1$, $P=0.002$, Fig. 4a)

Attraction of C. rubecula to Volatiles Induced by JA Treatment (Experiment 3) To investigate whether volatiles whose biosynthesis is dependent on the JA signaling pathway are involved in the differential attraction of *C. rubecula*, plants from the three wild populations were treated with JA. In the first set of experiments, OH plants treated with JA were more attractive than OH plants treated with control solution ($\chi 2=6.06$, $df=1$, $P=0.02$, Fig. 4b). However, parasitoids did not discriminate between JA-treated plants of the three populations when offered pair-wise combinations (Fig. 4b).

Headspace Analysis of Herbivore Infested Plants Forty-nine different compounds were detected in at least three samples of one plant population (Table 1). Interestingly, volatile breakdown products of GS (but-3-enyl isothiocyanate and prop-2-enyl isothiocyanate) were produced only by wild cabbage plants. Volatile quantities of 13 compounds, i.e., but-3-enyl isothiocyanate and 12 terpenes, were significantly different when the three wild populations were compared using the *Kruskal Wallis test*. However, none of their emission quantities ranked OH>KIM>WIN, i.e., the preference ranking of *C. rubecula*. Emissions of δ-3-carene ranked WIN>KIM>OH, suggesting that this compound might repel *C. rubecula*. A PLS-DA including volatiles emitted by the three wild cabbages that significantly explained some of the variance, i.e., those compounds that had VIP values >1 (23 compounds), resulted in a model with three significant principal components (PC). The first PC separated KIM samples from the OH and WIN samples, whereas the second PC further separated the OH and the WIN samples (Fig. 5). This means that the volatile blends emitted by OH and WIN plants were more similar to each other than to the blends emitted by KIM plants. The KIM plants were characterized by relatively high emissions of the alcohols 3-pentanol and (*Z*)-3-hexen-1-ol and low amounts of the volatiles located at the right hand side in

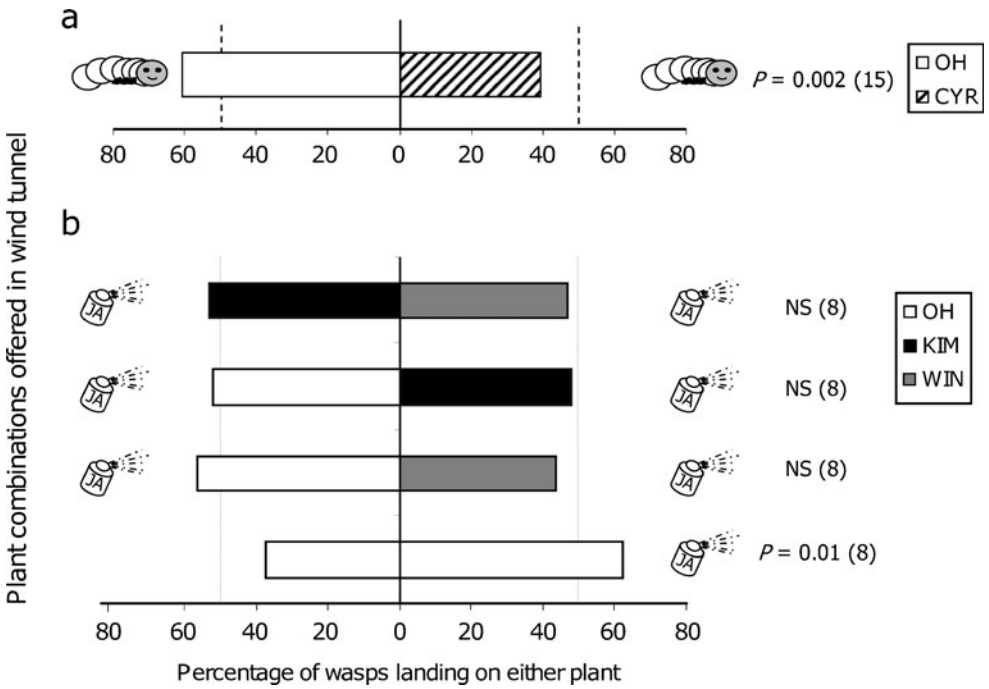

Fig. 4 Landing preference of *Cotesia rubecula* in a two-way comparison with cabbage plants. **a** Comparison of a host-infested cultivated (CYR) and wild (OH) plant and **b** pair-wise comparisons of JA-treated (1 mM) plants of the three wild *Brassica oleracea* populations, OH, KIM, and WIN (top three bars) and OH plants treated with JA or control solution (bottom bar). Experiments were performed in a wind tunnel. Significance levels indicate whether the preference for either plant offered in the bioassay is significantly different from a 50–50 distribution (*G-tests* for goodness of fit, NS = not significant). Numbers in brackets indicate the number of replicates. In each replicate 12 responding wasps were recorded

[a] Volatile emissions are given as mean peak area ± SE/g fresh weight of foliage with the number of samples between brackets

[b] ID corresponds with the numbers presented in Fig. 5, 6 and 7

[c] DMNT = (*E*)-3,4,8-dimethyl-1,3,7-nonatriene

!Numbers in superscript following emission quantities give the number of samples in which the compound was detected, if it was not found in all the samples of that population

* Compounds with asterisks indicate significant differences in emission quantities among the three wild populations (*Kruskal-Wallis* one-way ANOVA)

Fig. 5. A PLS-DA performed on WIN and OH samples, which were the least and most attractive populations, respectively, in the flight bioassay, resulted in a model with one significant PC (Fig. 6). From the 16 compounds that were included in the analysis, 3-methyl-butanenitrile and δ-3-carene (both produced in higher amounts by WIN plants, *Mann–Whitney U* tests, $P=0.052$ and $P<0.05$, respectively) and (*E*)-β-ocimene and (*E*)-3,4,8-dimethyl-1,3,7-nonatriene (=DMNT) (both produced in slightly higher amounts by OH plants, *Mann–Whitney U* tests, both $P=0.052$) contributed the most to the separation of the odor blends. Emission of the other 12 compounds did not differ significantly between the two populations. Similarly, CYR and OH volatiles were compared resulting in a model with two significant PC's (Fig. 7). Emissions of the 26 compounds that were included in the model differed significantly (all *P* values≤0.05 *Mann–Whitney U* tests) between OH and CYR plants. The only two compounds that contributed to the separation of the samples and were produced in higher amounts by OH plants were the N-containing volatiles, 3-methyl-3-butenenitrile and but-3-enyl isothiocyanate. However, when OH and WIN plants were compared, quantities of these compounds tended to be higher in WIN than in OH plants (*Mann–Whitney U* test: 3-methyl-3-butenenitrile, $P=0.052$; but-3-enyl isothiocyanate and $P=0.13$). Quantities of (*E*)-β-ocimene and DMNT, which matched the parasitoid preference ranking OH>WIN, did not significantly differ between OH and CYR plants ($P=0.79$ and $P=0.25$, respectively). Thus, emissions of these four compounds do not reflect parasitoid preference.

Discussion

This study showed that there were significant differences between the volatile profiles of the wild *B. oleracea* populations and the cultivar, as well as among the wild populations of this plant. Furthermore, the parasitoid *C. rubecula* was differentially attracted to *B. oleracea* plants from three different wild populations of this species even though they grow less than 20 km from each other in nature. *Cotesia rubecula* also was more attracted to OH plants than to the Brussels sprout variety on which the parasitoid had been reared for many generations. However, *C. rubecula* did not discriminate between volatile blends emitted by the three wild *B. oleracea* populations when treated with JA, a plant hormone that is the key component produced in the lipoxygenase pathway, and which is often used to mimic insect herbivory (Dicke et al. 1999; Thaler 1999; Bruinsma

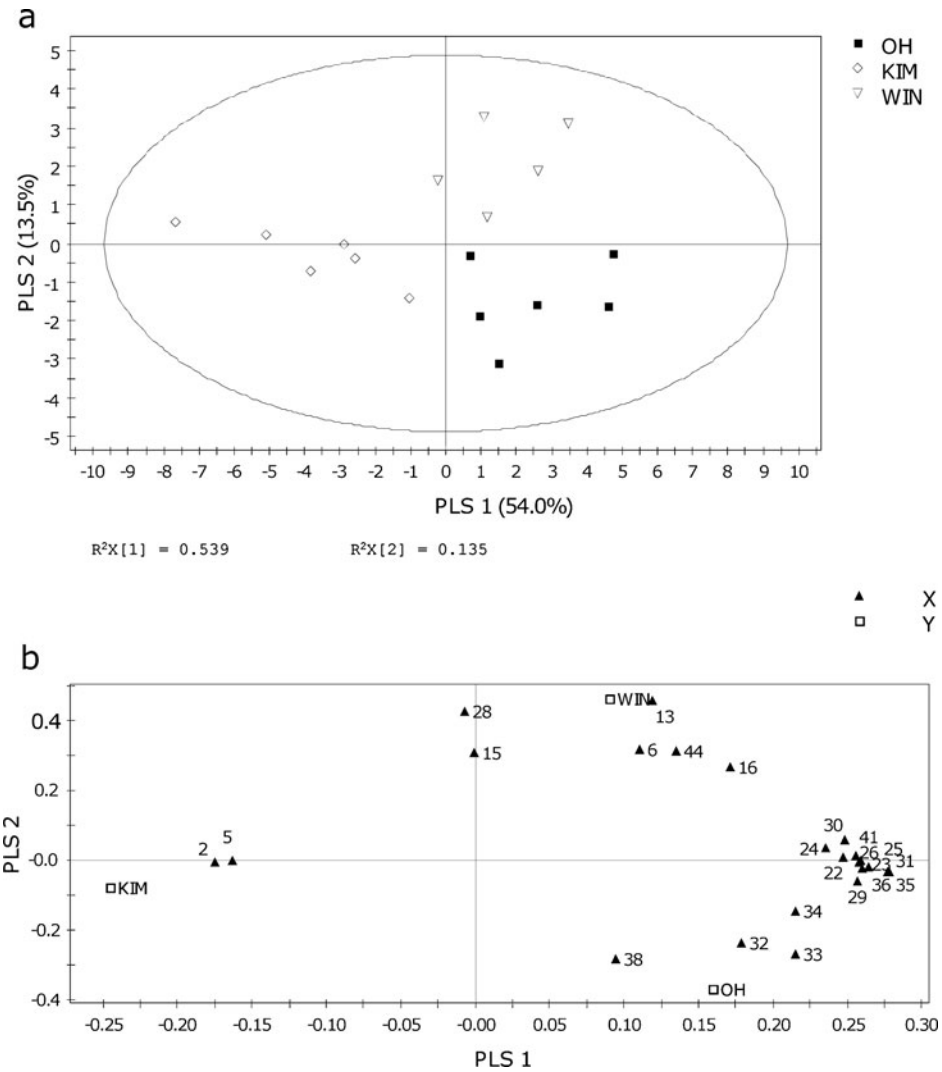

Fig. 5 PLS-DA (Projection to Latent Structures Discriminant Analysis) of quantities of volatile compounds produced by wild *Brassica oleracea* plants originating from three wild populations (OH, KIM, and WIN) in Dorset, UK, in response to *Pieris rapae* feeding. The score plot **a** visualizes the structure of the samples according to the first two PLS components with the explained variance in brackets. The ellipse in the score plot defines the Hotelling's T^2 confidence region, which is a multivariate generalization of Student's *t*-test and provides a 95% confidence interval for the observations. The loading plot **b** define the orientation of the PLS planes with the original variables in the X (volatile variables) and Y space ('class' variables), respectively. They reveal the magnitude and direction of correlation of the original variables with the first two PLS components. The PLS-DA resulted in a model with 3 significant components: R^2X= 0.77, R^2Y=0.82 Q^2=0.67. For compound identity see Table 1

et al. 2009; Zhang et al. 2009). Although each population produced distinctive profiles of volatile chemicals, these did not simply reflect the differences among populations in attractiveness to *C. rubecula.* Moreover, no single chemical matched the differences in attractiveness.

The importance of specific HIPVs in natural enemy attraction traditionally has focused on terpenes, fatty acid derivatives (especially those produced by the lipoxygenase pathway), and products from the phenylalanine lyase (PAL) pathway (Ozawa et al. 2000; Schnee et al. 2006; Shiojiri et al. 2006a; Halitschke et al. 2008; Zhang et al. 2009). Here, we showed that the terpenes (*E*)-β-ocimene and DMNT may play a limited role in *C. rubecula* attraction. For example, exposure to (*E*)-β-ocimene elicits a response in the antennae of *C. rubecula* (Smid et al. 2002) and (*E*)-β-ocimene and DMNT also are produced by Brussels sprout plants in response to exogenous treatment with JA (Bruinsma et al. 2009). Nevertheless, here, *C. rubecula* did not discriminate between JA-treated wild cabbage plants, suggesting that compounds independent of the lipoxygenase pathway are responsible for the differentiation in volatile emissions and consequent attraction of the parasitoid.

Breakdown products of GS represent another important group of volatiles that could be used by parasitoids to detect hosts that are specialist herbivores of brassicaceous plants. Species in this plant family all biosynthesize GS (Halkier and Gershenzon 2006). Glucosinolates function as direct defensive compounds against a range of attackers that include insect herbivores (Rask et al. 2000; Hopkins et al. 2009). Deterrence activity only emerges after tissue rupture, e.g., by caterpillar feeding, and concomitant release of the enzyme myrosinase, which is stored in specialized cells. This enzyme catalyzes the conversion of GS into toxic hydrolysis products of which many are volatile (Halkier and Gershenzon 2006). Glucosinolate concentrations are generally much lower in cultivated brassicaceous plant species compared to the levels found in wild conspecifics because of the effects of directional selection in plant breeding programs (Gols et al. 2008b; Harvey et al. 2011).

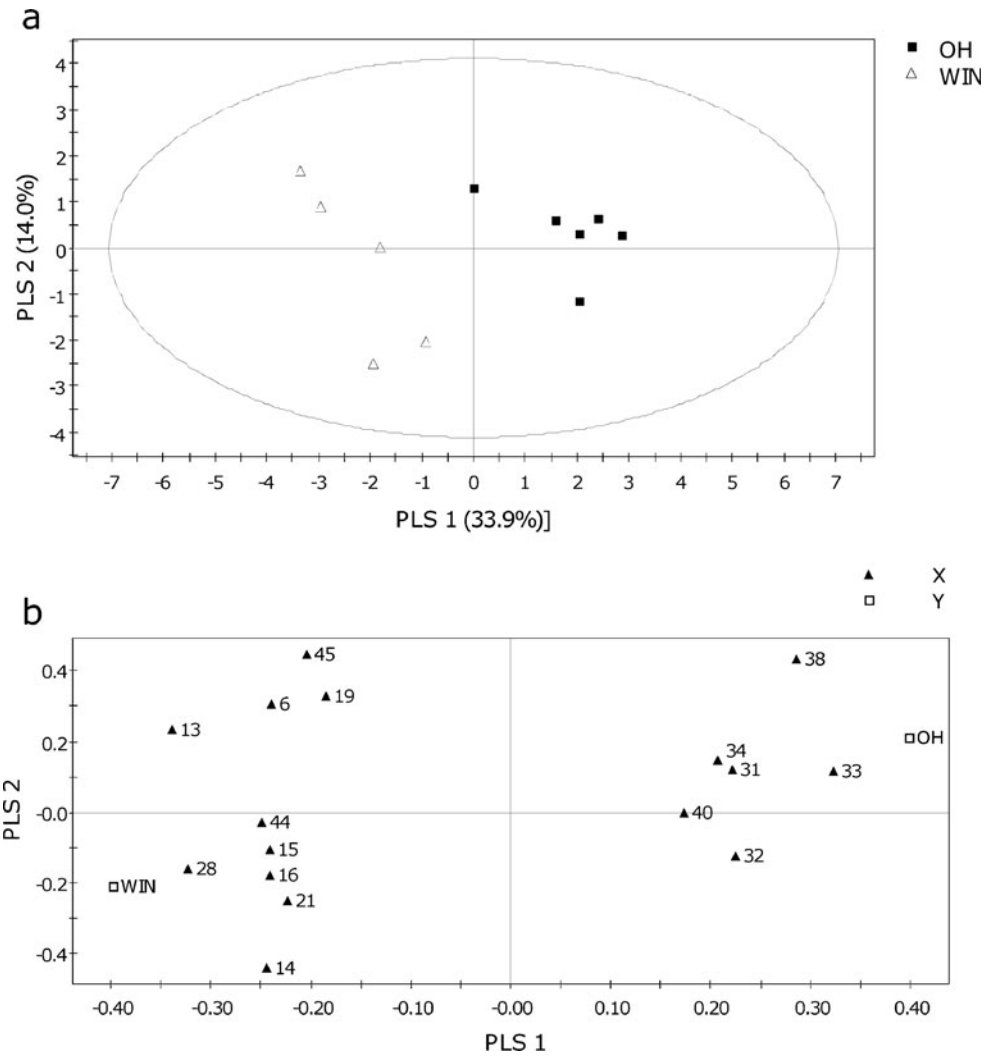

Fig. 6 PLS-DA comparison of quantities of volatile compounds produced by the wild OH and WIN populations of *Brassica oleracea* with the score plot of the samples (**a**) and loadings of the volatile variables (**b**). Percentage of the explained variance is given in brackets. The PLS-DA resulted in a model with 1 significant component: $R^2X=0.34$, $R^2Y=0.83$ $Q^2=0.70$ (the second axis is shown for representational purposes). For compound identity see Table 1

Importantly, the effects of volatile GS breakdown products on parasitoid attraction frequently have been overlooked because these products are not detected in HIPV blends emitted by cultivated brassicaceous plants (Geervliet et al. 1997; Bukovinszky et al. 2005), whereas they are emitted in large quantities by wild species in this family following herbivory (Gols et al. 2008c, 2009). Here, we also found that volatile GS breakdown products, i.e., but-3-enyl isothiocyanate and prop-2-enyl isothiocyanate, were produced only by wild cabbage plants. Thus far, few studies have investigated the attractiveness of GS hydrolysis products to parasitoids (Bradburne and Mithen 2000; Blande et al. 2007). The parasitoid *Diaeretiella rapae*, which attacks the *Brassica*-feeding aphid *Brevicoryne brassicae*, is not only attracted to plants producing isothiocyanates, but female wasps of this species even discriminate between plants producing different isothiocyanates (Bradburne and Mithen 2000). Interestingly, KIM plants had the lowest emission rates of these compounds, suggesting that other cues determine the relative attractiveness to *C. rubecula* of plants from the wild populations.

Volatile emissions are known to vary considerably in quality and quantity, both within and among brassicaceous plant species (Bukovinszky et al. 2005; Gols et al. 2008c). Here, we demonstrated that the volatile blend emitted by KIM plants differed clearly from those emitted by WIN and OH plants, whereas KIM plants were of intermediate attractiveness to *C. rubecula* in the flight bioassay. Our result suggests that the response of *C. rubecula* is based on far more complex choice rules than simple responses to a subset of specific volatile compounds. Several studies have reported that insect natural enemies are able to detect modifications in the emission of terpenes and fatty acid derivatives (Kappers et al. 2005; Shiojiri et al. 2006b; Halitschke et al. 2008). In addition, the emission of repellent compounds may decrease the attractiveness of a volatile blend (e.g., Soler et al. 2007). Combinations of qualitative and quantitative characteristics of the volatile blend could determine the relative importance of specific volatiles in an HIPV blend. Moreover, foraging choices by a parasitoid like *C. rubecula* may not be rigid. For example, pre-adult learning may influence the 'naïve' response of

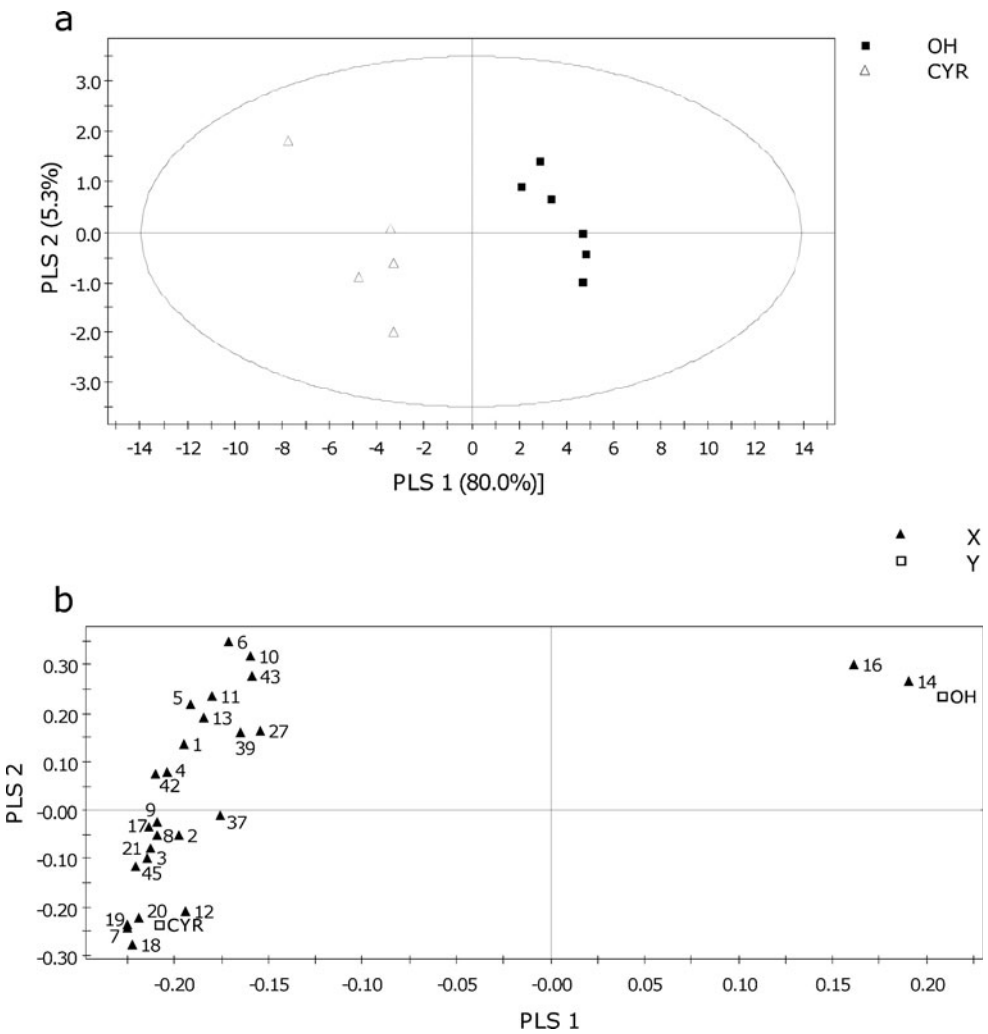

Fig. 7 PLS-DA comparison of quantities of volatile compounds produced by the wild OH population and the CYR cultivar of *Brassica oleracea* with the score plot of the samples (**a**) and loadings of the volatile variables (**b**). Percentage of the explained variance is given in brackets. The PLS-DA resulted in a model with 2 significant components: $R^2X=0.85$, $R^2Y=0.97$ $Q^2=0.90$. For compound identity see Table 1

adult wasps (Gandolfi et al. 2003). Remarkably, *C. rubecula* preferred wild OH over cultivated CYR plants despite their rearing history on the latter plant strain. This result suggests that the naïve response to volatiles emitted by wild plants is conserved. For example, isothiocyanates which were only produced by the wild cabbage plants could be the key components in separating wild from cultivated cabbage; other compounds such as terpenes may facilitate differential attraction among the wild populations.

In nature, *C. rubecula* has to search for hosts that can occur on different plant species in the Brassicaceae. *Pieris rapae* has two to three generations across much of its natural range in central Europe, and most of its food plants are annuals or biennials with short growing seasons. Many of these plants exhibit discrete periods of growth, with some species only occurring early in spring, others in late spring, and still others in summer (Fig. 2). This means that different generations of *C. rubecula* are likely to develop in hosts feeding on different food plant species that emit dramatically different HIPV blends (Bukovinszky et al. 2005; Gols et al. 2008c). Almost all studies of plant-herbivore-parasitoid interactions associated with *B. oleracea* have only used cultivars (Gols and Harvey 2009). Cues, such as volatile GS breakdown products, which are phylogenetically conserved, may be more reliable for naïve parasitoids than more general plant related cues (terpenes, fatty acid derivatives) (Dudareva et al. 2004). Explaining how parasitoids use local information in finding hosts over different spatial scales in natural environments has been little studied. Our findings suggest that it will be worthwhile to investigate how differences in HIPV blends among populations of wild *Brassica* species may structure local host-parasitoid communities, and how artificial selection by domestication impacts these processes.

To summarize, we have shown that there is considerable within and between population variability in volatile profiles of wild and cultivated cabbage plants. Moreover, *C. rubecula* females discriminated among three wild *B. oleracea* populations, as well as between one of the wild populations and a cabbage cultivar on which the parasitoid has been reared for many generations. In parasitoid species whose hosts may feed on different food plants,

selection may favor a flexible response to plant infochemicals when the variation among the blends emitted by different potential food-plant species is high. Although in laboratory studies it has been demonstrated that parasitoids like *C. rubecula* can discriminate between blends that differ in the emission of a single or a few compounds, these results are not conclusive in determining which specific volatiles are important for host plant location in nature. Moreover, the focus of these studies is phytocentric, i.e., unraveling the mechanisms underlying the biosynthesis of these compounds *in planta,* and conclusions are often based on results using cultivated plant species where there is little within-strain variation in the expression of traits like direct and indirect defense (van der Meijden and Klinkhamer 2000; Allison and Hare 2009; Kessler and Heil 2011). As shown here, HIPV blends emitted by cultivated plants whose chemistry has been modified in plant breeding programs may not resemble the volatile blends that are emitted by wild plant species with which the parasitoid has coevolved. Most importantly, these studies to a large extent ignore the biology and ecology of co-evolved multitrophic interactions involving wild plants, herbivores and parasitoids.

Acknowledgements We thank A. Gidding, F. van Aggelen, and L. Westerd for rearing of the insects, Unifarm for rearing of the plants. The help by Cees Hordijk (NIOO) who run the GC-MS analyses of the volatile samples is acknowledged.

Responses of Bark Beetle-Associated Bacteria to Host Monoterpenes and Their Relationship to Insect Life Histories

Abstract Bark beetles that colonize living conifers and their microbial associates encounter constitutive and induced chemical defenses of their host. Monoterpene hydrocarbons comprise a major component of these allelochemicals, and many are antibiotic to insects, fungi, and bacteria. Some bark beetle species exhaust these defenses by killing their host through mass attacks mediated by aggregation pheromones. Others lack adult aggregation pheromones and do not engage in pheromone-mediated mass attacks, but rather have the ability to complete development within live hosts. In the former species, the larvae develop in tissue largely depleted of host terpenes, whereas in the latter exposure to these compounds persists throughout development. A substantial literature exists on how monoterpenes affect bark beetles and their associated fungi, but little is known of how they affect bacteria, which in turn can influence beetle performance in various manners. We tested several bacteria from two bark beetle species for their ability to grow in the presence of a diversity of host monoterpenes. Bacteria were isolated from the mountain pine beetle, *Dendroctonus ponderosae* Hopkins, which typically kills trees during colonization, and the red turpentine beetle, *Dendroctonus valens* LeConte, which often lives in their host without causing mortality. Bacteria from *D. ponderosae* were gram-positive Actinobacteria and Bacilli; one yeast also was tested. Bacteria from *D. valens* were Actinobacteria, Bacilli, and γ-Proteobacteria. Bacteria from *D. valens* were more tolerant of monoterpenes than were those from *D. ponderosae*. Bacteria from *D. ponderosae* did not grow in the presence of α-pinene and 3-carene, and grew in, but were inhibited by, β-pinene and β-phellandrene. Limonene and myrcene had little inhibitory effect on bacteria from either beetle species. Tolerance to these antibiotic compounds appears to have resulted from adaptation to living in a terpene-rich environment.

Introduction

Bark beetles are major sources of conifer mortality, in scales ranging from localized pockets (Klepzig et al., 1991) to entire landscapes (Aukema et al., 2006; Bentz et al., 2010). Individual trees within a beetle's host range and preferred size class can often resist attack by utilizing terpenoid-based defenses (Lewinsohn et al., 1991; Brignolas et al., 1995; Keeling and Bohlmann, 2006). In particular, monoterpenes can kill or repel bark beetles, and inhibit growth of their fungal symbionts (Smith, 1963; Raffa and Smalley, 1995; Wallin and Raffa, 2000). These compounds are present in

constitutive resin and undergo enhanced production in response to biotic injury, and to a lesser extent to mechanical wounds (Raffa and Berryman, 1983; Raffa and Smalley, 1995). These terpene-based defenses play an important role in constraining populations of eruptive species from transitioning from endemic to epidemic population densities (Boone et al., 2011).

The largest insect outbreak in recorded history currently is underway in western Canada and the U.S. Rocky Mountains (Bentz et al., 2009). Here the mountain pine beetle, *Dendroctonus ponderosae* Hopkins, is causing high rates of mortality to lodgepole pine, *Pinus contorta* var. *latifolia* Dougl., including vigorously growing and well-defended trees (Boone et al., 2011). Elsewhere, they also kill large numbers of ponderosa pines, *Pinus ponderosa* Dougl. Ex Laws, and several other species, including high elevation pines like whitebark pine, *Pinus albicaulis* Engelmann (Logan et al., 2010). Once outbreaks have exhausted preferred hosts, *D. ponderosae* also may attack and kill spruce trees (Furniss and Schenk, 1969; Huber et al., 2009). The ability of these beetles to coordinate pheromone-mediated mass attack allows them to exhaust the resistance of vigorous, well-defended trees, and thereby provide their brood with a substrate with relatively low allelochemical concentrations. The resin content declines rapidly during successful mass attacks (Raffa et al., 1993). These mass attacks typically kill the tree, or in some cases result in strips of dead tissue (Rasmussen, 1974).

Recent warming trends are facilitating range expansion by populations of *D. ponderosae* into new regions and hosts (Carroll et al., 2003). On the east side of the Rocky Mountains in Alberta, mature stands of *P. contorta* are sympatric and hybridize with jack pine, *Pinus banksiana* Lamb. (Critchfield, 1985). Historically, *P. banksiana* has not been exposed to this insect due to the physical barrier of the Rocky Mountains and the cold climate in this region. In 2001, *D. ponderosae* breached this barrier and colonized *P. contorta*, *P. contorta*-*P. banksiana* hybrid, and later *P. banksiana* pines (Nealis and Peter, 2008; Cullingham et al., 2011). The extent to which *D. ponderosae* will impact this region and subsequently the boreal and eastern forests of North America is unknown (Carroll et al., 2003; Logan et al., 2003; Bentz et al., 2010; Safranyik et al., 2010). Similarly, *P. albicaulis* to a large extent historically escaped exposure to sustained *D. ponderosae* populations due to low temperatures of its subalpine habitat, but current warming trends are now facilitating continuous mortality by *D. ponderosae* (Bentz et al., 2010; Logan et al., 2010).

Some stem-colonizing bark beetle species do not engage in pheromone-mediated mass attacks or cause tree death, but rather have the ability to develop within living hosts without killing them (Coulson and Witter, 1984; Berryman, 1986). For example, the black turpentine beetle, *Dendroctonus terebrans* (Oliver) shows evidence of a mating, but not an aggregation, pheromone (Phillips et al., 1990). The red turpentine beetle, *Dendroctonus valens* LeConte, is native to much of North America, and colonizes a large number of pine species (Kelley and Farrell, 1998), and to a lesser extent *Abies*, *Larix*, and *Picea* (Wood, 1982). In the midwestern United States, its major hosts are red pine, *Pinus resinosa* Ait., and *P. banksiana*. A long-term study demonstrated that in Wisconsin, *D. valens* more commonly attacks living red pines prior to lethal attack by *Ips pini* (Say) than the opposite sequence (Aukema et al., 2010). Trees not attacked by *I. pini* the following year continued to live, and did not die until being attacked eventually by this stem-colonizing herbivore (Aukema et al., 2010). Fifty seven percent of these trees were attacked by only one pair of *D. valens* within a year, and 93% of the trees had four or fewer colonizing pairs. Unlike species that must mass attack and kill their hosts prior to reproducing, these beetles appear capable of surviving high monoterpene concentrations in living hosts throughout their development. This is evidenced by descriptions of *D. valens* that complete development in live trees without killing them, and the larvae remain in contact with large amounts of resin in such hosts (Hopkins, 1909; Smith, 1961; Schmid and Mata, 1991; Randall, 2006). In addition to live trees that are often stressed, and whose colonization can lead to subsequent lethal attack by tree-killing species, *D. valens* also colonize stumps from recently cut trees (Furniss and Carolin, 1977; Aukema et al., 2010; Owen et al., 2010). In the late 1990s, *D. valens* invaded parts of China, where it is attacking a new host, Chinese red pine, *Pinus tabuliformis* Carr., in higher numbers, and has become a primary mortality agent (Yan et al., 2005).

Beetles that colonize a diversity of hosts encounter variable monoterpene environments (Seybold et al., 2006). For example, the volatile fraction of *P. contorta* oleoresin is comprised primarily of β-phellandrene and to a lesser extent β-pinene (Zavarin et al., 1969; Raffa and Berryman, 1982a; Pureswaran et al., 2004). β-Phellandrene is rare or absent in other hosts of *D. ponderosae* (Smith, 2000). *Pinus ponderosa* oleoresin contains a more diverse monoterpene profile with relatively equal proportions of 3-carene and β-pinene, and substantial amounts of α-pinene, myrcene, and limonene (Sturgeon, 1979; Hobson et al., 1993). *Pinus albicaulis* oleoresin contains substantial amounts of 3-carene and myrcene (Smith, 2000). *Pinus banksiana* oleoresin contains primarily α-pinene, β-pinene, and 3-carene (Wallin and Raffa, 1999), whereas *P. resinosa* oleoresin contains primarily α-pinene and β-pinene (Raffa and Smalley, 1995).

Bark beetles are associated with a diversity of micro-organisms that facilitate their ability to exploit the subcortical environment (Whitney, 1982; Paine et al., 1997). Of these, fungi have been most thoroughly studied. Conifer mono-terpenes can strongly inhibit some of these fungi, although

toxicity varies among compounds and some fungi are relatively tolerant (Raffa et al., 1985; Paine and Hanlon, 1994; Klepzig et al., 1996; Hofstetter et al., 2005; DiGuistini et al., 2011). Recent studies have shown that some bacterial taxa are frequently associated with bark beetles (Adams et al., 2010; Hulcr et al., 2011) and fulfill important ecological functions. For example, Actinomycete bacteria associated with two beetle species inhibit the beetles' fungal antagonists (Cardoza et al., 2006; Scott et al., 2008), and Proteobacteria stimulate the growth and reproduction of beetle symbiotic fungi in the presence of the host compound α-pinene (Adams et al., 2009). Bacteria inhabiting guts of other wood-feeding insects, such as termites and cerambycid beetles, degrade plant-cell wall components, such as cellulose and lignin, and contribute to acquisition of nutrients from these generally recalcitrant woody-substrates (Warnecke et al., 2007; Geib et al., 2008). Some bacteria associated with bark beetles tolerate myrcene (Skrodenyte-Arbaciauskiene et al., 2006) and α-pinene (Adams et al., 2009), but their tolerance to other monoterpene components of conifer defense is unknown.

In this study, we tested how bacteria isolated from two bark beetle species that exhibit different host defense tolerances associated with their different host colonization behaviors (i.e., killing trees by mass attack vs. colonizing live trees without mass attacks or causing mortality) are affected by a diversity of monoterpenes from pine oleoresin. Specifically, we isolated bacteria from *D. ponderosae* and *D. valens* and exposed these bacteria to monoterpenes that comprise the major resin and phloem constituents of *P. contorta*, *P. banksiana*, *P. resinosa*, and *P. albicaulis*. We hypothesized that bacteria from both beetle species will grow in the presence of many monoterpenes, and that bacteria associated with *D. valens* will be more capable of tolerating these compounds given its life history.

Methods and Materials

Isolation of Microorganisms *Dendroctonus ponderosae* adults were collected in July 2008 from under the bark of naturally attacked trees in a stand of *P. contorta* and *P. contorta—P. banksiana* hybrid pines, near Grande Prairie, Alberta, Canada (54°43′N, 119°39′W). Beetles of both sexes were actively tunnelling in the egg gallery at the time of collection. *Dendroctonus valens* adults of both sexes were collected in May 2008 from under the bark of naturally colonized *P. resinosa* stumps in a spring-thinned plantation in Black River State Park, Black River Falls, WI, USA (44°14'57 N, 90°34'07"W). These beetles were actively tunnelling in egg galleries as well. For all beetles collected in this study, galleries were clear of resin and appeared to represent successful colonization of the host. During sampling, each adult was placed into individual, sterile vials, placed on ice, and transferred to the lab and stored at 4°C.

Within 24 hr, at least 25 beetles from each species were surface washed in phosphate buffered saline, pH 7.4 (Sigma-Aldrich Co., St. Louis, MO, USA) (PBS) with 1% Tween 20 (ICI America Inc., Wilmington, DE, USA) by vortexing for 30 sec, and rinsed in PBS. Bacteria were isolated by crushing beetles in PBS and plating serially diluted aliquots of the samples on 10% tryptic soy agar (TSA; Difco, Sparks, MD, USA). Petri dishes were stored at room temperature for up to 2 week, and colonies from a diversity of morphologies were selected from multiple beetles and obtained in pure culture for bioassay.

All bacteria were identified by direct sequencing of regions V5 of the rRNA 16S gene. Polymerase chain reaction (PCR) was used to amplify partial ribosomal RNA (rRNA) gene sequences (Holben et al., 2002), with the exception that PCR amplicons were used in direct sequencing reactions rather than for cloning. The primers 27f (5'-GAGAGTTTGATCCTGGCTCAG-3') and 1492r (5'-GGTTACCTTGTTACGACTT-3') (based on the *Escherichia coli* numbering system) were used for PCR. PCR reaction mixtures contained 25 µl GoTaq Green Mastermix (Promega, Madison, WI, USA), 2 µl of each primer 20 µl of water, and 1 µl of culture. PCR reactions were performed by using an initial denaturation of 5 min at 94°C, followed by 30 cycles of denaturation for 1 min at 94°C, primer annealing for 1 min at 55°C, and primer extension at 72°C for 2 min. This was followed by a final extension reaction at 72°C for 10 min. Sequencing of PCR products was performed by the University of Wisconsin Biotechnology Center (Madison, WI, USA). Sequences were deposited in GenBank (Table 1). National Center for Biotechnology Information (NCBI) similarity scores were obtained by using the NCBI search of previously deposited sequences in GenBank (www.ncbi.nlm.nih.gov).

Effects of Monoterpenes on Growth of Bacteria We quantified the effects of monoterpenes on growth of bacteria by using methods described by Middelbeek et al. (1992) and Adams et al. (2009). Briefly, 10 µl of actively growing culture were inoculated into 200 µl of 10% tryptic soy broth in 96-well plates (Becton Dickinson and Co., Franklin Lakes, NJ, USA). Wells were amended with 0%, 1%, or 5% concentrations (*v*/*v*) of one of 6 monoterpenes for isolates from *D. ponderosae*, and 5 monoterpenes for isolates from *D. valens*. The monoterpenes were racemic α-pinene (98%, Aldrich, Milwaukee, WI, USA), (−)-β-pinene (technical grade, approx. 86%, Aldrich), (*R*)-(+)-limonene (98%, Aldrich), myrcene (tech. grade, approx. 78%, Aldrich), and (+)-3-carene (90%, Aldrich), which were tested against all isolates, and β-phellandrene (Glidco

[a] Fungus

Organics Corp., Jackson, MS, USA), which was tested against isolates from *D. ponderosae*. Individual wells were sealed by using VIEWseal pressure sensitive adhesive (Greiner Bio-one, Maybachstraße, Germany). Cultures were shaken at medium speed (500 revolutions per min) and orbital directionality at 24°C, and optical density was measured every hour for up to 48 h by using a DXT 880 Multimode Detector (Beckman Coulter, Corona, CA, USA) at absorbance of 595 nm. Each isolate was exposed to each monoterpene and tested an average of two times to verify consistent growth patterns (Table 2).

Data Analysis We compared the doubling times of bacteria with and without monoterpene addition during the exponential phase of growth (Middelbeek et al., 1992). To determine the time period in which the exponential phase took place, growth of bacteria were monitored for up to 48 h, a period that encompassed the growth phase. Next, absorbance values were log transformed and the time interval with the most linear log-transformed absorbance values was selected by calculating the r^2 values of each possible time interval (StatView version 4.57, Abacus Concepts, Inc., Berkeley, CA, USA). During this period of exponential growth, an index of monoterpene impact on bacterial growth rate was calculated by using methods described by Middelbeek et al. (1992): the difference in absorbance values at the beginning and end of the exponential growth phase (representing the number of cell divisions) was divided by the $\log_2$ of the duration (number of hours) of the exponential growth phase. The reciprocal of this value is then taken to provide the number of hours per generation, or doubling time. The doubling time of each bacterium growing in each terpene concentration was calculated relative to controls by subtracting the doubling time of the isolate growing without terpene from the doubling time of the isolate growing with the terpene, and dividing this value by the doubling time of the isolate growing without terpene, x 100. Relative doubling times were grouped into five categories: −75% to −25%, stimulated growth; −25% to 25%, growth not affected; 25% to 100%, growth inhibited; > 100%, growth strongly inhibited; and no growth, complete inhibition.

Results

Isolation and Identification of Microorganisms Bacteria closely related to gram-positive actinobacterium *Micrococcus terreus* (isolate A7-1a), and Bacillales *Paenibacillus* spp. (isolates A3-1a and A5-1) and *Bacillus simplex* (isolate A3-1b) were isolated from *D. ponderosae* and tested in this study (Table 1). One yeast isolate (A9-4) most closely related to *Candida piceae*, also was obtained in culture and used in bioassays (Table 1).

Bacteria most closely related to an actinobacterium *Frigoribacterium* sp. (isolate Dv26) and Bacillales *Paenibacillus provencensis* (isolate Dv34) were isolated from *D. valens* and tested (Table 1). Three other isolates were most closely related to gram-negative γ-Proteobacteria *Enterobacter* spp. (isolates Dv3 and Dv6) and *Pseudomonas* sp. (isolate Dv25) (Table 1).

Effects of Monoterpenes on Growth Monoterpenes had substantial effects on bacterial growth (doubling time), and these varied with compound, isolate, and insect host (Table 2). Overall, growth of bacteria was most inhibited by (+)-3-carene and (±)-α-pinene, and was least inhibited by myrcene and limonene. Six of the ten isolates grew in the presence of α-pinene (Table 2, Fig. 1). The four isolates that

For table entries labeled “CI”, the isolates were completely inhibited

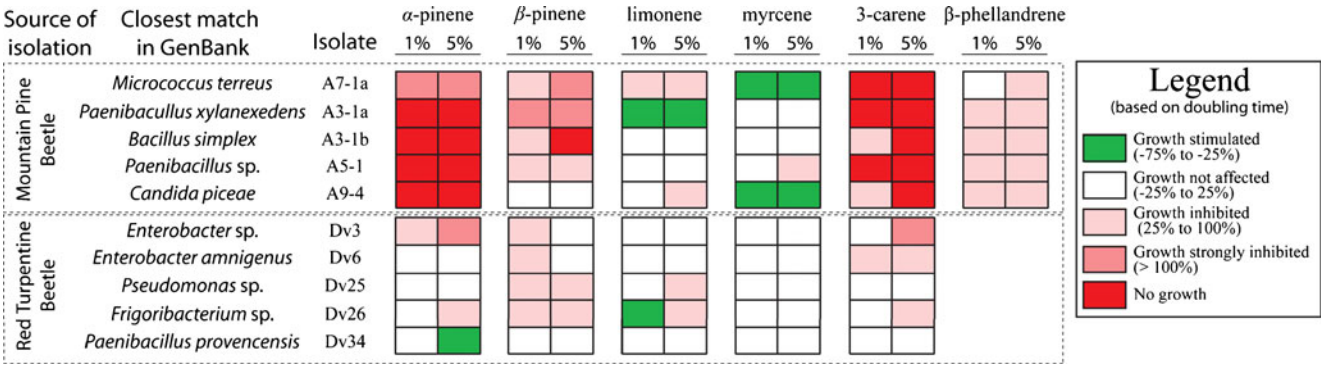

Fig. 1 Heat map representing the growth of bacterial isolates growing in the presence of monoterpenes relative to growing in the absence of monoterpenes. Percentages listed in the legend represent doubling time of each isolate growing with monoterpenes at 1% and 5% concentrations relative to each isolate growing in culture without terpenes

did not grow in any concentration of (±)-α-pinene were all isolated from *D. ponderosae*. One isolate, A7-1a, from *D. ponderosae* grew in, but was strongly inhibited by, both concentrations of α-pinene. All isolates from *D. valens* grew at 1% α-pinene, with no effect on four isolates and inhibition of one, isolate Dv3. All isolates also grew at 5% α-pinene, with an increase in growth of Dv34, no effect on Dv6 and Dv25, inhibition of Dv26, and strong inhibition of Dv3.

All isolates grew in the presence of (*S*)-(−)-β-pinene (Table 2, Fig. 1). All isolates from *D. ponderosae* grew at 1% β-pinene, and all but one isolate, A3-1b, grew at 5% β-pinene. Three isolates, A7-1a, A3-1b, and A5-1, were inhibited and isolate A3-1a was strongly inhibited at 1%. Isolate A5-1 was inhibited and isolates A7-1a and A3-1a were strongly inhibited at 5%. Growth of isolate A9-4 was not affected, and isolate A3-1b did not grow at 5%. All isolates from *D. valens* grew in both concentrations of β-pinene. All but isolate Dv34 were inhibited at 1%. At 5%, three isolates were unaffected, and Dv25 and Dv26 were inhibited.

All isolates grew in the presence of (*R*)-(+)-limonene (Table 2, Fig. 1). Isolate A3-1a from *D. ponderosae* was stimulated at both concentrations, isolate A7-1a was inhibited at both concentrations, and isolate A9-4 was inhibited at 5%. Three isolates from *D. valens* were unaffected by either concentration, and growth of isolate Dv26 was stimulated at 1%, and growth of isolates Dv25 and Dv26 was inhibited at 5%.

All bacterial isolates grew in the presence of myrcene (Table 2, Fig. 1). Isolates A7-1a and A9-4 from *D. ponderosae* were stimulated at both concentrations, and growth of isolates A3-1a and A3-1b was not affected at either concentration. Isolates A3-1a and A3-1b were unaffected at either concentration of myrcene and isolate A5-1 was inhibited at 5%. Growth of all isolates from *D. valens* was unaffected by myrcene.

All but two isolates were inhibited by (+)-3-carene under some condition (Table 2, Fig. 1). Isolates A7-1a, A3-1a, and A5-1 from *D. ponderosae* did not grow at either concentration, and isolates A3-1b and A9-4 were inhibited at 1% and did not grow at 5%. All bacteria from *D. valens* grew at both concentrations of (+)-3-carene. Isolate Dv6 was inhibited at 1% and 5%, and isolate Dv26 was inhibited and isolate Dv3 was strongly inhibited at 5%.

β-Phellandrene inhibited the growth of all bacteria from *D. ponderosae*, and all but isolate A7-1a were inhibited at 1%. However, no bacteria were totally or even strongly inhibited at either concentration (Table 2, Fig. 1).

Discussion

Bacteria isolated from *D. ponderosae* were more strongly inhibited by exposure to monoterpenes than those isolated from *D. valens*. This appears to correspond with a major difference in their life histories, namely that *D. ponderosae* deplete host monoterpene concentrations by mass attack, whereas *D. valens* in Wisconsin often conduct single or low density attacks and complete development within a terpene-rich environment. This pattern occurred even though similar bacterial taxa were tested. For example, Actinobacteria and Bacillales isolates from *D. valens* were more tolerant than those from *D. ponderosae* (Table 1). Actinobacteria occur in associations with both pine phloem (Adams et al., 2008; Hulcr et al., 2011) and bark beetles (Cardoza et al., 2006, 2009; Scott et al., 2008), so some tolerance to monoterpenes would seem necessary for their survival. Some bacteria in the Bacillales are capable of degrading various monoterpenes (Chang and Oriel, 1994; Savithiry et al., 1998) and similar hydrocarbons synthesized by plants (Wright et al., 1986; Jiménez et al., 2010). Unlike the isolates from *D. ponderosae*, three of the isolates from *D. valens* were γ-Proteobacteria.

The tolerance to monoterpenes by the yeast isolate from *D. ponderosae* is not entirely unexpected, given associations of yeasts with bark beetles (Shifrine and Phaff, 1956; Boone et al., 2008b; Davis et al., 2011). The adaptation of yeasts to the terpenoid-rich environment may be particularly beneficial for some species of bark beetles, as yeasts have been proposed to contribute to pheromone synthesis (Brand et al., 1977) and favor advantageous fungi (Davis et al., 2011). However, the extent to which yeasts contribute to pheromone communication in nature is uncertain, and some *Ips*-associated yeasts are relatively sensitive to some terpenes (Leufvén et al., 1988; Seybold et al., 2000). Yeast survival also could adversely affect larvae, as some natural enemies of bark beetles are attracted to yeast metabolites (Boone et al., 2008b).

Bacteria from *D. ponderosae* were more tolerant of β-phellandrene than (±)-α-pinene and (*S*)-(−)-β-pinene. β-Phellandrene is the predominant monoterpene of the primary host of *D. ponderosae*, whereas α- and β-pinene are the predominant monoterpenes of *P. banksiana*, which is the host into whose range populations of *D. ponderosae* are expanding. Further, these bacteria were highly tolerant of, and their growth was stimulated by, myrcene, which *D. ponderosae* exploits as a synergist of its aggregation pheromone to mass attack trees (Miller and Lindgren, 2000; Boone et al., 2008a; Borden et al., 2008). This compound also is an important component of *P. albicaulis* resin (Smith, 2000).

The antibacterial activity of 3-carene is particularly noteworthy. Specifically, this compound is correlated with resistance of conifers to *D. ponderosae* and the white pine weevil, *Pissodes strobi* (Peck) (Coleoptera: Curculionidae) (Ott, 2009; Robert et al., 2010), yet paradoxically frequently proves to be among the least bioactive in insect and fungal assays (Raffa et al., 1985; Klepzig et al., 1996; Lu et al., 2010). The antibacterial activity of 3-carene may be a mechanism that assists in tree resistance. Although 3-carene has a strong antibiotic effect on bacteria isolated from *D. ponderosae*, it caused little inhibition of bacteria isolated from *D. valens*. 3-Carene is a major volatile attractant (kairomone) for the flight response of *D. valens* adults (Hobson et al., 1993; Erbilgin et al., 2007). It is possible that bacteria closely associated with *D. valens* have adapted to be tolerant of this compound, given their inevitable exposure once the beetle penetrates the host.

α-Pinene, which occurs in *P. contorta* at low concentrations (Zavarin et al., 1969; Raffa and Berryman, 1983) but is a more predominant monoterpene in other hosts of *D. ponderosae* such as *P. ponderosa* and *P. albicaulis* (Sturgeon, 1979; Smith, 2000), was strongly antibiotic to microbes from *D. ponderosae*. In another study, however, *D. ponderosae*-associated bacteria tolerated α-pinene (Adams et al., 2009). This distinction may be due to difference among bacterial taxa tested, specifically *Pseudomonas* sp. that are tolerant of a diversity of aromatic compounds (Jiménez et al., 2010). α-Pinene also inhibits growth and germination of fungi associated with *D. valens* (Klepzig et al., 1996).

Two monoterpenes that all microbes tolerated were limonene and myrcene. These monoterpenes are found in relatively low concentrations in volatile profiles of many conifers, with an exception in *P. albicaulis* in which myrcene is a dominant component (Smith, 2000). Myrcene increases the attraction of the aggregation pheromone of *D. ponderosae* (Miller and Lindgren, 2000; Boone et al., 2008a; Borden et al., 2008) but has no or very little significant effect on the flight response of *D. valens* (Hobson et al., 1993; Sun et al., 2004). No evidence exists for a role of limonene in communication in *Dendroctonus*, but it is an attractant of *Ips typographus* (Reddemann and Reinhard, 1996). Myrcene and limonene inhibit growth of several bark beetle-associated fungi that colonize *P. jeffreyi* and *P. contorta* and grand fir, *Abies grandis* (Raffa et al., 1985; Paine and Hanlon, 1994), hosts with low concentrations of myrcene (Raffa and Berryman, 1982a,b, 1983; Smith, 2000). Myrcene also inhibits growth of fungi associated with *D. frontalis* Zimmerman to some extent; however, limonene has little effect on the same fungi (Hofstetter et al., 2005). Further work is necessary to fully characterize the antibiotic effects of limonene and myrcene on bark beetle-associated microorganisms.

Two of the most frequently reported bacteria associated with *Dendroctonus* beetles include *Bacillus* spp. and γ-Proteobacteria such as *Enterobacter* spp. and *Pseudomonas* spp., which have been detected with *D. valens*, *D. ponderosae*, spruce beetle (*D. rufipennis* Kirby), and *D. frontalis* (Cardoza et al., 2009; Morales-Jiménez et al., 2009; Adams et al., 2010). The other bacteria used in this study also have been detected in bark beetles, including *Micrococcus* spp. from *D. rufipennis* and *D. ponderosae* (Adams et al., 2008; Cardoza et al., 2009), and *Paenibacillus* sp. and *Frigoribacterium* sp. from *I. pini* (Delalibera et al., 2007; Cardoza et al., 2009). Yeasts such as *Candida* spp. previously have been isolated from a diversity of bark beetles, including *D. ponderosae* (Adams et al., 2008). Future studies are needed to determine the activities of blends of compounds, better quantify the frequencies of association of various bacterial taxa with bark beetles, better partition geographic ranges and life history strategies, and construct comparisons with outlier groups to improve our evolutionary understanding. With increasing focus on bacteria associated with bark beetles and insects in general, and new tools such as next-generation sequencing, our understanding of these ecological relationships will likely improve.

The chemical defenses of conifers provide strong resistance mechanisms to colonization by biotic agents, as is evident from the relatively few insects and pathogens that

colonize the phloem of living trees. We hypothesized that the ability of bark beetles that colonize living hosts to establish in new environments and hosts, which are facilitated by climate warming trends and human-facilitated transportation (Sun et al., 2004; Yan et al., 2005; Logan et al., 2010), may be in part due to activities of their microbial symbionts. Microbial symbionts perform a variety of functions important to the success of their animal hosts (Zilber-Rosenberg and Rosenberg, 2008), so their ability to survive a harsh environment, such as within trees, likely is critical to their animal host. In this study, we show that microbes associated with two species of bark beetle survived and grew in the presence of antimicrobial components of the chemical defense of conifers. Future studies are needed to investigate the metabolic capabilities of bacteria growing in the presence of individual resin components and blends.

Acknowledgments We thank N. Erbilgin (University of Alberta, Edmonton, AB) and K. Bleiker (Canadian Forest Service, Victoria, BC, Canada) for assistance in collecting mountain pine beetles. C. Currie (University of Wisconsin, Madison, WI, USA) for use of the microplate reader and S. Adams (University of Wisconsin, Madison, WI, USA) for sequencing. This research was supported by funding from the USDA National Research Initiative (2003-3502-13528) and the Natural Sciences and Engineering Research Council of Canada, Genome Canada and Genome British Columbia. Helpful critiques by three anonymous reviewers improved the quality of our paper and are much appreciated.

Abstract The jasmonic acid (JA) signaling pathway and defensive secondary metabolites such as glucosinolates are generally considered to play central roles in the defense of brassicaceous plants against herbivorous insects. To determine the function of specific plant genes in plant-insect interactions, signaling or biosynthetic mutants are needed. However, mutants are not yet available for brassicaceous plants other than *Arabidopsis thaliana,* e.g., cabbage (*Brassica oleracea*). We employed virus-induced gene silencing (VIGS) by using tobacco rattle virus (TRV) to knock down the endogenous expression of lipoxygenase (*LOX*), an upstream enzyme of the JA pathway and thioglucoside glucohydrolase: myrosinase (*TGG1/TGG2*), a hydrolytic enzyme that catalyzes the release of defensive volatile products originating from glucosinolates, in *Arabidopsis thaliana.* This was done by using the heterologous gene sequences from *B. oleracea.* Silencing these genes in *A. thaliana* plants is efficient and specific. Only 18 nucleotides with 100% identity between the trigger (*BoMYR*) and the target (*AtTGG1/2*) sequence are sufficient to achieve gene silencing. *LOX*-silenced plants showed significantly reduced *AtLOX2* transcript accumulation after *Pieris rapae* larval feeding. *TGG*-silenced plants exhibited significantly lower *TGG1/TGG2* transcript levels only after shorter larval feeding. The inhibition of *TGG1/TGG2* transcript accumulation *via* gene silencing may be overruled by longer larval feeding. Specialist *P. rapae* larvae developed significantly better on both types of silenced plants than on empty vector (EV) control plants, while generalist *Mamestra brassicae* larvae developed significantly better on the *TGG1/TGG2* silenced plants than on EV control plants. This shows that not only the generalist herbivore but also the Brassicaceae-specialist *P. rapae* is negatively affected by the ability of brassicaceous plants to produce their specific secondary metabolites, i.e., glucosinolates. Our results demonstrate the important roles of *AtLOX2* and *AtTGG1/TGG2* genes, which were silenced by heterologous gene sequences from *B. oleracea BoLOX* and *BoMYR,* in *A. thaliana* resistance to the specialist *P. rapae* and the generalist *M. brassicae.*

Key Words *Arabidopsis thaliana* · Lipoxygenase (*LOX*) · Myrosinase (*MYR*) · *Pieris rapae* · *Mamestra brassicae* · Virus-induced gene silencing (VIGS)

Introduction

An ecological genomics approach may contribute to the enhancement of ecological knowledge of interactions between different species (Kessler and Baldwin, 2002; Zheng and Dicke, 2008). Hence, molecular genetic knowledge and methods should be developed for ecological model species by transferring methods used for molecular genetic model

species to ecological model species. Advanced molecular techniques that were developed for *Arabidopsis thaliana*, e.g., microarrays, have been applied to *Brassica oleracea* for studying insect-induced transcriptional responses (Broekgaarden et al., 2007, 2008; Fatouros et al., 2008). *Brassica oleracea* is a well-studied ecological model species (Mattiacci et al., 1995; Eigenbrode et al., 1996; Shiojiri and Takabayashi, 2003; van Dam and Raaijmakers, 2006; Bukovinszky et al., 2008; Fatouros et al., 2008; Gols et al., 2008). However, thus far, little information at the molecular level has been available for this species.

To address the involvement of plant genes in *Brassica*-insect interactions, mutant plants are currently lacking that are altered in signaling or biosynthetic pathways involved in defense against insects. In contrast, such mutants are abundantly available for *A. thaliana*,. Therefore, other techniques are required to elucidate gene function. Virus-induced gene silencing (VIGS) offers an attractive alternative (Mitra et al., 2008; Pandey and Baldwin, 2008; Mantelin et al., 2009). Initially, VIGS was almost exclusively performed in the model plant species *Nicotiana benthamiana* by using vectors derived from tobacco mosaic virus (TMV) (Kumagai et al., 1995), potato virus X (Ratcliff et al., 1997), and tobacco rattle virus (TRV) (Ratcliff et al., 2001; Liu et al., 2002). In recent years, new protocols and vectors have expanded the list of both monocotyledonous and dicotyledonous plant species in which VIGS can be employed (Robertson, 2004; Scofield and Nelson, 2009). Currently, the most widely used VIGS vectors are based on TRV. Such VIGS vectors have been used to silence genes mainly in a number of solanaceous plant species, including tobacco, tomato, pepper, potato, and petunia (Shao et al., 2008). Optimized procedures aimed at improving the efficiency of agro-infiltration of *A. thaliana* have been reported in recent years (Burch-Smith et al., 2006; Wang et al., 2006; Pflieger et al., 2008; Zheng et al., 2010). VIGS has obvious advantages over other known approaches for gene function analysis (Scofield and Nelson, 2009). It is a rapid method that does not require the development of stable genetic transformation. Moreover, it can be applied for functional analysis of genes for which only partial sequences are available (Shao et al., 2008). This is especially important and useful because characterization of gene function *via* generating mutants by genetic transformation in *Brassica* species is still difficult and time-consuming.

Unfortunately, VIGS is not yet successfully developed for our ecological model plant *Brassica oleracea* and, therefore, we took an intermediate step in using *B. oleracea* gene sequences to silence defense-related genes in *Arabidopsis*. We developed a loss-of-function approach with TRV-mediated VIGS for *A. thaliana* plants (Zheng et al., 2010). We employed a heterologous gene sequence, i.e., *phytoene desaturase* (*BoPDS*) from *B. oleracea,* to silence its ortholog in *A. thaliana* plants. We found that disruption of this specific gene of the carotenoid biosynthetic pathway through VIGS affected vision-mediated oviposition behavior of the butterfly *Pieris rapae* (Zheng et al., 2010). In the present study, we used *B. oleracea* gene sequences to silence two genes, lipoxygenase (*AtLOX*) and thioglucoside glucohydrolase: myrosinase (*AtTGG*) in *A. thaliana* plants because silencing *BoLOX* and *BoMYR* in cabbage plants themselves has not yet been successful.

The *BoLOX* gene is likely to catalyze the first step in the oxylipin pathway leading to jasmonic acid (JA) biosynthesis, which is induced by mechanical wounding and herbivory (Zheng et al., 2007). The transcript levels of *BoLOX* are dramatically increased upon infestation by different herbivores and a pathogen (Zheng et al., 2007). However, it is still not clear whether *BoLOX* has the same function as *AtLOX2* in JA biosynthesis.

AtLOX2 is involved in wound-induced JA biosynthesis (Bell et al., 1995). It also has been shown that *AtLOX2* is induced by insect herbivory, and that *atlox2* antisense plants are impaired in tritrophic interactions, i.e., in induced attraction of the parasitoid *Cotesia rubecula* (van Poecke et al., 2001; van Poecke and Dicke, 2002).

In the Brassicaceae, another component of anti-herbivore defense is the glucosinolate-myrosinase system (β-thioglucoside glucohydrolase, TGG) (Rask et al., 2000; Ratzka et al., 2002; Wittstock et al., 2004). We assume that the enzyme thioglucoside glucohydrolase: myrosinase, encoded by *BoMYR,* is catalyzing the formation of glucosinolate breakdown products in *Brassica oleracea*. Myrosinase activity might even be important for plant defense against specialist herbivorous insects such as *Plutella xylostella* that have adapted to intact glucosinolates (Li et al., 2000). In addition, allyl-isothiocyanate, a glucosinolate breakdown product resulting from myrosinase activity, negatively affected another specialist herbivore, *Pieris rapae* (Agrawal and Kurashige, 2003). However, the performance of *P. xylostella* was unaffected when feeding on the *A. thaliana* myrosinase double mutant *tgg1tgg2*, while *P. rapae* even performed better on wildtype plants than on the double mutant, possibly due to reduced concentrations of feeding stimulants (Barth and Jander, 2006).

These results led us to investigate the effects of the silencing of *AtLOX2* and *AtTGG1/2* genes *via* heterologous gene sequences of *BoLOX* and *BoMYR* by applying VIGS to *A. thaliana.* Subsequently, we investigated the effects of silencing these genes on the performance of two insect herbivores, a specialist and a generalist. We found that VIGS applied to the two genes enhanced susceptibility of *Arabidopsis* to the specialist herbivore *P. rapae*, and that the effect of silencing *AtTGG1/TGG2* on the performance of the generalist *Mamestra brassicae* was even stronger This

indicates that maintaining the functions of both genes is important for plant resistance to herbivores.

Methods and Materials

Plants and Insects Seeds of the *Arabidopsis* ecotype Col-0 were sown and grown in a climate chamber at 60–70% RH, 23±1°C, 8:16 hL:D photoperiod under a light intensity of ca. 45 μmol m^{-2} sec^{-1}. Four-to-5-leaf seedlings were subjected to VIGS, approximately 21–25 d after sowing. Plants used for bioassays had been subjected to TRV-VIGS 21 d before.

Pieris rapae L. (small Cabbage White butterfly; Lepidoptera: Pieridae) and *Mamestra brassicae* L. (cabbage moth, Lepidoptera: Noctuidae) were routinely reared on cabbage plants (*B. oleracea* var. *gemmifera* cv. Cyrus) in a climate room at 21±1°C, 50–70% RH, 16:8 hL:D.

Construction of TRV Plasmids The pTRV1 (pYL192) and pTRV2 (pYL156) vectors described by Liu et al. (2002) were used in the present study. To generate lipoxygenase (*LOX*) and thioglucoside glucohydrolase: myrosinase (*TGG*) silencing VIGS plasmids, a 299-bp *BoLOX* cDNA fragment corresponding to nucleotides 1579–1877 from *B. oleracea* var. *gemmifera* cv. Cyrus cDNA (GenBank accession EF123056) (Zheng et al., 2007) and a 208-bp fragment corresponding to nucleotides 1–208 from the *BoMYR* cDNA fragment (GenBank accession DQ456999) were amplified by PCR with specific oligonucleotide primers. The following oligonucleotide primer combinations were used for amplification of *BoLOX* and *BoMYR* cDNA fragments: *BoLOX*-F1: 5'GCCATGGTGGCTATG GAATCTTGC3′ and *BoLOX*-R1: 5′CGAATTCCTCCA TAGTTTAGC3′; *BoMYR*-F1: 5′GCCATGGGCAGAAG GAAAGGTGAGTAGGGG′3 and *BoMYR*-R1: 5′ CGAATTCCTTTGAAACATAGATCCGCGTAG'3, respectively. These primers were designed with restriction enzyme recognition sites *Nco*I and *Eco*RI (underlined), respectively. The PCR products were purified and digested with *Nco*I with *Eco*RI. Subsequently, the resulting PCR products were inserted into *Eco*RI and *Nco*I-cut pTRV2, and generated antisense VIGS constructs pTRV2-*BoLOX* and pTRV2-*BoMYR*, respectively (Fig. 1). The cloned *BoLOX* fragment shares 90% nucleotide identity with the corresponding *A. thaliana* lipoxygenase (*AtLOX2*) mRNA. The cloned *BoMYR* fragment shares 79% and 80% nucleotide identity with the corresponding *A. thaliana* myrosinase *TGG1* (At5g26000) and *TGG2*(At5g25980) mRNA, respectively. Between the two *A. thaliana* myrosinase genes *TGG1* and *TGG2* there is 86% nucleotide identity. The obtained pYL156 recombinant constructs were confirmed by PCR using insert-specific primers (*BoLOX*-F1 and *BoLOX*-R1 or *BoMYR*-F1 and *BoMYR*-R1) and vector-specific primers 156F (5′- GGTCAAGGTACGTAGTAGAG −3′) and 156R (5′- CGAGAATGTCAATCTCGTAGG −3′), which span the multiple cloning site in TRV2 (Hileman et al., 2005). Both constructs then were purified, and the identity of the final constructs was verified by sequencing with the 156 F and 156R primers. Recombinant constructs were electroporated into competent cells of *Agrobacterium tumefaciens* strain AGL0 as previously described (Zheng et al., 2005) by a microPulser™ (Bio-Rad, Hercules, CA, USA). Colonies were screened by PCR using primers 156F and 156R for the presence of pTRV2-*BoLOX* or pTRV2-*BoMYR*. Glycerol stocks were made from single positive transformants.

Preparation of Agrobacterium Inoculation Cultures of *A. tumefaciens* strain AGL0 containing pTRV1, pTRV2, and pTRV2-*BoLOX* or pTRV2-*BoMYR* plasmid were cultured separately into 20 ml Luria-Betani (LB) medium containing 50 μg ml^{-1} kanamycin and 50 μg ml^{-1} rifampicin, and shaken at 28°C overnight. After centrifugation at 4000 rpm for 15 min, bacterial cell pellets were resuspended in infiltration buffer containing 1 mM MES (pH 5.8), 10 mM $MgCl_2$, and 100 μM acetasyringone to OD600−2, and allowed to stand at room temperature for 2 hr before infiltration. Suspensions of *A. tumefaciens* carrying pTRV1 and pTRV2-*BoLOX* or pTRV2-*BoMYR* were mixed 1:1 and infiltrated into the abaxial sides of the four upper leaves of 3-wk-old *A. thaliana* plants using a 2-ml syringe. To rule out an effect of an innate immunity response in silenced plants to the viral infection by the VIGS method, suspensions of *A. tumefaciens* carrying pTRV1 and pTRV2 also were mixed 1:1 and infiltrated the same way as above as empty vector control (referred to as EV control below). After agroinfiltration, *A. thaliana* plants were allowed to grow for 21 d in the same climate chamber as mentioned above.

Larval Performance of P. rapae and M. brassicae In total 12 plants from each treatment of *LOX*-silenced, *TGG*-silenced, and EV *A. thaliana* plants were offered to *P. rapae* butterflies to oviposit 5 eggs per plant. If butterflies laid more than 5 eggs on the plant, the extra eggs were removed. Another 12 intact plants in each treatment were also maintained in a climate chamber at 60–70% RH, 23±1°C, 16:8 hL:D photoperiod under a light intensity of ca. 45 μmol m^{-2} sec^{-1}. The eggs all hatched 4 d after oviposition on both plant types. The fresh body mass of individual larvae from 12 plants in each treatment was determined 7 d after oviposition (3 d of caterpillar feeding) using a CP2P Sartorius balance (Göttingen, Germany) with an accuracy of 0.001 mg.

In a second experiment, the time course of *TGG*-transcript accumulation in response to continuous larval

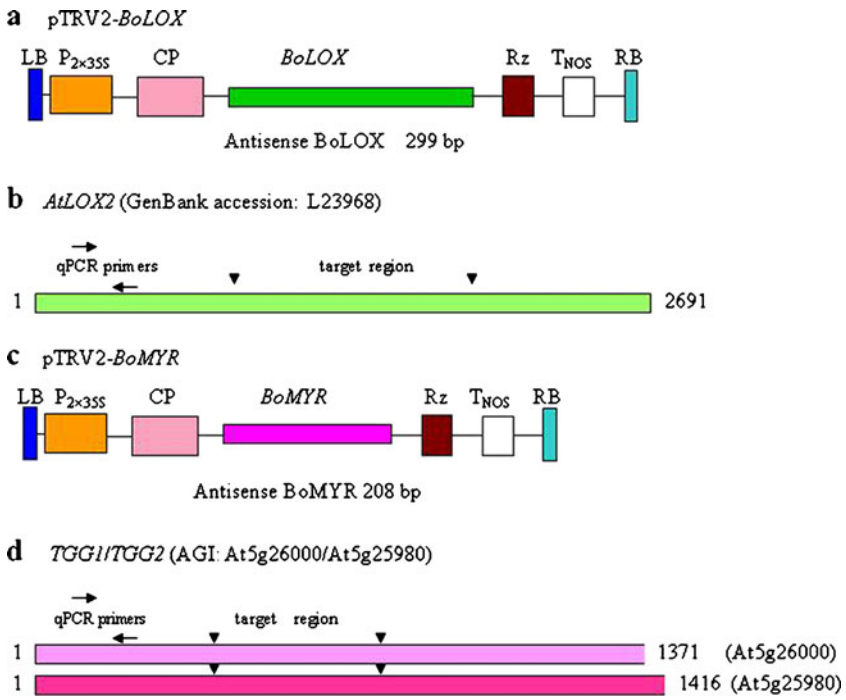

Fig. 1 Specific cDNA fragments from cabbage (*Brassica oleracea*) and TRV-based VIGS constructs used in this study. **a.** A 299-bp fragment (1579–1877 nt) from cabbage lipoxygenase (*BoLOX*) (GenBank accession EF123056) in antisense orientation cloned into TRV2 to generate pTRV2-*BoLOX*. $P_{2\times35S}$, duplicated CaMV 35S promoter; T_{NOS}; nopaline synthase terminator; CP, coat protein; LB and RB, left and right borders of T-DNA; Rz, self-cleaving ribozyme. **b.** Schematic representation of *Arabidopsis thaliana* lipoxygenase *AtLOX2* cDNA with the position of the primers (→ and ←) and size (not to scale) of amplification product used for qPCR. The fragment between two inverted triangles (▼) indicates a target region of 208-bp *TGG1/2* cDNA fragment corresponding to nucleotides 368–575 (*TGG1*) or 403–610 (*TGG2*) from *A. thaliana* cDNA by VIGS

feeding was assessed in *TGG*-silenced and EV *A. thaliana* plants. Plants were offered to *P. rapae* butterflies to oviposit 5 eggs per plant. In addition, another 12 intact plants in each treatment were also maintained in the same climate chamber. This experiment was executed in another climate room at 60–70% RH, 21±1°C, 16:8 hL:D photoperiod under a light intensity of ca. 45 µmol m^{-2} sec^{-1}. Due to the lower temperature, the plants grew a little slower and eggs hatched 1 d later compared to the previous experiment, i.e., at 5 d after oviposition on both *TGG*-silenced and EV plants. Fresh body mass of individual larvae was determined at 12 h, 1, 2, and 3 d after egg hatch using a CP2P Sartorius balance; thereafter, the corresponding leaf samples were collected for quantification of *TGG* transcripts with qPCR.

For *M. brassicae,* 5 neonate larvae that hatched from eggs that had been laid on white paper were introduced on a fully developed leaf in both EV and silenced plants. Fresh body mass of individual larvae was determined after the larvae had fed for 6 d. Because neonate *M. brassicae* caterpillars have an insignificant starting weight, final weights accurately represent weight gain. There was no test of *M. brassicae* feeding on *LOX*-silenced plants, and only *TGG*-silenced plants were used.

For all experiments leaf material was collected for real-time qPCR analysis of transcript levels (see below for details).

Real-Time qPCR For real-time qPCR experiments, primer pairs were designed outside the silencing target region of the *Arabidopsis AtLOX2* or *TGG1/TGG2* cDNA, which is corresponding to its orthologous *BoLOX* or *BoMYR* fragment (Fig. 1). This ensured that only the endogenous *Arabidopsis LOX* or *TGG* mRNA, not *BoLOX* or *BoMYR* was reverse-transcribed. Because the *BoMYR* fragment is expected to target two *Arabidopsis* genes, i.e., *TGG1* and *TGG2*, based on nucleotide identity between *TGG1* and *TGG2*, we designed identical primers from these two genes to generate a 99 bp amplification product for qPCR analysis. Leaf samples for real-time qPCR reactions were harvested from individual *LOX*-silenced, *TGG*-silenced and EV plants after finishing caterpillar-development experi-

ments. Four leaves from 4 individual plants were pooled as one biological replicate and immediately frozen in liquid nitrogen for later RNA isolation. There were three biological replicates in each treatment. Total RNA extraction, purification and cDNA synthesis, primer design, qPCR reactions, and gene expression quantification were the same as described previously (Zheng et al., 2007). For the internal control, *AtGAPDH* cDNA (GenBank accession M64116) (Shih et al., 1991) was used as reference. The target gene expression relative to *AtGAPDH* expression was quantified by comparing the threshold cycle for each PCR to their respective dilution series and dividing the resulting quantities. In order to investigate whether there is any off-target of heterologous gene sequences from *B. oleracea* by *LOX* or *TGG* silencing in Arabidopsis, other endogenous *Arabidopsis* genes such as phenylalanine ammonia lyase (*AtPAL1*) (GenBank accession AY303128) (Cochrane et al., 2004) and phytoene desaturase *AtPDS* (GenBank accession L16236) (Scolnik and Bartley, 1993) also were selected for qPCR analysis beyond BLAST searching. Gene-specific primers used for quantification of gene expression are listed in Table 1. The quantification of gene expression was performed with a Rotor-gene™ 6000 (Corbett, Australia).

Data Analysis The mean values of body mass of larvae subjected to various plant treatments were analyzed by a nested ANOVA, with the plant individual as the nested term in the analysis. Gene expression values were log-transformed and statistically analyzed by a one-way ANOVA.

Results

Silencing of Endogenous AtLOX2 and AtTGG1/2 Genes in A. thaliana Plants by B. oleracea BoLOX and BoMYR Gene Sequences We used the TRV system to generate antisense VIGS constructs pTRV2-*BoLOX* and pTRV2-*BoMYR* to silence corresponding *AtLOX2* and *AtTGG1/TGG2* genes in *A. thaliana* plants (Fig. 1). There were five stretches with more than 18 nucleotides sequence identity between the *A. thaliana* and *B. oleracea LOX* cDNAs (Fig. 2a). However, only one stretch with more than 18 nucleotides in sequence identity between the *A. thaliana TGG1/TGG2* and *B. oleracea MYR* cDNAs was found (Fig. 2b). We inoculated *A. thaliana* plants with *Agrobacterium*-harboring TRV constructs that contained an empty vector (EV) or *LOX* vector (pTRV1 and pTRV2-*BoLOX*), or *MYR* vector (pTRV1 and pTRV2-*BoMYR*) to generate silenced *lox* and *tgg* plants. A positive control was included by inoculating plants with *Agrobacterium*-harboring *PDS* vector (TRV1 and TRV2-*BoPDS1*). With this positive control, we knew that photobleaching symptoms were visible in *A. thaliana* plants 10 d after agroinfiltration (Zheng et al., 2010). There were no visually distinguishable phenotypic differences among EV control, *lox*, and *tgg* plants.

We found significant differences in *AtLOX2* relative transcript abundance between different silenced plants ($F_{2,8}$= 8.59, P=0.017). *LOX*-silenced plants had significantly reduced relative *AtLOX2* transcript levels compared to EV and *TGG*-silenced plants, respectively (Fig. 3a; P=0.044 and P=0.006). There was no difference in *AtLOX2* relative transcript levels between EV and *TGG*-silenced plants (Fig. 3a). *TGG*-silenced plants had reduced *TGG1/2* relative transcript levels compared to EV plants (Fig. 3b; P=0.011). As expected, there was no difference in *AtTGG1/2* relative transcript levels between EV and *LOX*-silenced plants (Fig. 3b; P= 0.074).

In order to rule out any off-target effects of the heterologous gene sequences from *B. oleracea* by *LOX*- or *TGG*-silencing in *A. thaliana*, BLAST searching was applied, and this showed that only *A. thaliana* lipoxygenase (*AtLOX2*) mRNA or *A. thaliana* thioglucoside glucohydro-

Table 1 Lists of primers used in qPCR

Gene	Type of primer	Sequence (from 5′ to 3′)	Nucleotide position in the coding sequence

Fig. 2 Sequence alignment of specific nucleotide fragments from *Brassica oleracea*, selected to trigger gene silencing, with their respective orthologs in *Arabidopsis thaliana.* **a.** *A. thaliana* lipoxygenase *AtLOX2* (L23968) aligned with *B. oleracea BoLOX* (EF123056); **b.** There is 79% nucleotide identity between *A. thaliana* myrosinase*TGG1* (At5g26000) and *B. oleracea BoMYR* (DQ456999); 80% nucleotide identity between *A. thaliana* myrosinase *TGG2* (At5g25980) and *B. oleracea BoMYR;* 86% nucleotide identity between *A. thaliana* myrosinase *TGG1* and *TGG2*. Asterisks (*) indicate identical nucleotides. Asterisks (*) in red designate the largest identity stretches of more than 18 nucleotides between the *A. thaliana* and *B. oleracea* cDNAs

lase (*AtTGG1/TGG2*) mRNAwas targeted (data not shown). In addition, other endogenous *A. thaliana* genes such as phenylalanine ammonia lyase (*AtPAL1*) and phytoene desaturase *AtPDS* also were subjected to transcript analysis. As expected, there were no differences in *AtPAL1* and *AtPDS* relative transcript levels among EV, *LOX*-silenced and *TGG*-silenced plants (Figs. 3c, d). This further confirms that silencing *A. thaliana* plants by using the corresponding gene sequences from *B. oleracea* is specific.

Overall, these results demonstrate that different heterologous gene sequences from *B. oleracea* can be used to silence their respective orthologs in *A. thaliana* plants for plant-insect interaction studies.

Silencing AtLOX2 *or* AtTGG1/2 *Genes in* A. thaliana *Plants Results in Enhanced Feeding by Both Specialist* P. rapae *and Generalist* M. brassicae *AtLOX2* relative transcript levels differed significantly between the different types of silenced plants after 3 d of *P. rapae* herbivory (Fig. 4a; $F_{2,8}$=9.48, P=0.014). *AtLOX2* relative transcript levels were dramatically increased in EV and *TGG*-silenced plants after *P. rapae* larval feeding (Fig. 4a) as compared to the transcript levels in undamaged plants (Fig. 3a). However, after *P. rapae* damage, *LOX*-silenced plants had significantly reduced *AtLOX2* relative transcript levels compared to EV and *TGG*-silenced plants, respectively (Fig. 4a; P=0.007 and P=0.014). There was no difference in *AtLOX2* transcript levels between EV and *TGG*-silenced *P. rapae*-infested plants. As expected, *TGG1/2* transcript levels were increased in EV and *LOX*-silenced plants after *P. rapae* larval feeding. Surprisingly, there was no difference in *TGG1/2* transcript levels in *TGG*-silenced plants vs. EV and *LOX*-silenced plants after *P. rapae* larval feeding for 3 d (Fig. 4b). In order to test the time course of the effect on

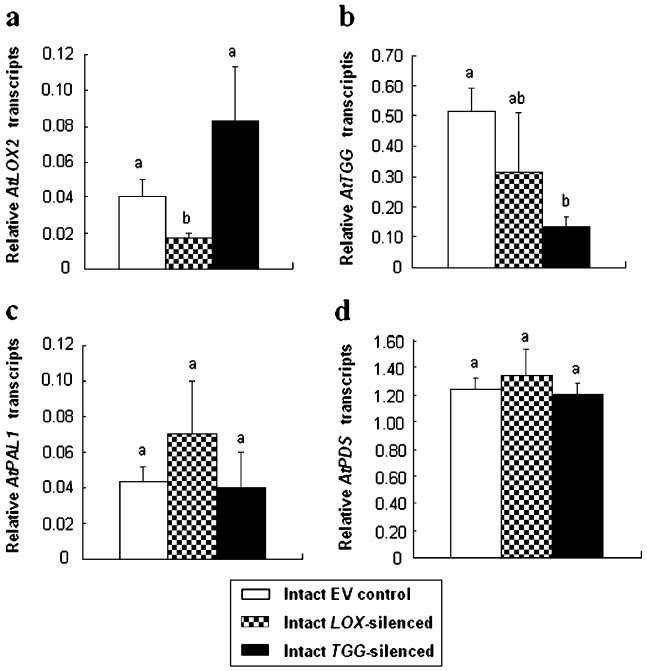

Fig. 3 Accumulation of endogenous *AtLOX2*, *TGG1/2*, *AtPAL1* and *AtPDS* transcripts relative to the levels of the *AtGAPDH* gene was analyzed by qPCR in intact *LOX*-silenced and *MYR*-silenced plants. EV denotes empty vector control plant. There were 3 biological replicates in each treatment. Different letters above bars indicate a significant difference at $P<0.05$; bars represent means and SE. One-way ANOVA was used to analyze gene expression. **a.** Silencing of endogenous lipoxygenase *AtLOX2* in *Arabidopsis thaliana* using the *BoLOX* sequence from *Brassica oleracea.* **b.** Silencing of endogenous myrosinase *TGG1/2* in *A. thaliana* using *BoMYR* sequence from *B. oleracea.* **c−d.** No off-target effects of endogenous phenylalanine ammonia lyase *AtPAL1* or phytoene desaturase *AtPDS* in *A. thaliana* by *LOX*-silenced or *TGG*-silenced plants using *BoLOX* or *BoMYR* sequences from *B. oleracea*

TGG transcripts induced by continuous larval feeding, we carried out a second experiment that employed different time periods of larval *P. rapae* feeding. There were significant differences in *TGG1/2* transcript levels between *TGG*-silenced and EV plants after larval feeding for less than 12 hr and 1 d, respectively (Fig. 5a; $P<0.05$). The reduction in *TGG1/2* transcript levels was obvious in *TGG*-silenced plants after *P. rapae* larval feeding for shorter periods compared to EV control plants. However, the differences in accumulation of *TGG1/2* transcript levels between *TGG*-silenced and EV plants disappeared after larval feeding up to 2 and 3 d, respectively (Fig. 5a). The accumulation of *TGG1/2* transcript levels in *TGG*-silenced plants after larval feeding for 3 d was consistent in these two experiments.

The body mass of larvae that fed on silenced plants was significantly enhanced compared to EV control plants. *Pieris rapae* larvae grew significantly faster on *LOX*-silenced or *TGG*-silenced plants compared to EV plants (Fig. 4c; $F_{2,35}=4.353$, $P=0.021$). Furthermore, larval performance of *P. rapae* was equal on *LOX*-silenced and *TGG*-silenced plants (Fig. 4c). In the second experiment that tested the effects of larval feeding on *TGG*-silenced plants at more time points, no significant differences in larval body mass were found after 12 h, 1 and 2 d (Fig. 5b). However, *TGG*-silencing significantly enhanced larval growth as determined after 3 d of feeding (Fig. 5b; $P<0.05$). Furthermore, after 6 d of feeding on *TGG*-silenced plants, the generalist *M. brassicae* gained 1.5 times more body weight than on EV control plants (Fig. 5c; $P<0.05$).

Discussion

Silencing Arabidopsis thaliana *Plants with Gene Sequences from* Brassica oleracea We recently reported on silencing genes in *A. thaliana, B. nigra,* and *N. benthamiana* plants by the application of TRV-mediated VIGS with a heterologous gene sequence, i.e., *BoPDS* from *B. oleracea* (Zheng et al., 2010). In the present study, we show that *BoLOX* and *BoMYR* sequences from *B. oleracea* can be used to silence their respective orthologs *AtLOX2* and *AtTGG1/2* in *A. thaliana* plants.

Silencing *AtLOX2* and *AtTGG1/2* in *A. thaliana* through sequences from the *BoLOX* and *BoMYR* genes, results in enhanced feeding by *P. rapae* larvae. In recent years, VIGS has been used successfully to unravel the functions of several plant genes belonging to the defense response pathways in the model species *N. benthamiana* and other solanaceous species like tomato and tobacco (Kandoth et al., 2007; Hartl et al., 2008; Wu et al., 2008). Despite the promise held by this strategy, there are still limitations to the way in which VIGS can be used for high-throughput functional genomics beyond these model species, mostly because of the difficulties of introducing the VIGS vector into other plant species, including the model plant *A. thaliana* (Burch-Smith et al., 2006; Wang et al., 2006; Pflieger et al., 2008). Although Senthil-Kumar et al. (2007) showed that TRV-mediated VIGS can be applied in a wide range of solanaceous plant species, and that heterologous gene sequences from distantly related plant species including *A. thaliana* can be used to silence their respective orthologs in the VIGS-efficient model plant *N. benthamiana*, the use of heterologous gene silencing in determining gene function in the context of plant-insect interactions has not been reported before.

The Function of AtLOX2 and AtTGG1/2 Silenced by BoLOX and BoMYR in Conferring Resistance to Herbivores The specific *LOX* gene that is involved in the JA biosynthesis pathway is induced in response to wounding or herbivory, and is involved in JA biosynthesis in plants such as *A.*

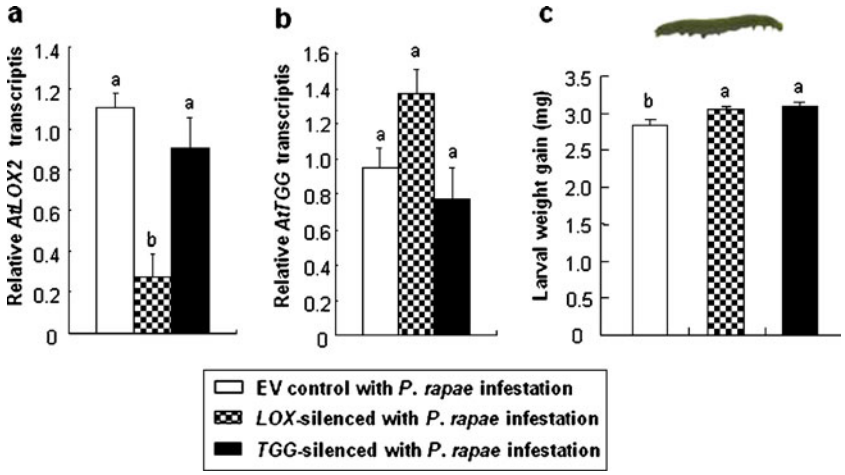

Fig. 4 Accumulation of induced *AtLOX2* and *TGG1/2* transcripts relative to the levels of the *AtGAPDH* gene as assessed by qPCR in *LOX*-silenced and *TGG*-silenced plants after 3 d of feeding by *Pieris rapae* larvae. Silencing *AtLOX2* or *TGG1/2* enhances *P. rapae* larvae performance in *Arabidopsis thaliana* plants. There were 3 biological replicates in each treatment. Different letters above bars indicate significant difference at $P<0.05$; bars represent means and SE. One-way ANOVA and a nested ANOVA were used to analyze gene expression and body mass, respectively. **a.** Silencing lipoxygenase in *A. thaliana* using a partial *BoLOX* sequence from *B. oleracea* significantly reduced *AtLOX2* transcripts after 3 d of feeding by *P. rapae* larvae. **b.** Silencing myrosinase *TGG1/2* in *A. thaliana* using a *BoMYR* sequence from *Brassica oleracea* did not significantly reduce *TGG1/2* transcript levels after 3 d of feeding by *P. rapae* larvae. **c.** Growth of *P. rapae* larvae ($F_{2,35}=4.353$, $P=0.021$) on different silenced plants in no-choice feeding experiment 3 d after caterpillar emergence from the egg (each genotype with 12 plants and 5 eggs per plant; larvae hatched 4 d after oviposition). EV denotes empty vector control plant. The leaf samples were harvested 7 d after *P. rapae* oviposition

thaliana, tobacco, rice, and tomato (Bell et al., 1995; Heitz et al., 1997; Halitschke and Baldwin, 2003; Zhou et al., 2009; Allmann et al., 2010). Disrupting this specific *LOX* mRNA accumulation, e.g., through antisense as-*lox* in tobacco and rice results in a plant phenotype that is impaired in defense against herbivorous insects such as caterpillars (Halitschke and Baldwin, 2003; Kessler et al., 2004; Zhou et al., 2009; Allmann et al., 2010). *AtLOX2* induction occurs upon insect herbivory and *AtLOX2* antisense plants are impaired in anti-insect defense (van Poecke et al., 2001; van Poecke and Dicke, 2002). We previously hypothesized that *BoLOX* is characteristic for a 13-lipoxygenase (13-LOX) involved in JA biosynthesis (Zheng et al., 2007). In this study, we demonstrated that a *BoLOX* sequence can silence *AtLOX2* in *Arabidopsis.* This indicates that there is sufficient identity between *BoLOX* and *AtLOX2* to mediate gene silencing and *BoLOX*, like *AtLOX2,* may be involved in the jasmonate signaling pathway and responsible for wound-induced JA biosynthesis (see also Zheng et al., 2007) which should be further proven by silencing *BoLOX* in *B. oleracea.* At present, however, silencing in *B. oleracea* is not yet sufficiently effective (Zheng, unpublished data).

In the Brassicaceae family, the glucosinolate-myrosinase system serves as the major chemical defense mechanism against insects (Rask et al., 2000; Ratzka et al., 2002; Wittstock et al., 2004). The enzyme myrosinase degrades glucosinolates to produce toxins such as isothiocyanates that deter herbivory. A role of isothiocyanates in *A. lyrata* and *B. oleracea* resistance against the specialist herbivore *P. rapae* has been suggested by incorporating micro-encapsulated isothiocyanate in an artificial diet (Agrawal and Kurashige, 2003). However, *P. rapae* larvae performed better on wild-type *A. thaliana* than on double mutant *tgg1tgg2* plants, ascribed to very low myrosinase activity and reduced levels of feeding stimulants (Barth and Jander, 2006). Our results partially agree with the conclusions of Barth and Jander (2006), who report that elimination of TGG activity results in an increase in mass in the Solanaceae-specialist *Manduca sexta,* and the generalist *Trichoplusia ni,* a decrease in mass gain in *P. rapae*, while they recorded no effects on mass gain in the specialist *Plutella xylostella.* Our results show that endogenous *TGG1/2* transcript levels in intact *TGG*-silenced plants were reduced by about 80% compared to EV plants (Fig. 3b; Fig. 5a). As a consequence, *P. rapae* larval growth was significantly enhanced after feeding for 3 d on silenced plants compared to feeding on EV plants (Fig. 4c; Fig. 5b) which supports the conclusions drawn by Agrawal and Kurashige (2003), i.e., that glucosinolate breakdown products such as isothiocyanates that are a result of myrosinase activity confer resistance to the crucifer specialist *P. rapae*. There were significant differences in the accumulation of *TGG1/2* transcript levels between *TGG*-silenced and EV plants after larval feeding for periods of only <12 hr and 1 d, respectively (Fig. 5a). However, no

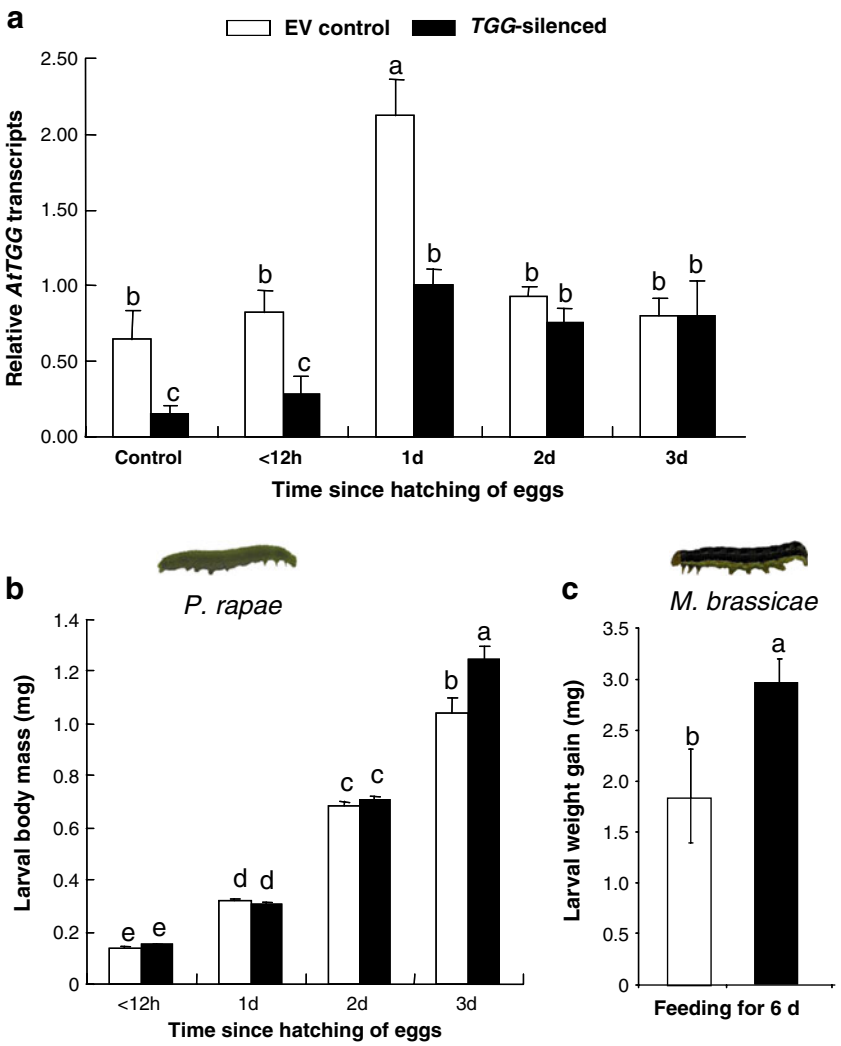

Fig. 5 Time course of accumulation of induced *TGG1/2* transcripts relative to the levels of the *AtGAPDH* gene and performance of *Pieris rapae* larvae on myrosinase *TGG1/2* silenced and empty vector control plants. There were 3 biological replicates in each treatment. Different letters above bars indicate significant difference at $P<0.05$; bars represent means and SE. One-way ANOVA and a nested ANOVA were used to analyze gene expression and body mass, respectively. **a**. Silencing myrosinase *TGG1/2* in *Arabidopsis thaliana* using *BoMYR* sequence from *Brassica oleracea* significantly reduces *TGG1/2* transcript levels in response to feeding by *P. rapae* larvae during less than 12 hr and 1 d, respectively. **b.** Silencing *TGG1/2* enhances *P. rapae* larval performance in *A. thaliana* plants in response to feeding by *P. rapae* larvae during 3 d, but not at earlier time points. Growth of *P. rapae* larvae on silenced or EV plants in a no-choice feeding experiment lasting 3 d after egg hatch. **c.** Silencing *TGG1/2* enhances growth of larvae of the generalist *Mamestra brassicae* after feeding for 6 d on *A. thaliana* plants. EV denotes empty vector control plant. The leaf samples were harvested at different time points as indicated as above

significant differences in *TGG1/2* transcript levels were detected upon *P. rapae* larval feeding for 2 and 3 d, respectively (Fig. 5a). This indicates that silencing *TGG1/2* genes has a delayed effect on larval development (Fig. 5b), which may be the result from a delay from transcription to translation that allows the effect to be noticeable. It would be interesting to measure additional parameters e.g., time to pupation, adult size, sex ratio, etc. However, due to the small size of the *A. thaliana* plants, five larvae could not complete development on a single plant. Furthermore, it will be interesting to quantify myrosinase protein levels, myrosinase activity, and glucosinolate breakdown products in future studies to assess the effects of changes in transcription level on the glucosinolate phenotype directly. The *P. rapae* caterpillars hatched from eggs that had been laid on the experimental plants. It is known that egg deposition may induce plant genes (Fatouros et al., 2008), and that extracts of crushed eggs may suppress the induction of plant defense genes (Bruessow et al., 2010). The *M. brassicae* caterpillars hatched from eggs that had been laid on paper. Our results show that in both cases caterpillar feeding induced a defense. Collectively, based on the comprehensive bioassays and gene expression studies, our results demonstrate an important role of *AtLOX2* and *AtTGG1/2* genes in *A. thaliana* plant resistance to the specialist and generalist herbivores *P. rapae* and *M. brassicae,* respectively.

Nucleotide Sequence Length Constraints for Heterologous Silencing Interestingly, we found that the overall homology between the heterologous gene sequence and the target gene sequence does not always correlate with gene silencing efficiency. A 299-bp *BoLOX* cDNA fragment used as trigger in the *LOX* vector has 90% of its nucleotides identical with the corresponding *AtLOX2* cDNA target fragment (Fig. 2a). However, intact *LOX*-silenced plants showed a reduction of approximately 50% in the abundance of *AtLOX2* transcripts compared to EV plants (Fig. 3a).

Moreover, intact *TGG*-silenced plants showed a reduction of approximately 80% in the abundance of *TGG1/2* transcripts compared to EV plants, although a 208-bp *BoMYR* cDNA fragment as trigger in *MYR* vector has only 79–80% identical nucle otides with the corresponding *AtTGG1/2* cDNA target fragment (Fig. 2B; Fig. 3B). Surprisingly, our data show that only 18 nucleotides (TACGCGGATC TATGTTTC) with 100% identity between the trigger and the target sequence are sufficient to achieve effective gene silencing (Fig. 2B). After BLAST searching of these 18 nucleotides and qPCR data on two other genes, *AtPAL1* and *AtPDS,* we did not find any off-target but only an effect on the target gene that codes for thioglucoside glucohydrolase (*AtTGG1/TGG2*) (data not shown). It has been reported that a minimum length of 21–23 nucleotides with 100% identity between the trigger and the target sequence is required to cause gene silencing (Zamore et al., 2000; Thomas et al., 2001; Voinnet, 2001). A 21-nucleotide stretch of 100% identity between the heterologous and endogenous gene sequences is not absolutely required for *PDS* gene silencing in *N. benthamiana* (Senthil-Kumar et al., 2007). Our results show that in *A. thaliana* another functional gene silencing can be achieved without the 21-nucleotide minimum length. Furthermore, the silenced *tgg* plants enhance larval performance of the specialist *P. rapae* and, more strongly so, of the generalist *M. brassicae* after 3 and 6 d, respectively, of feeding since egg hatch (Fig. 4C; Fig. 5B, C). It is important to target specific genes while avoiding off-target effects when using such short homologous gene sequences.

VIGS is a useful strategy for studying gene functions in plant-insect interactions, and EV plants were included to rule out an effect of innate immunity response in silenced plants to the viral infection. The next step is to develop VIGS successfully in *B. oleracea.* Especially, because there are no collections of genome-wide mutant populations generated by T-DNA insertion and transposon tagging in *Brassica* species. Generation of VIGS in *B. oleracea* has turned out to be more difficult than in *A. thaliana* (Zheng et al., 2010). Our present results address the use of heterologous gene sequences from the cultivated crop species *B. oleracea* to silence their respective orthologs in the model plant *A. thaliana*. This method is a first step in studies on the possible roles of *B. oleracea* genes by triggering gene silencing of corresponding heterologous genes in *Arabidopsis* plants for plant-insect interactions. Developing new protocols to improve silencing efficiency in *Brassica* species themselves will be the next step in our research to investigate the function of the *Brassica* genes. Furthermore, VIGS holds promise to silence particular genes of interest at different levels of silencing stringency. Linking different gene expression levels with quantified phenotypic plant traits will be vital to unravel mechanisms underlying plant-insect interactions (Zheng and Dicke, 2008).

Acknowledgements We thank L. Westerd, F. van Aggelen, and A. Gidding for insect rearing. We are grateful to S. P. Dinesh-Kumar (Yale University) for providing the VIGS vectors. We thank three anonymous reviewers for their constructive comments on a previous version of the manuscript. This work was financially supported by a VICI grant from the Netherlands Organization for Scientific Research, NWO (865.03.002).

Abstract Phytoestrogens are compounds that have moderate estrogenic or anti-estrogenic activity toward mammals. Although genistein and daidzein, the main phytoestrogens of soybean, have been the subject of thousands of studies that address their benefit to human health, relatively little is known about their benefits to plants that produce them. It has been suggested that genistein and daidzein protect plants against arthropod herbivores, but direct tests of this hypothesis are rare. In this study, we evaluated the effect of genistein and daidzein on the survivorship, growth, and fecundity of the gypsy moth, a generalist insect herbivore that does not encounter phytoestrogens in its normal diet. We compared survivorship, egg-to-pupa growth rate, and 4th instar performance of gypsy moth caterpillars on artificial diets containing no phytoestrogen, genistein, daidzein, or a combination of genistein and daidzein. Our results indicate that genistein and daidzein do not decrease survivorship, growth, or fecundity of this insect herbivore. Therefore, it seems unlikely that the primary function of these compounds in aboveground plant tissues is anti-herbivore defense.

Key Words Genistein · Daidzein · Phytoestrogen · Gypsy moth · Larval performance · Anti-herbivore defense

Introduction

Phytoestrogens are plant compounds that, because of their structurally similarity to estradiol, have moderate estrogenic or anti-estrogenic activity toward mammals. Phytoestrogens occur in over 300 species of plants, most notably legumes (Tham et al., 1998). Genistein and daidzein (Fig. 1), the primary phytoestrogen isoflavones of soybean, have been the subject of thousands of studies that address their beneficial effects on human health, including hormone-dependent breast and prostate cancers, osteoporosis, cardiovascular disease, immunity and inflammation, and reproduction and fertility in humans and other mammals (Cornwell et al., 2004; Xiao, 2008; Andres et al., 2009; Baber, 2010; Bhupathy et al., 2010).

Phytoestrogens have been proposed to confer three types of benefit to plants: facilitation of associations with below-ground mutualists including nitrogen-fixing bacteria and mycorrhizal fungi; protection against pathogens; and protection against herbivores. The first two are well-documented. Numerous studies have demonstrated the role of phytoestrogens in attracting and promoting colonization by mutualistic bacteria (Schultze and Kondorosi, 1998; Makoi and Ndakidemi, 2007; Bhattacharya et al., 2010) and fungi (Requena et al., 2007; Badri et al., 2009). It is also well established that the phytoalexin glyceollin, for which daidzein is a precursor, is induced by and protects plants against fungal pathogens (Lozovaya et al., 2007; Jasinski et al., 2009; Lygin et al., 2010). However, the efficacy of phytoestrogens as anti-herbivore compounds is far less clear.

Only a few studies have addressed the potential anti-herbivore benefits of phytoestrogen isoflavones, and most of these provide only indirect evidence. For instance, soybean extracts containing genistein and/or daidzein possess antifeedant or antibiotic activity toward mites

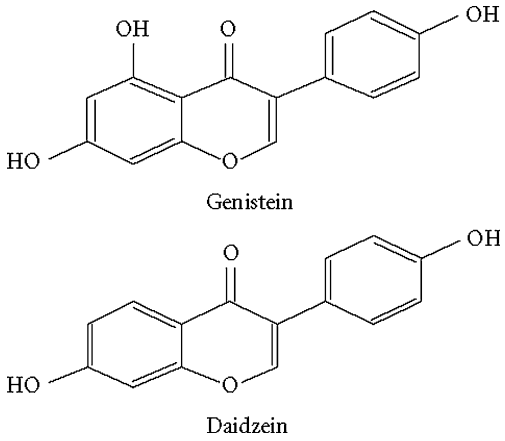

Fig. 1 Genistein and daidzein

(Wang et al., 1999), stink bugs (Piubelli et al., 2003), and lepidopterans (Hoffmann-Campo et al. 2001; Piubelli et al., 2005). However, as the authors note, these extracts contained many compounds, so it is not possible to unequivocally attribute deterrence or antibiosis to genistein and daidzein.

More convincing, but far less common, are controlled studies in which genistein and/or daidzein are applied to a neutral medium. Unfortunately, even in such controlled studies, evaluation of the anti-herbivore effects of genistein and daidzein is complicated by uncertainty about the ecological relevance of doses used (Sutherland et al., 1980; Sharma and Norris, 1991).

In a recent review of insect-soybean interactions, Parrott et al. (2008) called attention to "a notable lack of supportive research" into the role of phytoestrogens as deterrents to herbivory. We report here the results of a controlled study in which a generalist herbivore, the gypsy moth, was exposed to naturally-occurring levels of the two most abundant soybean phytoestrogens, genistein and daidzein.

Methods and Materials

The gypsy moth (*Lymantria dispar*) is a generalist herbivore that feeds on leaves of deciduous trees. Because gypsy moths do not feed on phytoestrogen-containing plants, we considered it to be particularly likely to be sensitive to genistein and/or daidzein.

Gypsy moth caterpillars were reared from hatching through the end of the final instar on gypsy moth artificial diet; both gypsy moth eggs and diet were generously provided by V. Mastro and C. Lokerson of the U.S.D.A. Plant Protection and Quarantine lab in Otis, MA, USA. Genistein and daidzein, the two major phytoestrogens in soybean (Liggins et al., 2000; Zhu et al., 2005), were purchased from LC Laboratories (Woburn, MA, USA). The rearing diet contained no phytoestrogen (control), 0.84 mg/g dry weight genistein, 0.84 mg/g dry weight daidzein, or 0.42 mg/g dry weight of both genistein and daidzein. These levels were chosen to reflect the highest reported concentration of genistein in any aboveground plant tissue (soybeans) (Dixon, 2004), and are substantially higher than levels found in leaves (Mazur and Adlercreutz, 1998).

Effect of Phytoestrogens on Survivorship To determine whether genistein and/or daidzein affects gypsy moth survivorship, 10 newly hatched larvae from each of 28 full-sib families were placed together into each of four 25-ml polystyrene cups in an environmental chamber at 30°C with a 16:8 hL:D cycle (N=1120 larvae). Each cup contained one of the four diets (control, genistein, daidzein, or genistein+ daidzein). Larvae were given fresh diet every 3 d. Upon molting into the 3rd instar, the 10 larvae from each family were divided equally between two cups to ensure sufficient space for the insects.

The first two larvae from each family on each diet that molted into the 4th instar were removed and used as wet/dry standards for the nutritional index study described below, and the fifth larva was used to measure nutritional indices. The third,fourth, sixth, and seventh larvae from each family on each diet that molted into the 4th instar were reared through to pupation on their respective diets (N=448 larvae; hereafter "egg-to-pupa larvae"). The remaining 3 larvae were discarded. After molting into the 4th instar, the 4 egg-to-pupa larvae were placed together in an 11-cm Petri dish and provided fresh food every 3 d or more often if necessary until pupation.

Early instar survivorship, defined as survivorship from hatching through the 3rd instar, was measured for all larvae, while late instar survivorship, defined as survivorship from the 4th instar through pupation, was measured only for the 448 egg-to-pupa larvae. Since larvae reared in the same cup are not independent replicates, early instar survivorship was first calculated for the 10 larvae from the same family on a given diet. Since survivorship was always at least 80%, differences among diets in early survivorship were determined by comparing the number of families with 100% vs. 80–90% survivorship by a *Chi-square* test. Similarly, differences among diets in late instar survivorship were determined by comparing the number of families with 100% vs. 75% survivorship by a *Chi-square* test. For both early and late instar survivorship, a Yates correction was applied when one or more expected value was less than 5.

Effect of Phytoestrogens on Growth The effect of genistein and daidzein on gypsy moth growth was determined in two ways. Egg-to-pupa growth rate (EPGR) was calculated for each of the 442 egg-to-pupa larvae that survived to pupation by drying pupae to constant weight at 60°C and

dividing the final pupal dry weight by the number of days from hatching to pupation. The initial dry weight of all larvae was assumed to be negligible. Upon pupation, the fresh weight of each pupa was also measured, and compared to the pupal dry weight to calculate pupal percent water. Since larvae reared in the same dish are not independent replicates, all measures were averaged separately for males and females sharing a dish (i.e., larvae of the same sex and from the same family on a given diet), and averages were compared among diets by ANOVA or, if data were not normal or variances were unequal, by Kruskal-Wallis tests. Sample sizes are slightly less than 28 because, on each diet, at least one dish yielded only male or female pupae.

Relative growth rate during the 4th instar and its components (consumption rate, digestive efficiency, and conversion efficiency) were measured for one larva per family per diet. As described above, the fifth larva from each family on each diet to molt to the 4th instar was used to in this experiment (N=28 larvae per diet). We chose the 4th instar since this is the last instar that does not end with pupation for either sex; males pupate after five instars and females pupate after six instars.

Upon molting into the 4th instar, each test larva was weighed and placed into a new 25-ml polystyrene cup containing a weighed amount of control, genistein, daidzein, or genistein+daidzein diet. Fresh diet was provided every other day. Upon molting into the 5th instar, each larva was weighed, frozen, dried to constant weight at 60°C, and reweighed. All uneaten food and all frass produced during the instar were also dried and weighed. Larval performance measures (Waldbauer, 1968; Karowe and Golston, 2007), based on dry weights, were calculated as follows:

$$\text{Relative consumption rate(RCR)} = \text{food ingested}/(\text{average larval weight})(\text{days})$$

$$\text{Approximate digestibility(AD)} = (\text{food ingested} - \text{frass})/\text{food ingested}$$

$$\text{Efficiency of conversion of digested food(ECD)} = \text{weight gained}/(\text{food ingested} - \text{frass})$$

$$\text{Efficiency of conversion of ingested food(ECI)} = \text{AD} \times \text{ECD}$$

$$\text{Relative growth rate (RGR)} = \text{weight gained}/(\text{average larval weight})(\text{days})$$

The effect of diet on nutritional indices and other measures of 4th instar performance (instar duration, final dry weight, and weight gained and frass produced during the 4th instar) was determined by one-way ANOVA followed by Tukey pairwise comparisons if data were normal and variances were equal, or by Kruskal-Wallis tests followed by pairwise Mann–Whitney U test if the assumptions of ANOVA were not met.

Results

Effect of Phytoestrogens on Survivorship Early instar survivorship ranged from 97.5% to 100% and did not differ significantly among the four diets (χ^2=6.89, $d.f.$=3, P=0.075; Fig. 2a). Late instar survivorship ranged from 99.1% to 100%. Since only a single late instar larva died, no statistical analysis was possible; however, it is clear that late instar survivorship did not differ among diets (Fig. 2b). It is unlikely that inclusion of the three discarded larvae per family per diet would have resulted in differences among diets. Although these were the slowest growing larvae, the great majority were growing nearly as well as their siblings. Across diets, only 0% to 3.7% of discarded larvae were in the 2nd instar, while 96.3% to 100% were in the 3rd instar (χ^2=3.4, $d.f.$=3, P>0.3).

Effect of Phytoestrogens on Egg-to-Pupa Growth Among females, measures of egg-to-pupa performance did not differ significantly among diets (Table 1). Egg-to-pupa growth rate ranged from 7.45 to 7.79 mg/day (P=0.49), the number of days from hatching to pupation ranged only from 53.9 to 54.5 (P=0.35), pupal dry weight ranged from 40.3 to 42.3 mg (P=0.45), and pupal water content ranged only from 77.2 to 77.6% (P=0.38).

Similarly, among males, most measures of egg-to-pupa performance did not differ among diets (Table 1). Egg-to-pupa growth rate ranged from 2.34 to 2.49 mg/day (P=0.41), the number of days from hatching to pupation ranged only from 48.0 to 48.7 (P=0.76), and pupal dry weight ranged from 11.3 to 12.1 mg (P=0.39). However, the water content of male pupae differed among diets (χ^2=8.16, $d.f.$=3, P=0.043). Water content was significantly higher on the genistein+daidzein diet than on the control, genistein, and daidzein diets.

Effect of Phytoestrogens on 4th Instar Performance Measures of 4th instar performance did not differ among larvae reared on control vs. phytoestrogen-containing diets (Table 2). No effect of diet was observed for any of the nutritional parameters, which generally differed by less than 5% among diets. Larger, but still nonsignificant, differences were noted for final dry weight, which differed by 17%

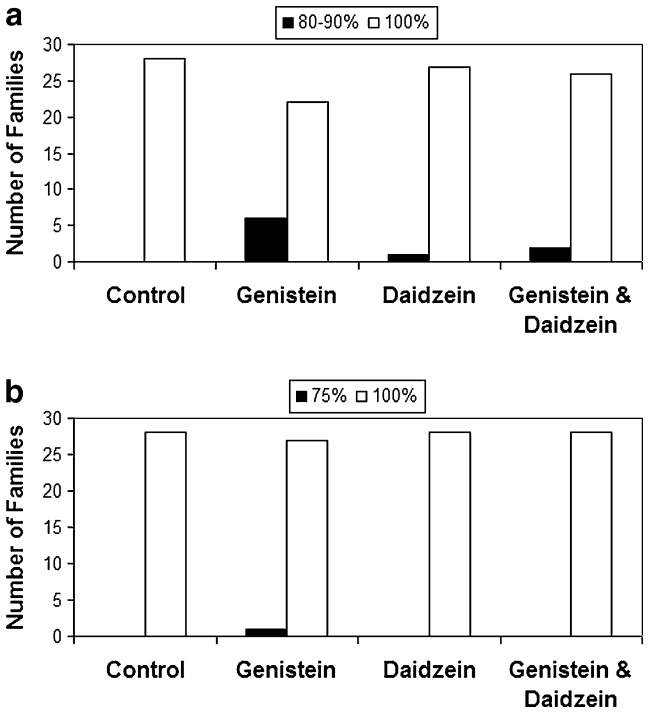

Fig. 2 (**a**, *top*) Early survivorship of gypsy moth (through the 3rd instar), expressed as the number of families on each diet that had 80–90% vs. 100% survivorship and (**b**, *bottom*) late survivorship (4th instar through pupation), expressed as the number of families on each diet that had 75% vs. 100% survivorship

among diets, total weight gained during the feeding trial, which differed by 20% among diets, and total food eaten during the feeding trial, which differed by 24% among diets.

Discussion

The results of this study indicate that the two most widely studied phytoestrogens, genistein and daidzein, have no dietary effect on a generalist herbivore, the gypsy moth. Even when these compounds were incorporated into an artificial diet at levels far above those normally found in leaves, gypsy moth survivorship was nearly 100%. Moreover, none of the measures of performance during the entire larval stage or during the 4th instar were compromised by genistein or daidzein, alone or in combination. Therefore, the results of this study do not support the hypothesis that these phytoestrogens occur in aboveground plant tissues and defend against generalist insect herbivores.

Previous studies have detected antifeedant and/or antibiotic effects of genistein and/or daidzein. For instance, when applied to agar-cellulose disks, genistein reduced consumption by the root-feeding scarab beetle, *Heteronychus arator* (Sutherland et al., 1980). Similarly, when applied to leaf disks, daidzein adversely affected growth and survivorship of the cabbage looper, *Trichoplusia ni* (Sharma and Norris, 1991). Unfortunately, since the weight of disks was not reported, it is not possible to determine whether these herbivores ingested phytoestrogens at levels known to occur in nature. We are aware of only one study in which it is possible to calculate exposure level. Wang et al. (1998) observed deterrence of redlegged earth mites, *Halotydeus destructor*, by a genistein-containing solution, but only at concentrations of 0.045% and above. Assuming the test solution had a density of approximately 1 g/ml, this concentration is more than five times the maximum genistein level reported from soybeans (Mazur and Adlercreutz, 1998; Dixon, 2004). It is not clear that adverse effects previously reported in the literature provide strong evidence of anti-herbivore effects of genistein or daidzein.

Consistent with our results, several studies have suggested that genistein does not possess anti-herbivore activity. For instance, genistein did not reduce feeding by scarab beetles *Costelytra zealandica* (Sutherland et al., 1980; Lane et al., 1987) or *Heteronychus arator* (Lane et al., 1987). In a related study (Lane et al., 1985), genistein did not reduce feeding by *C. zealandica* when incorporated into agar-cellulose disks at 0.2 mg/g, a concentration known to occur in soybean (Dixon, 2004). The authors suggested that this lack of activity might be due to the absence of an oxy function at the 2′ position of the B ring and, even more importantly, the absence of a B ring cyclic isoprenoid moiety.

It should be noted that most flavonoids and isoflavonoids exist in plant tissues primarily as glycosides rather than as aglycones such as genistein and daidzein. However, it is likely that in insects, as in humans, glycosides are readily converted into aglycones by β-glucosidases in the gut (Matsuura and Obata, 1993; Steensma et al., 1999) although that conversion has not been demonstrated for insects.

If genistein and daidzein do not provide effective defense against insect herbivores, then why are they present in aboveground plant parts? Phytoestrogens may defend plants by reducing fertility in herbivorous mammals (Jefferson et al., 2009) or seed-eating birds (Rochester and Millam, 2009), or by conferring resistance to fugal (Naoumkina et al., 2007) or viral (Andres et al., 2009) pathogens.

It is premature to rule out the possibility that phytoestrogens are in some cases effective defenses against insect herbivores. There was a slight indication in this study that genistein may decrease early instar survivorship (P=0.075; Fig. 2a), although the increase in mortality was very small. Furthermore, since it is highly polyphagous, the gypsy moth may be less susceptible than most insect herbivores to adverse effects of phytoestrogens. Although there is no reason to believe that gypsy moth encounters genistein or daidzein in its natural diet, it

does encounter the structurally similar compounds rutin and quercetin (Liebhold et al., 1995; Perić-Mataruga et al., 1997). However, since both rutin and quercetin inhibit development of gypsy moth caterpillars (Beninger and Abou-Zaid, 1997; Peric-Mataruga et al., 2001), it is unlikely that gypsy moths possess a broad ability to detoxify isoflavones. Our results, however, indicate that genistein and daidzein do not affect this insect herbivore. Therefore, it seems unlikely that the primary function of these compounds in aboveground plant tissues is deterrence of generalist herbivores.

Abstract Coastal marsh habitats are impacted by many disturbances, including habitat destruction, pollution, and the introduction of invasive species. The common reed, *Phragmites australis*, has been particularly invasive in the mesohaline regions of the Chesapeake Bay, but few studies have investigated its role in trophic interactions with North American marsh consumers. The marsh periwinkle snail *Littoraria irrorata* is a common grazer in marshes and grazes on the native grass *Spartina alterniflora*. Whether this snail grazes on *Phragmites* has not been addressed. We found *Spartina* leaves to be tougher than those of *Phragmites*, but despite this, snails consumed significantly more *Spartina* than *Phragmites*. Subsequent experiments demonstrated that *Phragmites* is chemically deterrent to snails by an unknown, moderately polar, compound. Further studies are required to more fully understand the interactions between *Phragmites*, herbivores, and *Spartina*, and how they may impact marsh ecosystems.

Key Words Estuarine · Exotic · Non-native · Plant-herbivore · Resistance to herbivory

Introduction

Tidal marsh habitats provide critical ecological services, such as buffering coastlines from wave action, filtering out sediments and pollutants, and serving as nursery habitats for commercially important species (Pennings and Bertness, 2001; reviewed in Gedan et al., 2009). Increasingly, marshes are suffering from a number of negative impacts, such as land use changes, pollutants, and eutrophication, all of which can alter species richness and abundance (Burdick and Konisky 2003; Jeffries et al., 2003; Gedan et al., 2009). Another stressor on marshes is the introduction of invasive species, which can decrease the species richness and abundance of native species through activities such as consumption (e.g., nutria, *Myocaster coypus*), burrowing (e.g., isopod, *Sphaeroma quoyantum*), and competition (e.g., common reed, *Phragmites australis*) (Ford and Grace, 1998; Talley et al., 2001; Burdick and Konisky, 2003).

Phragmites australis (Cav.) Trin. ex Steud., hereafter referred to as '*Phragmites*,' is an exotic marsh grass originally from Eurasia. It is found from freshwater to marine salinities along much of the Atlantic and Gulf coasts of the U.S. It is increasing in abundance in oligohaline and mesohaline regions of the Chesapeake Bay (Cross and Fleming, 1989; Rice et al., 2000; McCormick et al., 2010). As an example, in the Rhode River subestuary of the Bay, *Phragmites* coverage increased by about 2400% between 1971–2007 (McCormick et al., 2010). *Phragmites* was introduced to North America in the early nineteenth century, but went largely unnoticed, because there are several varieties (haplotypes) of *Phragmites* native to North America that are not invasive (Saltonstall, 2002). Invasion by *Phragmites* is correlated with decreased abundance of the most common native marsh grass *Spartina alterniflora* (hereafter referred to as '*Spartina*'), as well as native *Phragmites* haplotypes, and other vascular plant species (Chambers et al., 1999; Rice et al., 2000; Saltonstall, 2002). Thus, it has been inferred that *Phragmites* is responsible for the observed declines in native species. Replacement of *Spartina* by *Phragmites* generally increases marsh elevation and decreases the number of water-filled depressions and

the amount of standing water (Able and Hagan, 2003). In addition, the frequency of flooding, flooding depth, and duration may decrease as well (Osgood et al., 2003).

Several studies have investigated differences in associated fauna in *Spartina*- vs. *Phragmites*-dominated marsh, with mixed results. Some studies have found fewer fish, blue crabs, and macroinfaunal organisms, and differences in types of arthropods in *Phragmites*-dominated marshes, compared to marshes dominated by *Spartina* (Hanson et al., 2002; Jivoff and Able, 2003; Posey et al., 2003; Gratton and Denno, 2006). Other studies, however, have not detected faunal differences between marsh types (Hanson et al., 2002; Able and Hagan, 2003; Osgood et al., 2003; Raichel et al., 2003).

While several studies have investigated the impacts of *Phragmites* on marsh community structure, less is known regarding trophic interactions with this invader. Several herbivores, such as insects, crustaceans, and gastropods, are known to feed on native marsh grasses and, in some cases, can strongly influence the distribution and abundance of these species (Silliman and Bertness, 2002; Pennings and Silliman, 2005; Silliman et al., 2005; Holdredge et al., 2009). Few studies have investigated whether native marsh grazers feed on *Phragmites*. Gratton and Denno (2006) demonstrated that in *Phragmites*-dominated marshes, arthropods obtained most of their basal nutritional resources from benthic microalgae and detritus, and not directly from *Phragmites*. When these marshes were restored to *Spartina*-domination, arthropods contained the isotope signatures of *Spartina* feeding. Thus, it appears that *Phragmites* invasion may alter trophic interactions among organisms in tidal marshes, and may not provide a functional replacement of *Spartina* as a basal resource for all consumers. Given that biological control by herbivores has been suggested as a method of controlling *Phragmites* (Tewksbury et al., 2002), it is important to investigate the interaction between *Phragmites* and native marsh herbivores.

One common grazer in mesohaline and polyhaline marshes is the periwinkle marsh snail, *Littoraria irrorata*, which consumes *Spartina*, but also uses it as a substrate for growing a fungus, on which they feed (Newel and Barlocher, 1993; Graca et al., 2000; Silliman and Newell, 2003). This snail has been shown to limit the abundance of *Spartina*, especially when abundance of this grazer is high (Silliman and Bertness, 2002; Silliman et al., 2005). In southern latitudes, grazing by snails (*L. irrorata*) and planthoppers can induce a chemical defense in *Spartina*, which deters feeding by snails (Long et al., 2011).

Currently, much of the mesohaline region of the Chesapeake Bay salt marsh is now dominated by *Phragmites* (Rice et al., 2000) and *L. irrorata* are observed climbing on stalks of this grass (L. Hendricks, H. Mossop, and C. Kicklighter, pers. obs.). As a first step toward examining feeding preferences of grazers for this invader in comparison to the native grass, *Spartina*, we compared the toughness of *Phragmites* to that of *Spartina* and conducted *L. irrorata* feeding experiments on these two plants. In addition, *Phragmites'* chemical deterrents against *L. irrorata* grazing were examined.

Methods and Materials

Experimental Organisms Periwinkle marsh snails (*Littoraria irrorata*), *Spartina alterniflora*, *Phragmites australis*, and the green seaweed *Ulva lactuca* all occur together in mesohaline marsh areas in the Chesapeake Bay and were collected May–July 2008 from the same site on the grounds of the Chesapeake Bay Environmental Center in Grasonville, MD, USA (N38°57.386′ W076°14.206′). *Phragmites* was confirmed to be exotic by restriction fragment-length polymorphism (RFLP) analysis of non-coding chloroplast DNA regions, following the methods of Saltonstall (2003) (L. Hendricks unpub. data). Grass stalks were clipped just above the sediment surface with shears and placed in large plastic bags. Snails and *U. lactuca* were collected by hand and placed in separate plastic bags. The snails were maintained in 38-l tanks with approximately 1 l of 15 ppt seawater (Instant Ocean, Atlanta, GA, USA) and were fed once a week with the control food (*U. lactuca*). *Phragmites* and *Spartina* samples for toughness measurements were used within 3 hr of collection. All other grass samples were frozen until used.

Toughness Previous studies have found that plant toughness can deter consumption by herbivores, so we measured toughness in two ways (based on the methods of Pennings et al., 1998): the force necessary to tear a leaf blade and penetrate a leaf blade. These methods likely replicate the actions of piercing and chewing grazers, but it is likely that neither technique exactly mimicks the piercing and scraping action of the snail radula, but may provide an indication as to which plant might be more difficult for snails to consume. To measure tearing, a safety pin pierced the center of a 5 cm long leaf blade, about 6 mm from the bottom of the blade, and fastened. The leaf blade was oriented vertically, and the top was held with two fingers while a plastic cup, which was attached to the safety pin via a string, was slowly filled with sand until the safety pin tore through to the end of the leaf blade. After this occurred, the safety pin + string + cup + sand were weighed.

Leaf penetration was measured with a plastic cup with a dull pin point sticking out of the center of the bottom. The pin was placed so that it rested in the middle of a 5 cm long leaf blade lying on a piece of wood, such that there was a

depression in the wood underneath where the pin point rested on the leaf. The cup was slowly filled with sand until the pin penetrated the leaf blade. When this occurred, the cup + pin + sand were weighed.

For both toughness measurements, one leaf from each of 15 plants was tested. Because the data were normally distributed (Shapiro Wilk and D'Agostino and Pearson Omnibus normality tests) and had similar variances (Bartlett's test) (Zar, 1999), we examined toughness differences between the plants with an unpaired *t*-test using GraphPad Prism software (GraphPad Software, La Jolla, CA, USA).

Feeding Bioassays Initial assays offering pieces of fresh plant tissues to *Littoraria irrorata* were unsuccessful, as the snails fed so slowly that tissues wilted before significant feeding differences could be detected. Because we were concerned that wilted tissues might differ in palatability from fresh, intact tissues, we conducted assays used dried, ground plant tissues, based on a combination of methods in Bolser and Hay (1996) and Kicklighter and Hay (2006). Briefly, reconstituted foods were created by lyophilizing and then grinding plant tissues with a Wiley Mill (Thomas Scientific, Swedesboro, NJ, USA) into a fine powder. This was mixed with 0.03 $g ml^{-1}$ alginic acid, and distilled water was added to reconstitute plant tissues to a natural volume.

Three snails per replicate were offered equal amounts of ground *Spartina* and *Phragmites*, spread on opposite ends of window screen mesh strips. Snails fed until approximately half of one treatment was consumed (or for 24–48 h). Preference was determined by counting the number of squares of each food type consumed. Because samples were not normally distributed (as determined by Shapiro Wilk and D'Agostino and Pearson Omnibus normality tests) and variances were unequal (Bartlett's test), we analyzed food consumption with a Wilcoxon Matched Pairs Test ($N=12$ replicates) (Zar, 1999) using GraphPad Prism software.

To assess if *Phragmites* chemicals were responsible for feeding deterrence, a volumetric equivalent of *Phragmites* crude chemical extract or chemical fraction (see methods below) was resolubilized and added to a palatable control food (the seaweed *Ulva lactuca*) at a natural concentration found in the grass (as determined by volume). Three snails per replicate were offered equal amounts of the control food containing *Phragmites* chemicals vs. the control food without any chemicals added, as described above ($N=14$–31 replicates). Because samples were not normally distributed and variances were unequal (determined as described above), we analyzed food consumption with a Wilcoxon Matched Pairs Test (Zar, 1999) using GraphPad Prism software.

Crude Chemical Extraction and Separation Chemicals were extracted from *Phragmites* leaves, similar to Kicklighter et al. (2003). This method was chosen because it effectively extracts chemical defense compounds and avoids the use of dichloromethane, which can cause deterrent chemicals to degrade (Kicklighter and Hay, 2006). Leaves were cut up in approximately twice the volume of 100% methanol and 100% ethyl acetate, consecutively, for 2 hr each. Extracts were combined, filtered to remove solids, and the solvent removed with a rotary evaporator. This crude extract was combined with the control food at a natural concentration found in the grass and tested in a bioassay (as described above). To accomplish this, a volumetric equivalent of extract was resolubilized in methanol or ethyl acetate and transferred to a 20 ml scintillation vial. The solvent was removed by drying the extract under a stream of air. Previous assays demonstrated that the solvent carrier did not deter snail feeding, so any decreases in snail feeding on foods treated with *Phragmites'* chemicals should be attributed to the chemicals, and not to the solvent. Thus, control foods were not treated with the carrier solvent. Because the crude extract deterred snail feeding (as determined by a Wilcoxon Matched Pairs Test, $N=12$), we performed a modified inverse Kupchan solvent-solvent partition (Kupchan et al., 1975). Our one modification to this partitioning scheme was to omit the dichloromethane/water partition, since previous studies have found dichloromethane to degrade the activity of deterrent compounds (Kicklighter and Hay, 2006). This resulted in partitioning *Phragmites* chemicals into four fractions that differed in solubility: those chemicals that were soluble in hexanes, ethyl acetate, butanol, and water. Each fraction was tested in the bioassay against the palatable control food and feeding statistically analyzed, as described above. The deterrent fractions (butanol and ethyl acetate) were further separated by C18 reversed phase column chromatography. Mobile phases were progressive dilutions of water and methanol—100% water, 75:25 water:methanol, 50:50 water:methanol, 25:75 water:methanol, and 100% methanol (and a final wash of ethyl acetate which was added to this fraction). Subsequent active fractions were separated further by reversed phase chromatography and preparative thin layer chromatography (TLC), but repeated attempts resulted in loss of activity and further separation was not achieved.

Phenolic and Protein Assays Previous studies have suggested that phenolic compounds are responsible for deterring herbivores from feeding on plants, including marsh grasses (Coley et al., 1985; Herms and Mattson, 1992; Barlocher and Newell, 1994). In addition, *Phragmites* has been shown to contain these compounds (Rudrappa and Bias, 2008). Following the methods of Siska et al. (2002), who examined phenolic content of

marsh grasses, we measured phenolic concentrations using a Folin-Dennis reaction in our *Phragmites* butanol- and ethyl acetate-soluble fractions, and reversed phase column fractions of the ethyl acetate fraction. Aliquots of plant chemicals representing 0.1 ml of plant tissue were dissolved in 50 µl of 80% methanol and reacted with 750 µl deionized H_2O, 200 µl Folin-Ciocalteau reagent (Sigma-Aldrich, St. Louis, MO, USA), and 1000 µl 20% Na_2CO_3. After a 20-min incubation period, absorbance was read at 700 nm on a Thermo Electron Biomate 3 spectrophotometer (Thermo Electron Corp, Waltham, MA, USA). A standard curve was constructed using ferulic acid (Siska et al., 2002).

Because low nutritional quality can interact with chemical defenses to make them more potent (e.g., Hay et al., 1994), *Phragmites* and *Ulva lactuca* tissues were analyzed for protein content, using a standard Bradford assay (Bradford, 1976). Because *U. lactuca* contained less protein than *Phragmites*, we wanted to make sure that the lower nutritional quality of *U. lactuca* was not enhancing the deterrence of *Phragmites'* chemical defense and confounding our results. Thus, we performed a bioassay (as described above), where we added protein albumin (bovine serum albumin, Sigma-Aldrich, St. Louis, MO, USA) to the ground *U. lactuca* used to make the treatment (*Phragmites* crude extract added) and control foods to increase the protein concentration to a level comparable to *Phragmites* tissue. Because samples were not normally distributed and variances were unequal, we analyzed food consumption with a Wilcoxon Matched Pairs Test.

Results

When we compared the toughness of *Phragmites* to *Spartina*, we found that the force required to either tear through (Fig. 1a) or pierce (Fig. 1b) *Spartina* was 1.3X that of *Phragmites*. When plants were ground up into a fine power and reconstituted into a gelled food, however, *Littoraria irrorata* consumed 26X more *Spartina* than *Phragmites* (mean ± S.E.M=76.7%±4.7 vs. 2.9% ±2.0, respectively; Wilcoxon Matched Pairs Test, $P<0.001$, $N=12$).

The *Phragmites* crude extract strongly deterred snail feeding (Fig. 2), suggesting that a chemical deterrent best explains snail feeding preferences. When a *Phragmites* crude extract was fractioned using an inverse Kupchan partition, the water- and hexanes-soluble chemicals were not significantly deterrent, while both the butanol and ethyl acetate fractions deterred feeding (Fig. 3a). Both actively deterrent fractions were separated further by reversed phase chromatography. Of the five reversed phase column fractions from the ethyl acetate-soluble fraction, only the 50:50 water:methanol fraction actively deterred feeding

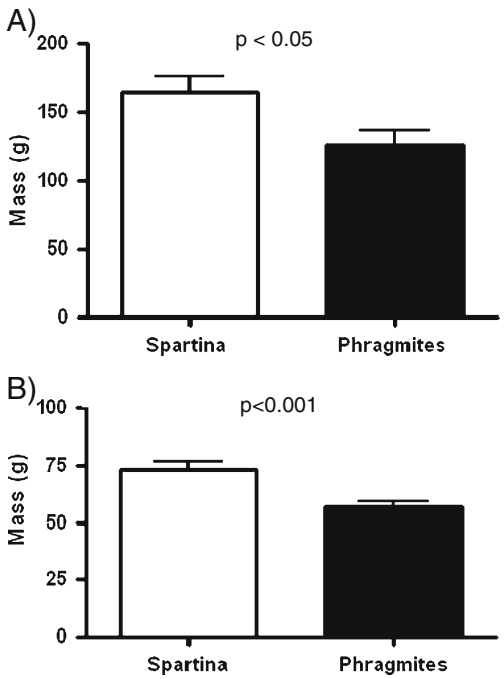

Fig. 1 Toughness of leaves of *Phragmites* and *Spartina* as measured by **a** tearing; and **b** penetration. $N=15$ leaves, analyzed with an unpaired *t*-test. Error bars represent standard error of the mean

(Fig. 3b). Similarly, only the 50:50 water:methanol fraction of the butanol reversed phase fractionation was deterrent (Fig. 3c).

We attempted further separation of the 50:50 water:methanol fraction from the butanol and ethyl acetate partitions by preparative thin layer chromatography and reversed phase column chromatography, but activity was repeatedly lost in the resulting fractions. Even when all the fractions of subsequent separation efforts were added back together at three times natural plant concentrations, the chemicals were not deterrent to feeding, suggesting that the active molecule(s) decomposed. Other separation techniques (e.g., LH-20 size exclusion chromatography, anion-exchange chromatography) were not attempted.

Because many plants are thought to utilize phenolic compounds as chemical defenses (Coley et al., 1985; Herms and Mattson, 1992; Barlocher and Newell, 1994), phenolic content was measured for the butanol and ethyl acetate fractions resulting from the Kupchan partition (Fig. 3a). Their concentrations were similar, with phenolic levels in both partitions being 0.12% of dry mass. Phenolic concentrations also were measured in all fractions in the reversed phase column separation of the ethyl acetate partition. Measured concentrations (as % of dry mass) were as follows: 0.001% in the 100% water fraction, 0.02% in 75:25 water:methanol, 0.03% in 50:50 water:methanol, 0.04% in 25:75 water:methanol, 0.03% in 100% methanol.

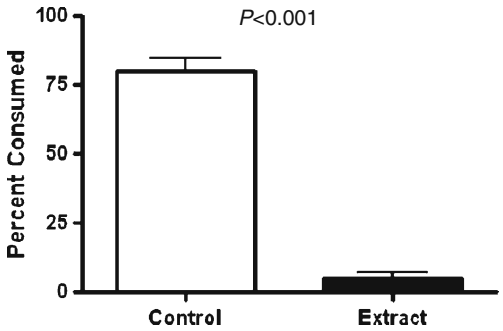

Fig. 2 Snail feeding on dried, ground, reconstituted *Ulva lactuca* lacking (*clear bar*) or mixed with (*black bar*) *Phragmites* crude extract. $N=14$ replicates, analyzed with a Wilcoxon Matched Pairs test. Error bars represent standard error of the mean

The protein content of ground *Phragmites* and *Ulva lactuca* were measured by Bradford assay. *Phragmites* had a protein content of approximately 0.0432 g protein ml^{-1}, while *Ulva* had approximately 0.0063 g protein ml^{-1}. Thus, *Phragmites* contains 6.9 times more protein than *U. lactuca*. When protein was added to *U. lactuca* to achieve the protein concentration of *Phragmites* and the crude extract feeding assay was retested, *Littoraria irrorata* still significantly preferred *U. lactuca* lacking the *Phragmites* crude extract (mean ± S.E.M.=76.1%±5.4 vs. 25.7%±8.9, Wilcoxon Matched Pairs Test, $P<0.001$, $N=14$). Thus, low nutritional value of our gelled food likely did not influence snail feeding.

Discussion

Mesohaline regions of the Chesapeake Bay are shifting from marshes dominated by *Spartina* to ones containing a large abundance of the invasive grass *Phragmites* (Rice et al., 2000; Lathrop et al., 2003; King et al., 2007). This may have important implications for marsh community structure through alteration of trophic interactions. When performing feeding assays using *Phragmites'* chemical extracts, snail feeding was depressed (Figs. 2 and 3), suggesting *Phragmites* is chemically defended against this grazer. *Spartina* was tougher to tear and penetrate than *Phragmites* (Fig. 1), however, the periwinkle marsh snail *Littoraria* preferred *Spartina* over *Phragmites* when offered reconstituted,

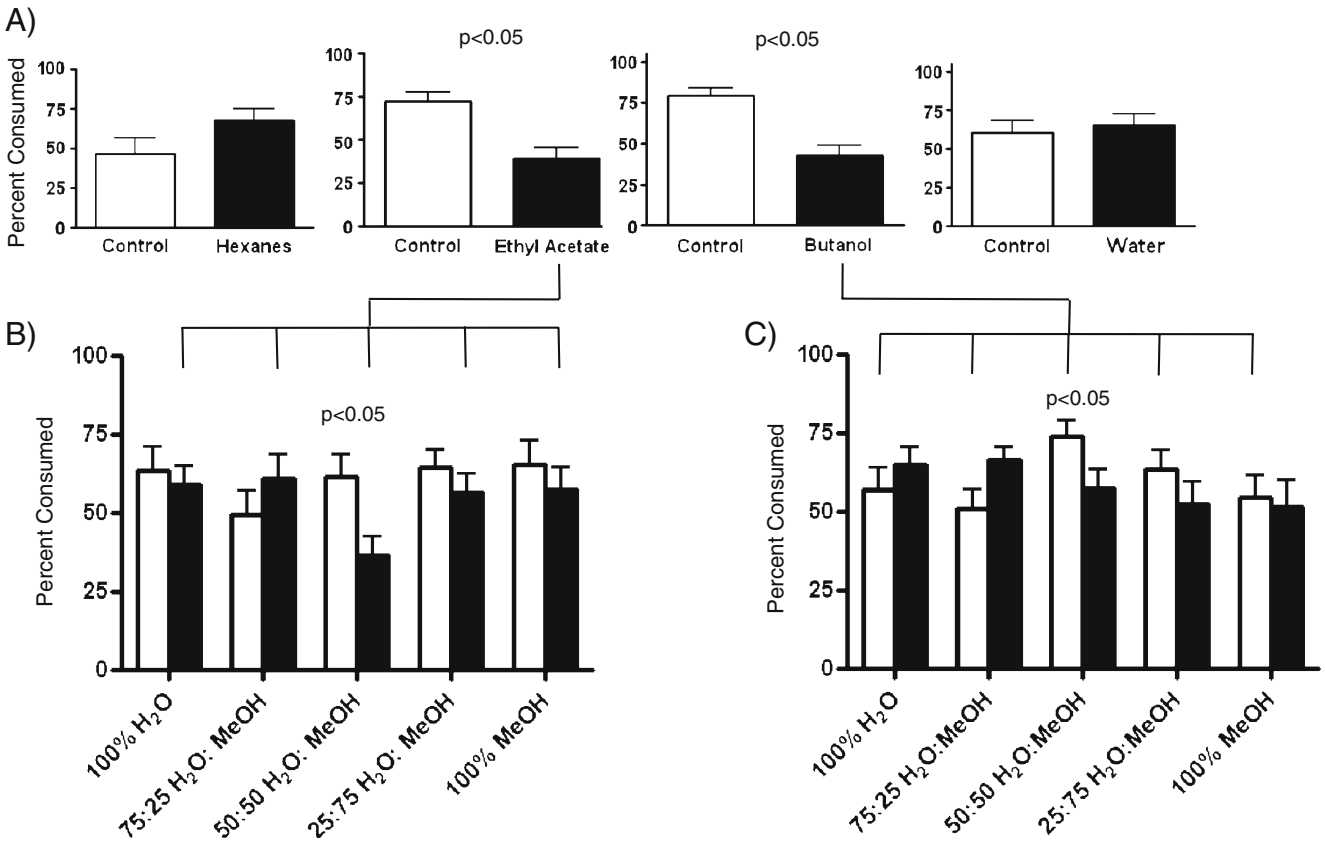

Fig. 3 Bioassay guided fractionation of the deterrent components in the *Phragmites* crude extract based on snail feeding deterrence. Consumption of control food vs. food mixed with *Phragmites* chemicals resulting from **a** solvent-solvent partition; **b** fractions produced by the reversed phase separation of the ethyl acetate partition produced in (**a**); and **c**) fractions produced by the reversed phase separation of the butanol partition produced in (**a**). $N=15–31$ replicates, data and analysis, and error bars as described in Fig. 2

ground tissues of these two plants. Ground tissues lacked the structural attributes of the natural plants, so the fact that the snails preferred *Spartina*, the tougher plant, suggests that plant structural attributes may be less important in determining snail feeding, which is similar to findings of Siska's et al. (2002) survey of salt marsh plants. Feeding assays with fresh, intact plants are required, however, to more fully understand mechanisms other than chemical defenses that may mediate snail feeding preferences.

Phragmites contained 6.9x the protein content as our palatable food (and 1.3x the protein of *Spartina*, L. Hendricks unpub. data), and we, therefore, excluded the possibility that *Phragmites* was eaten less than other plants due to poor nutritional quality. Previous studies have shown low nutritional quality to minimize herbivory (Cruz-Rivera and Hay, 2003). To account for low nutrition in our palatable control food, snails were offered a low-quality food choice with the chemical defense of the more nutritious plant, *Phragmites*. Snails may have avoided *U. lactuca* when it contained *Phragmites* chemicals because the food was simply too low in nutrition to be worth consuming deterrent chemicals. However, when protein albumin was added to *U. lactuca*, so that the food matched the protein concentration of *Phragmites*, the crude extract feeding assay yielded the same results: *Phragmites* chemicals deterred feeding. Thus, nutritional content did not appear to confound the results of the extract feeding assays.

Both the ethyl acetate and butanol partitions of the *Phragmites* crude extract deterred feeding (Fig. 3a), initially suggesting more than one deterrent compound. Further separation of both partitions, however, yielded active fractions of the same polarity (molecules soluble in a 50:50 water:methanol mixture) (Fig. 3b and c). Given this similarity and the fact that both the ethyl acetate- and butanol-derived 50:50 water:methanol fractions appeared similar by thin layer chromatography, we assumed that our deterrent compound(s) initially separated into both the butanol and ethyl acetate fractions and that the deterrent molecule(s) present in both 50:50 water:methanol fractions are the same. Because the active fraction contains molecules soluble in 50:50 water:methanol, they are moderately polar. This is similar to the findings of Siska et al. (2002) who demonstrated that polar fractions of some common marsh plants (*Aster tenuifolius*, *Iva frutescens*, *Spartina alterniflora*, and *S. patens*) from southern U.S. Atlantic regions deterred feeding by a crab. Long et al. (2011) also found a polar extract from *Spartina* that had induced a chemical defense to deter feeding by *L. irrorata*. Since our separation methods differed from the above studies, however, it cannot be determined whether *Phragmites*' deterrent compounds are the same or similar as those tested by Siska et al. (2002) and Long et al. (2011).

While our findings suggest that *Phragmites* is chemically defended, we were unable to isolate and identify the chemical(s) mediating its resistance against snail herbivory, due to repeated loss of deterrence of our chemical fractions. Even when all of these chemical fractions were recombined and used in a feeding assay at three times natural plant concentrations, there was no feeding deterrence, indicating that the deterrent compound(s) decomposed as a result of the separation process.

In an effort to gain some understanding of the molecules mediating *Phragmites'* chemical defense, we quantified phenolic concentrations in some of our *Phragmites* extracts. Several studies have suggested that phenolics are important chemical defenses for terrestrial plants, including *Spartina alterniflora*, and these compounds can be unstable (Barlocher and Newell, 1994; Herms and Mattson, 1992; Coley et al., 1985). In addition, *Phragmites* has been shown to contain phenolics (Rudrappa and Bias, 2008), thus, we examined *Phragmites* for these metabolites. We did detect phenolics in all samples tested, but at fairly low levels. The deterrent ethyl acetate and butanol partitions each only contained a total phenolics concentration of 0.12% dry mass, and fractions resulting from the reversed phase separation of the ethyl acetate partition had phenolics concentrations that ranged from 0.001% to 0.04% dry mass. In addition, a non-deterrent fraction (25:75 water:methanol) contained more phenolics than the deterrent fraction (50:50 water:methanol), suggesting that total phenolics do not play a role in *Phragmites'* defense. As a comparison, Siska et al. (2002) found phenolic concentrations in *Spartina alterniflora* leaves to be between 2.45% and 3.17% dry mass and it was the plants that contained the higher concentrations of phenolics that were less palatable to a crab and two insects. Based on our data, it is impossible to know whether phenolics mediate *Phragmites'* chemical defense against snails, but it seems unlikely that the total phenolics concentration is high enough for this function. It is possible, however, that a single phenolic compound, found in a low concentration in the 50:50 water:methanol fraction does mediate deterrence. Further studies are needed to confirm or refute this.

Gallic acid is secreted by the invasive form of *Phragmites* and has been shown to inhibit the growth of other plants (Rudrappa et al., 2007). It is possible that gallic acid also serves as a chemical defense for *Phragmites*, deterring snail feeding. Gallic acid is polar [our compound (s) is moderately polar], however, it displays thin layer chromatography characteristics different from our deterrent fraction. Thus, it is unlikely that it plays a defensive role against this herbivore.

Invasion of marshes by *Phragmites* may alter trophic interactions, resulting in disruption of the marsh community. If *Littoraria irrorata* preferentially consume *Spartina* and

use it for a substrate for growing fungus (Silliman and Newell, 2003) over *Phragmites*, this could facilitate the decline of *Spartina* and the spread of *Phragmites* in marshes where *L. irrorata* are abundant. Fewer fungal spores are found on *Phragmites* compared to *Spartina* plants in the same area (H. Mossop, unpub. data), suggesting that snails may not use *Phragmites* for growing fungus. Similarly, some insect herbivores (such as aphids and gall flies) preferentially consume native *Phragmites* over introduced *Phragmites*, which can result in new shoot death (Lambert, 2005), stunted growth (Park and Blossey, 2008), and decreased flowering (Lambert et al., 2007) in the native form. In areas dominated by *Phragmites* and devoid of *Spartina*, snails, and possibly other herbivores, may switch to alternate food sources, as has been shown for arthropod consumers by Gratton and Denno (2006), or decline in abundance. Further studies are required to more fully understand the interactions between *Phragmites*, herbivores, and *Spartina* and how they may impact marsh ecosystems.

Acknowledgments We thank Jordan Yoder for help with field collections and Ali Brock for snail care. Two anonymous reviewers improved the manuscript. Funding was provided to L.G.H. through a Goucher College Presidential fellowship and to H.M. and C.E.K. by the Goucher College summer research program.

Abstract Resistance in Triticeae to fusarium head blight (FHB) is quantitatively inherited. Metabolomics as a tool was used to better understand the mechanisms of resistance and to identify potential FHB resistance biomarker metabolites in barley. Five FHB-resistant two-row barley genotypes (CIho 4196, Zhedar-1, Zhedar-2, Fredrickson, and Harbin-2r) and one FHB-susceptible genotype (CH 9520–30) were each inoculated with either pathogen-suspension or mock-solution. Disease severity, quantified as the proportion of spikelets diseased, varied among genotypes, being the greatest in CH 9520–30. Spikelets were sampled, metabolites extracted with aqueous methanol, and analyzed using an LC-ESI-LTQ-Orbitrap system. A pair wise, resistant vs. susceptible, *t*-test identified 1774 significant treatment peaks. Canonical discriminant analysis of peak abundance allowed the genotypes to be sorted into three clusters: (i) CH9520-30, (ii) Harbin-2r, (iii) the remaining four genotypes. The *t*-test was further used to identify resistance-related (RR) and pathogenesis-related (PR) metabolites. The pathogen-produced virulence factor deoxynivalenol (DON), and its detoxification product, DON-3-*O*-glucoside (D3G) were designated as resistance indicator (RI) metabolites. Metabolites (RR, PR, or RI) occurring in at least two resistant genotypes, showing a two-fold or greater abundance in resistant vs. susceptible lines, and also known to have plant defense functions were selected as potential FHB resistance biomarker metabolites. These included phenylalanine, *p*-coumaric acid, jasmonate, linolenic acid, total DON produced (TDP), and the proportion of DON converted to D3G (PDC). Total DON was the lowest in CIho 4196, while PDC was the highest in Zhedar-2. The application of RR, PR, and RI metabolites as potential biomarkers to enhance resistance is discussed.

Introduction

Fusarium head blight (FHB) is a destructive disease of barley (*Hordeum vulgare* L.) and wheat (*Triticum aestivum* L.), with a worldwide economic impact (Gilbert and Tekauz, 2000). The disease is caused by several *Fusarium* species of which *F. graminearum* (teleomorph: *Gibberella zeae*) is of greatest relevance. *Fusarium graminearum* significantly reduces both grain yield and quality by producing trichothecene mycotoxins, such as deoxynivalenol (DON) (Desjardins 2006). Genetic improvement of host resistance to

FHB is considered the best disease management option to reduce mycotoxin production and mitigate yield loss.

Plant resistance mechanisms to pathogen attack can be classified as apparent or true (Agrios, 2005). Apparent resistance is not directly controlled through a genomic influence on metabolism, but rather the plant escapes disease. For example, the closed-floret two-row barley genotypes are more resistant to infection than open-floret six-row genotypes (Bai and Shaner, 2004; Tekauz et al., 2000). True resistance is genetically controlled, and the mechanisms are either structural or biochemical, where the latter can be associated with particular proteins or metabolites. Quantitative FHB resistance documented in wheat and barley is associated with resistances to spikelet infection (Type I), spreading of the infection within the spike (Type II), and limiting trichothecene accumulation (Type III), especially DON, following pathogen invasion (Miller et al., 1986). While these categories of resistance have served in genotypic screening, they do not speak to the issue of resistance mechanisms. As mutants of *F. graminearum* lacking DON/trichothecene production fail to spread within infected spikes of wheat, DON is clearly an important virulence factor (Proctor et al., 1995; Jansen et al., 2005). In general, barley exhibits high type II resistance, therefore the focus of breeding programs has been on improving type I resistance (Bai and Shaner, 2004). However, ranking of barley genotypes based on type I resistance has proven to be inconsistent over years and seasons. This variation generally has been attributed to environmental conditions. More than 100 FHB-resistance quantitative trait loci (QTL) have been identified, across all seven chromosomes of wheat and barley, but several of these are either unstable or often associated with pleiotropic effects (Choo, 2006; Buerstmayr et al., 2009). The mechanisms of true resistance have been partially elucidated for a single QTL (chromosome 3BS), which confers a high rate of conversion of DON to DON-3-*O*-Glucoside (D3G) in resistant lines through the enzymatic action of DON-glucosyltransferase (Lemmens et al., 2005). The identification of FHB resistance mechanisms in barley would not only explain the functions of over 100 known FHB resistance QTLs but also would provide molecular breeders with novel tools for selecting resistant genotypes. In the present study, barley genotypes commonly used as sources of resistance in breeding and in QTL mapping programs were selected to explore and provide an overview of FHB resistance mechanisms controlled by metabolites.

Metabolomics technology has been applied to identify resistance-related (RR, greater abundance in resistant than in susceptible genotype) metabolites in wheat and barley. Based on gas chromatography and mass spectrometry (GC-MS), several RR metabolites have been identified (Hamzehzarghani et al., 2008). However, metabolomics based on GC-MS detect only volatile metabolites (Vorst et al., 2005). Based on LC-hybrid-MS (LC-ESI-LTQ-Orbitrap), more than 3000 peaks have been detected, and several RR metabolites have been identified in spikelets of barley in response to FHB infection (Bollina et al., 2010; Kumaraswamy et al., 2011). The metabolites identified belonged to three main chemical groups: phenylpropanoids, fatty acids, and terpenoids. While prior studies were based on an analysis of paired resistant/susceptible genotypes, in this study, the occurrence of RR metabolites was investigated in more than one resistant genotype, using an LC-MS method.

Methods and Materials

Plant Production Five FHB-resistant two-row barley genotypes (CIho 4196, Fredrickson, Harbin-2r, Zhedar-1, and Zhedar-2) and one FHB-susceptible genotype (CH 9520–30) were used. Three seeds of each genotype were sown in individual 15 cm pots and maintained under greenhouse conditions at 22±3°C. Plants were irrigated daily and fertilized at 2 wk intervals with 200 ml of 0.3% PlantProd (20-20-20 NPK + trace elements). Following germination, only the main stem and a single tiller of each plant were retained. These genotypes, along with several others, also were sown in a field in Ottawa, Ontario, Canada, as detailed in Choo et al. (2004). For each genotype, 10 g of seeds were sown in two rows of 1.5 m in length.

Pathogen Production, Inoculation, and Incubation Fusarium graminearum Schwabe isolate 15–35 was maintained on potato dextrose agar media, and fresh cultures were produced on rye agar media. Seven-d old cultures were used to collect macroconidia. Barley spikelets were spray inoculated with 1×10^5 macroconidia ml^{-1} or an aqueous solution containing 0.02% Tween80 (mock), at 50% anthesis to early milky stage (GS=65–73; Zadoks et al., 1974). The inoculated plants were placed inside plastic bags the inner surfaces of which had been sprayed with sterile water. The plants were maintained under these conditions for 48 h in order to facilitate initial establishment of the infection.

Experimental Design and Statistical Analyses The greenhouse experiment was designed as a randomized complete block, with twelve treatments, consisting of six genotypes and two inoculations of mock-solution (M=0.02% Tween80) or pathogen (P = macroconidia in 0.02% Tween80), with five replicates in time, conducted at roughly weekly intervals. Each experimental unit consisted of a pooled sample of 50–60 spikelets, collected from 6 plants. The field experiment was designed as a randomized complete block with four replicates (Choo et al., 2004).

The experimental units consisted of 30 spikes per replicate. The resistance of the different genotypes was confirmed by assessing the proportion of spikelets diseased (PSD). The PSD was determined from the number of diseased spikelets in spray inoculated spikes 21 d after inoculation in the greenhouse or 1 mo after inoculation in the field.

Sampling and Metabolite Extraction Some 50–60 inoculated spikelets, from 6 spikes, were harvested 72 h after inoculation. The lemmas and paleas were removed and frozen in liquid nitrogen, and metabolites were extracted (Kumaraswamy et al., 2011). In brief, the samples were crushed in liquid nitrogen with a mortar and pestle. A finely powdered 100 mg (fresh weight) sample was placed in a 2.2 ml micro-centrifuge tube, to which 1400 µl of ice-cold methanol (HPLC grade 99.96% pure, Fisher Scientific), 200 pg of genistein, and 200 pg of ribitol as internal standards, and 1,500 µl of water were added. After vortex mixing for 10 sec, the samples were sonicated for 15 min at a frequency of 40 kHz in a water bath at room temperature. The tubes then were centrifuged for 10 min at 20,000 g. The supernatants were filtered through a 0.1 µm PVDF membrane filter (Millipore Corporation, Bedford, MA, USA), and the filtrate was collected and stored at −20°C, and analyzed within a week.

Metabolite Analysis Using LC-ESI-LTQ-Orbitrap Metabolites were analyzed using an LC-hybrid-MS system (LC-ESI-LTQ Orbitrap, Thermo Fisher, Waltham, MA, USA). Semipolar metabolites were analyzed with a capillary reverse phase C-18 column (500 µm i.d. × 10 cm) packed with Jupiter 5 µm particle 300 Å reverse-phase stationary material (Phenomenex, Torrance) (Kumaraswamy et al., 2011). Polar metabolites, mainly trichothecenes from pathogen inoculated samples, were analyzed with a polar column, C18 Kinetex (210 µm i.d×10 cm, with a particle size of 2.6 µm, Phenomenex). The column was maintained at 25°C, and the mobile phase was adjusted to a flow rate of 150 µl min^{-1} and eluted with water containing 2.5 mM ammonium acetate (A) and methanol (B). A gradient elution profile was used starting with 98% mobile phase A for 4 min, then changing to 10% mobile phase A over 26 min, and subsequently ramped to 90% mobile phase B over 5 min, followed by a 5 min ramp to 100% mobile phase B, and a rapid return to 100% mobile phase A. A blank sample was run after every experimental sample to reduce carry over. Some samples were analyzed in MS/MS mode, using 35 eV CID energy, to determine the fragmentation patterns. The compounds DON, 3ADON, and DON-3-*O*-glucoside (D3G) (Sigma-Aldrich, Oakville, ON, Canada) were spiked in different concentrations, using the above LC-hybrid-MS protocol. The abundances of DON, 3ADON, and D3G, rather than their acetate adducts, were used to develop regression models to predict their concentrations from abundances.

LC-MS Output Analysis Raw data obtained from LTQ Orbitrap, based on semipolar and polar columns, were separately aligned using XCMS 1.22.1 (Kumaraswamy et al., 2011). Data were processed with a signal to noise threshold of, *snthresh*=5:1 and band width of, *bw*=10 s. The CAMERA bioinformatics tool (Tautenhahn et al., 2007) was used to annotate peaks with isotopes, neutral losses, adducts, and dimmers, which represented multiple peaks of the same compound. The data on peak abundance (relative ion counts) were subjected to a student's *t*-test using SAS (version 9.2; SAS Institute Inc., Cary, NC, USA) to select metabolites that had significant treatment effects. The tests of hypotheses included four treatment combinations: RM vs. SM, RP vs. RM, SP vs. SM, RP vs. SP, where R = resistant, S = susceptible, M = mock, P = pathogen. The peaks with significant ($P<0.05$) treatment effects were designated as metabolites.

The log transformed abundances of treatment significant metabolites, from mock-inoculated and pathogen-inoculated, were separately (because of the complex design) subjected to canonical discriminant analysis (CDA), to group observations, and identify the metabolites significantly loading to a group of treatments. The treatment significant metabolites also were further used to select pathogenesis related (PR), resistance related (RR), and resistance indicator (RI) metabolites. A metabolite with significantly higher abundance in a pathogen-inoculated than in a mock-inoculated genotype was considered a PR metabolite, be it in resistant (PRr=RP>RM) or susceptible (PRs=SP>SM) genotypes. A metabolite with a higher abundance in the resistant genotype than in a susceptible one was considered an RR metabolite. An RR metabolite based on mock-inoculation was considered as a constitutive (RRC= RM>SM) metabolite. A PRr metabolite in a resistant genotype with abundance greater than that in the susceptible pathogen-inoculated was considered as RR induced (RRI= RP>RM and RP>SP) metabolite (Hamzehzarghani et al., 2008). A relative reduction in the accumulation of the virulence factor DON (Proctor et al., 1995) in a resistant vs. susceptible plant served to indirectly assess two different plant resistance mechanisms: i) the reduction in DON synthesis by the pathogen, possibly due to high abundance of phenolics and flavonoids in the resistant genotype (Boutigny et al., 2009; Kushalappa lab unpublished data); or ii) the increased detoxification or conversion of DON to D3G, through the enzyme DON-glucosyltransferase (Lemmens et al., 2005; Bollina et al., 2010). The concentration of total DON produced was calculated as TDP = DON + D3G, using the regression models developed here to calculate concentrations from abundances. The proportion of TDP

converted to D3G was calculated as: PDC = D3G/TDP. Both TDP and PDC were designated as resistance indicator (RI) metabolites. The PR, RR, and RI metabolites were assigned with putative names, based on accurate mass, fragmentation pattern that also considered manual verification, and isotope ratio, either matching with the spectra in databases or those obtained by spiking authentic standards (Bollina et al., 2010; Kumaraswamy et al., 2011).

Results

Disease Severity FHB severity (PSD), under greenhouse conditions, ranged from 0.54 in the susceptible genotype (CH 9520–30) to 0.17 in the most resistant genotype (CIho 4196). The PSD was not significantly different among five resistant genotypes tested, but was significantly lower in all resistant genotypes compared to the susceptible (Fig. 1). In field evaluations, the susceptible genotype CH 9520–30 had PSD of 0.48 as compared to 0.11 for CIho 4196. The ranking of six genotypes based on PSD in greenhouse evaluations were similar to those under field evaluations, except for Zhedar-1, which had higher PSD under field conditions.

Multivariate Analysis of Metabolic Profiles A total of 1774 metabolites had significant treatment effects. The abundances of the treatment-significant peaks from pathogen and mock-inoculated samples were separately subjected to canonical discriminant analysis (CDA) to better visualize the grouping of observations and genotypes. In both, the five replicates of different treatments were closely grouped, meaning there was little experimental error. In mock-inoculation (Fig. 2a), the CAN1 vector explained 60% of variance, with four resistant genotypes grouped together with high positive scores, and the fifth resistant genotype Harbin-2r as well as the susceptible genotype CH9520-30 both having negative scores. The genotypes CIho 4196 and Fredrickson had the highest positive scores. The metabolites with high positive loading to CAN1 vectors were: caffeoyl alcohol, kaempferol 7,4′-dirhamnoside, nallaflavanone, kaempferol 3-rhamnoside, linoleic acid, *p*-coumaric acid, and phenylalanine (Table S1a). In pathogen inoculated treatments (Fig. 2b), the CAN1 explained 41% of variance, where the resistant genotypes had high positive CAN1 scores, while the susceptible one had a highly negative CAN1 score. Although not all the high loading (L>0.9) metabolites were identified, among those that were, octadecanoic and *p*-coumaric acids had relatively high loadings (Table S1b).

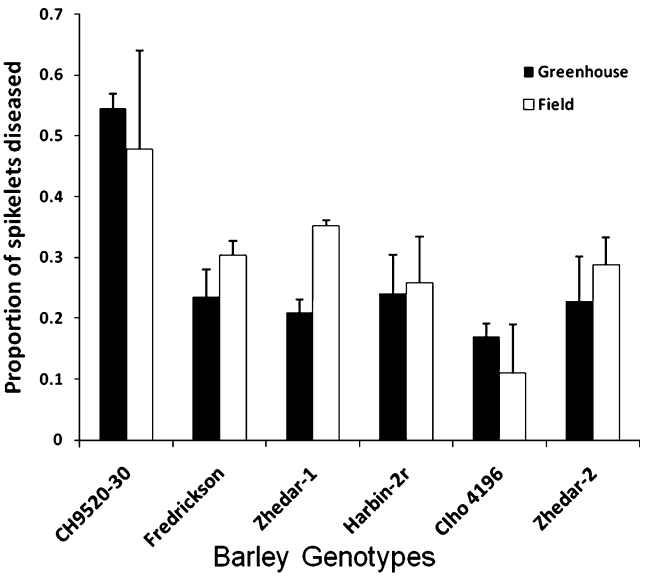

Fig. 1 Proportion of spikelets diseased in a spike (PSD), in six barley genotypes under greenhouse and field tests

Resistance Related Constitutive Metabolites (RRC) In total, 108, 84, 76, 106, and 69 RRC metabolites were detected in the genotypes CIho 4196, Zhedar-1, Zhedar-2, Fredrickson, and Harbin-2r, respectively (Table 1). Most of the RRC metabolites detected were phenylpropanoids. The magnitude of change in abundances of RRC metabolites relative to the susceptible variety varied among the resistant genotypes. A total of 14 RRC metabolites were common to two or more resistant genotypes, and their relative abundance was equal to or greater than two fold that in the susceptible genotype. The abundance of *p*-coumaric acid was 4.3 and 3.1 fold in Zhedar-2 and Fredrickson, respectively, while phenylalanine was nearly 2 fold in Zhedar-2, Zhedar-1, and Harbin-2r genotypes.

Pathogenesis Related (PR) and Resistance Related Induced Metabolites (RRI) The genotypes CIho 4196, Zhedar-1, Zhedar-2, Fredrickson, and Harbin-2r had 12, 11, 26, 14, and 13 significantly induced metabolites (PRr), respectively, following pathogen inoculation. However, the amount of induction in resistant genotypes was not significantly higher than in susceptible genotypes, meaning that none of these were RRI metabolites. Jasmonic acid was a PRr metabolite in all five resistant genotypes. Linolenic acid was common to two resistant genotypes and two fold greater in abundance than in the susceptible genotype.

Resistance Indicator Metabolites (RI) The extra cellular trichothecenes produced by the pathogen, DON, and 3ADON, and the plant enzymatic detoxification product of DON, D3G, were detected not only in their pure forms but also as their acetate (CH_3COO^-) adducts (Figs. S1, S2). The total amount of DON produced (TDP) by the pathogen, in lemma and palea, varied from 27 mg kg^{-1} in CIho 4196 to 53 mg kg^{-1} in Harbin-2r (Fig. 3a; Table 2). The amount

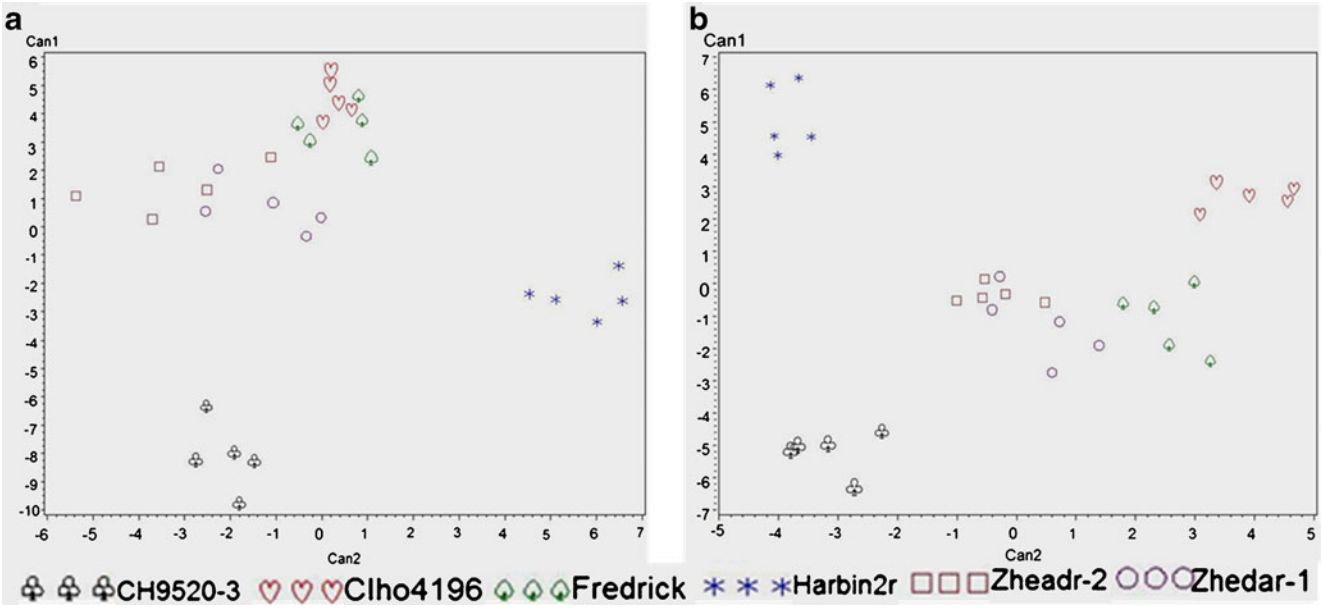

Fig. 2 Canonical discriminant analyses (CDA) of metabolic profiles of six barley genotypes: a = metabolic profiles of pathogen inoculated; b = metabolic profiles of mock-inoculated

of 3ADON, a precursor of DON, produced was quite low and it varied from 3.1 mg kg^{-1} in CH9520–30 to 4.4 mg kg^{-1} in Harbin-2r (Fig. 3a). The TDP was 50 mg kg^{-1} in susceptible genotypes CH9520–30, which was similar to the level in Harbin-2r. The PDC varied from 0.68 in CH9520–30 to 0.78 in Zhedar-2, and was moderate in Fredrickson, Harbin-2r, CIho 4196, Zhedar-1 (Fig. 3b; Table 2).

PR, RR and RI Metabolites in Resistant Genotypes

CIho 4196 The most resistant genotype CIho 4196 had 109 RRC and 12 PRr metabolites. Several of the RRC metabolites showed many fold (×) changes in abundance, especially for conjugates of kaempferol (e.g., 2.0–7.6 fold changes). The changes in abundance of other RRC metabolites were: *p*-Coumaric acid=2.8×, phenylalanine= 2.1×, linoleic acid=3.8×, JA=3.6×. Interestingly, the abundances of linoleic acid, linolenic acids, *p*-coumaric acid and phenylalanine increased more than two fold, following pathogen inoculation (PRr). The TDP was the lowest (27 mg kg^{-1}) and the PDC was moderate (0.70), among the genotypes tested in this study (Table 2).

Zhedar-1 Had 84 RRC and 11 PRr meabolites (Table 1). The highest fold changes in abundance of RRC metabolites were observed for traumatic acid=2.1×, linoleic acid=1.9×, phenylalanine =2.2×, and eucommin A (lignan)=3.2×. The changes for PRr metabolites were JA=2.3× and stearic acid= 2.1×. The TDP was the second lowest (33 mg kg^{-1}), but the PDC was quite low (0.70).

Zhedar-2 Had 76 RRC and 26 PRr metabolites. Large changes in abundance of RRC metabolites were observed for phenylalanine=2.4×, *p*-coumaric acid=4.3×, 4-geranyloxy-5-methylcoumarin=2.3×, and eucommin A (lignan)=1.4×, linolenic acid=3.7×, and oleic acid=1.9×. In addition, several flavonoids, as conjugates of kaempferol, were identified as RRC: 6-hydroxykaempferol 7,4′-dimethyl ether 3-sulfate (4.7×), kaempferol 7,4′-dirhamnoside (3.0×), kaempferide 5-glucoside-7-glucuronide (4.2×), kaempferol 3-(2″,3″-diacetyl-4″-*p*-coumarylrhamnoside (5.9×), and kaempferol 3-isorhamninoside (5.1×). The changes in abundance of PRr metabolites were: tuberculatin (lignan)= 1.3× and JA=3.0×. The TDP was moderate (37 mg kg^{-1}), but the PDC was the greatest among the genotypes evaluated (0.78) (Table 2).

Fredrickson This genotype had 106 RRC and 14 PRr metabolites. Several phenylpropanoids and fatty acids were identified as RRC metabolites (Table 1). The changes in abundance were: *p*-coumaric acid=3.1×, and an esterified coumaric acid, 4-geranyloxy-5-methyl coumarin=2.7×. Other RRC metabolites were caffeoyl alcohol, tuberculatin (a lignan), traumatic acid, and stearic acid. The PRr metabolites were JA, linolenic acid, and heptadecatrienoic acid.

Harbin-2r Had 69 RRC and 13 PRr metabolites. Among the ten RRC identified, four were phenylpropanoids and their change in abundance were: 4-geranyloxy-5-methyl coumarin=3.2×, phenylalanine =2.0×, calophyllolide= 2.3×, and podorhizol beta-D-glucoside (lignan)=1.7×. Among the four PRr metabolites identified, nortracheloge-

nin showd the greatest change (3.8×). The TDP was the highest (53 mg kg^{-1}), but the PDC was the second highest (0.74) among genotypes tested (Table 2).

Discussion

Barley genotypes, with different levels of resistance to FHB, varied in their metabolic profiles. We have identified several resistance related constitutive metabolites. These RRC metabolites mainly belonged to three chemical groups: phenylpropanoids, flavonoids, and fatty acids. The occurrence of RRC metabolites, and their magnitude of change in abundance relative to a susceptible genotype, varied across resistant genotypes. The RRC metabolites that occurred in two or more resistant genotypes with at least two fold greater abundance relative to the susceptible were *flavonoids*: several conjugates of kaempferol, quercetin 3-(6″-acetylglucoside), triphyllin A, kuwanon L; *phenylpropanoids*: *p*-coumaric acid, phenylalanine, 4-geranyloxy-5-methyl coumarin, calophyllolide; *fatty acids*: linolenic acid and traumatic acid. Interestingly, several conjugates of kaempherol occurred in high abundance across different genotypes, with the highest increase relative to the susceptible genotype being 7.6× for CIho 4196. All the pathogen inoculated genotypes, not only accumulated DON but also detoxified DON to D3G, in lemma and palea. The most resistant genotype CIho 4196 had the lowest amount of TDP, along with the second highest PDC, the highest being in Zhedar-2 which had moderate TDP. Even though several pathogenesis related metabolites were detected in resistant genotypes, following pathogen inoculation, no resistance-related induced metabolite was identified. Jasmonic acid was a PRr metabolite in all the genotypes, with an up to 3.6× change in abundance, relative to the mock-inoculated. The present study indicates that barley has high levels of constitutive resistance against *F. graminearum*, as has been reported previously in other studies on wheat and barley (Hamzehzarghani et al. 2008; Bollina et al. 2010; Kumaraswamy et al. 2011). These metabolites can be used as potential biomarkers for screening genotypes for resistance against FHB. In addition to metabolites, proteins also significantly contribute to the biochemical resistance mechanisms of the plant against *F. graminearum* (Boddu et al. 2006; Zhou et al. 2006; Golkari et al. 2007; Geddes et al. 2008; Jia et al. 2009).

Metabolic profiling is still an evolving biochemical tool. Several solvents are needed to extract, and different platforms are needed to detect most of the metabolites in plant. Accordingly, we have not detected all the metabolites present in spikelets of the barley genotypes tested here. Using aqueous methanol for extraction and LC-hybrid-MS with a semipolar column (Jupiter) for analysis, we detected more than 1000 metabolites. Still, this column failed to consistently detect DON, 3ADON, and D3G, all of which

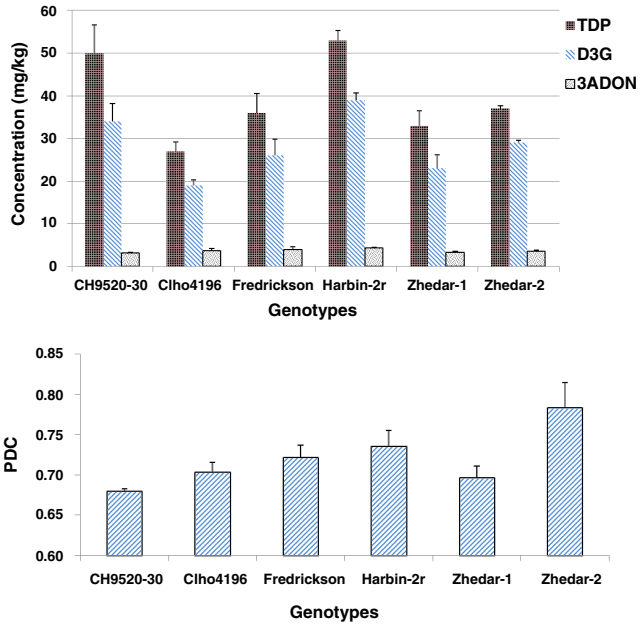

Fig. 3 **a** Total DON produced (TDP = DON + D3G), DON-3-*O*-glucoside (D3G), and 3ADON in lemma + palea of six barley genotypes, following *Fusarium graminearum* inoculation, based on LC-ESI-LTQ-Orbitrap, in mg kg^{-1} of fresh weight of lemma and palea; **b** Proportion of TDP converted to D3G (PDC) in lemma and palea of six barley genotypes

were well-detected with a polar column (Kinetex). Furthermore, we failed to identify any RRI metabolites. This may be due mainly to spray inoculation of spikelets, where the variation in proportion of spikelets infected was high among replicates, which in turn can influence the abundance of metabolites. Individual inoculation of spikelets in wheat has yielded several RRI metabolites, including phenylpropanoids and fatty acids (Hamzehzarghani et al. 2008). In this study, only lemma and palea of the spikelets were analyzed, excluding the rest of the floral organs, as the lemma and palea are the primary defense structures enclosing the ovary/caryopsis, especially in two-row barley that has cleistogamous florets (Yoshida et al. 2007). Although Ma and Bohnert (2007) showed that each organ or tissue type had a specific transcriptome expression in the *Arabidopsis* genome, Golkari et al. (2007) found that the lemma, palea, and glume had similar gene expression patterns, but were different from rachis of wheat inoculated with *F. graminearum*.

Potential Biomarker Metabolites for FHB Resistance

RRC and RI Metabolites The RRC and RI metabolites identified here, which met the following five criteria, were considered as potential biomarkers to screen barley genotypes for resistance against FHB: i) putatively identified (Table S2); ii) high fold change in abundance relative to susceptible; iii) highly significant, especially at $P<0.01$ and $P<0.001$ (Table S1); iv) occurred in more than one genotype; v) associated with plant defense function. Some of these metabolites, or precursors of these metabolites, also were identified as RR metabolites in our previous studies (Bollina et al. 2010; Kumaraswamy et al. 2011). Accordingly, these FHB resistance biomarker metabolites were grouped in their metabolic pathways.

Resistance Indicator Metabolites

Total DON Produced (TDP = DON + D3G) In this study, the most resistant genotype CIho 4196 accumulated the lowest amount of TDP, and moderately resistant genotypes accumulated moderate amounts of TDP, except for Harbin-2r, which accumulated the highest amounts of TDP, similar to the susceptible CH9520-30 (Fig. 3a; Table 2). The accumulation of relatively lower amount of TDP by a resistant genotype can be due to the inhibition of DON/trichothecene synthesis, by the presence of high amounts of antioxidants, especially phenylpropanoids, as has been demonstrated for ferulic acid *in vitro* (Boutigny et al. 2009) and for others (Kushalappa et al. unpublished data). Ferulic acid represses the expression of several trichodiene synthase genes (*Tri-genes*), consequently inhibiting the synthesis of trichothecenes. The amount of DON accumulation in the plant at any time, depends on the amount of DON synthesized, less that converted to D3G. So, the determination of TDP, in this study, has enabled us to better evaluate the factors that affect DON synthesis. DON may not be needed for the initial invasion of spikelets (Jansen et al. 2005), but reduced synthesis of DON may reduce the rate of lesion expansion within florets. However, in our study, the reduced amounts of DON in resistant genotypes also could be due to reduced mycelial biomass relative to susceptible genotypes, even though the DON synthesis can be completely inhibited with little reduction in fungal biomass by phenolic compounds (Boutigny et al. 2009; Kushalappa et al. unpublished data).

Proportion of DON Conversion (PDC = D3G/TDP) Even though RRI metabolites were not detected in our study, a resistance indicator (RI) metabolite, DON-3-*O*-glucoside, an enzymatic detoxification product of DON, by DON-

glucosyltransferase, was detected (Bollina et al. 2010). DON is a virulence factor, and a mutant lacking trichothecene/DON synthesis failed to spread within a spike, in wheat (Proctor et al. 1995). In our study, all six barley genotypes converted DON to D3G, and PDC was the highest by Zhedar-2 (Table 2). Higher conversion ratios of up to 9:1 (D3G/DON) have been reported for wheat recombinant inbred lines with QTL at 3BS, which is associated with resistance to expansion of lesion to spikelets within spike (Lemmens et al. 2005). It is possible that the reduction in TDP and increase in PDC, in lemma and palea of resistant genotypes, as reported here, can lead to reduced expansion of lesion to spikelets through rachis. The ratio of D3G/DON may not correctly identify the mechanisms of resistance, as the DON reduction can be due to both DON conversion to D3G and reduced synthesis (Boutigny et al. 2009).

Phenylpropanoid Pathway

Phenylalanine Phenylalanine, the precursor of the phenylpropanoid and flavonoid pathways, was detected as an RRC metabolite in Zhedar-1, Zhedar-2, and Harbin-2r. Although phenylalanine was not identified as an RR metabolite in our previous studies, several other metabolites related to the phenylalanine ammonia-lyase (PAL) pathway were (Bollina et al. 2010; Kumaraswamy et al. 2011). Although phenylalanine was detected in high amounts in Fredrickson, its level was not significantly different from that in the susceptible genotype. Two transcript-derived fragments TDF83 and TDF17 were strongly up-regulated upon *Fusarium* inoculation in FHB resistant genotypes, and both coded for phenylalanine ammonia-lyase (PAL) (Steiner et al. 2009).

p-Coumaric Acid This was identified as an RRC in Zhedar-2 (4.3×) and Fredrickson (3.1×). It was a PRr metabolite in CIho 4196 (2.8×). *p*-Coumaric acid was identified as an RRC and PRr in our previous studies (Bollina et al. 2010; Kumaraswamy et al. 2011). It inhibited the production of biomass by *F. graminearum* on solid media, with an LD_{50}= 2.5 mM (Kumaraswamy et al. 2011), and an LD_{50}=1.2 mM in liquid media (Bollina et al. 2010). It had a similar effect on both *F. graminearum* and *F. culmorum* at concentrations as low as 0.1 mg mL^{-1} *in vitro* (McKeehen et al. 1999). *p*-Coumaric acid accumulation also was associated with lignification of cell walls (Dixon 2001).

Flavonoid Pathway

Kaempferol Several kaempferol conjugates were identified as RRC metabolites, with up to 7.6× changes in abundance (Table 1). The number of kaempferol conjugates was the highest in Zhedar-2. These also were observed among RRC in our previous studies (Bollina et al. 2010). Naringenin, a precursor of kaempferol, was identified as an RRC metabolite in our previous studies (Bollina et al. 2010; Kumaraswamy et al. 2011). Flavonoids are synthesized in the downstream phenylpropanoid metabolic pathway. The LD_{50} concentration of kaempferol was 4.8 mM on *F. graminearum*, as compared to 1.6 mM for its precursor metabolite naringenin (Bollina et al. 2010). However, the former was not completely soluble in aqueous methanol, thus its conjugates must be tested. Two other flavonoids with high fold change were identified: quercetin 3-(6″-acetylglucoside) (7.7×) and triphyllin A (8.2×), but these metabolites failed to meet all the five criteria used here to select biomarkers.

Fatty Acid Pathway

Jasmonic Acid In this study, JA was identified as a PRr metabolite in all the five resistant genotypes. Even though it was not identified either as a RRC or as a RRI metabolite in this study (PRr not>PRs), it was considered here as a biomarker because of its importance as a signal molecule, especially in necrotrophic pathogenesis. Both JA and methyljasmonate (MeJA) were identified as PRr metabolites in our previous study, and the latter had LD_{50}=1.0 mM for inhibition of mycelial growth on solid media (Kumaraswamy et al. 2011). Plant oxylipins, such as JA and MeJA are synthesized from polyunsaturated fatty acids (Shah 2009). Jasmonic acid and MeJA are the major signaling molecules in establishing resistance against necrotrophic pathogens (Robert-Seilaniantz et al. 2007). In wheat–*F. graminearum* interactions, a total of 14 transcripts were up-regulated, and they were considered to either encode JA biosynthetic enzymes or respond to JA (Jia et al. 2009). Two proteins, ankyrin repeat protein and 12-oxo-phytodienoic acid reductase, related to this signaling pathway were induced 3 days after *F. graminearum* inoculation, in wheat (Zhou et al. 2006). CIho 4196, showed an increased abundance for PR-9 proteins, indicating the possible use of JA antioxidant signaling pathway in pathogen defense (Geddes et al. 2008), which agrees with the results observed in this study.

Linoleic and Linolenic Acids Zhedar-2 and Harbin-2r accumulated linolenic acid as an RRC metabolite. Linolenic acid, however, was also detected as a PRr metabolite in Fredrickson and CIho 4196. Linoleic acid, a precursor of linolenic acid, was identified as an RRC metabolite in Zhedar-1. Both linolenic and linoleic acids inhibited *F. graminearum in vitro* (LD_{50}=3.6 mM for both, based on solid media) (Kumaraswamy et al. 2011). Linolenic acid is

abundant in plasma membranes of wheat cells in the form of phospholipids (Li and Yen 2008), which serve as JA precursors. Linolenic acid can be released by the activities of a membrane-bound phospholipase, and then, oxidized to JA when the cells are under stress.

The potential biomarker metabolites for resistance in barley to *F. graminearum* established here can be used for screening barley genotypes for resistance against FHB, though further elucidation of the occurrence of these in other barley and wheat genotypes can better assess their suitability as biomarkers. Such studies also should identify more biomarkers, as in this study we failed to identify resistance-related induced metabolites, mainly because of high experimental error in spray inoculation. The monoisotopic accurate masses of these biomarkers can be selected in chromatography analyses to speed up the LC-hybrid-MS analysis and output process time. High throughput detection of several metabolites, based on direct infusion (metabolic fingerprinting), can be done in a few minutes. Alternatively, other cheaper tools such as HPLC can be standardized and used. Additionally, comprehensive proteomics can detect the enzymes involved in the biosynthesis of these biomarker metabolites, the sequence of which can be related to genes, which in turn, can be used in DNA marker assisted selections. Metabolic profiling tool, standardized here, can be applied to better understand mechanisms of multiple disease/stress resistance in plants.

UHPLC-ESI/TOFMS Determination of Salicylate-like Phenolic Gycosides in *Populus tremula* Leaves

Abstract Associations of salicylate-like phenolic glycosides (PGs) with biological activity have been reported in *Salix* and *Populus* trees, but only for a few compounds, and in relation to a limited number of herbivores. By considering the full diversity of PGs, we may improve our ability to recognize genotypes or chemotype groups and enhance our understanding of their ecological function. Here, we present a fast and efficient general method for salicylate determination in leaves of Eurasian aspen that uses ultra-high performance liquid chromatography-electrospray ionization/time-of-flight mass spectrometry (UHPLC-ESI/TOFMS). The time required for the liquid chromatography separations was 13.5 min per sample, compared to around 60 min per sample for most HPLC protocols. In leaf samples from identical *P. tremula* genotypes with diverse propagation and treatment histories, we identified nine PGs. We found the compound-specific mass chromatograms to be more informative than the UV-visible chromatograms for compound identification and when quantitating samples with large variability in PG content. Signature compounds previously reported for *P. tremoloides* (tremulacin, tremuloidin, salicin, and salicortin) always were present, and five PGs (2'-O-cinnamoyl-salicortin, 2'-O-acetyl-salicortin, 2'-O-acetyl-salicin, acetyl-tremulacin, and salicyloyl-salicin) were detected for the first time in *P. tremula*. By using information about the formic acid adduct that appeared for PGs in the LTQ-Orbitrap MS environment, novel compounds like acetyl-tremulacin could be tentatively identified without the use of standards. The novel PGs were consistently either present in genotypes regardless of propagation and damage treatment or were not detectable. In some genotypes, concentrations of 2'-O-acetyl-salicortin and 2'-O-cinnamoyl-salicortin were similar to levels of biologically active PGs in other Salicaceous trees. Our study suggests that we may expect a wide variation in PG content in aspen populations which is of interest both for studies of interactions with herbivores and for mapping population structure.

Key Words Eurasian aspen · PG · Salicylates · Salicinoids · Genotype recognition · Chemotyping · Diversity · Natural variation

Introduction

Phenolics are bioactive compounds in plants that play diverse roles including structural support of the cell wall, protection from UV irradiation, and defense from herbivory. These compounds derive from distinct branches of the

shikimate-phenylpropanoid pathway and include the lignins, flavonoids, anthocyanins, salicylate-like phenolic glycosides (PGs), and tannins. The biosynthesis of those phenolic classes that derive from *p*-coumaric acid are particularly well described and include monolignols (Sterky et al., 1998; Boerjan et al., 2003), flavonoids (Tsai et al., 2006; Chen et al., 2009), and condensed tannins (Tanner et al., 2003; Dixon et al., 2005). While PGs are suggested to branch from the shikimate-phenylpropanoid pathway "upstream" of *p*-coumaric acid at either chorismate or cinnamate, their biosynthesis remains poorly understood (Tsai et al., 2006; Morse et al., 2007; Chen et al., 2009; Babst et al., 2010).

Together with condensed tannins, PGs shape resistance against herbivores in the Salicaceous family, including trees of the genera *Populus* and *Salix* (Lindroth and Hwang, 1996; Orians et al., 1997; Albrectsen et al., 2007). In general, anti-insect toxicity appears to increase with the complexity of the PGs, in terms of their molecular weight and number of ring structures (Philippe and Bohlman, 2007).

PG profiles vary qualitatively among species but vary quantitatively within species (Palo, 1984; Julkunen-Tiitto, 1986; Greenaway et al., 1991; Orians et al., 1997). Aspen clones can be recognized by their relative PG contents across environments (Lindroth and Hwang, 1996; Mutikainen et al., 2000; Osier and Lindroth, 2006; Tsai et al., 2006; Donaldson and Lindroth, 2007; Chen et al., 2009). When compared to the entire metabolome, which appears to be both dynamic and diverse (Robinson et al., 2005, 2007), PGs are promising compounds for genotype recognition.

Eurasian aspen (*P. tremula*) is distributed widely across the Northern Hemisphere, and the European part of the population is characterized by a complex genetic structure (De Carvalho et al., 2010). In the Swedish aspen population (SwAsp) of 116 genotypes, this diversity is expressed by phenological variation in bud set and growth differences that mainly follow a latitudinal cline (Luquez et al., 2008). The latitudinal cline also is partly reflected in the distribution of the most abundant and persistent antagonists, rust (*Melampsora sp.*) and a mining moth (*Phyllocnistis labyrinthella*) (Albrectsen et al., 2010). However, the interaction between *P. tremula* and herbivores is poorly understood compared to that of *P. tremuloides* and its antagonists.

The description of PGs for Eurasian aspen has so far been built on information and methods developed for *P. tremuloides*, assuming similar PG profiles (Albrectsen et al., 2010). Advanced methods for chemical profiling increase our ability to explore the diversity and dynamics of defense compounds in plants. The purpose of the present study was to examine the PG profiles of *P. tremula* leaves, using liquid chromatography-mass spectrometry (LC-MS) in order to identify and quantify phenolic glycosides that occur at concentrations indicative of bioactivity. In addition, the study was designed to assess the reliability of this class of phenolic compounds as genotype indicators, and to evaluate their potential as markers to use in future studies of genetic structure and association with resistance traits as assessed through field surveys.

Methods and Materials

Chemicals Salicortin, salicyloyl-salicin, and tremuloidin standards were gifts from S.D. Mansfield (University of British Columbia, Canada), and 2'-O-cinnamoyl salicortin from C. Orians (Tufts University, MA, USA). Tremulacin and salicin were purchased from Sigma (St. Louis, MO, USA). We follow the nomenclature of Zapesochnaya et al. (2002), in which salicyloyl-salicin corresponds to salicoylsalicin according to Kammerer et al. (2005).

Plant Materials and Treatments All plants were *Populus tremula* L. genotypes from the SwAsp Collection (Luquez et al., 2008). The plants had various propagation and treatment histories since one aim of the analyses was to evaluate the robustness of the phenolic glycosides as genotype-specific markers.

For initial characterization and precision analyses, plants representing SwAsp genotypes 7, 13, 47, and 115 were selected. Clones of these genotypes were propagated directly from roots excavated in 2004. The plants were grown in a greenhouse in Umeå, Sweden under ambient conditions since 2005, and cut back so they were about 1 m in height in the fall of 2006. Bud flush occurred in March 2007. In May, when the trees were about 2 m tall, 10 mature leaves were harvested along a 1 m stem section from 2 trees representing each genotype. The harvested leaves were quick-frozen in liquid nitrogen, and stored at −80°C until LC-MS analysis.

Initial Genotypic Profiling For initial assessment of between-genotype differences in phenolic glycoside profiles, we used leaf material from SwAsp genotypes 5, 23, 36, 47, and 72 propagated as described above. We analyzed two biological replicates of each genotype and two technical replicates per plant.

Reliability of PGs for Genotyping To assess the reliability of phenolic glycosides as genotypic markers, we compared their profiles in damaged and undamaged plants. The plants used in this experiment included representatives of SwAsp genotypes 5, 23, 36, 47, 51, and 72, which had been propagated in MS tissue culture medium (Murashige and Skoog, 1962) since May 2007. After transfer to the greenhouse, and a month of acclimatization, on November 9th 2007 (at the height of 55.3±10.8 cm (SD), and with

15.8±3.2 leaves per plant), plants were randomly assigned to three treatments: simulated chewing damage; damage by aphids; and controls.

The aphid used in the experiment was *Chaitophorus populeti* (Panzer). In early September, individuals were collected on Umeå University campus from *Populus tremula*, where they aggregated with two other *Chaitophorus* species, probably *C. pentandrinus* (Ossiannilsson) and *C. vitellinae* (Schrank). Species were determined by Dr. Richa Raizada. Prior to the experiment, cultures of *C. populeti* were kept on aspen plants in the greenhouse where they rapidly developed and reproduced.

In *Populus*, orthostichous leaf positions are 5/10, 6/11 (Jones et al., 1993; Orians and Jones, 2001), i.e., vascular connections are shared between leaf positions 5 and 10, 6 and 11, and so on, with the first fully expanded leaf denoted as 'leaf 1'. The treatments involved punching multiple minute holes into leaves 11–16 (simulated damage treatment), or placing one reproductive female *C. populeti* per leaf (position 11–16, aphid treatment). After 96 h, six mature leaves above the experimental leaves (5–10) were harvested as described above. There were 2–3 biological replicates per genotype and treatment, and one technical replicate per plant (48 plants and samples in total).

Extraction Leaves were ground in a mortar kept frozen using liquid nitrogen, and the frozen powder from each sample (10–12 mg) was extracted by adding it to 1.00 ml of cold chloroform:methanol:H_2O (1:3:1) containing 7 ng/μl of [$^2H_6$]salicylic acid (Isotec, Miamisburg, OH, USA) as an internal standard. The mixture was agitated with a 3 mm tungsten carbide bead in a MM 301 Vibration Mill (Retsch GmbH and Co. KG, Haan, Germany) at 30 Hz for 3 min (Gullberg et al., 2004). To prevent contamination with tissue debris, extracts were centrifuged at 20,800 × *g* for 10 min at 4°C, and 200 μl of the supernatant were evaporated to dryness. The residue was dissolved in 10 μl cold methanol and diluted with 90 μl cold water containing 0.1% formic acid, prior to ultra high performance liquid chromatography (UHPLC)-electrospray ionization/time-of-flight mass spectrometry (ESI/TOFMS). A total sample extraction time of less than 2 h at 4°C, from thawing of leaf tissue to dried extract, was used to control decomposition of phenolic glycosides in the samples. Storage of solutions of the standard compounds at 4°C for this time period did not result in any decomposition of PGs.

UHPLC-TOFMS Analysis The PGs were analyzed by UHPLC-TOFMS using an Acquity™ system, equipped with a column oven (held at 40°C), a 2.1×100 mm, 1.7 μm C18 UPLC™ column and an Acquity photodiode array (PDA) detector coupled to an LCT Premier TOFMS (all from Waters, Milford, MA USA). The PGs in a 2 μl injection of each sample were separated with a mobile phase program consisting of 1–20% B over 0–4 min, 20–40% B (4–6 min), 40–95% B (6–9 min), 95% B (9–13.5 min). Solvent B was acetonitrile containing 0.1% formic acid, solvent A was H_2O containing 0.1% formic acid, and the flow rate was 500 μl min^{-1}. The eluate was passed through the PDA detector for scanning from 210 to 400 nm, at a sampling rate of 20 points s^{-1} and resolution of 1.2 nm, and then directly into the ESI source. The source temperature was 120°C, cone gas flow 10 l h^{-1}, desolvation temperature 320°C, nebulization gas flow 600 lh^{-1}, and the capillary and cone voltages were set at 2.5 kV (negative ionization mode) and 35 V, respectively. Data were acquired, in dynamic range enhancement (DRE) mode, every 0.1 s, with a 0.01 s interscan delay. Leucine enkephalin was the lock mass compound for accurate mass measurements, infused directly at 400 pg μl^{-1} in 50:50 acetonitrile:H_2O at 20 μl min^{-1}. The normal lock mass in DRE mode was the negative ^{13}C ion of leucine enkephalin (*m/z* 555.2654), and the extended lock mass was the normal negative ion at *m/z* 554.2620. Mass spectra were acquired in centroid mode, *m/z* 100–1000, with a data threshold value set to 3. In a complementary experiment, in-source fragmentation was increased by increasing the aperture 1 voltage from 5 to 45 V to exclude adduct ion formation.

Profiling–Data Processing The UHPLC-ESI/TOFMS instruments were operated with MassLynx™ v. 4.1 software (Waters, Milford, MA, USA), and the QuanLynx module of this package was used to assess relative amounts of phenolic glycosides by calculating peak areas from both mass chromatograms (see Table 1, ESI-MS *m/z* with 0.10 Da mass windows), and specific wavelength chromatograms using the compound-specific UV λ_{max} values (Table 1). The peak areas were normalized against that of the internal standard salicylic acid (M = [$C_7H_2{}^2H_4O_3$], RT = 5.01 min, *m/z* 141.0495, 187.0550, and 305.0883 for the $[M\text{-}H]^-$, $[M\text{-}H + HCOOH]^-$ and $[M_2{-}2H + Na]^-$ ions, respectively; λ_{max} 231 and 305 nm), as well as the mass of tissue used for extraction.

Phenolic Glycoside Structural Identification (UHPLC-LTQ/Orbitrap) To elucidate the structures of the compounds, they were separated by a Thermo Accela LC system, equipped with a column oven (held at 40°C) and a Hypersil C18 GOLD™ column (2.1×50 mm, 1.9 μm; mobile phase as for the UHPLC-ESI/TOFMS) and analyzed by tandem mass spectrometry using a LTQ/Orbitrap mass spectrometer (Thermo Fisher Scientific, Bremen, Germany). Centroid mass spectra of negative ions were collected in the Orbitrap mass analyzer, with a target mass resolution of 30,000 (full width at half maximum peak height, defined at *m/z* 400), after collision-induced dissociation (CID) in the LTQ cell,

Table 1 Salicylate-like phenolic glycosides in *Populus tremula* leaf extract identified by retention time (RT), electrospray ionization mass spectrometry (ESI-MS) and photodiode array detector (UV)

Name	Molecular formula	RT (min)	Theoretical *m/z* $(M-H)^-$; $(M-H+HCOOH)^-$	ESI-MS	[m/z]	UV λmax[a] (nm)
Salicin	$C_{13}H_{18}O_7$	2.37	285.0980; 331.1035	331.110[b](+20 ppm)	[285.12] [c]	212, 267[d]
2'-O-acetyl-salicin	$C_{15}H_{20}O_8$	3.73	327.1085; 373.1140	373.123 (+24 ppm)	[327.11]	212, 269
Salicortin	$C_{20}H_{24}O_{10}$	4.55	423.1297; 469.1351	469.175 (+85 ppm)	[423.13]	216, 270[d]
2'-O-acetyl-salicortin	$C_{22}H_{26}O_{11}$	5.45	465.1402; 511.1457	511.185 (+77 ppm)	[465.14]	213, 269
Tremuloidin	$C_{20}H_{22}O_8$	5.72	389.1242; 435.1297	435.169 (+90 ppm)	[389.13]	219, 270[d]
Salicyloyl-salicin	$C_{20}H_{22}O_9$	6.37	405.1191; 451.1246	405.164(+101) + 451.170(+111)		240, 270, 304[d]
Tremulacin	$C_{27}H_{28}O_{11}$	6.48	527.1559; 573.1614	573.199 (+66 ppm)	[527.16]	220, 270[d]

Acetyl-tremulacin	$C_{29}H_{30}O_{12}$	7.04	569.1665; 615.1719	615.182 (+16 ppm)	[569.18]	221, 272

a = λmax in UV spectrum from the PDA detector

b = compound mass detected in MS spectrum of plant extract (aperture 1 = 5 V), average *m/z* from 10 samples; with mass accuracy expressed in ppm (in parenthesis)

c = additional *m/z* detected with increased in-source dissociation (aperture 1 = 45 V), average *m/z* from 3 samples

d = data from standard compound

using a normalized collision energy of 20%. External mass calibration was performed according to the manufacturer's guidelines.

Analytical Precision To assess the precision of the analyses, 5 samples of leaves of each of 2 genotypes (7 and 115) were extracted, and part of each extract was analyzed in parallel, while the other parts were pooled by genotype. To test for methodical errors, the pooled extracts were each divided into 10 microvials, and analyzed by UHPLC-PDA-ESI/TOFMS. In addition, 5 repeat injections from 1 individual microvial were performed to determine injection and instrumentation errors. To check for retention time and mass accuracy throughout the experiment, a standard mix consisting of 5 standards (salicin, chlorogenic acid, rutin, nalidixic acid, and phloretin), each at 50 μM in 50% acetonitrile, was injected after every ten injections.

Concentration Determination Standards of various concentrations (0.5 ng–10 μg injected) were analyzed by UHPLC-PDA-ESI/TOFMS as described above, and the peak areas from the resulting mass chromatograms were used to construct calibration curves.

Statistical Analysis Multivariate analysis of PG profiles was performed using principal component analysis (PCA), with unit variance scaling, in SIMCA-P+ v. 12.0 (Umetrics AB, Umeå, Sweden). Relative standard deviations (RSD) were measured for reproducibility and RSD in the Umetrics software equals the coefficient of variation (CV).

Results

Identification With LC-ESI/TOFMS operating in negative ionization mode, we identified nine salicylate-like phenolic glycosides in *P. tremula* leaves: salicin, salicortin, tremuloidin, tremulacin, 2'-O-acetyl-salicin, 2'-O-acetyl-salicortin, salicyloyl-salicin, 2'-O-cinnamoyl-salicortin, and acetyl-tremulacin (Fig. 1, Table 1). The identifications were based on comparisons of the LC-retention times, UV spectra, and accurate masses of the compounds detected in the extracts with those of standards (Table 1). These nine phenolic glycosides were baseline-separated by the LC (Fig. 2a), and they constituted some of the most intense peaks in the total ion chromatograms, suggesting that they occurred in high concentrations (Fig. 2b).

Phenolic glycosides are aromatic, and thus can be detected by monitoring UV absorbance. The summed PDA absorbance (UV) chromatograms (Fig. 2c) had fewer peaks than the total ion chromatograms acquired by TOFMS (Fig. 2b). However, the peaks that were detected displayed characteristic absorbance spectra of phenolic glycosides, with two UV peaks (Fig. 2c insert and Table 1), one at about 215–220 nm (but 240 nm for salicyloyl-salicin), and a weaker one at 270 nm. Either wavelength could be used for quantification (Table 2).

A drawback of using ESI-MS is the formation of adducts. With the ESI/TOFMS instrument used in these analysis, adducts with acetonitrile, formic acid and/or sodium ion have been detected in the negative ionization mode, and ammonium adducts found in the positive mode. For all of the phenolic glycosides, the mass spectra showed a base peak of the deprotonated molecular ion as a formic

acid adduct $[M\text{-}H + HCOOH]^-$, presumably arising from combination with the formic acid present in the LC mobile phase. The intensity of the unmodified molecular ion was very low (Fig. 2b insert and Table 1) for the PGs, except for salicyloyl-salicin in the samples as well as in pure standards. In the complementary analysis with increased in-source dissociation in the ESI/TOFMS, the deprotonated molecular ion and the formic acid adduct were both present, confirming the phenolic glycoside masses.

The initial identifications of the three novel acetylated phenolic glycosides were based on their masses and absorbance spectra. To verify their identities, the extracts also were analyzed by LC-MS/MS using an LTQ/Orbitrap system (Hu et al., 2005; Makarov et al., 2006) (Fig. 3, Suppl. Fig. S1) and structural identification of the novel phenolic glycosides was obtained from the fragmentation patterns. The ESI system of this instrument also generated formic acid adducts, but it yielded deprotonated, unmodified ions at higher intensities, and the latter were preferentially selected by mass for the MS/MS analysis. Utilizing the high mass accuracy of the Orbitrap MS, the elemental compositions of these phenolic glycosides confirmed that they consisted of acetylated versions of salicin, salicortin, and tremulacin. The acetyl-salicortin (Fig. 3b) fragments were similar to those from salicortin (Suppl. Fig. S1d; Kammerer et al., 2005), with several fragments that increased by 42 Da in the acetyl-salicortin spectrum. Therefore, we concluded that the acetyl group was attached to the glucose moiety of the salicortin. Similar conclusions were drawn for acetyl-salicin (Fig. 3a) and acetyl-tremulacin (Fig. 3e). The characteristics of the UV spectra, as well as the slightly longer retention times compared to those of the non-acetylated phenolic glycosides (Table 1), corroborated our structural assignment. We suggest that the acetyl group of acetyl-tremulacin is bonded to the 6'-O of the glucose ring, since this seems to be the second most reactive position, as in diacetyl-salicortin (Ruuhola et al., 2003; Ruuhola and Julkunen-Tiitto, 2003). We propose that the 2'-O position is occupied by the benzoyl moiety in tremulacin, and that the acetyl groups of acetyl-salicin and acetyl-salicortin occupy the 2'-O-positions of salicin and salicortin, as found in willows (Ruuhola and Julkunen-Tiitto, 2000).

Since the PDA detector was connected between the LC-column and the TOFMS, the retention time was *ca.* 0.3 min shorter than in MS detection. *Asterisks* indicate peaks corresponding to phenolic glycosides. The LC-retention times are indicated

Method Reproducibility To validate the UHPLC-PDA-ESI/TOFMS method for analyzing phenolic glycosides we used it to analyze multiple sub-samples from the same (pooled) extract. The reproducibility was within acceptable ranges for detectable peaks with RSDs, of 4–7% for UV detection, and 6–12% for MS detection (Table 2). Sequential injections from the same microvial showed little variation, with RSDs as low as <2% for UV, and 1–5% for MS quantification (Table 2), indicating little instrumental variation. Parallel extractions from subsamples of the same plant tissue were performed to explore the reproducibility of all steps in the analysis, and resulted in somewhat higher variations (Table 2).

Phenolic Glycoside Concentrations Six standards (salicin, salicortin, tremuloidin, salicyloyl-salicin, tremulacin, and 2'-O-cinnamoyl-salicortin) at various concentrations were analyzed by UHPLC-PDA-ESI/TOFMS, and the calibration curves obtained from the resulting mass chromatograms were used for quantification. The UV and MS detection limits for individual phenolic glycosides varied (Table 3), but mass spectrometry could generally detect lower concentrations. Therefore, UV detection may not be optimal when screening several genotypes with highly variable phenolic glycoside concentrations. In such cases, MS detection may be more suitable for quantification, at the expense of somewhat lower reproducibility (Table 2).

Phenolic glycosides concentrations were calculated per unit mass of leaf powder (Table 3). Salicin was found at 0.5–2.4 μg mg^{-1} and tremulacin at 0.1–4.0 μg mg^{-1}, depending on the genotype. These levels are comparable to concentrations found in *P. tremuloides* (Lindroth and Hwang, 1996; Robinson et al., 2005; Harding et al., 2009). In some genotypes, 2'-O-cinnamoyl-salicortin was detected in concentrations up to 2.1 μg mg^{-1}, which is within the range of 0.75–5.6 μg mg^{-1} found in *Salix sericea* (Orians and Fritz, 1995). In other genotypes, this compound was below the detection limit of about 0.25 μg/mg tissue. Salicortin, tremuloidin, and salicyloyl-salicin were found within ranges of 1.8–6.9, 0.1–1.1, and 0–0.12 μg mg^{-1}, respectively. Preliminary calculations based on the assumption that concentration/signal intensity ratios

were similar to the corresponding unacetylated compounds suggest that acetyl-salicin, acetyl-salicortin, and acetyl-tremulacin were present at concentrations ranging from 0 to 1.9, 0 to 2.9, and 0 to 0.2 μg mg^{-1}, respectively.

Phenolic Glycosides as Genotype-Specific Markers PCA of the data acquired in the initial assessment of between-genotype differences in phenolic glycoside profiles suggests that the five tested genotypes clustered into three distinct chemotype-groups (score plot, Fig. 4a and Fig. S3) and that the nine phenolic glycosides all contributed to this pattern (loadings, Fig. 4a). The PCA model showed two significant components, explaining 81% of the variation in the data [R^2X(cum) = 0.812; Q^2(cum) = 0.565]. Variations in contents of 2'-O-cinnamoyl-salicortin, the acetylated phenolic glycosides, and to some extent tremulacin and tremuloidin were largely responsible for separating the genotypes along the first principal component axis (PC1).

Analysis of the phenolic glycoside profiles of representatives of an overlapping set of genotypes, following varying propagation and stress treatments, suggested a similar pattern; six genotypes formed two distinct clusters or chemotype-groups (Fig. 4b-I). One chemotype-group included three separate genotypes (47, 51, and 72) that contained acetylated phenolic glycosides, while the other included three genotypes (5, 23, 36) characterized by the presence of 2'-O-cinnamoyl-salicortin (Fig. 4b-I). Again, all

phenolic glycosides contributed to the clustering of the genotypes (loadings, Fig. 4b), although 2'-O-cinnamoyl-salicortin had the heaviest loading on the first axis (PC1). Since PCA did not detect any treatment effects (Fig. 4b-II), the phenolic glycosides appear to be potentially robust chemotype group markers and, to some extent genotype markers in *P. tremula*. The PCA model constructed from the data acquired from the analyses of samples of plants subjected to various treatments had four significant principal components, which together explained 96% of the variation in the data [R^2X(cum) = 0.955; Q^2(cum) = 0.831].

The consistent separation into chemotype-groups in the two data sets (Fig. 4a and b) was confirmed by studies of separate profiles for each plant and phenolic glycoside compound (Suppl. Fig. S2, showing normalized data obtained in the PG consistency analysis). Depending on the genotype, the phenolic glycosides 2'-O-acetyl-salicin, 2'-O-acetyl-salicortin, 2'-O-cinnamoyl-salicortin, and acetyl-tremulacin, were either consistently present in substantial amounts, or consistently below the detection limit. The structural similarities of the compounds that contributed significantly to the patterns detected in the multivariate analyses are indicated in the loading plot (Suppl. Fig. S3).

Discussion

Nine phenolic glycosides were found by UHPLC-ESI/TOFMS in extracts of European aspen (*P. tremula*) leaves. Salicin, salicortin, tremuloidin, and tremulacin were present in all tested genotypes, in agreement with the "signature" phenolic glycosides reported for *P. tremuloides* (Lindroth and Hwang, 1996; Harding et al., 2009). Salicyloyl-salicin also was found in most extracts. In addition, some genotypes contained considerable amounts of 2'-O-acetyl-salicin, 2'-O-acetyl-salicortin, 2'-O-cinnamoyl-salicortin, and/or acetyl-tremulacin, which have not been described previously in either *P. tremula* or *P. tremuloides*.

Strengths of UHPLC-MS A TOFMS instrument is suitable for identifying phenolics, when standard compounds are available, but it has limited utility for identifying novel compounds, since structural elucidations require MS/MS analysis for identification and confirmation. For this purpose, the high mass-accuracy LTQ/Orbitrap instrument was used here, although other MS/MS compatible instruments could have been used with equally good results. Selected reaction monitoring (SRM) methods using an instrument such as triple quadrupole (QQQ) might also have been used for quantification purposes, but would require prior knowledge about compound masses. Well established HPLC protocols take 40 to 60 min per sample to analyze phenolic glycosides (Ruuhola et al., 2003; Ruuhola and Julkunen-Tiitto, 2003; Warren et al., 2003). However, by using ultra high performance liquid chromatography (UHPLC), the analyses are faster and the resolution is better, resulting in higher precision. The methodology for phenolic glycosides presented here reduced the time required for the liquid chromatography separations to just 13.5 min.

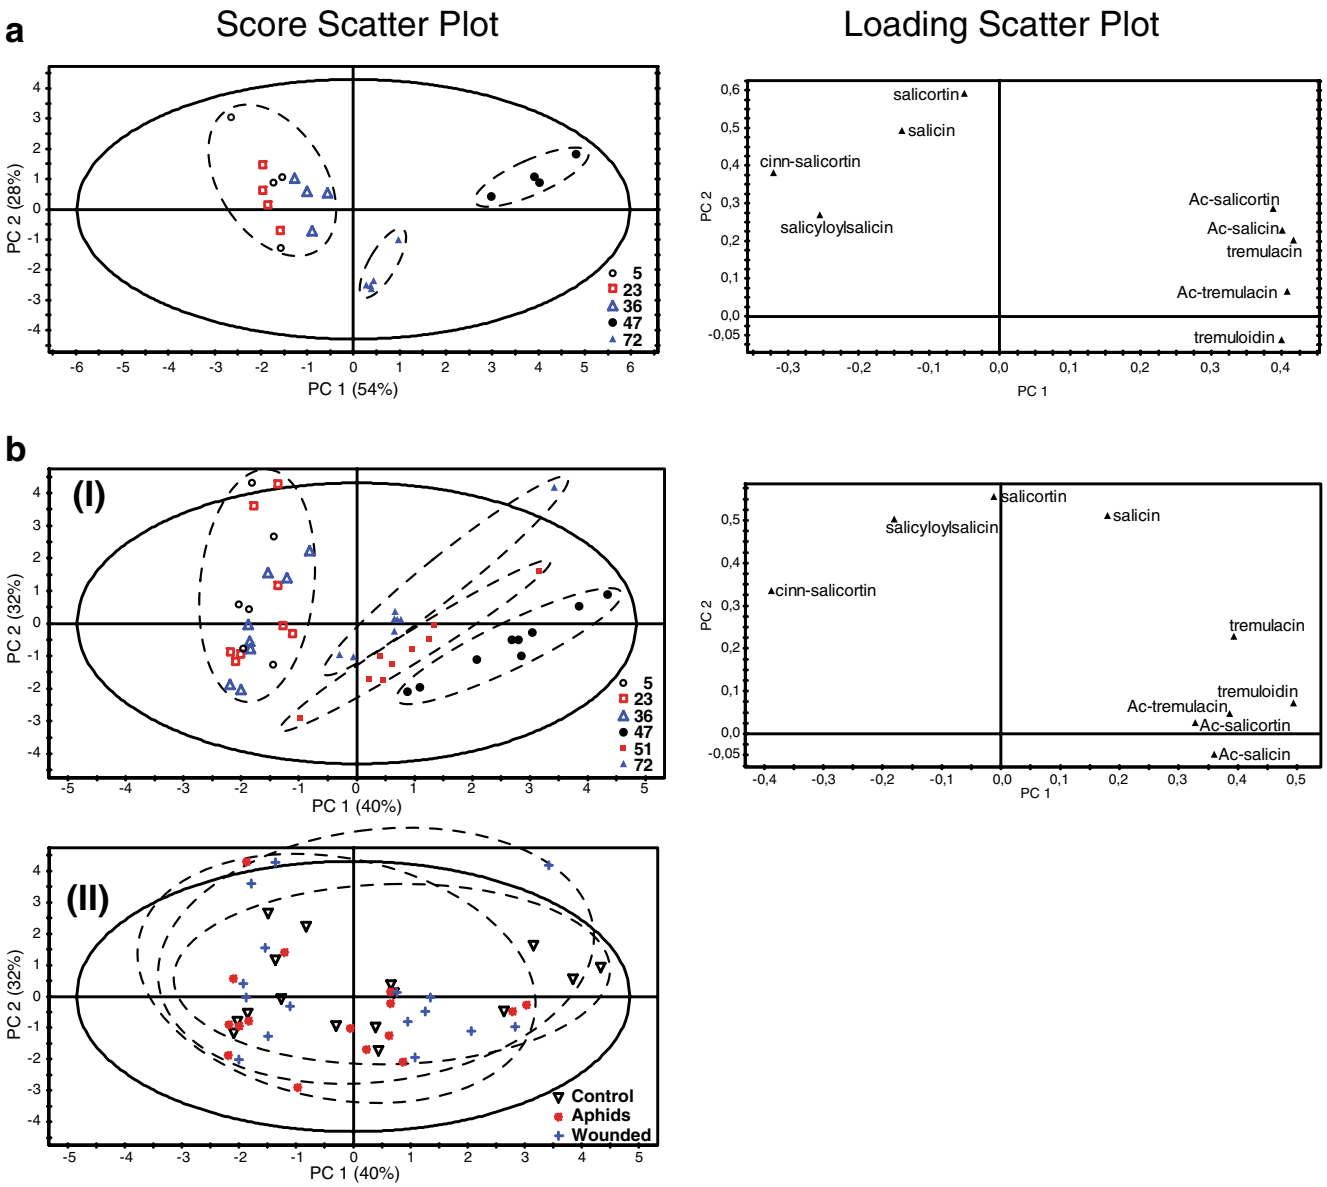

Fig. 4 Multivariate analysis of phenolic glycoside profiles of *Populus tremula* genotypes from the SwAsp collection. **a** PCA score plot (PC1 versus PC2) of data acquired from analyses of samples of greenhouse-grown plants representing five genotypes (5, 23, 36, 47, and 72), with data marked by genotype, and the corresponding loading plot. **b** Corresponding plots of data acquired from analyses of plants representing six genotypes (5, 23, 36, 47, 51, and 72) exposed to three treatments: simulated damage (= wounded), aphid infestation and controls, with data coded by (I) genotype, and (II) treatment. *Solid circles* show 95% Hotelling T^2 confidence regions, and *dashed circles* indicate chemotype-groups (in a, b-I), and treatment groups (in b-II)

Our results also showed the limitation of detection by UV, in comparison to MS. Although UV detection generally provided the best reproducibility for individual phenolic glycosides, it is less sensitive than MS for phenolic glycosides. When large numbers of samples with variable concentrations are to be analyzed, MS measurements are more suitable, since they can cope with a wider range of concentrations. In addition, an extracted mass chromatogram is more compound specific than an extracted UV-visible chromatogram; in the latter, contributions from coeluting compounds are harder to distinguish and might affect the quantification. Hence, the TOF and Orbitrap MS analysis was essential for characterizing the phenolic glycosides in the aspen leaf extracts. Depending on the objective, less powerful MS systems might be sufficient, although a rapidly scanning instrument is highly advantageous for collecting many data points over each chromatographic elution peak. While in recent years hundreds of UHPLC-base methods have been published for analyzing various classes of metabolites, this is the first method for phenolic glycoside analysis to date.

Can Phenolic Glycoside Profiles Be Used to Characterise Populus-Genotypes? Multivariate (PCA) analysis of the PG profiles clustered the genotypes into similar groups, regardless of the treatments applied (Fig. 4). Hence, the phenolic glycosides provided a means for recognizing chemotype groups of *P. tremula* across treatments. Salicin, salicortin, tremuloidin, and tremulacin were present in all samples and varied with genotype. These four compounds are well-known to vary quantitatively with *P. tremuloides* genotype (Lindroth and Hwang, 1996; Harding et al., 2009). In contrast, the five novel phenolic glycosides in *P. tremula* followed a discrete pattern of presence or absence in a given genotype. Moreover, when present, the novel compounds also varied in quantity in a genotypic specific pattern, and contents of 2'-O-cinnamoyl-salicortin, and the acetylated phenolic glycosides were largely responsible for separating the genotypes along the first principal component axis. (for profiles of particular phenolic glycosides see progeny data provided in Suppl. Fig. S2). The pattern of appearance of these novel phenolic glycosides suggests that they are potential Mendelian traits i.e., traits controlled by a single loci. Such traits are promising for studies of both herbivore resistance and genetic structure. Populations of *P. tremula* are polymorphic, and thus genetically highly variable for several growth traits (Ingvarsson, 2005; De Carvalho et al., 2010), many of which do not follow simple Mendelian inheritance (Luquez et al., 2008). The novel phenolic glycosides not only confirm that aspens in Sweden may constitute a complex genetic composition, but also offer new traits that may be helpful in understanding the population structure of Eurasian aspen.

Can We Expect to Find Other PGs in P. tremula? Novel phenolic glycosides were detected by identifying compounds with salicylate-like UV-spectra combined with LC-ESI/TOFMS-analysis. Peaks that had similarities to known phenolic glycosides were analyzed further by LTQ-Orbitrap MS, resulting in accurate mass determination, and tandem mass spectra for structural interpretation. At the population level, there may be more salicylate-like phenolic compounds to discover in *P. tremula*, and only careful survey of a larger number of genotypes will provide a comprehensive list of compounds. Many salicylate-like phenolic glycosides have been described in Salicaceous species (Ruuhola and Julkunen-Tiitto, 2000, 2003; Kammerer et al., 2005; Tsai et al., 2006), and although we can exclude the possibility that additional PGs were present in the major peaks in the samples that we screened, more genotypes should be screened to obtain information about their diversity at stand and population levels. In the samples examined in this study, the phenolic glycosides always were associated with formic acid under our LC-MS conditions, which led to the detection of acetyl-tremulacin. Thus, assuming that an acetylated tremuloidin compound would also associate with formic acid, we specifically searched for such a compound (using *m/z* 431.1348 and 477.1402 for the compound with and without a formic acid adduct) and concluded it was not present in our samples in detectable amounts.

Implications of PG Diversity Biosynthetic routes of the salicylate-like phenolic glycosides have proven less easy to elucidate compared to those for flavonoids (Tsai et al., 2006; Chen et al., 2009; Babst et al., 2010). On the basis of correlated patterns in the loading plots (Fig. 4), the biosynthesis of acetylated phenolic glycosides appear related to that of non-acetylated molecules with similar structures (Fig. 1), thus supporting conclusions drawn by Ruuhola and Julkunen-Tiitto (2003). Moreover, some phenolic glycosides might be metabolically interconverted (Ruuhola and Julkunen-Tiitto, 2003; Babst et al., 2010), a possibility which would agree with the close correlation between salicin and salicortin in our loading plots. Salicin and salicortin appear on the second principal component axis in the PCA plots, rather than the first component, which is responsible for the main separation among genotypes, providing further support for a dynamic interrelationship between salicin and salicortin.

Phenolic glycosides have well-established biological activities and utility for distinguishing among genotypes within and among species. Salicortin and tremulacin, for example, are associated with resistance to defoliating insect herbivores in *P. tremuloides* (Hemming and Lindroth, 1995; Osier and Lindroth, 2006; Donaldson and Lindroth, 2007; Wimp et al., 2007), while salicortin and 2'-O-cinnamoyl-salicortin are associated with resistance to a range of herbivores within the North American *Salix sericea* × *eriocephala* hybrid complex (Orians et al., 1997). Diverse phenolic glycoside composition also has been identified in Finnish and Swedish *Salix* spp., including 2'-O-acetyl-salicin and 2'-O-acetyl-salicortin in *S. pentandra* (Ruuhola and Julkunen-Tiitto, 2003); although in these species, the relationships between specific compounds and biological activities appear to be complex or non-existent, thus highlighting the ambiguous ecological functions of phenolic glycosides (Hjältén et al., 2007; Witzell and Martin, 2008; Albrectsen et al., 2010).

Compared to other Salicaceous study systems, we have little information regarding biological activity of phenolic glycosides in *P. tremula*. Generally, the intra-specific diversity expressed in the modest number of genotypes in the present study suggests that the phenolic glycoside composition of *P. tremula* is more complex than that of *P. tremuloides*. Given the great differences in damage regimes in the two aspen species and the defensive role that phenolic glycosides often play against various pests, the

differences in distribution of defense compounds, warrant further attention. Hence, a detailed comparative survey of phenolic glycoside diversity at population level in North American and Eurasian aspen may help to elucidate their ecological function.

Abstract Pale swallow-wort (*Vincetoxicum rossicum*) and black swallow-wort (*V. nigrum*) are two emerging invasive plant species in the northeastern United States and southeastern Canada that have shown rapid population expansion over the past 20 years. Using bioassay-guided fractionation, the known phytochemical phenanthroindolizidine alkaloid, (−)-antofine, was identified as a potent phytotoxin in roots, leaves, and seeds of both swallow-wort species. In seedling bioassays, (−)-antofine, at μM concentrations, resulted in greatly reduced root growth of *Asclepias tuberosa, A. syriaca,* and *Apocynum cannabinum*, three related, native plant species typically found in habitats where large stands of swallow-wort are present. In contrast, antofine exhibited moderate activity against lettuce, and it had little effect on germination and root growth of either black or pale swallow-wort. In disk diffusion assays, antifungal activity was observed at 10 μg and 100 μg, while antibacterial activity was seen only at the higher level. Although both swallow-wort species display multiple growth and reproductive characteristics that may play an important role in their invasiveness, the presence of the highly bioactive phytochemical (−)-antofine in root and seed tissues indicates a potential allelopathic role in swallow-worts' invasiveness.

Key Words Antofine · Phytotoxin · Swallow-worts · *Vincetoxicum* · *Cynanchum* · Allelopathy · Invasiveness · Allelopathic potential

Introduction

Two emerging invasive plant species in the northeastern United States and southeastern Canada are pale swallow-wort [*Vincetoxicum rossicum* (Kleopow) Barbarich = *Cynanchum rossicum* (Kleopow) Borhidi] and black swallow−wort [*V. nigrum* (L.) Moench = *C. louiseae* Kartesz & Gandhi]. Both exist as herbaceous, perennial, twining vines and are related to milkweeds (Apocynaceae, subfamily Asclepiadoideae). Pale swallow-wort is native to the Ukraine and European Russia and possesses pink to maroon flowers, whereas black swallow-wort is native to southwestern Europe and bears dark purple to black flowers (Markgraf, 1972). These species were introduced into North America, probably as ornamentals, in the mid- to late-1800s, but not until the 1970's were concerns raised about the invasive potential of swallow-worts (Pringle, 1973). The last 20 years have seen a rapid expansion of both species (Lawler, 2000; DiTommaso et al., 2005b), which are currently reported in 21 U.S. states from New England to Maryland and west to Nebraska and Kansas, with an additional report from California, and the Canadian provinces of Ontario and Quebec (Kartesz, 1999; DiTommaso et al., 2005b; USDA 2009). The primary infestations are in New England, New York, and Ontario, and both species are listed as noxious weeds or prohibited invasive species in Vermont, New Hampshire, Massachusetts, and Connecticut (USDA 2009).

Both pale and black swallow-wort have multiple growth and reproductive characteristics that may play a role in their invasiveness. Swallow-wort vines can grow 1–2 m or more during the growing season, producing dense, tangled masses of vines that climb up and over supporting vegetation (Christensen, 1998; Douglass et al., 2009). Stand densities can average 134 stems per m^2 and 1800

seedlings per m^2 (Smith et al., 2006). Large stands reportedly exclude most other vegetation, including the related milkweeds, and are encroaching on at least five threatened or endangered species in New York and New England and on the globally-rare alvar communities in Ontario and New York (Haribal and Renwick, 1998; Lawler, 2000; Tewksbury et al., 2002; Douglass et al., 2009). Perennating buds produced on the rootstock give rise to one or more herbaceous stems in the spring, and additional buds will sprout if stems are damaged (DiTommaso et al., 2005b). Flowering is indeterminate, extending from mid-May into August, and seeds bear an apical tuft of hairs, which aids in long-distance dispersal (Ladd and Cappuccino, 2005). Both swallow-wort species are self-compatible and can self-pollinate or are cross-pollinated by insects (Lumer and Yost, 1995; St. Denis and Cappuccino, 2004). Seed production can be prolific in high-light environments—around 32,000 seeds per m^2 for high density stands of pale swallow-wort, and seeds are polyembryonic, containing 1–8 embryos (Cappuccino, 2004; DiTommaso et al., 2005a; Smith et al., 2006). Polyembryony may contribute to enhanced seedling establishment and survival rates, which can be over 50% for pale swallow-wort (DiTommaso et al., 2005a; Ladd and Cappuccino, 2005; Hotchkiss et al., 2008). Both species are drought tolerant and can grow in soils of a wide range of pH (DiTommaso et al., 2005b; Magidow et al., 2008). Pale swallow-wort also is shade tolerant, although in heavily shaded areas, little reproduction by seed occurs (Smith et al., 2006; Hotchkiss et al., 2008).

What is not clear is whether allelopathy also plays a role in the invasiveness of swallow-wort. Members of the Apocynaceae (including the Asclepiadoideae) are regarded as poisonous to humans and other mammals (Wiegrebe et al., 1970; Haznagy and Toth, 1973; Haeggstrom, 1990). In North America, swallow-wort plants sustain minimal damage from herbivory, as deer rarely browse them and few arthropod herbivores feed on them (Christensen, 1998; DiTommaso et al., 2005b; Ernst and Cappuccino, 2005; Milbrath, 2010).

Phenanthroindolizidine alkaloids, primarily (−)-antofine and antofine oxide, as well as several less abundant derivatives, have been isolated from the roots and aerial parts of *V. hirundinaria* Medik. (Wiegrebe et al., 1969; Lavault et al., 1994; Staerk et al., 2000; Staerk et al., 2002). (−)-Antofine also has been reported from root tissues of *V. pumilum* Dcne. (Staerk et al., 2005) and the aerial parts of black swallow-wort (Capo and Saa, 1989). (−)-Antofine and its derivatives, including antofine oxide, possess antifungal, antibacterial, and cytotoxic activity due to potent inhibition of protein and nucleic acid synthesis and G2/M cell cycle arrest (Ferenczy et al., 1965/1966; Rao and Venkatachalam, 2000; Staerk et al., 2002; LEE et al., 2003). Root extracts of pale swallow-wort have phytotoxic and antifungal properties (Cappuccino, 2004); antofine was identified as the antimicrobial agent, while the component(s) responsible for phytotoxic or antifeedant activity has not been identified (Mogg et al., 2008). Similar phytotoxic effects of both root exudates and tissue leachates from pale and black swallow-wort on lettuce and butterfly milkweed root growth recently have been reported (Douglass et al., 2011).

We undertook this study to determine if specific phytochemical constituents from the swallow-worts possess phytotoxic activity, a necessary step to evaluate whether allelopathy could play a role in swallow-worts' ability to displace native plant species in the environment. We herein report that the known phytochemical antofine is present in root, shoot, and leaf, and seed extracts of both pale and black swallow-wort, and that it has significant phytotoxicity against some related native plant species with little effect against pale or black swallow-wort germination and root development.

Methods and Materials

Plant Material Five plants of pale swallow-wort were excavated from Robert G. Wehle State Park, Jefferson Co., New York, in May 2005, and placed into a cooler for transport to the laboratory where the roots (with stems attached) were rinsed in several volumes of water to remove remaining soil. After removal of the stem and crown area, roots were weighed, frozen at −20°C, and then lyophilized to dryness and stored at −20°C until extracted. Rootstocks of black swallow-wort were excavated from Bear Mountain State Park, Rockland Co., New York, in September 2005. They were held under refrigeration until January 2006 and then grown in a greenhouse for 4 mo until being harvested and prepared as noted above. For seed extractions, pale swallow-wort seed was collected in August 2008 from fields in Great Gully Preserve, (Cayuga Co.), New York, and black swallow-wort seed was collected in August 2008 from fields in Bear Mountain State Park, (Rockland Co.), New York. After pods were dried and crushed to release seeds, the majority of pod and pappus materials were removed by hand vacuum, and then seeds were sieved using mesh sizes of 30/64″, 25/64″, 19/64″, 15/64″, 11/64″, 9/64″, 7/64″, and 5/64.″ Filled pale swallow-wort seed was collected on the 7/64″ sieve, while filled black swallow-wort seed was collected on the 11/64″ and 9/64″ sieves. Cleaned seeds were stored at 4°C until use.

Seed Collections for Laboratory Bioassays For initial tests of phytotoxicity from crude swallow-wort extracts, seeds were obtained from the following sources: lettuce (*Lactuca sativa* L. cv. black-seeded Simpson) from a local gardener's supply store; black swallow-wort, Bear Mountain State

Park, Rockland Co., New York, summer 2005; pale swallow-wort, Great Gully Preserve, Cayuga Co., New York, summer 2005; *Asclepias syriaca* L. (common milkweed), Great Gully Preserve, Cayuga Co., New York, fall 2005; *Asclepias tuberosa* L. (butterfly milkweed), Clark Reservation State Park, Jamesville, Onondaga Co., New York, fall 2005; *Apocynum cannabinum* L. (Indianhemp), Great Gully Preserve, Cayuga Co., New York, fall 2005.

For phytotoxicity tests with purified antofine, seeds were obtained from the following sources: black swallow-wort, Bear Mountain State Park, Rockland Co., New York, fall 2008; pale swallow–wort, Great Gully Preserve, Cayuga Co., New York, fall 2008; *A. syriaca*, Everwilde Farms, Inc., Bloomer, WI, USA; *A. tuberosa*, Everwilde Farms, Inc., Bloomer, WI, USA; *A. cannabinum*, Great Gully Preserve, Cayuga Co., New York, fall 2008.

All seed, except lettuce, was air-dried, cleaned, and stored dry in sealed containers under refrigeration (4°C) for approximately 2 mo prior to stratification. To stratify seed for bioassays, approximately 5 g of seeds were wrapped in moist, brown paper toweling, and then stored in sealed glass jars with rubber gaskets or sealed petri dishes for 2–3 mo at 4°C.

Seedling Root Growth Bioassay Solutions were applied in 1.0 ml methanol to evenly coat the bottom of 10×10 cm square Petri plates. After solvent evaporation (30 min), 20 ml of 1.6% agarose were pipetted into each plate, agitated briefly by hand, and set to cool for 1 h at 22°C; tested concentrations are given as amount/ml agarose. Seeds were located in a row of 15 on the surface of each plate ca. 20 mm from the "top" edge of the plate with the root-ends all pointed in the same direction. Plates were covered, sealed with parafilm, and stored upright (with root-ends pointed down) in a chamber with a thermoperiod of 25:20°C and photoperiod of 14:10 hL:D. Root lengths were measured typically at 7 and 14 d. Two plates of 15 seeds each were used for each dosage of each compound, with each assay independently replicated at least twice. Measurements were averaged for each level, and % root length was calculated relative to the average root length observed on the methanol only control –treated plates.

Extraction of Swallow-Wort Plant Materials For initial phytotoxicity testing, approximately 10 g either of freeze-dried roots or shoot/leaf material of pale and black swallow-wort were sequentially extracted with hexane, dichloromethane, ethanol, and water. Each fraction was dried, and then reconstituted in methanol at 40 mg/ml and assayed for phytoxicity against lettuce seeds. For larger scale preparations and for chemical analysis, freeze-dried plant materials were extracted with 10 vol (v/wt) of dichloromethane:methanol (1:1). After gentle stirring for 24 h, the solvent was removed by filtration, and the residual powder was re-extracted for an additional 24 h with 10 vol (v/wt) of dichloromethane:methanol (1:1), treated as above, and then both extracts were combined, and dried *in vacuo* by rotary evaporation. Seed samples (2 g per replicate) were ground to a fine powder in a coffee mill, and then extracted as above. Extracts were combined and filtered through 2 layers of Whatman No. 1 filter paper and then dried *in vacuo* by rotary evaporation.

Preparative TLC Silica plates (Baker-500 μM thickness; 25×25 cm), loaded with 6 mg of pale swallow-wort extract, were used to preparatively separate the constituents of the active root fractions, using ethyl acetate:methanol (60:40) as a developing solvent. Bands observed under short and long-wave UV were recombined into seven fractions by scraping and elution in MeOH. Fractions were reanalyzed (Baker-40-μm; 25×0.5 cm) for confirmation of Rf prior to testing for phytotoxicitiy against lettuce seedlings.

Purification of Active Phytotoxic Fraction Freeze-dried root material (approximately 50 g) was ground to a fine powder in a coffee mill, and then extracted in dichloromethane:methanol (1:1) as described above to yield 3.3 g of a brownish-yellow gum. The crude extract then was partitioned between dichloromethane (1 vol) and water (2 vol), the organic layer was dried over anhydrous Na_2SO_4, and the solvent removed *in vacuo* to afford an oily yellowish-brown residue (0.76 g) that retained all of the original activity of the crude extract. This material was dissolved in dichloromethane and chromatographed on silica gel (Baker 40-μm; 300×25 mm), eluted with 400 ml each of 100% dichloromethane, 1, 2, 5, 10, 20, and 50% methanol in dichloromethane, and 100% methanol. The 10% MeOH fraction, which exhibited the greatest phyotoxic activity, was re-chromatographed on silica column (Baker-40-μm; 25×1 cm) eluted with 50 ml 100% dichloromethane, 200 ml each of 10%, 20%, and 50% methanol in dichloromethane. Phytotoxic activity was recovered in the 10% methanol fraction that afforded (−)-antofine (approx. 90%)(22.3 mg). At each step in the purification, fractions were monitored using TLC on silica with ethyl acetate:methanol (60:40) as the mobile phase. Semi-preparative HPLC was used to obtain purified material for spectral analysis.

Antimicrobial Bioassay **(−)-**antofine was tested in a disk diffusion assay against bacterial strains (*Escherichia coli, Bacillus cereus,* and *Bacillus subtilis*) grown on nutrient agar plates (9 cm) and against fungal target strains (*Colletotrichum acutatum, Fusarium graminearum, Beauveria bassiana,* and *Metarhizium anisopliae*) grown on potato

dextrose agar plates. Plates spread with 0.5 ml aliquots of a liquid bacterial culture grown for 24 h in nutrient broth or with 0.5 ml of a fungal spore suspension (1×10^6 spores/ml) were allowed to dry for 1 h. Test samples were applied to 4-mm filter paper disks in 10 μl methanol, air-dried for 1 h, and then placed on test plates. Zones of inhibition were measured after 48 h. Antofine was tested at 10 and 100 μg/disk. Methanol was used as a negative control (10 μl); positive controls used were iturin (10 μg) or filipin (10 μg) (Sigma) applied in methanol for fungal assays and commercial disks (Sigma) pretreated with ampicillin (10 μg) or erythromycin (15 μg) for bacterial assays.

HPLC Analysis Analytical HPLC was carried out by a modification of the method of Cui et al. (2004) employing a reversed phase C18 column (Varian, 5 μm, 250×4.6 mm), premixed isocratic mobile phase of methanol: 20 mM ammonium acetate (1:1 v/v), flow rate of 1 ml/min, with primary detection by UV at 260 nm and a wavelength scan of 200 to 350 nm. Retention time (RT) of antofine under these conditions was 6.5 min, with limit of detection (s/n=10) established at 0.2 μg on-column. The peak corresponding to antofine oxide (RT=6.0 min) possessed an almost identical photo diode array (PDA) spectrum and was quantified using peak area equivalences to antofine. Semi-preparative HPLC was carried out using a (ODS)3 column (end capped C18, Phenomenex, 5 μm, 250×4.6 mm), premixed isocratic mobile phase of methanol: 20 mM ammonium acetate (3:2 v/v), flow rate of 1 ml/min, with primary detection by UV at 260 nm and a wavelength scan of 200 to 350 nm, that allowed longer retention times for peak collection of the phytotoxic components.

Spectrometric Measurements Low-resolution electrospray ionization mass spectra (LRESIMS) spectra were acquired by infusion of methanolic solutions at 5 μl/min by a syringe pump (Harvard apparatus) into a Micromass ZMD-4000 spectrometer. Positive-ion-mode spectra were acquired with capillary cone voltages of 3.2 kV and 40 V, respectively; negative-ion-mode spectra were acquired with capillary and cone voltages of 4.0 kVand 20 V, respectively. High-resolution electrospray ionization mass spectrometry (HRESIMS) data were acquired by the mass spectrometry facility at the University of Illinois, Urbana Campus, USA.

Statistical Analysis Data was analyzed using JMP® statistical software, version 8.0.1; Tukey-Kramer's *post-hoc* test ($P<0.05$) was used for comparisons within treatments of solvent-tissue extracts and for initial effects on plant species. Dose–response curves were fit to a 4-parameter logistic model (Streibig et al., 1993), and I_{50} values were estimated from these curves.

Results

Concentration-dependent Phytotoxicity of Swallow-wort Extracts Sequential extraction of root and combined leaf and shoot materials from pale swallow-wort followed by bioassay testing using lettuce seedlings at 0.5 mg/ml applied dose revealed that the phytotoxic activity resided primarily in the dichloromethane and ethanol fractions (Fig. 1), which represented 1.5% and 2.5%, respectively, of the root dry weight, and 1.8% and 3.8%, respectively, of the dry weight of the shoot/leaf material. For further analysis and subsequent purification of the phytotoxic principles, both pale and black swallow-wort root tissue were extracted with dichloromethane: methanol (1:1). To assess activity against seed germination and root growth of native plant species, extracts were tested at 0.25 mg/ml and 1 mg/ml. Inhibitory activity of pale swallow-wort extract was evident at both levels against a number of native plant species that co-occur with invasive swallow-worts (Fig. 2). Black swallow-wort extract was not as potent, showing activity only at the 1 mg/ml level (data not shown). Little activity was noted with either extract, when tested against itself or the congeneric species (Fig. 2).

Identification of the Phytotoxic Constitutent of Pale and Black Swallow-Wort

Phytotoxic activity was confined to a single TLC band (Rf=.62) visible as a dark spot under long wave UV that represented less than 1% of the original extract. Combined

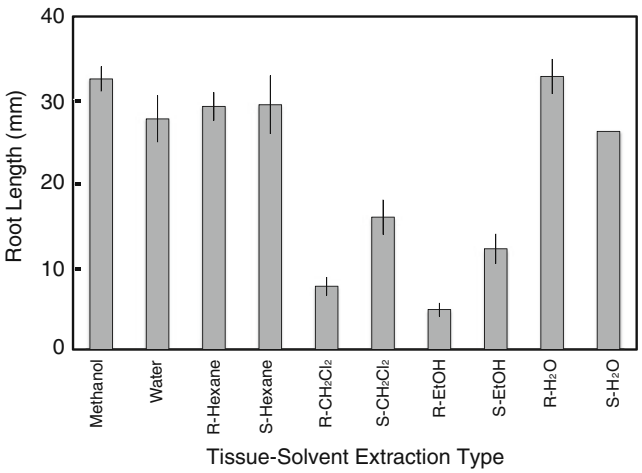

Fig. 1 Effect of sequential extractions of root and shoot/leaf tissues of pale swallow-wort on lettuce seedling root length. Measurements were taken at 1 wk of growth with a thermoperiod of 25:20°C and photoperiod of 14:8 hL:D using methanol and water as negative controls with 0.5 mg/ml applied dose of each extract. Data plotted are the mean ± SE, ($N=30$). R = root tissue; S = shoot and leaf tissue

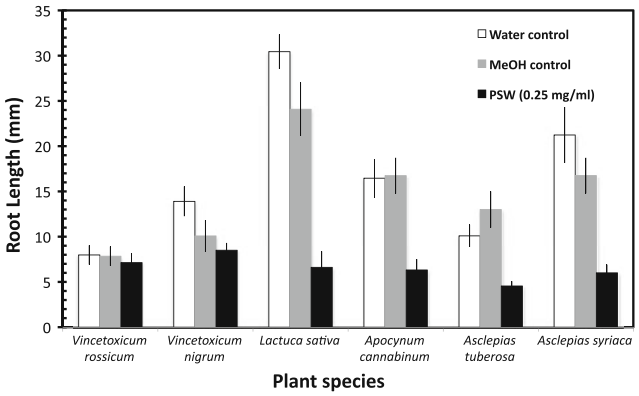

Fig. 2 Effect of pale swallow-wort (PSW) root extract at 0.25 mg/ml applied dose on root lengths of plant seedlings measured at 1 wk. Plates were incubated with a thermoperiod of 25:20°C and photoperiod of 14:8 hL:D. Data plotted are the mean ± SE, (N= 30)

fractions from silica gel chromatography were monitored by dose equivalence bioassay and by analytical TLC to monitor the elution of the major phytotoxic principle. Phytotoxic activity was recovered in the 10% methanol:dichloromethane fraction, representing 0.05% dry wt of the starting material.

LRESIMS analyses of the phytotoxic fraction indicated the presence of a major component with a molecular weight of *m/z* [M+H]+= 364, which is consistent with the major phenanthroindolizidine alkaloid, (−)-antofine, previously identified from shoot tissues of *V. rossicum* and *V. nigrum* and related *Vincetoxicum* species (Wiegrebe et al., 1970; Capo and Saa, 1989; Staerk et al., 2000, 2005; LEE et al., 2003), and recently reported from root extracts of *V. rossicum* (Mogg et al., 2008). Semi-preparative HPLC was used to collect one minor (RT=6.5 min) and two major peaks (RTs=8.0 and 13.5 min), all of which had elution and UV spectral characteristics consistent with published values for antofine (Wiegrebe et al., 1969; Cui et al., 2004). The minor peak was putatively identified as hydroxy antofine oxide based on LRESIMS of *m/z* [M+H]+= 396, and was not examined further. HRESIMS data for the major component eluting at RT=13.5 min was consistent with the molecular formula $C_{23}H_{26}NO_3$ (for $[M+H]^+$, obsd *m/z* 364.1911; calcd 364.1913). The component eluting at RT=8.0 min, with a molecular weight of *m/z* [M+H]+= 380 on LRESIMS, was consistent with antofine oxide, another known compound reported from *Vincetoxicum* species. HRESIMS data for this component was consistent with the molecular formula $C_{23}H_{26}NO_4$ (for $[M+H]^+$, obsd *m/z* 380.1860; calcd 380.1862). The purified active fraction represented 0.05% (dry wt basis) from pale swallow-wort roots and 0.015% from black swallow-wort roots, similar to concentrations of antofine reported from *V. pumilum* and *V. rossicum* root tissue (Staerk et al., 2005; Mogg et al., 2008).

Phytochemical Activity of Antofine Activity of the antofine preparation was tested over a concentration range from 0.1 to 75 μg/ml using the seedling bioassay system. Root growth of all tested plant species was inhibited by antofine to some degree, but differential sensitivity to the phytotoxin was evident when activity was tested against three native plant species. Little inhibition of root growth of pale and black swallow-wort seedlings was seen up to a concentration of 75 μg/ml, while lettuce was moderately affected, producing an I_{50}=12.5 μg/ml (34 μM) (Fig. 3). In contrast, root growth of *A. tuberosa* and *A. syriaca* was markedly inhibited by antofine, with I_{50}=1.25 and 3.1 μg/ml (3.4 and 8.6 μM), respectively (Fig. 4). *Apocynum cannabinum* root growth also was inhibited but at slightly higher concentrations (I_{50}= 3.75 μg/ml; 10.3 μM). Extensive browning of the root tip was visible on all of these native species, with little to no growth by 25 μg/ml (69 μM). In bioassays against pale or black swallow-wort, root growth was only slightly reduced at the highest concentration of 75 μg/ml (206 μM) with little visible tissue damage.

Detection of (−)-Antofine in Seeds of Pale and Black Swallow-Wort HPLC and LRESIMS data indicated that antofine was present in seeds of both black and pale swallow-wort seeds, a previously undocumented source of phenanthroindolizidine alkaloids, which have been reported only from roots and aerial portions of *Vincetoxicum.* As assessed by HPLC, antofine was detectable at concentrations of 1.10% (fresh wt) and 0.45% in seeds of pale and black swallow-wort, respectively.

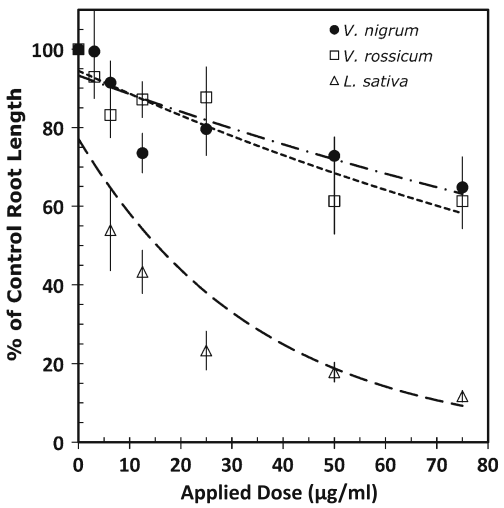

Fig. 3 Dose response profiles, plotted as a percentage (%) of the control root length in the absence of antofine, of *Vincetoxicum nigrum, V. rossicum*, and *Lactuca sativa* seeds germinated in the presence of varying concentrations of antofine. Plates were incubated with a thermoperiod of 25:20°C and photoperiod of 14:8 hL:D, and scored after 14 d. Data plotted are the mean ± SE, (N= 30)

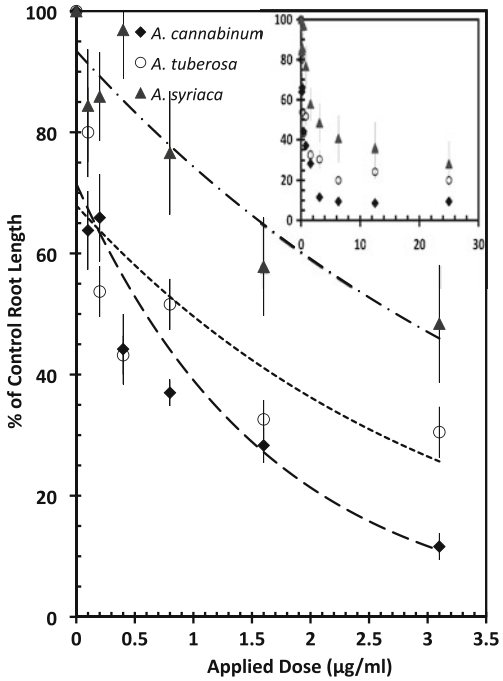

Fig. 4 Dose response profiles, plotted as a percentage (%) of the control root length in the absence of antofine, of *Apocynum cannabinum, Asclepias tuberosa, and A. syriaca* seeds germinated in the presence of varying concentrations of antofine. Plates were incubated with a thermoperiod of 25:20°C and photoperiod of 14:8 hL:D, and scored after 14 d. Inset shows response under an expanded range of concentrations, with little/no root growth evident at concentrations >25 µg/ml applied dose. Data plotted are the mean ± SE, (N= 30)

Antibiotic Activity At 48 h, clear zones of antifungal activity were evident from the 100 µg antofine treatment similar to that observed with the positive controls (Table 1). Much smaller zones were visible with the 10 µg antofine treatment, at levels consistent with previous reports (Baumgartner et al., 1990; Mogg et al., 2008). The antibacterial activity was less pronounced at the same concentrations; no activity was observed with 10 µg antofine, while only small clear zones of inhibition (2 mm) were observed at the higher level in comparison to the large kill zones from all positive controls (Table 1).

Discussion

We undertook the current study to assess the potential contribution of phytotoxins to swallow-worts' invasiveness through allelochemical interactions. Among the many hypotheses advanced to understand the dynamics of invasive species, the "novel weapons" or "allelopathic advantage against resident species" (AARS) hypothesis (Bais et al., 2003; Callaway and Ridenour, 2004) is based on the production of allelochemicals in sufficient quantities by the invasive species to produce phytotoxicity in a group of susceptible, or non-adapted, plants. This hypothesis was originally based on a series of observations that *Centauraea diffusa* and *C. maculosa* were at a competitive advantage relative to native species in the invaded range compared to their native range (Callaway and Aschehoug, 2000; Bais et al., 2003). Debate about this hypothesis continues because of conflicting estimates of (±) catechin levels from *Centaurea* species in soils that call into question whether concentrations are sufficient to cause phytotoxicity (Blair et al., 2005). Much of the original work has been discredited

Table 1 antimicrobial activity of (−)-antofine

Test Organism				
	Metarhizium acridum	*Beauveria bassiana*	*Fusarium graminearum*	*Colletotrichum acutatum*

nt not tested

(see Blair et al., 2006; Norton et al., 2008; Duke et al., 2009); at least one paper has been withdrawn (Weir et al., 2003) and soil and exudate concentrations have been revised (Weir et al., 2009; Bais et al., 2010), leaving questions as to whether allelochemicals can contribute to invasiveness. Recent field evidence has indicated that root exudates containing (±) catechin are allelopathic against species that co-occur in the invaded range, but do not cause a similar inhibitory effect in the native range (Thorpe et al., 2009). Some of these difficulties may be due to experimental problems with detection, extraction from various soil types, the possibility of pulsed releases, and stability of the compound in the soil (Inderjit et al., 2008a). The novel weapons hypothesis continues to be attractive given the numerous examples of allelopathic effects of exudates (Hierro and Callaway, 2003; Inderjit et al., 2008b) and the presence of novel chemistries in invasive exotic plants (Cappuccino and Arnason, 2006), although few chemicals have been tied specifically to an environmentally relevant allelopathic trait associated with invasiveness.

Previous observations have led to the suggestion that swallow-worts might affect rhizosphere dynamics through the production of allelochemicals. Shifts in arbuscular mycorrhizal fungi that benefit swallow-wort growth have been detected (Greipsson and DiTommaso, 2006; Smith et al., 2008). When evaluating potential Allee effects (latency in the rate of spread) in *V. rossicum* populations, Cappuccino (2004) noted the greater suppression of background vegetation by larger patches relative to smaller plant treatments. Others have suggested that purported allelochemicals could play a role in competitive plant interactions (DiTommaso et al., 2005b). Antofine was identified in *V. rossicum* root extracts and shown to have broad-spectrum antifungal activity (Mogg et al., 2008), but anti-feedant activity against sawfly larvae and masked birch caterpillar was attributed to an as-yet unidentified compound. Allelopathic activity from *V. rossicum* has been reported, but the chemistry involved was not identified (Cappuccino, 2004; Douglass et al., 2011).

This study extends the spectrum of antofine's bioactivity to include phytotoxicity which is especially potent against native asclepiads. We attributed phytotoxicity of root extracts of pale and black swallow-worts to the presence of (−)-antofine, an antimicrobial and cytotoxic phenanthroindolizidine alkaloid previously reported from *Vincetoxicum* species. The concentration of antofine in pale and black swallow-wort extracts correlates with the level of crude extract required for biological activity in seedling bioassays; in our preparations, pale swallow-wort root tissues had approximately four times the level of that found in black swallow-wort roots. We also documented antifungal and antibacterial activity of antofine at submilligram levels as shown previously, but we discovered that antofine also was biologically active at μM concentrations in seedling bioassays. Antofine demonstrated potent phytoxicity against a few native North American plant species that typically are found in areas being invaded by the non-native swallow-worts, although there was little activity seen when tested against either pale or black swallow-wort. We also report the presence of antofine in seeds, at concentrations approximately 2–3 times higher than that detected in roots or aerial portions of the plant. All of these findings point to antofine, and perhaps antofine oxide and other closely related alkaloids also reported to have cytotoxic activity (Staerk et al., 2000, 2002, 2005), as potential candidate phytochemicals that could exhibit allelopathic effects on surrounding vegetation and rhizosphere dynamics. Our preliminary experiments using antofine-spiked soil indicate that antofine is capable of causing root growth inhibition but at higher concentrations than found in the seedling bioassay system. We anticipate that soil type and pH will affect adsorption, stability, and availability of antofine as a potential allelochemical, so experiments are underway to determine antofine concentrations in undisturbed rhizospheres as well as the efffective recovery rates as a function of soil type and extraction method.

Invasive plants typically exhibit a suite of attributes that collectively contribute to their invasiveness. In the case of the swallow-worts, their success as invasive weeds in the northeastern U.S. may be due, at least in part, to their high fecundity (Smith et al., 2006) and their ability to adapt to a variety of habitats (Sheeley and Raynal, 1996; DiTommaso et al., 2005b), leading to an displacement of native species within native and disturbed environments (Ladd and Cappuccino, 2005; Douglass et al., 2009). The disproportionate production of root biomass relative to aerial plant development in pale swallow-wort would provide significant advantages for obtaining nutrients (Cappuccino, 2004; Smith et al., 2006; Milbrath, 2008); once established in satellite populations, the plants exhibit profuse and aggressive growth that can alter the light canopy, among other environmental factors (DiTommaso et al., 2005b). Whether this active growth phase also involves allelochemical interactions that aid in the displacement of native populations is as yet unproven. This study provides laboratory evidence that the phytochemical properties of antofine could contribute to swallow-worts' invasiveness in non-native habitats. Future studies are needed to determine whether antofine and related compounds are present at sufficient levels within the soil and rhizosphere to cause physiological responses relevant to invasion ecology of pale and black swallow-wort populations.

Abstract The root system is central for plant adaptation to soil heterogeneity and is organized primarily by root branching. To search for compounds that regulate root branching, a forward chemical genetics screen was employed, and 4-methylumbelliferone (4-MU), a coumarin derivative, was found to be a potent regulator of lateral root formation. Exogenous application of 4-MU to *Arabidopsis thaliana* seeds affected germination and led to reduced primary root growth, the formation of bulbous root hairs, and irregular detached root caps accompanied by reorganization of the actin cytoskeleton in root tips before seedling establishment. Abundant lateral roots formed after exposure to 125 μM 4-MU for 22 days. Molecular, biochemical, and phytochemical approaches were used to determine the effect of 4-MU on root growth and root branching. *Arabidopsis* seedlings grown in the presence of 4-MU accumulated this compound only in roots, where it was partially transformed by UDP-glycosyltransferases (UGTs) into 4-methylumbelliferyl-β-D-glucoside (4-MU-Glc). The presence of 4-MU-Glc in seedling roots was consistent with the upregulation of several genes that encode UGTs in the roots. This shows that UGTs play an integral role in the detoxification of 4-MU in plants. The increased expression of two auxin efflux facilitator genes (*PIN2* and *PIN3*) in response to 4-MU and the lack of response of the auxin receptor *TIR1* and the key auxin biosynthetic gene *YUCCA1* suggest that auxin redistribution, rather than auxin biosynthesis, may directly or indirectly mediate 4-MU-induced root branching.

Key Words Coumarin · 4-methylumbelliferone · Glycosyltransferases · Detoxification · Lateral root

Introduction

Plants are sessile and must endure environmental challenges, which include changes in water and nutrient availability and their heterogenous distribution in the soil. To acquire water and nutrients efficiently, plants dynamically modulate their root systems by regulating primary root growth, lateral root formation, and root hair number (de Dorlodot et al., 2007; Osmont et al., 2007; Nibau et al., 2008). Although progress has been made in dissecting the hormonal, genetic, and nutritional control of lateral root development (de Dorlodot et al., 2007; Osmont et al., 2007; Nibau et al., 2008; Peret et al., 2009), the mechanisms underlying the initiation and emergence of lateral roots are unclear. The formation of lateral roots is dependent on the coordinated action of many factors. In *Arabidopsis thaliana*, more than seventy genes have been shown to influence lateral root development (De Smet et al., 2006); however, the plant hormone auxin and its polar transport and redistribution have emerged as key factors (Fukaki et al., 2002; Nibau et al., 2008; Peret et al., 2009; Vanneste and Friml, 2009). Intercellular auxin movement is controlled by several plant-specific pin-formed (PIN) proteins that facilitate auxin efflux (Vanneste and Friml, 2009).

Coumarins (1, 2-benzopyrones) are secondary metabolites often found in roots of higher plants where they originate from the general phenylpropanoid pathway (Bourgaud et al., 2006). While their exact biological function in plants remains unclear, historically they are known to be involved in plant defense (Baumert et al., 2001; Carpinella et al., 2005; Brooker et al., 2007) along with flavonoids, phenolics, and alkaloids. Unlike most other secondary metabolites, coumarins appear to specifically inhibit seed germination and root growth (Svensson, 1971; Abenavoli et al., 2001, 2004, 2006, 2008; DeBolt et al., 2007), and this is consistent with previous observations that coumarins accumulate mainly in roots. They also influence membrane transport in the root tip (Lupini et al., 2010) and nitrogen uptake and metabolism (Abenavoli et al., 2001, 2003). Some natural coumarins also have received attention for their pharmacological properties, such as inhibition of HIV-1 and in treating thromboembolic diseases (Kostova et al., 2006).

Chemical genetics has been used extensively in plant biology for the identification of metabolites and their candidate genes involved in specific biochemical pathways (Blackwell and Zhao, 2003). As part of our efforts to characterize natural products that affect seed germination, root growth, and root architecture, we used forward chemical genetics to screen a small-molecule chemical library. Here, we focused on a coumarin derivative, 4-methylumbelliferone (4-MU), which inhibited germination and primary root growth, but promoted root branching after seedling establishment. We investigated the role of this compound on these parameters in more detail and demonstrated that 4-MU specifically accumulates in roots, where it is transformed into 4-methylumbelliferyl-β-D-glucoside (4-MU-Glc) by the action of UDP-glycosyltransferases (UGTs). We propose that UGTs play an integral role in the biochemical detoxification of 4-MU in *Arabidopsis* during seed germination and seedling development.

Methods and Materials

Plants, Chemicals and Forward Chemical Genetic Screens All chemical standards were purchased from Sigma-Aldrich (St. Louis, MO, USA). Solvents used were high-pressure liquid chromatography (HPLC) grade. *Arabidopsis thaliana* ecotype Columbia (Col-0) was obtained from the *Arabidopsis* Biological Resource Center (Columbus OH, USA). Seeds were cold-treated at 4°C for 2 d before germination. A collection of 128 natural compounds was screened by germinating and growing *Arabidopsis* on sterile Murashige and Skoog (MS) medium (Sigma) supplemented with 1.2% agarose and 0, 25, 50, or 125 μM compound. Germination and seedling growth were conducted in a growth cabinet with 16 hr of light (22°C), 8 hr dark (18°C) and 60% relative humidity. Plants were grown for different lengths of time in 4-MU MS media based on the objectives of the experiments. For observation of 4-MU effects on seed germination and primary root growth, plants were treated for 6 d. For auxin transport analysis and MUG assays in root systems, plants were harvested after treatment for 14 d when lateral root branching has been initiated and *DR5::GUS* was actively expressed (Supplementary Data Fig. 1). To measure the effect of 4-MU on seedling establishment and root architecture, plants were treated for up to 22 d when seedlings and root branching were well established. Fresh weight and root length were measured immediately after harvest. The *35S::ABD-GFP* (Motes et al., 2005) construct was provided by Dr. Elison B. Blancaflor, and the *DR5::GUS* transgenic line (Ulmasov et al., 1997) by Dr. Tom Guilfoyle (University of Missouri).

GUS Expression Analysis Quantitative analysis of GUS activity was conducted using 4-methylumbelliferyl β-D-glucuronide hydrate (MUG) fluorometric assays (Jefferson, 1987). Seedlings (200 mg) were ground with 1 ml of GUS extraction buffer containing 0.1 M Na_2HPO_4 (pH 7.5), 10 mM EDTA, 0.1% Triton X-100, and 10 mM β-mercaptoethanol at 4°C. After centrifugation, 100 μl of the extract were incubated with 2 mM MUG in extraction buffer in a final volume of 1 ml for 3 hr at 37°C. Three independent replicates were conducted.

Fluorescent Confocal Microscopy Laser scanning confocal and differential interference contrast microscopy was performed with a Carl Zeiss LSM150 microscope (Department of Veterinary Biomedical Sciences, University of Saskatchewan). GFP fluorescence was detected using excitation and emission wavelengths of 488 and 505 nm, respectively. The data shown are representative of three independent experiments. The images were analyzed using NIH Image J 1.37 software (http://rsb.info.nih.gov/ij/).

Identification and Purification of 4-MU-O-β-D-Glucopyranoside Arabidopsis roots were harvested and frozen at −80°C from plants grown 6 d either in the presence or absence of 4-MU. A 100 mg sample of frozen roots was ground in liquid nitrogen in a 20 ml Potter-Elvehjem, followed by grinding in 10 ml methanol/water (80:20; v/v) for 10 min. After filtration, the pellet was extracted again with methanol/water overnight at 4°C in the dark. The two extracts were combined and dried at 35°C under vacuum, and the dried extract was resuspended at 1 mg ml^{-1} with methanol/water (50:50; v/v). HPLC/UV analysis was conducted using a Hewlett Packard Agilent 1100 chromatograph, a G-7120 diode array detector, HP Chemstation ver. 08.01 software and a Zorbax C_{18} column

(150×4.6 mm, 5 μm, Mississauga, ON, Canada) with a 60 min linear gradient of 5–75% methanol v/v, a flow rate of 1.0 ml min^{-1}, and an injection volume of 2 μl. LC-MS profiles were obtained on an Agilent 1100 HPLC and an API QStar XL pulsar hybrid system (Applied Biosystems, Foster City, CA, USA) (Li et al., 2011).

Identical chromatography conditions were used for semi-preparative purification of 4-MU-*β*-D-glucoside (4-MU-Glc) from 5 g of 4-MU-treated frozen root tissue, except that the flow rate was 3.0 ml min^{-1} and a Zorbax C_{18} column (150 mm x 2.5 cm, Mississauga, ON, Canada) was used. The major peak was isolated, dried in a rotary evaporatory, and then the compound was dissolved in 510 μl of fresh methanol (Sigma). ^{1}H NMR, ^{1}H-^{1}H COSY, and HMBC spectra were measured on the isolated compound with a Bruker Advance 500 NMR spectrometer equipped with a Bruker 5 mm inverse tripe resonance TXI probe (Bruker Biospin, Rheinstetten, Germany) at the Saskatchewan Structural Science Centre, University of Saskatchewan. Chemical shifts (Table 1) (δ) were expressed in parts per million (ppm) and coupling constants (*J*) in Hertz (Hz).
