Abstract Many neurotransmitters, such as γ-amino butyric acid (GABA), can act as chemical cues influencing settlement and metamorphosis in benthic marine invertebrates. This effect has been described especially in mollusks, such as mussels, clams, or haliotids. This study describes the first record of the effect of GABA on patellogastropod populations. Special attention was paid to the effect of the compound on recruitment processes. The experiment was carried out using 10×10 cm artificial limestone plates that were drilled into intertidal rocks at different inclinations, and periodically treated with a 1 mM GABA solution. A total of five limpet species was considered (four patellid limpet species and the pulmonate *Siphonaria pectinata*). Each individual recorded on the plates as well as within a 20×20 cm quadrant was measured, identified to species level, and its straight-line distance to the application point was registered. Treated surfaces were the first to possess both adults and recruits. Individuals also were found in a higher number around GABA-treated plates than around controls. The results indicated that the compound may not only enhance recruitment, but also might accelerate it. Recruits were located at higher distances from GABA treated plates than from control surfaces. This supports the hypothesis that this is the life history stage most sensitive to the compound. The behavior shown by the individuals belonging to the two endangered patellid species present in the study area (*Patella ferruginea* and *Cymbula nigra*) also were analyzed. For the former, the results indicated that the use of GABA may have similar effects on recruitment similar to the presence of adult conspecifics. This is the first report of the effect of GABA on patellid limpet recruitment and population dynamics. Conservational implications of the results are discussed.

Introduction

The life history of many benthic marine invertebrate species includes a planktonic phase, after which individuals settle on the substrate to start a new and less mobile life stage. This process, referred to as "settlement" throughout, is mediated not only by physical processes, but also by chemical cues in a wide variety of species (e.g., Morse et al., 1979a; Burke, 1984; Pearce and Scheibling, 1990; Swanson et al., 2004; García-Lavandeira et al., 2005). Later, the surviving "settlers", after reaching a size of 2–3 mm, become "recruits" and are then visible and can be studied further (for definitions see the review by Rodríguez et al., 1993). After some time (which depends on the species considered), recruits acquire a certain size/age when sexual maturity is achieved. These sexually mature individuals, become "adults".

The factors that influence settlement and the selection of substrates by larvae of benthic species have been studied for decades, as they can determine local densities and distribution (Grosberg, 1982; Keough and Downes, 1982; Butler, 1986; Sutherland, 1990). Hydrodynamic factors are important controllers of larvae recruitment in both soft-sediment (Eckman, 1983; Butman, 1987) and hard-bottom benthic species (Pawlik et al., 1991). Since the 1970s,

larvae recruitment as a response to chemical compounds produced by conspecifics (Burke, 1984), prey (Hadfield and Scheuer, 1985) and biofilms (Wieczorek and Todd, 1998) has been described in a wide range of invertebrates. Chemical compounds are capable of attracting the larvae of these species to conditions more favorable than if they settled indiscriminately (Thorson, 1950; Burke, 1983; Pawlik, 1990, 1992) and naturally produce a gregarious settlement. Such stimuli can enhance the chances for larvae survival, as falling or selecting a non-appropriate substrate and the impossibility of moving towards more favorable conditions can lead to the death of an individual, and eventually to the collapse of the population.

A great variety of larvae-attracting compounds have been reported, ranging from low molecular weight water-soluble compounds (Hadfield and Pennington, 1990; Gibson and Chia, 1994; Swanson et al., 2006) to high molecular weight carbohydrates (Morse and Morse, 1991; Krug and Manzi, 1999), proteins (Jensen and Morse, 1990) and lipids (Takahashi et al., 2002). Among these compounds, *L*-3,4-dihydroxyphenylalanine (Coon et al., 1985), epinephrine (Pearce and Scheibling, 1990), or histamine (Swanson et al., 2004) have been identified.

Gamma-amino butyric acid (GABA) ($C_4H_9NO_2$) is a bioactive molecule widely known for its function as a neurotransmitter. The effect of GABA as a settlement inducer has been studied in many gastropod species (Hadfield, 1984; García-Lavandeira et al., 2005; Mesías-Gansbiller et al., 2008). This effect was described first in abalones by Morse et al. (1979a). Haliotid species are important commercially, and factors that promote their settlement have been well studied (Morse et al., 1979b; Bryan and Qian, 1998; Li et al., 2006; Searcy-Bernal and Anguiano-Beltrán, 2007). Until 2008, GABA was considered to be an artificial inducer of settlement. However, it recently has been shown that GABA is naturally produced by abalone species and other mollusks (Laimek et al., 2008).

The main objective of the present study was to determine the effect of GABA on limpet recruitment. Our study site was the coast of Ceuta, a city located in North Africa (Strait of Gibraltar) where a high diversity of limpet species is found: the pulmonate *Siphonaria pectinata* and patellid limpets such as *Patella caerulea, P. rustica*, or *P. ulyssiponensis*. In this area, we additionally find important populations of two endangered species: *P. ferruginea* and *Cymbula nigra*. Even though *P. ferruginea* generally was distributed throughout the Western Mediterranean basin during the Pleistocene, since the beginning of the 20th century, its population has suffered a clear reduction in number (Laborel-Deguen and Laborel, 1991; Templado, 2001) mainly because of human exploitation (Aversano, 1986; Guerra-García et al., 2004; Moreno, 2004). It is because of this situation that the species has been considered as one of the most endangered invertebrate species in Europe. Recently, the Spanish National Strategy for the Conservation of the species was developed (MMAMRM, 2008), which establishes several management measures and conservation proposals. One of these measures is the development of adequate protocols for the translocation of individuals for repopulation purposes. Among these protocols, we can find some proposals as the collection of recruits through experimental plates, which could be later translocated. It is in this context that the main objectives of the present study were established.

Methods and Materials

Objectives and Hypotheses The main objective of the present study was to determine how GABA affects limpet populations (especially recruitment). There is no available information regarding the influence of chemical cues on the settlement of patellid limpets. GABA was selected because it is a product known to influence such processes in a wide variety of gastropod species, and is naturally produced by similar species such as haliotids (Laimek et al., 2008). The study was conducted using two monitoring methodologies: a) documenting the colonization of plates in the intertidal zone that were or were not treated with GABA; b) analyzing the limpet community around the GABA-treated plates and comparing the results with those obtained around control (non-treated) areas. This allowed us to determine if the compound had some effect on limpet individuals surrounding treated areas and to infer generally on the scale of influence of GABA in the marine environment. Additionally, other parameters were taken into consideration: bi) the straight-line distance between the GABA application point on both adults and recruits to confirm that GABA was not repulsive and that adults were not also influencing settlement; bii) the effect of the presence of adult conspecifics on recruitment. Regarding this latter point, special attention was paid to the two protected limpet species located in the area: *P. ferruginea* and *C. nigra*. Both species naturally present a gregarious distribution (Espinosa et al., 2006; Rivera-Ingraham et al., in press). This may be the result of larvae preferentially settling on or near adult conspecifics, which could be explained by the fact that adults may produce naturally some kind of product that would result in larval attraction. Taking this into account, the effect of the presence of adults on recruitment in control areas was compared with the effect of GABA on recruitment where no adults are found.

Three different locations and three different substrate inclinations were used in the present study as fixed factors. Regarding the latter, all surfaces considered in the study

were classified as three different inclinations (horizontal= 0–20°, inclined=20–60°, and vertical=>60°), in order to assure that neither this factor nor location affected the results.

Experimental Design Patella ferruginea was chosen as a representative species for developing the experimental design since it is the most endangered patellid species in the area. It is an upper mid-littoral species (Espinosa, 2006) and shares the habitat with many other patellid limpets. Considering that the species is commonly present on artificial substrates (Guerra-García et al., 2004), three different artificial breakwaters in Ceuta were selected (Fig. 1): "Chorrillo", located in the city's South Bay and where great *P. ferruginea* densities can be found; "Foso de San Felipe", which constitutes the southern exit of Ceuta's commercial port (South Bay); and finally, "Parque del Mediterráneo", located inside the city's commercial port. The latter is completely closed to human access because it is private property and holds one of the most important *P. ferruginea* (Espinosa et al., 2009) and *C. nigra* (Rivera-Ingraham et al., in press) populations in terms of density and size distribution. These three locations were used as three different spatial replicates, in order to confirm that the results were not dependent on location.

In the present study, 10×10 cm limestone plates were used. The surface was modified so that it matched the heterogeneity of *P. ferruginea*'s natural habitat. In January 2009, 30 of these cement plates were fixed during low tide to the intertidal rocks of each area (a total of 90 plates), paying special attention that every plate was placed within *P. ferruginea*'s habitat. This was done by using a pneumatic drill connected to a scuba-diving tank to make the necessary holes. After inserting a rawl, the plate was fastened to the substrate by one screw located in the plate's center. A polycarbonate surface of the same size was placed between the plate and the rock in order to minimize the impact caused by waves. For each site, the 30 plates were arranged in five different replicas. Each replica was composed of two sets of 3 plates (6 plates per replica), each in a different inclination: vertical (>60°), inclined (60°–20°) and horizontal (<20°) (refer to Fig. 1 for more details).

A 1 mM γ-amino butyric acid, GABA (Sigma-Aldrich Chemie GmbH, Germany) stock solution was prepared in distilled water. This concentration was selected because recent findings have shown that other similar species (such as haliotids) present an average concentration of 0.68 mM GABA in the pedal mucus (Laimek et al., 2008). In any case, these values are significantly higher than those used in the laboratory and aquaculture conditions (Gapasin and Polohan, 2004), but in the present study, the solution was continuously dissolved and washed away by waves. After placing all plates, the solution was applied alternatively to one of the two subsets of each of the replicas. Our main hypothesis was that GABA may be present in the pedal mucus of limpets (as seen in *Haliotis* sp) (Laimek et al., 2008). Mucus has been found to persist around 5 d in *Patella vulgata* (Davies et al., 1992) and up to 2.5 wk in the case of *Littorina littorea* (Davies and Blackwell, 2007). Taking this into account, the application of the GABA solution was performed weekly during February and March 2009, coinciding with the *P. ferruginea* recruitment period (Espinosa, 2006). This task was carried out during low tide periods with the help of a paintbrush. In successive weeks, the solution was applied to the complete plate, even if animals were found on them. The solution was allowed to dry naturally on the plates, which only took some minutes thanks to the windy conditions predominant in the area. At the same time, all individuals located on the plates were identified and their maximum shell length was registered.

After 2 mo, no additional GABA was applied to the experimental surfaces. The registration of individuals located on the plates then was carried out monthly until September 2009. Additionally, pictures of every plate and the surrounding area were taken using a 20×20 quadrant (with the corresponding limestone plate located in its center) on three occasions: immediately after the last GABA application (T=0), 1 mo (T=1), and 2 mo (T=2) after the last GABA application (March, April, and May, 2009 respectively). This analysis was carried out in order to register the evolution of the composition of the population on the plates and adjacent areas after having treated the plates with GABA for 2 mo, and to show whether the population changed after application of the compound. These photographs then were used for further image analysis, in which each of the individuals located inside the 20×20 cm quadrant was registered and identified to the species level (when possible). Additionally, maximum shell length and minimum distance to the plate were measured for each individual. In order to achieve this, a matrix consisting of 50 quadrants was superimposed over each of the pictures taken using Photoshop 6.0 © (1989–2000 Adobe Systems Incorporated). This matrix served as a reference in order to make the counting of the individuals easier. With this same software, each individual was marked with the paintbrush tool. Additionally, images were saved in a bmp extension so they could be exported to Scion Image Alpha 4.0.3.2. © (2000–2001 Scion Corporation). With this software, and using a known distance as a reference (10 cm for our case, which was the total length of the limestone plate), the maximum shell length and minimum distance to the plate were recorded for each individual. Finally, all individuals

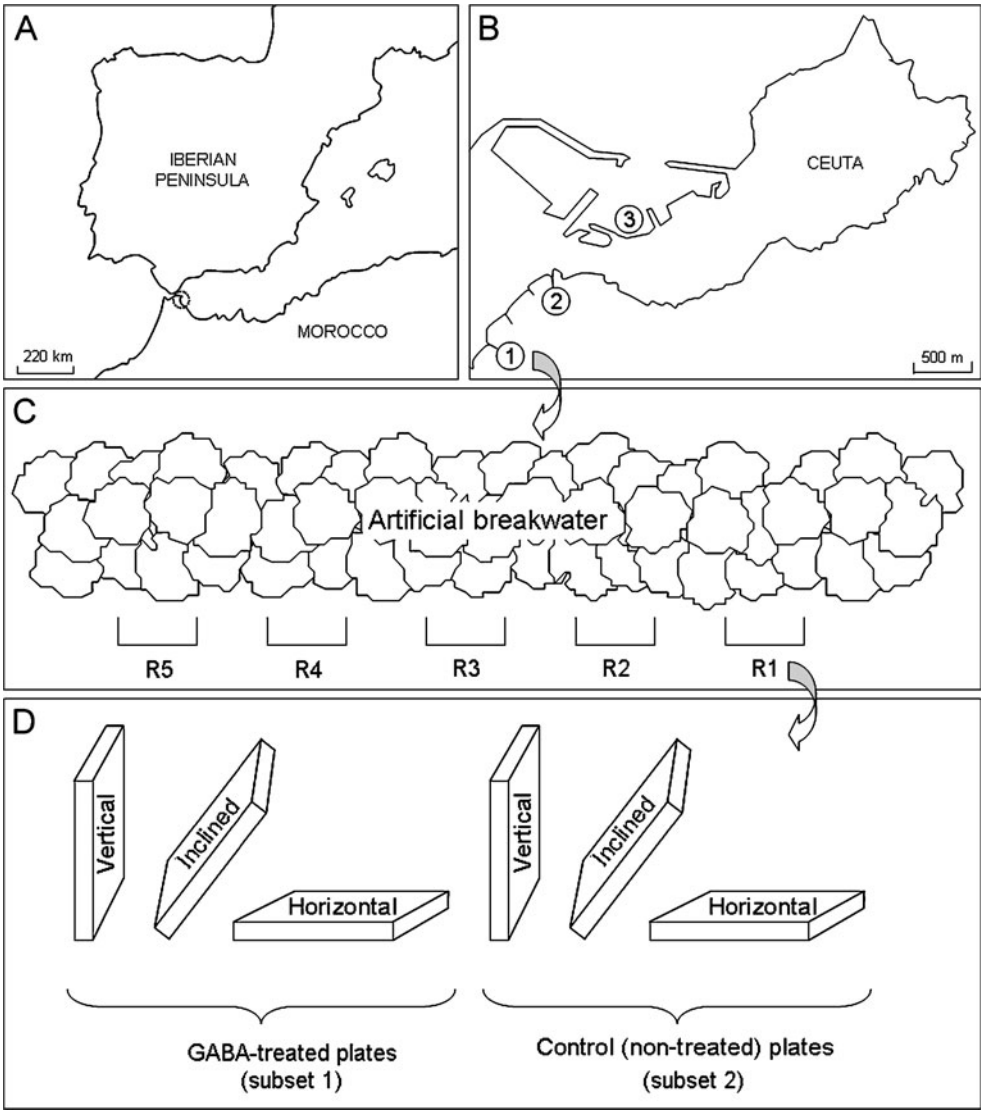

Fig. 1 Location of the study site. A.: Spain. B.: Ceuta, where 1: Chorrillo (South Bay); 2: Foso de San Felipe (South Bay); 3: Parque del Mediterráneo (North Bay). C.: General structure of the artificial breakwaters present in each location and distribution of the replicas (five replicas and 30 plates per location). D.: replica structure. Each replica was composed of 6 plates (divided in 2 subsets of 3 plates each). Each plate in a subset was fixed in a different inclination: horizontal (0–20°), inclined (20–60°) and vertical (>60°). One subset per replica was treated with the GABA solution

recorded on the plates and on the surrounding substrates were classified as adults or recruits, based on the size of first maturation recorded for the species: in this sense, *Siphonaria pectinata* individuals of less than 5 mm were considered recruits, based on the reports from Ocaña and Emson (1999); for the cases of the giant limpet species *P. ferruginea* and *C. nigra*, a limit of 20 mm was considered, while for *P. caerulea* and *P. rustica*, a limit of 10 mm was established (Frenkiel, 1975).

Statistical analyses were carried out with the SPSS 14.0 statistical package. One-way ANOVA tests were used in order to determine if there were significant differences between GABA-treated plates and non-treated plates, after confirming the compliance of the normal distribution (Kolmogorof-Smirnov test) and equal variance (Levene test) assumptions. For those cases where these conditions were not met, non-parametric analyses were carried out using the same statistical software.

Results

A) *Plate Colonization*. Results regarding this part of the study are presented in Fig. 2, which shows the frequency of individuals of each of the considered species per treatment and through time. It is interesting to note that the GABA plates were the first to register individuals, and *P. caerulea* adults were the first to colonize the plates. They were present three and five weeks into the experiment on GABA-treated plates and controls, respectively. Regarding recruits, *C. nigra* individuals were the first to be registered on both treated (time = +4 weeks) and control plates (time = +7 weeks). All *C. nigra* individuals recorded on the plates (a total of 12) were recruits, and four of them were obtained during the GABA application period. Returning to Fig. 2, we observe how, after the last GABA treatment, the number of *C. nigra* recruits significantly increased on treated

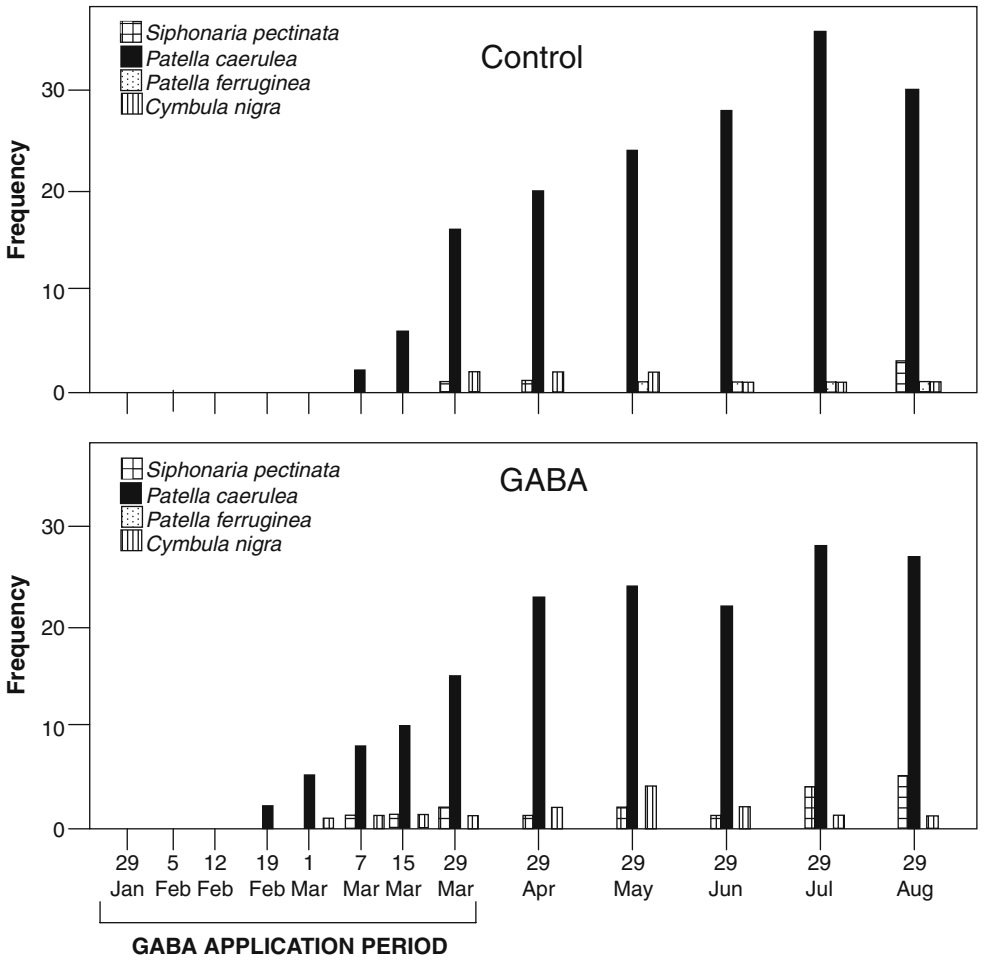

Fig. 2 Total number of individuals recorded over limestone plates, per species (*Siphonaria, Patella, Cymbula*), treatment, and sampling date. The experiment began at the end of January 2009 with the establishment of the plates in the intertidal zone and with the first GABA treatment. After that, the solution was applied to the plates weekly for two months

plates. A similar pattern was seen with *S. pectinata* recruits, which also experienced important growth in numbers during the last two months of the study, which was significantly greater on the treated plates. Regarding *P. ferruginea*, only one individual was located on the limestone plates. This individual was a recruit that settled on a non-treated plate in June, three months after the last application of GABA.

B) *Population Composition in Quadrants*. The total number of individuals found per quadrant around the treated plates was significantly higher (28.79± 15.16 ind) than around control areas (21.47± 14.78 ind) at T=0 (F=5.25; P=0.024). These differences were maintained through time, at T=1 (F=4.52; P=0.036) and T=2 (F=6.29; P=0.014).

As a general pattern, the average number of adults and recruits was usually higher around treated than control areas (adults: Chi^2=4.94; P<0.05; recruits: Chi^2= 7.08; P<0.01) (Fig. 3). However, there were some exceptions, such as the case of *P. rustica* recruits, which were present in higher numbers around the control areas over the entire duration of the experiment, although no significant differences were recorded between treatments. With respect to adults, it was interesting to note that only *P. caerulea* individuals showed differences between treatments, and were present in a significantly higher number around the GABA-treated plates. When considering the recruit fraction of the populations, the two endangered species (*P. ferruginea* and *C. nigra*) presented significantly greater numbers associated with GABA treatment. It also was noticeable how these differences disappeared at T=1 for *P. caerulea* and *C. nigra*, while they were maintained up to T=2 for *P. ferruginea* recruits. It was also noted that for the latter, while the number of recruits decreased at T=2, the number of adults did not rise, meaning that the loss of recruits was not due to the normal growth process of the individuals. Also noticeable was the case of *S. pectinata*, which presented no significant differences between treatments at T=0 and T=1, but presented a significantly greater number of recruits around the GABA-treated plates at T=2 (two months after the last application).

The distance of adults to the plates was not significant between treatments at T=0 (F=3.319; P=0.069). However, recruits presented significantly greater distances to treated plates than to controls, from T=0 (F=10.737; P=0.001) up

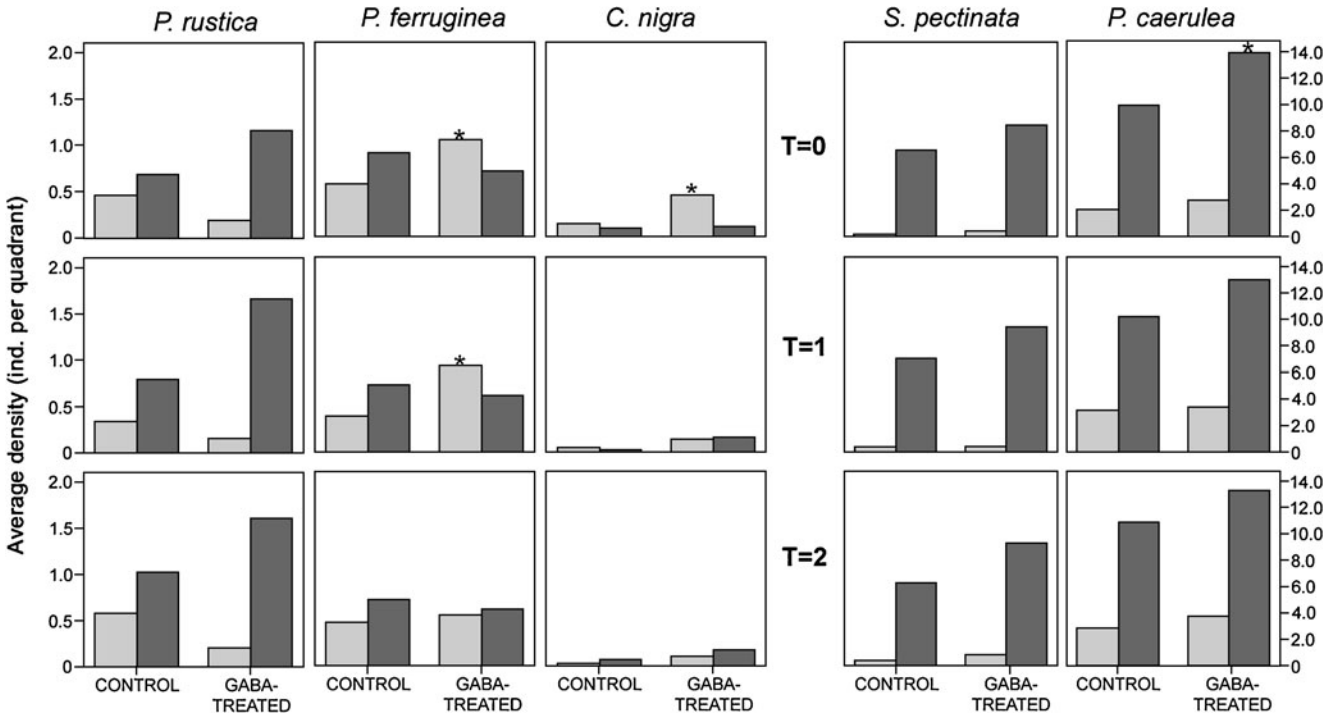

Fig. 3 Average number of individuals registered in 20×20 cm quadrant according to size, species, treatment, and sampling dates. T=0, March 2009, after the last GABA application; T=1, April 2009, one month after the last GABA application; T=2, May 2009, two months after the last GABA application. Dark bars represent adults, while grey bars represent recruits (less than 5 mm *Siphonaria pectinata*; less than 10 mm for *Patella caerulea* and *P. rustica*; less than 20 mm for *P. ferruginea* and *Cymbula nigra*). *$P<0.05$

to T=2 ($F=4.595$, $P=0.033$). This indicated that even two months after the last GABA application, there still was evidence of the effects of the solution. *Patella caerulea* recruits followed the above mentioned pattern, and individuals located around treated surfaces presented greater distances to the plates than individuals around the controls. *Patella ferruginea* did not show any differences for recruits ($F=2.346$; P = n.s.) nor for adults ($F=0.179$; P = n.s.). *Cymbula nigra* did not show differences for recruits ($F=0.378$; P = n.s.) either, but surprisingly did for adults ($F=7.727$; $P=0.024$) which were found to be significantly closer to the treated plates than to the controls (refer to Table 1 for further data).

The affect of the presence of adult conspecifics on recruitment also was inferred based on the data collected for the case of the two endangered species (*P. ferruginea* and *C. nigra*). All 90 plates used in the experiment were classified into four different categories based on the composition of adults and recruits. Figure 4 shows the results for *P. ferruginea*. Control treatments showed a considerably higher number of plates with no individuals than the positive treatment. Moreover, a high number of treated plates presented only recruits, while the number of plates presenting both adults and recruits were similar in number between treatments. Additionally, 70% of the control plates that presented *P. ferruginea* recruits could be explained by the presence of adult conspecifics. For the case of *C. nigra*, the total number of individuals recorded was not enough to conduct the analysis.

The influence of substrate inclination on recruitment also was analyzed. Vertical substrates showed the lowest number of recruits, although no significant differences were found between this and the other inclinations considered (mean values: horizontal susbtrata=4.27±4.18 individuals; inclined substrates=4.50±3.92 individuals; vertical substrates=3.34±3.60 individuals) ($F=0.72$; P = n.s). Similar-

Table 1 Mean distances to GABA application points for recruits and adults found (for each species) around GABA-treated plates for each of the considered species at T=0

Species	Mean ± SD (cm) (Recruits)	Mean ± SD (cm) (Adults)

ly, location did not apparently influence limpet recruitment either (F=1.34; P=n.s.).

Discussion

The present study presents the first results regarding the effect of GABA on patellid limpet recruitment and population dynamics. Through monitoring the colonization of experimental plates and their surrounding areas, we determined that the compound not only enhanced the recruitment processes, but also accelerated it. Surprisingly, adults were also affected by GABA, and adult *P. caerulea* immigrants were found in significantly higher numbers around the treated plates and were the first to be recorded. This is an interesting point, as many of the prosobranch limpets found on rocky shores are known to exhibit "homing behavior" (Gray and Hodgson, 1998), meaning that after foraging excursions, individuals usually return to their home scars. The fact that adults were found on plates means that these individuals have abandoned their original home scars, and established new ones on the experimental surfaces. For the case of *P. ferruginea*, this type of change has been associated with unfavorable growth conditions on the original scar (pers. obs.), because of being occupied by another individual or because low tide arrived before the individual returned to the scar (Espinosa et al., 2008). It is also reasonable to accept that recruits (especially those from *C. nigra* and *P. ferruginea*) are effectively attracted by GABA, and also present different behavior mediated by the presence of this compound.

The differences between treatments (for both adults and recruits) were usually maintained up to one month after the last GABA application. After that, the number of individuals was again similar to the ones found around controls, indicating that adults and recruits previously attracted by the solution may have changed home scar guided by some other chemical cue of natural origin. These results may suggest additionally that individuals are receptive to chemical stimuli over the entire lifespan and, in consequence, these cues may have not only a recruitment function. Moreover, it has been been shown recently that *P. ferruginea* is able to detect the presence of larger conspecifics and adjust the timing of sex change accordingly (Rivera-Ingraham 2010), meaning that chemical cues indeed play an important role during their lifetime and may also influence adults in other processes such as reproduction.

The present study also provides indirect results regarding the spatio-temporal influence of GABA on limpets. These data indicate that apart from the organisms located on the treated surfaces, individuals located in areas up to at least five centimeters around the application point also were affected. Additionally, a significant increase in the number of *S. pectinata* recruits was obtained around the treated plates four months after the last GABA application (end of July 2009). The timing of this increase could be due to the fact that the spawning period of the species occurs from March to June (Ocaña and Emson, 1999). The fact that this increase occurred around treated plates, however, could only indicate that the product had some effect on limpet communities for at least one month after the last application (when *S. pectinata* settlement probably took place).

Another important factor that should be taken into account is product concentration. The effect of GABA on patellid limpet may be a natural pattern produced as the result of the influence of a naturally-produced compound, or on the contrary, GABA may not be naturally produced by conspecifics. In the latter case, it might exert a toxic effect on the most sensitive fraction of populations, recruits. This is supported by the fact that *P. caerulea* recruits appeared with higher distances to GABA application points than to controls. However, no significantly higher mortality rates were observed on the treated plates, especially considering the fact that individuals were in direct contact with the 1 mM GABA solution as part of the normal application process. During the last decades, many studies have been conducted in order to determine the effective doses for larval settlement and tolerance to various concentrations of compounds. Regarding the latter, GABA concentrations of 0.5 μM to 10 μM have been described for

Haliotis sp. (see Morse et al., 1979a, b; Yang and Wu, 1995; Bryan and Qian, 1998; Gapasin and Polohan, 2004; Li et al., 2006; Searcy-Bernal and Anguiano-Beltrán, 2007). In all cases, however, the authors could effectively control these values as they were working in limited areas such as aquariums. Regarding toxic GABA concentrations, studies in abalone have reported values of 0.1 mM (Yang and Wu, 1995; Bryan and Qian, 1998).

Finally, we were able to determine that for the case of *P. ferruginea*, GABA seemed to produce an effect similar to that produced by the adults. Many of those control areas that showed *P. ferruginea* recruits could frequently be explained by the presence of adult conspecifics. Future studies should be conducted to determine the specific effect of adults on recruitment rates. It has been suggested previously that chemical cues may be involved in patellid limpet recruitment (Laborel-Deguen and Laborel, 1990), but this is the first evidence that directly supports this hypothesis.

Conservational Implications for Endangered Species Taking into account the results and observations of the present study, new considerations can be made regarding the proposal of obtaining *P. ferruginea* recruits through the use of artificial plates that could be later translocated for conservational purposes (Spanish National Strategy for the Conservation of *P. ferruginea*) (MMAMRM, 2008). We suggest the use of limestone plates similar to the ones described here. These plates should present a medium to high heterogeneity surface (surface rugosity coefficient >1.15, measured as in Wright, 1983), as the presence of microstructures have been proven to favor settlement and recruitment as well as serve as refuge and increase larval survival rates (Bulleri, 2005; Moschella et al., 2005; Rivera-Ingraham, 2010). The use of large surfaces should be avoided, as they can be torn easily apart by wave action, as has occurred in a recent study developed by Espinosa et al. (unpublished results).

Acknowledgements This study was financed with a predoctoral grant from the Spanish Ministry of Science awarded to G. A. Rivera-Ingraham (AP2006-04220) and by "Autoridad Portuaria de Ceuta". The authors express their gratitude to "Consejería de Medio Ambiente-Obimasa" in Ceuta for its support and legal assessment and to three anonymous referees for their comments and corrections on the original manuscript.

Abstract Many organisms provision offspring with antipredator chemicals. Adult blue-ringed octopuses (*Hapalochlaena* spp.) harbor tetrodotoxin (TTX), which may be produced by symbiotic bacteria. Regardless of the ultimate source, we find that females invest TTX into offspring and offspring TTX levels are significantly correlated with female TTX levels. Because diversion of TTX to offspring begins during the earliest stages of egg formation, when females are still actively foraging and looking for mates, females may face an evolutionary tradeoff between provisioning larger stores of TTX in eggs and retaining that TTX for their own defense and offense (venom). Given that total TTX levels appear to increase during development and that female TTX levels correlate with those of offspring, investment may be an active adaptive process. Even after eggs have been laid, TTX levels continue to increase, suggesting that offspring or their symbionts begin producing TTX independently. The maternal investment of TTX in offspring of *Hapalochlaena* spp. represents a rare examination of chemical defenses, excepting ink, in cephalopods.

Key Words Tetrodotoxin · Blue-ringed octopus · *Hapalochlaena lunulata* · *Hapalochlaena fasciata* · Maternal investment · Egg · Paralarva · Ontogeny

Introduction

Many chemically defended organisms endow their offspring with their own toxic protection. Examples of plant seeds invested with secondary metabolites are ubiquitous (reviewed by Janzen, 1978). Insects, through physiological resistance to plant toxins, have repeatedly co-opted plant defensive compounds for their own and their offsprings' defense. For example, moths of the genus *Utetheisa* provision their eggs with pyrollizidine alkaloids that were accumulated from their legume host, and these alkaloids protect clutches from predators and parasitoids (Eisner and Meinwald, 1995; Eisner et al., 2000; Bezzerides et al., 2004). Although vertebrate examples are fewer, amphibians are known for defensive compounds produced in granular glands (reviewed by Toledo and Jared, 1995), and many amphibians provision their eggs with these defensive compounds (e.g., Fuhrman et al., 1969). Rough skinned newts (*Taricha*) endow eggs with tetrodotoxin (TTX; e.g., Hanifin et al., 2003), and toads (*Rhinella*) invest eggs with bufadienolides (e.g., Akizawa et al., 1994). An Asian snake (*Rhabdophis tirgrinus*) even sequesters these bufadienolides from its bufonid prey (*Bufo*), and transfers the usurped chemical defenses to its own offspring (Hutchinson et al., 2008).

Many marine vertebrate and invertebrate eggs and larvae also are invested with a chemical defense from a toxic

parent. For example, at least two ascidian species (sea squirts or tunicates) produce such deterrents as the bipyrrole alkaloid tambjamine C and several didemnin cyclic peptides that render both adults and larvae distasteful to predators (Lindquist et al., 1992). Puffer fish eggs often contain tetrodotoxin (TTX), as do adults (Kao, 1966; Fuhrman et al., 1969). Examples of maternal provisioning also exist in both terrestrial and marine gastropods. Miriamin is an antipredator diterpene invested in the eggs of a slug (*Arion* sp.; Schroeder et al., 1999), and the nudibranch (*Hexabranchus sanguineus*) redirects antipredator macrolides sequestered from its sponge diet into egg ribbons (Pawlik et al., 1988). Clearly, maternal provisioning of offspring with defensive compounds is prevalent across the spectrum of life on earth, whether the toxin is produced endogenously or obtained exogenously by the donating parent.

However, provisioning offspring with chemical defenses may be costly. Metabolic costs of defense compete with growth and reproduction, for example, in aspens and wild parsnip, respectively (Zangerl and Berenbaum, 1997; Häikiö et al., 2009). Additionally, autotoxicity from defensive compounds in young embryos may inhibit growth (e.g., Orians and Janzen, 1974). These costs likely explain, in part, why all chemically defended adults do not invest offspring with defensive compounds (e.g., Tarjuelo et al., 2002).

When present, the chemical defenses in eggs and offspring often coincide with adults bearing the same toxin (Lindquist et al., 1992). Adult blue-ring octopuses are well-known for possessing the potent neurotoxin, TTX, which has been identified in 3 species of blue-ringed octopus, *Hapalochlaena fasciata* (e.g., Sheumack et al., 1978; Williams and Caldwell, 2009), *H. maculosa* (e.g., Yotsu-Yamashita et al., 2007), and *H. lunulata* (e.g., Williams and Caldwell, 2009). Based on symptoms of human envenomation (e.g., McMichael, 1964), other species of *Hapalochlaena* also appear to contain TTX. Sheumack et al. (1984) identified TTX in the eggs of one of these species (probably *H. fasciata* based on the authors' locality), but quantity, variation, and ontogeny of the TTX were not described. Although the ultimate origin of the TTX present in octopuses is unclear, TTX appears to be produced by bacteria in the posterior salivary gland (PSG) of *H.* cf. *lunulata* from the Philippines (Hwang et al., 1989).

Regardless of the source in adults, TTX also may serve as a powerful defense (e.g., Mosher et al., 1964; Kawasaki et al., 1973) against predation for eggs and young blue-ringed octopuses. If TTX is defensive, investment by *H. lunulata* and *H. fasciata* in offspring and the ontogeny of TTX production in *H. lunulata* would add to the sparse knowledge of chemical defenses in cephalopods. One unusual octopod gathers Portuguese Man-o-war tentacles and presents the cnemotocyst armory to potential predators (Jones, 1963). However, the most common and well-studied form of chemical defenses in cephalopods is ink (reviewed by Hanlon and Messenger, 1996; Derby, 2007). Investigations of other chemical defenses, and the maternal investment thereof, are few.

Other adult cephalopods, such as the flamboyant cuttlefish (*Metasepia pfefferi*) and the striped pyjama squid (*Sepiolodia lineolata*), are known to be toxic (Norman, M., pers. comm.). Additionally, an unnamed arm dropper octopus (*Abdopus* species 5) contains saxitoxin, which is functionally similar to TTX (Robertson et al., 2004). Any of these cephalopods also may invest chemical defenses into their offspring.

Although the presence of TTX has been identified in the eggs of *H. fasciata* (Sheumack et al., 1984), the ontogeny of TTX quantities has not been examined in this or other *Hapalochlaena* species. *Hapalochlaena lunulata* lay large clutches (~100–300 eggs), and clutches hatch diurnally and synchronously (Overath and von Boletzky, 1974; pers. obs.)—three conditions that correlate with toxicity in other pelagic larvae (Lindquist and Hay, 1996). Here, we determined whether female *H. lunulata* provision their eggs with TTX and whether these stores persist in paralarvae at hatching. We investigated TTX levels of adult females, paralarvae, and eggs at multiple stages of development to ascertain the relationship between maternal and offspring TTX levels, and to evaluate the ontogeny of TTX levels through hatching.

Methods and Materials

Sampling We obtained 18 female, 42 male, and 12 sex unknown adult and sub-adult *Hapalochlaena lunulata,* shipped from Bali, Indonesia, through the tropical aquarium industry between June 2004 and November 2006. Octopuses were wild-caught at our request and according to the importer were in transit no more than 1 wk. We also obtained 5 male and 2 female adults of *Octopus cf. mercatorus* via the pet trade from Florida; these small octopuses occupy a habitat similar to that of *H. lunulata* and provide a non-TTX bearing control. Octopuses were housed in 38 L aquaria. Artificial seawater was mixed at 34 ppt (Aqua Craft, Inc.). Every third day octopuses were fed live grass shrimp, ghost shrimp, snails, brine shrimp, or thawed prawn or fish pieces as availability permitted. Males were introduced into home aquaria of the females for mating (see Cheng and Caldwell, 2000 for a detailed analysis of mating). Females that deposited eggs were offered food approximately twice weekly. However, these semelparous octopuses often forgo feeding during brooding and expire soon after eggs are hatched (Tranter and Augustine, 1973; Overath and von Boletzky, 1974), and this pattern was consistent with the

H. lunulata and *O. cf. mercatorus* we observed. Only one female (*H. lunulata*) continued to feed after oviposition, albeit at a reduced frequency and volume as compared to her pre-oviposition meals.

Opportunistically, we were able to examine two female *H. fasciata*—one with hatchlings and one sexually immature individual. Unlike *H. lunulata,* which produce pelagic paralarvae (Overath and von Boletzky, 1974), *H. fasciata* produce benthic hatchlings (Tranter and Augustine, 1973). The adult that produced hatchlings was collected with eggs by hand near the Manly Ferry Station in Manly Cove, New South Wales, Australia, in February 2006. Hatchlings emerged from the eggs within 4 hr after collection, at which time the female and hatchlings were frozen at −20°C. In April 2006, this female was dissected, and her tissues and individual hatchlings were desiccated for 48 hr using Dririte©. An additional female was collected in April 2006 near the Manly boat harbor and transported live to the United States. Upon our return to the lab, both fresh and desiccated samples were frozen at −80°C before analysis for TTX.

Nine female *H. lunulata* and their paralarvae or eggs (collected before and after oviposition) were sampled at various stages of development; we divided the range of samples into eight stages (Table 1). For detailed reviews of cephalopod development, see von Boletzky (1989, 2003). Tetrodotoxin content in the posterior salivary glands (PSG) was used as a proxy for total female TTX levels because these two quantities are highly correlated and PSG is more easily assayed (Williams and Caldwell, 2009). Toxicity assays are destructive, thus female samples were collected at the reproductive stage indicated by eggs/paralarvae. Previously, we found TTX in oviducal glands of *H. fasciata* (Williams and Caldwell, 2009)*;* thus, three oviducal glands of *H. lunulata* and one of *H. fasciata* also were sampled.

Tetrodotoxin Extraction and Quantification We extracted TTX by grinding the sample in 100 µl (for eggs and oviducal glands) or 200–400 µl (for PSG) of 0.05 N acetic acid with a 1 ml Dounce glass homogenizer (Wheaton, USA). Extracts were heated to 100°C in boiling water for 5 min to denature protein contaminants, cooled in an ice bath, and centrifuged at 13,000 rpm for 15 min. We then filtered the supernatant through 5,000 nominal molecular weight limit 0.5 ml Ultrafree-MC Millipore tubes by centrifugation for 20 min at 13,000 rpm. Filtrates were stored at −80°C until quantification.

We quantified TTX in sample extracts using reverse phase high performance liquid chromatography (HPLC) by modifying the procedures of Yotsu et al. (1989), and Hanifin et al. (1999). Twenty µl aliquots of samples were eluted with an isocratic gradient of 1.0% by volume acetonitrile, 1.28% by weight heptafluorobutyric acid, and 0.29% by volume acetic acid. The mobile phase was adjusted to pH 5.0 with 50% NH_4OH. We separated analytes with a Synergi 4 µ Hydro-RP 80A C18 column (250×4.6 mm, Phenomenex, USA). A Beckman Coulter System Gold 126 Solvent Module provided a primary flow rate of 0.5 ml per min for the mobile phase and a secondary flow rate of 1.0 ml per min of 5 N sodium hydroxide for mixing post-column. A Pickering CRX 400 reactor (1 ml reaction volume) then heated elutants to 115°C after mixing to break down TTX and any possible analogs. A water jacket cooled the derivatization products before detection by a Jasco FP-1512 fluorescence detector with excitation wavelength set at 365 nm and emission wavelength at 510 nm. Beckman System Gold Software recorded the chromatographs and calculated peak areas. Tetrodotoxin peaks in tissue samples were identified and quantified by comparison with a standard (Sigma) of 1.0 µg/ml TTX in 0.10 N acetic acid. Tissues and offspring of *H. lunulata* and *H. fasciata* were compared with those of *O. cf. mercatorus* as a control. We used a peak skimming formula to conservatively calculate peak areas where the TTX peak eluted on top of a broad band.

Table 1 Descriptions of developmental stages assigned to eggs and paralarvae

Dev. Stage	Description
1	eggs largely undifferentiated in organic matrix
2	eggs differentiated, but still in organic matrix
3	eggs formed in ovary, chorion deposited by follicular syncytium of the ovary (Boyle and Chevis, 1992)
4	eggs deposited
5	1 wk after eggs deposited
6	2 wk after eggs deposited, eyespots have formed
7	3 wk after eggs deposited, chromatophores functional, eyes developed, and embryos have begun turning in preparation for hatching
8	paralarvae hatched (~ 4 wk after eggs deposited)

Statistical Analyses We used multiple regression analyses to evaluate: 1) the influence of female TTX levels and developmental stage on mean TTX levels of egg(s) or paralarva(e); and 2) the influence of female size and developmental stage of eggs on female TTX levels. For these two analyses, variables were transformed by the equation log (X+0.1) to better approximate a normal distribution (as evaluated by Shapiro-Wilk tests). Where replicates were available (indicated by sample size and SE in Table 3), we used the mean TTX levels of offspring to avoid pseudoreplication in the multiple regression. In addition, only stage 6 offspring of female #28 were used in this analysis to avoid psuedoreplication; this was the only female we were able to sample at multiple time points.

We used mantle length as an indicator of female size because a significant portion of the female's body mass is likely lost during egg deposition, whereas mantle length will remain more constant. Tetrodotoxin levels were measured as μg TTX/g tissue. We also were able to track toxicity within one clutch over development (female #28). With these data we analyzed how egg and paralarvae toxicity changed with developmental stage by using Spearman's Rank Correlation (ρ). Analyses were performed in JMP 7© 2007.

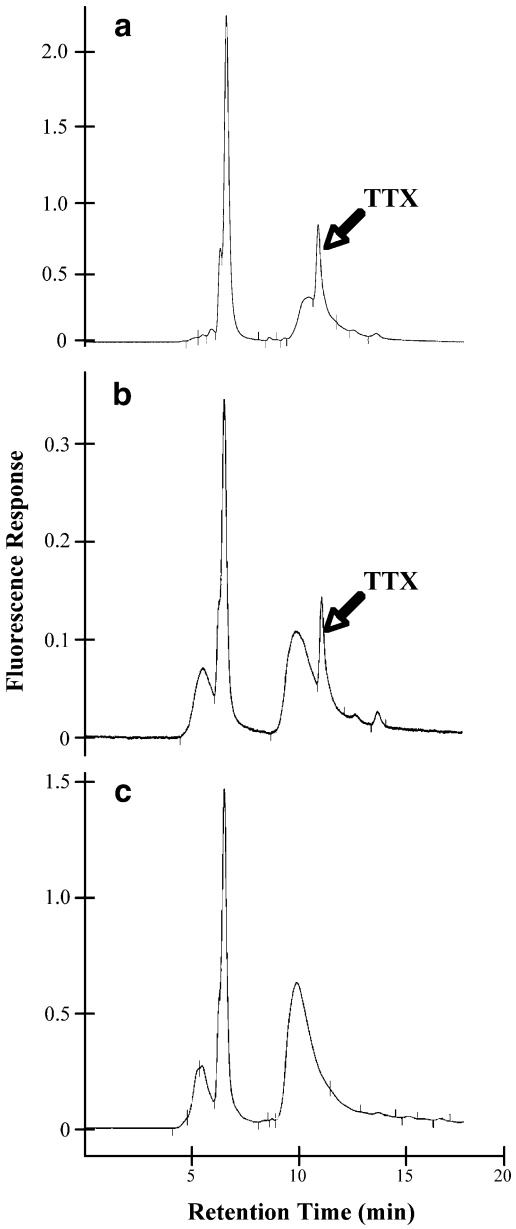

Fig. 1 Chromatograph illustrating the presence of tetrodotoxin (TTX) in tissues of *Hapalochlaena lunulata*: **a** Profile of the posterior salivary gland of an adult female #27 **b** Profile of a whole paralarva from female # 28 within 24 hr of hatching (stage 8 Table 1) **c** Profile of the control hatchling (*Octopus cf. mercatorus*) showing an absence of TTX

Table 2 Tetrodotoxin (TTX) levels in *Hapalochlaena fasciata*

	Female 4	Female 5
μg TTX in PSG	29.10	0.06
ng TTX per ovary	420	NE
ng TTX per oviducal gland	210	NE
ng TTX per hatchling (N=3)	NE	90, 150, 180

Results

Two clutches of *H. lunulata* (females # 4 and 28) and two clutches of *O. cf. mercatorus* developed successfully to hatching. Two additional *H. lunulata* females deposited eggs that did not hatch; one set of eggs did not develop (female #13) and one set began development but ceased after the death of the brooding female (#27). Tetrodotoxin was detectable in many, but not all of the tissues sampled (Fig. 1). Tetrodotoxin was the main and prominent analog, with traces of the presumed equilibrium products 4-epi TTX and 4,9 anhydro TTX (e.g., Goto et al., 1965; Mosher, 1986); these are represented (their identities are inferred only as they were not compared with authentic standards, which were unavailable) by the two peaks following that of TTX with retention times of ~13 and 14 min, respectively (Fig. 1). The proportion of these equilibrium products did not appear to change over time, nor were any other analogs of TTX apparent at any timepoint. No traces of TTX or its analogs were present in adult tissues or hatchlings of control octopuses (*O. cf. mercatorus*). No TTX was apparent in oviducal glands of the 3 *H. lunulata* tested, but TTX was present in the oviducal gland in the single *H. fasciata* for which this tissue was tested (Table 2). The benthic young of the second of the two female *H. fasciata* contained TTX (Table 2). Considerable variation in TTX levels was found between and within clutches and between females of *H. lunulata* (Table 3). Even so, several trends were readily discernable.

Egg/parlarva TTX levels (μg TTX/g tissue) were positively correlated with female TTX levels (μg TTX/g tissue) after accounting for the effect of developmental stage (N=9, df=1, F=7.98, P=0.030). Egg/paralarva TTX levels showed an increasing, but non-statistically significant, trend with respect to developmental stage (N=9, df=1, F=5.60, P=0.056). The within-clutch analysis of development post-oviposition by Spearman's Rank Correlation, however, revealed that egg–paralarva toxicity (ng TTX/egg or hatchling) did increase from stage 6 to 8 (N=9, ρ= 0.8808, P=0.002; Fig. 2). Because females cease feeding

Table 3 Tetrodotoxin (TTX) levels in *Hapalochlaena lunulata* and their offspring*

Female ID	Mean μg TTX per g paralarvae or egg (± SE)	*N*	Dev. Stage	Female Mantle Length (mm)	μg TTX per g PSG of Female	Total TTX in PSG of Female (μg)
7	0	~8*	1	23	0.21	0.01
9	3.64	~12*	1	32	114.34	12.12
11	3.12	~24*	1	35	55.45	4.88
15	15.84 (1.18)	2	2	28	65.4	7.32

N=number of samples

BDL Below detectable level

*Female identification numbers correspond to those in Williams and Caldwell (2009) and females # 27 and 28 correspond to collector # BLW 198 and 131, respectively

**Individual eggs were unformed at developmental stage 1 and sample size represents the best estimate for the number of eggs that were forming; these samples were pooled into a single toxicological analysis and included the organic matrix surrounding the developing egg mass

during brooding (Tranter and Augustine, 1973; Overath and von Boletzky, 1974) and given that egg/parlarva TTX levels increase as development progresses, one might expect to see female TTX levels decrease concordantly. However, this was not the case; female TTX levels (μg TTX/g tissue) were not related to offspring developmental stage (N=9, df=1, F=0.245, P=0.636). Female TTX levels were, however, positively correlated with female size (N=9, df=1, F=11.96, P=0.014).

Discussion

Both *H. lunulata* and *H. fasciata* appear to invest TTX into their offspring. Tetrodotoxin was present in the ovary of both species at the earliest stage of development before individual eggs had differentiated and would be capable of producing their own TTX or individually supporting bacterial symbionts. Thus, we conclude that females influence the distribution of TTX stores and possibly the distribution or provisioning of any TTX-producing symbionts. This is further supported by the positive relationship between egg/parlarva TTX levels and female TTX levels in *H. lunulata,* which may suggest either passive diffusion into eggs or female control over this chemical investment. TTX was invested in eggs even as they were aggregating from the organic matrix of the ovary (stage 1 in this study; Table 1) when females are still actively foraging and accumulating resources before mating and reproduction. At this time, the potential for an adaptive tradeoff is greatest between investment in offspring and self-defense or use of TTX as venom for prey capture. In contrast to previous work on *H. lunulata* (Williams and Caldwell, 2009), we found female size positively correlated with TTX levels.

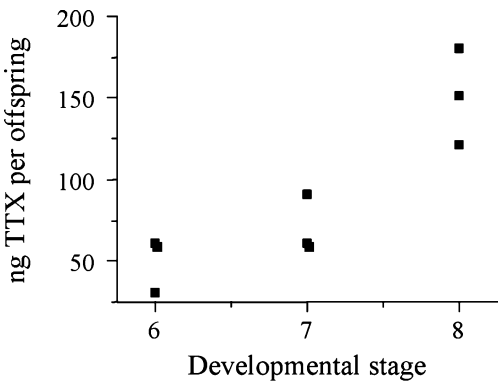

Fig. 2 Increase of tetrodotoxin (TTX) in 9 embryos from one clutch (female #28) of *Hapalochlaena lunulata* from 2 weeks after eggs were laid (stage 6) through hatching (stage 8; N=9, ρ=0.8808, P=0.002)

Eggs of some species provisioned with chemical defenses, such as those of the western toad (*Anaxyrus boreus*), lose toxicity during development (e.g., Benard and Fordyce, 2003). Time held in the lab may result in decreased TTX levels in *H. lunulata* if bacterial symbionts produce the TTX and are negatively affected by the captive environment. However, we found that TTX stores in *H. lunulata* embryos increase throughout egg and paralarval development, even after oviposition (Fig. 2). Females of *H. lunulata* and *H. fasciata* brood eggs until hatching (Tranter and Augustine, 1973; Overath and von Boletzky, 1974);

thus, continual investment of TTX into eggs by females theoretically is possible. If additional TTX is provided by females after oviposition, we might expect TTX levels in females to drop over development; however, our data revealed no such trend. Additionally, to our knowledge, there is no evidence of transfer of maternal provisions, such as nutrients or chemical defenses, from maternal octopuses across the chorion to embryos after oviposition. Because TTX is water soluble, a carrier would be required to transfer TTX to the eggs to prevent diffusion into the seawater. Seemingly, investing TTX into eggs before the deposition of the egg coat and cement, which serves as an environmental barrier, rather than continuing provision after oviposition would be a more effective method of transfer. While females could coat the eggs with external chemical defenses, we noted no external coating during egg collection. Further, TTX levels in freshly hatched paralarvae nearly triple after oviposition (Fig. 2), suggesting that the increase in TTX is not due simply to a coating on the eggs, which is discarded during hatching. Thus, although continued female investment of TTX after oviposition should be ruled out in future work, we suspect that embryos or the their symbionts begin production of TTX independently of female investment after oviposition.

Hwang et al. (1989) reported TTX-producing bacteria from the posterior salivary glands (PSG) of *H. cf. lunulata* from Cebu Island, the Philippines. Thus, the possibility exists that females inoculate developing embryos with TTX-producing bacteria. Female squid harbor symbiotic bacteria in accessory nidamental glands (ANG) and pass these bacteria onto the egg coat of their young (e.g., Biggs and Epel, 1991). However, the ANG that houses these symbionts is not fully developed in hatchling squid, and their ANG is colonized much later, from bacteria in the surrounding seawater rather than from maternal bacteria (Kaufman et al., 1998). In cephalopods, the nidamental glands and oviducal glands both deposit substances on the egg coat (chorion) before oviposition (reviewed in von Boletzky, 2003). Immediately prior to oviposition in octopuses, the oviducal gland coats the eggs with two secretions that harden into cement upon contact with sea water (Froesch and Marthy, 1975). Here, the 3 *H. lunulata* tested showed no evidence of TTX in their oviducal glands; however, 2 *H. fasciata* possessed TTX in these organs (this study; Williams and Caldwell, 2009). Whether symbiotic bacteria reside in the oviducal gland in addition to PSG remains untested. We verified that females invest eggs with TTX by demonstrating the presence of TTX in the ovary before individual eggs were formed and by the correlation between female and offspring TTX levels—a relationship that would not be present if females simply inoculated offspring with bacterial symbionts (Piel, 2004). However, we were unable to ascertain whether these females also provide bacteria to developing embryos.

Just as we found that TTX increases in octopus embryos after laying, TTX increases in puffer fish embryos (Matsumura, 1998). Matsumura (1998) takes this as an indication of endogenous production of TTX in the puffer fish rather than vertical transmission of symbiotic bacteria. While Matsui et al. (1982) found captive puffer fish (*Takifugu niphobles*) lacked TTX, Matsumura (1996) found that captive puffer fish (*Takifugu rubripes*) did possess low levels of TTX. Saxitoxin is structurally similar to TTX (Kao, 1966), and also was previously thought to be produced by symbiotic bacteria (reviewed by Piel, 2004). Martins et al. (2003) and Matsumura (1995, 2001) note that techniques for identifying saxitoxin and TTX production in bacteria, respectively, are not specific enough, and the media used to grow the purported symbionts actually yield a false positive identification of the toxins. These are the same techniques used by Hwang et al. (1989) to identify TTX production in bacteria of *Hapalochlaena*; thus, their conclusions have been called into question and need additional verification before the presence of bacterial symbionts in the octopuses can be accepted.

Regardless of the origin of TTX in eggs and young octopuses, the investment of TTX in young may be costly. The multi-ring structure of this small molecule (Goto et al., 1965; Tsuda et al., 1964; Woodward, 1964), the difficulty in identifying a natural biosynthetic pathway (Shimizu and Kobayashi, 1983; Ohyabu et al., 2003), and the stereospecificity of TTX (Furusaki et al., 1970) all suggest that it is not a byproduct of another pathway and may be metabolically expensive to produce. An octopus (or its symbiotic bacteria) can produce more than 0.4 mg of TTX (Williams and Caldwell, 2009), representing a potentially substantial investment. If symbionts produce the TTX, the cost of maintaining symbiotic colonies may be sizeable, as it is in plant-mycorrhizae and nematode-bacteria interactions (e.g., Cameron et al., 2008; Emelianoff et al., 2008). Although dietary bioaccumulation of TTX occurs in some organisms (e.g., pufferfish; Kono et al., 2008) and may represent a lower-cost source of the toxin, dietary accumulation of TTX by these octopuses is unlikely to be the primary source because egg/parlarva TTX levels increase after oviposition but before feeding (Fig. 2), and maternal TTX levels do not decrease concordantly. If TTX production is costly, this increase suggests adaptive benefits of the toxin for the young octopuses.

Tetrodotoxin may serve adaptively as a chemical defense or offense in blue-ringed octopus eggs and paralarvae or hatchlings. Many puffer fish have TTX in their eggs (e.g., Kao, 1966; Fuhrman et al., 1969), and Gladstone (1987) found that eggs and larvae of Sharpnose pufferfish (*Canthegaster valentini*) are distasteful to two other species

of reef fish. Gladstone (1987) speculates that TTX conferred the distastefulness but had no empirical evidence that eggs contained TTX or that TTX repelled the predators tested. The antipredator efficacy of TTX has only been empirically demonstrated in one species of newt (*Taricha granulosa*; e.g., Williams et al., 2010). In the genus *Hapalochlaena* the function of adult TTX is assumed to be both venom and defensive compound. Whether TTX provides an antipredator defense or represents developing venom for paralarvae or hatchlings of blue-ring octopuses is currently unknown.

In summary, females of *H. lunulata* and *H. fasciata* invest TTX into their offspring. Counter to predictions, embryos increase in TTX levels even after oviposition; however, female TTX levels do not decrease concordantly. This may indicate that embryos or their bacterial symbionts begin independent production of TTX before hatching. Whether females inoculate eggs with TTX-producing bacteria is unknown, as is the ecological function of TTX in the eggs and paralarvae or hatchlings. Work is necessary to determine the ultimate origin of TTX in blue-ringed octopuses (*Hapalochlaena* spp.) and the functional ecology associated with this potent neurotoxin in this group.

Acknowledgements David Baxter provided *H. fasciata* natural history information and assistance collecting in Manly. Collecting permits for *H. fasciata* were supplied by the New South Wales Fisheries Department, Australia (permit #s P05/0101-1.0 & P05/0101-2.0). Julie Himes provided help with animal care and octopus breeding at the University of California, Berkeley (UCB). Drs. Michael Pfrender, Daryll DeWald, Jon Takemoto, and Paul Wolf at Utah State University (USU) shared equipment and advice. Dr. Daniel Mulcahy at Brigham Young University volunteered for fieldwork and Dr. Christine Huffard at Monterey Bay Research Institute assisted with octopus dissections. We thank Dr. Isao Kubo for discussions on the structure and chemistry of TTX. Stephanie Bush, Joey Pakes, Jean Alupay, and Dr. David Lindberg at UCB, Dr. Christine Huffard at MBARI, and Dr. Christopher Feldman at the University of Nevada, Reno, provided comments on earlier drafts of this manuscript and their aid was appreciated. The Department of Integrative Biology (UCB) and the University of California Museum Of Paleontology funded this project through the Summer Research Grant and Graduate Student Research Grant to BLW. Funding was also provided by NSF grant #DEB-031572 to EDB Jr.

Volatile Emissions from *Alnus glutionosa* Induced by Herbivory are Quantitatively Related to the Extent of Damage

Lucian Copolovici · Astrid Kännaste · Triinu Remmel · Vivian Vislap · Ülo Niinemets

Abstract Plant volatile organic compounds (VOCs) elicited in response to herbivory serve as cues for parasitic and predatory insects. Knowledge about quantitative relationships between the extent of herbivore-induced damage and the quantities of VOCs released is scarce. We studied the kinetics of VOC-emissions from foliage of the deciduous tree *Alnus glutinosa* induced by feeding activity of larvae of the geometrid moth *Cabera pusaria.* Quantitative relationships between the intensity of stress and strength of plant response were determined. Intensity of biotic stress was characterized by herbivore numbers (0–8 larvae) and by the amount of leaf area eaten. The strength of plant response was characterized by monitoring (i) changes in photosynthesis, (ii) leaf ultrastructure, and (iii) plant volatiles. Net assimilation rate displayed compensatory responses in herbivore-damaged leaves compared with control leaves. This compensatory response was associated with an overall increase in chloroplast size. Feeding-induced emissions of products of the lipoxygenase pathway (LOX products; (*E*)-2-hexenal, (*Z*)-3-hexenol, 1-hexanol, and (*Z*)-3-hexenyl acetate) peaked at day 1 after larval feeding started, followed by an increase of emissions of ubiquitous monoterpenes peaking on days 2 and 3. The emission of the monoterpene (*E*)-β-ocimene and of the nerolidol-derived homoterpene 4,8-dimethyl-nona-1,3,7-triene (DMNT) peaked on day 3. Furthermore, the emission kinetics of the sesquiterpene (*E,E*)-α-farnesene tended to be biphasic with peaks on days 2 and 4 after start of larval feeding. Emission rates of the induced LOX products, of (*E*)-β-ocimene and (*E,E*)-α-farnesene were positively correlated with the number of larvae feeding. In contrast, the emission of DMNT was independent of the number of feeders. These data show quantitative relationships between the strength of herbivory and the emissions of LOX products and most of the terpenoids elicited in response to feeding. Thus, herbivory-elicited LOX products and terpenoid emissions may convey both quantitative and qualitative signals to antagonists of the herbivores. In contrast, our data suggest that the feeding-induced homoterpene DMNT conveys the information "presence of herbivores" rather than information about the quantities of herbivores to predators and parasitoids.

Introduction

Plants have developed a variety of defense strategies that cope with insect attacks. Direct defenses act directly against the herbivores, whereas indirect plant defenses may act by release of plant volatile organic compounds (VOCs) that attract natural enemies of the herbivores (see for reviews Gershenzon and Dudareva, 2007; Poelman et al., 2008; Dicke, 2009). Quantitative and qualitative herbivore-induced changes in VOC emissions have attracted special attention (Holopainen, 2004; Arimura et al., 2005; Brilli et

al., 2009; Dicke, 2009; Kännaste et al., 2009; Wu and Baldwin, 2009; Schaub et al., 2010).

The first, almost instantaneous response of plants to wounding is the emission of volatile products of the lipoxygenase pathway, i.e., LOX products (various C6-aldehydes, -alcohols, and -esters, also called green leaf volatiles; Pinto et al., 2007; Gosset et al., 2009). Lipoxygenase (LOX) pathway products are induced in a variety of plant species during different stress conditions (e.g., Heiden et al., 2003; Copolovici and Niinemets, 2010) in a process where free octadecanoid fatty acids are released from plant membranes by phospholipases. As further responses to continued herbivory, emissions of LOX volatiles are enhanced and a wide range of other herbivore-induced VOCs is released: e.g., terpenes produced via the mevalonic acid (MVA) pathway and/or the 2-C-methyl-D-erythritol 4-phosphate (MEP) pathway or methyl salicylate biosynthesized via the shikimic acid pathway (Holopainen, 2004; Dudareva et al., 2006).

Although extensive evidence for the induction of plant volatiles by herbivory is available, studies of herbivore-induced plant VOCs often provide only information of the spectrum of compounds emitted, but no quantitative data (De Boer et al., 2004; Kännaste et al., 2008, 2009). Even in quantitative analyses that have determined the amount of compounds emitted by damaged plants (Dicke et al., 1999; Mumm et al., 2003; Schuman et al., 2009), quantitative relationships between the amounts of compounds emitted and degree of damage or the number of insects feeding rarely have been reported (Gouinguene et al., 2003). However, the strength of the signal may significantly alter the degree of attraction of the parasitoids and predators of herbivores (De Boer and Dicke, 2004; Chen and Fadamiro, 2007; Bruinsma et al., 2009). Thus, quantitative relationships between plant VOC emissions and degree of herbivory damage are of key importance for understanding multitrophic plant—insect interactions. Stress strength vs. emission response relationships have been studied for a few abiotic stresses (Beauchamp et al., 2005; Niinemets, 2010). These studies provide evidence that plant VOC emissions are quantitatively associated with stress strength. Such quantitative relationships are needed to develop large-scale models of VOC release in response to biotic stresses (Arneth and Niinemets, 2010).

In the current study, we tested the hypothesis that plant VOC emissions are quantitatively associated with the degree of damage by herbivores. We used *Alnus glutinosa*, an early successional alder species, and larvae of the geometrid moth *Cabera pusaria* for our analysis. The plant species we studied is a temperate deciduous tree species that is wide-spread in Europe and is colonizing habitats along streambanks and wet forests. Due to the capacity of nitrogen-fixation, protein-rich foliage of *Alnus spp*. is under strong herbivory pressure in natural environments. So far, only a few studies have investigated VOCs induced by herbivore attack in *Alnus* spp. (e.g., Dolch and Tscharntke, 2000; Tscharntke et al., 2001; Giertych et al., 2006; Blande et al., 2010). Larvae of *C. pusaria* are common defoliators of deciduous trees throughout the Palearctic region; the oligophagous larvae feed solitarily and externally in the foliage of deciduous trees late in the season. Herbivorous larvae, such as geometrids, cause considerable damage to deciduous trees, ranging from the consumption of a notable percentage of total leaf area (Marquis and Whelan, 1994; Martel and Mauffette, 1997) to complete defoliation in extreme cases (Wesolowski and Rowinski, 2006; van Asch and Visser, 2007).

We analyzed the kinetics of VOC emission in *A. glutinosa* leaves during and after grazing by *C. pusaria* larvae, and we determined quantitative relationships between the intensity of stress (leaf damage and herbivore numbers) and strength of plant response (photosynthesis and emissions of the lipoxygenase pathway products and terpenes).

Methods and Materials

Plant Material Alnus glutinosa plants were grown from seeds (seed source: Oudewater, The Netherlands, 52° 01′N, 4° 52′E). After germination, seedlings were grown in 3 L clay pots filled with a 1:1 mixture of quartz sand and commercial potting soil (Biolan Oy, Finland) under light intensity of 200 μmol m^{-2} s^{-1} (HPI-T Plus 400 W metal halide lamps, Philips) for a 12 h light period and day/night temperatures of 24/18°C. Plants were watered daily and fertilized once per month with slow release NPK (3-1-2 ratio) fertilizer containing microelements. In all experiments, we used similar-sized 1-yr-old seedlings with 15–20 leaves.

Insects Larvae of *Cabera pusaria* were collected from a deciduous-conifer mixed forest (58°23′N, 26°40′E) in the vicinity of Tartu, Estonia, and reared in the laboratory for 15 d in 200 ml containers at varying temperatures to synchronize the larval stages. Before the experiment, larvae were supplied with fresh alder leaves that were changed on alternate days. We used larvae in the beginning of their final instar for the experiments; at this age they have gained about 350 to 400 mg in body mass.

Experimental Setup Whole plants were placed in a dynamic headspace sampling cuvette system consisting of four 3 L glass chambers described in detail by Toome et al. (2010). In this system, above-ground plant parts were hermetically sealed in individual cuvettes, while the root system with

potting medium stayed outside. The air flow through each chamber was 0.3 $L min^{-1}$, and a fan (Sunon Group, Bejing, China) was installed in the chamber resulting in high turbulence. Assuming fully turbulent conditions and first-order exponential decay kinetics, the half-time of the chamber air corresponding to this chamber size and the flow rate was 6.9 min. (Li-Cor Inc., 2001; Niinemets, 2011). During the experiment, light was provided by the HPI-T Plus 400 W metal halide lamps for a 12 h photoperiod. Light intensity at the leaf surface was 200 $\mu mol\ m^{-2}\ s^{-1}$. After hermetic installation of the plants (day -1), they were left untreated for 24 h for stabilization. By the end of the stabilization period (day 0), treatment was started by placing 2, 4, or 8 larvae of *C. pusaria* on individual plants, while one plant was left untreated as control. After introduction of the larvae, plants were kept in the system in the dynamic air flow for one more hour before VOC sampling. Larvae were allowed to feed from the leaves for 4 d. After 4 d, they were removed, and the plants were maintained in the chambers for a further day for the collection of VOCs.

Morphological and Chemical Measurements On the 5th day, all leaves were harvested and scanned at 300 dpi. Projected leaf area was determined from the scanned images by custom made software. Leaf fresh mass was then determined immediately, and leaf dry mass was estimated after drying the leaves for 48 h at 70°C. Nitrogen content was determined by Vario Max CNS (Elementar Analyse System GmbH, Hanau, Germany).

The experiment was conducted on plants with fully mature leaves, and no leaf area expansion was observed throughout the experiment in either the control or insect-treated plants. Leaf area eaten by larvae was calculated as the difference between leaf area before the start of the experiment and the leaf area after all measurements.

Anatomical Measurements Samples for anatomical measurements were collected at the end of the experiment. From the middle part of a fully developed leaf, 1×1 mm pieces were cut between the main veins. In the damaged plants, all leaves were partly damaged, and leaves with ca. 10% damage were sampled, while intact leaves were sampled in the control plants. Leaf material was fixed by infiltrating with 2% glutaric aldehyde in 0.2 M phosphate buffer (pH 7.2) in a syringe under negative pressure. After fixation, leaf material was dehydrated in ethanol and finally embedded into Epoxy Embedding Medium (Sigma-Aldrich Chemie, Steinheim, Germany) as described by Bozzola and Russell (1992). After embedding and curing in a ventilated oven at 60°C for 48 h, semi-thin (0.5–0.2 μm) and ultra-thin (70–90 nm) cross sections were cut with an OM U2 Ultra Microtome (American Optical Corporation, Reichert Products, Buffalo, NY, USA) using a 45° diamond knife (Diatome, Hatfield, PA, USA). Semi-thin sections for light microscopy were stained with Toluidine Blue as described in Burns (1978) and Mercer (1963) for 30 sec, and photos were taken with a Zeiss Axioplan 2 (Carl Zeiss Microscopy, Jena, Germany) at 40× magnification with 0.63×lens and a digital camera AxioCam HRc (Carl Zeiss Microscopy, Jena, Germany). Images were analyzed with UTHSCSA Image Tool for Windows Version 3.00 (UTHSCSA, Texas, USA 1995–2002). Thickness of the leaf, palisade and spongy mesophyll, and upper and lower epidermis were measured from 10 sections per treatment.

Samples for transmission electron microscopy (TEM) were contrasted with 2% uranyl acetate in 50% ethanol solution for 2 min and in 0.2% lead citrate in 0.1 M sodium hydroxide solution for 2 min (Bozzola and Russell, 1992). Samples were viewed with a Philips Tecnai 10 TEM (FEI, Eindhoven, Netherlands) with an accelerating voltage of 80 kV. 1100–2900x magnification was used to measure mesophyll cells size, and chloroplast and mesophyll surface area exposed to intercellular air space (Sc and Sm). Sc and Sm were calculated according to Evans et al. (1994) by using 2100–4200x magnification for length, thickness and area of chloroplasts, mitochondria and starch grains in the chloroplasts. Finally, 7000–14000x magnification was used for measurements of cell wall thickness and chloroplast distance from the cell wall. All parameters were assessed separately for palisade and spongy mesophyll cells. Based on the measurements we calculated the chloroplast surface area exposed to intercellular air spaces per unit leaf area, mesophyll surface area exposed to intercellular air spaces per unit leaf area, chloroplast area/mesophyll area, and starch grain area relative to chloroplast area.

Photosynthesis Measurements The photosynthetic parameters of the plants during larval feeding were monitored using a set up described in detail earlier (Rasulov et al., 2009; Copolovici and Niinemets, 2010). Light intensity was kept at 200 $nmol\ m^{-2}\ s^{-1}$, temperature at 28°C, and ambient CO_2 concentration was 380–400 $\mu mol\ mol^{-1}$. CO_2 and H_2O concentrations at the chamber in- and outlets were measured with an infra-red dual-channel gas analyzer operated in differential mode (CIRAS II, PP-systems, Amesbury, MA, USA). The rates of net assimilation (A), transpiration (E), and stomatal conductance to water vapour (g_s) were calculated from these measurements according to von Caemmerer and Farquhar (1981).

VOC Sampling and GC-MS Analysis VOC sampling was performed via the outlets of each cuvette every morning with a flow rate of 200 $ml\ min^{-1}$ for 20 min by using a constant flow air sample pump (1003-SKC, SKC Inc.,

Houston, TX, USA). Air was drawn through a multibed stainless steel cartridge (10.5 cm length, 0.3 cm inner diam., Supelco, Bellefonte, PA, USA) filled with Carbotrap C 20/40 mesh (0.2 g), Carbopack C 40/60 mesh (0.1 g), and Carbotrap X 20/40 mesh (0.1 g) adsorbents (Supelco, Bellefonte, PA, USA). In addition, a sample was taken from the air inlet prior to the cuvettes to estimate background VOC concentrations. Adsorbent cartridges were analyzed for lipoxygenase (LOX) pathway products, mono-, homo-, and sesquiterpene emissions with a combined Shimadzu TD20 automated cartridge desorber and Shimadzu 2010 plus GC MS instrument (Shimadzu Corporation, Kyoto, Japan) using a method as detailed in Copolovici et al. (2009) and Toome et al. (2010). The background (blank) VOC concentrations were subtracted from emission samples of the seedlings.

Separate samples were collected from larvae without plants. Emissions of volatile compounds from insects were below the detection limits of our system (range from 1.4 to 5.2 nmol mol^{-1} for all compounds (Copolovici et al., 2009).

Statistical Analysis and Data Handling Experiments were replicated three times with independent samples of plants and larvae. Means were statistically compared by Tukey's test and Student ANOVA *post-hoc* test using ORIGIN 8 (OriginLab corporation, MA, USA) and STATISTICA 6.0 (StatSoft, Inc., Tulsa, OK, USA).

Results

Plant Damage by Herbivory The percentage of total *Alnus* leaf area eaten by the geometrid *C. pusaria* larvae varied between 8 and 17%. Leaf area eaten correlated positively with the number of larvae feeding, which varied from 2 to 8 (Fig. 1a). The amount of leaf dry mass eaten by 2 and 4 larvae was 27.1±2.0 mg DW/larva. For 8 larvae, the amount decreased significantly to 15.0±2.0 mg DW/larva ($P<0.05$ for the comparison between 2 and 4 larvae and 8 larvae), i.e., 8 larvae together were eating about as much as 4 larvae. Leaf mass eaten per larva and larval number correlated negatively (Fig. 1b).

Herbivory Effects on Leaf Structure, Chemistr,y and Photosynthetic Characteristics The average (±SE) leaf dry mass per unit area of *A. glutinosa* leaves was 45±5 $g m^{-2}$, and leaf dry to fresh mass ratio was 0.29±0.02 $g g^{-1}$ (no statistical differences between the insect treatments for either trait, $P>0.1$). Nitrogen content of the leaves varied between 3.6 and 3.8% in control and between 2.3 and 3.2% in the infested plants. Nitrogen content of the bulk leaf material decreased with increase of the amount of leaf area eaten, indicating that larvae were eating primarily the N-rich intercostal leaf areas (Fig. 2).

Chloroplast length and overall cross-sectional area increased by the end of the treatment with increasing degree of *C. pusaria* feeding (Table 1A). As a result, the total chloroplast cross-sectional area relative to mesophyll area increased (Table 1B). In addition, chloroplasts tended to be adhered closer to the cell walls in herbivore-damaged than in the control leaves (Table 1A). In addition, the size of the starch grains and the overall area of chloroplasts covered by starch grains increased with increase of *C. pusaria* feeding (Table 1A).

Net assimilation rate *A* was stable at a level of 16–17 μmol m^{-2} s^{-1} throughout the feeding treatment in both control plants and in those infested with the largest number of larvae (Fig. 3a). Although a small increase of ca 5% to 18–19 μmol m^{-2} s^{-1} was detected after larvae removal (Fig. 3b), this effect was non-significant for the three replicates studied ($P>0.05$) (Fig. 3a). Analogously to the net assimilation rate *A*, stomatal conductance was stable at 65 mmol m^{-2} s^{-1} throughout the study in both control and infested plants (Fig. 3b). No feeding effects on photosynthetic characteristics were detected in the treatments with intermediate herbivory.

VOC Emission Lipoxygenase pathway products (LOX compounds) were the first volatiles induced by *C. pusaria* larval feeding. On the first day of the experiment, plants with 4 larvae emitted significantly more of the lipoxyge-

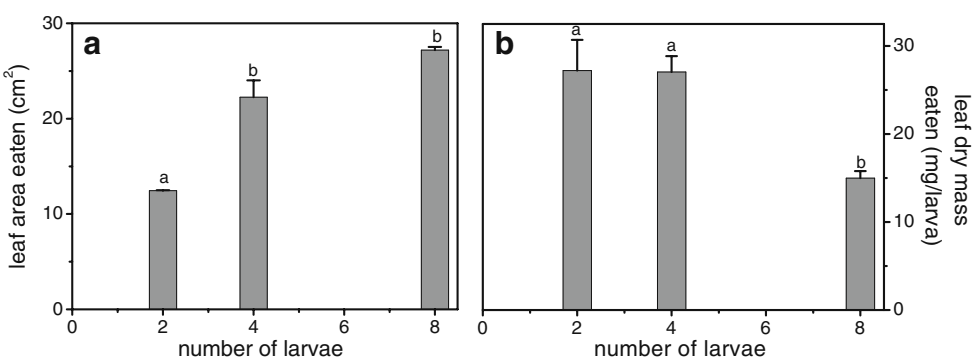

Fig. 1 Leaf area (**a**) and leaf dry mass (**b**) eaten per *Cabera pusaria* larva when different numbers of larvae were exposed to foliage of *Alnus glutinosa*. Measurement: at the end of experiment (d 5). Each data point represents the mean (±SE) of 3 independent replicates. Means were evaluated by Tukey's test, and different letters indicate means that are statistically different at $P<0.05$

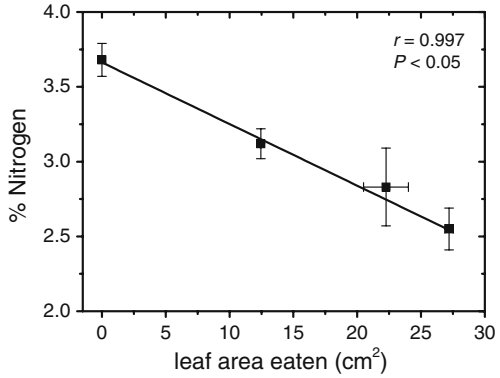

Fig. 2 Leaf nitrogen content (%) in relation to leaf area eaten (cm^2) per *Cabera pusaria* larva when different numbers of larvae were exposed to the foliage of *Alnus glutinosa*. Data show means ± SE of all leaves of 3 independent replicates

nase pathway compounds (*E*)-2-hexenal ($P<0.01$), (*Z*)-3-hexenol ($P<0.01$), 1-hexanol ($P<0.01$), and (*Z*)-3-hexenyl acetate ($P<0.01$) than uninfested plants (Fig. 4). A similar effect was observed in the treatment with 2 larvae. Emissions of the LOX products were maintained at the high level during day two (for comparison of LOX emission rate between day 1 and 4: $P<0.001$, $P<0.05$, $P<0.05$ for 2, 4, and 8 larvae, respectively) (Fig. 5a).

Low emissions of terpenes, close to the baseline level of 0.03 nmol m^{-2} s^{-1}, were observed in control plants. Induction of the monoterpenes α-pinene ($P=0.012$), β-pinene ($P=0.025$), limonene ($P=0.016$), (*E*)-β-ocimene ($P=0.021$), and the sesquiterpene (*E*,*E*)-α-farnesene ($P=0.021$) was observed already on the first day of larval feeding (Figs. 4 and 5). Significant increase of emission of the homoterpene 4,8-dimethyl-1,3,7-nonatriene (DMNT) was observed at day 2 of larval feeding ($P>0.3$ for differences between treatments on day 1, $P<0.001$ for day 2, Fig. 6). These emissions had a particularly strong increase on the 3rd day, and a 50% decrease by the 4th day.

On the 1st day after larval infestation, emissions of all induced compounds were not significantly different between the plants treated with different number of larvae ($P=0.95$ for total monoterpenes, and $P=0.78$ for (*E*,*E*)-α-farnesene). Only for LOX emissions, two larvae induced lower emissions than either 4 or 8 larvae ($P=0.008$, Fig. 5). Emissions of monoterpenes decreased on day 2 for the treatment with 2 larvae, but remained constant at the high level for plants with 4 and 8 larvae. By the 4th day, emissions of monoterpenes released by plants with 2, 4, and 8 larvae differed considerably ($P<0.01$, least significant difference of 0.071 nmol m^{-2} s^{-1}).

No significant difference in the release of (*E*)-β-ocimene and (*E*,*E*)-α-farnesene was observed among the treatments with different numbers of larvae during the first 3 days of the experiment ($P>0.1$). However, by the 4th day, emission rates of (*E*)-β-ocimene and (*E*,*E*)-α-farnesene differed significantly among plants with 2, 4, and 8 larvae ($P<0.001$). Feeding by different number of larvae did not cause statistically different emissions of DMNT ($P>0.1$).

Table 1 Effects of *Cabera pusaria* larvae on foliage of *Alnus glutinosa*: anatomical characteristics

Trait	Average ± SE (*N*=10)				*F*	*P*

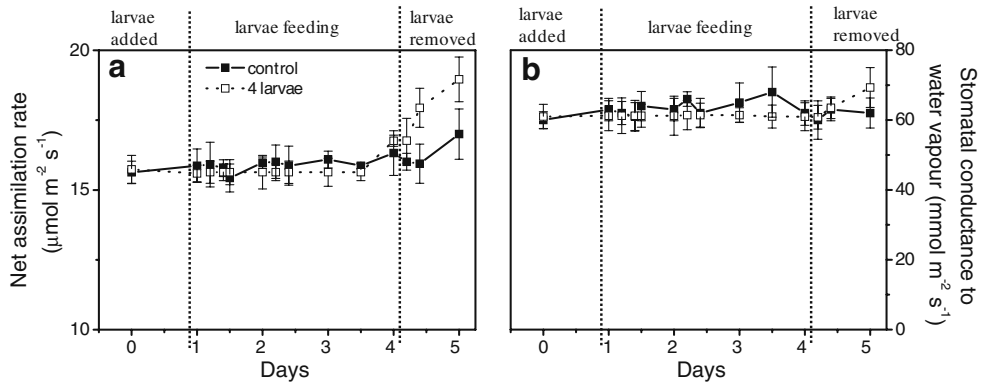

Fig. 3 Net assimilation rate (**a**) and stomatal conductance to water vapor (**b**) in seedlings of *Alnus glutinosa* without insects—control (*filled square*) and with four larvae of *Cabera pusaria* (*white square*). Measurements were conducted at a quantum flux density of 200 μmol m^{-2} s^{-1}, air temperature of 28°C, and at ambient CO_2 concentrations of 380±20 μmol mol^{-1}. Data are expressed per unit projected leaf area. Each data point is the mean (±SE) of 4 independent replicate experiments. At d -1, plants without insects were measured, at d 0 insects were added, and after d 4 the insects were removed

We observed that the kinetics of (*E*,*E*)-α-farnesene emissions tended to be biphasic (Fig. 6). (*E*,*E*)-α-Farnesene emissions of plants with 8 larvae were not statistically different (P=0.4) between day 1 and 2, but between day 3 and 4 emissions differed considerably (P<0.1). These biphasic kinetics were reproduced in all replicates and with different numbers of larvae. In addition, a biphasic model (cubic) fitted the data (r^2=0.84) better than a monophasic (parabola) model (r^2=0.59). On the 4th day, larvae were removed from plants, and by the 5th day, the emission of all compounds decreased to the level close to the start of the experiment (Fig. 6).

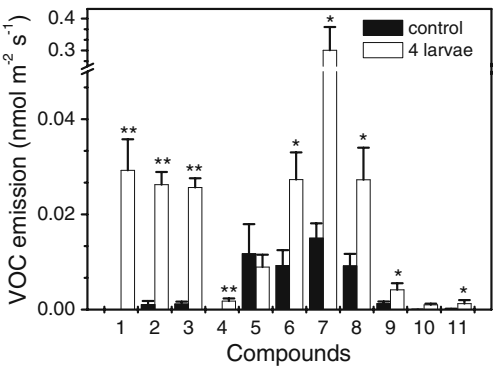

Fig. 4 Volatile organic compound (VOC) emissions from herbivore-attacked (*white bars*) and control (*black bars*) *Alnus glutinosa* plants (means + SE) on the first day of insect feeding (treatment with 4 larvae). Asterisks above the compound numbers indicate significant differences in VOC emissions between control and larvae-infested sample for each compound (*: P>0.05; **: P> 0.01). In other cases, VOC emissions were not significantly different among the treatments (ANOVA *post-hoc* test). Compounds: (*1*) 1-hexanol, (*2*) (*E*)-2-hexenal, (*3*) (*Z*)-3-hexenol, (*4*) (*Z*)-3-hexenyl acetate, (*5*) 6-methyl-5-hepten-2-one, (*6*) limonene (*7*) α-pinene, (*8*) β-pinene, (*9*) (*E*)-β-ocimene, (*10*) DMNT, (*11*) (*E,E*)-α-farnesene

Quantitative Relationships between VOC Emission and Damage by Herbivory Emission of total monoterpenes, LOX products, and (*E*,*E*)-α-farnesene on day 4 were positively correlated with the leaf area eaten by larvae (Fig. 7). The trends were exponential with good correlation coefficients (r>0.98). However, the emission rates of DMNT did not increase with an increase of the number of larvae (r=0.57, P>0.1).

Discussion

Herbivory Effects on Leaf Structure, Chemistry, and Photosynthetic Characteristics Foliage nitrogen content decreased with increase of damage (Fig. 2). As nitrogen content of the major veins is less than that of the intercostal areas (Niinemets et al., 2007), reduction of whole leaf nitrogen content may reflect the selective feeding of intercostal N-rich mesophyll. It is also known that lower leaf quality reduces the rate of larval growth and development (Tikkanen and Julkunen-Tiitto, 2003; Silla et al., 2008). Thus, lower leaf nitrogen content has been suggested to be a direct defense strategy reducing insect herbivory (Cornelissen and Fernandes, 2001).

Previous studies have shown that plant photosynthetic responses to biotic stresses such as herbivory or rust can range from impairment, no net effect, to a stimulating effect (Paige, 1999; Delaney, 2008; Delaney et al., 2008). In our study, there was no net effect on photosynthetic rate per unit leaf area (Fig. 3). This is surprising, given the overall reduction of leaf nitrogen content as the result of selective feeding of photosynthetically active N-rich tissues. Given this reduction, a constant net assimilation rate actually reveals compensatory responses in herbivore-damaged leaves relative to foliage of

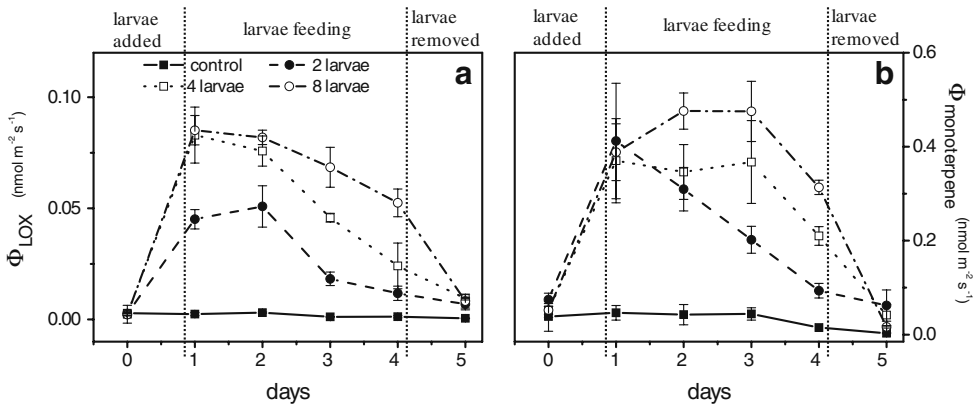

Fig. 5 Emission time-courses (in nmol m^{-2} s^{-1}) of total LOX products (**a**) and monoterpenes (**b**) in the case of healthy leaves and in leaves fed by different numbers of larvae of *Caberia pusaria*. Treatments and data presentation as in Fig. 3

the control plants. In our study, this compensatory response was associated with the overall increase in chloroplast size (Table 1A). Additionally, adherence of chloroplasts closer to the cell wall surface can reduce the CO_2 diffusion resistance from substomatal cavities to chloroplasts (Evans et al., 2009; Niinemets et al., 2009), thereby further compensating for the reduction of N-rich mesophyll.

It has been suggested that compensatory photosynthesis usually is found when herbivory alters the strength of the source-sink relationships, thus increasing the relative or absolute demand of sinks for carbohydrates (Delaney et al., 2008). In our study, we actually observed accumulation of starch in the herbivore-damaged plants (Table 1), suggesting that sink demands were reduced. Reduction of plant growth activity is common in feeding-damaged plants (Poveda et al., 2003) and can reflect the shift of metabolism towards synthesis of protective high molecular mass secondary compounds such as tannins (Bernays et al., 1989; Dudt and Shure, 1994; Hattenschwiler and Schafellner, 1999) in agreement with the largely discredited carbon/nutrient balance hypothesis (Reichardt et al., 1991). Although no changes in net assimilation rates were observed, these data collectively suggest that herbivory-driven modifications in leaf ultrastructure and in sink-source balance occurred during the experiment.

Elicitation of LOX Products When *C. pusaria* larvae damaged leaves of *A. glutinosa*, the production of lipoxygenase (LOX) pathway compounds was the first signal of the induction of a plant stress response, already achieving the maximum emission rate on the first day of feeding. This result is consistent with the observations that oxidative stress and electrolyte leakage are induced by insect damage (Bruinsma et al., 2010). Emissions were present throughout the feeding treatment, reflecting continuous damage of foliage during feeding, while emissions decreased drastically after larvae were removed and the stress was relieved (Figs. 4 and 5a).

Previously, LOX products emission has been shown to scale with the severity of water (Capitani et al., 2009) and ozone (Beauchamp et al., 2005) stresses. Here, we found strong correlation of maximum LOX emission rates with the number of feeding larvae and with the amount of leaf area eaten (Fig. 7b), providing evidence that quantitative stress dose (number of larvae feeding) vs. stress response relationships can also be determined for biotic stresses.

Induction of Ubiquitous Terpenoid Emissions Leaves of *A. glutinosa* do not accumulate terpenes (monoterpenes, sesquiterpenes, or terpenoid derivatives), and do not emit any of these compounds under non-stressed conditions (Isebrands et al., 1999; Lindfors et al., 2000). In control plants analyzed in our study, terpenoid emissions were very low, close to the detection limit, further confirming that *A. glutinosa* is no constitutive terpene emitter.

The feeding by *C. pusaria* caterpillars resulted in induced emissions of ubiquitous monoterpenoids on the first day (Fig. 5b). The emissions peaked at days 2 and remained high in the following days of feeding. Analogously, increases in ubiquitous terpene emissions within the first 2 h of feeding and greater emission following the night period have been observed in a field experiment with hybrid aspen during feeding by larvae of the winter autumn moth *Epirrita autumnata* (Schaub et al., 2010). Continuous increase of ubiquitous emissions was observed until day 3 for experiments with more than 4 larvae per plant (Fig. 4b). In a similar manner, in herbivory experiments with *Chrysomela populi* leaf beetles, the rate of monoterpene emission from poplar leaves increased for the first 4 days of feeding (Brilli et al., 2009). However, emission rates already were strongly reduced by day 1 in our study in the treatment with fewer larvae (Fig. 5b). Overall, strong positive correlations were found between the rate of ubiquitous monoterpene emissions and the number of feeding larvae and the amount of leaf area eaten, again demonstrating a quantitative stress dose vs. plant response.

Induction of Stress-Specific Terpenes While emissions of LOX and ubiquitous monoterpenes were detected 1 day after larval feeding started, emissions of the monoterpene

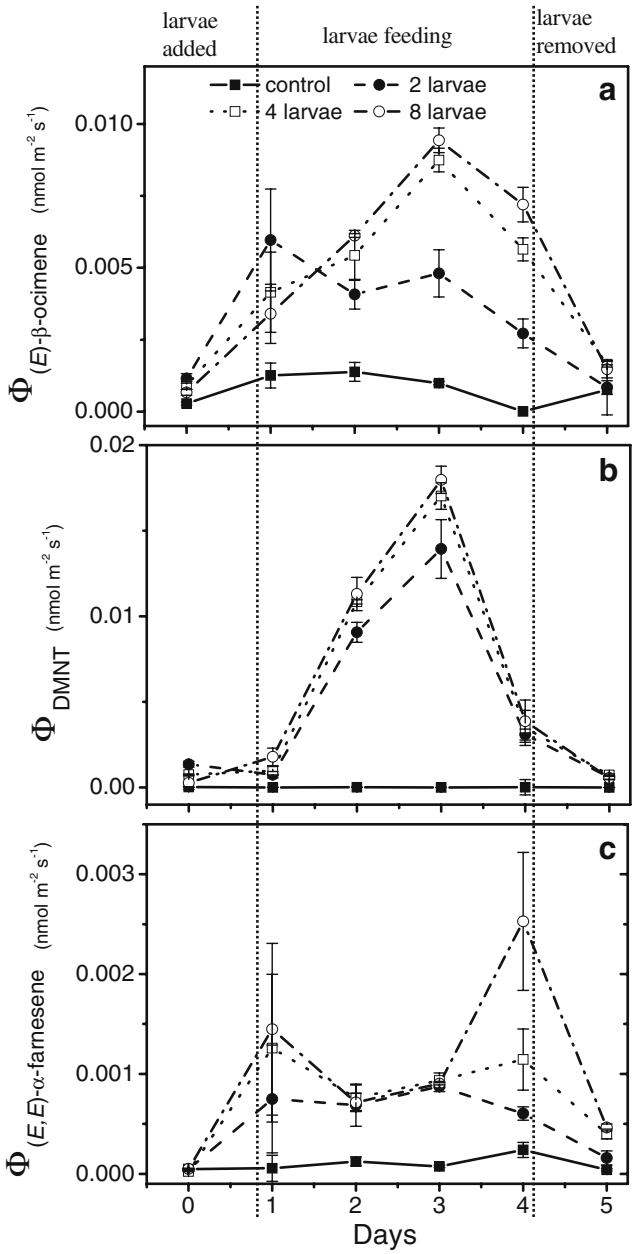

Fig. 6 Temporal variation of (*E*)-β-ocimene (**a**), DMNT (**b**), and (*E*,*E*)-α-farnesene (**c**) emissions (in nmol m^{-2} s^{-1}) from *Alnus glutinosa* plants fed by *Caberia pusaria* larvae. Treatments and data presentation as in Fig. 3

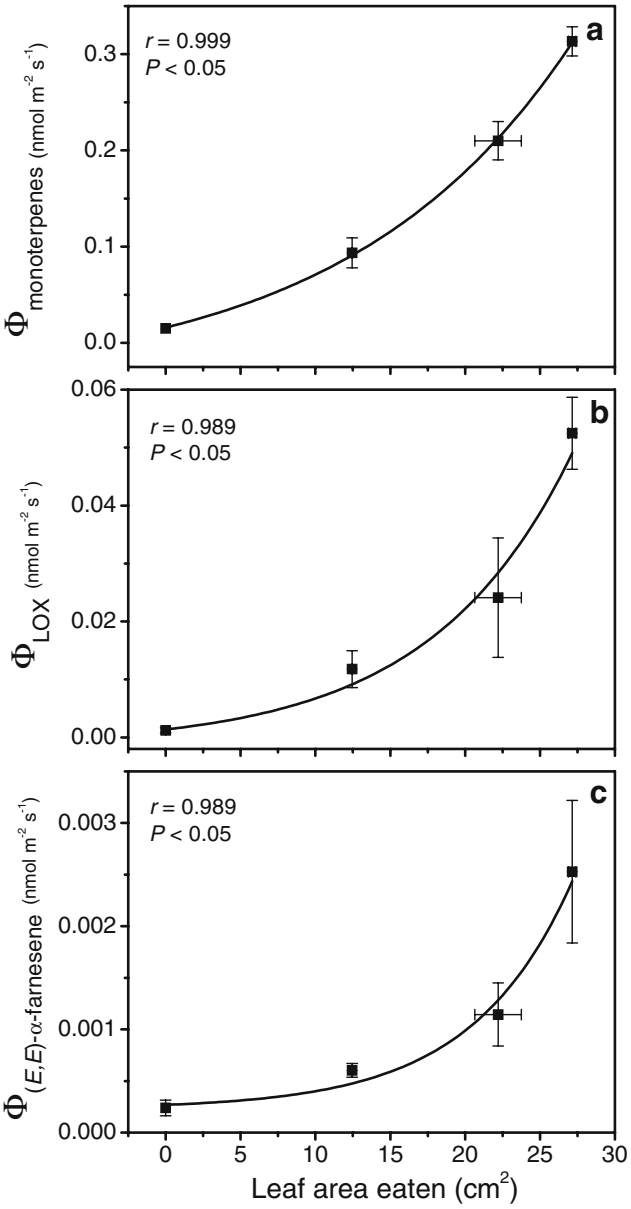

Fig. 7 Correlations of total monoterpenes (**a**), LOX products (**b**), and (*E*,*E*)-α-farnesene (**c**) emissions (in nmol m^{-2} s^{-1}) with the amount of leaf area of *Alnus glutinosa* eaten by *Caberia pusaria* larvae in the 4th day of feeding. Data were fitted by non-linear regressions in the form $y = a \cdot e^{b \cdot x}$. All other conditions and data presentation as in Fig. 3

(*E*)-β-ocimene, the homoterpene DMNT, and the sesquiterpene (*E*,*E*)-α-farnesene were observed only on the 2nd day. Hence, biosynthesis of these compounds apparently starts later than those of LOX products and other ubiquitous monoterpenes (Brilli et al., 2009).

We observed that the kinetics of (*E*,*E*)-α-farnesene emissions tended to be biphasic (Fig. 6). In previous studies, multiphasic emission responses of LOX volatiles and methanol after stress have been demonstrated (Beauchamp et al., 2005). Statistical comparisons among days did not confirm the biphasic response, but nevertheless the kinetics were reproducible, and fitting all data by biphasic function yielded a higher degree of explained variance. Interestingly, the first peak of (*E*,*E*)-α-farnesene emissions co-occurred with the onset of enhanced emissions of ubiquitous monoterpenes and (*E*)-β-ocimene, while the second peak followed the peak in DMNT emissions (Fig. 6). There is evidence that different terpenoid classes are synthesized in different subcellular compartments, with the production of sesquiterpenes being traditionally thought to be located in the cytosol, while the

production of monoterpenoids is confined to the plastids (Nagegowda, 2010). Furthermore, enzymes of the mevalonate (MVA) pathway are present in the cytosol, while typically the genes coding for enzymes of the mevalonate pathway are presented in the chloroplast and in the mitochondrial compartments (Lee and Chappell, 2008). This suggests different pathways for synthesis of (*E*,*E*)-α-farnesene and (*E*)-β-ocimene. Nevertheless, there are numerous examples of coordination of expression of nuclear and chloroplastic genes during biotic stress (e.g., De Coninck et al., 2010). Furthermore, there is now conclusive evidence of plastidial synthesis of sesquiterpenes as well (Sallaud et al., 2009). Thus, it is tempting to speculate that the first peak of (*E*,*E*)-α-farnesene emission coinciding with (*E*)-β-ocimene emission reflects activation of chloroplastic sesquiterpene synthesis, while the second peak coinciding with DMNT reflects activation of the cytosolic pathway.

Previous studies demonstrate that (*E*)-β-ocimene synthase is induced by insect herbivory in *Medicago truncatula* leaves (Navia-Gine et al., 2009), and that induction of expression of terpene and sesquiterpene synthases genes are involved in the overall defense response in *Oryza sativa* plants (Yuan et al., 2008). Elicitation of defense isoprenoid emissions can further elicit defense genes in undamaged lima bean leaves (Arimura et al., 2000), and biosynthesis of different β-ocimene isomers are almost exclusively fuelled by the recently assimilated photosynthetic carbon according to the plastidial 2-C-methyl-D-erythritol 4-P (MEP) pathway (Arimura et al., 2008). On the other hand, in bean plants, the emission of induced (*E*)-β-ocimene was reduced when the whiteflies *Bemisia tabaci* attacked spider mite-infested plants (Zhang et al., 2009). Although our data cannot be used to resolve the cause/effect relationships in the sequence of various terpenoids emitted, we suggest that the secondary peak in (*E*,*E*)-α-farnesene emissions is associated with systemic induction of DMNT in undamaged leaves of an herbivore-infested plant.

After larvae were removed, emission of (*E*,*E*)-α-farnesene and (*E*)-β-ocimene rapidly decreased until reaching the level of non-stressed plants (Fig. 6). Previous studies have demonstrated that specific elicitors in the regurgitant of the caterpillar enhance the amount of several released volatiles (Halitschke et al., 2000; Rose and Tumlinson, 2005), Thus, reductions in volatile emissions after feeding and removal of larvae can reflect the lack of these elicitors. However, the emissions of DMNT started to decrease already during insect feeding, suggesting a different mechanism of induction. Different mechanisms of action are consistent with previous experiments employing various elicitors. Bartram et al. (2006) demonstrated that insect feeding resulted in induction of volatile release predominantly via activation of the MVA pathway, while exposure to fungal elicitor alamethicin stimulated the production of DMNT mainly via the MEP pathway.

As with ubiquitous terpenes, the emission rates of (*E*)-β-ocimene and (*E*,*E*)-α-farnesene were quantitatively related to the strength of biotic stress (Fig. 7). However, no such pattern was visible in the case of DMNT. We suggest that the quantitaties of (*E*)-β-ocimene and (*E*,*E*)-α-farnesene can be important for attraction of natural enemies of the herbivores, as the attraction effect of certain compounds may depend on their relative amounts compared to other volatiles (Beyaert et al., 2010).

In summary, these data provide evidence that biotic stress effects on plant VOC emissions are quantitative for ubiquitous monoterpenes, (*E*)-β-ocimene, and (*E*,*E*)-α-farnesene. To our knowledge, this quantitative relationship between plant VOC emission and extent of plant damage by herbivory has not been shown in deciduous trees. In contrast to the other compounds, DMNT emissions were not quantitatively related to the extent of herbivory stress. Thus, we hypothesize that DMNT can serve as a qualitative signal for predators and parasitoids that conveys the information "presence of herbivores", while the emission of mono- and sesquiterpenes or their amounts relative to other volatiles provides information about the abundance of the herbivores. Parasitoid and predator attraction experiments are needed to test this hypothesis.

Acknowledgements We thank Prof. Jarmo Holopainen, University of Eastern Finland, Kuopio, Finland, for the 4,8-dimethyl-nona-1,3,7-triene (DMNT) standard. The Estonian Ministry of Science and Education (grants SF1090065s07 and SF0180122S08), the Estonian Science Foundation (post-doctoral grants JD101, MJD14 and grant 7645) and the European Commission through the European Regional Development Fund (Center of Excellence FIBIR) provided financial support for this research.

Abstract The emerald ash borer (EAB; *Agrilus planipennis* Fairmaire; Coleoptera: Buprestidae), is an exotic wood-boring beetle that has been threatening North American ash (*Fraxinus* spp.) resources since its discovery in Michigan and Ontario in 2002. In this study, we investigated the phytochemical responses of the three most common North American ash species (black, green, and white ash) in northeastern USA to EAB adult feeding. Black ash was the least responsive to EAB adult feeding in terms of the induction of volatile compounds, and levels of only two (indole and benzyl cyanide) of the 11 compounds studied increased. In green ash, levels of two [(*E*)-*β*-ocimene and indole] of the 11 volatile compounds studied were elevated, while the levels of two green leaf volatiles [hexanal and (*E*)-2-hexenal] decreased. White ash showed the greatest response with an increase in levels of seven of the 11 compounds studied. Qualitative differences among ash species were detected. Among the phenolic compounds detected, ligustroside was the only one detected in all three species. Oleuropein aglycone and 2 unidentified compounds were found only in black ash; coumaroylquinic acid and feruloylquinic acid were detected only in green ash; and verbascoside hexoside was detected only in white ash. EAB adult feeding did not elicit or decrease concentrations of any selected individual phenolic compounds. However, although levels of total phenolics from black and green ash foliage were not affected by EAB adult feeding, they decreased significantly in white ash. EAB adult feeding elevated chymotrypsin inhibitors in black ash. The possible ecological implications of these findings are discussed.

Introduction

Many volatile and non-volatile phytochemicals have various ecological and physiological functions in interactions with biotic and abiotic factors. Some adversely affect colonization or development by herbivores (Berenbaum 1995; Duffey and Stout 1996), while some function as herbivore attractants or attractants for natural enemies of herbivores (Dicke et al. 1990; Turlings et al. 1991). In response to herbivore damage, many of these compounds can accumulate in plant tissues (Karban and Baldwin 1997; Chen et al. 2008, 2009) with significant effects on herbivore interactions with conspecifics and heterospecifics (Agrawal and Karban 2000). For instance, increased density of pigment glands (containing terpenoids such as gossypol) of cotton leaves induced by strawberry mites, *Tetranychus turkestani* Ugarov & Nikolskii (Prostigmata: Tetranychidae), significantly reduced beet armyworm growth [*Spodoptera exigua* Hübner (Lepidoptera: Noctuidae)] (Agrawal and Karban 2000). Beet armyworm larvae also can distinguish between previously damaged and intact

(control) cotton leaves and will consume more control leaves than previously damaged leaves in dual-choice tests (McAuslane et al. 1997).

The exotic emerald ash borer (EAB; *Agrilus planipennis* Fairmaire; Coleoptera: Buprestidae) has been threatening North American ash (*Fraxinus* spp.) trees since its discovery in Michigan and Ontario in 2002 (MSU 2010). Although North American ash species, such as black ash (*F. nigra* Marshall), green ash (*F. pennsylvanica* Marshall), and white ash (*F. americana* L.) are all susceptible to EAB compared to the Asian ash (e.g., Manchurian ash, *F. mandshurica* Ruprecht) (Rebek et al. 2008), evidence points to inter-specific variation in constitutive foliar chemistry among these North American species (Pureswaran and Poland 2009). Differences in feeding and infestation preference in laboratory studies appear to be associated with such phytochemical variability (Pureswaran and Poland 2009, Chen and Poland 2010). Intact black, green, and white ash release many volatiles that trigger electro-antennal responses of EAB adults (Rodriguez-Saona et al. 2006; de Groot et al. 2008) and possess a wide variety of phenolics (Eyles et al. 2007) and protease inhibitors (Chen and Poland 2009b) that may confer resistance against EAB. Phenolics generally denature plant proteins and thus reduce nutritive values of plants (Dudt and Shure 1994; Ossipov et al. 2001). Phenolics also can inhibit the absorption of key amino acids. Many protease inhibitors are involved in herbivore defense (Ryan 1990; Zavala et al. 2004). Protease inhibitors impair herbivore growth by eventual depletion of essential amino acids that result from an herbivore's compensatory production of digestive proteases (Broadway and Duffey 1986).

Many phytochemicals can be induced by herbivore damage. However, little is known about the physiological response of North American ash species to EAB adult feeding. Differential responses of ash species to EAB adult feeding may change the dynamics of ash foliar phytochemicals, which can further affect the behavior of EAB, other herbivores of ash trees, and potential natural enemies of EAB larvae. Elucidating inter-specific variation among these compounds also might contribute to understanding differences in feeding and infestation preference among North American species. Our objectives in this study were to determine: (1) the quantity and composition of volatile organic compounds (VOCs), polyphenols, and trypsin and trypsin inhibitors of the three ash species in response to EAB adult feeding; (2) if the magnitude of induction differs among the three species.

Methods and Materials

Ash Seedlings Green, white, and black ash seedlings (2-yr-old and ca. 30–50 cm tall) were purchased from Lawyer Nursery Inc. (West Plains, MT, USA) in February, 2009. Trees were stored in a dark room at 4°C until potting. Seedlings were potted in TPOT2 tree pots (width: 15 cm; height: 41 cm; volume: 6.23 L; Stuewe & Sons, Inc., Corvallis, OR, USA) using Fafard #52 soil (BFG Supply Co., Burton, OH, USA) as planting medium. They were grown during April-May, 2009 (ca. L14: D10), in a greenhouse set at approximately 25±2°C. The greenhouse is located at the Tree Research Center, Michigan State University, East Lansing, MI, USA. Seedlings were fertilized once every 3-4 day with approximately 2 L nutrient solution containing 200 ppm N, 60 ppm P, 150 ppm K, 80 ppm Ca, 40 ppm Mg, 60 ppm S, 0.15 ppm Cu, 4 ppm Fe, 0.8 ppm Mn, and 0.32 ppm Zn.

EAB Adult Females EAB adult females were collected from 90-cm long logs cut from naturally infested ash trees felled at the end of 2008 and early 2009 in Ingham County, MI, USA. Logs were held in cold storage at 4°C until needed, then removed to allow beetles to emerge. Beetles were separated by sex and kept in 295 ml plastic beverage containers with an evergreen ash, *F. uhdei* (Wenzig) Linglesh, leaf in a vial of water for feeding. Containers with beetles were stored in growth chambers (25°C) with a photoperiod of 14:10 hL:D, and >70% relative humidity. Leaves were replaced twice a week, until needed for experiments.

Headspace Leaf Volatile Collection and Analysis Constitutive headspace volatile profiles of the three species used were investigated in Pureswaran and Poland (2009). Headspace leaf volatiles of EAB damaged leaves (a whole branch from "induced treatment", see below) and those without EAB damage (a whole branch from "control treatment") of the same ash species attached to live seedlings were collected and compared in this study.

EAB treated leaves were prepared by caging a branch bearing 5–8 mature compound leaves within a nylon sleeve with both ends tied. Mature leaves were chosen because EAB adults are known to prefer mature over young foliage (Chen and Poland 2009b). To simulate common levels of foliage damage in nature by EAB, adults (personal observations), ten 8- to 10-d-old adult females were placed inside the sleeve and allowed to feed for 48 h. Adult females then were removed and frass gently brushed from the leaves. Approximately 5–10% of the foliage was visually estimated to be consumed within the 48 h ("induced treatment"). Control leaves also were enclosed by a sleeve but without beetles ("control treatment").

The volatile compounds of the whole branch, either from "induced treatment" or "control treatment", subsequently

were collected with a push-pull system described in Rodriguez-Saona et al. (2006). Briefly, the branch was enclosed in a 4 L glass cylinder (height: 30.5 cm; diam: 15.2 cm; Analytical Research Systems, Inc., Gainesville, FL, USA). Activated charcoal-purified air generated by a pump entered the top of the glass cylinder at a rate of 2 L/min. Half of the air with a rate of 1 L/min passed through a volatile collection trap (VCT) located 5 cm above the base of the cylinder by a vacuum pump. The VCT was filled with 30 mg Alltech Super-Q absorbent material. Volatiles were collected in the laboratory under 25±1°C with about 40% RH for 24 h. The room was illuminated with four 40 W fluorescent light tubes. At the end of volatile collection, the aerated portion of the seedling was clipped, and dry weights (oven-dried at ca. 60 C) of aerated tissue were recorded. Each treatment (EAB vs. control) was replicated 8 times. Volatile collection was conducted separately by species (i.e., black, green, and white ash) due to the limitation of available volatile collection systems. Volatile collection was conducted approximately 4 week after potting of the seedlings.

Methods of volatile extraction and analysis are described in Chen and Poland (2009a). Collected volatiles were extracted from the Super-Q adsorbent by flushing with 250 μl of pentane-hexane (both HPLC grade; purity: pentane >99%; hexane: ≥ 95%) mixture (1.5:1 ratio) containing 1 ng μl^{-1} of heptyl acetate (internal standard; purity >98%) with a stream of nitrogen gas. Two μl of each sample were injected into a Thermo Scientific Trace GC gas chromatograph equipped with a DSQ-II MS mass spectrometer and a 30 m × 0.25 mm id, 0.25 μm thick TR-1MS column by using splitless injections and helium as the carrier gas. The oven temperature began at 60°C for 1 min, increased by 10°C/min to 190°C, then by 35°C/min to 300°C, and held for 5 min. The following 11 compounds were detected consistently: hexanal, (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, (*Z,E*)-α-farnesene, α-humulene, β-caryophyllene, cubenene, (*E*)-β-ocimene, indole, benzyl cyanide, and nonanal. They were quantified based on comparison of peak areas with that of the internal standard and calibration curves generated with synthetic standards. The purity of these synthetic standards was 98% (hexanal), 98% [(*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, (*Z,E*)-α-farnesene, α-humulene, β-caryophyllene, and cubenene], 70% [(*E*)-β-ocimene and indole], 99% (benzyl cyanide), and 95% (nonanal). The amount of each compound of interest was calculated in ng g^{-1} dry weight of tissue. All reagents and solvents used were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Determination of Non-volatile Defensive Compound We examined the following non-volatile foliar defense responses to EAB adult feeding: soluble phenolics (total and individual), trypsin, and chymotrypsin inhibitors. Analyses were run for both treatments, EAB damaged (induced) and no damage (control), for all species examined above. The preparation of EAB feeding was as described in the preceding experiment. Mature leaves with (a branch from "induced treatment") and without (a branch from "control treatment") EAB feeding damage were cut and flash frozen in liquid nitrogen approximately 4 week after seedling potting. Samples then were ground to a fine powder with a mortar and pestle in liquid nitrogen.

Extraction of Soluble Phenolics Phenolics were extracted according to Eyles et al. 2007. Briefly, ~80–120 mg of homogenized foliage tissue were extracted twice overnight in the dark at 4 C with 500 μl of 100% MeOH. Extracts were pooled and transferred into a 1.5-ml microcentrifuge tube and centrifuged (12,000xg for 5 min) to remove solids. Samples were stored at -20 C and used in subsequent HPLC analyses.

Analysis and Identification of Soluble Phenolics HPLC-ESI-MS (Varian 500 MS; Palo Alto, CA, USA) in parallel with a PDA detector (Varian ProStar 335) were employed to detect and identify phenolics. Chromatographic separation of phenolics was carried out using a Waters Xterra™ RP18 analytical column (3.9 μm). The binary mobile phase consisted of water/acetic acid (99.9:0.1 v/v) (eluant A) and methanol/acetic acid (99.9:0.1 v/v) (eluant B) with a flow rate of 1 ml/min. The gradient was as follows (percentages refer to proportions of eluant B): 5–15% (0–15 min); 15–30% (15–35 min); 30–40% (35–40 min); 40–60% (40–50 min); 60–90% (50–55 min); 90–100% (55–60 min). The injection volume for all samples was 10 μl. Compound separation was achieved by post-column splitting (1:1), and passing the LC effluent through the PDA Detector (scanning range, 200–400 nm) and an electrospray source (parameters below). The ESI was in negative ion mode. The MS detector was optimized to obtain maximum yields of $[M-H]^-$ ions of apigenin, luteolin, rutin, oleuropein, tyrosol, and verbascoside standards. The optimized MS parameters were: capillary voltage, -80 V; needle voltage, -5 kV. The atmospheric pressure ionization (API) parameters were as follows: API nebulizing gas (air) 25 psi; API drying gas (nitrogen) 15 psi at 350 C. Survey scan was set to detect molecules between 50–1,000 m/z. Each treatment was run using both the TurboDDS scan type in the enhanced scan mode and full scan mode. The TurboDDS trigger threshold was set to 20,000 counts (parent ion counts). In the TurboDDS scan mode, MS scan parameters were set on-the-fly by the instrument to detect the most abundant parent ions. If TurboDDS was triggered, the mode temporarily switched

to MSn mode to perform daughter scans of the putative parent ions. The TurboDDS trigger threshold for daughter ions was 20,000, 2,000, and 200 ions for MS2, MS3, and MS4, respectively. Full scan parameters were set following the conditions mentioned above. Full scan chromatograms were overlaid with the PDA chromatogram traces at 280 nm to match $[M-H]^-$ parent ions to λ_{max} of individual phenolics. PDA data of individual compounds were analyzed using PolyView software (Varian). Phenolics were identified based on the congruence of parent and daughter ions, λ_{max}, and order of time compared to the published literature (Eyles et al. 2007). Data acquisition and processing were performed using MS Workstation 6 (Varian).

Quantitation and Analysis of Soluble Phenolics with HPLC-UV Quantitation of identified phenolics was performed using HPLC-UV. HPLC-UV analyses were performed on an Alliance 2690 separation module (Waters, Milford, MA, USA) equipped with an autosampler and a 996 PDA (Waters). The autosampler and column temperatures were set to 4 and 30 C, respectively. The binary mobile phase consisted of water/acetic acid (98:2, v/v) (eluant A) and methanol/acetic acid (98:2, v/v) (eluant B), with a flow rate of 1 ml/min. The elution program matched the conditions used for HPLC-ESI-MS-PDA analysis mentioned above. The injection volume for all samples was 10 µl. Samples were scanned in the range 200–400 nm. Individual compounds were quantified in mg g^{-1} FW. The identity of hydroxytyrosol, verbascoside, oleuropein, rutin, apigenin, and luteolin were unequivocally confirmed by spiking samples with the respective standards and matching retention times and UV maxima. Due to a lack of external standards for all compounds, samples were quantified following the method of Eyles et al. 2007. Compounds were expressed as hydroxytyrosol equivalents for hydroxytyrosol hexoside and tyrosol hexoside, verbascoside equivalents for verbascoside hexoside, oleuropein equivalents for elenolic acid derivative, ligustroside, nuzhenide, and oleuropein aglycone, apigenin equivalents for apigenin rutinoside, and luteolin equivalents for kaempherol rutinoside and kaempherol rhamnosylhexoside. Quantitation of individual compounds was carried out by comparing peak areas at 280 nm against a standard curve of the equivalent external standard. Total peak areas were taken to represent total phenolics (Bonello and Blodgett 2003; Blodgett et al. 2005). Total and individual peak areas at 280 nm for all species and treatment combinations were normalized to 100 mg dry weight.

Trypsin and Chymotrypsin Inhibitor Extraction and Analysis Trypsin and chymotrypsin inhibitors were extracted with a 10 mM Tris buffer (pH 7.5) containing 1 mM ethylenediaminetetraacetic acid (EDTA), 0.1 mM phenylmethylsulfonyl fluoride (PMSF), a solution modified from Chen et al. (2007). The mixture was centrifuged at 10,000 g for 10 min. The supernatant was used for assay. The trypsin and chymotrypsin inhibitor assays followed Walsh and Wilcox (1970), and Broadway (1993) using *N*α-*p*-tosyl-L-arginine methyl ester (TAME) and *N*-benzoyl-L-tyrosine ethyl ester (BTEE) as substrates for trypsin and chymotrypsin determination, respectively. Each treatment was replicated 8 times.

Statistical Analysis Concentrations of volatile and non-volatile foliar compounds were compared individually between treatments using independent *t*-tests. Concentrations of volatiles and phenolics were square root transformed to homogenize variance, while no transformation was necessary for protease inhibitor data. All analyses were conducted in SAS with α=0.05 (SAS Institute 1999).

Results

Foliar Volatile Compound Responses to EAB Adult Feeding Induction of foliage volatile compounds by EAB adult feeding in black, green, and white ash is shown in Table 1. The most abundant volatiles were the three green leaf volatiles, hexanal, (*E*)-2-hexenal, and (*Z*)-3-hexenyl acetate, and a sesquiterpene, *Z,E*-α-farnesene, irrespective of species. Release of indole and benzyl cyanide by black ash was significantly induced, over 7-fold. Emanation of indole and (*E*)-β-ocimene (monoterpene) of green ash was elevated, while two green ash leaf volatiles, hexanal and (*E*)-2-hexenal, decreased. Release of seven volatiles of white ash, (*Z,E*)-α-farnesene, α-humulene, β-caryophyllene, cubenene, (*E*)-β-ocimene, indole, benzyl cyanide, increased. The magnitude of increase ranged from 5-fold [(*Z,E*)-α-farnesene] to over 100-fold (benzyl cyanide). No other compound of the three species was significantly affected by EAB adult feeding.

Foliar Non-volatile Compound Responses to EAB Adult Feeding HPLC-UV chromatographic profiles of control (undamaged) black, green, and white ash are shown in Fig. 1. Tentatively identified and characterized phenolics are presented in Table 2. Only qualitative differences among species were detected (Tables 2, 3). A total of six, 13, and 10 phenolics were detected in black, green, and white ash, respectively. Among those, ligustroside was the only one detected in all three species. Oleuropein aglycone and 2 unidentified compounds (peak # 2 and 4) were found

[a] Ash foliage was fed upon by 10, 8-10-d old EAB female adults for 48 h; * and ** denote significant difference at α=0.05 and 0.01 between control and EAB treatments within the same ash species, respectively

only in black ash; coumaroylquinic acid and feruloylquinic acid were detected only in green ash; and verbascoside hexoside was detected only in white ash (Tables 2, 3). EAB adult feeding did not elicit or decrease concentrations of any of a number of selected compounds (most prominent peaks in their respective chromatograms,,Table 3). The levels of total foliar phenolics in white ash decreased significantly upon EAB feeding but were unaffected in black and green ash foliage (Fig. 2).

EAB adult feeding did not affect production of trypsin inhibitor in any species (Fig. 3a). Neither was production of chymotrypsin inhibitor in green or white ash changed (Fig. 3b). Chymotrypsin inhibitor concentration of EAB adult-fed black ash foliage was greater than that of undamaged control (Fig. 3b).

Discussion

The most abundant constitutive volatiles from all three species were three green leaf volatiles [hexanal, (*E*)-2-hexenal, and (*Z*)-3-hexenyl acetate] and a sesquiterpene (*Z,E*-α-farnesene). Indole was induced by EAB adult feeding in all three species. However, in previous work, indole did not elicit any electro-antennal activities of EAB females or males (Rodriguez-Saona et al. 2006).

Other volatiles detected from foliage responded differentially to EAB adult feeding. Headspace concentrations of hexanal and (*E*)-2-hexenal of black and white ash were not affected by EAB adult feeding, while they were suppressed in green ash. Both the reduction of these two compounds and the effect on EAB need further investigation because EAB males and females have been shown to be responsive to hexanal and (*E*)-2-hexenal in GC-EAD bioassays (Rodriguez-Saona et al. 2006; de Groot et al. 2008). However, neither of these two compounds seemed to be attractive to EAB males or females under field conditions (de Groot et al. 2008).

The monoterpene (*E*)-β-ocimene was among the most commonly released volatiles following herbivore damage. Its emission was not elevated in black ash, while it increased significantly in green and white ash. Many herbivores, including the sphinx moth *Manduca sexta* (Lepidoptera: Noctuidae) (Fraser et al. 2003) and EAB (Rodriguez-Saona et al. 2006) have been observed to respond to (*E*)-β-ocimene in EAD bioassays.

Elevated levels of four volatiles, (*Z,E*)-α-farnesene, α-humulene, β-caryophyllene, and cubenene, were induced by EAB feeding in white ash. These compounds have been suggested to be involved in host plant location by many herbivores and host location by some parasitoids (Dicke et al. 1990; Meiners et al. 2003). They have been found to be antennally-active in EAB (Rodriguez-Saona et al. 2006; Crook et al. 2008), and the latter three are components of *Manuka* oil which is attractive to EAB in the field (Crook et al. 2008).

Benzyl cyanide emission was elevated 6-fold by EAB feeding in black ash and 100-fold in white ash, while it was not affected in green ash. Benzyl cyanide is produced by both plants (Bartlet et al. 1997, Rodriguez-Saona et al. 2006) and insects (Seidelmann et al. 2000, Fatouros et al. 2008), and it has been hypothesized to have many ecological functions in intraspecific and interspecific interactions. For instance,

benzyl cyanide released from oilseed rape (*Brassica napus* L.) serves as an attractant for cabbage seed weevil *Ceutorhynchus assimilis* (Coleoptera: Curculionidae) (Bartlet et al. 1997). In insects, male-originated benzyl cyanide functions as an anti-aphrodisiac for females and kairomones for *Trichogramma brassicae* (Hymenoptera:Trichogrammatidae), the egg parasitoid of *P. brassicae* females (Fatouros et al. 2005). However, benzyl cyanide was not among the volatile compounds in Manchurian ash that elicited electroantennal activity in EAB adult males or females (Rodriguez-Saona et al. 2006).

Three noteworthy points concerning volatile ash emissions in this study are: (1) A lack of antennal or behavioral response by EAB to significantly induced volatiles such as indole does not necessarily negate an effect on other organisms such as predators and parasitoids of EAB. Attraction of herbivore-induced plant volatiles to natural enemies of herbivores is well documented (Heil 2008; Chen et al. 2010); (2) Although not significantly elevated, levels of (*Z,E*)-α-farnesene, α-humulene, β-caryophyllene, and cubenene in EAB fed seedlings of green and black ash were numerically higher than those in respective control seedlings. The effects of potential increases of these compounds on attraction of EAB requires further investigation; (3) The effects of changes in ratios of these compounds deserve further examination because not only trap placement, trap size and color, but also ratios and release rates of VOCs, are important in trapping and detection of EAB (Crook and Mastro 2010).

Table 3 Concentrations (mean±1SE mg g^{-1} fresh weight) of selected individual phenolic compounds in green, white, and black ash

No significant differences for each individual phenolic compound were found from the same ash species between control and induced foliage

[a] See Table 2 for tentative identification; Ash foliage was fed upon by 10, 8-10-d old EAB female adults for 48 h

[b] ND=Not detected

Phenolics generally denature plant proteins and thus reduce nutritive values of plants (Dudt and Shure 1994; Ossipov et al. 2001). Phenolics also can inhibit the absorption of key amino acids. For example, cyclochampedol, a flavonoid from acetone bark extracts of the tree *Arctocarpus champeden* (Thunb.) Merr., inhibits absorption of leucine in the midgut of the silkworm, *Bombyx mori* L. (Lepidoptera: Bombycidae) (Parenti et al. 1998). Significant qualitative differences among the three ash species were observed. Qualitative difference of phloem phenolics between the Asian ash species, Manchurian ash, and two North American species, green and white ash, have been noted previously (Eyles et al. 2007). Our study shows also, however, that compared to phloem, ash foliage appears to contain fewer phenolic compounds, regardless of ash species.

EAB adult feeding did not induce accumulation of individual selected foliar phenolics in the present study, irrespective of species, perhaps due to the nutrient regime used. For example, many volatile and non-volatile compounds that are involved in cotton (*Gossypium hirsutum* cv. FiberMax 989) or Austrian pine (*Pinus nigra* Arnold) defense are suppressed by high nitrogen fertilization (Blodgett et al. 2005; Chen et al. 2008), and the nitrogen supply in the present study was relatively high. Second, the lack of induction likely was due to a phenomenon called "delayed induced resistance" (DIR) in which induction of defensive compounds occurs in the years following defoliation. Induced resistance can be either DIR or "rapidly induced resistance" (RIR) in which defensive compounds appear shortly after damage (Karban and Myers 1989). DIR has been observed in many plant species, in particular, in trees (Kaitaniemi et al. 1998). Third, the lack of induction might reflect a general pattern of the response of mature foliage to biotic and abiotic stress (Nichole-Orians 1991; McAuslane et al. 1997; Chen and Poland 2009b).

However, EAB adult feeding induced a decrease of total soluble phenolics in white ash (Fig. 1). This may partially explain why EAB adults consumed more white ash foliage given choices between black and white ash foliage (Chen and Poland 2010). Furthermore, the

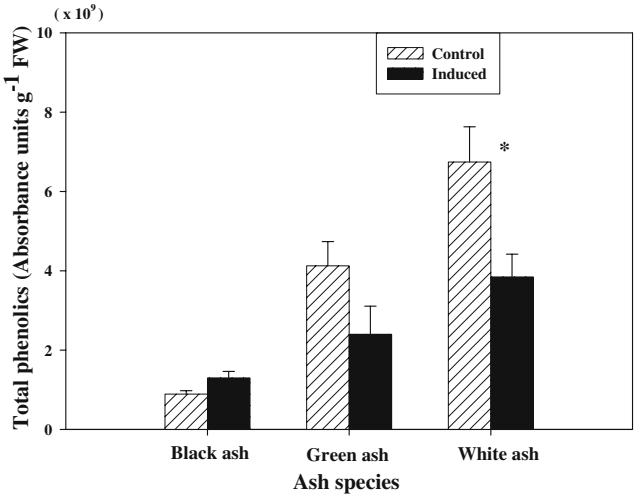

Fig. 2 Total soluble phenolics (mean±SE absorbance units g^{-1} fresh weight tissue) in control (undamaged) foliage and foliage induced by emerald ash borer (EAB) adult feeding of black, green, and white ash. Data were analyzed by independent *t*-test, separately for ash species. Significant differences within species are indicated by asterisks (*: $P<0.05$). Black ash: $N_{Control}=8$; $N_{EAB}=8$; Green ash: $N_{Control}=8$; $N_{EAB}=8$; White ash: $N_{Control}=7$; $N_{EAB}=7$

longevity of EAB adults was greater when fed white ash compared to black ash (Chen and Poland 2010). The three phenolics uniquely detected in black ash (oleuropein aglycone, unknowns #1 and 2; Table 2) might also cause EAB adults to prefer green and white ash over black ash (Chen and Poland 2010). Compared to green and white ash, black ash is phylogenetically more closely related to Manchurian ash (Wallander 2008), which has been observed to be more resistant to EAB infestation (Rebek et al. 2008).

Many protease inhibitors are involved in herbivore defense (Ryan 1990, Zavala et al. 2004). Protease inhibitors impair herbivore growth by eventual depletion of essential amino acids resulting from a herbivore's compensatory production of digestive proteases (Broadway and Duffey 1986). EAB feeding did not affect trypsin inhibitors of black, green, or white ash (Fig. 3a), or chymotrypsin inhibitors of green or white ash (Fig. 3b). The activity of chymotrypsin inhibitors, however, did increase in black ash as a result of EAB feeding (Fig. 3b), which, together with the unique phenolics in black ash discussed above, might contribute to the preference of EAB adults for green and white ash over black ash (Chen and Poland 2010).

In summary, EAB adult feeding differentially affected volatile and non-volatile compounds of the three most common ash species in northeastern USA. Black ash was the least responsive species in terms of volatile induction with only two (indole and benzyl cyanide) of eleven compounds responding. Green ash was more responsive than black ash, with two [(*E*)-β-ocimene and indole] of eleven volatiles induced while two green leaf volatiles [hexanal and (*E*)-2-hexenal] decreased. White ash showed the strongest response with an increase in seven of eleven compounds. Black and white ash seedlings were more responsive to EAB adult feeding than green ash in terms of two non-volatile, putatively defensive compound groups, i.e., phenolics and protease inhibitors. Phenolic production decreased in white ash while chymotrypsin increased in black ash. The induction of chymotrypsin inhibitors by EAB feeding, together with unique phenolics in black ash, might explain, in part, EAB adults' preference for green and white ash over black ash (Chen and Poland 2010). Future studies will focus on screening of potent compounds from ash foliar volatile and non-volatile compounds identified in this study and incorporating them into ash breeding programs to develop resistant trees.

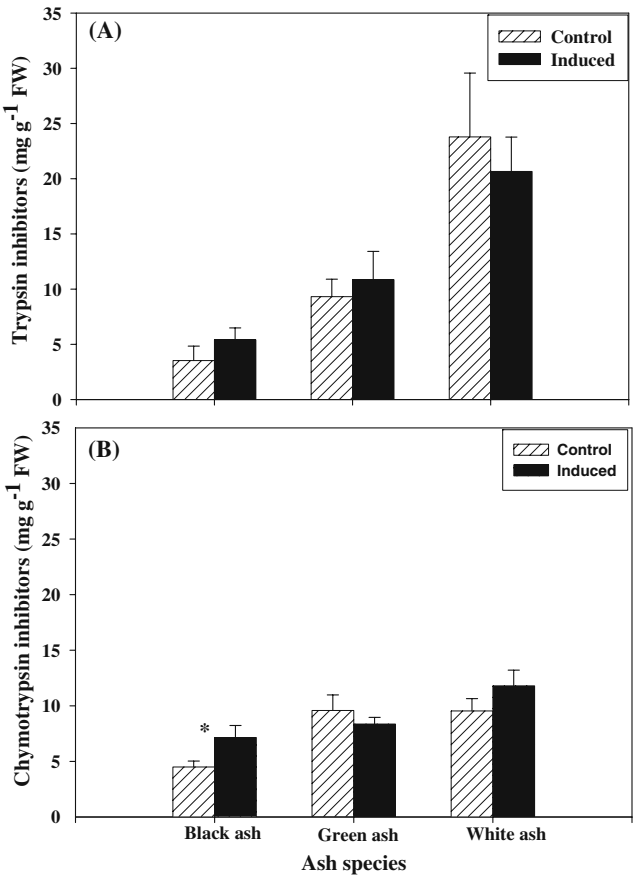

Fig. 3 Total concentrations (mean±1SE mg g^{-1} fresh weight tissue) of foliar trypsin **a** and chymotrypsin inhibitors **b** in control (undamaged) foliage and foliage induced by emerald ash borer (EAB) adult feeding of black, green, and white ash. Data were analyzed by independent *t*-test, separately for ash species. Significant differences within species are indicated by asterisks (*: $P<0.05$). Black ash: $N_{Control}=8$; $N_{EAB}=8$; Green ash: $N_{Control}=8$; $N_{EAB}=8$; White ash: $N_{Control}=8$; $N_{EAB}=8$

Acknowledgments We thank Tina Ciaramitaro and Deborah Miller for maintenance of the EAB colony and trees in the greenhouse. Tina Ciaramitaro also helped with volatile collection. We are grateful to Drs. Dawn Olson (USDA-ARS, Tifton, GA), Jennifer Koch (USDA Forest Service, Delaware, OH), and two anonymous reviewers for insightful comments that improved an earlier version of the manuscript. The research was supported by the USDA Forest Service, NA FHP, by the USDA APHIS/USDA Forest Service Accelerated Emerald Ash Borer Research Program (GRT00011769/60016270), and by State and Federal funds appropriated to the Ohio Agricultural Research and Development Center, the Ohio State University.

Behavioral Responses of the Leafhopper, *Cicadulina storeyi* China, a Major Vector of Maize Streak Virus, to Volatile Cues from Intact and Leafhopper-Damaged Maize

Abstract The chemical ecology of the leafhopper, *Cicadulina storeyi* China (Homoptera: Cicadellidae), an important vector of Maize Streak Virus (MSV), was studied with a view to developing novel leafhopper control strategies in sub-Saharan Africa. Choice tests using a Y-tube olfactometer revealed that odors from uninfested maize seedlings (*Zea mays* cv. Delprim) were significantly more attractive to *C. storeyi* than odors from *C. storeyi*-infested seedlings. Headspace samples of volatile organic compounds (VOCs) collected from 10 to 12 day-old uninfested seedlings were more attractive than those collected from infested seedlings. While VOCs collected from uninfested maize seedlings were attractive, VOCs collected from C. *storeyi*-infested seedlings were significantly repellent. Analysis of the collected VOCs by gas chromatography (GC) and coupled GC-mass spectrometry (GC-MS) led to the identification of myrcene, linalool, (*E*)-2-decen-1-ol, and decanal from uninfested seedlings, and (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), methyl salicylate, benzyl acetate, indole, geranyl acetate, (*E*)-caryophyllene, α-bergamotene, (*E*)-β-farnesene, β-sesquiphellandrene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) from infested seedlings. Of these, methyl salicylate, (*E*)-caryophyllene, (*E*)-β-farnesene, and TMTT were identified previously as volatile semiochemicals involved in plant defense against other sucking insect pests. When tested individually for behavioral activity, all compounds were repellent for *C. storeyi*. Moreover, when these induced VOCs were added to the blend of VOCs from uninfested maize seedlings, a shift from attraction to repellency was observed. Addition of methyl salicylate, (*E*)-β-farnesene, or TMTT resulted in a choice for the solvent control (i.e., repulsion), whereas addition of (*E*)-caryophyllene resulted in no reduction in host VOC attractiveness. These results show that VOCs induced in maize have the potential to be exploited in the control of viruliferous leafhoppers in sub-Saharan Africa.

Introduction

Maize, *Zea mays* L. (Poaceae), is the third major cereal crop in the world after wheat and rice, and is the most important crop in sub-Saharan Africa, where it has gradually displaced native food crops such as sorghum and millet, and is grown for human consumption, animal feed, and several industrial uses. The greatest constraints to higher yields are pests, diseases, and parasitic weeds (Efron et al., 1989). Maize can supply 50% of the caloric intake in sub-Saharan Africa, but in certain years, a farmer's entire crop can be wiped out by Maize Streak Virus (MSV) (Geminiviridae: genus *Mastrevirus*), an endemic pathogen of native African grasses, which is the most important virus disease of maize in sub-Saharan Africa (Thottappilly et al., 1993). It is acquired and

transmitted in a persistent manner by *Cicadulina* spp. leafhoppers (Homoptera: Cicadellidae), although the ability to transmit MSV varies among species. A vector insect can retain and transmit the virus throughout its lifespan. There are five *Cicadulina* species, *C. storeyi, C. mbila, C. arachidis, C. ghaurii*, and *C. dabrowskii*, associated with MSV transmission in Nigeria, the two former species being the most efficient vectors (Asanzi et al., 1995; Oluwafemi et al., 2007). The timing of infection, the maize genotype, and prevailing climatic conditions can all influence the extent of damage, which is often economically significant. In Nigeria, 100% infection has been recorded in some fields (Fajemisin et al., 1976), while outbreaks of the disease, causing economic losses, have been reported in over 20 countries (Kim et al., 1981).

Control of MSV disease has been based on cultural practices, including time of planting and rotation of maize crops, the use of chemical insecticides incorporated in the soil at planting, and the use of resistant varieties. However, these practices do not control the leafhopper vectors, since both virus and vectors have wide alternative host ranges in wild grasses around maize fields, and survive on wild grasses during off seasons when maize is not cultivated. In addition, the gradual increase in the use of irrigation in African agriculture has extended the growing period for maize, which in turn has increased vector populations and the source of virus inoculums. Chemical insecticides are expensive for resource-poor farmers, and are perceived as having a negative environmental impact. Breeding of maize for durable resistance to MSV has been a long-term research strategy for protection of maize crops (Fajemisin et al., 1984). Quantitative Trait Loci (QTLs) for maize resistance to MSV have been mapped (Pernet et al., 1999), and an MSV-resistant transgenic maize has been developed (Shepherd et al., 2007). However, such technology is unlikely to be available for the poorest of sub-Saharan maize farmers. Taken together, barriers to the deployment of insecticide and genetic-based strategies for MSV control make the search for alternative strategies, such as exploitation of naturally-occurring plant defense processes, urgent.

One possibility is to exploit volatile semiochemicals (naturally-occurring behavior and development-modifying chemicals) released by plants following insect herbivory, which can deter herbivore colonization, while at the same time attracting insects antagonistic to herbivores, such as parasitoids and predators (Dicke et al., 1993, 2003; Karban and Baldwin, 1997). Knowledge of the induced plant defense chemistry in maize upon leafhopper damage could lead to the selection and/or development of varieties with more durable resistance, through enhanced constitutive or induced plant defense (Bernasconi et al., 1998; Stout and Davis, 2009).

This study provides the first examination of the chemical ecology of the interaction between maize and *C. storeyi*, specifically an investigation of the behavioral responses of *C. storeyi* to volatile organic compounds (VOCs) released by maize seedlings when infested by *C. storeyi,* and the response to such VOCs in laboratory bioassays. Our findings provide the first steps in developing novel control options that exploit naturally occurring processes by which maize plants resist damage by leafhoppers.

Methods and Materials

Insects and Plant Material *Cicadulina storeyi* China (Homoptera: Cicadellidae) leafhoppers, free of Maize Streak Virus (MSV), were collected from the mass rearing colony of the International Institute of Tropical Agriculture (IITA), Ibadan, Nigeria, and reared on pearl millet, *Pennisetum americanum* (= *typhoides*) in a quarantine growth facility (23±2°C, 40% RH, 16:8 h, L:D) at Rothamsted Research, Harpenden, Hertfordshire, UK. The leafhoppers and host plants were placed in plexi-glass cages (44×44×70 cm) with two netted openings (12×12 cm) in the front while a third netted opening (11×11 cm) at the back was fitted with an electric fan for air circulation. Maize, *Zea mays* (cv. Delprim) seeds were bought from Delley Samen und Pflanzen AG, Delley Semences et Plantes SA, Le Chateau, Switzerland, and grown under controlled conditions at Rothamsted (25±1°C; 16:8 h, L:D; 150 $\mu E.m^{-2}.s^{-1}$).

Y-Tube Olfactometer Bioassay Bioassays were conducted in a controlled environment room (22±1°C, 40% Relative Humidity) fitted with an extraction fan. A glass Y-tube olfactometer (2 cm internal diam., 16 cm stem length, 14 cm arms length) was set up in a black cage (60×60×76 cm) consisting of a steel frame covered with black cardboard paper to avoid external visual cues. The olfactometer was clamped onto a tripod in an inclined position (70° from the horizontal plane). Uniform illumination was provided by two fluorescent light tubes (70 W; Luminux) positioned approximately 25 cm above the Y-tube junction. A charcoal filtered airstream (200 ml min^{-1}) was supplied to each arm of the olfactometer by using an electric pump. Each airstream then passed through a glass jar containing test material (either live uninfested or *C. storeyi*-infested maize seedlings, or a piece of filter paper dosed with 1 µl of VOC sample or solution of synthetic chemical). *C. storeyi* were collected from rearing cages in a separate insectary room and starved for 2 hr before each trial. Ten adult *C. storeyi* were used in each replicate, and the experiments were replicated ten times. After each replicate, the olfactometer was rotated 180° to avoid directional effects. The numbers

of leafhoppers entering each arm as a final choice were recorded. A leafhopper was deemed to have made a final choice if it entered an arm but did not return back within 10 min to enter the opposite arm. Bioassays were conducted throughout the day, but with treatments alternated, to avoid any effect of time of day on response. No effects were observed regarding the effect of time of day on *C. storeyi* behavior.

Four series of dual-choice test bioassay experiments were carried out. In Series 1, *C. storeyi* were directly exposed to odors ducted from single maize seedlings. Responses to odors from uninfested and *C. storeyi*–infested maize seedlings were compared, the latter of which were prepared by infestation with 50 leafhoppers for a period of 24 hr prior to use. In Series 2, responses to VOCs collected from seedlings were compared as follows: (i) uninfested VOCs vs. diethyl ether solvent; (ii) *C. storeyi*—infested VOCs vs. diethyl ether solvent; and (iii) uninfested VOCs vs. *C. storeyi*—infested VOCs. In Series 3, responses to synthetic compounds (1 μg in 1 μl hexane) identified as being induced by *C. storeyi* were tested against the solvent control. Finally, in Series 4, responses to a headspace sample of uninfested maize VOCs alone and in combination with 1 μg doses of synthetic equivalents of *C. storeyi*-induced compounds were compared to a solvent control. The dose of headspace sample (from clean and infested maize) used per bioassay was equivalent to the VOCs emitted by one maize seedling / hr.

Statistical Analysis The Y-tube olfactometer data were analyzed using a paired *t*-test with statistical software (GenStat Version 10, VSN International Ltd.) after ensuring that data were normally distributed.

Volatile Organic Compound (VOC) Collection Air entrainment (also referred to as dynamic headspace collection) was carried out following standard procedures (Agelopoulos et al. 1999) using 10 to 12 day-old maize seedlings. Seeds were pre-germinated and then planted singly in 13 cm (5″) plastic pots inside a growth chamber (25°C, 16:8 h, L:D). For each collection, a single seedling was enclosed in a glass vessel (22 cm high × 6.5 cm internal diam) open at the bottom with two collection ports at the top (one for inlet and the other for outlet). The bottom was closed without pressure around the plant stem by using two semicircular aluminium plates with a hole in the center to accommodate the stem. The plates were clipped to a flange on the open end of the glass vessel. Air, purified by passage through an activated charcoal filter, was pumped into the vessel through the inlet port at 700 ml min^{-1} (flow rate controlled by a needle valve and measured by a flow meter). Air was drawn out at 600 ml min^{-1} through Porapak Q (50 mgs) in a 5-mm diam glass tube (Alltech Associates, Camforth, Lancashire, UK). The difference in flow rates created a slight positive pressure to ensure that unfiltered air did not enter the system, thus removing the need for an airtight seal around the stem. All connections were made with polytetrafluoroethylene (PTFE) tubing (Alltech Associates) with brass ferrules and fittings (North London Valve, London, UK) and sealed with PTFE tape (Gibbs & Dany, Luton, UK). Glassware, metal plates, and other equipment were washed with Teepol detergent (Herts County Supplies, Herts, UK) in an aqueous solution, acetone, and distilled water, and then baked overnight at 180°C. Porapak Q tubes were conditioned before use by washing with redistilled diethyl ether (1 ml) and heated to 132°C for 2 hr under a stream of constant nitrogen. Charcoal filters (BDH, 10–14 mesh, 50 g) were conditioned before use by purging with nitrogen inside an oven (150°C) for a minimum of 2 hr. Once conditioned, filters were sealed using Swagelok cap fittings and left to cool to ambient temperature prior to use. VOCs collected on Porapak Q were eluted with freshly distilled diethyl ether (750 μl). Eluted samples were then concentrated to *ca.* 100 μl under a gentle stream of nitrogen and stored in tightly capped microvials in a freezer (−20°C) until required for use. Plants were entrained for 7 d, but the Porapak Q tubes were changed daily, ensuring 24 hr entrainment periods. VOCs were collected from clean and *C. storeyi*—infested maize seedlings. For the latter, seedlings were infested with 50 adults per plant, and allowed to settle for 1 hr prior to commencement of VOC collection. For behavior assays and chemical analysis, VOC samples collected during 24–48 hr, 48–72 hr, and 72–96 hr were pooled together and concentrated to ca. 100 μl, to provide headspace samples equivalent to VOCs emitted by one maize seedling / hr. 0–24 Hr samples were excluded as behavior assays with live plants were conducted 24 hr after infestation, and samples collected beyond 96 hr were excluded to avoid possible interference from stress caused by placement of plants in volatile collection chambers. Entrainments from clean and infested plants were replicated 3 times.

Gas Chromatography (GC) Analysis VOCs were analyzed on a Hewlett-Packard 6890 GC equipped with a cool-on-column injector, a flame ionization detector (FID), and a non-polar HP-1 bonded phase fused silica capillary column (50 m×0.32 mm i.d., film thickness 0.52 μm). The oven temperature was maintained at 30°C for 1 min, and programmed at 5°C min^{-1} to 150°C and held for 0.1 min, then 10°C min^{-1} to 230°C. The carrier gas was hydrogen. Four μl of each eluted sample were injected into the injector port of the GC instrument. Data were analyzed using HP Chemstation software.

Coupled GC-Mass Spectrometry (GC-MS) GC-MS analysis of collected VOCs was performed using a fused silica capillary column (50 m×0.32 mm i.d., film thickness 0.52 μm, DB-1), attached to a cool on-column injector, which was directly coupled to a magnetic sector mass spectrometer (Autospec Ultima, Fisons Instruments, Manchester, UK). Ionization was by electron impact (70 eV, source temperature 250°C). Helium was the carrier gas. The oven temperature was maintained at 30°C for 5 min, and then programmed at 5°C min^{-1} to 250°C. Tentative identifications were made by comparison of spectra with mass spectral databases (NIST, 2005). Identifications were confirmed by peak enhancement on GC using authentic compounds (Pickett, 1990).

Chemicals Porapak Q (80/100 mesh) was purchased from Alltech (PA, USA). Diethyl ether (purris.) was purchased from Sigma Aldrich. Hexane (95% pesticide residue) was purchased from Fisher Scientific (Loughborough, Leicestershire, UK) and distilled prior to use. Methyl salicylate and (*E*)-caryophyllene were purchased from Sigma Aldrich (Steinheim, Germany). (*E*)-β-Farnesene (>98%) was synthesized from (*E*)-farnesyl chloride (Kang et al., 1987). (*E*, *E*)-4,8,12-Trimethyl-1,3,7,11-tridecatetraene (TMTT) was synthesized from (*E,E*)-farnesol, by oxidation to its corresponding aldehyde (*E,E*)-farnesal, followed by Wittig methylenation (Leopold, 1990).

Results

Bioassay Series 1—Responses to Odors from Uninfested and Infested Maize Seedlings In dual-choice Y-tube olfactometer bioassays, *C. storeyi* preferred the odor from uninfested maize seedlings to the odor from *C. storeyi* infested seedlings (P=0.018) (Fig. 1).

Bioassay Series 2—Responses to VOC Samples VOCs collected from uninfested maize were attractive (P=0.003), while VOCs from *C. storeyi*-infested maize were repellent (P=0.021) (Fig. 2). In a dual-choice experiment, *C. storeyi* preferred VOCs from uninfested maize seedlings compared to VOCs from *C. storeyi*-infested seedlings (P<0.001) (Fig. 2).

VOC Analysis The VOC profile of 10 to 12 day-old maize seedlings was altered markedly when plants were infested with *C. storeyi*. Analysis of the odor blends, which were collected in 24–48 hr, 48–72 hr, and 72–96 hr periods and combined, using GC and coupled GC-MS (Fig. 3), showed that myrcene, linalool, and decanol were produced by both uninfested and infested plants. However, seedlings infested with *C. storeyi* additionally produced (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), benzyl acetate, methyl salicylate, indole, geranyl acetate, (*E*)-caryophyllene, α-bergamotene, (*E*)-β-farnesene, β-sesquiphellandene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT). The identity of methyl salicylate, (*E*)-caryophyllene, (*E*)-β-farnesene, and TMTT was confirmed by GC peak enhancement using authentic samples. Replication (N=3) of VOC collection over the same 7 d period confirmed consistent emissions from clean and infested seedlings (data not shown).

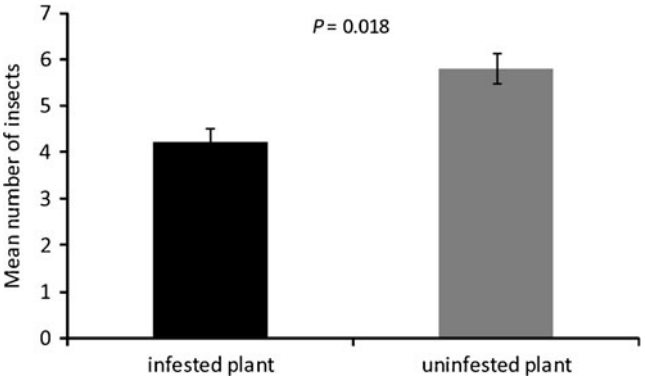

Fig. 1 Mean (± standard error) number of leafhoppers, *Cicadulina storeyi*, choosing odors from infested and uninfested maize seedlings in a Y-tube olfactometer. Statistics: *t*-test; N=10 replicates each with 10 individuals

Bioassay Series 3—Responses to Synthetic VOCs *C. storeyi* preferred the solvent control over methyl salicylate (P=0.002) (Fig. 4). Similarly, the induced VOCs (*E*)-β-farnesene, (*E*)-caryophyllene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) were repellent compared to the solvent control (P=0.034, P=0.043 and P=0.048, respectively) (Fig. 4).

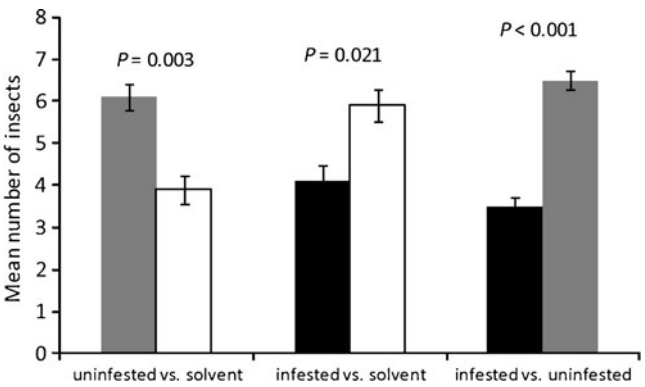

Fig. 2 Mean (± standard error) number of leafhoppers, *Cicadulina storeyi*, choosing VOCs or solvent control in a Y-tube olfactometer. Statistics: *t*-test; N=10 replicates each with 10 individuals

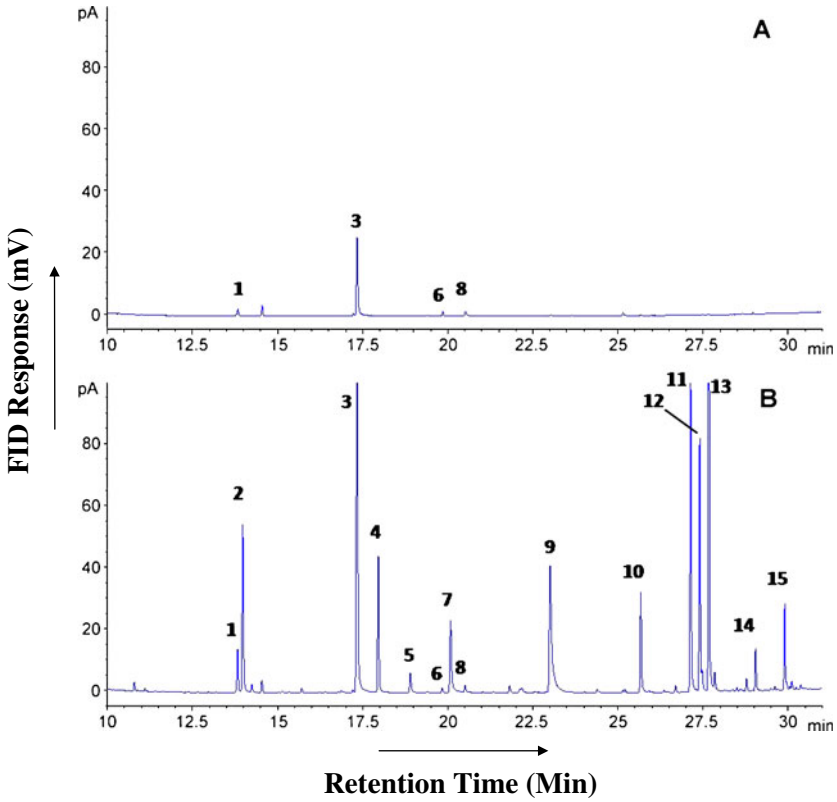

Fig. 3 Gas chromatograms of VOCs emitted by maize seedlings (cv. Delprim) 2–4 d after infestation. A. Uninfested maize seedlings. B. Maize seedlings infested with *Cicadulina storeyi* Key: 1. Myrcene 2. (*Z*)-3-Hexenyl acetate 3. Linalool 4. (*E*)-4,8-Dimethyl-1,3,7-nonatriene (DMNT) 5. Benzyl acetate 6. (*E*)-2-Decen-1-ol 7. Methyl salicylate 8. Decanal 9. Indole 10. Geranyl acetate 11. (*E*)-Caryophyllene 12. α-Bergamotene 13. (*E*)-β-Farnesene 14. β-Sesquiphellandrene 15. (*E,E*)-4,8,12-Trimethyl-1,3,7,11-tridecatetraene (TMTT). Compound identifications remain tentative apart from 7, 11, 13 and 15, which were confirmed by GC peak enhancement using authentic samples

Bioassay Series 4—Responses to C. storeyi-Inducible Compounds in the Presence of VOCs from Uninfested Maize When methyl salicylate was added to VOCs collected from uninfested maize, more *C. storeyi* preferred the solvent control ($P<0.001$) (Fig. 5). Addition of (*E*)-β-farnesene and TMTT to VOCs from uninfested maize also resulted in preference for the solvent control ($P=0.003$ and $P=0.048$, respectively), whereas *C. storeyi* still preferred VOCs from uninfested maize despite the addition of (*E*)-caryophyllene ($P=0.01$) (Fig. 5).

Discussion

Analysis of the VOCs collected from maize seedlings (cv. Delprim) infested with *C. storeyi* by gas chromatography

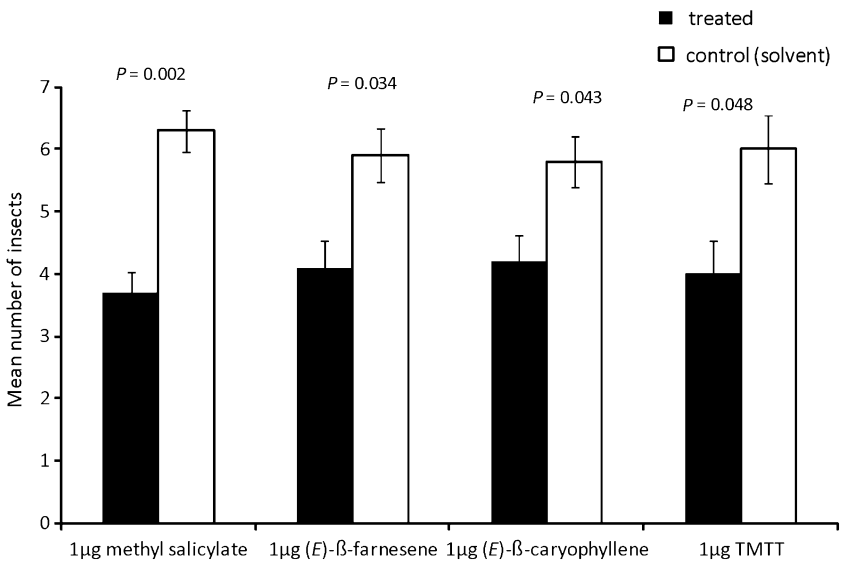

Fig. 4 Mean (± standard error) number of leafhoppers, *Cicadulina storeyi*, choosing synthetic induced VOCs or solvent control in a Y-tube olfactometer. Statistics: *t*-test; $N=10$ replicates each with 10 individuals

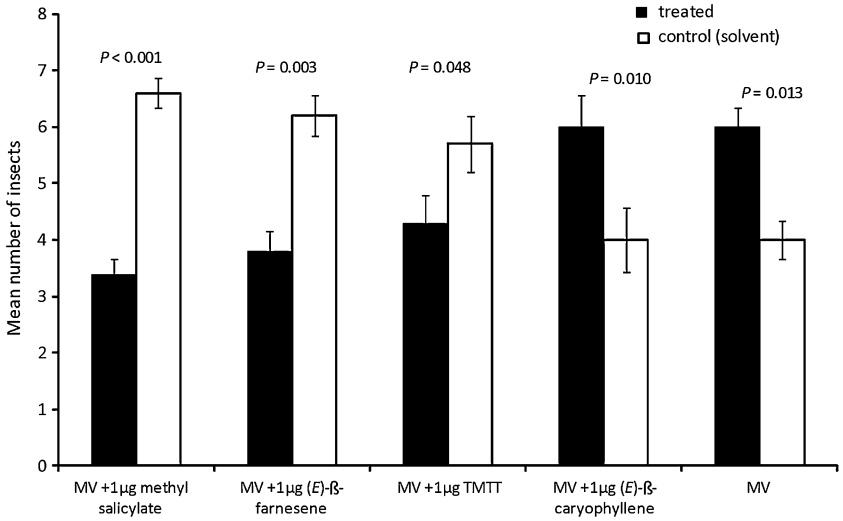

Fig. 5 Mean (± standard error) number of leafhoppers, *Cicadulina storeyi*, choosing maize VOCs (MV) in combination with synthetic induced VOCs or solvent control (indicated by MV only) in a Y-tube olfactometer. Statistics: *t*-test; *N*=10 replicates each with 10 individuals

(GC) and coupled GC-mass spectrometry (GC-MS) showed that the VOC profile was similar to those induced by the leafhopper, *Euscelidius variegatus* (Erb, 2009), and *Spodoptera* spp. caterpillers (*S. littoralis* and *S. exigua*) (Hoballah et al., 2002, 2004; Hoballah and Turlings, 2005; Gouinguene et al., 2003, 2005; Farag et al., 2005; Schmelz et al., 2003). Tentative identifications included myrcene, linalool, (*E*)-2-decen-1-ol, and decanal from uninfested seedlings, and (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), methyl salicylate, benzyl acetate, indole, geranyl acetate, (*E*)-caryophyllene, α-bergamotene, (*E*)-β-farnesene, β-sesquiphellandrene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) from infested seedlings. Replication of volatile collections from clean and infested plants confirmed a consistent pattern in VOC profiles. Although samples collected beyond 96 hr were excluded to avoid possible interference from stress caused by placement of plants in volatile collection chambers, no visible sign in the production of stress cues was observed (data not shown). The strong induced emission of methyl salicylate following *C. storeyi* infestation contrasts with a previous study with *E. variegatus* (Erb, 2009), where no methyl salicylate was reported. This difference cannot be attributed to differences in feeding behavior, as both *C. storeyi* and *E. variegatus* are known to be phloem-feeders, but instead could be due to the fact that a longer duration of VOC collection was used in our study, compared to that of Erb (2009). It is possible that this strong induction of emission of methyl salicylate contributes to systemic immunity against MSV infection, as the compound has been demonstrated to act as a critical mobile signal in plants to mediate systemic immunity against viral and bacterial diseases (Park et al., 2007; Vlot et al., 2008).

The induction of plant defense in maize by leafhoppers appears to be much weaker on a per individual basis compared to caterpillars. In our study, five adult leafhoppers were used per maize seedling in preliminary experiments (data not shown), and an increase in insect density, to 50 individuals per seedling, was required in order to achieve detectable amounts of VOCs. Erb (2009) also used 40 adults of *E. variegatus* per maize seedling to achieve emission of a quantity of volatiles similar to 3 sec instars of *S. littoralis*. This was attributed to the lower amounts of damage inflicted by the stylets of *E. variegatus*, compared to the chewing mouthparts of *S. littoralis*. Furthermore, previous studies in our laboratory have shown that there is diel periodicity in the production and release of VOCs by maize (Chamberlain et al., 2006). Thus, future work will investigate the dynamics of VOC release in maize upon leafhopper infestation.

VOC production in maize has been shown to be induced by elicitors that originate from herbivores, e.g., volicitin, which was originally isolated and identified from the regurgitant of *S. exigua* (Alborn et al., 1997; Frey et al., 2000), and caeliferins, which were isolated and identified from the American bird grasshopper, *Schistocerca americana* (Alborn et al., 2007). VOC production is linked to transcription of specific genes, e.g., terpene synthase genes for the production of sesquiterpenes, DMNT and TMTT, of which several have been isolated and characterised (Degenhardt et al., 2009 and refs therein), and *IGL* that encodes indole-3-glycerol phosphate lyase for the production of indole (Frey et al., 2000). Production of methyl salicylate in tobacco is under the control of salicylate methyltransferase (SAMT) (Ross et al., 1999). Interestingly, salicylate methyltransferase activity in *Arabidopsis* is controlled by the *AtBSMT1* gene, for which transcription induction is strongly responsive to infestation by larvae of *Plutella xylostella*, physical wounding, and treatment with methyl jasmonate (Chen et al., 2003). Although a herbivore-inducible salicylate methyltransferase gene homologue has been cloned from maize (Lawrence and Novak, 2004), it has not been demonstrated that this gene is actually responsible for emission of methyl salicylate. The

results in our study suggest the production of an elicitor of plant defense by *C. storeyi*, which is capable of inducing defense genes as for other elicitors. Further work is underway to investigate the induction of mRNA transcripts for defense genes following *C. storeyi* infestation, and to characterize the elicitor of plant defense from this major plant disease vector.

The Y-tube olfactometer data presented here show that *C. storeyi* was attracted to VOCs from fresh, uninfested maize seedlings but was repelled by VOCs from *C. storeyi*-infested seedlings. Furthermore, VOCs from uninfested seedlings were more attractive than those from infested seedlings. Bioassays with synthetic compounds were limited to those induced by *C. storeyi* infestation, specifically those reported elsewhere as volatile semiochemicals involved in plant defense against other sucking insect pests, i.e., methyl salicylate, (*E*)-caryophyllene, (*E*)-β-farnesene, and TMTT. The identification of behaviorally active compounds involved in location of uninfested seedlings was not proceeded with, as this was outside the scope of the study. Methyl salicylate, (*E*)-caryophyllene, (*E*)-β-farnesene, and TMTT were significantly repellent when tested alone at a single dose (1 μg). Furthermore, addition of either methyl salicylate, (*E*)-β-farnesene, or TMTT at the same dose as an attractive blend of maize VOCs not only masked the attractiveness of the blend, but made it repellent to *C. storeyi*. Further dose-response studies are required to confirm the behavioral role of these compounds, particularly at much lower, ecologically relevant levels.

As stated above, although the results in this study represent one of the first reports of plant defense induction by leafhoppers, methyl salicylate, (*E*)-β-farnesene, and TMTT have all been reported elsewhere as volatile semiochemicals involved in plant defense against other sucking insect pests. A number of aphid species (Homoptera: Aphididae) have strong antennal electrophysiological responses to methyl salicylate, including *Rhopalosiphum padi*, *Sitobion avenae* and *Metopolophium dirhodum*, all of which have been shown to possess a specific olfactory neuron for this compound (Pettersson et al., 1994). Furthermore, methyl salicylate is a winter host plant component involved in mediating spring migration from winter to summer host plants (Pettersson et al., 1994). Induction of methyl salicylate production also has been reported from soybean, *Glycine max*, following exposure to the soybean aphid, *Aphis glycines*, with this compound being reported as an olfactory cue exploited by aphidophagous ladybirds (Zhu and Park, 2005). The sesquiterpene (*E*)-β-farnesene is an alarm pheromone for many aphid species (Pickett and Glinwood, 2007 and references therein). TMTT is a potent repellent for aphids, and an attractant for aphid and stinkbug parasitoids, when released by cotton, soybean and *Arabidopsis thaliana* following exposure to the plant activator *cis*-jasmone (Birkett and Bruce, unpublished data; Bruce et al., 2008; Moraes et al., 2009). Furthermore, aphid parasitoids possess a specific olfactory neuron for this compound (Bruce et al., 2008).

Methyl salicylate, (*E*)-β-farnesene, and TMTT have been shown to possess potent field activity against aphids. Application of slow-release formulations of methyl salicylate to wheat significantly reduced (by 30–40%) the overall number of aphids colonizing the crop (Pettersson et al., 1994), while application of controlled release dispensers of the same compound in hop yards and grape blocks resulted in enhancement of aphid biological control (James et al., 2005, James and Grasswitz, 2005; Zhu and Park, 2005). Application of slow-release formulations of *Hemizygia petiolata* essential oil, enriched in (*E*)-β-farnesene, reduces pea aphid populations on bean crops (Bruce et al., 2005). To our knowledge, there are no reports of using slow-release formulations of other insect-induced maize VOCs in the field. However, their constitutive release from intact plants, such as *Melinis minutiflora*, has been exploited in the development of the push-pull strategy for the control of lepidopterous stem borers in maize subsistence farms in East Africa (Kimani et al., 2000; Hassanali et al., 2008).

The behavioral activity of induced volatile semiochemicals against *C. storeyi* leafhoppers in this study suggests that they have potential for use in leafhopper control, and reduce the prevalence of plant diseases through reduced vector activity, either as outright repellents, or as attractants of natural enemies such as hymenopterous parasitoids (e.g. Moya-Raygoza et al., 2006). However, the release of such materials, either as slow-release formulations, or *via* genetically-transformed plants (Beale et al., 2006), is not feasible for resource-poor farmers based in Western Africa. Maize shows relatively high genetic and VOC variability, both intrinsically and in herbivore-induced emissions (Gouinguene et al., 2001; Degen et al., 2004). Work is currently underway to investigate the emission of the induced semiochemicals, i.e., methyl salicylate, (*E*)-β-farnesene, and TMTT, identified in this study, in local wild and elite, i.e., African cultivars, which could be developed for use in the manipulation of leafhopper or natural enemy behavior.

Abstract *Dryocosmus kuriphilus* is one of the most damaging pests of *Castanea* spp. Behavioral, chemical, and electrophysiological investigations were employed to examine the role of plant volatiles for host location by this thelytokuos cynipid. Y-tube olfactometer bioassays showed that adult wasps are significantly attracted by *C. sativa* twigs with at least 1-hr-old mechanical damage. Odors of undamaged host seedlings, intact twigs, and twigs with a fresh mechanical damage were not attractive. Wasps were repelled by plant materials of the non-host *Prunus laurocerasus*. Fourteen compounds, mainly general green leaf volatiles, were identified in the head-space of attractive host plant twigs by gas chromatography coupled to mass spectrometry. All compounds elicited dose-dependent antennal responses in adult wasps. A synthetic blend comprising all identified compounds in the same ratio as in the attractive host source induced significant positive responses in Y-tube olfactometer bioassays. The study gives a basis for future identification of host plant attractants that could contribute to semiochemical-based monitoring and management practices of this pest.

Key Words Y-tube bioassay · Head-space analysis · SPME · GC-MS · Electroantennogram · Green leaf volatiles · Plant volatiles

Introduction

The chestnut gall wasp *Dryocosmus kuriphilus* Yasumatsu (Hymenoptera: Cynipidae) is one of the most damaging pests of *Castanea* spp. (Abe et al., 2007). The species is univoltine and thelytokous (Zhu et al., 2007). Adults lay eggs in chestnut buds in early summer, and larvae remain latent until buds expand the following spring. Larvae induce the formation of leaf and twig galls that disrupt shoot elongation, reduce fruit yield by 50%–75%, and even cause the death of young trees as a result of severe consecutive attacks (Payne et al., 1983; Kato and Hijii, 1997). The effectiveness of chemical control is limited by the cryptic nature of the insect, which is in dormant buds for the majority of its life cycle, and by the difficulty of precisely detecting adult emergence. Moreover, chemical treatments often are impracticable due to the natural distribution of chestnut trees in steep terrain.

Gall-inducing cynipids are host-plant specific (Ronquist and Liljeblad, 2001). The oviposition of cynipids and subsequent gall development can be sensitive to host attributes including genotype, age, size, phenology, and nutritional status (Stone et al., 2002). The compositions of cynipid gall-wasp communities correlate with host plant chemistry (Abrahamson et al., 2003), and there is evidence that galls are manipulated by galling cynipids that enhance their food and protective value (Allison and Schultz, 2005).

Given the specificity of the host plant-cypnid interactions, plant volatiles are expected to play a crucial role in host recognition. Changes in host plant chemistry associated with galls provide cues for mate location by adult males in *Antistrophus rufus* Gillette (Hymenoptera: Cynipidae) (Tooker et al., 2002; Tooker and Hanks, 2004). Females of the same species respond positively to a four-component blend of plant monoterpenes in Y-tube olfactometer bio-

assays, thus suggesting that plant volatiles probably serve as an olfactory cue for host plant location (Tooker et al., 2005).

Identification of semiochemicals involved in host location by *D. kuriphilus* is of interest not only from an ecological perspective but also for development of novel pest control strategies. Host plant cues are particularly important in light of the thelytokous parthenogenesis characteristic of this species and the consequent lack of a sex pheromone system. Attractive semiochemicals could be incorporated into traps to detect adult wasps in new areas and to improve the timing of control measures.

In a preliminary study that tested the hypothesis that chestnut leaf volatiles are perceived by antennae of *D. kuriphilus* adults, electroantennographic (EAG) recordings showed that these insects can detect a wide range of plant volatiles. In addition, some EAG-active compounds were individually attractive to adult wasps in a Y-tube olfactometer bioassay (Germinara et al., 2009a). To better understand the chemical basis of host plant location by *D. kuriphilus* and in an attempt to find an attractive blend of host-related volatiles, comprehensive behavioral, chemical, and electrophysiological investigations were carried out.

Methods and Materials

Insects Chestnut galls containing immature stages of the chestnut gall wasp were collected in an infested orchard near Avellino (southern Italy) during June and July and kept in glass containers at 25±2°C, 55±5% relative humidity, and under natural light conditions. Newly emerged adults were collected daily and kept individually in glass vials (i.d. 2×8 cm) covered with a fine mesh net and starved for at least 12 hr prior to behavioral and electrophysiological tests.

Plants We used the host plant wild *Castanea sativa* Mill. and the non-host plant *Prunus laurocerasus* L. (Rosales). One meter long branches were cut from plants grown in a field near the University of Molise in Campobasso, Italy and placed individually into 2000-ml glass jars containing water. Branches were used for the experiments within 24 hr of cutting the branch from the tree. For some experiments, *C. sativa* seedlings about 1-yr-old (8–10 leaves, length 20–30 cm) were supplied by the Fruit Tree Unit of the Agricultural Research Council (Caserta, Italy). All plants used were in the flowering stage (June–July) when infestation by *D. kuriphilus* occurs in the field.

Chemicals (*E*)-2-hexenal, hexyl acetate, (*Z*)-3-hexenyl acetate, (*E*)-2-hexenyl acetate, hexanol, (*E*)-3-hexenol, (*Z*)-3-hexenol, (*E*)-2-hexenol, (*Z*)-3-hexenyl butyrate, (*E*)-2-hexenyl butyrate, (*E*)-caryophyllene, (*Z*)-3-hexenyl hexanoate, methyl salicylate, geranyl acetate were purchased from Sigma-Aldrich (Milan, Italy), and were 97–99% pure. (*E*)-caryophyllene was an enantiomeric mixture.

Olfactometer Bioassays A glass Y-tube olfactometer (each arm 23 cm long at 75°C angle, stem 30 cm long, 3.0 cm i.d.) was used to examine the behavioral responses of *D. kuriphilus* adults to plant volatiles. Each arm of the Y-tube was connected to a glass cylinder (9 cm long and 3.0 cm i.d.) as an odor source container. The apparatus was put into an observation chamber (90×75×40 cm) and illuminated from above by two 36-W cool white fluorescent lamps providing uniform lighting (2500 lux) inside the tube. A purified (activated charcoal) and humidified airflow maintained at 60 ml/min by a flowmeter was pumped through each arm.

In order to determine an attractive source of host plant volatiles, four dual-choice experiments were performed with host plant materials: (1) host plant seedlings vs. clean air; (2) intact host plant twigs with two leaves and three buds vs. clean air; (3) host plant twigs 0–60 min after mechanical damage (fresh damage) vs. clean air; (4) host plant twigs 60–120 min after mechanical damage (old damage) vs. clean air.

To prevent contamination of volatiles emitted by host plant seedlings, the surface of the soil around the stem of the plant was covered with pieces of aluminum foil. Individual seedlings were equilibrated for 1 hr at room temperature in a two-part glass vessel 60 cm high and with a diameter of 32 cm. The upper part of the vessel was provided with a Drechsel-bottle head with the inlet connected to the flowmeter and the outlet to an arm of the olfactometer. An empty glass vessel was used as a control.

To test the specificity of the host plant signal, three additional tests were carried out: (1) intact non-host plant twigs vs. clean air; (2) non-host plant twigs with old mechanical damage vs. clean air; (3) host plant twigs with old mechanical damage vs. non-host plant twigs with old mechanical damage. Twigs used for the experiments were taken from the cut branches just before the start of the experiment, and their cut ends were placed in glass tubes containing water to maintain the physiological water content (Tasin et al., 2005). Each twig (ca. 2 g) included at least two leaves and three buds. Mechanical damage was achieved by cutting twigs into pieces (0.5 cm wide) (van Tol et al., 2002).

We determined the response of adult wasps to a synthetic blend comprising 14 identified compounds mixed in the same ratio as in the head-space sample of host plant twigs with old mechanical damage. In this case, the odor chamber contained a filter paper disk (0.5 cm^2) loaded with 5 µl of a 0.01, 0.1 or 1 M synthetic volatile blend dissolved in

mineral oil (Sigma-Aldrich, Milan, Italy), while the control chamber contained a filter paper disk loaded with 5 μl of mineral oil. Both disks were suspended in the center of the cross section.

Individual chestnut wasps were released at the open end of the stem. Each experiment lasted 10 min. A choice was recorded when the insect moved 3 cm up an arm of the Y-tube crossing the decision line (marked on both arms) and remained beyond that line for more then 30 sec. The time spent by test insects in each arm also was recorded.

After 5 individuals were tested, the olfactometer was cleaned with acetone and dried (200°C for 30 min). Treatments between arms were switched to avoid position bias. For each test stimulus at least 30 wasps were tested.

Sampling of Volatiles Volatiles emitted by *C. sativa* twigs were collected by Solid Phase Microextraction (SPME) using a manual SPME holder with a polydimethylsiloxane coated fiber (100 μm) (Supelco, Bellefonte, PA). A chestnut twig similar to those used for behavioral tests was cut into pieces (0.5 cm) on aluminum foil and was used immediately for the extraction, or was kept exposed to air at room temperature (23±1°C) for 60 min. Plant material then was enclosed in a 25 ml screw top mini flask with a PTFE thread Mininert™ Valve (Sigma-Aldrich, Milan, Italy) and a SPME was exposed to the head-space of the sample. Individual analyses were standardized following the method for volatile organic compounds described in Bech et al. (2008). The method parameters were P=permeation time=1 min, E= exposure time=60 min, S=storage time=30 sec, and T= thermal desorption of SPME fiber time=15 min. Before each extraction, the fiber was conditioned for 30 min in a GC injection port at 250°C. For both fresh and old mechanical damage, samples from five different plants were analyzed.

Coupled Gas Chromatography-Mass Spectrometry (GC-MS) SPME extracts were analyzed in a Fisons 8000 series gas chromatograph coupled with a Fisons MD 800 quadrupole mass spectrometer using a CPWAX 52 CB capillary column (30 m×0.32 mm i.d., 0.25 μm film thickness) (Ruther, 2000). The oven temperature was kept at 40°C for 3 min, programmed to rise 3°C min^{-1} to 230°C and hold at 230°C for 30 min. Injection temperature was kept at 240°C. Helium was used as carrier gas at a flow rate of 2 ml min^{-1}. Mass spectra were recorded in the electron impact mode (EI) at 70 eV and at a source temperature of 200°C. Mass range was from 25 to 450 m/z at a scan time of 0.9 sec and an interscan delay of 0.1 sec. Compounds were identified tentatively by comparison of mass spectra with those of authentic samples in the NIST database (2005) and confirmed by comparison of mass spectra and retention times with those of authentic reference compounds. In order to determine the relative composition of plant extracts, for each analysis the sum of peak areas was set to 100% and the mean contribution of each individual compound was calculated.

Electroantennography (EAG) Electrophysiological activity of identified compounds to adult wasps was determined by EAG (Germinara et al., 2009a). The head of a 1-d-old specimen was cut off and a glass pipette filled with 0.1 M KCl solution, which served as the neutral electrode, was inserted into its base. The distal end of the last antennal segment was put in contact with the end of a similar pipette (0.2–0.3 mm i.d.) serving as the recording electrode. AgCl-coated silver wires were used to maintain the electrical continuity between the antennal preparation and an AC/DC UN-6 amplifier in DC mode connected to a PC equipped with the EAG 2.0 program (Syntech Laboratories, Hilversum, The Netherlands). A stream of charcoal-filtered humidified air (500 ml/min) was directed constantly onto the antenna through a stainless steel delivery tube (1 cm i. d.) with the outlet positioned at approximately 1 cm from the antenna.

Just before the experiment, solutions of authentic standards of identified compounds were applied to filter paper (Whatman No. 1) strips (1 cm^2) inserted in a Pasteur pipette (15 cm long) and used as an odor cartridge. For each compound, seven doses ranging from 10^{-3} to 40 μM in 10 μl mineral oil were tested. Over 1 sec, 2.5 cm^3 of vapor from an odor cartridge were blown by a disposable syringe into the air stream flowing over the antennal preparation. Stimuli were applied in ascending doses. Control (10 μl of mineral oil) and standard stimuli (10 μl of 1 M *Z*3-hexen-1-ol solution) were applied at the beginning of the experiment, and after each group of 3 randomly selected odors. Intervals between stimuli were 30 sec. For each compound, EAG responses were recorded from 5 antennae of different insects.

Data Analysis The amplitude (mV) of the EAG response to each test stimulus was adjusted to compensate for solvent and/or mechanosensory artefacts by subtracting the mean EAG response of the two nearest mineral oil controls (Raguso and Light, 1998). To compensate for the decrease of the antennal responsiveness during the experiment, the resulting EAG amplitude was corrected according to the EAG response to the standard stimulus (Den Otter et al., 1991).

In dose-response curves, the activation threshold was considered to be the lowest dose at which the lower limit of the standard error of the mean response was greater than the upper limit of the standard error for the lowest dilution tested (Sant'ana and Dickens, 1998). Saturation level was taken as the lowest dose at which the mean response was equal to or less than the previous dose (Germinara et al., 2009b).

Table 1 Response of *Dryocosmus kuriphilus* adults in a Y-tube olfactometer to different odor sources of host (*Castanea sativa*) and non-host (*Prunus laurocerasus*) plants

Odor sources	N^a	First choice			Number of minutes spent in arm (mean ± SE)			
		Treated[b]	χ^2	*P*-value	Treated	Control	*t*-value	*P*-value
Host seedling vs. control air	32 (25)	0.56	0.36	0.549	2.3±0.4	2.8±0.6	−0.615	0.544
Host intact twigs vs. control air	33 (25)	0.56	0.36	0.317	2.5±0.4	2.2±0.4	0.515	0.611
Host twigs with fresh damage vs. control air	34 (30)	0.60	1.20	0.273	2.9±0.4	2.7±0.5	0.207	0.837
Host twigs with old damage vs. control air	33 (30)	0.80	10.80	0.001	5.1±0.6	2.4±0.6	2.688	0.012

[a]Total sample size (*N*, number of individuals that made a choice in parentheses)

[b]Proportion of individuals (of those that made a choice) that chose the treated arm first

A χ^2 test was employed to determine the significance of differences between the number of wasps choosing the treatment or control arm of the olfactometer. A paired-sample *t*-test was used to analyze the differences between the time spent by wasps in each arm.

Results

Behavioral Response to Plant Materials In behavioral tests with plant materials, the percentage of adult wasps responding was generally high. Odors from undamaged host seedlings, intact twigs, and twigs with fresh mechanical damage did not elicit a significant response from adult wasps measured either as first choice or as time spent in the treatment arm when clean air was the alternative (Table 1). Insects presented with host twigs with old mechanical damage vs. clean-air control exhibited a significant preference for the damaged twigs (χ^2=10.80, *d.f.*=1, *P*=0.001) and spent significantly more time in the treatment arm (Table 1).

When insects could choose between non-host intact twigs and clean air, there was no preference but they spent significantly more time in the control arm (Table 1). Moreover, insects presented with non-host plant twigs with old mechanical damage vs. clean air control significantly preferred and spent more time in the control arm (Table 1). A significant positive response to host twigs with old mechanical damage was confirmed also in the presence of non-host twigs with a similar damage (Table 1).

Chemical Analyses GC-MS analysis revealed 15 volatile compounds in the SPME extracts from damaged chestnut twigs (Table 2). Fourteen of them were confirmed by comparison of retention times and mass spectra to those of authentic samples, while one compound remained unidentified. Chemical analysis showed differences between the volatiles collected from chestnut twigs with fresh or old mechanical damage. The volatile blend collected from freshly damaged twigs lacked the green leaf aldehyde (*E*)-2-hexenal. One hour after mechanical damage, there was a significant reduction in the relative amount of (*Z*)-3-hexenyl acetate and a significant increase in that of hexanol and (*E*)-2-hexenol (Table 2).

Table 2 Mean relative peak areas (±SE) of compounds detected in the head-space of damaged chestnut twigs. Volatiles were collected by SPME for 60 min immediately (fresh) or 1 hr (old) after mechanical damage and subsequently analyzed by gas chromatography coupled with mass spectrometry. Asterisks indicate significant differences between fresh and old damage (*t*-test, * $P<0.05$; ** $P<0.01$)

Compounds	Fresh damage [a]	Old damage
(*E*)-2-hexenal	0.0±0.0	1.9±0.9 *
Hexyl acetate	5.7±0.2	5.4±0.7
(*Z*)-3-hexenyl acetate	70.9±2.9	51.9±4.1**
(*E*)-2-hexenyl acetate	2.5±0.6	4.5±0.7
Hexanol	0.8±0.1	2.8±0.7*
(*E*)-3-hexenol	0.1±0.1	0.2±0.1
(*Z*)-3-hexenol	12.5±1.8	18.3±1.8
(*E*)-2-hexenol	0.3±0.1	1.5±0.4 *
(*Z*)-3-hexenyl butyrate	2.5±0.4	5.3±3.1
(*E*)-2-hexenyl butyrate	0.1±0.1	0.7±0.4
(*E*)-Caryophyllene	1.4±0.8	0.3±0.2

[a]For each extraction, percentages are calculated by dividing the peak area of a compound by the total area of compounds detected

[b]Unidentified

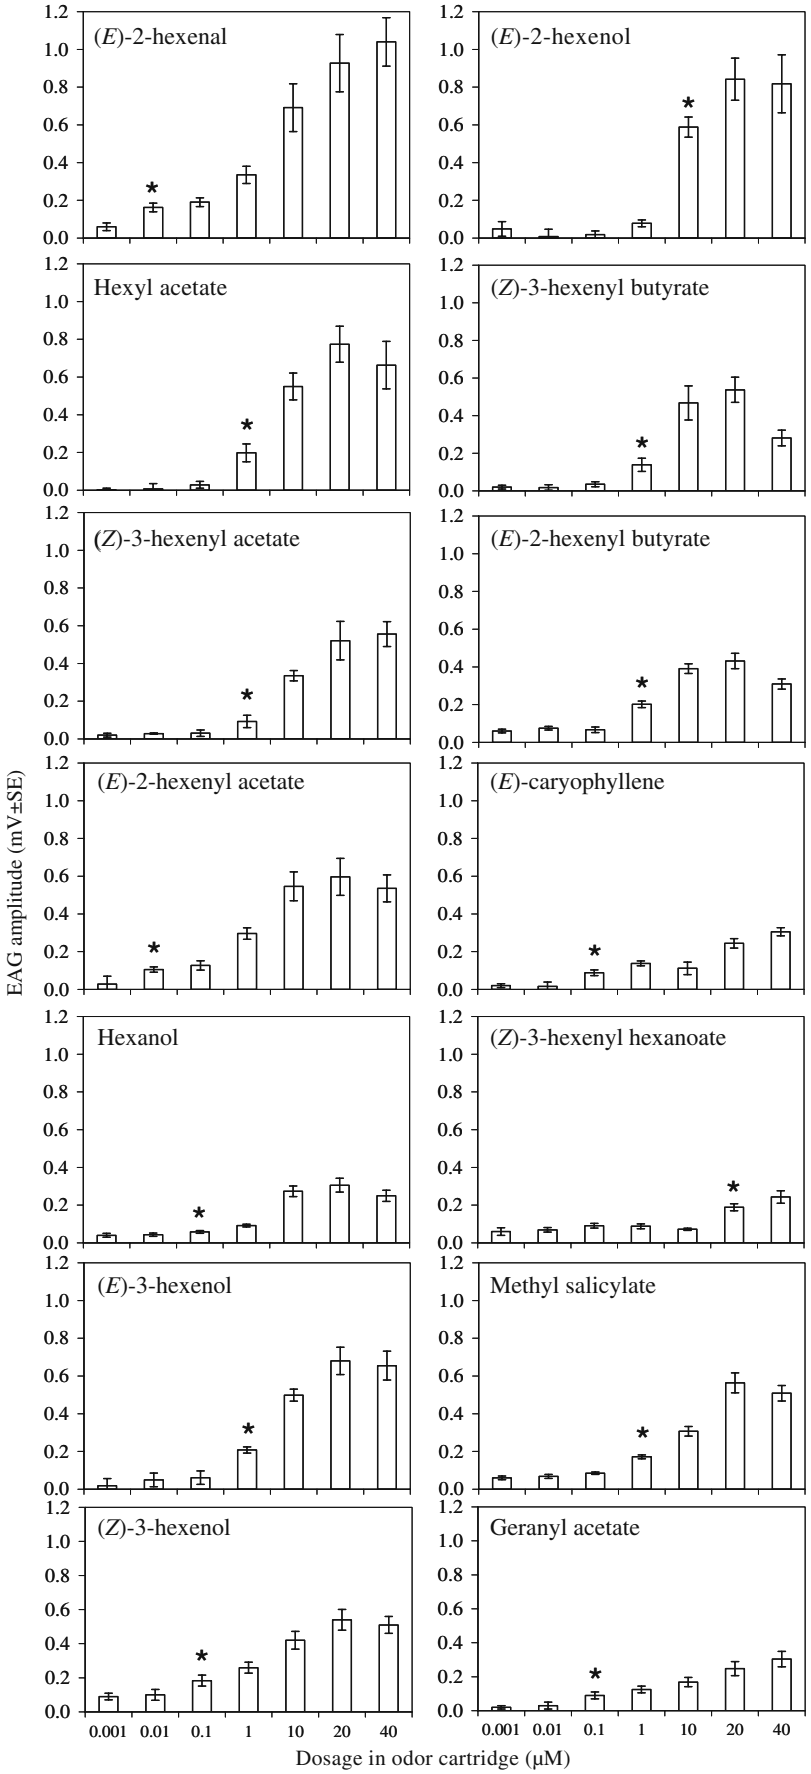

Fig. 1 Electroantennogram dose-response profiles of *Dryocosmus kuriphilus* adults (n=5) to compounds identified in the head-space of damaged *Castanea sativa* twigs. Asterisks indicate the activation thresholds

EAG Dose-Response Characterization The sensitivity of adult *D. kuriphilus* antennae toward increasing concentrations of authentic standards of identified compounds are reported in Fig. 1. For all compounds, the amplitude of the EAG response increased with dose. The lowest activation thresholds were recorded for (*E*)-2-hexenal and (*E*)-2-hexenyl acetate at the 0.01 μM dose. The activation threshold for the remaining compounds was 0.1 μM for hexanol, (*Z*)-3-hexenol, (*E*)-caryophyllene, and geranyl acetate, 1 μM for hexyl acetate, (*Z*)-3-hexenyl acetate, (*E*)-3-hexenol, (*Z*)-3-hexenyl butyrate, (*E*)-2-hexenyl butyrate, and methyl salicylate, and 10 and 20 μM for (*E*)-2-hexenol and (*Z*)-3-hexenyl hexanoate, respectively.

The amplitude of the EAG response to hexyl acetate, (*E*)-2-hexenyl acetate, hexanol, (*E*)-3-hexenol, (*Z*)-3-hexenol, (*E*)-2-hexenol, (*Z*)-3-hexenyl butyrate, (*E*)-2-hexenyl butyrate, and methyl salicylate decreased from 20 to 40 μM doses indicating saturation of receptors at the lowest dose.

Behavioral Response to a Synthetic Blend The behavioral responses of adult wasps to different doses of a multicomponent blend comprising the 14 commercially available authentic standards in the same ratio as in the head-space sample of host plant twigs with old mechanical damage are reported in Table 3.

At the 0.05 and 0.5 μM doses, a significant attraction of adult wasps, either as first choice or time spent in the treatment arm of the olfactometer was recorded. At the 5 μM dose, adult wasps did not show any significant preference for either the treatment or the control arm.

Discussion

In Y-tube olfactometer bioassays, adults of the chestnut gall wasp were attracted by odors of leaf- and bud-bearing *C. sativa* twigs with at least one-h-old mechanical damage. Odors of undamaged host seedlings, intact twigs, and twigs with fresh mechanical damage were unattractive. Moreover, insects were able to discriminate between host and non-host plant materials, suggesting specificity of host-plant chemical signals. Chemical analysis showed that the blend of volatiles emitted by artificially damaged *C. sativa* twigs changed significantly over time. From the first to the second hour after mechanical damage, the additional presence of (*E*)-2-hexenal was detected. In addition, there was a significant decrease in the relative proportion of (*Z*)-3-hexenyl acetate and a significant increase in that of hexanol and of (*E*)-2-hexenol. These changes might account for the attractiveness of old mechanically damaged twigs compared to the neutral effect of the freshly damaged ones.

The majority of compounds identified in the head-space of attractive host-plant samples were C_6 alcohols, esters, and the aldehyde (*E*)-2-hexenal. These so-called green leaf volatiles (GLVs) contribute to the "green odor" of the leaves of numerous plant species. GLVs may be produced constitutively or induced by leaf damage caused abiotically or by herbivory (Visser, 1986; Loughrin et al., 1996; Turlings et al., 1998; Ruther et al., 2002) and by light-dark transitions (Graus et al., 2004; Chamberlain et al., 2006). Additional components were the terpenoids (*E*)-caryophyllene and geranyl acetate and the aromatic methyl salicylate. These compounds are released in response to plant damage (Takabayashi et al., 1994; Bolter et al., 1997; Hoballah and Turlings, 2005).

Volatile compounds emitted upon mechanical and/or herbivore damage are important in the host selection process for several phytophagous insects (Loughrin et al., 1996; Dickens, 2000; Kalberer et al., 2001; van Tol et al., 2002). In some cases, a neutral effect of undamaged host plant material also has been recorded (Bolter et al., 1997; Ruther et al., 2000; van Tol et al., 2004). The advantages of adult *D. kuriphilus* being attracted to a damaged plant remain unclear.

All identified compounds elicited EAG dose-dependent responses with different activation thresholds. At doses from 0.05 to 0.5 μM, a synthetic blend comprised of all 14 EAG-active volatiles in the same ratio as in the head-space

Table 3 Response of *Dryocosmus kuriphilus* adults in a Y-tube olfactometer to increasing doses of a synthetic blend comprising all identified compounds in the same ratio as in the head-space sample of host plant twigs with old mechanical damage

Dose (μM)	*N*[a]	First choice			Number of minutes spent in arm (mean ± SE)			
		Treated[b]	χ^2	*P*-value	Treated	Control	*t*-value	*P*-value

of the attractive host plant materials elicited a significant attraction in adult wasps, suggesting that these compounds are involved in locating host plants. One compound could not be identified and therefore it was not included in the EAG and behavioral tests. However, it seems unlikely that this compound may play a role in host plant location since its relative proportion in the natural blend did not change significantly over time.

In a previous study, (*E*)-2-hexenal did not elicit a positive response in the adult wasps (Germinara et al., 2009a), therefore, the additional presence of this compound in the odor blend of old mechanically damaged twigs could not explain its attractiveness as compared to the blend of freshly damaged twigs. This, along with the ubiquitous nature of all identified chestnut volatiles, suggests that host location by the chestnut wasp is more likely mediated by a host-specific ratio of ubiquitous volatiles rather than by a single compound. The exploitation of ubiquitous compounds even by the monophagous *D. kuriphilus* supports the hypothesis of ratio-specific odor recognition as the most prevalent mechanism mediating host plant location by phytophagous insects (Visser, 1986; Bruce et al., 2005).

Adult wasps were significantly repelled by non-host volatiles, indicating that these compounds may act as antagonists. This evidence is in accordance with previous reports on the tendency of specialists to be deterred (Bernays et al., 2000) or repelled (Linn et al., 2005) by non-host compounds. The capability of the adult wasps to actively avoid non-host plant volatiles and not just to passively ignore them could be important for optimizing host location, and it could have important evolutionary consequences (Forbes et al., 2005; Feder and Forbes, 2007). Moreover, repellent compounds from non-host plants may have potential for the use in the control of insect pests (Ukeh et al., 2010).

Many previous studies have shown that only a small number of host plant volatiles out of all of those electrophysiologically active to an insect are involved in host location (Rojas, 1999; Dickens, 2000; Fraser et al., 2004; Tasin et al., 2006), suggesting that not all 14 components of the synthetic blend are necessary for attraction. Laboratory and field studies examining the behavioral responses of *D. kuriphilus* with various dosages of individual synthetic compounds and their mixtures are in progress to find out those that are crucial in host plant location. Identification of such compounds may contribute to the development of effective monitoring and management tools for this pest.

Abstract The literature on proanthocyanidins (tannins) in ecological systems is dominated by quantitative studies. Despite evidence that the qualitative characteristics (subunit type, polymer chain length) of these complex polyphenolics are important determinants of biological activity, little is known about genetic and environmental controls on the type of proanthocyanidins produced by plants. We tested the hypothesis that genetics, season, developmental stage, and environment determine proanthocyanidin qualitative characteristics by using four *Populus* "cross types" (narrowleaf [*P. angustifolia*], Fremont [*P. fremontii*], F1 hybrids, and backcrosses to narrowleaf). We used thiolysis and HPLC analysis to characterize the proanthocyanidins, and found that genetics strongly control composition. The narrowleaf plants accumulate mixed procyanidin/prodelphinidins with average composition epicatechin$_{11}$-epigallocatechin$_8$-catechin$_2$-catechin$_{(terminal)}$. Backcross genotypes produce mixed procyanidin/prodelphinidins similar to narrowleaf, while Fremont makes procyanidin dimers, and the F1 plants contain procyanidin heptamers. Less striking effects were noted for genotype × environment, while season and developmental zone had little effect on proanthocyanidin composition or chain length. We discuss the metabolic and ecological consequences of differences in condensed tannin qualitative traits.

Introduction

Secondary plant products including phenolics have important roles in regulating the interactions between plants and other organisms, in determining the responses of plants to abiotic stresses, and in governing ecosystem processes. As a consequence, investigation of how genetics, development, and environment control production of secondary compounds is essential for understanding plant physiology and ecology. Ideally, studies of secondary product accumulation include both qualitative and quantitative measures. Qualitative assessments that reveal production of specific compounds are important (Yarnes et al., 2008), since bioactivity is usually associated with specific compounds, not classes of compounds. Quantitative assays are useful for establishing metabolic flux and utilization of resources such as C and N to make broad classes of compounds (Arnold and Schultz, 2002).

Studies of secondary compound accumulation often target phenolics because of their wide distribution and diverse functions. In general, phenolic compounds can be divided into the low molecular weight phenolics and the polymeric polyphenolics (tannins). The low molecular weight phenolics include numerous compounds such as phenolic acids, glycosides, esters, and flavonoids, while the

polyphenolics generally are classified as either hydrolyzable tannins (gallotannins and ellagitannins) or proanthocyanidins (condensed tannins) (Yoshida et al., 2005).

Genetics, development, environment, and their interactions strongly influence production of low molecular weight, nontannin phenolics. Levels of phenolic glycosides in *Populus* are influenced by genotype and by developmental and environmental factors such as age (Donaldson et al., 2006), CO_2 and nutrient levels (Lindroth et al., 2001), and defoliation or leaf damage (Stevens and Lindroth, 2005). Qualitative profiles of low molecular weight phenolics also are controlled by the interaction of genetics with developmental and environmental cues. Genetic control predominates over phenolic glycoside composition of parent and F1 offspring of *Salix*, with inheritance under directional dominance (Orians et al., 2000). In contrast, in three species of *Betula*, juvenile leaves had similar profiles of low molecular weight phenolics, but mature tissue had species-specific compositions, suggesting ontogenetic influence on genetically specified phenolic composition (Laitinen et al., 2005).

Regulation of hydrolyzable tannin accumulation is similar to regulation for simple phenolics. Some oaks accumulate high levels of hydrolyzable tannin (bur, pin, or willow) while other species (cherrybark, Northern red) accumulate far smaller amounts (Foss and Rieske, 2003), suggesting an overall genetic constraint on the total quantity of hydrolyzable tannin that can be produced. Within that limit, both simple phenolics and complex ellagitannins are accumulated in patterns that are genetically controlled (Yarnes et al., 2006), with distinct tannin chemotypes identified in a population of *Quercus gambelii x Q. grisea* (Yarnes et al., 2008). During the growing season, oak leaves produce compounds sequentially in a pattern reflecting proposed biosynthetic relationships, with simple gallotannins appearing earlier in the growing season and ellagitannins accumulating later, thus demonstrating ontogenetic control over qualitative composition of hydrolyzable tannins (Salminen et al., 2004). Levels of accumulated hydrolyzable tannins are influenced by environmental conditions such as light and CO_2, which independently modulate the amounts of gallotannins and ellagitannins produced in *Acer saccharum* (Agrell et al., 2000).

In contrast to simple phenolics and hydrolyzable tannins, our understanding of the regulation of proanthocyanidin production is based almost entirely on quantitative assessments. Many studies have demonstrated that overall proanthocyanidin level is genetically controlled, and that environmental conditions may modify those levels. For example, in *Populus* (Osier and Lindroth, 2006), *Salix* (Orians et al., 2000), and *Betula* (Laitinen et al., 2000), the quantity of proanthocyanidin accumulated is genetically determined. Levels of proanthocyanidins in *Populus*, *Salix*, *Betula*, and *Fagus* are affected by environmental conditions such as levels of light, nutrients, CO_2, and ozone (Lindroth et al., 2001; Lower and Orians, 2003; Karonen et al., 2006; Osier and Lindroth, 2006). Almost nothing is known about what factors dictate accumulation of specific proanthocyanidins. Subunit composition, interflavan bond position, and chain length are important variables in determining proanthocyanidin activity (Ayres et al., 1997; Kraus et al., 2003), but little is known about how these features are determined. Koupai-Abyazani et al. (Koupai-Abyazani et al., 1993a) reported that in *Sainfoin*, subunit composition of proanthocyanidins changed as the leaves matured, suggesting developmental influence over proanthocyanidin accumulation. However, technical difficulties in differentiating individual proanthocyanidins have prevented us from establishing whether qualitative differences in proanthocyanidins are controlled genetically, developmentally, or environmentally. This limitation has slowed our understanding of the specific functions that proanthocyanidins contribute to biological systems.

We have conducted detailed qualitative studies of proanthocyanidin accumulation in *Populus*, examining the effects of genetics, season, developmental stage, and environmental factors. Wide-ranging "genes-to-ecosystems" studies of the *Populus* model system have provided insight into the relationships between plant genetics, chemistry and ecology (Whitham et al., 2006). *Populus* is an attractive taxon for studies of proanthocyanidin accumulation because its species do not produce hydrolyzable tannins. *Populus* does accumulate small phenolic glycosides, but via metabolic pathways distinct from the flavonoid metabolism that yields proanthocyanidins (Tsai et al., 2006). Recently Rehill et al. (2006) used quantitative assays to examine proanthocyanidin accumulation in four *Populus* "crosstypes" (two species and two hybrid types), across season, developmental stage, and location of garden plot. Similar to small phenolics, the quanitity of proanthocyanidins accumulated in leaf tissue was strongly genetically determined. The levels of proanthocyanidins in the F1 and backcross hybrids generally were intermediate to the parents (narrowleaf [*P. angustifolia*] and Fremont [*P. fremontii]*), suggesting additive inheritance. As noted for other phenolics, environmental factors including season and location modulated the levels of proanthocyanidins. In addition, significant variation in quantity of proanthocyanidin was associated with foliar developmental zone (i.e., mature and juvenile zones on individual trees) indicating developmental control of proanthocyanidin biosynthesis. Rehill et al. (2006) did not examine qualitative features of the *Populus* proanthocyanidins.

We hypothesized that qualitative characteristics of the proanthocyanidins in *Populus* would be controlled mainly

by genetics, just as composition of low molecular weight phenolics is mainly under genetic control. We predicted that subunit composition and chain length in F1 and backcross *Populus* would reflect the proanthocyanidins of their parents. We predicted that season, developmental stage, and environmental factors would have minimal effects on *Populus* proanthocyanidin composition. We tested these hypotheses by using leaf samples from four crosstypes of *Populus* collected across a growing season, at two developmental stages, and from gardens in three locations. Proanthocyanidins were extracted from the tissue, chemically derivatized with phenylmethanethiol (toluene-α-thiol), and analyzed by high performance liquid chromatography to establish subunit composition and average chain length.

Methods and Materials

Plants We sampled leaf tissue from the four crosstypes of *Populus* described in Rehill et al. (2006): Fremont (*P. fremontii*), narrowleaf (*P. angustifolia*), F1 hybrids, and the backcrosses to narrowleaf. Genetic introgression in this system is unidirectional: hence the F1 hybrids cross only with narrowleaf, not with Fremont. All plant tissue was collected and processed as described in Rehill et al. (2006). Briefly, leaves were clipped from their petioles, flash-frozen between blocks of dry ice, and shipped to the University of Wisconsin, Madison, Wisconsin (U.S.A.). The frozen leaves were freeze-dried, then ground in a Wiley mill (#40 mesh), and stored at −20°C. Samples were sent to Miami University, Oxford, Ohio (U.S.A.) for qualitative analysis via thiolysis.

To evaluate the effects of season on the composition of proanthocyanidins, leaf samples from mature branches of 7–10 trees from each of the four cross types were collected from the common garden at the Ogden Nature Center (ONC) in late May, late June, and late July 2003 (105 samples). The ONC common garden (41°14′48″ N, 111°59′59″ W; elevation 1300 m) represents *Populus* genotypes sampled from across a 13-km hybrid zone and from pure zones along the Weber River. Replicated genotypes of each of the four *Populus* cross types were planted in a random arrangement in the garden.

To evaluate the role of developmental stage on composition of proanthocyanidins, in June 2007 leaves were collected from both the juvenile zone and the mature zone of four trees from each of five narrowleaf genotypes (1000, 1008, 1020, He-10, WC5) for a total of 40 samples. The developmental stage of the leaves was determined by the presence of catkins or catkin scars on the branches (Rehill et al., 2006). Leaves used for comparisons among developmental stages were collected only from trees growing in the ONC garden.

To evaluate the effects of environmental conditions on composition of proanthocyanidin, leaves were collected from mature branches of the same genotypes planted at three different common garden locations: North Pit, ONC, and Taggart gardens, all planted between 1981 and 1992. From all three common gardens, leaves from 2 to 5 plants from each of the following genotypes were collected in June 2007: backcross genotype 10, narrowleaf genotypes 1000, 1008, and 1019 (41 samples). The ONC garden, described above, is dry most of the year, but a small creek adjacent to the garden provides water intermittently. The North Pit garden (41°08′00″ N, 111°54′05″ W; elevation 1395 m) is at the entrance to Weber Canyon on a gravelly slope, near the edge of a gravel pit at the mouth of Weber Canyon. The pit garden is dry, and is exposed to constant, strong winds coming out of Weber Canyon. Neither ONC nor North Pit has supplemental irrigation. The Taggart common garden (41°03′ 38″ N, 111°34′25″ W; elevation 1587 m) is located 6 km east of Morgan, UT, USA in the channel of the Weber River. Therefore, temperatures are cooler and water is constantly available at Taggart, while both the North Pit garden and the Ogden Nature Center garden have similar, warmer temperatures and little water.

Proanthocyanidin Extraction For samples from narrowleaf, F1, and backcross samples, about 10 mg of freeze-dried, ground tissue were weighed into a 1.7 ml microfuge tube. The samples were mixed with 250 μl of chloroform:methanol (2:1, v/v) with constant stirring for 30 min to remove chlorophyll and pigments, centrifuged for two min at 9300 × *g*, and the supernatants were discarded. The remaining tissue was treated with 250 μl ethyl acetate with constant stirring for 15 min to remove the remaining pigments and free phenolics. Samples were centrifuged as above, and ethyl acetate was discarded. After a second ethyl acetate extraction, tissues were briefly dried under flowing nitrogen gas to remove any remaining ethyl acetate. Tissues were then extracted with 200 μl of methanol with constant stirring for 60 min.

The extraction protocol was modified for Fremont samples to accommodate the very low level of proanthocyanidins in this cross type. Approximately 40 mg of tissue were weighed into 1.7 ml microfuge tubes and extracted with twice the volume of solvents compared with the other cross types (500 μl chloroform methanol, 500 μl ethyl acetate, 400 μl methanol). The remaining steps in the extraction were as described above.

Thiolysis Each plant extract was reacted with phenylmethanethiol (toluene-α-thiol) to yield terminal flavan-3-ols and the thiol derivatives of the extender flavan-3-ols (Guyot et al., 2001a). The reaction was started by mixing 100 μl of the plant extract with 10 μl of hydrochloric acid in methanol (32% by volume) and 24 μl of phenyl-

methanethiol in methanol (5% by volume). The reaction mixtures were incubated at 40°C for 30 min, and reactions were stopped by placing samples at −5°C for 5 min. Samples were then stored at −80°C until analysis, with all analyses conducted within 24 h of completing the reactions.

In order to determine proanthocyanidin composition, we needed standards for the flavan-3-ol thiol derivatives. We prepared the standards by carrying out thiolysis (Guyot et al., 2001b) on the proanthocyanidins from well-characterized plant sources, isolating the thiol products by column chromatography (Hagerman and Butler, 1980) and establishing identity of each product by mass spectrometry (Souquet et al., 1996). We then used these standards to identify thiol adducts in our *Populus* extracts by retention time on HPLC. Epicatechin thiol was obtained from *Sorghum bicolor* grain (Gupta and Haslam, 1978), catechin thiol from catechin trimer C-2 (Kolodzieg, 1990), epigallocatechin thiol from sainfoin leaves (Koupai-Abyazani et al., 1993b), and gallocatechin thiol from *Populus tremuloides* leaves (Hagerman, unpublished).

The thiolysis reaction products for standards and experimental *Populus* samples were run on reversed phase HPLC on an Agilent 1100 system with ChemStation Rev. A.09.03 software (Agilent, Santa Clara, CA, USA). The column was an Agilent Zorbax RP-8 column, 4.6×150 mm with 5 μm packing. The chromatography employed gradient programming with a gradient comprised of 0.13% trifluoroacetic acid (TFA) in water (v/v) and 0.1% TFA in acetonitrile (v/v) as the mobile phase at a flow rate 0.5 ml/min. For the first 3 min of each run, the mobile phase was maintained with 15% of the organic phase. Linear gradients increased solvent strength to 20% organic phase at 8 min, and to 30% at 10 min. Between 28 and 32 min, a linear gradient brought the mobile phase to 70% organic. A linear gradient from 37 to 40 min returned the mobile phase to the initial condition of 15% organic, and the column was re-equilibrated from 40 to 45 min. The same solvents with a slightly different gradient program were used in a few preliminary analyses employing a Zorbax C-18 column.

Two modes of detection were used: UV at 220 nm and electrochemical detection. The 12 channel CoulArray detector was employed over the voltage range from 180 to 840 mV with 60 mV increments between channels (ESA Chelmsford, MA, USA). The chromatograms were integrated automatically by using the ChemStation Rev.A.09.03 software for the UV data and Coularray for Windows Data Processing ver. 2.00 (ESA Chelmsford MA, USA) software for the electrochemical data. Baselines were set to accommodate changes in background absorbance with the gradient.

To confirm the identity of the standards, HPLC-MS was run under the same conditions but substituting acetic acid for TFA in the mobile phase. The Agilent HPLC was interfaced with an Esquire LC ion trap instrument (Bruker Daltonics, Billerica, MA USA). The electrospray ionization source (ESI) was operated in negative mode. A nominal target mass was set to 1000 before fine tuning. The capillary, skimmer 1, and trap drive voltages were −100, −30, and 45 V, respectively. The ion charge control was on with a target of 30,000. The 300°C nitrogen dry gas flow rate was 4 L/min and the nebulization gas pressure was 11 psi. Each data point in the spectrum consisted of an average of 4 scans over a mass range of 120–1000 m/z.

Acid Butanol Analysis To evaluate soluble and cell wall bound phenolics in the four cross types of *Populus*, 20 mg samples of tissue were extracted 3 times with 5 ml of aqueous acetone (3:7, water: acetone, v/v) in 50 ml falcon tubes. Subsamples (25 or 50 μl) of each extract (containing soluble proanthocyanidins) were reacted with 800 μl acid butanol (5% concentrated HCl in butanol, v/v) and 33 μl of iron reagent (2% ferric ammonium sulfate in 2 N aqueous HCl) for 10 min in a boiling water bath (Porter et al., 1986). The cell wall debris (containing bound proanthocyanidins), remaining after the exhaustive extraction, was reacted with 45 ml acid butanol and 1.8 ml ferric ammonium sulfate for 10 min in a boiling water bath with continuous stirring of the suspension. After heating, samples were cooled, and absorbances were determined at 550 nm.

Statistics The experimental designs employed were orthogonal. Mixed model analysis of variance (ANOVA) models with least squares estimation were used to analyze compositional data for proanthocyanidins, via PROC MIXED (SAS version 9.1 for Windows). Effects were tested for three extenders (epicatechin, epigallocatechin, and catechin) and for chain length. Gallocatechin extender data were not statistically analyzed because this trace component was found only in relatively few backcross and narrowleaf samples from June 2003. Individual trees served as replicates for assessment of proanthocyanidins among genotypes, developmental zones, and genotype × zone interaction effects. Genotype was nested within garden with individual trees serving as replicates for the assessment of proanthocyanidins across genotypes and gardens (G × E). For comparisons of proanthocyanidins across months within and between crosstypes, we used repeated measures ANOVA with month and crosstype as fixed effects and location as the random effect.

Results

Validation of Analytical Methods Thiolysis is a well-accepted method for establishing composition and chain

length of proanthocyanidins. The acid-catalyzed oxidative cleavage of 4,6 or 4,8 interflavan bonds yields a carbocation intermediate that reacts with the nucleophilic phenylmethanethiol to yield a thiol-derivitized flavan-3-ol. Under optimized conditions (Guyot et al., 2001a), the polymer is degraded completely to thiol adducts for all extender groups. The terminal unit is released as the underivitized flavan-3-ol.

Commercially available flavan-3-ols (Fig. 1) were used to determine retention times for the epimeric pairs of the possible terminal units (Table 1). The order of elution was the same for either the C18 or C8 column, and was consistent with the trihydroxylated (delphinidin-type) B ring (gallocatechin or epigallocatechin) increasing the polarity of the compounds relative to the dihydroxylated (cyanidin-type) B ring (catechin or epicatechin).

We prepared the thiol adducts of the four common flavan-3-ols (catechin thiol, epicatechin thiol, gallocatechin thiol, and epigallocatechin thiol (Fig. 1)) from plant tannins of known composition, and confirmed the identity of each by negative ion mode electrospray MS (Table 1). On the C-8 column the retention times of the thiols were inverted within the epimeric pairs compared to the free flavan-3-ols, so that although catechin (2R, 3S) eluted earlier than epicatechin (2R, 3R), catechin thiol eluted later than epicatechin thiol (Table 1). In contrast, using a C18 column we found that the epimeric pairs of the flavan-3-ols and their corresponding thiol adducts eluted in the same order (Table 1). With either type of column, the prodelphinidin-type thiols (gallocatechin, epigallocatechin) eluted earlier than the procyanidin-type compounds (catechin, epicatechin), similar to the order for the simple flavan-3-ols. It clearly is important to identify carefully each member of the epimeric pair for any HPLC system since small changes in chromatographic conditions can change the relative retention times.

We quantitated the flavan-3-ol terminal units and the thiol extender units based on detection at 220 nm and peak integration. We ran standard curves for the commercial flavan-3-ols and for the isolated thiols, establishing that the UV-response is equivalent on a molar basis for these four flavan-3-ols and their thiol adducts. For plant tissues that contained very low levels of proanthocyanidins, the UV peaks were too small to integrate accurately. For these samples, we used electrochemical detection to achieve a four-fold increase in sensitivity. Using a coularray detector, each compound was detected in a voltage window that gave the best linear response. The voltage windows were 240–

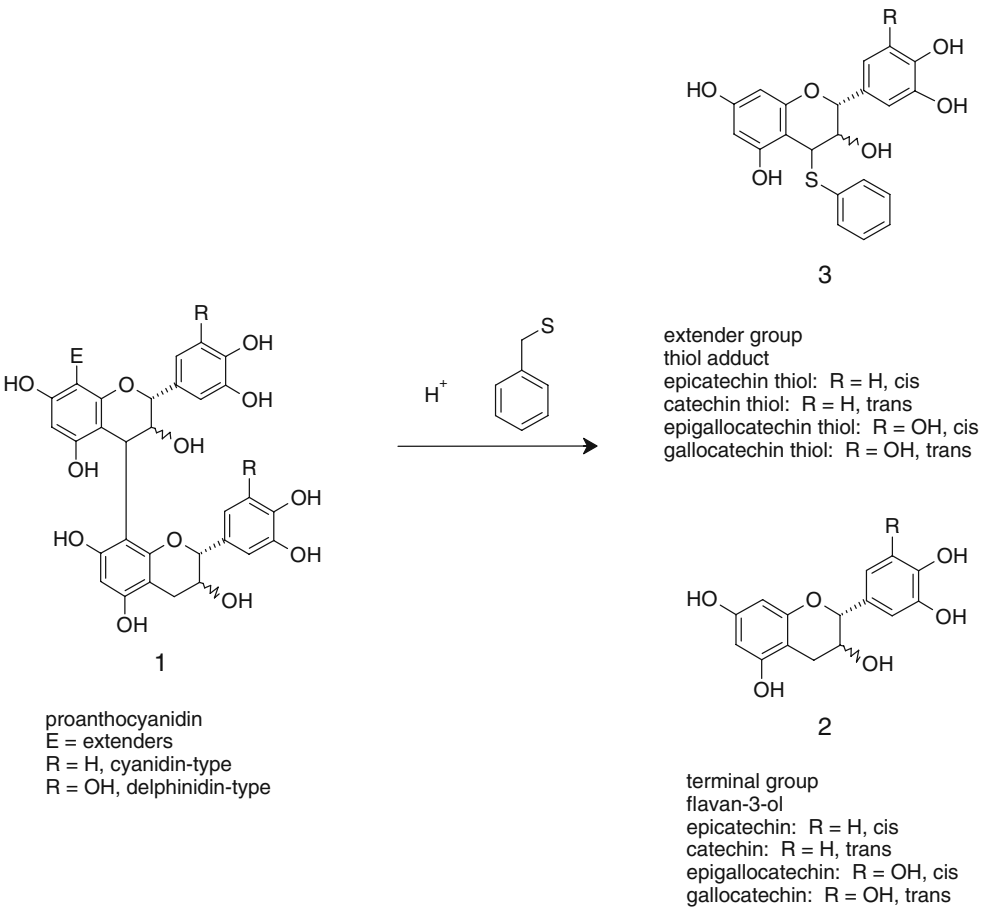

Fig. 1 Proanthocyanidin precursor and thiolysis reaction products. In the presence of acid and benzyl mercaptan, proanthocyanidins (1) react to yield the terminal group as a free flavan-3-ol (2) and the extenders as thiol adducts (3). The dihydroxylated flavan-3-ols (catechin, epicatechin) are characteristic of procyanidins, and the trihydroxylated flavan-3-ols (gallocatechin, epigallocatechin) are characteristic of prodelphinidins

Table 1 Retention times[a] and ms data for flavan-3-ols and thiols produced by reaction of proanthocyanidins with phenylmethanethiol in acidic conditions

Compound	Source	C18 (min)	C8 (min)	[M-H⁻] *m/z*	MS^2 *m/z*
Gallocatechin (2R, 3S)	Commercial	4.0	3.5		
Epigallocatechin (2R, 3R)	Commercial	4.3	4.1		
Catechin (2R, 3S)	Commercial	6.3	5.0		
Epicatechin (2R, 3R)	Commercial	7.0	6.6		
Gallocatechin thiol (2R, 3S)	Aspen proanthocyanidin	12.9	17.3	426.9	302.9
Epigallocatechin thiol (2R, 3R)	Sainfoin proanthocyanidin	12.6	18.3	426.9	302.9
Catechin thiol (2R, 3S)	C2 trimer	15.2	26.3	410.9	287.1
Epicatechin thiol (2R, 3R)	Sorghum proanthocyanidin	14.5	27.6	410.9	287.1

[a] Gradient HPLC with trifluoroacetic acid-modified aqueous and acetonitrile mobile phases was carried out on reversed phase columns with either C18 or C8 stationary phases. Detection was at 220 nm.

360 mV (catechin), 180–300 mV (catechin thiol), 360–480 mV (epigallocatechin thiol), and 240–360 mV (epicatechin thiol). The other flavan-3-ols and thiol adducts were not present in our plant samples, so we did not optimize their electrochemical detection. We confirmed the validity of the EC detection by comparing the compositions determined by EC to the compositions determined by UV for narrowleaf samples that contained large amounts of proanthocyanidins, easily detected with either method.

We converted peak areas obtained from either UV or electrochemical detection to moles using the standard curve, and then calculated moles relative to the moles of terminal flavan-3-ol, giving average composition for the proanthocyanidin from each sample. The sum of the mole ratios provided an estimate of the average degree of polymerization.

Direct thiolysis was carried out on a methanol extract of proanthocyanidins from the dried, ground leaf tissue. It was essential to extract pigments and free flavan-3-ols before extracting proanthocyanidins to prevent interference in terminal unit determination. Plant tissue was extracted first with 2:1 (v/v) chloroform in methanol to remove pigments and then with ethyl acetate to remove free flavan-3-ols. HPLC analysis of the ethyl acetate fractions showed that the characteristic broad peak due to proanthocyanidins was never present in the ethyl acetate fraction, consistent with the poor solubility of proanthocyanidins in ethyl acetate. Methanol extracts of plant tissues not extracted with ethyl acetate contained catechin, but the pre-extraction with ethyl acetate removed all of the free catechin from the tissue so the methanol extracts contained only the broad, unresolved peak characteristic of proanthocyanidins on RP-HPLC.

After thiolysis the products were qualitatively and quantitatively analyzed by HPLC. As expected, thiolysis reaction products did not include the typical proanthocyanidin peak but comprised peaks with retention times consistent with the underivitized flavan-3-ol, catechin; and with the various thiol derivatives of flavan-3-ols. The thiols produced from *Populus* proanthocyanidins included epicatechin thiol and epigallocatechin thiol, with lower levels of catechin thiol. Gallocatechin thiol was rarely detected. There was no evidence for branched proanthocyanidins (4,6 linkages), A-type linkages, or galloyl esters. All of these variations produce thiolysis products that are chromatographically distinct from the standard 4-thiol derivatives of the flavan-3-ols, and all the products from thiolysis reactions of *Poplulus* leaves corresponded to the standard derivatives.

Acid butanol analysis was used to evaluate the distribution of proanthocyanidins between soluble and cell wall-bound fractions in the four cross types. Distribution between soluble and bound forms was consistent across cross types, with less than 10% of the total proanthocyanidin associated tightly with the cell walls in any of the plants. Because there was no quantitative variation in cell wall-bound proanthocyanidins, and because methods for qualitative analysis of cell wall-bound proanthocyanidins have not been developed, we restricted the remainder of our analyses to the soluble proanthocyanidins.

Effect of Genetics on Proanthocyanidin Composition and Chain Length The strongest effect on proanthocyanidin composition was cross type (Table 2). Leaf proanthocyanidins from narrowleaf and backcross were similar in composition (Table 3, Fig. 2). The proanthocyanidins in these two cross types were made up of about 40–50% prodelphinidin-type (epigallocatechin) extenders. A typical narrowleaf proanthocyanidin in June comprises epicatechin$_{11}$-epigallocatechin$_8$-catechin$_2$-catechin$_{(terminal)}$ with less than one gallocatechin per chain (Table 3). In June, backcross proanthocyanidin has a slightly higher degree of polymerization and averages one gallocatechin per chain (Table 3).

The Fremont proanthocyanidin was distinctly different from the proanthocyanidins from the other cross types (Table 3, Fig. 2). In contrast to narrowleaf or backcross proanthocyanidins, the Fremont samples yielded very small

[a] Effects were not tested for gallocatechin, which was above the limit of detection only in some narrowleaf and backcross samples from June 2003.

[b] Samples of each cross type collected in late May, late June, and late July 2003 in the ONC common garden.

[c] Samples were collected in June 2007 from both the juvenile zone and the mature zone of four trees each from five narrowleaf genotypes in the ONC common garden.

[d] Samples were collected in June 2007 from mature branches of the same genotypes planted at three different common garden locations: North Pit, ONC and Taggart gardens.

amounts of the prodelphinidin type subunits (epigallocatechin, gallocatechin). Furthermore, the Fremont proanthocyanidins were short chain, so typically Fremont yielded dimers comprised of an epicatechin or catechin extender with catechin terminal.

The composition of the proanthocyanidins from the F1 cross type was intermediate to the narrowleaf and Fremont parents but was more similar to Fremont (Table 3, Fig. 2). Like Fremont, the proanthocyanidin from F1 cross types was comprised primarily of procyanidin-type subunits. Chain lengths were shorter than narrowleaf but are longer than Fremont. A typical composition for leaves collected in June is epicatechin$_4$-catechin$_2$-catechin$_{(terminal)}$ with less than one epigallocatechin per chain (Table 3).

Effect of Season, Developmental Zone, and Environment on Proanthocyanidin Composition and Chain Length Season had little effect on proanthocyanidin composition (Table 2, Fig. 2). For each cross type, tissue samples collected in May, June, and July from the ONC common garden exhibited no differences in the major proanthocyanidin subunits epicatechin or epigallocatechin, or in chain length. There were more statistically significantly catechin extenders in June than in May or July in narrowleaf, backcross and F1 crosstypes, but the chemical significance of the difference is questionable, since the change is less than one catechin extender per average chain (Table 2, Fig. 2). The rare subunit gallocatechin was detected only in samples from June, and only in narrowleaf and backcross plants. We conclude that proanthocyanidin composition in *Populus* changes little over the growing season, and that any effects are limited to the less common flavan-3-ol subunits.

Developmental zone did not affect the major proanthocyanidin subunits epicatechin or epigallocatechin, or chain length, in the narrowleaf crosstype (Table 2, Fig. 3). The only effect of developmental zone was limited to the

Table 3 Composition and chain length of proanthocyanidins in four cross types of *populus*[a]

Cross type (n)	Epicatechin (SEM)		Epigallocatechin (SEM)		Catechin (SEM)		Gallocatechin (SEM)		Chain Length (SEM)[b]	
Narrowleaf (9)	11.3	(3.0)	7.6	(2.4)	1.6	(0.3)	0.5	(0.3)	21.9	(5.6)
Fremont (10)	0.4	(0.1)	0.2	(0.1)	0.4	(0.1)	nd[c]		1.9	(0.1)
F1 (8)	4.4	(1.3)	0.4	(0.4)	1.5	(0.3)	nd		7.3	(1.8)
Backcross (10)	16.1	(4.2)	15.6	(6.2)	1.5	(0.3)	1.1	(0.5)	35.3	(10.6)

[a] Samples were collected in late June of 2003. Composition is in moles relative to the terminal unit for all proanthocyanidins, catechin and is expressed as the average and the standard error of the mean (SEM).

[b] Chain length is calculated as the sum of the extenders plus one terminal catechin.

[c] *nd* Not detected.

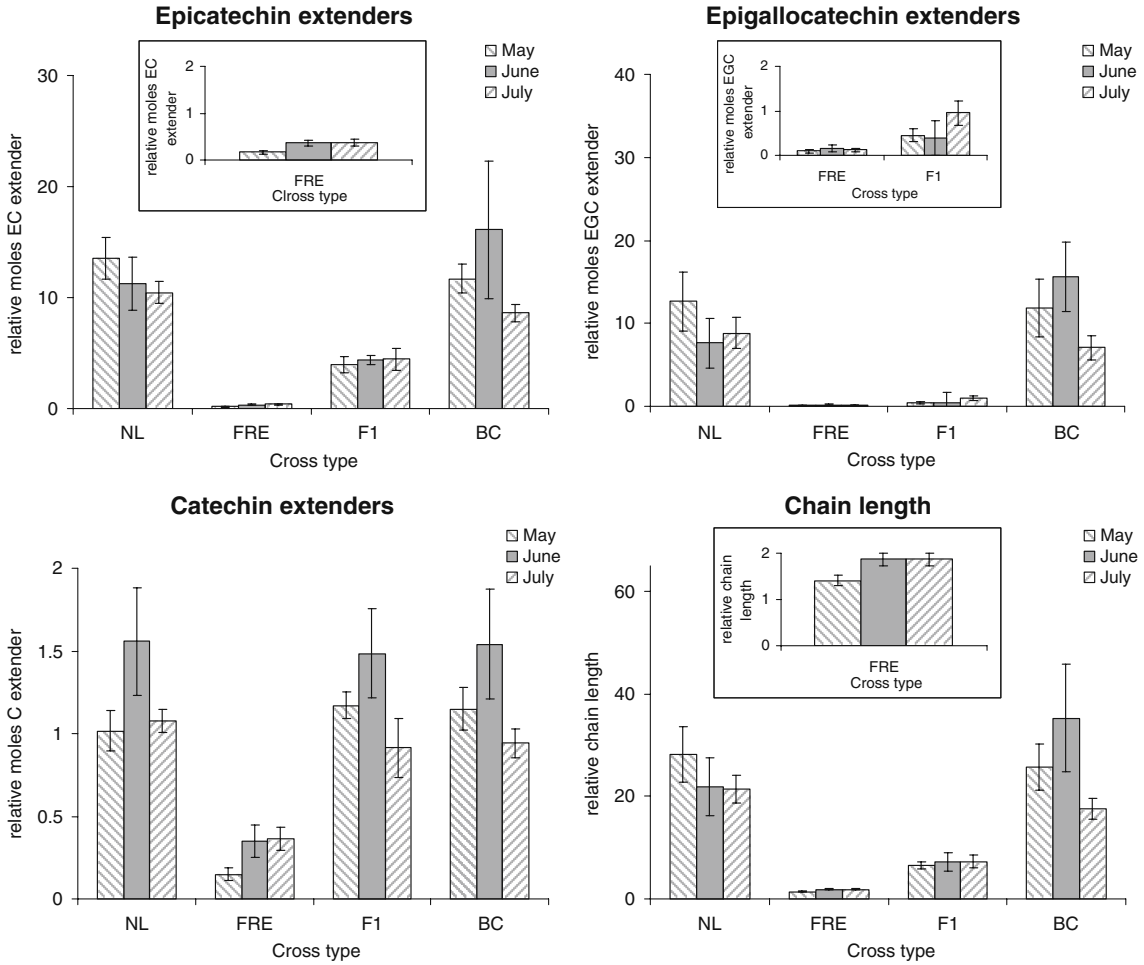

Fig. 2 *Populus* proanthocyanidin composition and chain length as a function of season. Samples of mature leaves were collected from four crosstypes [narrowleaf (NL), Fremont (FRE), F1 and backcross (BC)] growing in the ONC garden center in late June, late July and late August 2003. *Bars* show mean for N=7–10, error bars are 1 SEM

relatively uncommon subunit catechin, which was more abundant in proanthocyanidins from mature tissue than from juvenile tissue in all five genotypes (Table 2, Fig. 3). We conclude that reproductive maturity in *Populus* does not change the major foliar tannin composition.

Distinct environmental conditions found in the three gardens led to an environment × genotype effect on proanthocyanidin composition in three clones of narrowleaf, but had no effect on one clone of backcross (Table 2, Fig. 4). Although trees in the three gardens were of different ages, the dominant differences between the gardens were most likely environmental and not age-related. Trees in all three gardens were at least 15 years old, and previous work with the related *Populus tremuloides* revealed that age-related variation in leaf chemistry in trees of this age is minimal (Donaldson et al., 2006). The largest effect of environment was on narrowleaf clone 1019, which produced much shorter chain length proanthocyanidins in the ONC garden than in the NP or T gardens. In ONC plants, this proanthocyanidin had an average composition of epicatechin$_3$-epigallocatechin$_2$-catechin$_1$-catechin$_{(terminal)}$ with less than one gallocatechin per chain.

Discussion

In previous studies of proanthocyanidin accumulation in cross types of *Populus*, the proanthocyanidins were examined quantitatively but not qualitatively. For example, Rehill et al. (2006) found important quantitative differences in proanthocyanidins among cross types. Relatively large amounts of proanthocyanidin were found in leaves from backcross and narrowleaf, while Fremont and F1 accumulated significantly smaller amounts of proanthocyanidins. Our study confirmed those quantitative differences. Proanthocyanidins in both backcross and narrowleaf were easily

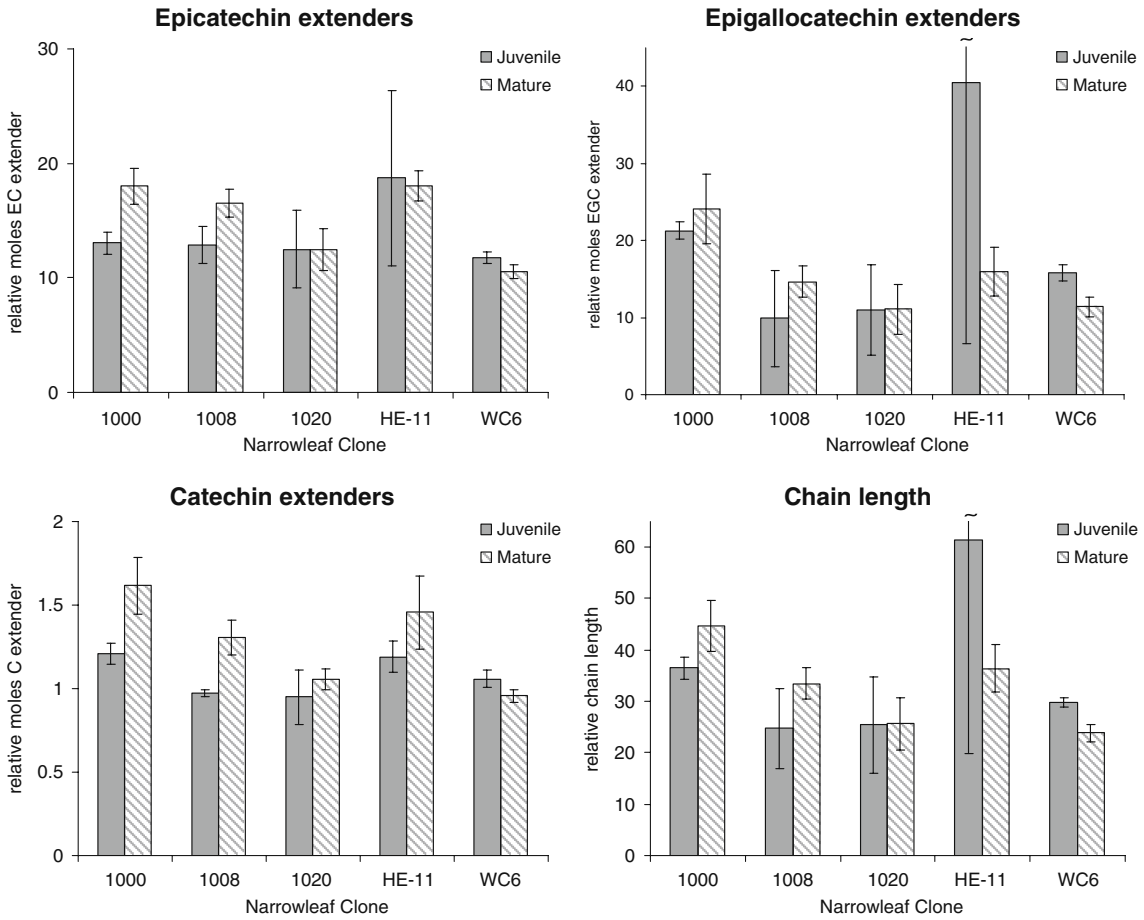

Fig. 3 *Populus* proanthocyanidin composition and chain length as a function of developmental zone. Samples of juvenile or mature leaves were collected from the same trees for five clones of narrowleaf growing in the ONC garden center in June 2007. *Bars* show mean for $N=4$, error bars are 1 SEM. Upper error bars are truncated for epigallocatechin and chain length

analyzed by thiolysis with UV-HPLC detection. Leaf tissue from F1 genotypes contained far less proanthocyanidin, but UV-HPLC analysis was still possible. Fremont contained very low levels of proanthocyanidin, and the thiolysis products could only be analyzed with the additional sensitivity afforded by EC detection.

Acid butanol analysis of soluble and cell wall-bound proanthocyanidins indicated that the quantitative differences in extractible tannins reflect differences in total proanthocyanidins, not differences in subcellular localization of proanthocyanidins. In all cross types there is little cell wall-bound proanthocyanidin. Analyses of methanol-soluble proanthocyanidins by acid butanol assays (Rehill et al., 2006) or by thiolysis (this paper) provide reliable information for *Populus* leaf tissue.

Our study expands and elucidates the qualitative description of proanthocyanidins reported for *P. balsamifera* and *P. tremuloides* by Ayres et al. (1997). These species contained mixed condensed tannins, with procyanidin (dihydroxylation, see Fig. 1) dominating the *P. balsamifera* tannin and prodelphinidin (trihydroxylation, see Fig. 1) dominating in *P. tremuloides*. We found that *P. angustifolia* also contains mixed procyanidin-prodelphinidin condensed tannin with roughly equal amounts of the two types of subunits. However, *P. fremontii* contains a simple procyanidin made up of epicatechin- and catechin-type monomers. The F1 cross type in our study predominantly accumulates the procyanidin-type flavan-3-ols, but the effect of the narrowleaf parent is obvious in the slightly elevated level of the trihydroxylated epigallocatechin compared with Fremont. The backcross cross type is more similar to the narrowleaf, producing a mixed procyanidin-prodelphinidin tannin with neither type of subunit dominating the composition.

A highly variable qualitative feature of the *Populus* cross types is proanthocyanidin chain length. The proanthocyanidins from narrowleaf are polymers with 20–28 flavan-3-ol subunits, while the Fremont proanthocyanidin is a dimer. The F1 crosses of Fremont × narrowleaf are oligomers of six to seven subunits, making them more similar to Fremont than to narrowleaf. The proanthocyanidin chain length for backcross genotypes are polymers with 17–35 subunits, similar but more variable than the narrowleaf parent.

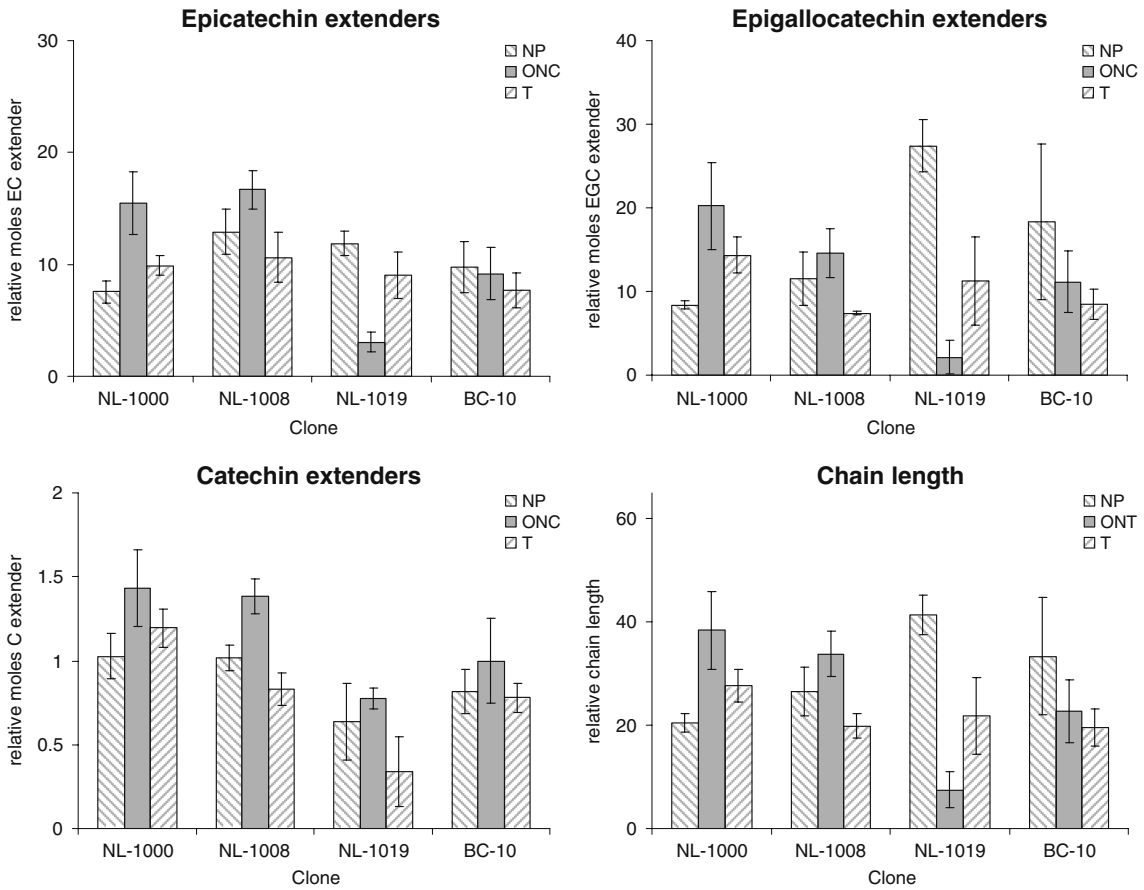

Fig. 4 *Populus* proanthocyanidin composition and chain length as a function of environment. Samples of mature leaves were collected from three five clones of narrowleaf (NL) or one clone of backcross (BC) in June 2007. Plants were growing in the North Pit (NP), the Ogden Nature Center (ONC), or the Taggart (T) common garden. Bars show mean for N=2–5, error bars are 1 SEM

Our work suggests that qualitative attributes such as proanthocyanidin composition and chain length may be controlled by dominant inheritance in both F1 and backcross cross types. This result is partly consistent with reports that quantity of proanthocyanidins is controlled by dominant inheritance in backcrosses (Driebe and Whitham, 2000), but contrasts with some other reports of additive inheritance for proanthocyanidin levels (Rehill et al., 2006). The heritability of phenolic glycoside composition in *Populus* is controlled via dominance (Rehill et al., 2006) but flavonoid composition appears to involve additive control at the F1 generation and dominance in backcrosses (Crawford, 1974). Further studies on the mode of inheritance of qualitative traits such as proanthocyanidin composition and chain length could be initiated by using methods of chemical analysis similar to those we used here.

The effect of environment on narrowleaf proanthocyanidins differed among genotypes (environment × genotype interaction). The strongest effect was for narrowleaf clone 1019: in the ONC garden, proanthocyanidin chain length for genotype 1019 (7.5) was similar to that of F1 plants (7.0). However, the importance of the prodelphinidin-type subunit in the clone 1019 proanthocyanidin was typical of narrowleaf, not F1 plants. It was surprising that this difference was noted only in the ONC garden, which has environmental conditions most similar to the NP garden.

Our study did not identify any strong effect on qualitative characteristics of proanthocyanidins due to season or developmental zone. Season and developmental zone statistically influenced the minor proanthocyanidin subunit catechin, but the difference is not chemically meaningful. Although catechin is elevated slightly in tissue collected in June or in mature tissue, the chain length is not significantly different for either season or developmental zone, indicating that the change in catechin is not chemically significant. This result contrasts with quantitative studies, in which tissue developmental zone had a strong effect on the amount of proanthocyanidins in *Populus,* with mature tissue containing about twice as much tannin as juvenile tissue (Rehill et al., 2006). In *Populus*, quantitative and qualitative expression of proanthocyanidins are controlled independently, at least in part.

Qualitative traits that vary may provide insight into metabolic capabilities and regulatory steps in cases where

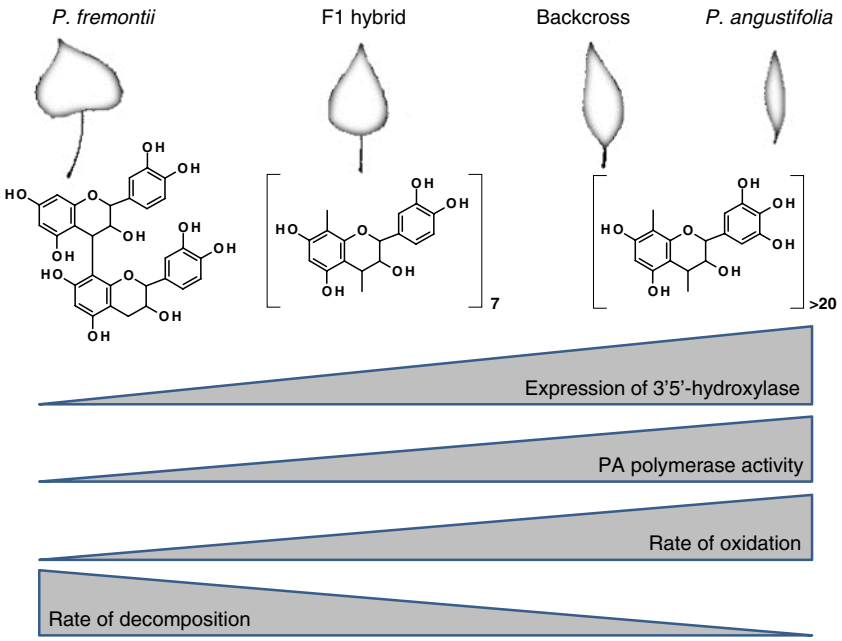

Fig. 5 Relationships among the plants, the qualitative features of the proanthocyanidins, and biochemical and ecological hypotheses. The leaf icons represent the parent species *Populus fremontii* and *Populus angustifolia*, the F1 hybrid and the backcross. Under each leaf is a structural formula summarizing type of subunit (procyanidin or prodephinidin) and chain length typical of the proanthocyanidin found in that plant. The gray triangles depict the proposed metabolic and ecological trends, with the large end of the triangle representing high level of 3′5′-hydroxylase expression, leading to prodelphinidin subunits; high level of putative proanthocyanidin polymerase activity, resulting in longer chain lengths; and rapid oxidation or decomposition in the environment, predicted based on chemical reactivity and tentatively confirmed by work from Barbehenn et al., 2006 and Driebe and Whitham, 2000

the fundamental metabolic processes are known. For proanthocyanidins, differences in monomer composition presumably reflect flavonoid metabolism, while differences in chain length reflect aspects of the polymerization steps. The biosynthetic steps leading to the monomeric precursors of the proanthocyanidins are well defined. Some of the most detailed studies of the pathway have been conducted with *Populus* (Tsai et al., 2006). Despite many efforts to elucidate the final steps of proanthocyanidin synthesis, the exact details of the polymerization steps are unknown.

Proanthocyanidin composition is determined by the precursors supplied by the metabolic grid (network of pathways) characteristicof flavonoid production (Stafford, 1990). In *Populus*, the differences between cross types involve B-ring hydroxylation. Narrowleaf proanthocyanidins contain both dihydroxylated (3′4′-hydroxyl) and trihydroxylated (3′4′5′-hydroxyl) subunits, while Fremont is restricted to the dihydroxylated flavan-3-ol units. B-ring hydroxylation is carried out by two enzymes, flavonoid 3′-hydroxylase (CYP75B) and flavonoid 3′,5′-hydroxylase (CYP75A) (Ayabe and Akashi, 2006). Both enzymes are cytochrome P450 monooxygenases that use NADPH, but sequence and mechanistic studies have indicated that the two enzymes diverged early (Seitz et al., 2007). The *Populus* genome is reported to have one copy of the flavonoid 3′-hydroxylase gene and two duplicated flavonoid 3′,5′-hydroxylase genes (Tsai et al., 2006), so cross type differences in proanthocyanidin composition may reflect genetically dictated differences at the expression level.

In tissue that does not express the flavonoid 3′,5′-hydroxylase, the trihydroxylated prodelphinidin- type flavonoids are not produced. Our data suggest that Fremont does not express the flavonoid 3′,5′-hydroxylase gene but that narrowleaf does produce that enzyme in sufficient quantity to make the prodelphinidin-type proanthocyanidins. Chemosystematic studies that focus on flavonoid metabolism support that hypothesis. For example, Crawford (Crawford, 1974) reported that an important chemical difference between narrowleaf and Fremont was the accumulation of myrecetin, a trihydroxylated flavonol glycoside, in narrowleaf but not in Fremont. Only 3′-hydroxylated or 3′,4′-hydroxylated flavonoids were found in Fremont, consistent with the absence of flavonoid 3′,5′-hydroxylase from that cross type. We found that F1 hybrids of narrowleaf and Fremont accumulated proanthocyanidins with some prodelphinidin-type subunits, so we speculate that low levels of the enzyme must be expressed in the hybrid tissue. Molecular studies support that perspective, with RT-PCR analysis of an F1 hybrid indicating that flavonoid 3′,5′-hydroxylase is expressed in leaf tissue of a F1 hybrid (Tsai et al., 2006). An examination of the expression of the two hydroxylases in narrowleaf, Fremont,

and backcross leaf tissue would provide an additional test of our hypothesis that composition of proanthocyanidins in *Populus* reflects the levels of flavonoid 3′,5′-hydroxylase.

Proanthocyanidin chain length may reflect either differences in substrate supply or differences in the expression of a polymerizing enzyme. Limited production of chain extenders, or overproduction of terminal units, would result in production of short chain proanthocyanidins. Proanthocyanidin substrate supply is controlled by the flavonoid pathway. Although the details of polymerization are not well established, flavan-3-ols are the most likely chain elongation units (Gupta and Haslam, 1978). Flavan-3-ols are produced by action of flavanone 3-hydroxylase on the central metabolite naringenin (Tsai et al., 2006). We hypothesize that proanthocyanidin chain length in Fremont is limited by supply of substrate due to absence of flavanone 3-hydroxylase. That hypothesis is supported by surveys of flavonoid production that showed that Fremont accumulated flavones and flavanones, but not flavonols (Crawford, 1974; Greenaway et al., 1989). In contrast, narrowleaf accumulates flavonols as the predominant flavonoid (Crawford, 1974), consistent with expression of flavanone 3-hydroxylase, and consistent with abundant substrate for production of polymeric proanthocyanidins. Since F1 hybrids produce oligomeric proanthocyanidins, we postulate that this cross type expresses only low levels of the flavanone 3-hydroxylase, and that notion is confirmed by expression studies in which weak expression of flavanone 3-hydroxylase was reported in leaf tissue of an F1 hybrid (Tsai et al., 2006). Additional gene expression studies in all four cross types would test this hypothesis more completely.

An alternative explanation for the production of short chain proanthocyanidins in Fremont would be absence of the enzyme responsible for polymerization. Unfortunately, the chain elongation step of proanthocyanidin biosynthesis has not been characterized for any system (Xie and Dixon, 2005). We suggest that gene expression studies of closely related cross types that produce proanthocyanidins with very different chain lengths, such as narrowleaf, Fremont, and F1 hybrid *Populus*, might provide useful leads to the elusive polymerase enzyme.

We restricted our analyses of *Populus* proanthocyanidin composition to leaf tissue. However, in grapes, production of proanthocyanidins is tissue-selective, with skins producing mixed procyanidin/prodelphinidin tannins and seeds producing only procyanidin (Monagas et al., 2003) There is little information on proanthocyanidins from other tissues of *Populus*, but tissue-specific expression of the flavonoid 3′-hydroxylase and flavonoid 3′,5′-hydroxylase have been reported (Tsai et al., 2006). Based on that information, we predict that proanthocyanidins from the root tips of F1 may comprise only cyanidin-type subunits, since RT-PCR suggests that this tissue does not have the enzyme required to produce the trihydroxylated precursors to prodelphinidin-type subunits (Tsai et al., 2006). Tissue-selective expression of proanthocyanidins needs to be more fully explored using tools that elucidate qualitative differences.

The idea that "tannins", broadly encompassing both proanthocyanidins and hydroyzable tannins, have a quantitative effect on ecosystem processes has been a cornerstone of chemical ecology for decades (Feeny, 1976). Despite many refinements to the original ideas, most studies treat tannins strictly quantitatively. Nonspecific quantitative methodology and limited qualitative analysis are the norms for studies that include consideration of tannins. For example, the rates of litter decomposition for *Populus* cross types were correlated with levels of proanthocyanidins (Driebe and Whitham, 2000). Leaves from Fremont decomposed quickly (0.007 day^{-1}), backcross decayed two- to three-times more slowly (0.17 day^{-1}), and narrowleaf and F1 decomposed at an intermediate rate (0.012 day^{-1}). For Fremont and narrowleaf, there appeared to be a strong relationship between rate of decomposition and level of proanthocyanidin, supporting the generally held view that levels of proanthocyanidins dictate biological activity. However, a more complex relationship was revealed by the data from narrowleaf and F1 hybrids. Leaves from these two cross types decomposed at the same rate even though levels of proanthocyanidins were four- to five-times higher in narrowleaf crosstypes than in F1 hybrids. We propose that the qualitative traits of subunit composition and polymer chain length of proanthocyanidins are important determinants of bioactivities such as decomposition rate. For example, comparing the results of our study to the litter decomposition studies, we see that both prodelphinidin subunit composition and proanthocyanidin chain length are inversely correlated to the rate of decomposition, with the cross type we identified as having the longest chain length and highest% prodelphinidin subunit (narrowleaf) also having the slowest decomposition. Nierop et al. (2006) noted that prodelphinidins slowed N mineralization rates more than procyanidins in Corsican pine litter amended with structurally well defined condensed tannins. Litter decomposition was negatively correlated with degree of polymerization of condensed tannins for several species of tropical trees, but the correlation was strongly driven by a single species containing very highly polymerized tannins (Coq et al., 2010). Explicit tests that use well characterized, diverse tannins, of the relationship between condensed tannin structure and rate of litter decomposition are needed

Activities other than rate of decomposition of leaf litter also may be significantly affected by the qualitative characteristics of proanthocyanidins. For example, Barbehenn et al. (2006) demonstrated that polymeric prodelphinidins were more susceptible to oxidative browning than lower

molecular weight prodelphinidins. In the same study, procyanidins were more resistant to oxidation than prodelphinidins. Oxidative browning and radical formation might be important determinants of toxicity and metabolic fate of proanthocyanidins in insects with alkaline gastrointestinal conditions, leading to the conclusion that proanthocyanidin qualitative traits might govern the role of these compounds in plant-herbivore interactions.

Our work demonstrates that in *Populus* leaf tissue, genetics (i.e., cross type) is the primary determinant of proanthocyanidin quality—both chain length and monomer composition. Environment has a less important role in determining proanthocyanidin quality, and developmental zone and season are much less important. In contrast, the quantity of proanthocyanidin is influenced by developmental factors as well as genetics and environment (Rehill et al., 2006). The variation in proanthocyanidin composition and chain length found in these four well-characterized *Populus* cross types suggest that this hybridizing complex might serve as an excellent model for examining the functional role of proanthocyanidin quality more carefully (Fig. 5). The cross types also may provide an excellent system for further exploration of the enzymology of proanthocyanidin polymerization, and for probing the metabolic regulation of proanthocyanidin composition (Fig. 5).

Abstract The chemical quality of forage may determine landscape use and habitat quality for some herbivorous species. However, studies that investigate the relationship between foliar chemistry and foraging choices in wild vertebrates are rare. *Petauroides volans* (the greater glider) is unique among Australian marsupial folivores because it glides. It also frequently consumes foliage from both major *Eucalyptus* subgenera, *Eucalyptus* (common name "monocalypt") and *Symphyomyrtus* (common name "symphyomyrtle"), which differ markedly in their foliar chemistry. Such differences are thought to be a product of co-evolution that also led to guild-specific plant secondary metabolite (PSM) specialization among other marsupial eucalypt folivores. To explore whether foliar chemistry influences tree use, we analyzed foliage from eucalypt trees in which we observed *P. volans* during a radio tracking study and from eucalypt trees in which animals were never observed. We used a combination of chemical assays and near infrared spectrophotometry (NIRS) to determine concentrations of nitrogen (N), *in vitro* available nitrogen (AvailN), and *in vitro* digestible dry matter (DDM) from foliage sampled from the monocalypt and symphyomyrtle species, and total formylated phloroglucinol compounds (FPCs) and sideroxylonals (a class of FPCs) from the symphyomyrtle species (FPCs do not occur in monocalypts). Tree size and spatially-dependent, intraspecific variations in sideroxylonals and DDM concentrations in the symphyomyrtle foliage and of N, AvailN, and DDM in the monocalypt species were important indicators of tree use and habitat suitability for *P. volans*. The results i) demonstrate that guild-specific PSMs do not always lead to guild-specific foraging; ii) provide a compelling co-evolutionary case for the development of gliding in *P. volans*; and iii) have implications for the management and conservation of this and other folivorous species.

Introduction

Variations in plant nutrients and herbivore-deterrent plant secondary metabolites (PSMs) across a landscape create a chemically complex environment that may influence the distribution and abundance of animal species (Braithwaite et al. 1983; Stephens and Krebs 1986; Moore et al. 2010). Identifying the factors that determine habitat suitability is essential for the conservation of species and communities. Those species that survive in a relatively narrow niche, both in terms of the range of food-types available and the variation of chemical composition that they can tolerate, may be particularly sensitive to landscape and climatic changes that can affect the quality and availability of their food (Lawler et al. 1997; Moore et al. 2004).

Eucalyptus (L'Herit) foliage contains relatively low concentrations of nutrients, particularly nitrogen (N), but high concentrations of PSMs that can cause toxicosis and reduce the digestibility of plant nutrients (Cork and Foley 1991; Moore et al. 2004; Scrivener et al. 2004). Concentrations of

nutrients and PSMs in eucalypts often vary considerably from tree to tree, even within the same species (Wallis et al. 2002; Andrew et al. 2005). Several studies have demonstrated how variation in N, tannins, and formylated phloroglucinol compounds (FPCs) differentially affect feeding by *Phascolarctos cinereus* (the koala), *Pseudocheirus peregrinus* (the common ringtail possum), and *Trichosurus vulpecula* (the common brushtail possum) (Lawler et al. 1998a; Wallis et al. 2002; Marsh et al. 2003a, b; Moore and Foley 2005; Moore et al. 2005). It is not known whether intraspecific variations in FPCs or N availability influence the foraging of *Petauroides volans* (the greater glider, Fig. 1), a marsupial folivore that, like *P. cinereus*, feeds almost exclusively on eucalypt leaves.

Fig. 1 The greater glider (*Petauroides volans*), shown here in light (**a**) and dark (**b**) color phases, is a marsupial folivore that feeds primarily on *Eucalyptus* leaves. Photographs by David Lindenmayer

Differential susceptibility to PSMs may reduce competition among co-occurring herbivores by restricting them to eating plants that contain the unique chemical signature they have evolved to tolerate (Moore et al. 2004). It may be appropriate to consider leaf-eating animals, not as folivores *per se,* but as specialists on particular metabolites. Determining the PSM tolerances of co-occurring herbivorous species also could shed light on evolutionary relationships between plants and animals and current patterns of species distributions and biodiversity in particular habitats.

In addition to intraspecific variation in foliar chemistry, there are also differences in chemistry among eucalypt species in the two major eucalypt subgenera, *Eucalyptus* (common name "monocalypt") and *Symphyomyrtus* (common name "symphyomyrtle"). Symphyomyrtle species produce FPCs that, when ingested by mammals, stimulate the serotonergic systems and probably induce sensations of nausea (Lawler et al. 1998b). When feeding on eucalypts, both *P. cinereus* and *T. vulpecula* feed mainly on symphyomyrtle species. Although tolerant of FPCs, captive animals eat less as foliar concentrations of these compounds increase (Lawler et al. 1998a; Wallis et al. 2002). Similarly, FPCs, including sideroxylonals, influence tree use by free-living *T. vulpecula* and *P. cinereus* (Scrivener et al. 2004; Moore and Foley 2005; Moore et al. 2010). In contrast, *P. peregrinus* is relatively intolerant of FPCs and feeds primarily on monocalypt species (Lawler et al. 1998a; Moore et al. 2004).

Monocalypts do not produce FPCs (Eschler et al. 2000) but their foliage contains high concentrations of tannins (Wallis et al. 2010) that can bind to nitrogenous compounds in plant tissues and reduce the digestibility of plant proteins (Silanikove et al. 1996; Marsh et al. 2003b). Using an *in vitro* assay (DeGabriel et al. 2008), Wallis et al. (2010) showed that the foliage of 31 monocalypt species contained about half the available nitrogen (AvailN) of that of 82 symphyomyrtle species due to N binding by tannins. Tannins influence the physiology and foraging behavior of many herbivorous species, although not all marsupial folivores appear to be affected equally (Osawa and Sly 1992; Silanikove et al. 1996; Marsh et al. 2003a). When tannins are inactivated by coating leaves with polyethylene glycol (PEG), some herbivores, including *T. vulpecula*, eat more of the treated material, while others, such as *P. peregrinus*, do not (Marsh et al. 2003b). DeGabriel et al. (2009) showed that N availability in eucalypt foliage is an important determinant of reproductive success for *T. vulpecula* in the wild.

In mixed stands of eucalypt trees, representatives from both major subgenera tend to co-dominate and this is known as Pryor's Rule (Pryor 1959). Thus, one can suggest that by specializing on the PSMs produced by a particular eucalypt subgenus, folivores could inhabit the same tracts

of forest without competing for food (Marsh et al. 2003a). In turn, coevolution between plants and animals may have influenced the diversity of plant chemotypes and foraging adaptations of herbivores (Ehrlich and Raven 1964; Thompson 1994; Futuyma 2000; Becerra 2007). As a result of such co-evolutionary relationships, guild-specific PSMs are often thought to lead to guild-specific foraging (Thompson 1994; Rausher 2001).

We focused on *P. volans*, the only Australian folivorous marsupial that glides. Although past studies have linked foliar concentrations of N and tannins to tree species preference and forage consumption (Foley and Hume 1987; Kavanagh and Lambert 1990; McIlwee et al. 2001), we do not know how this animal responds to variation in the concentrations of AvailN or FPCs. Although *P. volans* is argued to be a monocalypt and tannin specialist, like the closely related *P. peregrinus* (Family *Pseudocheiridae*) (Moore et al. 2004), field studies have indicated that it regularly consumes foliage from eucalypt species of both major subgenera (Kavanagh and Lambert 1990; Cunningham et al. 2004).

We posed a series of questions to investigate the role of eucalypt foliage chemistry on tree choice, landscape use, and the habitat requirements of *P. volans*. Due to the association of particular PSMs (e.g., FPCs) with particular eucalypt subgenera, the first three questions were investigated on the monocalypt and symphyomyrtle species independently. 1) Are there significant differences in foliar concentrations of FPCs (total FPCs and sideroxylonals), N, AvailN, and digestible dry matter (DDM) among trees in which *P. volans* was and was not observed? 2) Is the relationship between *P. volans* tree use and foliar concentrations of N, AvailN, and DDM the same for trees from both major subgenera of *Eucalyptus*? 3) Are feeding-specific observations or spatial considerations (i.e., the distance of trees with no animal observations to trees with observations) important for determining whether there is a relationship between foliage chemistry and tree use? 4) Do our results agree with current hypotheses about the foraging niche of *P. volans* as a "specialist" folivore? 5) Do our results have implications for the conservation of *P. volans* and other folivorous species?

Methods and Materials

Study Area Our study site was 100 km west of Canberra in Buccleuch State Forest, New South Wales, Australia 148° 40′ E, 35°10′ S. The area includes a 50,000 ha exotic pine (*Pinus radiata)* plantation bordered by native eucalypt forest and grazing farmland. Extensive areas of native forest were cleared from the late 1930s through the 1980s to establish the pine plantation, leaving patches of remnant eucalypt forest (1–100 ha) embedded within the pine (Lindenmayer et al. 1999). Five neighboring eucalypt forest remnants were selected for a separate radio-tracking study to investigate *P. volans* home-range size and tree use in a fragmented forest ecosystem (Pope et al. 2004). These remnants ranged in size from 1.6 to 18.2 hectares and varied in shape, but they had similar vegetation communities dominated by narrow-leaved peppermint [*Eucalyptus radiata* (monocalypt)], ribbon gum [*E. viminalis* (symphyomyrtle)] and mountain gum (*E. dalrympleana* [symphyomyrtle)]. A more complete description of the study area, including a list of common canopy and understory vegetation is in Lindenmayer et al. (1999).

Radio-tracking Forty *P. volans* from the five neighboring eucalypt forest remnants were captured and fitted with single-stage radio-transmitter collars (Faunatech Pty Ltd, Victoria, Australia). Effort was taken to ensure that every *P. volans* in the selected remnants was included in the study (see Pope et al. 2004 for details). Tracking occurred over five consecutive nights each month from September 1997 to October 1998. Animals were tracked to one tree per night, and the tracking sequence was varied randomly (for a description of tracking methodology see Cunningham et al. 2004). Once we located a *P. volans*, we recorded its behavior (feeding, grooming, perching, mating, and not observable), tagged the tree in which it was observed, and recorded the tree location with a differentially-corrected, hand-held GPS (Global Star Pty Ltd, Melbourne).

Tree-leaf Sampling Radio-tracking data provided a unique opportunity to investigate tree use by *P. volans* in relation to recently identified PSMs and a newly described measure of forage quality (available nitrogen). A study published on tree use by wild *P. cinereus* based on tree location data recorded from 1993 to 2004 established the feasibility of sampling foliage from feeding trees identified during earlier tracking efforts (Moore et al. 2005). No large-scale changes to the selected remnant areas, such as harvesting of the surrounding pines, which might alter the concentrations of foliar chemistry, have occurred since the original radio-tracking.

In December 2006, we revisited the five fragments and relocated 261 of the original 433 trees used at night time by *P. volans*. Lost tree tags made it impossible to identify all trees from the original study. We collected leaves from all tree species in which *P. volans* was observed (see Cunningham et al. 2004 for a complete list). The vast majority of observations occurred in *E. radiata* (41% of eucalypt tree use) and *E. viminalis-E. dalrympleana* (35%) (Cunningham et al. 2004; Pope et al. 2004). Due to the relatively small number of observations in other species, we focused our analysis solely on these three tree species. Data for *E.*

viminalis and *E. dalrympleana* were pooled during the radio-tracking study due to the difficulty of distinguishing these closely related trees in the field. Both species produce FPCs, and both are eaten by *P. volans*, so grouping them also was appropriate for this study.

We collected foliage from one or more untagged neighboring trees of the same species and similar size [±10% diam. at breast height (DBH)] as each numbered tree (N=112). Cunningham and others (2004) found a correlation between tree size and tree use by *P. volans*, so we selected similar-sized trees to minimize the effect of this potentially confounding factor. If a tree did not have a suitable neighbor within 20 m, we did not sample a neighbor. Where possible, we also sampled canopy trees from the few areas within the remnant patches where no *P. volans* were observed. These trees were more than 20 m from any other tree with an animal observation (N=53). The purpose of this sampling strategy was to document the chemical composition of eucalypts within the proximity of the animals' home-ranges without introducing a potentially confounding distance factor. The aim of the original radio-tracking study was to determine home-range size rather than total tree use (Pope et al. 2004). Animals invariably used trees in addition to those in which they were observed. We recognize that *P. volans* may have used some of the "no observations" trees, though we assumed a bias towards a non-use status for trees in which we did not observe an animal.

We obtained leaf samples by shooting a branch from the top half of the canopy using a 0.222 caliber rifle, and then recorded tree height and DBH at 1.3 m from the forest floor on the uphill side of the tree by using a laser clinometer and a measuring tape, respectively. We collected about 50 g of fully expanded, healthy adult leaves from each tree. *Petauroides volans* feeds on both young and mature foliage but we chose mature foliage because concentrations of both N and PSMs can change considerably as a leaf ages (Choo et al. 1981; Kavanagh and Lambert 1990). Thus, selecting mature foliage—that available for most of the year—ensured that leaf phenology did not obscure the relative concentrations of compounds between trees. We placed the leaf samples in a portable freezer (Engel MT17: Brisbane, Australia) and transported them to the laboratory where they were freeze-dried and then ground to pass a 1 mm sieve using a Cyclotec 1093 mill (Tecator, Sweden).

NIR Spectrometry We placed samples of freeze-dried, ground leaf in an oven (40°C) for 12 h to equilibrate atmospheric moisture. After cooling in a desiccator, we recorded the spectra (400 nm to 2,500 nm at 2-nm intervals) with a NIRSystems Model 6500 Scanning Spectrophotometer (Foss NIRSystems, Laurel, MD, USA) fitted with a spinning cup module. The spectrophotometer was housed in a room at 22°C–24°C and at 55%–60% RH. We checked the accuracy of measurements at regular intervals by using a standard of known chemical composition. We converted reflectance spectra (R) to absorbance values [A=log(1/R)] and transformed them to a first-derivative spectrum to emphasize changes in slope and reduce variation resulting from differences in particle size (Osborne et al. 1993). We collected spectra from each sample in duplicate, and these were averaged once the spectral noise [the root mean square of the difference between replicates $(1/R)/10^6$)] was less than 250.

We determined foliar concentrations of N, available N, and DDM on a calibration set of 100 samples selected to represent the population of all sampled eucalypts based on a Mahalanobis distance calculation of spectral variation (WinISI II V. 1.02a; InfraSoft International, Port Matilda, PA, USA). We developed calibration equations by using a modified partial least squares regression (MPLS: Shenk and Westerhaus 1991), and a standard normal variate and detrend scatter correction (SNV detrend). We tested various combinations of Savitzy-Golay derivative-based spectral smoothing functions provided by the ISI software (Win ISI; Port Matilda, PA, USA) to remove unnecessary spectral signal components and to improve the accuracy of the prediction models. We report the best results from the application of these mathematical transformations in Table 1. The use of MPLS requires cross-validation to prevent over-fitting the model for which we used a leave-one-out (LOO) resubstitution method. The LOO cross-validation

Table 1 Results from MPLS regression with cross-validation for modeling the relationship between spectral characteristics of eucalypt foliage and foliar concentrations of nitrogen (N), available nitrogen (AvailN), and digestible dry matter (DDM)

Constituent	SNV detrend + math treatment	*N*	Mean	SD	SEC	R^2	SECV	*1-VR*
N	2841	96	1.21	0.20	0.04	0.97	0.06	0.92
AvailN	1441	78	0.37	0.31	0.06	0.96	0.10	0.90
DDM	1441	89	0.44	0.12	0.02	0.97	0.03	0.93

Math treatment refers to the Savitzy-Golay derivative based spectral smoothing and includes the derivatives and the number of data points across which the smoothing functions were calculated; SEC is standard error of calibration and SECV is standard error of cross-validation predictions; the degree of correlation between predicted and actual measured values is indicated by the R^2 and by *1-VR* for the cross-validation data. The prediction equation and validation are based on all species of *Eucalyptus* collected.

provides an estimate of model error based on data resampling (Elisseeff and Pontil 2002). We divided data into n groups and left one group out of the model in rotation so that the learning algorithm was trained multiple times on the n-1 group, while the remaining group tested the model's accuracy. We generated a standard error of cross-validation by pooling residuals from each prediction (Table 1). Finally, we validated the approach for N using 20 additional tree-leaf samples not included in the prediction model.

Chemical Assays We used freeze-dried ground material for all analyses and corrected for residual moisture by drying 1.00 g of material to constant mass at 50°C. The N content of foliage was determined on duplicate samples (250± 10 mg) using a semi-micro Kjeldahl technique calibrated with ammonium sulphate. We determined *in vitro* DDM and AvailN using the method of DeGabriel et al. (2008). This involved digesting the samples in porous bags (Ankom F57, Ankom Technology, Macedon, NY, USA), first with pepsin (24 h) and then with cellulase (48 h) to mimic digestion in a hindgut-fermenting herbivore. The purpose of the assay was to rank trees with regard to AvailN and DDM rather than trying to give precise *in vivo* values for these constituents. We discarded values if the coefficient of variation between duplicates was more than 2% (N) or 7% (AvailN and DDM) and repeated the assay.

We extracted formylated phloroglucinol compounds by sonicating single 50 mg foliage samples with a known mass (ca 4.0 g) of solvent (7% water in acetonitrile containing 0.1% trifluoroacetic acid and 0.3000 g per liter of the internal standard 2-ethylphenol) for 5 min (Wallis and Foley 2005). The resulting mixture was filtered (0.2 um) directly into an autosampler vial and then we injected 20 ul onto a Wakosil 250×4 mm GL 3C18RS (SGE Analytical: Ringwood, Australia) column maintained at 37°C with a flow rate of 0.75 ml/min on a Waters Alliance Model HPLC. We eluted the FPCs under gradient conditions with 0.1% TFA acid in water (A) and 0.1% TFA in acetonitrile (B) as follows: 40% A/60% B for 5 min, linear gradient to 90% B/10% A at 60 min, held for 10 min and returned to starting conditions over 10 min. We measured the peak response at 275 nm. We quantified the specific FPCs present by using authentic standards purified in the laboratory. The coefficient of variation between duplicate measurements is typically less than 4% (Wallis et al. 2010).

Statistical Analyses We conducted statistical analyses separately on the *Eucalyptus* (monocalypt) and *Symphyomyrtus* (symphyomyrtle) subgenera. We compared foliar concentrations of N, AvailN, and DDM among the different tree categories. These were: 1) trees in which we observed *P. volans* feeding once (feeding observation); 2) trees in which we saw an animal feeding multiple times (multiple feeding observations); 3) trees in which we observed *P. volans* in a non-feeding activity only (non-feeding observation); 4) neighboring trees with no animal observations (no observation neighbor); and 5) trees more than 20 m from any tree in which we observed an animal (no observation area). We also compared foliar concentrations of total FPCs and sideroxylonals (a class of FPC) among these tree-use categories for the symphyomyrtle species.

We combined feeding and multiple feeding trees for the following analyses due to the relatively small number of trees in each category. We assessed the distribution of data with a normal-quantile plot. Where data were normally distributed, we used ANOVAs to test the hypothesis that two population means were equal. We used a Kruskal-Wallis test when the normality assumption for ANOVAs could not be met and when our samples sizes were less than 30 but greater than 14 (Hollander and Wolfe 1999). Larger trees were less likely than smaller ones to have a suitable neighbor within a 20 m radius. Therefore, despite our effort, this resulted in a disproportionate sampling of smaller trees in the no observation categories when compared to some of the observation categories. Where significant differences were observed for several potentially confounding variables, we used logistic, binomial Generalized Linear Models (GLMs) to investigate whether a significant difference in a chemical constituent concentration remained once we controlled for other significant explanatory variables, such as the DBH.

Monocalypt trees in which we saw *P. volans* feeding repeatedly did not appear to have the same variance for N as monocalypt trees with no observations. There were sufficient multiple feeding observation trees in this monocalypt group to investigate the trend by using non-parametric statistics. First, we used an Ansari-Bradley test to determine equality of variance (Hollander and Wolfe 1999). To test whether animals avoided feeding repeatedly on trees with low concentrations of N, we determined the number of trees with no *P. volans* observations that had a lower concentration of N than any tree with multiple feeding observations. We then calculated the probability of this number or a greater number occurring by chance at either extreme of the distribution.

Results

Foliar Chemistry and Measured Tree Attributes We successfully modeled the relationship between absorbance spectra from eucalypt foliage and foliar concentrations of N, AvailN, and DDM (Table 1). The independent validation of N samples (N=20) resulted in excellent agreement between the predicted and analyzed values (R^2=0.96;

RMSE=0.042). This suggested that the samples we selected for the training algorithm by the Mahalanobis distance calculation method were representative of the spectral range of our data.

We illustrate the distributions of data for each variable according to eucalypt subgenera, monocalypt and symphyomyrtle (Fig. 2). These distributions were further segregated by tree use category (no observation area, no observation neighbor, non-feeding observation, feeding observation, and multiple feeding observations). The symphyomyrtle species (*E. viminalis* and *E. dalrympleana*) had higher concentrations of AvailN ($P<.001$, $t=22.94$, mean of the differences= 0.48% dry matter (DM)) and DDM ($P<.001$, $t=27.96$, mean of the differences=0.19 g.g^{-1} DM) than did the monocalypt

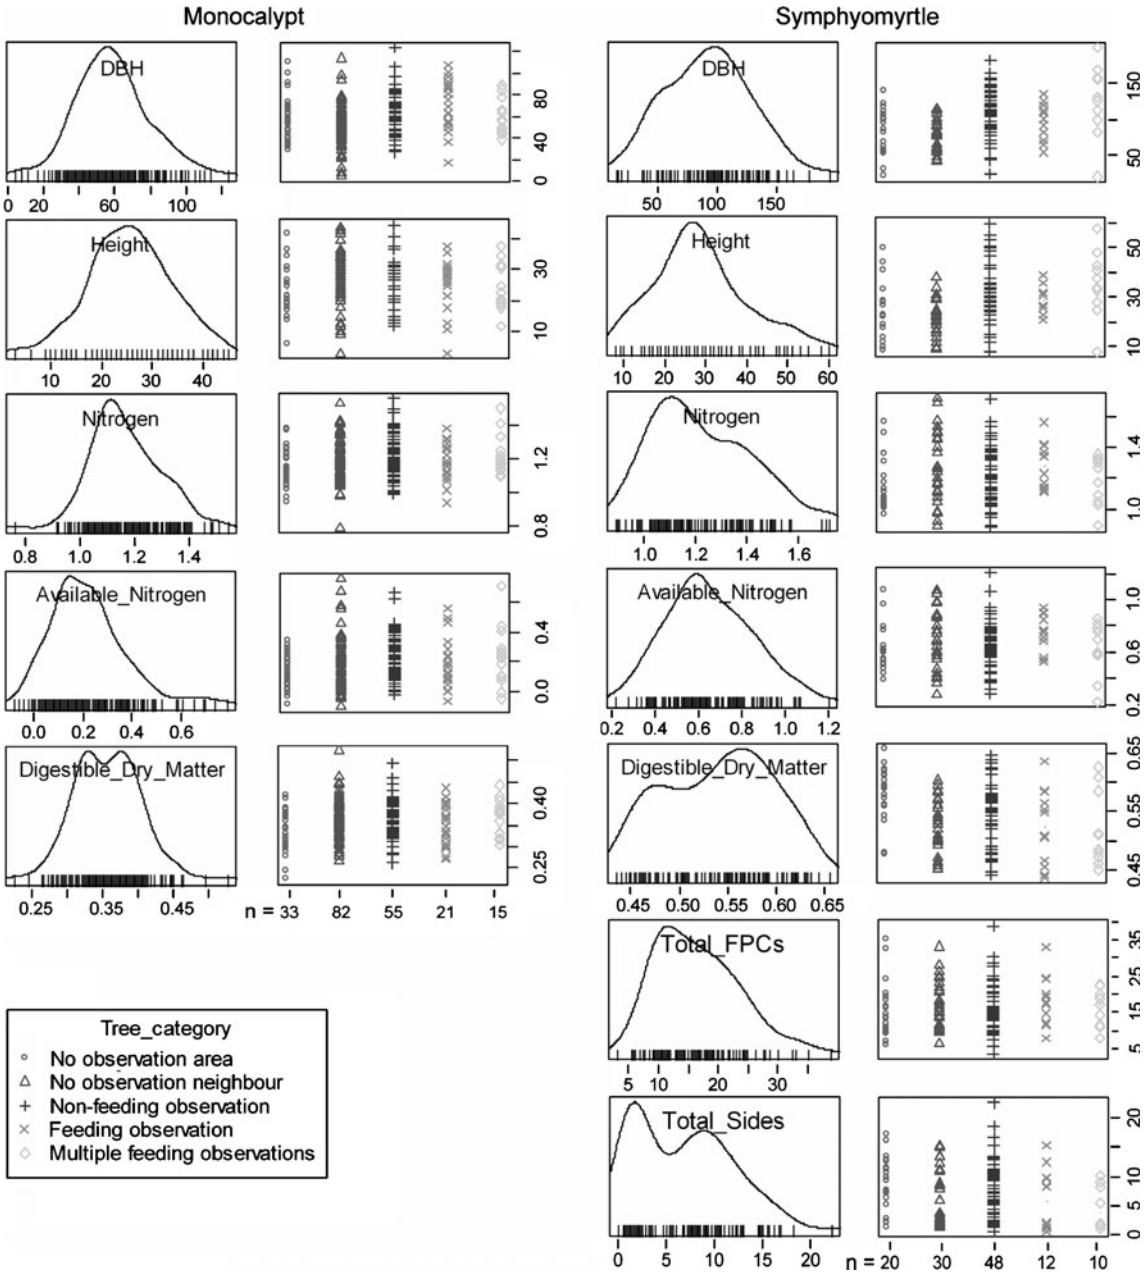

Fig. 2 Distribution of variables overall (scaled kernel density estimates) and among tree categories for monocalypts (*Eucalyptus radiata*) and symphyomyrtles (*Eucalyptus viminalis* and *Eucalyptus dalrympleana*). Variables include diameter at breast height (DBH; cm), height (m), and foliar concentrations of nitrogen (N; % dry matter (DM)), available nitrogen (AvailN; % DM), digestible dry matter (DDM; g.g^{-1} DM), total formylated phloroglucinol compounds (total FPCs; mg.g^{-1} DM), and sideroxylonals (Total Sides mg.g^{-1} DM). The sample size for each tree category is provided under the tree category distributions

species (*E. radiata*) (*P*-values from Student's *t*-test of means not included in Fig. 2).

We explored the interactions among the data by using a Pearson's correlation matrix (Table 2). The correlation between the concentrations of N and AvailN in the monocalypts was much lower ($r=0.462$, $P<0.001$) than in the symphyomyrtles ($r=0.914$, $P<0.001$). The monocalypts also showed a weak positive correlation between N and DDM ($r=0.170$, $P=0.02$). This relationship was negative in the symphyomyrtles ($r=-0.602$, $P<0.001$). Likewise, the concentration of AvailN was positively correlated with DDM in the monocalypt species ($r=0.617$, $P<0.001$) and negatively correlated in the symphyomyrtles ($r=-0.445$, $P<0.001$). When we converted tree use category to an ordinal variable, which assumed a linear relationship of increasing preference as a feeding tree from 0 to 4 (Table 2), we identified a significant correlation between tree use category and DBH for both the monocalypt ($r=0.206$, $P=0.003$) and symphyomyrtle ($r=0.376$, $P<0.001$) classes and between tree use category and tree height for symphyomyrtles ($r=0.321$, $P<0.001$). We also observed a weak but significant correlation between tree use category and AvailN ($r=0.146$, $P=0.03$) for the monocalypts and between tree use category and sideroxylonals ($r=-0.242$, $P=0.008$) in the symphyomyrtles. We identified a negative correlation for both N and AvailN with sideroxylonals ($r=0.575$, $P<0.001$ and $r=0.519$, $P<0.001$, respectively) and a positive correlation for N and AvailN with total FPCs ($r=0.669$, $P<0.001$ and $r=0.713$, $P<0.001$, respectively).

Tree Use by P. volans When comparing all symphyomyrtle trees in which we observed *P. volans* to trees with no observations, only DBH ($P<0.001$) and height ($P<0.001$) differed significantly (Table 3). Monocalypt trees in which we saw animals also had a larger DBH ($P<0.001$) than did those in which we did not observe *P. volans*. A GLM that included both DBH and AvailN (near significant in monocalypt means test, $P=0.058$) suggested that both variables were important in explaining the difference among monocalypt trees in which an animal was, and was not, observed ($P<0.001$ and $P=0.042$, respectively) (Table 4).

We separated the trees in which we did not observe *P. volans* into two categories: "no observation neighbor" and "no observation area". Trees from areas where we did not observe *P. volans* explained most of the chemical differences among categories (Table 3). Size was the only significant difference among neighboring trees in which an animal was not observed and trees in which an animal was observed. Despite our attempt to control for these differences through our sampling criteria, symphyomyrtle trees with an animal observation were significantly taller ($P<0.001$) and had a larger DBH ($P<0.001$) than did neighboring trees in which we did not see an animal. Monocalypt neighbors also had a smaller DBH ($P<0.001$) compared to the adjacent monocalypts in which we observed *P. volans*.

We found a similar difference in average height and DBH among trees sampled from areas of the forest patches where we did not observe any *P. volans* and trees in which we saw an animal (Table 3). In addition, both monocalypt

Significance ($P \leq 0.05$) is indicated in bold. Variables include diam at breast height (DBH; cm), height (m), and foliar concentrations of nitrogen (N; % dry matter (DM)), available nitrogen (AvailN; % DM), digestible dry matter (DDM; $g.g^{-1}$ DM), and sideroxylonals (Total Sides; $mg.g^{-1}$ DM)

and symphyomyrtle trees from these two categories differed chemically. The GLMs that controlled for potentially confounding size variables showed that sideroxylonals (P=0.039) and DDM (P=0.016) explained a significant amount of the variation among symphyomyrtle tree populations from areas where *P. volans* was and was not observed (Table 4). Likewise, N (P=0.044), available N (P=0.007), and DDM (P=0.049) explained differences in tree use between these two tree categories for monocalypt trees.

Symphyomyrtle trees in which we observed *P. volans* feeding were taller (P<0.001) and had a larger DBH (P< 0.001) than neighboring trees with no animal observations (Table 3). Monocalypt trees from the same categories differed only in mean DBH (P=0.002). We found this same trend in height (P=0.054) and DBH (P=0.025) among symphyomyrtle trees sampled from areas where we did not observe *P. volans*, and among trees in which we observed *P. volans* feeding. Monocalypt trees from these categories had no significant difference in DBH (P=0.072). Allowing for tree size, GLMs showed that symphyomyrtle trees with feeding observations had lower concentrations of sideroxylonals (P=0.031) and DDM (P=0.016) than did trees from areas where *P. volans* was not observed (Table 4). Similarly, GLMs showed that monocalypt trees in which we observed *P. volans* feeding were likely to have more AvailN (P=0.033) and have a larger DBH (P=0.046) than trees sampled from areas where we did not see any animals. A monocalypt GLM that included N and DBH showed no significant values for either attribute (P=0.096 and P=0.071, respectively).

Symphyomyrtle trees in which we observed an animal feeding had lower concentrations of sideroxylonals (P= 0.022) than did trees in which we observed *P. volans* in a non-feeding activity only (Table 3). Monocalypt trees from these categories did not differ chemically.

Monocalypt trees in which we repeatedly observed *P. volans* feeding had less variable N concentrations (P= 0.041) than did trees in which we did not observe the animal. It appears that *P. volans* avoided feeding repeatedly from trees with N concentrations that reflected the lower range of measured N values—as found in the distribution of foliar N among all no observation trees (P=0.048) and no observation area trees (P=0.017).

Discussion

Tree Use and Foliar Chemistry The eucalypt trees in which we observed *P. volans* differed chemically from trees of the same species in nearby areas with no animal observations. In addition, symphyomyrtle trees in which animals fed differed chemically from the symphyomyrtle trees in which we observed *P. volans* engaged in a non-feeding activity only. Our findings refute the null hypothesis that there are no chemical differences among trees in which we observed *P. volans* and those in which we did not. The study demonstrates that intraspecific variations in sideroxylonals and DDM concentrations in the foliage of *E. viminalis* and *E. dalrympleana* and of N, AvailN, and DDM in *E. radiata*, play a role in tree use and hence habitat suitability for *P. volans*.

Subgenera Dependent Responses of P. volans to Foliar Chemistry The foliage of trees from the two major eucalypt subgenera pose different problems for foraging animals. The lower average concentrations of AvailN in the monocalypt, *E. radiata,* compared with the symphyomyrtles, *E. viminalis* and *E. dalrympleana,* may explain why this constituent had a significant positive relationship with *P. volans* tree use in the monocalypt species that was not seen in the other subgenus. Our data also suggest that *P. volans* may not forage repeatedly in *E. radiata* trees with concentration of foliar N below a particular threshold (around 1% dry matter). This finding is consistent with other research indicating that foliar N may be a limiting environmental factor for *P. volans* (Foley and Hume 1987; Kavanagh and Lambert 1990). In contrast, the concentration of sideroxylonals was more important than was any measure of N for influencing the use of *E. viminalis* and *E. dalrympleana*.

The concentration of DDM played opposing roles in explaining differences among tree categories for monocalypts and symphyomyrtles. This measure of forage digestibility is governed largely by a negative relation to concentrations of foliar lignin and phenols (e.g., tannins) (Choo et al. 1981). Presumably, the indigestible dry matter of monocalypts contains much of the foliar N bound by tannins and as a result, DDM had a stronger positive correlation to foliar concentrations of AvailN than N. This supports the pattern of tree use by *P. volans* when foraging in *E. radiata*; they should seek trees whose foliage contains lower concentrations of tannins and thus higher concentrations of available nitrogen.

In contrast, we observed a negative relationship between DDM and concentrations of both N and AvailN in the symphyomyrtle species. We also found a positive correlation between the concentrations of DDM and sideroxylonals. These correlations create a nutritional dilemma for animals eating those leaves because the most digestible components of the foliage contain the most sideroxylonal but the least N and AvailN, which may be bound to other non-digestible lignin compounds (Cork and Foley 1991; Dyckmans et al. 2002). We would not expect this strong negative relationship between DDM and N in immature leaves, which have a higher ratio of N to ligno-cellulose than do mature leaves (Kavanagh and Lambert 1990; Cork

and Foley 1991). The age variability of this ratio is greater for *E. viminalis* than for other species like *E. radiata* and, not surprisingly, some field studies have reported that *P. volans* will forage preferentially on young leaves, particularly from *E. viminalis* (Kavanagh and Lambert 1990). We propose that the opposing roles that DDM played in explaining *P. volans* tree use in the two subgenera results from the relationship between DDM and these other foliage constituents.

Relevance of Feeding Observations and Spatial Considerations for Determining Relationship between Foliar Chemistry and Tree Use Specific observations of feeding strengthened the negative relationship between the choice of feeding tree and the sideroxylonal concentration of foliage for *E. viminalis* and *E. dalrympleana*. Feeding-specific observations also were useful in identifying significant differences in the variance of N concentrations among tree categories for the monocalypt species. In most instances, however, feeding observations were not required to identify chemical differences among tree categories. This concurs with Moore and Foley (2005), who showed that we could learn much about the chemistry of trees that were preferred by *P. cinereus* from animal location data alone.

We found that the proximity of sampled trees to any tree in which *P. volans* was observed was important to identify a relationship between foliar chemistry and tree use. Most of the differences among trees in which we saw an animal and those in which we did not were apparent only when the "no observation trees" were more than 20 m from any tree with an observation. This suggests a spatial genetic effect similar to that shown for the concentration of PSMs in the foliage of *E. melliodora*, whereby individual trees within 20 m of each other tended to be more closely related and thus more similar chemically than more distant trees (Andrew et al. 2007).

Differences in the physical characteristics of the monocalypt and symphyomyrtle species that we examined may affect spatial distributions and influence their use by *P. volans*. Both *E. viminalis* and *E. dalrympleana* grow taller and wider leaving more space between mature trees than typically occurs for *E. radiata*. Consequently, there were fewer appropriate neighbor trees for the symphyomyrtles than for the monocalypts. In addition, symphyomyrtle trees in which we saw *P. volans* in activities other than feeding often were more than 20 m from any feeding-observation tree. These differing spatial relationships could explain why non-feeding and feeding tree categories differed only for the symphyomyrtles.

Foraging Niche of P. volans Herbivores that forage primarily from a single plant genus or family, such as *P. volans*, are often labeled as "specialists" (Lindenmayer 1997; Shipley et al. 2009). However, chemical and physical attributes that can vary substantially among plants within the same species and that may occur across plant taxa generally show a stronger association to herbivore dietary specialization than does plant taxonomy (Shipley et al. 2009). In hypothesizing about the foraging niche of marsupial eucalypt folivores, Moore et al. (2004) placed *P. volans* with *P. peregrinus*, a monocalypt and tannin specialist that also consumes non-eucalypt foliage. *Pseudocheirus peregrinus* is the smallest marsupial folivore and uses caecotrophy and a specialized caecum to free N from tannins in the gut (McArthur and Sanson 1991; Marsh et al. 2003a). Consequently, laboratory studies have found only a weak relationship between feeding choices and concentrations of tannins for this species (Marsh et al. 2003b). *Petauroides volans* also feeds on tannin-rich monocalypt species, and both species can survive on a diet of monocalypt foliage in captivity (Chilcott and Hume 1984; Foley and Hume 1987). We found, however, that the activity of tannins, as indicated by the concentration of AvailN in the leaves, strongly influenced its tree use. This suggests that *P. volans* is more sensitive to tannins and their influence on N availability than is *P. peregrinus*. If *P. volans* is not as efficient at liberating tannin bound N, then it may need to feed on the more AvailN-rich symphyomyrtle foliage, particularly when N requirements increase during pregnancy or lactation or in sites where low soil N is reflected in low foliar N. It is important to recognize that this hypothesis is based on the comparison of an *in vivo* laboratory study with a field study that relied on *in vitro* methodology and requires further laboratory investigations to verify.

Petauroides volans, like other eucalypt folivores, can consume foliage containing sideroxylonals, although it showed a strong preference for foliage with lower concentrations of these chemicals. In addition, both *E. viminalis* and *E. dalrympleana* contain low concentrations of sideroxylonals, compared with some symphyomyrtle species that other arboreal folivores eat that contain high levels of sideroxylonals but no other FPCs (e.g., *E. melliodora* and *E. polyanthemos*; Wallis et al. 2002). We would not expect *P. cinereus* or *T. vulpecula* to feed selectively when faced with the concentrations of sideroxylonals that influenced tree choice in *P. volans* (Lawler et al. 1998a; Wallis et al. 2002). Unlike *P. cinereus*, *P. volans* also showed a stronger response to the concentration of sideroxylonals than to total FPCs (Moore et al. 2005). Laboratory feeding studies are necessary to determine whether *P. volans* is less sensitive to other FPC derivatives, such as macrocarpals. In addition, research is necessary to determine how concentrations of PSMs and nutrients influence feeding behavior on immature leaves, since we conducted our analyses on mature leaf samples only. We do not know whether *P. volans*, like *P. cinereus* and *T. vulpecula*, can persist on a diet of

symphyomyrtle foliage alone (Moore et al. 2004); however, it appears that *P. volans* is very susceptible to the physiological effects of sideroxylonals while also lacking the adaptations of *P. peregrinus* to cope with high levels of tannins.

Studies of captive animals may show that the strategy of *P. volans* is intermediate between that of *P. peregrinus*, which specializes on foliage containing large concentrations of tannins, and that of *P. cinereus*, which specializes on foliage with significant concentrations of FPCs. In terms of PSM specialization, we propose that *P. volans* is more of a generalist than *P. peregrinus* or *P. cinereus*. A test of the detoxification limitation hypothesis (reviewed by Marsh et al. 2006) should reveal that *P. peregrinus* and *P. cinereus* have a higher rate of foliage consumption and detoxification of PSMs from their preferred subgenus than does *P. volans*. However, *P. volans* should be able to eat more when presented with foliage from preferred monocalypt and symphyomyrtle species simultaneously, each requiring different PSM detoxification pathways. In other words, *P. volans* will eat foliage from the symphyomyrtle species until the physiological effects of the FPCs force it to stop. Because monocalypts do not contain FPCs, *P. volans* can consume the foliage of *E. radiata* while detoxification processes remove the FPCs. It then can revert to eating symphyomyrtle foliage before ingesting debilitating amounts of tannins in the monocalypts (Marsh et al. 2006).

Petauroides volans may use this strategy to maintain its nutrient and energy requirements despite its small body size and poor-quality diet. Observations of free-living *P. volans* in our study area suggest that it may divide its feeding time between monocalypt and symphyomyrtle tree species (Cunningham et al. 2004). Energy and detoxification requirements, coupled with the general paucity of nutrients in eucalypt foliage, may have favored the development of a more energy efficient means of moving through the forest, namely gliding. This adaptation also would enable *P. volans* to take advantage of favorable variations in foliage chemistry as a result of leaf age and/or distribution of genetic variability in both major eucalypt subgenera at a minimal energy cost compared to other forms of movement (Jackson 2000).

Conservation Implications Factors that confine an animal's use of the landscape, such as a highly selective diet, make them particularly susceptible to landscape change. *Petauroides volans* and other herbivores that persist on nutritionally-poor foliage or foliage that contains high levels of certain PSMs may be vulnerable to environmental changes that could further reduce the nutritional quality or increase the toxicity of their forage (Lawler et al. 1997; Zvereva and Kozlov 2006). Higher levels of atmospheric CO_2 have been shown to increase the production of tannins and reduce the concentration of N in plant tissues (Lawler et al. 1997; Gleadow et al. 1998; Mansfield et al. 1999). Thus, some plants grown under elevated CO_2 have reduced herbivore damage (Knepp et al. 2005). The potential effects of climate change on nutrient availability and plant toxicity need study (Lindroth 2010; Pinto et al. 2010).

We recommend that land managers give preference to conserving tracts of eucalypt forest where marsupial folivores occur. Areas where animals are not sighted may not have the same capacity to support them for several reasons, including inadequate forage quality. The ability to accurately measure variation in plant nutrients and PSMs on a landscape scale could become an important conservation tool. Large-scale mapping of foliage chemistry could help to identify areas that are suitable or unsuitable habitat for certain animals and to monitor changes to the chemical quality of landscapes that could influence their ability to support some species.

Acknowledgements The authors thank Dr. Karen Marsh for assistance with the field and laboratory components of this research. We also thank Nicole Coggan, Sarah Ugalde, Jeff Whiting, and Stewart Archer for help in the field. Two reviewers provided constructive comments that improved our original manuscript. This research was made possible by the support of The Hermon Slade Foundation, The Wilderness Society, Ecological Society of Australia, The Fenner School of Environment and Society and Botany and Zoology in the Research School of Biology at Australian National University. This research was conducted with the permission of State Forests New South Wales (permit CO32438) and National Parks (permit S12036). This project was approved by the Animal Experimentation Ethics Committee at Australian National University (project number C.RE.47.06).

Abstract The chrysomelid beetle *Phyllotreta striolata* is an important pest of Brassicaceae in Southeast Asia and North America. Here, we identified the aggregation pheromone of a population of *P. striolata* from Taiwan, and host plant volatiles that interact with the pheromone. Volatiles emitted by feeding male *P. striolata* attracted males and females in the field. Headspace volatile analyses revealed that six sesquiterpenes were emitted specifically by feeding males. Only one of these, however, elicited an electrophysiological response from antennae of both sexes. A number of host plant volatiles, e.g., 1-hexanol, (*Z*)-3-hexen-1-ol, and the glucosinolate hydrolysis products allyl isothiocyanate (AITC), 3-butenyl isothiocyanate, and 4-pentenyl isothiocyanate also elicited clear responses from the antenna. The active male-specific compound was identified as (+)-(6*R*,7*S*)-himachala-9,11-diene by chiral stationary phase gas-chromatography with coupled mass spectrometry, and by comparison with reference samples from *Abies nordmanniana*, which is known to produce the corresponding enantiomer. The pheromone compound was synthesized starting from (–)-α-himachalene isolated from *Cedrus atlantica*. Under field conditions, the activity of the synthetic pheromone required concomitant presence of the host plant volatile allyl isothiocyanate. However, both synthetic (+)-(6*R*,7*S*)-himachala-9,11-diene alone and in combination with AITC were attractive in a two-choice laboratory assay devoid of other natural olfactory stimuli. We hypothesize that *P. striolata* adults respond to the pheromone only if

specific host volatiles are present. In the same laboratory set up, more beetles were attracted by feeding males than by the synthetic stimuli. Thus, further research will be necessary to reveal the components of a more complex blend of host or male-produced semiochemicals that might enhance trap attractiveness in the field.

Introduction

Flea beetles (Alticinae) of the genus *Phyllotreta* (Chevrolat) (Coleoptera: Chrysomelidae) are specialized herbivores on the Brassicaceae and related plant families. *Phyllotreta striolata* (Fabricius) is a pest of economically important *Brassica* crops (Lamb, 1989) and widely distributed in North America, Europe, and Asia. In Southeast Asia, it is the dominant *Phyllotreta* species (Parker et al., 1995; Mohamedsaid, 2004) with up to eleven generations per year (Chen et al., 1991). The adults feed mainly on host plant leaves, and females oviposit at the plant–soil interface. The larvae feed on root hairs of host plants, and pupate in the soil (Feeny et al., 1970; Burgess, 1977).

Glucosinolates are characteristic secondary metabolites in the Brassicaceae (Fahey et al., 2001), and the role of the glucosinolate–myrosinase system in host plant location and acceptance of *Phyllotreta* sp. has been studied intensively in the past (Nielsen, 1988; Mitchell, 1994; Nielsen et al., 2001). Upon feeding, glucosinolates are hydrolyzed by the plant enzyme myrosinase, producing a blend of volatile and non-volatile hydrolysis products that represent potential host-finding cues for specialists such as *P. striolata* (Renwick, 2002). Field trapping experiments have shown that only a few volatile glucosinolate hydrolysis products are attractive for adult flea beetles (Görnitz, 1956; Feeny et al., 1970; Pivnick et al., 1992; Csonka et al., 2007). The hydrolysis product of allyl glucosinolate, allyl isothiocyanate (AITC), is a plant-derived attractant for several *Phyllotreta* species in the field, including *P. striolata* (Pivnick et al., 1992; Tóth et al., 2007). However, in order to catch high numbers of flea beetles, an evaporation rate of 4 mg AITC per day per trap, corresponding to the release from 2,000 freshly damaged plants or 270,000 intact plants of *Brassica juncea* (L.) in the flower bud stage, is necessary (Pivnick and Jarvis, 1991; Pivnick et al., 1992). It is, therefore, unlikely that AITC is a key stimulus used for host plant location by *Phyllotreta* sp. on its own. Recently, several host plant volatiles, e.g., 1-hexanol, 1-pentanol, and (*Z*)-3-hexen-1-ol, were shown to be more attractive than AITC for the congeneric species *Phyllotreta cruciferae* (Goeze) in olfactometer bioassays (Gruber et al., 2009).

Male-produced aggregation pheromones have been described for several chrysomelid subfamilies, e.g., Alticinae, Chrysomelinae, Criocerinae, and Galerucinae. In most cases, however, the synthetic pheromone compounds alone are only weakly attractive (Cossé et al., 2002; Dickens et al., 2002; Rao et al., 2003; Soroka et al., 2005; Tóth et al., 2005; Bartelt et al., 2006; Zilkowski et al., 2006). Peng and Weiss (1992) first provided evidence for a male-produced aggregation pheromone in *P. cruciferae,* and subsequently six male-specific sesquiterpenes were identified, four of which have been synthesized (Bartelt et al., 2001, 2003; Muto et al., 2004). In field trapping experiments, the synthetic compounds alone were not or only slightly attractive. The sesquiterpene (+)-(6*R*,7*S*)-himachala-9,11-diene was identified as the only behaviorally active compound of *P. cruciferae* (Tóth et al., 2005).

Host plant volatiles are known to affect the response to pheromones of phytophagous insects (Landolt and Phillips, 1997; Reddy and Guerrero, 2004; Seybold et al., 2006). For example, the leaf beetle, *Diorhabda elongata* (Brullé), is attracted to green leaf volatiles emitted from its host plant salt cedar, *Tamarix* spp., and these compounds interact synergistically with the male-produced aggregation pheromones of this species (Cossé et al., 2006). Similarly, Colorado potato beetles, *Leptinotarsa decemlineata* (Say), in y-tube experiments prefer a combination of the aggregation pheromone with host plant volatiles over the aggregation pheromone alone (Dickens, 2006). Also, in *P. cruciferae*, the aggregation pheromone enhances the attractiveness of the host plant volatile AITC synergistically (Soroka et al., 2005; Tóth et al., 2005).

The objective of this study was to identify the aggregation pheromone of the Taiwanese population of *P. striolata*, and, by using both plants and synthetic compounds, to study how host plant volatiles interact with the pheromone.

Methods and Materials

Insects Adult *Phyllotreta striolata* were collected from fields with crucifer crops at AVRDC-The World Vegetable Center in Shanhua, Taiwan, and maintained in cages with potted *Brassica juncea* cv. Bau-Sin plants. Eggs were collected by washing the leaves. They were subsequently transferred to pots with *Brassica rapa* var. *chinensis* cv. Ching-Chiang plants. After 2 wk, plants were cut, and pots were covered with fine mesh until adults emerged. Adults used in laboratory experiments were shipped to the Max Planck

Institute for Chemical Ecology, Jena, Germany,[1] where they were maintained on savoy cabbage, *B. oleracea* var. *sabauda* in an environmental chamber at 25°C, 75% humidity, and L12:D12 until use. The sex of *P. striolata* adults was determined based on the sexual dimorphism of the antennae. The fifth antennomer is enlarged in males, whereas it is about the same diameter as the other antennal segments in females (Heikertinger, 1941).

Plants Seeds of *B. juncea* cv. Bau Sin and *B. rapa* var. *chinensis* cv. Ching-Chiang were purchased from Known-You Seed Co. LTD, Taiwan. Savoy cabbage, *B. oleracea* var. *sabauda*, was purchased at a local grocery store. *Abies nordmanniana* twigs were obtained from the botanical garden in Jena, Germany.

Volatile Collections Headspace collections were carried out in a closed loop system operated by a rotary vane vacuum and pressure pump (model G12/01 EB, Gardner Denver, Inc., Puchheim, Germany), equipped with stainless steel adapters (IQSG-M54 Jenpneumatik, Jena, Germany), creating an airflow of 0.5 l/min though the system. All tubings was made of Teflon (OD 4 mm). Samples were placed in a silanized 50 ml flask closed with a custom made polyether ether ketone (PEEK) stopper. The incoming air stream was purified on an activated charcoal filter before entering the flask though a stainless steel exhaust silencer (SSD50, Jenpneumatik, Jena, Germany). Volatiles were trapped on an activated charcoal filter (1.5 mg CLSA filter, Gränicher & Quartero, Daumazan sur Arize, France) attached to the stopper with a custom made PEEK adapter. Volatiles emitted from 30 male or female *P. striolata* feeding on one cut *B. juncea* cv. Bau Sin leaf were collected for 12 or 24 hr in the laboratory. Beetles and foliage were changed for each volatile collection. Headspace volatiles from cut *A. nordmanniana* needles were collected for 24 hr. Filters were eluted with 30 µl hexane containing 10 ng/µl bromodecane (Sigma-Aldrich) as an internal standard. Between volatile collections all parts were cleaned. Glassware, teflon, and PEEK were heated at 230°C for 2 hr; adapters with plastic and rubber parts were heated at 90°C for 2 hr in a drying oven.

Gas Chromatography-Mass Spectrometry (GC-MS) Volatile samples were analyzed by coupled gas chromatography-mass spectrometry by using an Agilent 6890 N gas chromatograph (GC) equipped with an HP-5MS capillary column (30 m×0.25 mm ID with 0.25 µm film thickness) and coupled to a quadrupole mass spectrometer Agilent 5975B. The carrier gas was helium at a constant flow rate (1.1 ml/min). Injection temperature was 250°C. The oven program started at 40°C for 3 min and increased at 10°C/min to 280°C. One µl of each sample was injected in splitless mode. MS conditions were electron impact mode (70 eV), and scan mode 33–350 amu. Bartelt et al. (2001) reported that several flea beetle compounds decompose at high injector temperatures (250°C). Thus several samples also were analyzed with the injector temperature set to 200°C without finding any impact of the lowered injector temperature on the composition of the samples. Compounds were identified by comparison of mass spectra to the NIST (National Institute of Standards, USA) mass spectral library and confirmed by using authentic reference substances purchased from commercial sources, unless otherwise stated. The sesquiterpene content was calculated as TIC peak area relative to the internal standard bromodecane. The configuration of chiral compounds was ascertained via GC with a chiral stationary phase (Cyclosil-B column, 30 m×0.25 mm ID with 0.25 µm film thickness, Agilent) and comparison of mass spectra and retention times to samples of known chemical composition. The oven program was 60°C for 1 min and increased at 1°C/min (chiral analysis of compound A) or 3°C/min (compounds B and D) to 160°C and at 30°C/min to 200°C held for 2 min. The carrier gas was helium at a constant flow rate (1.1 ml/min). MS parameters were as stated above.

Electrophysiology Physiologically active volatiles from male *P. striolata* feeding on host plant leaves were identified by gas chromatography coupled with electroantennographic detection (GC-EAD). Volatile collections were separated on an Agilent 6890 N GC equipped with an HP-5MS capillary column (30 m×0.32 mm ID with 0.25 µm film thickness, Agilent). The carrier gas was helium with a constant flow rate (2 ml/min). The oven program started at 40°C for 3 min and increased at 20°C/min to 280°C. The GC effluent was split 1:1 at a Graphpack 3D/2 cross piece (Gerstel, Mülheim, Germany) to a flame ionization detector (FID) and an electroantennographic detector with He (40 kPa) added as make up gas. GC effluents were carried at 280°C though a flexible transfer line (ODP3, Gerstel) to the electroantennographic detector. A permanent flow of 0.5 l/min clean moistened air was added to the GC effluents within the ODP head. A PEEK outlet (ID 7 mm) carried this air stream to the antennal preparation. Pasteur pipettes loaded with 100 ng AITC in 10 µl hexane or 10 µl pure hexane on filter paper served to deliver reference stimulus pulses before and after each GC-EAD run though a hole in the PEEK outlet (ID 2 mm). Pulses had 0.5 s duration at a flow rate of 0.8 l/min. Airflow and pulses were controlled by a CS-55 stimulus controller (Syntech, Hinterzarten, Germany). Antennal responses were recorded from beetles restrained in a cut pipette tip with one antenna immobilized. Connections to

[1] Import authorization obtained under Dir 2008/61/EC

the recording unit were established with the antennal tip inserted into an Ag/AgCl glass capillary electrode filled with Ringer solution (Kaissling, 1971). The reference electrode was inserted into an eye. EAD responses were amplified 10× by using a Universal AC/DC Probe connected to an IDAC 4 signal converter (Syntech, Hinterzarten, Germany). GC-EAD runs were recorded on a standard PC with Syntech GC-EAD Software. Volatile collections from feeding male *P. striolata* were analyzed by using antennae from at least five females and males, respectively.

Retention time indices (Van Den Dool and Kratz, 1963) were calculated based on injections of C7-C26 alkanes to identify GC peaks across instrumental conditions. Physiological responses of putatively identified compounds were ascertained by using authentic reference compounds as indicated.

Synthesis of (+)-(6R,7S)-himachala-9,11-diene The putative aggregation pheromone was prepared in the steps from (–)-α-himachalene (**1**) (Fig. 1). In the first step, the exocyclic double bond of (–)-α-himachalene was catalytically hydrogenated to yield a mixture of diastereomeric products. In the second step, the remaining double bond was brominated, and finally, elimination of two molecules of hydrogen bromide yielded the target compound (**4**) and byproducts. Nuclear magnetic resonance (NMR) spectra

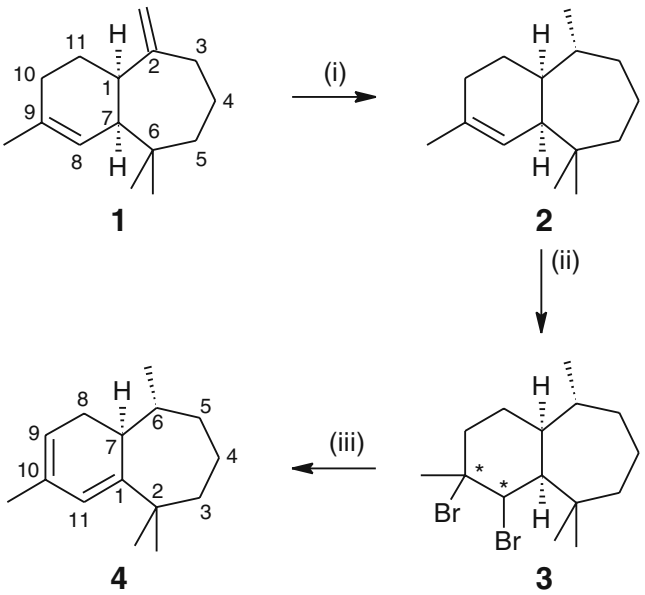

Fig. 1 Preparation of (+)-(6*R*,7*S*)-himachala-9,11-diene (**4**) from (–)-α-himachalene (**1**) (1*R*,7*S*). Conditions: (i) hydrogen (g), platinum(iv) oxide, ethanol, room temperature, only the (1*S*,2*R*)-isomer is shown. (ii) bromine, chloroform, 0–5°C, 2 h. Only the (1*S*,2*R*)-isomers are shown. The configuration at C-8 and C-9 is not known. (iii) DBU, THF, room temperature. Only the desired stereoisomer (6*R*,7*S*) is shown. IUPAC numbering is used

were recorded on a Bruker Avance DRX 500 NMR spectrometer. The spectra are referenced to the residual solvent signal. Thin-layer chromatography (TLC) was carried out on 4×8 cm silica-coated glass plates. Compounds were detected by cerium ammonium nitrate staining. Mass spectra were measured on a ThermoQuest Trace GC 2000 Series–ThermoQuest MS dyad (CE Instruments, Austin, TX, USA) using a ZB-5 column (15 m with 10 m pre-column×0.25 mm ID with 0.25 μm film thickness, Phenomenex, Aschaffenburg, Germany). The carrier gas was helium with a constant flow rate (1.5 ml/min). The oven program started at 50°C for 1 min and increased at 15°C/min to 300°C. Injection temperature was 280°C. MS condition was electron impact mode (70 eV). High resolution mass spectra were measured on a MasSpec (Micromass, UK) coupled with an HP 6890 GC (Agilent) using a ZB-5MS column (30 m×0.25 mm ID with 0.25 μm film thickness, Phenomenex). The carrier gas was helium at a constant flow rate (1 ml/min). Injection temperature was 220°C. MS condition was electron impact mode (70 eV).

The starting compound (–)-α-himachalene and the reference compound (+)-β-himachalene were distilled from *Cedrus atlantica* essential oil under reduced pressure (2.5 mbar) though a 170 cm column filled with Sulzer DX packing (Sulzer Chemtech AG, Switzerland). Both (–)-α-himachalene and (+)-β-himachalene were obtained with a purity each of 97.5%. Relative stereochemistry of both sesquiterpenes was ascertained with NMR (Joseph and Dev, 1968; Sano and Mori, 1999).

(–)-α-himachalene (αD20=–181, neat, 1 dm):

^{1}H NMR (400 MHz, $CDCl_3$): δ 0.96 (s, 3 H), 1.00 (s, 3 H), 1.11–1.18 (m, 1 H), 1.24–1.37 (m, 1 H), 1.54–1.65 (m, 2 H), 1.67 (s, 3 H), 1.72–1.95 (m, 4 H), 2.04 (t, J=12.3 Hz, 1 H), 2.10–2.21 (m, 2 H), 2.80–2.84 (m, 1 H), 4.72 (s, 1 H), 4.76 (s, 1 H), 5.48 (s, 1 H).

MS (EI): 204 (17), 189 (36), 161 (27), 119 (61), 105 (64), 94 (64), 93 (88), 91 (85), 79 (82), 41 (100).

(+)-β-himachalene (αD20=239, neat, 1 dm):

^{1}H NMR (400 MHz, $CDCl_3$): δ 0.73 (s, 3 H), 0.97 (s, 3 H), 1.35–1.58 (m, 4 H), 1.71 (s, 3 H), 1.74 (s, 3 H), 1.83–1.99 (m, 4 H), 2.40–2.49 (m, 1 H), 2.57–2.66 (m, 1 H), 2.89 (s, 1 H), 5.41 (s, 1 H).

MS (EI): 204 (30), 134 (32), 121 (33), 119 (100), 105 (47), 93 (39), 91 (60), 41 (55).

2,6,6,9-Tetramethylbicyclo[5.4.0]undec-8-ene (Fig. 1, **2**): (–)-α-Himachalene (1.039 g, 5.08 mmol) was dissolved in 60 ml ethanol and hydrogenated at room temperature in the presence of platinum(iv) oxide (497 mg). Hydrogen consumption was measured by using a mercury gas burette, and stalled at 1.3 eq. after 30 min stirring. The reaction was monitored by TLC. The reaction mixture was filtered through an analytical filter paper, the flask and the filter

were rinsed with ethanol, and the filtrate was evaporated *in vacuo* to obtain the product as colorless oil. Yield 1.049 g (100%), diastereomeric ratio 2*R*:2*S*≈9:1 (calculated from the integral values of the ^{1}H NMR signals of H-8).

Major 2*R* diastereomer: ^{1}H NMR ($CDCl_3$) δ=0.90 (s, 3 H, Me-6), 0.94 (d, ^3J=6.4 Hz, 3 H, Me-2), 0.96 (s, 3 H, Me-6), 1.18–2.14 (m, 13 H, H-1–7,10–11), 5.45 (m, 1 H, H-8).

Minor 2*S* diastereomer: ^{1}H NMR ($CDCl_3$) δ=0.90 (s, 3 H, Me-6), 0.92 (d, $^3J_{2,2a}$=7.1 Hz, 3 H, Me-2), 0.96 (s, 3 H, Me-6), 1.18–2.14 (m, 13 H, H-1–7,10–11), 5.52 ppm (m, 1 H, H-8).

Mixture of diastereomers: ^{1}H NMR (benzene-d_6) δ=0.95 (d, $^3J_{2,2a}$=6.6 Hz, 3 H, Me-2), 0.97 (s, 3 H, Me-6), 1.00 (s, 3 H, Me-6), 1.25 (m, 1 H), 1.30–2.00 (m, 14 H), 2.11 (m, 1 H), 5.56 (s, 1 H, H-8), 5.62 ppm (s, 0.17 H, H-8).

GC retention time of the major 2*R* diastereomer: 8.16 min; MS (EI): 206.1 (63, $M^{+\bullet}$), 163.0 (23), 150.0 (9), 134.9 (29), 120.9 (100); retention time of the minor 2*S* diastereomer: 8.25 min, *m/z*=206.0 (82%, $M^{+\bullet}$), 162.9 (24%), 150.0 (11%), 135.0 (30%), 120.6 (80%), 108.9 (61%), 92.9 (100%). R_f : 0.79 (*n*-pentane).

8,9-Dibromo-2,6,6,9-tetramethylbicyclo[5.4.0]undec-8-ene (Fig. 1, **3**): Bromination of **2** was carried out analogously to the procedure of Hofmann et al. (1994). Thus, the starting olefin (2.81 g, 13.6 mmol, 1 eq.) was dissolved in chloroform (50 ml), and the solution was cooled to 0–5°C. A solution of bromine (2.36 g, 14.8 mmol, 1.09 eq.) in chloroform (50 ml) was added dropwise over the period of 27 min, and the reaction mixture was stirred at 0–5°C for 2 h. The reaction mixture was evaporated *in vacuo* and the residue was dried. The crude product was used directly in the next step without further purification.

2,2,6,10-Tetramethylbicyclo[5.4.0]undeca-1(11),9-diene [(+)-(6R,7S)-himachala-9,11-diene] (Fig. 1, **4**): The reaction was carried out analogously to the procedure of Van Epp et al. (1981). Thus, the dibromide (1.094 g, 2.99 mmol, 1 eq.) was dissolved in dry tetrahydrofuran (THF, 1 ml) and a solution of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU, 929 mg, 6.10 mmol, 2.04 eq.) in dry THF (25 ml) was added. The reaction mixture was stirred for 2 hr at room temperature and was partitioned between dichloromethane (25 ml) and water (25 ml). The organic phase was separated and evaporated *in vacuo* and the product mixture was quickly dried. The product mixture was analyzed by GC-MS. The position of the double bonds was proven by a reaction with 4-phenyl-1,2,4-tetrazoline-3,5-dione.

The synthetic product contained the physiologically active (+)-(6*R*,7*S*)-himachala-9,11-diene (4%), *ar*-himachalene (5%), which is also emitted from feeding *P. striolata* males, and several other by-products that were not characterized. *ar*-Himachalene apparently is formed by aromatization of the six-membered ring during the didehydrobromination. Field tests in Taiwan (see section below) were performed with the raw product of the synthesis. For laboratory bioassays, (+)-(6*R*,7*S*)-himachala-9,11-diene was isolated by preparative gas chromatography with an Agilent 7890A GC instrument equipped with an HP5 capillary column (30 m×0.53 mm ID with 1.5 μm film thickness, Agilent) connected to a preparative fraction collector with a cryostatic trap cooler (PFC, Gerstel). The oven program was 40°C for 1 min, increased at 20°C/min to 120°C, then with 10°C/min to 210°C, and finally with 30°C/min to 300°C. The carrier gas was helium with a constant flow rate (4.8 ml/min). The obtained (+)-(6*R*,7*S*)-himachala-9,11-diene had a purity of 95% calculated from peak area of a GC-MS TIC. It was diluted in hexane to a concentration of 1 μg/μl for laboratory bioassays. (MS (EI+): 204.2 (30, $M^{+\bullet}$), 161.1 (24), 133.1 (100), 119.1 (78), 105.1 (72), 93.0 (28), 91.0 (39), 69.0 (18), 55.0 (21), 41.0 (29), GC-HRMS (EI) [M^+] ($C_{15}H_{24}$) calculated: 204.187801; found: 204.187019). (6*R*,7*S*)-Himachala-9,11-diene was characterized previously (incl. NMR and optical properties) by Muto et al. (2004).

Field Bioassays During Spring 2010, field bioassays were conducted at the experimental farm of AVRDC-The World Vegetable Center in Taiwan. Traps modified from Peng and Weiss (1992) served to assess the attractiveness of volatiles emitted by the host plant *B. juncea* and by *P. striolata* adults. *Brassica juncea* seedlings were grown to the second extended leaf in 11 cm diam plastic pots half filled with growing substrate (Blumenerdewerk Stender GmbH, Germany). Pots were covered with fine mesh, wrapped in a plastic bag and placed in a glass petri dish with a diameter of 15 cm and a height of 2 cm filled with soapy water. Beetles trapped in the soapy water were collected after 24 hr, counted, and sexed by inspection of the antenna and genitalia. Traps were arranged in a harvested crucifer field, which was previously infested with *P.striolata*, in a randomized complete block design with 15 replicates per experiment. The distance between traps in the block was 5 m, and blocks were 6 m apart.

Experiment 1 (February 23–25, 2010) The attractiveness of volatiles emitted from (a) intact *B. juncea* seedlings; (b) seedlings previously feeding-damaged by 20 *P. striolata* males; (c) seedlings previously feeding-damaged by 20 *P. striolata* females; (d) seedlings with 20 actively feeding females; and (e) seedlings with 20 actively feeding males, was assessed. Prior to the experiment, beetles were allowed to feed for 24 hr on the host plants in treatments (b) and (c). They were removed immediately before the experiment started.

Experiment 2 (February 25–27, 2010) The attractiveness of (a) moistened soil; (b) 20 males on moistened soil; (c) intact

seedlings with 20 males in a separate screened plastic vial with moistened tissue; was compared with (d) feeding-damaged seedlings (from 20 males for 24 hr) also separated from 20 males as in treatment (c); and (e) 20 actively feeding *P.striolata* males.

A field trapping experiment was conducted at the experimental farm of AVRDC-The World Vegetable Center from March 5 to 8 2010 to test the attractiveness of synthetic (+)-(6*R*,7*S*)-himachala-9,11-diene and AITC. Natural rubber septa (10×20 mm, Wheaton, Millville, NJ, USA) were used as pheromone dispensers. They were cleaned by sonification for 4 hr in dichloromethane and air-dried in a fume hood before use. The synthesis product containing (+)-(6*R*,7*S*)-himachala-9,11-diene was diluted in hexane to a concentration of about 5 μg/μl of the putative pheromone. A total of 250 μg (+)-(6*R*,7*S*)-himachala-9,11-diene was loaded onto each test septum. Control septa were treated with the same amount of hexane. The emission rate from pheromone septa was not tested. Soroka et al. (2005) determined the mean emission rate of (+)-(6*R*,7*S*)-himachala-9,11-diene from rubber septa loaded with 250 μg to be 11.8 μg/d in the laboratory at 27°C. Pure AITC (94% purity, Acros Organics) at a dose of 40 mg was applied in 0.5 ml PE tubes. Empty tubes served as control. Septa and opened PE tubes were placed close to each other in the center of sticky traps (20×25 cm sticky area, Jackson Traps, Jhen Yong Company, Taiwan). Traps were placed in a Chinese cabbage field with 1 m distance to infested host plants and arranged in a randomized complete block design with 10 replicates. The distance between traps in one block was 4 m and at least 6 m between blocks. Trap catches were evaluated once at the end of the experiment.

Experiment 3 Traps without bait were used as (a) control and compared to sticky traps baited with (b) 40 mg AITC; (c) 250 μg (+)-(6*R*,7*S*)-himachala-9,11-diene; and (d) 40 mg AITC combined with 250 μg of (+)-(6*R*,7*S*)-himachala-9,11-diene.

Two-Choice Bioassay Behavioral responses of *P. striolata* adults to natural and synthetic odors also were analyzed in a two-choice bioassay. Two traps were placed in a plastic container (295×230×185 mm). A wide hole was cut into the lid of the container and closed with fine mesh for air supply. Traps were transparent plastic tubes (height 10 cm, ID 4.5 cm) containing the test odor, and closed with a foam rubber plug. The plug was perforated in the center with a cut 1 ml pipette tip as entrance. The distance between traps was 10 cm, and positions were changed between replicates. Fifty starved *P. striolata* unsexed adults were placed inside the container and kept in an environmental chamber at 24°C with 65% humidity and L12:D12. The number of beetles that had entered each trap was counted after 24 hr.

Experiment 4 The bioassay set up was tested with the natural odor blend from (I) 25 male *P. striolata* feeding on a cut *B. rapa* var. *chinensis* leaf vs. an empty control, and (II) 25 male *P. striolata* vs. 25 female *P. striolata* both provided with a cut *B. rapa* var. *chinensis* leaf to feed on. Beetles and foliage representing the odor source were caged in transparent plastic tubes (height 5 cm, ID 3.3 cm) closed with a fine mesh within the traps.

Experiment 5 The attractiveness of (I) purified synthetic (+)-(6*R*,7*S*)-himachala-9,11-diene was tested by applying 5 μg of the compound on a piece of filter paper in test traps and the equivalent amount of pure hexane in control traps, and (II) 5 μg (+)-(6*R*,7*S*)-himachala-9,11-diene combined with 100 μg AITC was compared to the attractiveness of 100 μg AITC. Each treatment combination was replicated 10 times in Experiment 4, and 12 times in Experiment 5.

Statistics Statistical analyses were conducted with the software SAS Version 9.1 (SAS Institute 2001). Field data were log(x+1)-transformed and analyzed by analysis of variance (ANOVA) and *post-hoc* Tukey's HSD test. Data from the two-choice bioassays was analyzed by Wilcoxon signed rank test.

Results

Identification of Male-specific Compounds Volatile collections from male and female *P. striolata* feeding on cut *B. juncea* leaves were compared, and six male-specific sesquiterpenes A–F were identified. Compounds A, C, E, and F dominated the blend, (Table 1, Fig. 2a). The blend ratio was comparable between volatile collections and the mean total amount of detected sesquiterpenes was 18.4± 4.4 ng/male/d. Compound A was the most abundant in the blend (about 30%), and it was the only male-specific sesquiterpene eliciting an antennal response in females and males (Fig. 2b). It was identified as himachala-9,11-diene based on its mass spectrum (Bartelt et al., 2001). Muto et al. (2004) clarified the absolute configuration of several flea beetle derived sesquiterpenes by enantioselective synthesis and assigned the (+)-(6*R*,7*S*)-configuration to himachala-9,11-diene emitted by *P. cruciferae* and *Aphthona flava* (Guillebeau). This was shown to be the opposite configuration of the enantiomer (–)-(6*S*,7*R*)-himachala-9,11-diene present in *A. nordmanniana* (Bartelt et al., 2001). In our experiments, the himachala-9,11-dienes from *P. striolata* males and *A. nordmanniana* had the same retention time on an HP-5 column (Fig. 3c). However, himachala-9,11-dienes from both sources were separated by a retention time difference of 0.25 min by chiral stationary phase GC. Male

E γ-Cadinene	1534	21.4±2.1	Bartelt et al.	
F (*R*)-*ar*-Himachalene	1559	15.9±5.3	Bartelt et al.	chiral stationary phase GC, *A. nordmanniana* (see above)

[a] Relative abundance of the single compounds in the blend is given in percent of the total male-specific sesquiterpene blend

Means were calculated from 10 volatile collections

[b] National Institute of Standards (NIST) mass spectral library

[c] Mass spectrum and retention time of authentic reference compound

[d] Mass spectrum published by Bartelt et al. (2001)

P. striolata, therefore, emit the (+)-(6*R*,7*S*)-himachala-9,11-diene enantiomer (Fig. 3a, b). The minor compound B was identified as α-himachalene based on its mass spectrum and retention time on the HP-5 column by comparison with the authentic reference compound (–)-α-himachalene isolated from *C. atlantica*. When analyzed on the chiral GC column, the retention time of the putative α-himachalene from *P. striolata* differed from the (–)-α-himachalene standard. The liverwort *Scapania undulata* (L.) is known to contain (+)-α-himachalene (Andersen et al., 1977), and a sample of *S. undulata* extract (donated by S. Garms; Dept. of Bioorganic Chemistry; MPI CE Jena) was compared with the male-specific sesquiterpenes. By comparison of retention times using a chiral GC column, compound B was identified as (+)-α-himachalene. The mass spectrum of compound C is similar to the mass spectrum of α-himachalene. However, the delayed retention time suggests that this compound is *trans*-α-himachalene, as previously described for *P. cruciferae*, and *Aphthona* spp. (Bartelt et al., 2001). Compound D was identified as β-himachalene by comparison with β-himachalene distilled from *C. atlantica* samples using standard and chiral stationary phase GC. Compounds E and F were identified as γ-cadinene and *ar*-himachalene, respectively, by comparison of their mass spectra with published mass spectra (Bartelt et al., 2001). γ-Cadinene and *ar*-himachalene also were found in headspace volatiles from *A. nordmanniana*. γ-Cadinene from the beetle and Nordmann fir did not separate on standard and chiral GC columns, suggesting that γ-cadinene from both sources have the same stereochemistry. *ar*-Himachalene from *P. striolata* and *A. nordmanniana* co-eluted on the non-polar column, but could be separated with chiral stationary phase GC by 1.4 min, and are therefore enantiomers. Enantioselective synthesis has clarified the absolute configuration of the leaf beetle-produced *ar*-himachalene to be (*R*) (Muto et al., 2004), while *ar*-himachalene isolated from different Abietoideae species has been determined to be (*S*) (Pandy and Dev, 1968; Muto et al., 2004). Previously, *ar*-himachalene

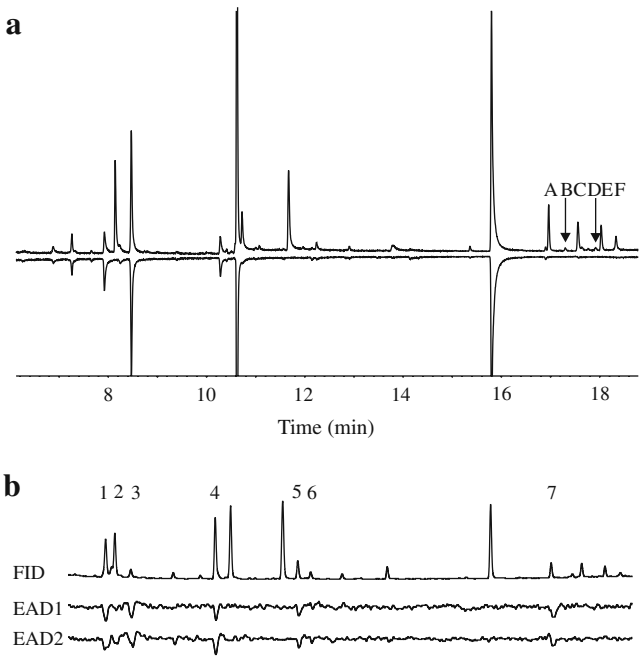

Fig. 2 Identification of male specific compounds and antennal responses to male and host plant volatiles: **a** Comparison of chromatograms (GC-MS) from male (*top*) and female (*inverted*) *Phyllotreta striolata* feeding for 12 hr on one cut *Brassica juncea* leaf. The sesquiterpenes A to F were not detectable in collections from females. **b** EAD responses of two male antennae. Seven compounds are physiologically active with compound 7 corresponding to the male-specific sesquiterpene A (Fig. 2**a**). The other compounds are the host plant volatiles (1) (*Z*)-3-hexen-1-ol, (2) 1-hexanol, (3) allyl isothiocyanate, (4) 3-butenyl isothiocyanate, (5) 4-pentenyl isothiocyanate, and (6) nonanal

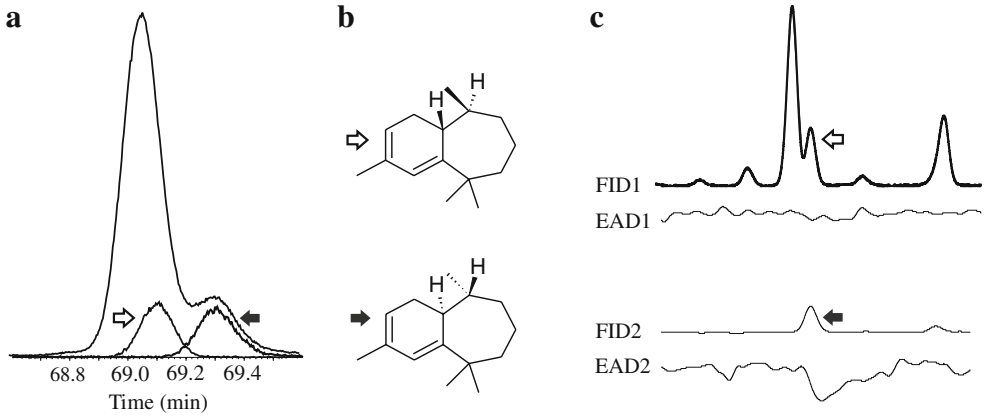

Fig. 3 Determination of the absolute configuration of himachala-9,11-diene emitted from male *Phyllotreta striolata*. **a** Overlay of gas chromatograms measured with a chiral column of (i) a co-injection of headspace samples from *Abies nordmanniana* and feeding male *P. striolata* (ii) headspace from *A. nordmanniana* (*white arrow*), (iii) headspace from feeding male *P. striolata* (*black arrow*). **b** white arrow: (–)-(6*S*,7*R*)-himachala-9,11-diene from *A. nordmanniana*, black arrow: (+)-(6*R*,7*S*)- himachala-9,11-diene from male *P. striolata*. **c** GC-EAD responses (HP-5 column) of female *P. striolata* antennae to headspace from *A. nordmanniana* (traces 1) and headspace from feeding male *P. striolata* (traces 2). The enantiomer present in the beetle extracts (*black arrow*) elicits an antennal response, while the one in *A. nordmanniana* headspace (*white arrow*) does not. The himachala-9,11-diene peak is preceded by ß-caryophyllene in the *A. nordmanniana* headspace extract

from both sources was considered to have the same configuration since both were reported to have a positive rotation (Pandy and Dev, 1968; Bartelt et al., 2001). However, Mori (2005) demonstrated that the optical rotation of (*R*)-ar-himachalene depends on the solvent in which it is measured. It is dextrorotatory in hexane, but levorotatory in chloroform, which led to the initial confusion.

Electrophysiology In GC-EAD experiments, the antennal responses of male and female *P. striolata* to host plant volatiles and male specific sesquiterpenes present in volatile collections from feeding *P. striolata* males were analyzed (Fig. 2b). Out of the six male-specific compounds, only (+)-(6*R*,7*S*)-himachala-9,11-diene (A), elicited EAD responses, and was detected by male and female antennae at levels<5 ng per GC-EAD run. The enantiomer (–)-(6*S*,7*R*)-himachale-9,11-diene from *A. nordmanniana* was not physiologically active (Fig. 3c). The male-specific compounds B to F were not EAD-active at levels present in headspace extracts. Furthermore, beetle antennae responded to several host plant volatiles. These included thee alkenyl glucosinolate hydrolysis products, allyl isothiocyanate, 3-butenyl isothiocyanate, and 4-pentenyl isothiocyanate, as well as the green leaf alcohols (*Z*)-3-hexenol and 1-hexanol. Since the synthetic (+)-(6*R*,7*S*)-himachala-9,11-diene could not be purified prior to field testing, the synthetic blend also was analyzed via GC-EAD. Synthetic (+)-(6*R*,7*S*)-himachala-9,11-diene was the only compound in the synthetic blend that elicited antennal responses in *P. striolata* males and females.

Field Bioassays Male *P. striolata* feeding on *B.juncea* seedlings attracted significantly more beetles (198) than any other treatment in Experiment 1 (Table 1). About the same number of conspecifics was attracted by volatiles emanating from intact seedlings (22); seedlings that had been damaged by either males (48) or females with beetles removed (38); or volatiles from seedlings with feeding females (31). Both sexes were almost equally attracted to the volatile blend from feeding males (54% females). In Experiment 2, males feeding on the host plants attracted significantly more beetles (220) than any other treatment. The number of beetles attracted by males on moistened soil (17); males separated from intact *B. juncea* plants (19); or males separated from feeding-damaged plants (23) was not significantly different from the number attracted by moistened soil alone (6) (Table 2). The sex ratio (58% females) of the beetles caught in traps baited with actively feeding male *P. striolata* was not different from Experiment 1.

Field Testing of (+)-(6R,7S)-himachala-9,11-diene Traps baited with (+)-(6*R*,7*S*)-himachala-9,11-diene alone did not attract more beetles (147) than control traps (129). AITC baited traps attracted significantly more beetles (259) than both control traps and traps baited with (+)-(6*R*,7*S*)-himachala-9,11-diene. However, traps with a combined stimulus of AITC and (+)-(6*S*,7*R*)-himachala-9,11-diene attracted significantly more beetles than any other treatment (416) (Table 3, Experiment 3).

Discussion

Field bioassays revealed that volatiles emitted by *P. striolata* males feeding on host plants attract both sexes of the species. Active feeding or contact with the host plant is mandatory for the males to be attractive, since damaged host plants or male beetles alone, which had had the opportunity to feed on the host plant prior to the experiment, failed to attract conspecifics (Table 2). These findings match reports from diverse subfamilies of Chrysomelidae, where male-produced aggregation pheromones have been identified. Consistently, males release pheromonal compounds only while feeding on the host (Peng et al., 1999; Dickens et al., 2002; Cossé et al., 2002; Tóth et al., 2005; Zilkowski et al., 2006; Bartelt et al., 2006). However, from a physiological perspective, it is an open question whether actual feeding or contact with the host plant triggers the release of the aggregation pheromone.

By comparative chemical analyses, we identified six sesquiterpenes specifically emitted by feeding male *P. striolata* (Fig. 2a, Table 1). Among these compounds, only (+)-(6*R*,7*S*)-himachala-9,11-diene (A) elicited responses from *P. striolata* adult antennae, when using headspace samples in GC-EAD experiments. (+)-(6*R*,7*S*)-himachala-9,11-diene was synthesized from (–)-α-himachalene (Fig. 1) with known stereochemical configuration (Joseph and Dev, 1968). The configuration of the synthetic himachala-9,11-diene was identical to the corresponding compounds from male beetles based on retention times and mass spectra obtained with standard and chiral stationary phase GC-MS. Of the compounds present in the raw product of the synthesis, only (+)-(6*R*,7*S*)-himachala-9,11-diene, and none of the by-products, elicited antennal responses in *P. striolata* adults. In a field setting close to potential host plants the (+)-(6*R*,7*S*)-himachala-9,11-diene raw product enhanced the attractiveness of AITC, a known attractant for both sexes significantly, but was not behaviorally active on its own. In contrast, (+)-(6*R*,7*S*)-himachala-9,11-diene *per se* attracts *P. striolata* in a laboratory two-choice assay when offered as purified compound without other competing odor sources. However, when using natural odor sources, the number on non-responders dropped and more beetles were attracted to the natural volatile bouquet from *P. striolata* males feeding on *B. rapa* var. *chinensis* (Table 4, Experiment 4) compared to the numbers of beetles responding and being attracted to the synthetic pheromone compound alone or combined with AITC (Experiment 5). These data show that (+)-(6*R*,7*S*)-himachala-9,11-diene acts as aggregation pheromone of *P. striolata*. We cannot rule out that other compounds present in the raw product of the pheromone synthesis prevented the attractiveness of (+)-(6*R*,7*S*)-himachala-9,11-diene in the field. Nevertheless, this option is considered unlikely

Table 4 Two-choice laboratory bioassay of the response of *Phyllotreta striolata* to natural volatile sources and synthetic compounds

Treatment	Mean number of *P. striolata* per trap	Wilcoxon signed-rank test

(+)-(6*R*,7*S*)-himachala-9,11-diene and AITC	3	Z=2.995
AITC	0.17	P=0.003

since none of the other potentially relevant compounds present at the same or even higher concentration elicited physiological responses from the beetle antennae (data not shown). The combined data from field and laboratory experiments suggest that in a reduced environment the pheromone is attractive, while at a complex natural odor background the simultaneous presence of host plant volatiles, e.g., AITC, is required to trigger the behavioral response of *P. striolata* beetles to the aggregation pheromone. Moreover, the laboratory assays indicate that more plant and/or pheromone compounds than those identified to date are behaviorally active if offered as blend.

In the Alticinae, male-specific sesquiterpenoid compounds overlap among different species and genera. Of the six male-specific sesquiterpenes emitted by *P. striolata*, four (A, C, E, F; Table 1) were identified previously in male headspace extracts from the flea beetle species *P. cruciferae*, *Aphthona flava*, *A. czwalinae* (Weise), and *A. cyparissiae* (Koch) (Bartelt et al., 2001). Compounds A and F also were emitted by male *Epitrix fuscula* (Crotch) (Zilkowski et al., 2006). The behavioral function of these sesquiterpene blends was not further investigated in *Aphthona* spp. and *E. fuscula*. Bartelt and co-authors raised the hypothesis that the male-specific sesquiterpene blend constitutes the aggregation pheromone of the corresponding flea beetle species (Bartelt et al., 2001). However, in the European population of *P. cruciferae*, (+)-(6*R*,7*S*)-himachala-9,11-diene was as attractive as a synthetic blend of male-specific sesquiterpenes with AITC present in all treatments (Tóth et al., 2005). Moreover, traps baited with a sesquiterpene blend containing (+)-(6*R*,7*S*)-himachala-9,11-diene and AITC also attracted adults of congeneric species (Tóth et al., 2005). These results indicate that male aggregation pheromone compounds, individually or as blend, may attract flea beetles across species limits. Examples of cross-attraction of aggregation, but also sex pheromones, in congeneric species are known for several Coleoptera (Bartelt et al., 1995; Ayres et al., 2001; Wertheim et al., 2004). In the family Chrysomelidae, it has been shown that *Galerucella calmariensis* (L.) and *G. pusilla* (Duftschmidt) produce the same dimethylfuran lactone, and conspecifics of both species are attracted to the synthetic compound (Bartelt et al., 2006). In the scarab beetles *Melolontha melolontha* (L.) and *M. hippocastani* (Fabricius), three compounds, i.e., 1,4-benzoquinone, toluquinone, and phenol, are present in females of either species and function as sex pheromone. Male *Melolontha* beetles are attracted to females irrespective of the species. However, conspecific females are preferred when females from both species are offered simultaneously (Reinecke et al., 2006). Following these lines, aggregation pheromone blends may be attractive across species in flea beetles, but may nevertheless serve as species recognition cues in a natural choice situation. Adult *Phyllotreta* beetles may approach odor sources that resemble a species-specific olfactory search picture and finally decide for the best, i.e., species-specific stimulus. This hypothesis depends on the ability of the beetles to detect more than one compound of the male specific pheromone blend, and remains to be tested using more sensitive electrophysiological methodology.

Tóth et al. (2005) found physiological responses of *P. cruciferae* antennae to thee out of six male-specific compounds, (+)-(6*R*,7*S*)-himachala-9,11-diene being one of them. Zilkowski et al. (2006) demonstrated that himachalene-derived sesquiterpenes emitted by *E.fuscula* did not elicit physiological responses from the antennae, when used at the low concentrations present in headspace samples, but when stimulating with synthetic sesquiterpenes at a dose of 10 ng per compound, three compounds, again including (+)-(6*R*,7*S*)-himachala-9,11-diene, were active in EAD studies. In the male headspace samples used in the present study, minor compounds were present at a concentration below 1 ng/µl extract. Except for *ar*-himachalene, which was part of the raw product of the pheromone synthesis, physiological detection of other

male-specific sesquiterpenes from *P. striolata* may become apparent at higher doses only.

The glucosinolate hydrolysis products allyl-, 3-butenyl-, and 4-pentenyl isothiocyanate were present in the headspace of feeding-damaged *B. juncea* leaves, and they were all EAD-active. Any combination of these isothiocyanates with an aggregation pheromone, therefore, constitutes a reliable cue not only of a host plant, but a host plant already assessed and accepted by conspecifics. Correspondingly, AITC attracted *P. striolata* beetles *per se*, but adding the aggregation pheromone to the traps enhanced its attractiveness. AITC is also an attractant in other *Phyllotreta* species (Pivnick et al., 1992; Tóth et al., 2007). Even if combined with the aggregation pheromone, however, the evaporated amount of AITC required to attract flea beetles in our and in previous experiments (Soroka et al., 2005; Tóth et al., 2005) exceeds host plant emission rates by far (Pivnick and Jarvis, 1991). Moreover, glucosinolate contents and accordingly the amount of volatile hydrolysis products present in the headspace may vary to a wide extent in *Phyllotreta* host plants (Fahey et al., 2001; Verkerk et al., 2009). These findings lead to the hypothesis that a blend of host plant volatiles, glucosinolate hydrolysis products and/or other plant volatiles, constitutes the relevant stimulus that indicates a suitable host plant to *Phyllotreta* beetles. The high number of beetles attracted to the combined stimulus of beetles and host plants in the laboratory bioassay supports this hypothesis.

Interaction between insect pheromones and plant volatiles are well-documented in many species (Landolt and Phillips, 1997; Reddy and Guerrero, 2004; Seybold et al., 2006). For instance, female *Melolontha* cockchafers (Coleoptera: Scarabeidae) emit sex pheromones, which require the concomitant presence of green leaf volatiles to be behaviorally active (Ruther et al., 2000, 2002; Reinecke et al., 2002a, b). These examples demonstrate that rather unspecific plant volatiles may become an important part of the chemical orientation and communication if combined with more specific host or insect signals. Interestingly, the volatile green leaf alcohols 1-hexanol, and (*Z*)-3-hexenol were physiologically active in our electroantennographic experiments, and both compounds were more attractive than allyl isothiocyanate in olfactometer experiments with *P. cruciferae* (Gruber et al., 2009). However, when tested in the field individually or as binary combination, these leaf alcohols did not attract *P. striolata* adults, (data not shown). Combinations of (+)-(6*R*,7*S*)-himachala-9,11-diene with leaf volatiles were not tested during the past field season due to limited supply with the aggregation pheromone.

Another observation indicates that our current understanding of volatile glucosinolate hydrolysis products as kairomones for *P. striolata* may not fully reflect function and source of these compounds. When male *P. striolata* were allowed to feed on *Brassica* cultivars that do not produce alkenyl glucosinolates, relevant concentrations of AITC and/or 3-butenyl isothiocyanate were detected in the headspace, but were below detection limit when the plants were mechanically wounded (Beran, unpublished data). The beetles themselves thus are potential emitters of AITC synthesized from precursors acquired from the plant. The actual source of volatile isothiocyantes and the function of different host plant volatiles in the aggregation behavior of *P. striolata* are objects of ongoing research.

Acknowledgments We thank the Gesellschaft für Technische Zusammenarbeit (GTZ) and the Max Planck Gesellschaft for funding. FB was supported by a grant from FAZIT-Stiftung, Germany. The authors thank Stefan Garms for advice and support regarding the identification of sesquiterpenes and for providing the *Scapania undulata* extract, Lin Mei-ying and the staff of Entomology unit at AVRDC-The World Vegetable Center for supporting field experiments, and Daniel Veit, head of the workshop at ICE Jena for his continued support and advice with experimental equipment. Hervé Mosimann is indebted to Xavier Garnier for technical skill in performing large scale distillation. Jiří Svoboda thanks his father, Prof. Jiří Svoboda, for help with the catalytic hydrogenation of (–)-α-himachalene.

Author contributions F.B. designed and performed experiments, analyzed natural extracts and synthetic products, and prepared the manuscript; I.M., C.U., R.S., and C.B. designed experiments, provided experimental facilities, insects, and acquired GTZ funding; C.V. and H.M. performed isolation of the precursor and reference substances and designed the synthetis pathway of A; J.S. and W.B. performed the synthesis of A and confirmed the structure of the product; A.R. and B.S.H. designed experiments and prepared the manuscript; MPG funding was provided though B.S.H.

Chemical Profiles of Body Surfaces and Nests from Six Bornean Stingless Bee Species

Abstract Stingless bees (Apidae: Meliponini) are the most diverse group of Apid bees and represent common pollinators in tropical ecosystems. Like honeybees they live in large eusocial colonies and rely on complex chemical recognition and communication systems. In contrast to honeybees, their ecology and especially their chemical ecology have received only little attention, particularly in the Old World. We previously have analyzed the chemical profiles of six paleotropical stingless bee species from Borneo and revealed the presence of species-specific cuticular terpenes— an environmentally derived compound class so far unique among social insects. Here, we compared the bees' surface profiles to the chemistry of their nest material. Terpenes, alkanes, and alkenes were the dominant compound groups on both body surfaces and nest material. However, bee profiles and nests strongly differed in their chemical composition. Body surfaces thus did not merely mirror nests, rendering a passive compound transfer from nests to bees unlikely. The difference between nests and bees was particularly pronounced when all resin-derived compounds (terpenes) were excluded and only genetically determined compounds were considered. When terpenes were included, bee profiles and nest material still differed, because whole groups of terpenes (e.g., sesquiterpenes) were found in nest material of some species, but missing in their chemical profile, indicating that bees are able to influence the terpene composition both in their nests and on their surfaces.

Key Words Stingless bees · Meliponines · Cuticular profile · Wax chemistry · Resin · Terpenes

Introduction

Social insects— such as ants, termites, wasps and bees— live in large colonies with up to several thousands workers per colony. In order to communicate within colonies, they rely on a sophisticated communication system based on chemical cues (Blum et al. 1970). In addition to pheromones, waxy lipids on the cuticle (frequently referred to as cuticular profile or chemical profile) play an important role for communication (Blum et al. 1970; Buckner 1993), but also preserve insects from desiccation, cuticle abrasion, and infection (Lockey 1988; St. Leger 1995). The cuticular compounds comprise various chemical classes, with non-polar aliphatic compounds, such as methyl-branched alkanes, n-alkanes, and n-alkenes, dominating in ants (Hölldobler 1995; Endler et al. 2004), termites (Howard et al. 1982; Kaib et al. 2004), and social wasps (Espelie et al. 1994). In addition to these non-polar compounds, polar substances (with functional groups), such as alcohols, aldehydes, esters, and carboxylic acids, are found in various bee species (Ayasse et al. 1999; Paulmier et al. 1999; Fröhlich et al. 2000b; Abdalla et al. 2003; Jungnickel et al. 2004; Kerr et al. 2004; Mant et al. 2005; Nunes et al. 2008; Sramkova et al. 2008; Nunes et al. 2009). Moreover, we recently reported on yet another class of compounds in stingless bees from Borneo: besides non-polar aliphatic hydrocarbons, their cuticular profiles comprise large amounts of terpenes (Leonhardt et al. 2009), which most

likely are derived from plant resins collected (unpublished data).

In contrast to the environmentally derived terpenes in the chemical profiles of stingless bees, honeybees acquire compounds from self-produced comb wax (Breed et al. 1995, 1998, 2004). Therefore, the same compound classes can be found in comb wax and in the chemical profiles of honeybees, albeit in varying quantities (Blomquist et al. 1980; Fröhlich et al. 2000b; Breed et al. 2004). However, direct comparisons between bee profiles and nest material (such as comb wax) rarely have been made (but see Blomquist et al. 1980; Fröhlich et al. 2000b), which is surprising given that interactions between the bees and their nest material are supposed to play an important role in the origin of recognition cues (Breed et al. 1995, 1998, 2004). Bees even are able to distinguish between wax of their own and a foreign colony (Fröhlich et al. 2000a; Hepburn et al. 2010).

Here, we compared nest material and chemical profiles of six stingless bee species from Borneo. The chemical profiles of these bees strongly differ among species, with regard to both resin-derived terpenoid compounds and genetically determined non-terpenoid compounds (aliphatic compounds) (Leonhardt et al. 2009). Resin is the main nest building material in stingless bees, but it frequently is mixed with self-produced wax (Roubik 1989, 2006). Because stingless bees have both resin-derived compounds and genetically determined aliphatic hydrocarbons on their cuticle (Leonhardt et al. 2009), we asked whether they simply acquire their cuticular compounds from their nesting substrate, which would result in similar bee and nest profiles. The bees alternatively might be able to exclude or modify nest compounds before acquiring them on their body surface or produce cuticular profiles independent of their nest profiles. In this case, the chemical composition of the bees' body surfaces and their nest material might differ in resin-derived and/or genetically determined compounds.

Methods and Materials

Study Sites and Bees Bee specimens and nest material were collected at the Danum Valley Conservation Area (DVC: Sabah, 4°55′N 117°40′E, 100 m asl) and the Kabili Sepilok Reserve (KSR: Sabah, 5°54′N, 118°04′E, 20–120 m asl) in Sabah, Borneo (Malaysia). Sampling was performed in February and March 2007. KSR covers an area of 4294 ha of coastal dipterocarp and mangrove forest (Fox 1973) surrounded by oil palm plantations. DVC represents one of the major remaining patches of Sabah's primary lowland dipterocarp rainforest (43 800 ha) (Marsh and Greer 1992). The two sites have a typical equatorial rainforest climate with a mean annual temperature of 26–30°C and yearly rainfall of 2600–3000 mm (Fox 1973).

Eltz (2004) and Dworschak and Blüthgen (2010) found 15 stingless bee species (species and genus names as in Moure 1961) in DVC, whereas 15 to 20 species can be found in KSR according to specimen collections held by the Forestry Research Centre in Sepilok and our own studies (Leonhardt and Blüthgen 2009).

Sampling of Bees and Nest Material We caught departing workers from 29 colonies belonging to six species. These were *Tetragonula fuscobalteata, T. geissleri, T. melanocephala, Tetragonilla collina, Pariotrigona pendleburyi,* and *Lepidotrigona terminata*. Sixteen colonies were located in DVC and 13 in KSR (see also Leonhardt et al. 2009; note that *Tetragonula melina* was excluded from this study because nest material could not be obtained from this species). Bees were caught at their colonies' nest entrances by putting a clean transparent plastic bag over the nest entrance tube.

Nest material was obtained from 15 of the 16 colonies from DVC (comprising all 6 species), by breaking of small pieces of the nest entrance tube (max. ~1 mg). To test whether old and new nest material had the same chemical composition, we returned to 6 nests (including colonies from all species except *Tetragonula fuscobalteata*) after 1–9 d and additionally collected fresh, recently added nest material. Only fresh nest material was collected from two *Tetragonula geissleri* colonies.

Extraction and Chemical Analysis The bees were killed in a freezer. Dead bees and nest material collected were transferred into 2 ml sample vials containing 1.5 ml hexane for extraction. Bees were extracted for 10 min and then discarded; nest material was kept in hexane for the rest of the analysis. Extracts from bees and nest materials were analyzed by a Hewlett Packard HP 6890 Series GC System coupled to a Hewlett Packard HP 5973 Mass Selective Detector (Agilent Technologies, Böblingen, Germany) as described in Leonhardt et al. (2009).

Compounds found in the extracts were characterized by their mass spectra and retention times. Compounds with identical mass spectra and retention times were regarded as the same substance. Compound classes characterized comprised alkanes, aldehydes, alcohols, esters as well as mono-, sesqui-, and triterpenes. They were (tentatively) identified by comparison with three commercially available mass spectra libraries (Wiley 275, NIST 98 and Adams EO library 2205) and with compounds from dipterocarp tree resins known to comprise mono-, sesqui-, and triterpenes (see also Leonhardt et al. 2009). Compounds were confirmed by synthetic standards if standards were available (Sigma-Aldrich, Munich, Germany).

Statistical Analysis Prior to analyses, we condensed the dataset by removing trace compounds (for which mass

N1=number of compounds per species

N2=total number of compounds found for a given substance class across species

*Proportions are obtained by dividing the peak area of a substance class by the total peak area of all compounds in a species (colonies pooled).

spectra could not be characterized) as well as compounds that accounted for less than 5% of the total peak area across all samples. The analysis is based on a total of 309 compounds, with 253 found in nest material and 195 in bee profiles. The compounds were quantified as proportions by dividing the peak area of each single compound by the total area of all peaks remaining after having condensed the dataset.

First, we analyzed species specific differences in the chemical composition of nests. Then, we compared nest materials and bee profiles to investigate whether bees chemically resemble their nests. Analyses were performed for all compounds, only terpenoid compounds, and only non-terpenoid compounds to distinguish between the contributions of resin-derived terpenoids and genetically determined compounds. Two-dimensional NMDS (non-metric dimensional scaling) based on Bray-Curtis distances of the proportions of each compound (start configuration: PCoA, 1000 iterations) was used to produce ordination figures. Groups were compared by an "Adonis" test (R Statistical software 2.9.2, vegan package; command for a randomization-based analysis of dissimilarities), based on the Bray-Curtis distance matrix of the proportions of each compound.

If surface profiles of bees merely mirrored their nest profiles, chemical differences between bees and their nest of origin should be less pronounced than between bees and nests of different colonies. To test whether chemical differences were more pronounced within nests and/or bee profiles or between nests and the equivalent bee profiles, we compared the mean Bray-Curtis distances for the two bee species with the largest sample sizes (*T. fuscobalteata* and *T. melanocephala*).

Results

Nest material of the six stingless bee species analyzed contained large amounts of resin-derived terpenes (particularly sesqui- and triterpenes), as well as wax-derived aliphatic compounds (Table 1). The chemical composition of nests from different species strongly differed both qualitatively and particularly quantitatively (Adonis: R^2=0.90, P<0.001; Fig. 1a; Table 1). Differences among species were similarly pronounced when only terpenoids were included in the analyses (Adonis: R^2=0.90, P<0.001; Fig. 1c) and slightly less for non-terpenoids (Adonis: R^2=0.86, P< 0.001; Fig. 1b). We found no differences in the chemical composition between old and fresh nest material (Adonis: R^2=0.02, P=0.98; Fig. 1).

One hundred and forty compounds were shared by both nest material and bee profiles, whereas 114 compounds

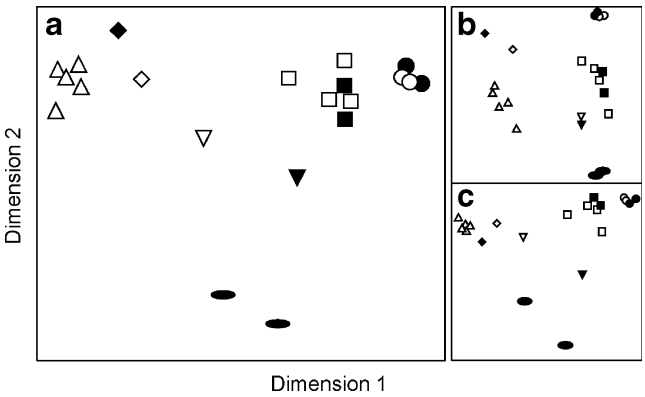

Fig. 1 Similarity in the chemical composition of nest material from six stingless bee species including (**a**) all compounds, (**b**) only non-terpenoid compounds, and (**c**) only terpenoid compounds (each symbol represents one colony). NMDS ordination based on Bray-Curtis distances: triangles *Tetragonula fuscobalteata*, diamonds *Lepidotrigona terminata*, triangles upside down *Pariotrigona pendleburyi*, squares *T. melanocephala*, circles *Tetragonilla collina*, ellipses *T. geissleri*; open symbols indicate old nest material and filled symbols indicate fresh nest material

were exclusively found in nest material and 55 exclusively in bee profiles. When nest material and bee profiles were combined in one analysis, both nests and bee profiles still could be discriminated (Adonis: all compounds: R^2=0.90, P<0.001; Fig. 2a; non-terpenoids: R^2=0.88, P<0.001; Fig. 2b; terpenoids: R^2=0.86, P<0.001; Fig. 2c). Nest and bee profiles were more similar chemically to one another than nests and their equivalent bee profiles, in both 1) *T. fuscobalteata* (mean Bray-Curtis distances ± SD between bee profiles: 0.20±0.13; between nest profiles: 0.19±0.06; between nest and equivalent bee profiles: 0.32±0.07) and 2) *T. melanocephala* (between bee profiles: 0.22 ± 0.03; between nest profiles: 0.33±0.07; between nest and equivalent bee profiles: 0.74±0.08). The same trend was observed for the Bray-Curtis distance matrices of only terpenoid compounds (*T. fuscobalteat*a: between bee profiles: 0.18±0.14; between nest profiles: 0.15±0.07; between nest and equivalent bee profiles: 0.22±0.10; and *T. melanocephala*: between bee profiles: 0.16±0.05; between nest profiles: 0.31± 0.07; between nest and equivalent bee profiles: 0.75±0.10) and for non-terpenoid compounds (*T. fuscobalteat*a: between bee profiles: 0.27±0.12; between nest profiles: 0.32±0.09; between nest and equivalent bee profiles: 0.62±0.04; *T. melanocephala*: between bee profiles: 0.32±0.10; between nest profiles: 0.38±0.15; between nest and equivalent bee profiles: 0.72±0.10).

For terpenoids, bee and nest profiles with sesquiterpenes and without sesquiterpenes were clearly separated (Fig. 2c), but discrimination was less pronounced for bee and nest profiles that solely contained triterpenes (Adonis: R^2=0.67, P<0.001; Fig. 2c). Notably, sesquiterpenes were present in hexane extracts of both nest material and bee surfaces of

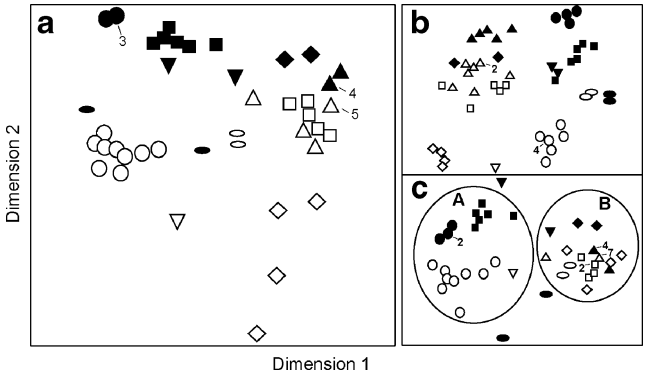

Fig. 2 NMDS of chemical compounds from hexane extracts of nest material and bee profiles combined of six bee species including (**a**) all compounds, (**b**) only non-terpenoid compounds, and (**c**) only terpenoid compounds (each symbol represents one colony); symbol codes as in Fig. 1; filled symbols indicate nest material and open symbols indicate bee profiles. Numbers indicate where several symbols were entirely overlapping. The two circles (in 2c) comprise samples with sesquiterpenes (*A*) and without sesquiterpenes (*B*)

some species (e.g., *T. collina*) (Fig. 3a, c, Table 1), whereas they were found only in trace amounts on the body surfaces of other species (e.g., *T. melanocephala*), while present in their nest material (Fig. 3b, d, Table 1).

Discussion

The chemical composition of nest material from six Bornean stingless bee species strongly differed both qualitatively and quantitatively. These differences prevailed in freshly collected nest material, indicating that the chemical composition remained constant over time. Moreover, bee profiles did not merely mirror the chemical profiles of their nests, because bee and nest profiles were clearly separated by their chemical composition. Furthermore, chemical distances were more pronounced between bees and their nests of origin than within bees and/or within nests from different colonies. Discrimination was about equally accurate when analyses were confined to either terpenoid or non-terpenoid compounds. The least discrimination was revealed for surface profiles and nests with triterpenes as sole terpene group, indicating that triterpenes were qualitatively and quantitatively similar across species' nests and surface profiles.

Besides terpenes, bee surfaces comprised alkanes, alkenes, branched alkanes, and alkadienes as well as compound classes with functional groups (such as esters or alcohols) (see also Leonhardt et al. 2009), whereas nest material mainly contained terpenes, alkanes, and alkenes. These findings are in accordance with studies of Milborrow et al. (1987) and Blomquist et al. (1985) that also revealed non-polar hydrocarbons and compounds from exogenous materials (terpenes) as dominant compound groups in the nesting substrate of stingless bees. Hence, genetically determined non-terpenoid compounds of stingless bees comprise mainly, partly even exclusively, non-polar aliphatic hydrocarbons (n-alkanes, alkenes and branched alkanes) and only few compounds with functional groups (see also: Abdalla et al. 2003; Jungnickel et al. 2004; Kerr et al. 2004; Nunes et al. 2008, 2009; Leonhardt et al. 2009). By contrast, honeybees have non-polar compounds and compounds with functional groups in equal quantities both on their body surfaces and in their nest material (comb wax) (Blomquist et al. 1980; Francis et al. 1985, 1989; Fröhlich et al. 2000b). Moreover, honeybees more closely resemble their nest material than do stingless bees (Blomquist et al. 1980; Fröhlich et al. 2000b). Besides genetically

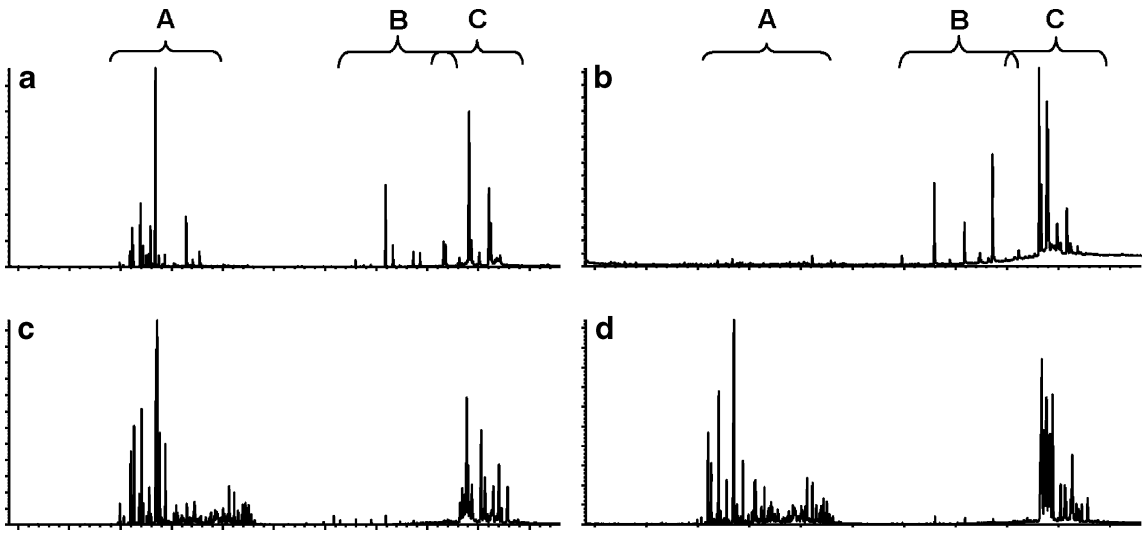

Fig. 3 Chromatograms of hexane extracts from (**a**) the chemical profile of a *Tetragonilla collina* worker, (**b**) the chemical profile of a *Tetragonula melanocephala* worker, (**c**) nest material of *T. collina*, and (**d**) nest material of *T. melanocephala*. Capital letters above chromatograms indicate substance classes of peaks/compounds: *A* mainly sesquiterpenes, *B* non-terpenoid compounds, and *C* triterpenes and non-terpenoid compounds

determined aliphatic hydrocarbons, the stingless bee species studied here have large amounts of resin-derived terpenes (especially sesqui- and triterpenes) both on their body surfaces and in their nests. This compound group is completely missing in surface profiles of honeybees (let alone any other social insect).

Because most substances (e.g., terpenes) were found in both nest material and surface profiles of stingless bees, compound transfer from nests to surfaces appears likely and would be in accordance with findings in honeybees, whose cuticular surfaces are influenced by compounds derived from beeswax (especially fatty acids and esters) (Breed et al. 1995, 1998, 2004). However, in stingless bees, resin-derived terpenes are not passively transferred from their nest material to their surface, because, in some species (e.g., *T. melanocephala*), one group of terpenes (sesquiterpenes) is found in nests, but completely lacking on body surfaces. Such a lack of sesquiterpenes suggests that stingless bees are able to actively influence the chemical composition of compounds in nests and on their surface by, for instance, excluding a whole group of terpenes. This idea is supported further by the highly species-specific distribution of different groups of terpenes among surface profiles of different bee species (Leonhardt et al. 2009). The species-specific terpene profiles contrast with the bees' generalistic resin collection behavior where all bee species largely visit the same set of tree species (unpublished data). Moreover, even nest material of different species can be discriminated based on terpenes alone (with chemical compositions remaining constant over time), rendering a purely opportunistic inclusion of resin-derived compounds in nest material unlikely. It appears most likely that resin and thus resin-derived compounds are processed prior to nest building, because resin foragers do not alter the resin collected directly at resin wounds (unpublished data). How stingless bees process plant resins remains as yet uninvestigated. They may be able to modify them by using specific enzymes or with the help of mutualistic microbes.

Stingless bees respond to terpenes, as they use these compounds to locate and re-recognize resin sources (wounds) at trees (Leonhardt et al. 2010b). Moreover, adding sesquiterpenes to the surface profile of species that lack sesquiterpenes themselves reduces aggression in these species, indicating that terpenes affect the bees' recognition system (Leonhardt et al. 2010a). Whether terpenes are involved further in nestmate recognition remains to be tested, but the species-specific distribution in both the bees' surface profiles and their nests suggests that terpenes represent more than pure contamination by plant resins.

Acknowledgements We are grateful to the Economic Planning Unit (EPU) for giving us permission to perform research in Malaysia, and the Royal Society for their help with planning and conducting field work in Borneo. Dr. Chey Vun Khen and Dr. Arthur Chung (Forestry Research Centre, Sandakan) kindly supported this project. The comments of two anonymous reviewers greatly improved the manuscript. SDL was supported by a grant of the German *Excellence Initiative* to the Graduate School of Life Science, University of Würzburg, and NB and TS by the Sonderforschungsbereich SFB 554 (Mechanisms and Evolution of Arthropod Behaviour) of the Deutsche Forschungsgemeinschaft (DFG).

Abstract The subfamily Geometrinae (Lepidoptera: Geometridae) includes many species called emerald moths. Based on our recent finding of novel polyenyl compounds, including a double bond at the 12-position from two geometrine species, *Hemithea tritonaria* and *Thalassodes immissaria intaminata*, (6*Z*,9*Z*,12*Z*)-6,9,12-trienes and (3*Z*,6*Z*,9*Z*,12*Z*)-3,6,9,12-tetraenes with a C_{17}–C_{20} straight chain were synthesized and analyzed by GC-MS. The 6,9,12-trienes, which were prepared by a double Wittig reaction between two alkanals and an ylide derived from (*Z*)-1,6-diiodo-3-hexene, characteristically produced fragment ions at *m/z* 79, 150, and M–98. The 3,6,9,12-tetraenes, which were prepared by a coupling between (*Z*)-3-alkenal and an ylide derived from (3*Z*,6*Z*)-1-iodo-3,6-nonadiene, showed fragment ions at *m/z* 79, 148, and M–96. These diagnostic ions were useful to distinguish these compounds from other known polyenyl pheromones, such as 4,6,9- and 6,9,11-trienes and 1,3,6,9-tetraenes. With reference to the GC-MS data, pheromone extracts of other species in Geometrinae inhabiting the Iriomote Islands were analyzed, and the 6,9,12-trienes were identified in the pheromone gland extracts of *Pamphlebia rubrolimbraria rubrolimbraria* and *Maxates versicauda microptera*. Furthermore, a field evaluation of the synthetic polyenes in a mixed forest of Tokyo revealed the following new male attractants for emerald moths: *Idiochlora ussuriaria* by a C_{17} 6,9,12-triene and *Jodis lactearia* by a C_{20} 3,6,9,12-tetraene, indicating the characteristic chemical structures of Geometrinae pheromones. On the other hand, through reexamination of the pheromone extract of *H. tritonaria*, (3*E*,6*E*)-α-farnesene was identified as an electrophysiologically active component in addition to the C_{17} 6,9,12-triene. The binary mixture attracted more males than the single component lure baited with the triene in the Iriomote Islands.

Key Words Female sex pheromone · Lepidoptera · Geometridae · Geometrinae · 6,9,12-Triene · 3,6,9,12-Tetraene · α-Farnesene · Male attraction

Introduction

Lepidopteran sex pheromones, which have been identified from more than 600 species (Ando, 2010; El-Sayed, 2010), are divided primarily into two groups according to their chemical structure (Ando et al., 2004). Unsaturated C_{10}–C_{18} fatty alcohols and their derivatives compose Type I pheromones, and Type II pheromones consist of C_{17}–C_{23} polyunsaturated hydrocarbons and their epoxy derivatives. After the first discovery of a Type II pheromone from an Arctiidae species, *Estigmene acrea* Drury (Hill and Roelofs, 1981), (6*Z*,9*Z*)-6,9-dienes, (3*Z*,6*Z*,9*Z*)-3,6,9-trienes, and the epoxy derivatives were identified from many species in the relatively derived families, i.e., Geometridae, Noctuidae, Arctiidae, and Lymantriidae (Ando, 2010; El-Sayed, 2010). The dienes and trienes are believed to be biosynthesized starting from (9*Z*,12*Z*)-9,12-octadecadienoic acid (linoleic acid) and (9*Z*,12*Z*,15*Z*)-9,12,15-octadecatrienoic acid (linolenic acid), respectively, by chain elongation and decarboxylation for the polyenes with an odd numbered chain

(Jurenka, 2004; Ando et al., 2008) and additional α-oxidation for the polyenes with an even numbered chain (Goller et al., 2007). In addition to these compounds, polyenes modified by additional desaturation at the 1-, 4-, or 11-position and the epoxy derivatives have been found (Ando et al., 2004; Ando, 2010; El-Sayed, 2010). Based on these identifications, we systematically synthesized candidates of the Type II pheromones and, by random screening tests, discovered new instances of male attraction in several geometrid and noctuid species (Ando et al., 1993, 1995; Yamamoto et al., 2008).

Geometridae is subclassified into several subfamilies, including Larentiinae, Ennominae, and Geometrinae. Sex pheromones have been studied only in species of the former two subfamilies (Ando, 2010; El-Sayed, 2010) and not in those in Geometrinae, which includes many species, such as emerald moths, with green wings. Thus, it is highly possible to find new pheromone compounds from the species in the Geometrinae. We collected male and female emerald moths using a light trap in the subtropical Iriomote Islands, and successfully identified novel pheromone components, (6*Z*,9*Z*,12*Z*)-6,9,12-octadecatriene from *Hemithea tritonaria* Walker and (3*Z*,6*Z*,9*Z*,12*Z*)-3,6,9,12-icosatetraene from *Thalassodes immissaria intaminata* Inoue (Yamakawa et al., 2009). This identification revealed that desaturation at the ω12-position of biosynthetic acyl precursors occured, at least in the above two species, establishing a species-specific pheromone system. There are about 2,300 Geometrinae species in the world, 86 species of which are distributed in Japan. It would be interesting to determine whether such desaturation is characteristic of the pheromones of Geometrinae species. To answer this question, we started synthesis of (6*Z*,9*Z*,12*Z*)-6,9,12-trienes and (3*Z*,6*Z*,9*Z*,12*Z*)-3,6,9,12-tetraenes with a C_{17}–C_{20} straight chain and accumulated their GC-MS data. Using the obtained spectral information, we analyzed the sex pheromones of other Geometrinae females, and the (6*Z*,9*Z*,12*Z*)-6,9,12-trienes were detected in pheromone gland extracts of two additional species, *Pamphlebia rubrolimbraria rubrolimbraria* Guenée and *Maxates versicauda microptera* Inoue. Next, we utilized the synthetic compounds in field surveys, and found new male attractants for two other species, *Idiochlora ussuriaria* Bremer and *Jodis lactearia* Linnaeus. On the other hand, it has been reported that *H. tritonaria* females produce an unknown pheromone component (Yamakawa et al., 2009). We reexamined the GC-MS data, and the compound is now assigned to be (3*E*,6*E*)-α-farnesene, which has not been detected in pheromone gland extracts of other species. The role of the sesquiterpene in the mating communication of *H. tritonaria* was evaluated in the field. This paper deals with unique communication systems developed by these five emerald moth species.

Methods and Materials

Insects and Pheromone Extraction Adults of two Geometrinae species, *Pamphlebia rubrolimbraria rubrolimbraria* and *Maxates versicauda microptera*, were collected with a black light in a mixed forest area including many evergreen broad-leaved trees in the Iriomote Islands, which are located in a subtropical zone (24.29°N, 123.86°E). The collection was carried out from 17:00 to 23:00 on several days in 2008 and 2009. The captured moths were placed separately in small glass vials and sent to the laboratory of TUAT in Tokyo. Eggs were obtained from the mated females of *P. r. rubrolimbraria*, and the larvae were reared on a semi-synthetic diet (Insecta LF, Nippon-Nosan-Kogyo Co., Yokohama, Japan) under a 16:8 h L:D cycle at 25°C. The abdominal tips of the virgin females were excised 1 h after the beginning of scotophase, and soaked in hexane (100 μl/tip) for 15 min to extract the pheromone. In the case of *M. v. microptera*, a pheromone extract was prepared from wild females.

Instruments for Analysis and Purification Gas chromatography with an electroantennographic detector (GC-EAD) was used to identify physiologically active compounds in female gland extracts. An HP-5890 Series II GC (Hewlatt-Packard, Wilmington, DE, USA) was equipped with a DB-23 column (0.25 mm ID, 30 m length, 0.25 μm film thickness, J & W Scientific, Folsom, CA, USA). The column temperature was programmed from 50°C for 2 min, 10°C/min to 160°C, and 4°C/min to 220°C. The effluent from the column was split 1:1 into two lines, which led to a flame ionization detector (FID) and EAD (Inomata et al., 2005). GC-mass spectrometry (GC-MS) in the electron impact (EI) ionization mode (70 eV) was achieved using an HP-5975 MS system (quadrupole type, Hewlett-Packard) equipped with the same DB-23 column operated at the same temperatures as the GC-EAD. The HPLC system employed a pump (PU-980, JASCO), an RI detector (RI-98SCOPE, Labo System, Tokyo, Japan), an integrator (807-IT, JASCO), and an ODS column (Senshu Pack ODS-SH, 0.8 cm ID×15 cm; Senshukagaku, Tokyo, Japan). As the eluent, 5% H_2O in methanol was used at a flow rate of 1.0 ml/min for purification of synthetic polyenes.

Chemicals The chemical structures of polyunsaturated hydrocarbons are abbreviated as follows: Z = (*Z*)-double bond, number before the hyphen = position of the double bond, number after the hyphen = carbon number of the straight chain, and H = compound without terminal functional group. For example, (5*Z*,8*Z*,11*Z*)-5,8,11-heptadecatriene is abbreviated as Z6,Z9,Z12-17:H. The synthesis of Z6,Z9,Z12-18:H and Z3,Z6,Z9,Z12-20:H has been reported briefly (Yamakawa et al., 2009). The other trienes and tetraenes with a C_{17}–C_{20}

chain were prepared in a similar manner, as shown in Fig. 1. (3*E*,6*E*)-α-Farnesene (>98% purity) used for a field test was prepared by HPLC purification of a sample purchased from the Sigma-Aldrich Company. This sample included geometrical isomers of α-farnesene (3,7,11-trimethyl-1,3,6,10-dodecatetraene) and β-farnesene (7,11-dimethyl-3-methylene-1,6,10-dodecatriene), which also were isolated and used as an authentic standard of a GC-MS analysis after structure analysis by NMR. Details of the isolation and characterization will be reported elsewhere.

(6Z,9Z,12Z)-6,9,12-Trienes (Scheme A) Z6,Z9,Z12-17:H was synthesized starting from 3-hexyne-1,6-diol (**1**), which was converted into 1,6-diiodo-(*Z*)-3-hexene (**2**) by partial hydrogenation and iodination (Yamamoto et al., 2008). With the phosphonium salt of **2**, bis-ylide (**3**) was prepared (Pohnert and Boland, 2000) and treated with a 1:1 mixture of pentanal and hexanal to yield the objective C_{17} triene mixed with C_{16} and C_{18} trienyl by-product. Purification of Z6,Z9,Z12-17:H was achieved by preparative HPLC with an ODS column. In the same manner, Z6,Z9,Z12-19:H was synthesized by double Wittig coupling of **3** with a 1:1 mixture of hexanal and heptanal, and Z6,Z9,Z12-20:H was synthesized with a 1:1 mixture of hexanal and octanal. Undesired byproducts were removed by the preparative HPLC. ^{1}H NMR δ ppm: 0.98 (6H, t, *J*=7 Hz), ~1.3 (10H–16H for C_{17}–C_{20} trienes, m), 2.06 (4H, dt, *J*=7, 7 Hz), 2.81 (4H, dd, *J*=6, 6 Hz), 5.37 (6H, m). ^{13}C NMR δ ppm: Z6,Z9,Z12-17:H, 14.0 (C-17), 14.1 (C-1), 22.4 (C-16), 22.6 (C-2), 25.6 (× 2, C-8, 11), 27.0 (C-14), 27.2 (C-5), 29.4 (C-4), 31.5 (C-3), 31.9 (C-15), 127.67, 127.69 (C-7, 12), 128.3 (× 2, C-9, 10), 130.36 (C-13), 130.42 (C-6); Z6,Z9,Z12-18:H, 14.1 (C-1, 18), 22.6 (C-2, 17), 25.6 (C-8, 11), 27.2 (C-5, 14), 29.4 (C-4, 15), 31.6 (C-3, 16), 127.7 (C-7, 12), 128.3 (C-9, 10), 130.4 (C-6, 13); Z6,Z9,Z12-19:H, 14.07, 14.10 (C-1, 19), 22.6, 22.7 (C-2, 18), 25.7 (× 2, C-8, 11), 27.25, 27.29 (C-5, 14), 29.0, 29.4, 29.7 (C-4, 15, 16), 31.6 (C-3), 31.8 (C-17), 127.7 (× 2, C-7, 12), 128.30 (× 2, C-9, 10), 130.4 (× 2, C-6, 13); Z6,Z9,Z12-20:H, 14.08, 14.12 (C-1, 20), 22.6, 22.7 (C-2, 19), 25.6 (×2, C-8, 11), 27.2, 27.3 (C-5, 14), 29.2, 29.3, 29.4, 29.7 (C-4, 15, 16, 17), 31.5 (C-3), 31.9 (C-18), 127.7 (× 2, C-7, 12), 128.27, 128.29 (C-9, 10), 130.4 (× 2, C-6, 13).

(3Z,6Z,9Z,12Z)-3,6,9,12-Tetraenes (Scheme B) Z3,Z6,Z9,Z12-17:H was synthesized starting from commercialized (*Z*)-3-octen-1-ol (**6a**). By oxidation with 1-hydroxy-1,2-benziodoxol-3(1*H*)-one 1-oxide (IBX), the alcohol was converted into the corresponding β,γ-unsaturated aldehyde with (*Z*)-configuration (**7a**). We used Dess-Martin oxidation with periodinate [1,1,1-tris(acetyloxy)-1,1-dihydro-1,2-benziodoxol-3(1*H*)-one], but IBX was sufficient for the oxidation. NMR data for **7a**, which were differentiated easily from those of the corresponding (*E*)-isomer (Yamakawa et al., 2009), indicated high purity. Without any purification, the aldehyde was coupled with an ylide (**8**), which was prepared from the phosphonium salt of an iodide derived from (3*Z*,6*Z*)-3,6-nonadien-1-ol, to give the objective C_{17} tetraene. Z3,Z6,Z9,Z12-18:H was synthesized *via* (*Z*)-3-nonenal (**7b**), which was prepared by oxidation of commercially available (*Z*)-3-nonen-1-ol (**6b**). Z3,Z6,Z9,Z12-19:H was synthesized starting from 3-butyn-1-ol (**4**). After protection of the alcohol as THP ether, 1-bromohexane was coupled with it to yield 3-octynyl compound (**5c**). Partial hydrogenation with Pd-$CaCO_3$-Pb and deprotection of **5c** gave (*Z*)-3-decen-1-ol (**6c**). The

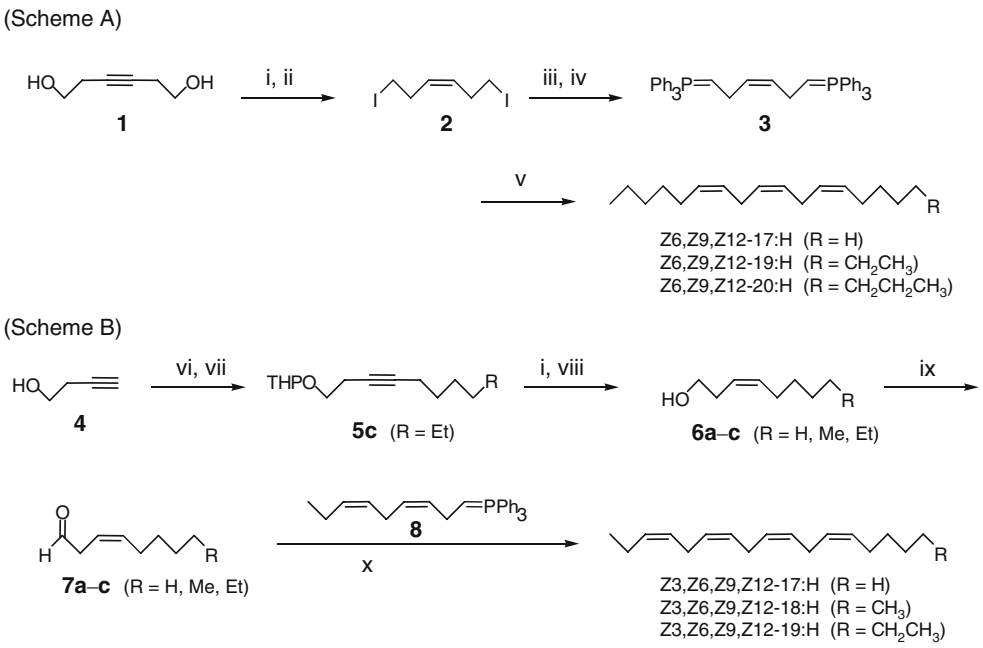

Fig. 1 Synthetic schemes for C_{17}–C_{20} (6*Z*,9*Z*,12*Z*)-6,9,12-trienes (Scheme A) and (3*Z*,6*Z*3,9*Z*,12*Z*)-3,6,9,12-tetraenes (Scheme B). Reagents: (i) H_2/Pd-$CaCO_3$-Pb/MeOH; (ii) I_2-PPh_3/imidazole/THF; (iii) PPh_3/benzene; (iv) $NaN(SiMe_3)_3$/THF; (v) $CH_3(CH_2)_4CHO$ + $CH_3(CH_2)_nCHO$ (*n*=3–6); (vi) DHP/PTSA; (vii) (1) BuLi/THF, (2) $CH_3(CH_2)_5Br$/HMPA; (viii) PTSA/EtOH; (ix) IBX/DMSO; (x) ylide **8**/THF

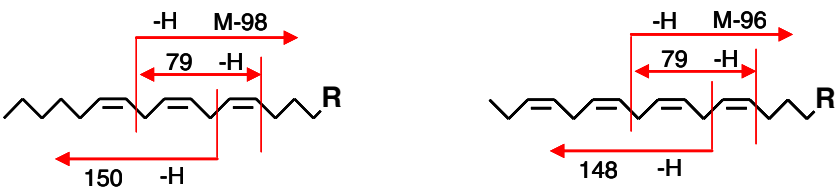
alcohol was oxidized to (*Z*)-3-decenal (**7c**), which was coupled with the ylide (**8**) to yield the C_{19} tetraene. ^{1}H NMR δ ppm: 0.88 (3H, d, *J*=7 Hz), 0.98 (3H, t, *J* = 7.5 Hz), ~1.3 (4H–8H for C_{17}–C_{19} tetraenes, m), 2.06 (4H, m), 2.82 (6H, m), 5.37 (8H, m). ^{13}C NMR δ ppm: Z3,Z6,Z9,Z12-17:H, 14.0 (C-17), 14.3 (C-1), 20.6 (C-2), 22.4 (C-16), 25.55, 25.63 and 25.64 (C-5, 8, 11), 27.0 (C-14), 31.8 (C-15), 127.1 (C-4), 127.6 (C-12), 127.96, 128.00, 128.50, and 128.52 (C-6, 7, 9, 10), 130.4 (C-13), and 132.0 (C-3); Z3,Z6,Z9,Z12-18:H, 14.1 (C-18), 14.3 (C-1), 20.6 (C-2), 22.7 (C-17), 25.56, 25.63 and 25.66 (C-5, 8, 11), 27.3 (C-14), 29.3 (C-15), 31.9 (C-16), 127.1 (C-4), 127.6 (C-12), 127.96, 128.01, 128.50, and 128.52 (C-6, 7, 9, 10), 130.5 (C-13), and 132.0 (C-3); Z3,Z6,Z9,Z12-19:H, 14.1 (C-19), 14.3 (C-1), 20.6 (C-2), 22.7 (C-18), 25.55, 25.63 and 25.66 (C-5, 8, 11), 27.3 (C-14), 29.0 and 29.7 (C-15, 16), 31.8 (C-17), 127.1 (C-4), 127.6 (C-12), 127.95, 128.01, 128.49, and 128.52 (C-6, 7, 9, 10), 130.5 (C-13), 132.0 (C-3); Z3,Z6,Z9,Z12-20:H, 14.1 (C-20), 14.3 (C-1), 20.6 (C-2), 22.7 (C-19), 25.56, 25.63 and 25.66 (C-5, 8, 11), 27.3 (C-14), 29.25, 29.31 and 29.7 (C-15, 16, 17), 31.9 (C-18), 127.1 (C-4), 127.6 (C-12), 127.95, 128.00, 128.49, and 128.52 (C-6, 7, 9, 10), 130.5 (C-13), 132.0 (C-3).



Field Trapping of Male Moths Rubber septa (white rubber, OD 8 mm; Sigma-Aldrich, St. Louis, MO, USA) were used as dispensers, and synthetic components (>98% purities on GC-MS analyses) dissolved in hexane (100 μl) were applied to them. Each lure was placed at the center of a sticky board trap (a 30×27 cm bottom plate with a roof; Sumitomo Chem. Co., Tokyo, Japan), which was set separately from the others by at least 10 m at about 1.5 m above the ground. Random screening tests for the synthetic polyenes were carried out in a mixed forest at Tama Forest Science Park in Hachioji in western Tokyo (24.42°N, 123.78°E), which includes many deciduous and broad-leaved evergreen trees, as well as many conifers, in 2008 and 2009. Three traps were used for each lure, and three other traps, including septa treated with only hexane (100 μl), were tested as a control to confirm specific attraction of male moths of two Geometrinae species, *Idiochlora ussuriaria* and *Jodis lactearia*. The lures were renewed every 3 mo, and the captured insects were examined twice a month from March to October. Synthetic pheromone lures targeting the *Hemithea tritonaria* males were evaluated at the forest in the Iriomote Islands, where the females were collected with a black light, in 2010 in a similar manner as for the random tests.

Table 1 Relative intensities of M^+ and some fragment ions in EI mass spectra of synthetic 6,9,12-trienes, 3,6,9,12-tetraenes, and the positional isomers

		Relative intensity (%) of fragment ions at indicated *m/z*									M^+	
		m/z	79[a-c]	80[a]	108[b]	110[c]	150[a]	163[c]	M–98[a]	M–56[b]	*m/z*	(%)

GC-MS of each compound was measured by EI ionization operated at 70 eV

[a-f] The diagnostic fragment ions for 6,9,12-treines (a), 3,6,9-trienes (b), 6,9,11-trienes (c), 3,6,9,12-tetraenes (d), 1,3,6,9-tetraenes (e), 3,6,9,11-tetraenes (f). The spectra data of 3,6,9- and 6,9,11-trienes and 1,3,6,9- and 3,6,9,11-tetraenes have been reported in our precious paper (Yamamoto et al., 2008) and other publications (Bestmann et al., 1982; Wong et al., 1984; Frérot et al., 1993; Millar, 2000). The following structures are proposals for the formation of diagnostic fragment ions of 6,9,12-trienes and 3,6,9,12-tetraenes

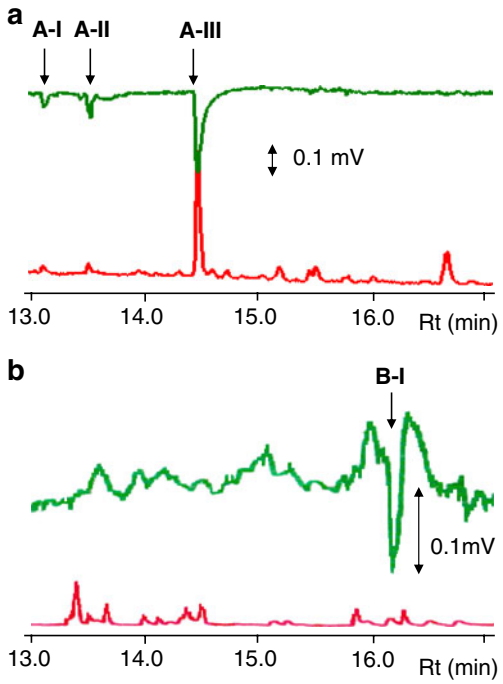

Fig. 2 GC-EAD analysis of the sex pheromone components of two Geometrinae species. **a**) Analysis of a crude pheromone extract of *Pamphlebia rubrolimbraria rubrolimbraria* (0.5 FE), indicating three EAG-active components [**A-I** (Z6,Z9-17:H), Rt 13.1 min; **A-II** (Z6, Z9,Z12-17:H), Rt 13.5 min; **A-III** (Z6,Z9,Z12-18:H), Rt 14.5 min]; and **b**) analysis of a crude pheromone extract of *Maxates versicauda microptera* (0.5 FE), indicating one EAG-active component [**B-I** (Z6, Z9,Z12-20:H), Rt 16.2 min]

Results

Characterization of Synthetic 6,9,12-Trienes and 3,6,9,12-Tetraenes The chemical structures of the synthetic polyenes were confirmed by NMR analysis. ^{1}H NMR analysis of each (6*Z*,9*Z*,12*Z*)-6,9,12-triene showed signals of six olefinic protons overlapped at δ 5.37 ppm. The ^{13}C NMR spectrum of Z6,Z9,Z12-18:H showed only nine signals because of its symmetric structure, and the allylic carbon signal at δ 27.2 ppm and double-allylic carbon signal at δ 25.6 ppm indicated the (*Z*)-configuration of three double bonds. Since the structures of other (6*Z*,9*Z*,12*Z*)-6,9,12-trienes are almost symmetric, overlapped signals of six olefinic carbons were recorded at similar chemical shifts of Z6,Z9,Z12-18:H. ^{1}H NMR analysis of each (3*Z*,6*Z*,9*Z*,12*Z*)-3,6,9,12-tetraene showed signals of eight olefinic protons also overlapped at δ 5.37 ppm. The ^{13}C NMR spectrum of each tetraene included eight olefinic carbon signals, which were interspersed from δ 127.1 ppm to δ 132.0 ppm with a similar pattern as that of (3*Z*,6*Z*,9*Z*)-3,6,9-trienes (Ando et al., 1993). The chemical shifts of three double-allylic carbon signals that appeared around δ 25.6 ppm indicated (*Z*)-configuration of four double bonds.

Table 1 shows the relative intensities of M^+ and some fragment ions in the EI mass spectra. While Z6,Z9,Z12-19:H and Z6,Z9,Z12-20:H produced a base peak at *m/z* 80, the 6,9,12-trienes universally showed $[H(CH=CH)_3]^+$ with a strong intensity at *m/z* 79. The spectra of four 6,9,12-trienes indicated that fragment ions at *m/z* 79, 80, 150, and M–98 are diagnostic. In the spectra of the 6,9,12-trienes, the relative intensities of ions at *m/z* 108 and M–56, which are diagnostic for 3,6,9-trienes, and ions at *m/z* 110 and 163, which are diagnostic for 6,9,11-trienes, are weak. Therefore, the 6,9,12-tienes are distinguished easily from the positional isomers. The mass spectra of four 3,6,9,12-tetraenes indicated diagnostic ions at *m/z* 79, 148, and M–96, but the intensities of latter two ions were not high. In the spectra of the 3,6,9,12-tetraenes, the relative intensities of ions at *m/z* 106 and M–54, which are diagnostic for

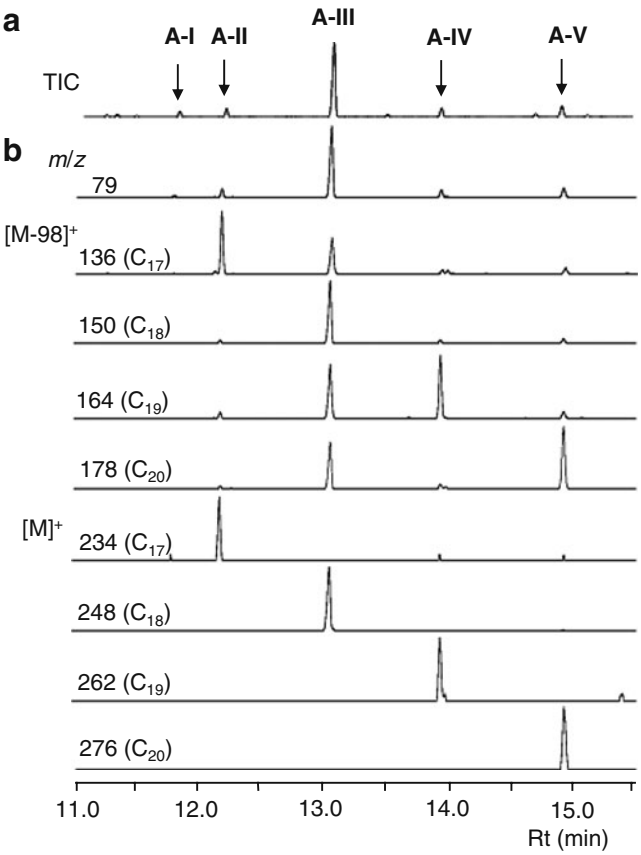

Fig. 3 GC-MS analysis of a crude pheromone extract of *Pamphlebia rubrolimbraria rubrolimbraria* (0.5 FE). **a**) Total ion chromatogram (TIC); and **b**) mass chromatograms of the ion at *m/z* 79 (a base peak) and other diagnostic ions of C_{17}–C_{20} 6,9,12-trienes, i.e., $[M–98]^+$ at *m/z* 136, 150, 164, and 178, and M^+ at *m/z* 234, 248, 262, and 276. The chromatograms show elution of the following four trienes: **A-II** (Z6,Z9,Z12-17:H), Rt 12.17 min; **A-III** (Z6,Z9,Z12-18:H), Rt 13.06 min; **A-IV** (Z6,Z9,Z12-19:H), Rt 13.91 min; and **A-V** (Z6,Z9, Z12-20:H), Rt 14.92 min

Table 2 Field attraction of male emerald moths by synthetic polyenes at a mixed forest in Tokyo

Lure	Numbers of captured males of Geometrinae species (A–C) [a]								
	March	Apr.	May	June	July	Aug.	Sept.	Oct.	Total
Z6,Z9,Z12-17:H	0	0	0	A: 5	A: 35	A: 17	A: 21	0	A: 78
Z6,Z9,Z12-20:H	0	0	0	B: 4	0	0	0	0	B: 4
Z3,Z6,Z9,Z12-20:H	0	C: 135	C: 63	0	0	0	0	0	C: 198
Others [b]	0	0	0	0	0	0	0	0	0

Three traps were used for each lure

[a] A, *Idiochlora ussuriaria*; B, Gen. et sp.; C, *Jodis lactearia*

[b] Control and other 6,9,12-trienes and 3,6,9,12-tetraenes with a C_{17}–C_{20} chain

1,3,6,9-tetraenes, and ions at *m/z* 108 and M–82, which are diagnostic for 3,6,9,11-tetraenes, are very weak. The 3,6,9,12-tetraenes are distinguished easily from these positional isomers.

Analysis of Pheromone Gland Extracts from Two Geometrinae Species A GC-EAD analysis of a pheromone gland extract (0.5 female equivalent, FE) from *P. r. rubrolimbraria* recorded three EAG-active components (**A-I**, **A-II**, and **A-III**) as shown in Fig. 2a. While the contents of **A-I** and **A-II** were low and the activities were weak, the antennal responses were reproducibly observed (N=3). The extract (0.5 FE) was analyzed by GC-MS to reveal the structures. Figure 3 shows mass chromatograms, which monitor M^+ of C_{17}–C_{20} 6,9,12-trienes (*m/z* 234, 248, 262, and 276) and their diagnostic fragment ions at *m/z* M–98 (*m/z* 136, 150, 164, and 178) and *m/z* 79. In addition to the identification of Z6,Z9,Z12-17:H for **A-II** and Z6,Z9,Z12-18:H for **A-III**, this analysis also indicates inclusion of two other trienyl components, Z6,Z9,Z12-19:H (**A-IV**) and Z6,Z9,Z12-20:H (**A-V**). The Rt values and mass spectra of **A-II**–**A-V** coincided with those of the synthetic 6,9,12-trienes. The GC-MS data of **A-I** (Rt 11.80 min), which showed M^+ at *m/z* 236 and characteristic fragment ions at *m/z* 67, 81, and 110, coincided with those of C_{17} 6,9-diene, i.e., Z6,Z9-17:H. The total ion chromatogram (TIC) indicated the mixing ratio of **A-I** – **A-V** to be about 5:10:100:10:15. On the other hand, a GC-EAD analysis of a pheromone gland extract (0.5 FE) from *M. v. microptera* recorded only one EAG-active component (**B-I**), as shown in Fig. 2b. The GC-MS analysis revealed it to be Z6,Z9, Z12-20:H, while the mass chromatograms did not suggest inclusion of other unsaturated hydrocarbons.

Attraction of Geometrinae Males by the Polyenes To obtain information about sex pheromones of the species inhabiting the main island of Japan, each of the synthetic 6,9,12-trienes and 3,6,9,12-tetraenes with a C_{17}–C_{20} chain was evaluated as a single component lure in the suburb of Tokyo. To date, new male attraction of two Geometrinae species has been found as follows: *Idiochlora ussuriaria* by Z6,Z9,Z12-17:H and *Jodis lactearia* by Z3,Z6,Z9,Z12-20:H. Table 2 shows the numbers of captured males, which were totaled each month. *Idiochlora ussuriaria* is a defoliator in a chestnut orchard and tea garden, and is recognized as a pest insect in Japan. The males of each species were attracted specifically by one polyene. Neither traps for control nor traps baited with other compounds captured males of these species. Although the attraction was uncertain because of how few males were trapped, one

Table 3 GC-MS data of authentic farnesenes and the pheromone component $\mathbf{X_1}$ produced by *H. tritonaria* females

Each compound was chromatographed on a DB-23 capillary column (0.25 mm ID×30 m) under programmed temperature (50°C for 2 min, 10°C/min to 160°C, and 4°C/min to 220°C), and the mass spectrum was measured by EI ionization operated at 70 eV

	Rt (min)	Relative intensity (%) of M^+ and fragment ions at indicated *m/z*

(3*E*,6*Z*)-Isomer	11.23	63	100	48	50	8	23	9	12	4
(3*E*,6*E*)-Isomer	11.42	50	100	48	42	36	6	2	5	1
Comp. $\mathbf{X_1}$	11.42	49	100	49	42	38	6	3	6	1

more Geometrinae species (Gen. et sp.) was captured using Z6,Z9,Z12-20:H. In this field screening test, the polyenes attracted no male moths belonging to other geometrid subfamilies or other lepidopteran families.

Identification of (3E,6E)-α-Farnesene In addition to Z6,Z9,Z12-18:H, the pheromone extract from *H. tritonaria* females included an unknown EAG-active substance, which was expressed as component $\mathbf{X_1}$ in our previous report (Yamakawa et al., 2009). The GC-MS analysis showed a short Rt, and M^+ at *m/z* 204, suggesting a C_{15} tetraene with a structure related to Z6,Z9,Z12-18:H. The base peak at *m/z* 93, however, cast doubt upon this possibility. In fact, synthetic Z3,Z6,Z9,Z12-15:H showed the same base peak at *m/z* 79 as the other 3,6,9,12-tetraenes did and was eliminated as a candidate. Eventually, analysis with a mass spectral database (NIST 98) indicated $\mathbf{X_1}$ to be α-farnesene. Direct comparison of the GC-MS data of $\mathbf{X_1}$ and the authentic standards of farnesene confirmed the identification, as shown in Table 3. Since the (3*Z*,6*E*)- and (3*E*,6*Z*)-isomers eluted faster than (3*E*,6*E*)-α-farnesene from the polar GC column used in this analysis, the Rt value of the (3*Z*,6*Z*)-isomer might be the smallest of four geometrical isomers of α-farnesene. GC-MS data of $\mathbf{X_1}$ coincided with those of (3*E*,6*E*)-α-farnesene. Although the authentic (3*Z*,6*Z*)-isomer was not available for a direct comparison, the (3*E*,6*E*)-configuration for $\mathbf{X_1}$ seems most likely.

Field Evaluation of (3E,6E)-α-Farnesene The activities of synthetic lures baited with a mixture of Z6,Z9,Z12-18:H and (3*E*,6*E*)-α-farnesene in a ratio of 10:0, 8:2, 5:5, 2:8, and 0:10 were examined in the Iriomote Islands. While the triene unmixed with farnesene captured a few males of *H. tritonaria*, as in our previous field test (Yamakawa et al., 2009), the number of captured males was significantly higher with the addition of farnesene (Fig. 4).

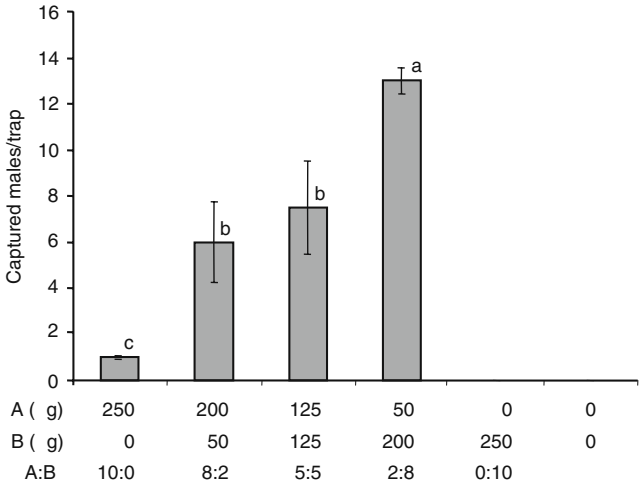

Fig. 4 Field evaluation of Z6,Z9,Z12-18:H (A) mixed with (3*E*,6*E*)-α-farnesene (B) for attraction of *Hemithea tritonaria* males. Tested at the Iriomote Islands from 1 July to 6 August 2009 using three traps for each lure. The bar indicates the means±standard errors (N=3). Columns with different lowercase letters are significantly different at P<0.05 by the Tukey-Kramer test

Discussion

As in a previous study of *Hemithea tritonaria* and *Thalassodes immissaria intaminata* (Yamakawa et al., 2009), we found novel 6,9,12-trienes in pheromone gland extracts from the females of *Pamphlebia rubrolimbraria rubrolimbraria* and *Maxates versicauda microptera* inhabiting a subtropical Japanese island (Figs. 2 and 3). Furthermore, field evaluation of the synthetic 6,9,12-trienes and 3,6,9,12-tetraenes revealed new instances of male attraction of other emerald moth species, *Idiochlora ussuriaria* and *Jodis lactearia*, on the main island (Table 2). Sex pheromones have not been investigated with any other Geometrinae species, and information about their pheromones is limited. These results, however, indicate that the double bond at a 12-position is characteristic of the sex pheromones secreted by some emerald moth species. Although many species of Geometrinae are defoliators, some agricultural pests, such as *I. ussuriaria*, belong to this taxonomic group.

As other Type II pheromones, 6,9,12-trienes and 3,6,9,12-tetraenes are expected to be produced starting from linoleic and linolenic acids, respectively, via biochemical reactions, such as chain elongation and decarboxylation. However, the key biosynthetic step is additional desaturation at the ω12-position of the dietary acids or the corresponding long-chain acids. The species in highly evolved lepidopteran groups mainly communicate by utilizing 6,9-dienes, 3,6,9-trienes, and their epoxides, which are derived from the acids without further modification of the polyene system (Ando et al., 2008). The newly identified 4,6,9- and 6,9,11-trienes, 1,3,6,9- and 3,6,9,11-tetraenes, and their epoxides (Ando et al., 2004; Ando, 2010) reveal additional pheromone diversity in this group of moths. These polyenes include an additional double bond at a conjugated position. The polyenes, which are unsaturated at the unique 12-position without a conjugated system, have not been identified from any species in Macrolepidoptera except for the emerald moths. Recently, 3,6,9,12,15-tricosapentaene and pentacosapentaene were discovered from three species in Pyralidae (Leal et al., 2005; Millar et al., 2005), many other species of which produce solely Type I pheromones. The pentaenes may be biosynthesized from linolenic acid by two additional desaturation steps, such as the biosynthesis of arachidonic acid from linolic acid (desaturation at the ω12- and ω15-positions). The Geometrinae pheromones found in our study are new natural products, which can be derived from

linolic or linolenic acids by only one desaturation at the ω12-position. It would be interesting to determine whether or not this limited desaturation is universally characteristic of the pheromones of many Geometrinae species.

It is noteworthy that (3*E*,6*E*)-α-farnesene was found in a pheromone extract of an emerald moth, *H. tritonaria*. The male antennae responded to synthetic (3*E*,6*E*)-α-farnesene, and inclusion of this sesquiterpene synergized the attraction of males to Z6,Z9,Z12-18:H. α-Farnesene was isolated from natural coating of apples, and Dufour's gland in ants in the 1960s. Since then, the compound has been identified from many plants and insects (El-Sayed, 2010). α-Farnesene from plants wounded by herbivores is thought to play a role in plant defense by attracting predators and parasitoids (Van den Boom et al., 2004). In the case of Lepidoptera, α-farnesene occurs in androconial organs in males of a swift moth (Schulz et al., 1990) and Danainae butterflies (Schulz et al., 1993), and larvae of some Papilionidae butterflies secrete β-farnesene from osmeteria to defend the attacks of predatory enemies, but this is the first instance in which farnesene is part of a female moth sex pheromone. *In vivo* experiments with ^{13}C-labeled precursors revealed that β-farnesene was biosynthesized by the usual terpenoid pathway in the organ (Honda, 1990), suggesting the possibility of *de novo* synthesis of α-farnesene in the emerald moth. Females of many species, including moths (Yan et al., 2003; Binder et al., 1995), recognize α-farnesene as a chemical cue to find their host plants, indicating that the antennae of females evolved receptors specific to this compound. The *H. tritonaria* males evidently have a similar perception system to smell α-farnesene from virgin conspecific females. How and why emerald moth incorporate this commonly occurring sesquiterpene in sex pheromone is mysterious. Further investigation with other species of Geometrinae should be developed to understand the specificity of this unique combination of compounds from two different biochemical pathways, and to determine if β-farnesene or other geometrical isomers of α-farnesene are pheromone components in other species.

Acknowledgments We are grateful to Drs. F. Mochizuki and T. Fukumoto of Shin-Etsu Chemical Co., Ltd for supplying 3-hexyne-1,6-diol and (3*Z*,6*Z*)-3,6-nonadien-1-ol and Dr. S. Hashimoto for identification of geometrid species and Dr. T. Inoue of Tama Forest Science Park for helpful comments and support in the field evaluation in Tokyo. This study was supported in part by a Grand-in-Aid for Scientific Research (20380031) from the Ministry of Education, Culture, Sports, Science, and Technology of Japan.

Abstract We previously identified the basic structure of the female-produced sex attractant pheromone of the cerambycid beetle, *Prionus californicus* Motschulsky (Cerambycidae: Prioninae), as 3,5-dimethyldodecanoic acid. A synthesized mixture of the four stereoisomers of 3,5-dimethyldodecanoic acid was highly attractive to male beetles. Here, we describe stereoselective syntheses of three of the four possible stereoisomers, and the results of laboratory and field bioassays showing that male beetles are attracted specifically to (3*R*,5*S*)-3,5-dimethyldodecanoic acid, but not to its enantiomer, (3*S*,5*R*)-3,5-dimethyldodecanoic acid, indicating that the (3*R*,5*S*)-enantiomer is the active pheromone component. The diastereomeric (3*R*,5*R*)- and (3*S*,5*S*)-enantiomers were excluded from consideration because their gas chromatographic retention times were different from that of the insect-produced compound. The mixture of the four stereoisomers of 3,5-dimethyldodecanoic acid was as attractive to male *P. californicus* as the (3*R*,5*S*)-enantiomer, indicating that none of the other three stereoisomers inhibited responses to the active enantiomer. Beetles responded to as little as 10 ng and 10 μg of synthetic 3,5-dimethyldodecanoic acid in laboratory and field studies, respectively. Field studies indicated that capture rate did not increase with dosages of 3,5-dimethyldodecanoic acid greater than 100 μg. In field bioassays, males of a congeneric species, *P. lecontei* Lameere, were captured in southern California but not in Idaho.

Introduction

Volatile male-produced sex or aggregation pheromones have been reported for an increasing number of cerambycid beetle species (Silk et al., 2007; Lacey et al., 2009; Millar et al., 2009, and references therein; Ray et al., 2009a, b), most of which are members of the subfamilies Aseminae and Cerambycinae (Monné and Hovore, 2005). Female-produced pheromones also have been identified for two species that formerly were placed in the Cerambycidae, *Migdolus fryanus* Westwood and *Verperus xatarti* Dufour (Leal et al., 1994; Boyer et al., 1997), but whose family-level taxonomy is uncertain (Napp, 1994; Bense, 1995; Dong and Yang, 2003). Many cerambycid species in the subfamily Prioninae have morphological and behavioral traits that are associated with production of pheromones by females in other types of insects (Thornhill and Alcock, 1983; Gemeno and Schal, 2003), including more elaborate

antennal structures in males than females, and a more sedentary nature in females than males (Summerland, 1932; Benham and Farrar, 1976; Santos Ferreira, 1980; Hovore, 1981). Moreover, males of some prionine species display behaviors indicative of responses to volatile pheromones produced by females (Rotrou, 1936; Edwards, 1961; Benham and Farrar, 1976; Gwynne and Hostetler, 1978).

The prionine species *Prionus californicus* Motschulsky, is broadly distributed in western North America and is an economically important pest of hop, *Humulus lupulus* L. (Urticales: Cannabaceae), in the northwestern United States (Bishop et al., 1984). Adult *P. californicus* are active during summer and early fall, and are crepuscular (Linsley, 1962). They are among the largest cerambycids in North America, ranging in body length from 2.5 to 4.5 cm (volumes indexed in Linsley and Chemsak, 1997). Adult females oviposit in soil near the base of living woody plants; larvae feed on roots and rhizomes, requiring 3–5 yr to complete development (Linsley, 1962).

We previously reported that female *P. californicus* produce a volatile sex pheromone associated with an eversible structure on the ovipositor, and that males are strongly attracted to this pheromone (Cervantes et al., 2006; Barbour et al., 2007). The basic structure of the pheromone was identified as 3,5-dimethyldodecanoic acid by gas chromatographic (GC) retention time and mass spectral matches with those of one of the two peaks in a synthetic standard composed of an approximately equal mixture of all four stereoisomers of this compound (Rodstein et al., 2009). In the work reported here, we determined that the biologically active stereoisomer is (3*R*,5*S*)-dimethyldodecanoic acid and confirmed the activity of the synthetic pheromone in laboratory and field bioassays. We also showed that the mixture of stereoisomers is as active as the insect-produced enantiomer, indicating that the unnatural stereoisomers do not antagonize attraction to the natural enantiomer.

Methods and Materials

Source of Insects Larvae of *P. californicus* were collected in fall of 2007 from commercial hop yards in southwestern Idaho and reared to adulthood in a field plot at the Southwest Idaho Research and Extension Center (Canyon Co., ID, USA). Larvae were reared individually in 19-l plastic buckets buried in the ground to within ~10 cm of their tops. Each bucket had two 0.75 cm holes in the bottom for drainage, and buckets were filled with soil to ~10 cm from the top. We collected late stage larvae (5–7.5 cm long) from uprooted hop crowns, and buried each larva ~10 cm deep in the soil in a bucket, with a section of fresh hop rhizome for food.

We cut back hop plants growing from rhizomes in the buckets in early spring 2008, and we fitted buckets with lids that had the centers replaced with aluminum screen. Each bucket was drip-irrigated (8 l/hr) for 10 min every other day. Adult beetles emerged in buckets in July 2008 and were collected and held individually in the laboratory in ventilated glass jars (~500–1000 ml; 22°C, 16:8 hr L:D). Males and females were unmated and held in separate growth chambers. Beetles used in bioassays were 1–14-d-old, vigorous, and apparently healthy.

Syntheses of Stereoisomers of 3,5-Dimethyldodecanoic Acid Tetrahydrofuran was dried and purified by distillation from sodium-benzophenone ketyl under argon. Solutions of crude products were dried over anhydrous Na_2SO_4 and concentrated by rotary evaporation under reduced pressure, unless specified otherwise. Crude products were purified by flash or vacuum flash chromatography on 230–400-mesh silica gel. ^{1}H- and ^{13}C-NMR spectra were recorded on a Varian INOVA-400 spectrometer (Palo Alto, CA, USA) (400 and 100.5 MHz, respectively), as $CDCl_3$ solutions. Integer resolution mass spectra were obtained with a Hewlett-Packard (HP) 6890 GC (Avondale, PA) interfaced to an HP 5973 mass spectrometer (MS), in EI mode (70 eV) with helium carrier gas. The GC was equipped with a DB5-MS column (25 m×0.20 mm ID × 0.25 μ film). Resolutions of enantiomers were attempted on a Cyclodex-B column (30 m×0.3 mm ID, J&W Scientific, Folsom, CA, USA) using isothermal conditions or temperature programs of 2–4°C per min. Optical rotations were measured in CH_2Cl_2 on a Perkin Elmer 241 polarimeter (Na and Hg lamps) (Perkin Elmer, Waltham, MA, USA) in a 1 ml water-jacketed cell (10 cm path length) at 24°C. All rotations were averaged over three or four measurements. IR spectra were taken as films on NaCl plates on a Bruker Equinox 55 FTIR instrument (Freemont, CA, USA).

*Methyl (E)-2-Decenoate (**2**) (Fig. 1)* (*E*)-2-decenoic acid (**1**) (20.91 g, 123 mmol, Acros Organics, Morris Plains, NJ, USA) was dissolved in methanol (82 ml) in a dry flask under argon at room temperature. Acetyl chloride (1.74 ml, 25 mmol) was added carefully dropwise (vigorous reaction!), and the reaction stirred for 16 h and then quenched with aqueous sodium bicarbonate. The resulting mixture was extracted x 4 with ether. The combined ether extracts were washed with brine, dried, and concentrated. The resulting oil was Kugelrohr distilled (oven temp. ~87°C, 1 Torr) to yield 14.95 g (81 mmol, 66%) of methyl (*E*)-2-decenoate (**2**). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.89 (t, *J*= 6.8 Hz, 3 H), 1.29 (m, 8 H), 1.46 (m, 2 H), 2.16–2.23 (m, 2 H), 3.73 (s, 3 H), 5.82 (d, *J*=15.6 Hz, 1 H), 6.98 (dt, *J*= 15.4, 7.0 Hz, 1 H). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 14.2, 22.8, 28.2, 29.3 (2C), 31.9, 32.4, 51.5, 120.9, 150.0, 167.4.

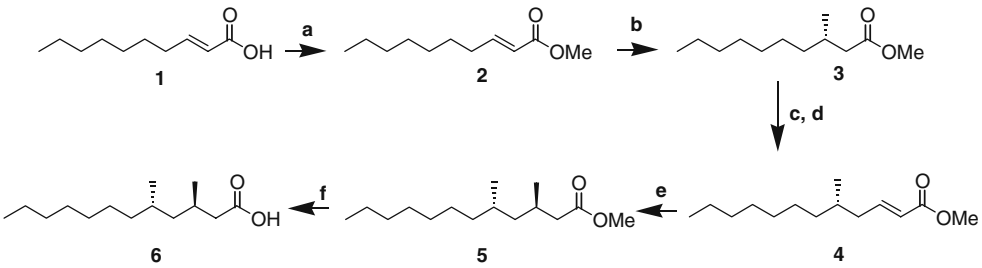

Fig. 1 Synthesis of (*3R,5S*)-(+)-3,5-dimethyldodecanoic acid. a) acetyl chloride, MeOH; b) MeMgBr, CuI, (*S*)-Tol-BINAP, *t*-butylmethyl ether; c) DIBAL-H, hexane; d) methyl (triphenylphosphoranylidene) acetate, THF; e) MeMgBr, CuI, (*R*)-Tol-BINAP, *t*-butylmethyl ether; f) KOH, MeOH/H_2O

MS: *m/z* (%): 153 (M^+ - 31, 3), 141 (3), 110 (20), 96 (17), 87 (81), 69 (40), 55 (86). IR (film): 2953, 2928, 2856, 1728, 1658, 1460, 1436, 1378, 1313, 1270, 1197, 1170, 1127, 1041, 979, 921, 854, 720 cm^{-1}.

*Methyl (S)-(-)-3-Methyldecanoate (***3***)* (*S*)-(-)-2,2′-Bis(di-*p*-tolylphosphino)-1,1′-binaphthyl (= (*S*)-Tol-BINAP, 0.45 g, 0.66 mmol; Alfa Aesar, Ward Hill, MA, USA) and CuI (84 mg, 0.44 mmol) were added to a dry three-neck flask charged with CH_2Cl_2 (55 ml) under argon. After stirring 30 min, the CH_2Cl_2 was removed *in vacuo* and replaced with *t*-BuOMe (27 ml), and the mixture stirred for 30 min. The *t*-BuOMe was removed *in vacuo* and the resulting neon green-yellow solid diluted with a second portion of *t*-BuOMe (88 ml). The mixture then was cooled to −20°C and MeMgBr (38.3 ml, 2.4 M solution in Et_2O, 92 mmol) added dropwise. After stirring for 20 min, a solution of methyl (*E*)-2-decenoate **2** (4.07 g, 22.1 mmol) in *t*-BuOMe (27 ml) was added via syringe pump over 4.5 h, maintaining the temperature at or slightly below −20°C. After stirring at −20°C for another 2 h, the reaction mixture was quenched with MeOH (10 ml), followed by saturated NH_4Cl solution. The mixture was extracted with Et_2O (4×75 ml) and the combined organic extracts were washed with brine, dried, and concentrated. The residue was purified by flash chromatography (hexane/EtOAc 97:3), then Kugelrohr distilled (oven temp. ~92°C, 1 Torr) yielding 2.39 g (11.9 mmol, 53%) of methyl (*S*)-(-)-3-methyldecanoate (**3**). $[\alpha]_D^{20}$=−4.2° (c=2.03, CH_2Cl_2). ^1H NMR (400 MHz, $CDCl_3$): δ 0.88 (t, *J*=6.7 Hz, 3 H), 0.93 (d, *J*=6.6 Hz, 3 H), 1.26 (m, 12 H), 1.95 (m, 1 H), 2.09 (m, 1 H), 2.31 (dd, *J*=14.7, 6.0 Hz, 1 H), 3.67 (s, 3 H). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 14.3, 19.9, 22.9, 27.1, 29.5, 29.9, 30.6, 32.1, 36.9, 41.9, 51.5, 174.0. MS: *m/z* (%): 200 (M^+, 1), 185 (1), 169 (3), 157 (3), 143 (2), 101 (39), 87 (5), 74 (100), 55 (16), 43 (38). IR (film) 2957, 2928, 2855, 1732, 1460, 1437, 1379, 1167 cm^{-1}.

*Methyl (2E,5S)-(-)-5-Methyldodec-2-enoate (***4***)* Methyl (*S*)-(-)-3-methyldecanoate (**3**) (1.79 g, 8.93 mmol) was dissolved in hexane (10 ml) in a dry flask under argon, and cooled to −78°C. Diisobutylaluminum hydride (DIBAL-H, 1 M in hexane, 9.8 ml, 9.8 mmol; Aldrich Chemical Co., Milwaukee, WI, USA) was added dropwise. The mixture was stirred for 1 hr, and then another 1 ml of DIBAL-H was added to reduce small amounts of residual starting material. After stirring another 30 min, MeOH (1.13 ml) was added dropwise, and the mixture stirred for 30 min during which time a white suspension formed. Methyl (triphenylphosphoranylidene) acetate (5.97 g, 17.9 mmol; Aldrich Chemical Co.) then was added at −78°C, followed by THF (45 ml). The reaction was allowed to warm to room temperature overnight and stirred for an additional 48 h. The mixture was diluted with Et_2O (20 ml) and 6 M HCl (40 ml), and stirred until two clear layers were observed. After separation of the organic layer, the aqueous phase was extracted x 3 with Et_2O, and the combined organic extracts were washed with saturated aqueous $NaHCO_3$ and brine, dried, and concentrated. The residue was taken up in hexane and filtered through a small plug of silica gel to remove the bulk of the triphenylphosphine oxide. The filtrate was concentrated and purified by flash chromatography (hexane/EtOAc 98:2 then 96:4). The product was purified further by Kugelrohr distillation (oven temp. ~110°C, 1 Torr) to yield methyl (2*E*,5*S*)-(-)-5-methyldodec-2-enoate (**4**) (1.01 g, 2.5 mmol, 50%). $[\alpha]_D^{20}$=−1.3° (c=1.99, CH_2Cl_2). ^1H NMR (400 MHz, $CDCl_3$): δ 0.88 (t, *J*= 6.4 Hz, 3 H), 0.89 (d, *J*=6.8, 3 H), 1.26 (m, 12 H), 1.60 (m, 1 H), 2.03 (m, 1 H), 2.20 (m, 1 H), 3.73 (s, 3 H), 5.81 (d, *J*= 15.6 Hz, 1 H), 6.95 (m, 1 H). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 14.3, 19.8, 22.9, 27.2, 29.5, 30.0, 32.1, 32.7, 36.8, 39.9, 51.5, 122.1, 148.9, 167.3. MS: *m/z* (%): 195 (2, M^+-33), 155 (1), 142 (5), 100 (100), 85 (11), 71 (21), 57 (27), 43 (60). IR (film) 3054, 2956, 2927, 2855, 2306, 1718, 1655, 1437, 1378, 1322, 1265, 1195, 1143, 982, 909, 737 cm^{-1}.

*Methyl (3R,5S)-(+)-3,5-Dimethyldodecanoate (***5***)* (*R*)-Tol-BINAP (54 mg, 0.08 mmol) and CuI (10 mg, 0.053 mmol) were stirred in CH_2Cl_2 (10 ml) in a dry flask under argon. After 30 min, the solvent was removed *in vacuo* and replaced with *t*-BuOMe (10 ml), and the mixture stirred for 30 min. The *t*-BuOMe was removed *in vacuo*, and the resulting green-yellow solid was resuspended in *t*-BuOMe (10 ml). The mixture was cooled to −20°C and MeMgBr (5.4 ml, 2.5 M solution in Et_2O, 13.5 mmol) added dropwise. After stirring for 20 min, a solution of methyl (2*E*,5*S*)-(-)-5-methyldodec-2-enoate (**4**) (0.6 g, 2.6 mmol)

in *t*-BuOMe (3.2 ml) was added via syringe pump over 4.5 hr. After stirring at −20°C for another 2 hr, the reaction mixture was quenched with MeOH (3 ml), followed by saturated NH_4Cl solution. The mixture was extracted with Et_2O (4x), and the combined organic extracts were washed with brine, dried, and concentrated. The residue was purified by flash chromatography (hexane/EtOAc, 97:3), then Kugelrohr distillation (oven temp. ~100°C, 1 Torr) to yield 0.074 g (0.31 mmol, 12%) of methyl (*3R,5S*)-(+)-3,5-dimethyldodecanoate (**5**) (diastereomeric purity 90.7% by GC). $[\alpha]_D^{20}$=+16.0º (c=1.4, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.84 (t, *J*=6.8 Hz, 3 H), 0.89 (d, *J*=6.8 Hz, 3 H), 0.90 (d, *J*=6.4 Hz, 3 H), 1.12 (m, 2 H), 1.27 (m, 12 H), 1.46 (br s, 1 H), 2.08 (m, 2 H), 2.27 (dd, *J*=14.4, 6.0 Hz, 1 H), 3.67 (s, 3 H). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 14.3, 19.5, 19.6, 22.9, 27.2, 28.0, 29.6, 30.1, 30.2, 32.1, 37.9, 42.6, 44.6, 51.5, 173.9. MS: *m/z* (%): 242 (M^+, 1), 227 (1), 211 (1), 185 (4), 169 (2), 157 (1), 143 (4), 125 (2), 115 (5), 101 (40), 83 (12), 74 (100), 55 (24), 43 (47). IR (film) 2957, 2927, 2854, 1733, 1461, 1436, 1379, 1191, 1007, 910 cm^{-1}.

*(3R,5S)-(+)-3,5-Dimethyldodecanoic Acid (**6**)* A mixture of methanol (1.1 ml), water (1.2 ml), KOH (0.32 g, 5.2 mmol), and methyl (3*R*,5*S*)-(+)-3,5-dimethyldodecanoate (**5**) (70 mg, 0.29 mmol) were stirred overnight at room temperature. The mixture was extracted with hexane, and the remaining aqueous layer acidified with 1M HCl and extracted three times with Et_2O. The combined ether layers were washed with brine, dried, and concentrated, yielding (3*R*,5*S*)-(+)-3,5-dimethyldodecanoic acid (**6**) (54.2 mg, 82%). $[\alpha]_D^{20}$=+18.1º (c=1.08, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.87 (m, 6 H), 0.94 (d, *J*=6.4 Hz, 3 H), 1.14 (m, 2 H), 1.27 (m, 12 H), 1.46 (br s, 1 H), 2.06 (m, 1 H), 2.17 (dd, *J*=14.8, 8.0 Hz, 1 H), 2.31 (dd, *J*=14.8, 6.0 Hz, 1 H). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 14.3, 19.5, 19.6, 22.9, 27.2, 27.8, 29.5, 30.1, 30.2, 32.1, 37.9, 42.4, 44.5, 179.1. MS: *m/z* (%): 228 (M^+, 1), 171 (8), 129 (14), 111 (11), 101 (13), 87 (74), 69 (42), 57 (57), 43 (100). IR (film) 2958, 2925, 2872, 2854, 1709, 1463, 1410, 1379, 1296, 1233, 1196, 937, 722 cm^{-1}.

*Methyl (R)-(+)-3-Methyldecanoate (**7**)* This compound was prepared in analogous fashion to compound **3** from methyl (*E*)-2-decenoate (**2**), using (*R*)-(+)-2,2′-bis(di-p-tolylphosphino)-1,1′-binaphthyl (= (*R*)-Tol-BINAP) as catalyst, yielding methyl (*R*)-(+)-3-methyldecanoate (**7**) in 49% isolated yield. $[\alpha]_D^{20}$=+4.8° (c=2.02, CH_2Cl_2). ^{1}H NMR, ^{13}C NMR, IR, and mass spectra matched those of the (*S*)-enantiomer (**3**).

*Methyl (2E,5R)-(+)-5-Methyldodec-2-enoate (**8**)* This compound was made in analogous fashion to compound **4** by using methyl (*R*)-(+)-3-methyldecanoate (**7**) instead of the methyl (*S*)-(-)-3-methyldecanoate (**3**) to afford the desired (*E*)-alkenoate in 27% yield after purification. A further 41% of a mixture of the (*E*)- and (*Z*)-isomers also was obtained. $[\alpha]_D^{20}$=+1.8º (c=2.06, CH_2Cl_2). The ^{1}H NMR, ^{13}C NMR, IR, and mass spectra agreed with those of the (*S*)-enantiomer **4**.

*Methyl (3S,5R)-(-)-3,5-Dimethyldodecanoate (**9**)* This enantiomer was made in analogous fashion to compound **5** in 23% isolated yield from methyl (2*E*,5*R*)-(+)-5-methyl-2-dodecenoate (**8**) (diastereoisomeric purity, 92.5%), using (*S*)-Tol-BINAP instead of (*R*)-Tol-BINAP as catalyst. $[\alpha]_D^{20}$=−18.2° (c=1.13, CH_2Cl_2). ^{1}H NMR, ^{13}C NMR, IR, and mass spectra matched those of the corresponding (3*R*,5*S*)-(+)-enantiomer (**5**).

*(3S,5R)-(-)-3,5-Dimethyldodecanoic Acid (**10**)* Methyl (3*S*,5*R*)-(-)-3,5-dimethyldodecanoate (**9**) was hydrolyzed in similar fashion to compound **6**, yielding (3*S*,5*R*)-(-)-3,5-dimethyldodecanoic acid (**10**) in 46% yield. $[\alpha]_D^{20}$= −19.2 º (c=0.48, CH_2Cl_2). ^{1}H NMR, ^{13}C NMR, IR, and mass spectra matched those of the corresponding (3*R*,5*S*)-enantiomer (**6**).

*Methyl (3S,5S)-(-)-3,5-Dimethyldodecanoate (**11**)* This diastereomer was made in analogous fashion in 84% isolated yield from methyl (2*E*,5*S*)-(-)-5-methyl-2-dodecenoate (**4**) (diastereomeric purity, 97.5% by GC), using (*S*)-Tol-BINAP as catalyst for the asymmetric addition reaction. $[\alpha]_D^{20}$=−2.2° (c=1.54, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.87 (t, *J*=6.8 Hz, 3 H), 0.91 (d, J=9.2 Hz, 3 H), 0.93 (d, *J*=6.4 Hz, 3 H), 1.03 (m, 2 H), 1.27 (m, 12 H), 1.45 (br, 1 H), 2.05 (m, 2 H), 2.31 (m, 1 H), 3.67 (s, 3 H). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 14.3, 20.3, 20.6, 22.9, 27.0, 28.1, 29.6, 30.1, 30.2, 32.1, 36.9, 41.8, 44.9, 51.5, 174.0. MS: *m/z* (%): 242 (2), 227 (1), 211 (2), 185 (11), 166 (3), 143 (9), 125 (3), 111 (7), 101 (73), 83 (17), 74 (100), 55 (32), 43 (54). IR (film) 2966, 2906, 2848, 2257, 1740, 1464, 1441, 1373, 1165, 1010, 913, 838, 733 cm^{-1}.

Laboratory Bioassays of Synthetic Pheromone We tested the responses of male *P. californicus* to synthetic pheromone using a rectangular olfactometer (80×10×19.5 cm, L × H × W) constructed of polyethylene with a removable glass top (see Cervantes et al., 2006). Both openings, at one end of the olfactometer were fitted with PVC female adapters (3.75 cm diam), to which we attached containers (17.8 cm-long sections of 3.75 cm diam clear PVC pipe, covered with aluminum screen at one end, and the other end inserted into a screened PVC male adapter) that held sample or control odor sources. Air was pulled (3.2 $m.s^{-1}$) from outside the

building through an activated charcoal filter, then through the sample containers and into the olfactometer chamber.

We conducted bioassays in July 2008 under a 25-W incandescent red light to minimize the influence of visual signals, during the 2nd to 6th hr of scotophase, when adult beetles typically are active (Barbour et al., 2007). All males walked rather than attempting to fly in the olfactometer. A positive score was given to males that walked upwind and reached a sample container that held the pheromone lure within 5 min. A negative score was given to those that reached the control container within 5 min. Beetles that did not reach either container within 5 min were scored "no response". We washed the olfactometer with soap (1–2% Micro-90®, Cole Parmer Instrument Co., Vernon Hills, IL, USA) and water after every five trials, then rinsed it with acetone, allowed it to air dry, and switched sample containers between sides to control for location effects. We tested at least five males against each treatment/dose and repeated the bioassays on at least 3 d ($N \geq 15$ for each treatment).

We tested the response of male *P. californicus* to synthetic 3,5-dimethyldodecanoic acid in the olfactometer using 1, 10, or 100 ng of material in 10 µl hexane (HPLC grade, Chromasolv®, Sigma-Aldrich, St. Louis, MO, USA). A filter paper disc (1.5 cm diam., Grade 413, VWR, West Chester, PA, USA) was placed on a piece of clean aluminum foil (~2.5 cm^2) and pheromone solution applied to the paper. The aluminum foil square and disc were placed into a randomly-selected sample container. A piece of aluminum foil and paper disc treated with 10 µl of hexane (control) was placed in the other container. Bioassays on each day were conducted using the lowest dose (1 ng) first, and then sequentially higher doses, so as to minimize any effects from contamination of the olfactometer by a previous treatment.

We compared the responses of males to (3*R*,5*S*)- and (3*S*,5*R*)-dimethyldodecanoic acid in the olfactometer using the methods described above. We tested 0.25, 2.5, and 25 ng of each enantiomer, corresponding to the approximate amount of each of the four stereoisomers in the 1, 10, and 100 ng range of doses of 3,5-dimethyldodecanoic acid that previously had been tested. To further evaluate the activity of (3*S*,5*R*)-dimethyldodecanoic acid, we ran bioassays using the lowest dose that had elicited a significant positive response from males to the (3*R*,5*S*)-enantiomer (2.5 ng; see Results) tested against a solvent control. The two diastereomers, (3*R*,5*R*)- and (3*S*,5*S*)-dimethyldodecanoic acid, were not tested in laboratory or field bioassays because their GC retention times were different from that of the insect-produced pheromone, conclusively eliminating them as candidates for the pheromone (see below). The mixture of four 3,5-dimethyldecanoic acid stereoisomers was synthesized as previously described (Rodstein et al., 2009), and the syntheses of the stereoisomers are described above.

Field Bioassays of Synthetic Pheromone Field bioassays of 3,5-dimethyldodecanoic acid and (3*R*,5*S*)-dimethyldodecanoic acid were conducted in southern California and Idaho. Our primary study site in southern California was the Santa Rosa Plateau Ecological Reserve (SRPER; Riverside Co.), a 5,600-ha area with extensive stands of mature oaks (*Quercus agrifolia* Née and *Q. engelmannii* Greene), coastal sage scrub, and chaparral. Adult *P. californicus* are commonly attracted to lights at the visitor center (SRPER staff, pers. comm.). Field bioassays at SRPER were conducted 2–6 July 2008 (maximum air temperatures 28–35°C, no precipitation). Field bioassays also were conducted in commercial hop yards (4–17 ha) in Canyon County, Idaho, that were naturally infested with *P. californicus* (unpub. data). Bioassays in Idaho were conducted 8–15 July 2008 (maximum air temperatures 28–36°C, no precipitation).

Traps used in California consisted of ~1.9-l wide-mouth plastic jars (P.E.T.; model 55–650, General Bottle Supply Company, Los Angeles, CA, USA), fitted with a 1.9-l plastic funnel, with the spout cut off to leave a ~3.5 cm diam hole at the bottom. A ~3.5 cm diam hole was cut into the threaded lid of the jar, and the funnel spout inserted into the hole and glued in place so that the spout was inside the jar. We treated interior surfaces of funnels and jars with Rain-X® glass treatment (Houston, TX, USA) to render them slippery. Traps were buried so that the rim of the funnel was nearly flush with the ground and, as required, a ramp to the funnel rim was built from soil and leaf litter. Lures were suspended ~15 cm over the trap with a stiff wire that was attached to the funnel. It was not possible to set up traps in linear transects at SRPER because of the abundant large rocks and boulders, so they were positioned arbitrarily under the canopy of oaks, at least ~10 m apart.

Traps in Idaho consisted of 19-l polypropylene buckets (38 cm tall × 30 cm diam) fitted with aluminum funnels (model 2815B, BioQuip, Rancho Dominguez, CA, USA). Traps were buried 90 m apart, within rows of hop plants, with the tops of funnels flush with the soil surface. Lures were suspended over funnels by attaching them to the wire bucket handles, which had been modified to remain upright.

Lures for traps in both California and Idaho consisted of clear low density polyethylene press-seal bags (Bagette model 14770, 5.1×7.6 cm, 0.05 mm wall thickness, Cousin Corp., Largo, FL, USA). Dilutions of synthetic pheromone or solvent were pipetted into the bags, which then were sealed. Experiments were set up in late afternoon or dusk, and treatments were assigned randomly to traps. Beetles were collected from traps the next morning or the morning

of the second day. In both locations, captured beetles were released into vegetation, at least 25 m away from the nearest trap, immediately after they were collected from traps.

Treatments in bioassays conducted at SRPER in southern California were as follows: 3,5-dimethyldodecanoic acid (10 mg in 100 μl hexane), (3*R*,5*S*)-dimethyldodecanoic acid (2.5 mg in 100 μl hexane), (3*S*,5*R*)-dimethyldodecanoic acid (2.5 mg in 100 μl hexane), and control (100 μl hexane). Treatments were assigned randomly to four traps in each of four blocks (at least 400 m apart) on 2 and 3 July 2008. We recorded the number of male *P. californicus* in traps (no females were captured), and rotated traps one position within blocks after the first day. Males of the congeneric species, *Prionus lecontei* Lameere, also were caught in traps at the southern California site, and trap captures recorded.

Lure doses in bioassays conducted in Idaho were as follows: 3,5-dimethyldodecanoic acid (1 mg in 100 μl hexane), (3*R*,5*S*)-dimethyldodecanoic acid (250 μg in 100 μl hexane), and control (100 μl hexane). We also included positive control traps, which were baited with a single live female *P. californicus*, to compare responses of males to natural *versus* synthetic pheromone. Unmated females were reared as described above, and were confined in a wire-mesh cage attached to the wire handle of trap buckets, analogous to the positioning of the synthetic lures. Treatments were randomized in each of four different hop yards on 14 July 2008. Captured males were collected from traps the next morning. The experiment was replicated on 15 July 2008 with treatments re-randomized, and using fresh females.

Dose–response trials with the synthetic pheromone were conducted in both southern California and Idaho. At SRPER in California, five traps in each of the four blocks (see above) were assigned randomly to lures containing 0, 10, 32, 100, and 320 μg of 3,5-dimethyldodecanoic acid in 100 μl of hexane. The experiment was set up on 4 July 2008 and run for three consecutive days (treatments rotated each day). In Idaho, we conducted two dose–response experiments, each in the same four hop yards. In the first (high-dose) experiment, traps were baited with 0, 10, 100, 1000, or 10^4 μg of the synthetic mixture of isomers (in 100 μl hexane) on 8 and 9 July 2008. The second (low-dose) experiment tested the responses of male beetles to 0, 0.1, 1, 10, and 100 μg in 100 μl hexane on 10 and 11 July 2008.

Statistics For laboratory bioassays, we compared the number of males that responded positively to treatments *versus* controls, or to one of the two enantiomers, with χ^2 goodness-of-fit tests. For field experiments, differences between treatments in numbers of beetles captured were tested separately for *P. californicus* and *P. lecontei* with the nonparametric Friedman's test (blocking by replicate; PROC FREQ with CMH option; SAS Institute, 2001), because assumptions of analysis of variance were violated by heteroscedasticity (Sokal and Rohlf, 1995). We tested differences between pairs of means with the REGWQ means-separation test to control maximum experiment-wise error rates (SAS Institute, 2001). Replicates that captured fewer than three beetles across all treatments were dropped from the analyses for each species.

Voucher specimens of the two *Prionus* species have been submitted to the W. F. Barr Entomology Museum at the University of Idaho and the Entomology Research Museum at the University of California, Riverside.

Results

Identification of the Insect-produced Stereoisomer 3,5-Dimethyldodecanoic acid, with two chiral centers, has four possible stereoisomers. The mixture of the four was separated cleanly into two GC peaks on an achiral DB-5 column, that corresponded to the *syn* (3*R**,5*R**) and *anti* (3*R**,5*S**) diastereomeric pairs of enantiomers (Rodstein et al., 2009). The corresponding methyl esters eluted in the same order as the parent acids and were also resolved to baseline, with the additional advantages that the peaks were more symmetrical and the retention times less variable than those of the parent acids. The retention times of the insect-produced acid and its methyl ester matched those of the later-eluting diastereomer of the synthesized acid and its methyl ester, respectively. These were proven to be the *anti*-diastereomers by comparing their retention times with those of *anti* (3*S*,5*R*)-3,5-dimethyldodecanoic acid and its ester; as expected, the retention times of *syn* (3*S*,5*S*)-dimethyldodecanoic acid and its ester matched those of the earlier eluting peaks in the synthetic mixtures of all four stereoisomers of the acid and their esters, respectively. However, we were not able to determine the absolute configuration of the insect-produced compound by analytical methods, because all attempts at resolving the methyl esters of the enantiomers on a chiral stationary phase GC column (Cyclodex-B) were unsuccessful. Thus, laboratory and field bioassays were used to indirectly determine the naturally-produced enantiomer.

Stereoselective Syntheses of Stereoisomers of 3,5-Dimethyldodecanoic Acid (Fig. 1) Three of the four possible stereoisomers of 3,5-dimethyldodecanoic acid were synthesized in good stereoisomeric purity, using the copper-catalyzed asymmetric conjugate addition of alkylmagnesium bromides to α,β-unsaturated methyl esters

(Lum et al., 2008) as the key reaction for introducing each of the two chiral methyl groups. Thus, (*E*)-2-decenoic acid (**1**) was converted to the corresponding methyl ester (**2**) by treatment with HCl in methanol, generated *in situ*. The first chiral methyl group then was introduced by reaction of α,β-unsaturated ester (**2**) with methylmagnesium bromide, with CuI and (*S*)-Tol-BINAP catalysis, to give methyl (*S*)-(-)-3-methyldecanoate (**3**). This compound was reduced to the corresponding aldehyde with DIBAL-H in hexane, followed by stabilized Wittig olefination in the same pot with methyl (triphenylphosphoranylidene) acetate to yield methyl (*S*)-(-)-5-methyl-2-dodecenoate as a mixture of (*Z*)- and (*E*)-isomers. These were separable by flash chromatography, giving the geometrically pure methyl (2*E*,5*S*)-(-)-5-methyl-2-dodecenoate (**4**) required for the next step. α,β-Unsaturated ester (**4**) then was subjected to the same copper-catalyzed asymmetric conjugate addition conditions with methylmagnesium bromide, CuI, and (*R*)-Tol-BINAP, yielding methyl (3*R*,5*S*)-(-)-3,5-dimethyldodecanoate (**5**). Hydrolysis of the ester with KOH in aqueous ethanol gave the free acid (**6**).

The enantiomeric (3*S*,5*R*)-(+)-3,5-dimethyldodecanoic acid (**10**) was made in analogous fashion by the same sequence of reactions, but using the catalysts with the opposite configuration to those used in the first sequence. Thus, unsaturated ester (**2**) was reacted with methylmagnesium bromide, CuI, and (*R*)-Tol-BINAP to give methyl (*R*)-(-)-3-methyldecanoate (**7**). DIBAL-H reduction and chain extension with methyl (triphenylphosphoranylidene) acetate yielded methyl (*R*)-(-)-5-methyl-2-dodecenoate (**8**). Asymmetric conjugate addition of compound **8** with methylmagnesium bromide, CuI, and (*S*)-Tol-BINAP yielded methyl (3*S*,5*R*)-(+)-3,5-dimethyldodecanoate (**9**), which was hydrolyzed to give (3*S*,5*R*)-(+)-3,5-dimethyldodecanoic acid (**10**).

Finally, reaction of methyl (2*E*,5*S*)-(-)-5-methyl-2-dodecenoate (**4**) with methylmagnesium bromide, CuI, and (*S*)-Tol-BINAP, gave the diastereomeric methyl (3*S*,5*S*)-(-)-dimethyldodecanoate (**11**).

Laboratory Bioassays of Synthetic Pheromone In olfactometer bioassays, 18 of 22 male *P. californicus* (82%) responded positively to 100 ng of 3,5-dimethyldodecanoic acid, and 36 of 41 males (88%) responded to 10 ng (treatments different from 1:1 positive:negative responses for both: $\chi^2_{1,\ 22}=21.8$, $P=0.003$; $\chi^2_{1,\ 41}=23.4$, $P<0.001$, respectively). However, only 13 of 22 (62%) males responded to 1 ng of 3,5-dimethyldodecanoic acid (treatment not different from 1:1: $\chi^2_{1,\ 21}=1.19$, $P=0.28$).

When equal doses of the two enantiomers were directly compared in olfactometer bioassays, 13 of 14 males (93%) and 13 of 16 males (81%) moved to the olfactometer arm baited with (3*R*,5*S*)- dimethyldodecanoic acid, at doses of 25 and 2.5 ng, respectively (treatments different from 1:1; $\chi^2_{1,\ 14}=10.3$, $P=0.001$; $\chi^2_{1,\ 16}=6.25$, $P=0.012$). Males showed a marginal positive response to (3*R*,5*S*)- over 3*S*,5*R*-dimethyldodecanoic acid at 0.25 ng (8 of 10 males [80%]; $\chi^2_{1,\ 10}=3.6$, $P=0.058$). Males did not respond to either 0.25 or 2.5 ng of (3*S*,5*R*)-dimethyldodecanoic acid when this enantiomer was tested against a solvent control (6 of 13 males [48%] and 10 of 17 [59%]: not different from 1:1; $\chi^2_{1,\ 25}=0.04$, $P=0.84$; $\chi^2_{1,\ 17}=0.53$, $P=0.47$, respectively).

Field Bioassays of Synthetic Pheromones Traps in southern California baited with 3,5-dimethyldodecanoic acid, (3*R*,5*S*)-dimethyldodecanoic acid, or (3*S*,5*R*)-dimethyldodecanoic acid, captured a total of 100 male *P. californicus* and 23 male *P. lecontei*. No females of either species were caught. The numbers of male *P. californicus* and *P. lecontei* captured were strongly and similarly affected by experimental treatment (Friedman's $Q_{3,\ 28}=18.2$, $P<0.001$, $Q_{3,16}=9.4$, $P=0.025$, respectively). Male *P. californicus* responded strongly and equally to 3,5-dimethyldodecanoic acid and (3*R*,5*S*)-dimethyldodecanoic, but showed little attraction to (3*S*,5*R*)-dimethyldodecanoic acid or controls (Fig. 2). Male *P. lecontei* were most strongly attracted to (3*R*,5*S*)-dimethyldodecanoic acid, showed intermediate attraction to 3,5-dimethyldodecanoic acid, and were not attracted to (3*S*,5*R*)-dimethyldodecanoic acid or controls (Fig. 2).

Traps baited with 3,5-dimethyldodecanoic acid, (3*R*,5*S*)-dimethyldodecanoic acid, or live female *P. californicus* in Idaho captured a total of 252 male *P. californicus*, but no *P. lecontei*. Trap catches of male *P. californicus* again were affected by experimental treatment (Fig. 3; Friedman's $Q_{3,31}=23.4$, $P<0.001$). 3,5-Dimethyldodecanoic acid and (3*R*,5*S*)-dimethyldodecanoic acid attracted similar numbers of males. Significantly fewer males were captured in traps baited with virgin females or in controls (Fig. 3). The latter

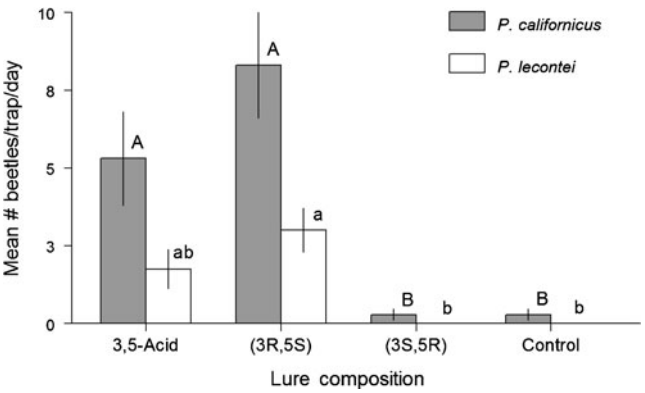

Fig. 2 Mean number (± SE) of male *Prionus californicus* (*N*=100) and *Prionus lecontei* (*N*=23) captured in southern California by traps baited with 3,5-dimethyldodecanoic acid ("3,5-Acid"), (3*R*,5*S*)-dimethyldodecanoic acid, (3*S*,5*R*)-dimethyldodecanoic acid, and solvent lures ("Control"). Bars with different letters of the same case are significantly different (REGWQ test, $P<0.05$)

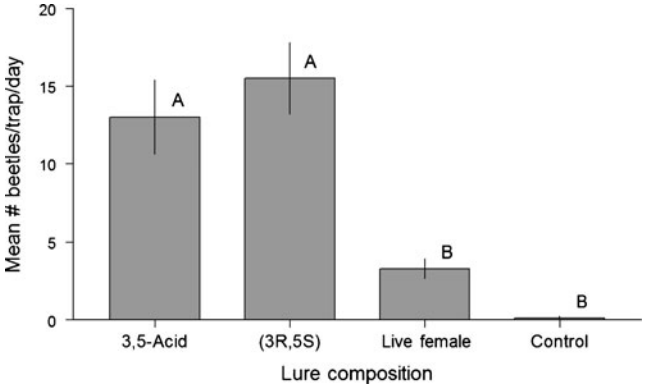

Fig. 3 Mean number (± SE) of *Prionus californicus* males (N=252) captured in Idaho by traps baited with racemic 3,5-dimethyldodecanoic acid ("3,5-Acid", 1 mg), (3*R*,5*S*)-dimethyldodecanoic acid (0.25 mg), a live female *Prionus californicus*, and control lures treated with solvent ("Control"). Bars with different letters are significantly different (REGWQ test, P<0.05)

two treatments did not differ in the number of beetles captured (Fig. 3).

In the dose–response bioassay in southern California, traps captured totals of 62 male *P. californicus* and 44 male *P. lecontei.* There were too few replicates that captured three or more *P. lecontei* to allow a robust statistical analysis. For *P. californicus*, trap catch was affected by dose (Fig. 4, top; Friedman's $Q_{4,50}$=17.2, P=0.002), with only traps in the 320 μg treatment capturing more beetles than control traps. The high- and low-dose trials for the dose–response bioassays in Idaho captured 145 and 139 male *P. californicus*, respectively, and the number of males captured was affected by pheromone dose in both trials (Fig. 4, bottom; Friedman's $Q_{4,30}$=21.2, P<0.001, $Q_{4,45}$= 32.0, P<0.001, respectively). The two trials were consistent in capturing no beetles in control traps, and in traps baited with doses higher than 100 μg (high-dose trial) or 10 μg (low-dose trials) capturing more male *P. californicus* than control traps (Fig. 4, bottom). The number of males captured did not differ for pheromone doses of 0.1 mg and higher in the high-dose trial, but in the low-dose trial, the number of males captured was higher for 100 μg than for 1 and 10 μg (Fig. 4, bottom).

Discussion

Identification and Synthesis of the Stereoisomers To verify the identification of the basic carbon skeleton of the pheromone, we previously had developed a nonstereoselective synthesis of the mixture of all four stereoisomers of 3,5-dimethyldodecanoic acid (Rodstein et al., 2009). Although the diastereomers or their methyl esters were readily separable on GC, we did not know which diastereomer corresponded to which peak. Thus, we stereoselectively synthesized three of the four possible stereoisomers, with the goal of first determining the relative stereochemistry of the methyl groups in the pheromone (i.e., the correct diastereomer), followed by determination of the natural enantiomer. With these standards in hand, we showed unequivocally that the insect-produced compound was the *anti* diastereomer. Although we were not able to resolve the enantiomers (as their methyl esters) on a chiral stationary phase GC column, the question as to which enantiomer was produced by the insects was resolved indirectly by the results of both laboratory and field bioassays, in which (3*R*,5*S*)-3.5-dimethyldodecanoic acid was highly attractive to male beetles, whereas its enantiomer was virtually inactive.

The enantiomers of 3,5-dimethyldodecanoic acid were synthesized using the asymmetric conjugate addition developed by Lum et al. (2008) to place each of the chiral methyl groups. Use of this method has several

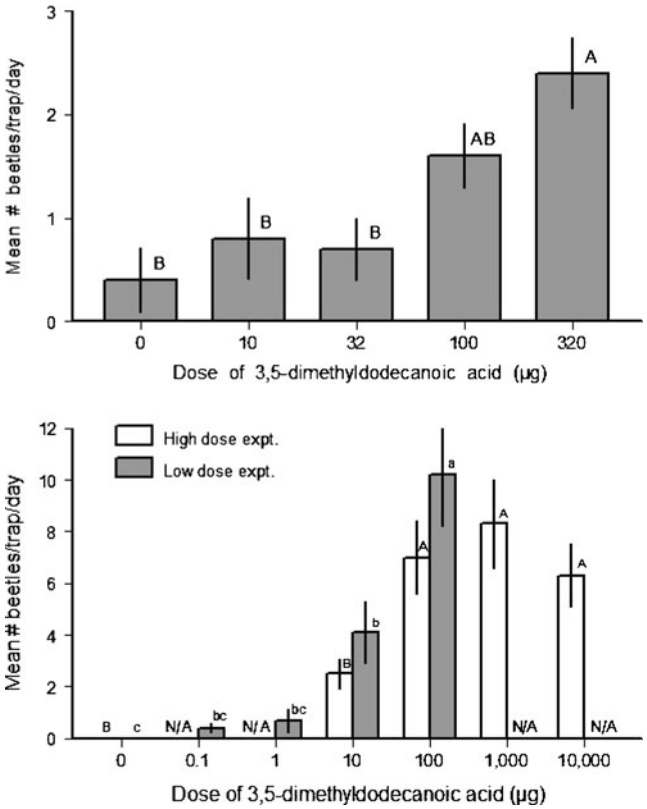

Fig. 4 Mean number (± SE) of adult male *Prionus californicus* captured in traps baited with various doses of racemic 3,5-dimethyldodecanoic acid. *Top*; bioassays conducted in California (N= 62); *Bottom*: bioassays conducted in Idaho testing high and low doses (N=145 and 139 males, respectively). N/A indicates dosages that were not included in a particular experiment. Bars with different letters of the same case are significantly different (REGWQ test, P<0.05)

advantages. First, each conjugate addition step proceeds with high enantioselectivity, yielding products of known absolute configuration. Second, either enantiomer is equally accessible simply by changing the chiral ligand in the reaction (i.e., (*R*)-Tol-BINAP or (*S*)-Tol-BINAP). Third, the reaction can be applied readily in iterative fashion, so that the same reaction can be used to place each methyl group sequentially. However, this route was not without minor problems. For example, it proved to be critically important to use the α, β-unsaturated methyl esters for the addition reaction; use of the analogous ethyl esters resulted in a decrease in stereoselectivity.

During the course of these reactions, all direct attempts at determining the enantiomeric purities of intermediates, final products, or several derivatives thereof, were unsuccessful. Thus, enantiomeric pairs of methyl esters **3** and **7**, **4** and **8**, and **5** and **9** were not resolved on the Cyclodex-B column, nor were the corresponding alcohols from reduction of these esters resolved. Furthermore, the enantiomers of 1-bromo-2-methylnonane, derived from hydrolysis of methyl 3-methyldecanoate followed by decarboxylative halogenation by the Cristol-Firth modification of the Hunsdieker reaction (Cristol and Firth, 1961), failed to resolve on this column, and the analogous enantiomers of 1-bromo-2,4-dimethylundecane also were not resolved. Whereas the diastereomeric purities of the (3*S*,5*R*)-, (3*R*,5*S*)-, and (3*S*,5*S*)-stereoisomers were 92.5, 90.7, and 97.5%, respectively, as determined by the ratios of their GC peak areas, the enantiomeric purities must necessarily be much higher because almost all of the enantiomeric impurity formed in the first asymmetric reaction is converted to a diastereomer of the desired product in the second asymmetric reaction. Similarly, any loss of stereospecificity in the second asymmetric reaction results in a diastereomer of the desired product rather than the undesired enantiomer.

Bioassay Results The fact that only males of *P. californicus* were attracted to synthetic pheromone in field bioassays confirmed that (3*R*,5*S*)-dimethyldodecanoic acid is a female-produced sex pheromone for this species. This compound does not function as an aggregation pheromone, as appears to be the case for the male-produced pheromone of many species in the subfamilies Aseminae and Cerambycinae (see Introduction). Male *P. californicus* were quite sensitive to the pheromone, as indicated by the 0.25–2.5 ng response threshold in the olfactometer bioassays. This level of sensitivity is consistent with the strong responses of males to live females, dead females, and even their excised ovipositors, demonstrated in an earlier study (Cervantes et al., 2006). The response was entirely enantiospecific: males showed no response in laboratory or field studies to the unnatural enantiomer, (3*S*,5*R*)-dimethyldodecanoic acid. There was no indication that any of the unnatural stereoisomers inhibited behavioral responses to the insect-produced stereoisomer, with male *P. californicus* responding as well to the mixture of the four stereoisomers as they did to (3*R*,5*S*)-dimethyldodecanoic acid. This strong attraction to the mixture of stereoisomers will be useful for commercial development of the pheromone because it circumvents the need for an expensive chiral synthesis.

Dose–response bioassays in the field demonstrated that males responded to doses of synthetic pheromone as low as 10 μg when dispensed from plastic bag dispensers, consistent with their responses to minute quantities of pheromones in olfactometer bioassays. As doses increased, the numbers of males captured reached a plateau midway through the series, with doses >100 μg attracting similar numbers of males. Traps baited with the synthetic pheromone captured greater numbers of males than did the caged females used as positive controls. In previous studies, we demonstrated that traps baited with live females capture large numbers of males when not competing with pheromone traps (Cervantes et al., 2006). Taken together, these results suggest that the pheromone of this species consists of (3*R*,5*S*)-dimethyldodecanoic acid as a single component, despite the fact that extracts from females contain both homologs (with longer chains) and analogs (methyl esters of the acids) of 3,5-dimethyldodecanoic acid (Rodstein et al., 2009).

Our capture of male *P. lecontei* in southern California in traps baited with the pheromone of *P. californicus* was unexpected, and suggests that females of *P. lecontei* also produce a sex pheromone that contains (3*R*,5*S*)-dimethyldodecanoic acid. To date, we have not been able to confirm this, because all attempts at collecting female *P. lecontei* at light or light traps have been fruitless. The dose–response profile of male *P. lecontei* to (3*R*,5*S*)-dimethyldodecanoic acid was similar to that of male *P. californicus*, which further suggests that this compound is a major, if not the only, component of the pheromones of both species. What remains unclear is how these congeners maintain reproductive isolation, because they are sympatric in at least some areas of southern California (Monné and Hovore, 2005), and clearly have overlapping annual flight periods (i.e., substantial numbers of males of both species were caught during field trials in midsummer). It is possible that one or more of the other components in the crude extracts from *P. californicus* females may serve to inhibit the responses of male *P. lecontei*. This possibility remains to be tested once the other components have been synthesized and are available for follow-up field trials.

The complete absence of *P. lecontei* in Idaho may have been due to our sampling only in hop yards, or because southwest Idaho lies outside the geographic range of *P. lecontei*. Both *P. lecontei* and *P. californicus* are distributed in western North America, but there is little information available about their altitudinal distribution, beyond the fact that *P. californicus* occurs in the Rocky Mountains, whereas *P. lecontei* appears to be limited to a more western distribution (Linsley, 1962). Overall, these results indicate that traps baited with 3,5-dimethyldodecanoic acid will be an ideal tool to characterize the distribution and abundance of these congeners over their entire ranges.

The strong attraction of male *P. californicus* to even small amounts of synthetic pheromone also suggests that this compound has potential for monitoring and managing this species in agricultural and horticultural situations, where it is an important pest. As described above, *P. californicus* is one of the most important pests of hop in the Pacific Northwest. In addition, *P. californicus* and *P. lecontei* are chronic pests of a variety of tree crops, including apples and stone fruits (Solomon, 1995). We currently are evaluating potential uses of the pheromone for control of *P. californicus* in hop production by mating disruption or mass trapping.

Acknowledgements We thank Wittko Franke for helpful discussions during identification of the pheromone, Steven Lingafelter for taxonomic assistance, and Carole Bell at Santa Rosa Plateau Ecological Reserve for permitting access to field sites. The project was supported by the Hop Research Council, USDA/Western Region IPM grant number 207-03623 (to JDB, JGM, and LMH), and the National Research Initiative (NRI) Arthropod and Nematode Biology and Management Program of the USDA Cooperative State Research, Education and Extension Service (CSREES) grant number 2006-35302-17457 (to JGM and LMH), and the Alphawood Foundation (to LMH).

Abstract A GC-MS method to analyze the stereoisomeric composition of chiral secondary alcohols found in whole body extracts of pine sawfly females was developed. The tested alcohols were derivatized with optically pure (*S*)-2-acetoxypropionyl chloride prior to GC-MS analysis. Baseline separation was obtained for all sixteen stereoisomers of 3,7,9-trimethyltridecan-2-ol and for the four 3-methylpentadecan-2-ol stereoisomers. For 3,7-dimethyltridecan-2-ol, 3,7-dimethyltetradecan-2-ol and 3,7-dimethylpentadecan-2-ol baseline separation was obtained for 6 of the possible 8 stereoisomers. When a mixture of 16 stereoisomers of 3,7,11-trimethyltridecan-2-ol was tested, baseline separation of 7 peaks out of 16 possible was obtained. The investigated alcohols are pheromone precursors for some pine sawfly species that are severe defoliators of pine. Females from several *Diprion, Neodiprion, Macrodiprion, Microdiprion*, and *Gilpinia* species emit esters of such secondary alcohols as sex pheromones that attract males for mating. To quantify the small amounts of the precursor alcohol and its stereoisomeric composition found in whole body extracts from female pine sawflies, a purification method was optimized. An extract of 20 females of *D. pini* contained about 8 ng of (2*S*,3*R*,7*R*)-3,7-dimethyltridecan-2-ol per female, and three extracts of 18, 20, and 90 females of *N. sertifer* contained between 5 and 13 ng of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol per female.

Introduction

Pine sawflies of the family Diprionidae (Hymenoptera: Symphyta) are severe defoliators of pines in the Northern hemisphere (Smith, 1993). Larvae consume the needles, which results in reduced growth or even death of the trees. Most of these species belong to the genera *Diprion* or *Neodiprion*, but also members of other genera such as *Gilpinia*, *Macrodiprion*, and *Microdiprion* cause damage (Bergström et al., 1995; Anderbrant et al., 2005). Forest outbreaks of pine sawflies normally are controlled by chemical insecticides. With increased environmental concern, however, there is a growing interest in finding less harmful methods. Females of several pine sawfly species emit sex pheromones that attract males for mating. An alternative method to control and reduce the population is to use the insects own sex pheromone for monitoring, mass capture or mating disruption (Östrand et al., 1999; Rieske et al., 2001; Martini et al., 2002). The pheromone is stored as an alcohol precursor in the female body, which is esterified at the moment of release from the insect (Jewett et al., 1976; Anderbrant et al., 2005). Females from *Neodiprion sertifer* have the acetate or propionate of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol as the main component of their sex pheromone (Anderbrant et al., 2000). In this case, esters of (2*S*,3*R*,7*R*)-3,7-dimethylpentadecan-2-ol act as antago-

nists, and decrease the male response from esters of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol, even at concentrations as low as 0.1% (Anderbrant et al., 1992). Total inhibition of the response is obtained at concentrations above 2% of esters of (2*S*,3*R*,7*R*)-3,7-dimethylpentadecan-2-ol (Anderbrant et al., 1992). Thus, it is crucial to have a sensitive analytical method to quantify and determine the composition of the stereoisomers in females. Diastereomers, such as (2*S*,3*R*,7*R*)- and (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol, have very small differences in their physical properties, and separating them directly by using standard GC chiral columns is difficult. Enantiomers, such as (2*R*,3*R*,7*R*)- and (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol, can either be separated directly on a chiral column, or indirectly by using a chiral derivatizing reagent (Gübitz and Schmid, 2001; Srinivas, 2004) to form diastereomers. Stereoisomeric analysis of secondary alcohols has been accomplished via derivatization with chiral acid chlorides, benzoyl chloride, or isopropyl isocyanate, sometimes in combination with chiral columns (Brooks et al., 1973; Doolittle and Heath, 1984; Högberg et al., 1990; Wassgren and Bergström, 1995). Pre-purification of whole body extracts from pine sawflies prior to derivatization normally is necessary, and often is done with Solid Phase Extraction on a SiOH-column with gradient elution (Bergström et al., 1995; Wassgren and Bergström, 1995; Östrand et al., 2003).

The aim of the present study was to develop a method, based on chiral derivatization and analysis by GC-MS, by which stereoisomers of chiral secondary alcohols found in whole body extracts from female pine sawflies can be determined and quantified. The method was developed by using pure stereoisomers or mixtures of synthetic 3,7-dimethyltridecan-2-ol, 3,7,9-trimethyltridecan-2-ol, 3,7,11-trimethyltridecan-2-ol, 3,7-dimethyltetradecan-2-ol, 3,7-dimethylpentadecan-2-ol, and 3-methylpentadecan-2-ol as references. The alcohols selected for the study are used as pheromone precursors in *Diprion pini*, *Macrodiprion nemoralis*, *Microdiprion pallipes Gilpinia pallida*, *N. sertifer*, *Gilpinia frutetorum*, and *Gilpinia socia*. For demonstration, the method was applied on whole body extracts from *D. pini* and *N. sertifer*. Figure 1 shows the structures of all the alcohols thus far identified in pine sawfly species (Bergström et al., 1995; Tai et al., 1998; Anderbrant et al., 2000; Wassgren et al., 2000; Östrand et al., 2003; Hedenström et al., 2006, 2009).

Methods and Materials

Chemicals Solvents used for purification and derivatization were of spectrophotometric grade or higher, and purchased from Sigma-Aldrich, Schnelldorf, Germany. (*S*)-2-Acetoxypropionyl chloride (*Fluka Chemicals* Ltd.) and 2-naphthoyl chloride (98%) also were purchased from Sigma-Aldrich. The 100 mg Teflon coated Orochem Silica Superclean solid phase columns were purchased from Dalco Chromtech AB, Sollentuna, Sweden, and the 500 mg Strata SI-1 Silica Teflon coated solid phase columns from Skandinaviska Genetec AB, Västra Frölunda, Sweden. All alcohols, in pure stereoisomeric forms or in mixtures, previously had been synthesized in our laboratory (Högberg et al., 1990; Bergström et al., 1995; Hedenström et al., 2002). Thus, some of the reference alcohols were used as pure stereoisomers and some as different mixtures of isomers to develop the separation method.

Extract Whole bodies of insect females were extracted in ethyl acetate according to Wassgren et al. (1992). To an extract, corresponding to 21 female *D. pini* (France), 200 ng of 2-tridecanol were added as an internal standard for quantification. From the same original *D. pini* sample, to an amount corresponding to 20 females, 198 ng 2-tridecanol and 355 ng of (2*R**,3*S**,7*R*/*S*)-3,7-dimethyltridecan-2-ol [1:1:1:1 mixture of the isomers (2*R*,3*S*,7*R*), (2*R*,3*S*,7*S*), (2*S*,3*R*,7*S*), and (2*S*,3*R*,7*R*)] were added. To three different extracts of *N. sertifer* (Uppland and Värmland, Sweden), between 200 and 873 ng (depending on the number of insects in the extracts) of 2-pentadecanol were added as an internal standard.

Purification Gradient elution on solid phase columns was used for purification of extracts (Bergström et al., 1995; Wassgren and Bergström, 1995; Östrand et al., 2003). The method was optimized with a reference mixture of 3,7-dimethyltridecan-2-ol and 2-tridecanol (used as internal standard). To eliminate co-eluting contaminants from ordinary polypropylene columns, Teflon coated columns were used. For extracts of 1–10 insects, a 100 mg Teflon coated Orochem Silica Superclean solid phase column was used, and a 500 mg Strata SI-1 Silica Teflon coated solid phase column was used for extracts of more than 10 insects. The column was cleaned and conditioned with three column volumes each of ethyl acetate, 10% ethyl acetate in pentane, and pentane. For large or contaminated samples, the extract was divided into smaller portions (100–200 ng), purified separately, and then combined. Internal standard was added to the extract before purification. 2-Tridecanol was used as internal standard for the analysis of 3,7-dimethyltridecan-2-ol (*D. pini*), and 2-pentadecanol for the analysis of 3,7-dimethylpentadecan-2-ol (*N. sertifer*). The extract solution was evaporated to dryness under a stream of argon at room temperature, and resolved in 100–200 μl of pentane. The solution was purified on the solid phase column with gradient elution, stepwise with 1–11% ethyl acetate in pentane in steps of 1% (fractions 1–11). An elution and collection volume of 150 μl for each fraction

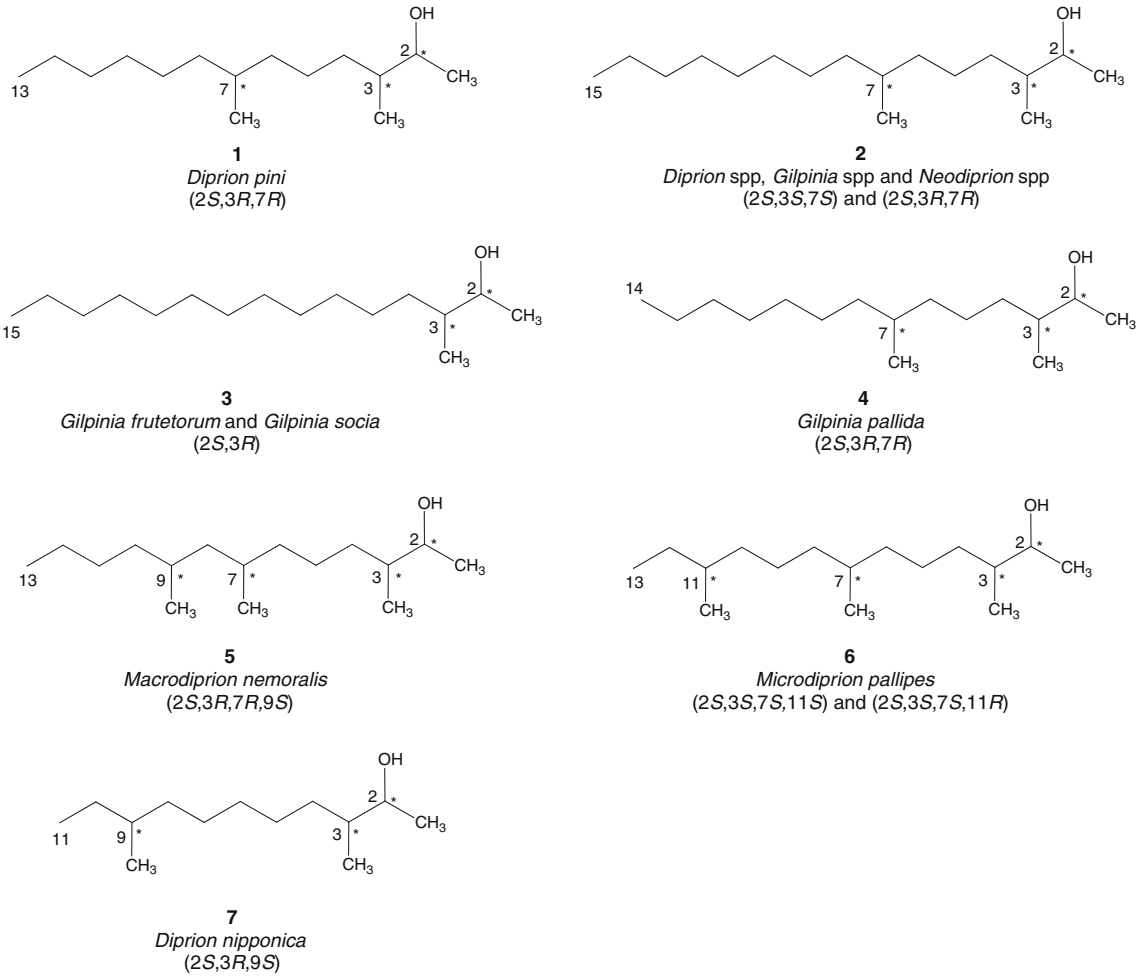

Fig. 1 Structures of the chiral alcohols that have been identified in pine sawfly species as sex pheromone precursors

was used for 100 mg columns with twice the elution and collection volume for fractions 9–11, and 750 µl for 500 mg columns with twice the elution and collection volume for fractions 9–11. The later fractions, containing the alcohols as judged by GC, were collected and combined in a vial and evaporated to dryness under a stream of argon at room temperature. Pentane (1 ml) was added, and the solution was washed with 200 µl of 0.2 M KOH. The organic layer was collected with a Pasteur pipette, and dried by passing through a second Pasteur pipette containing dry sodium sulphate, a piece of glass wool that was rinsed with ethyl acetate, and pentane, and thereafter dried before use. The obtained alcohol containing solution was evaporated to dryness under a stream of argon at room temperature, and resolved in 50 µl cyclohexane. An injection of the sample was made on GC-MS for identification of the alcohols, and thereafter the remaining sample was derivatized as below.

Derivatization The reference solutions and the purified extracts in 50 µl cyclohexane were derivatized with (*S*)-2-acetoxypropionyl chloride (Doolittle and Heath, 1984) by adding 65 µl of 1% pyridine in cyclohexane (containing 3 Å molecular sieves), and then 100 µl of 1% (*S*)-2-acetoxypropionyl chloride in dichloromethane were added under a stream of argon. The solution was mixed and heated for 30 min in an oil bath at 80°C with a needle through the vial septum and then evaporated to dryness with argon through an additional needle. Pentane (1 ml) and 0.2 ml 1 M HCl (aq) were added to the vial, and the solution mixed. The organic layer was collected with a Pasteur pipette, dried by passing through a new Pasteur pipette containing dry sodium sulphate as above. The solution was evaporated to dryness under a stream of argon at room temperature, and the residue redissolved in 50 µl cyclohexane.

Derivatization of (2*S*,3*S*,7*R*)- and (2*S*,3*S*,7*S*)-3,7-dimethyltridecan-2-ol with 2-naphthoyl chloride was made according to the method used in Wassgren and Bergström (1995) for other acid chlorides, but with some modifications. The mixture was heated for 60 min on an oil bath at 70°C, 10 µl methanol were added, and the solution was kept in the oil bath for an additional 5 min to transform the excess of naphthoyl chloride to its methyl ester. The

solution was evaporated to dryness with argon in the oil bath. H_2O (20 μl) was added, and the formed ester extracted with 2×100 μl pentane. The organic phase was washed with 2×10 μl H_20, and dried with sodium sulphate as previously.

Gas Chromatography and Mass Spectrometry The GC-MS analysis was performed on a Hewlett-Packard 6890N (GC), and an HP 5973 mass spectrometer (MS) with electron impact (EI) ionization. The carrier gas, 1 ml/min, was helium; 1 μl of the sample was injected splitless, the injector temperature was 250°C, and the aux temperature was 280°C.

Different GC-columns were evaluated with a stereoisomeric mixture of (2*R**,3*S**,7*R/S*)-3,7-dimethyltridecan-2-ol for optimal separation efficiency: ALPHA-DEX 120, BETA-DEX 120 and GAMMA-DEX 120 (all chiral) from Supelco, HP-1ms (non-polar) and HP-5ms (non-polar) from Agilent Technologies, factorFOUR VF-23ms (polar) from Varian (all 30 m×0.25 mm i.d., d_f=0.25 μm), CP-Sil 88 (polar) from Chrompack (50 m×0.25 mm i.d., d_f= 0.20 μm), and HP-88 (polar) from Agilent Technologies (100 m×0.25 mm i.d., d_f=0.20 μm). The factorFOUR VF-23ms column was chosen for method development due to good separation in combination with high inertness and low bleed.

For identification of the alcohols in purified extracts, the column temperature was increased from 50°C by 10°C/min up to 230°C. Full scan mode was used, and the retention times and MS-spectra of the eluting peaks were compared with reference samples. For separation and identification of the stereoisomers of the reference samples and extracts derivatized with (*S*)-2-acetoxypropionyl chloride, selected ion monitoring (SIM) was used to maximize sensitivity and reduce the number of interfering peaks. Temperature gradients and the ions for SIM mode were selected according to Table 1. The ions *m/z* 87, 115, and 133 originate from the (*S*)-2-acetoxypropionyl part (m/z 115), with *m/z* 87=115–CO and m/z 133 [due to double hydrogen rearrangement i.e., McLafferty + 1 (McLafferty, 1959)]. The other selected ions originate from the alcohol part: *m/z* 210 from 3,7-dimethyltridecan-2-ol, *m/z* 224 from 3-methylpentadecan-2-ol, 3,7-dimethyltetradecan-2-ol, 3,7,9-trimethyltridecan-2-ol, and 3,7,11-trimethyltridecan-2-ol, and *m/z* 238 from 3,7-dimethylpentadecan-2-ol (See Table 1 for mass spectra data). For the analysis of extracts with internal standards, *m/z* 182 from 2-tridecanol (*D. pini*) and *m/z* 210 from 2-pentadecanol (*N. sertifer*) also were selected.

For the references derivatized with 2-naphthoyl chloride, the temperature gradient and the ions for SIM mode were selected according to Table 1. The ions *m/z* 127, 155, and 172 originate from the 2-naphthoyl part (*m/z* 155), with *m/z* 127=155–CO and *m/z* 172 [due to McLafferty rearrangement (McLafferty, 1959)]. The *m/z* 210 ion originate from the alcohol part and *m/z* 382 the molecular ion (See Table 1 for mass spectra data).

Results

Purification Experiments The purification method was optimized by eluting a reference mixture of 3,7-dimethyltridecan-2-ol and 2-tridecanol (internal standard) on the SiOH column, with 1–15% ethyl acetate in pentane in steps of 1%, and by collecting and analyzing the fractions by GC-MS. The best result for collecting the alcohol was achieved when eluting with 9–11% of ethyl acetate in

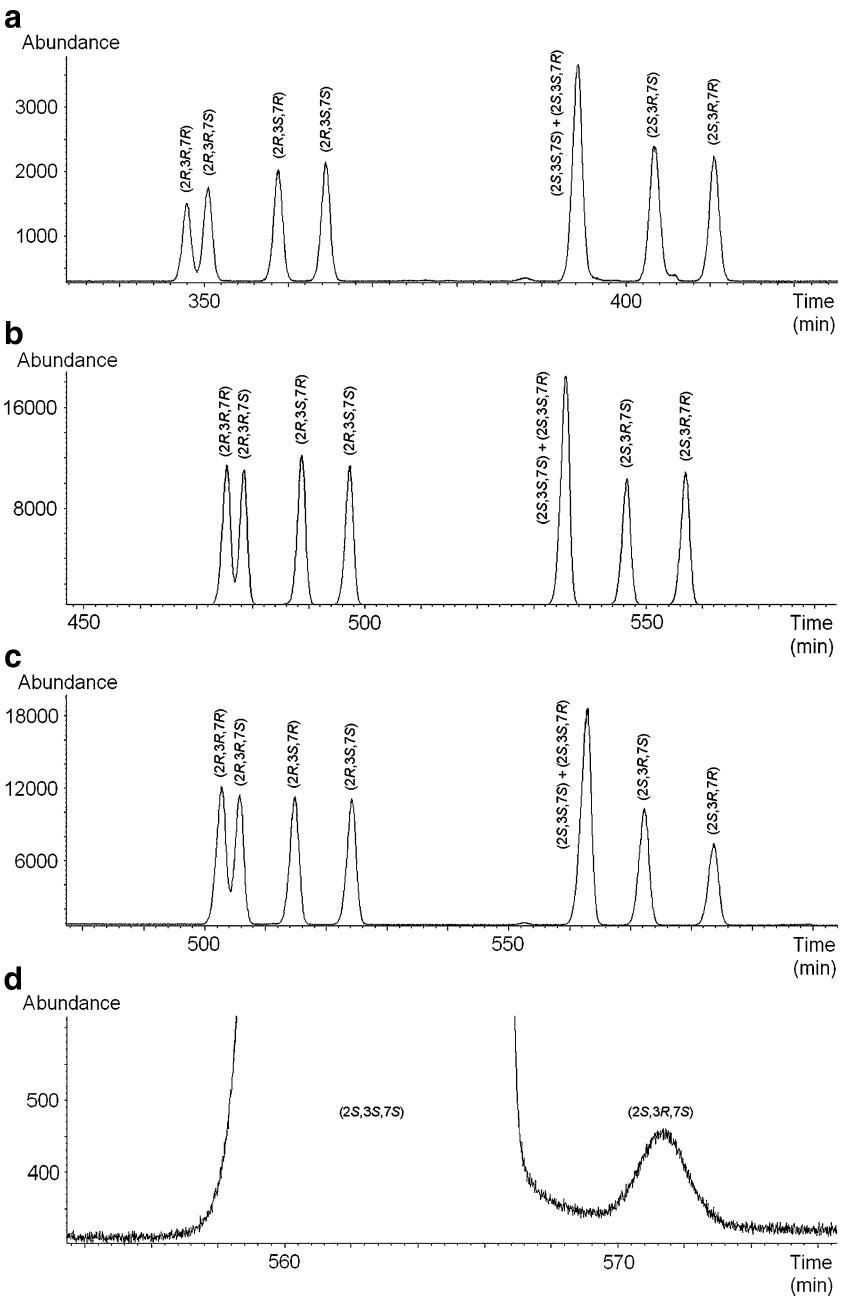
[a]Derivatized with (*S*)-2-acetoxypropionyl chloride and analysed on the HP-88 column

[b]Derivatized with 2-naphthoyl chloride and analysed on the factor FOUR VF-23ms column

pentane, using twice the dead volume of the column for these fractions which contained the alcohol. This was repeated with 3,7-dimethylpentadecan-2-ol and 2-pentadecanol (internal standard), which gave the same good result.

Derivatization Experiments A reference solution of (2*R**, 3*S**,7*R/S*)-3,7-dimethyltridecan-2-ol diluted in cyclohexane was derivatized with (*S*)-2-acetoxypropionyl chloride. The method was optimized by varying the molar ratio of 3,7-dimethyltridecan-2-ol and (*S*)-2-acetoxypropionyl chloride between 1:3 and 1:100, the reaction time between 10 and 60 min, and the temperature of the oil bath between 40°C and 80°C. A molar ratio of 1:10 and a reaction time of 30 min at 80°C were found to be sufficient. The optimized method was used for derivatization of all different alcohols.

Separation Experiments Out of the eight different GC-columns that were tested (ALPHA-DEX 120, BETA-DEX 120, GAMMA-DEX 120, HP-1ms, HP-5ms, factorFOUR VF-23ms, CP-Sil 88, and HP-88) by using a standard solution of (2*R**,3*S**,7*R/S*)-3,7-dimethyltridecan-2-ol derivatized with (*S*)-2-acetoxypropionyl chloride, the HP-88



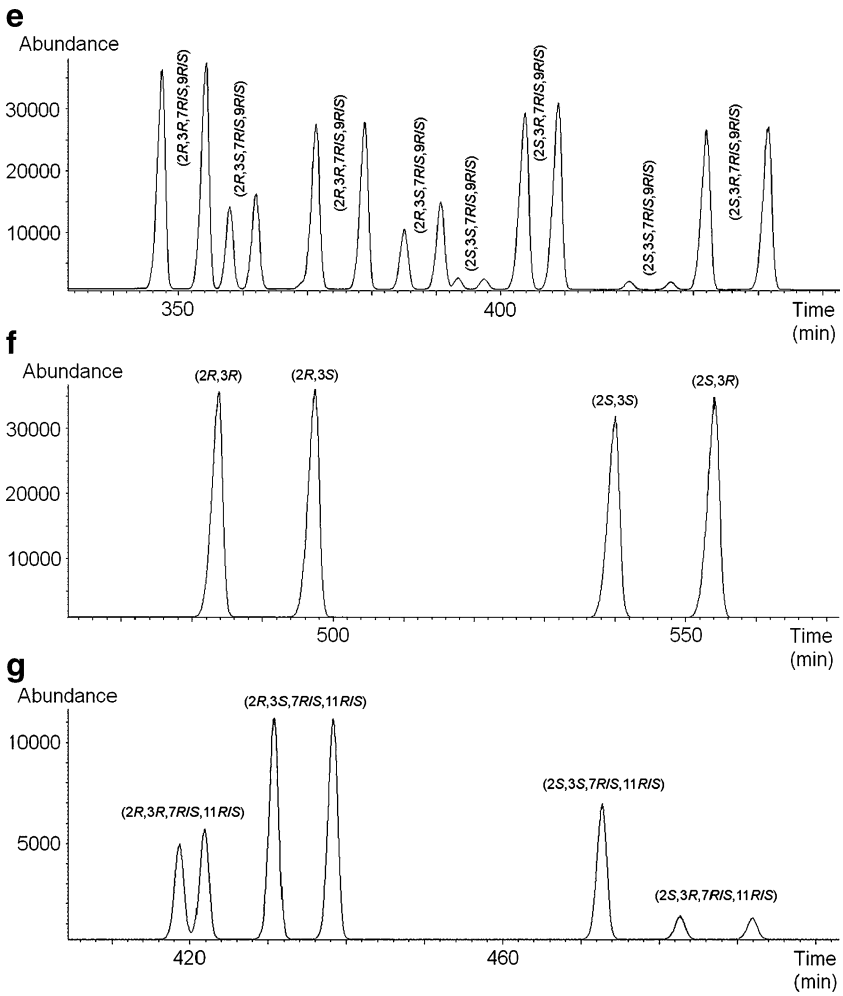


Fig. 2 GC-MS chromatogram after derivatization with (*S*)-2-acetoxypropionyl chloride of the stereoisomers of; **a** 3,7-dimethyltridecan-2-ol; **b** 3,7-dimethyltetradecan-2-ol; **c** 3,7-dimethylpentadecan-2-ol; **d** (*2S,3S,7S*)- containing 0.1% (*2S,3R,7S*)-3,7-dimethylpentadecan-2-ol; **e** 3,7,9-trimethyltridecan-2-ol (the individual peaks were not assigned to a corresponding stereoisomer); **f** 3-methylpentadecan-2-ol; **g** 3,7,11-trimethyltridecan-2-ol (the individual peaks were not assigned to a corresponding stereoisomer). See Table 1 for details

Fig. 2 (continued)

gave the best separation. Since it is not bonded or cross-linked and relatively expensive, however, it was used only for the optimized methods for the analysis of synthetic reference mixtures of the precursor alcohols and the extracts. For the development of the purification and derivatization methods, the factor FOUR VF-23ms column was used, because of its higher inertness and longer life time, and a separation performance that was close to that for the HP-88 column.

Of the eight stereoisomers of 3,7-dimethyltridecan-2-ol, 3,7-dimethyltetradecan-2-ol and 3,7-dimethylpentadecan-2-ol, respectively, the four (2*R**,3*S**,7*R*/*S*)-isomers, separated easily into four peaks with baseline separation (Fig. 2a–c). For the four (2*R**,3*R**,7*R*/*S*)-isomers, [(2*R*,3*R*,7*R*), (2*R*,3*R*,7*S*), (2*S*,3*S*,7*S*), and (2*S*,3*S*,7*R*)] the (2*R*,3*R*,7*R*)- and (2*R*,3*R*,7*S*)-isomers separated, on the HP-88 column almost with baseline separation, but no separation at all was achieved for the (2*S*,3*S*,7*S*)- and (2*S*,3*S*,7*R*)-isomers (Fig. 2a–c).

An experiment also was made by derivatizing a reference compound (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol containing 0.1% of the (2*S*,3*R*,7*S*)-isomer. The injected amount of (2*S*,3*R*,7*S*) was 83 pg, and its peak was separated clearly from the peak of (2*S*,3*S*,7*S*) (Fig. 2d).

Baseline separation of all the 16 isomers was obtained when a, derivatized, reference mixture of 16 stereoisomers of 3,7,9-trimethyltridecan-2-ol with (*S*)-2-acetoxypropionyl chloride derivatized was analysed (Fig. 2e). Similarly, all four stereoisomers of 3-methylpentadecan-2-ol gave good baseline separation (Fig. 2f).

For the 16 stereoisomeric mixture of 3,7,11-trimethyltridecan-2-ol, the result was baseline separation of seven peaks, but separation of all individual isomers was not possible with this method (Fig. 2g).

Because complete separation of (2*S*,3*S*,7*R*)- and (2*S*,3*S*,7*S*)-3,7-dimethyltridecan-2-ol isomers derivatized with (*S*)-2-acetoxypropionyl chloride was not accomplished, we used 2-naphthoyl chloride as a derivatizing reagent instead. This gave baseline separation between the peaks on the factor FOUR VF-23ms column (Fig. 3). However, with this method some of the other isomers co-eluted (not shown).

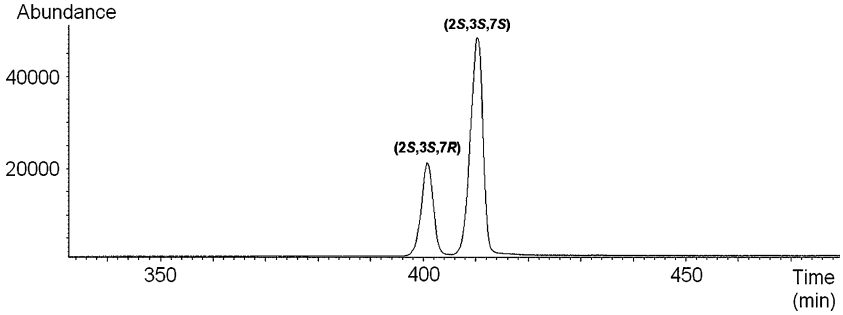

Fig. 3 GC-MS chromatogram of (2*S*,3*S*,7*R*)- and (2*S*,3*S*,7*S*)-3,7-dimethyltridecan-2-ol after derivatization with 2-naphthoyl chloride. See Table 1 for details

Analysis of Extracts The extract of female *D. pini* (France) contained about 8 ng of (2*S*,3*R*,7*R*)-3,7-dimethyltridecan-2-ol per female (Fig. 4, Table 2). The amount was calculated by adding a known amount of *(2R*,3S*,7R/S)*-3,7-dimethyltridecan-2-ol to one part of the sample and comparing the area of the (2*S*,3*R*,7*R*)-peak with the areas of the three other compounds.

The three extracts of *N. sertifer* (Sweden) contained between 5 and 13 ng of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol per female (Fig. 5 and Table 2). The amounts were calculated by comparing the area of the (2*S*,3*S*,7*S*)-peaks with the area of the internal standard and correcting for difference in response and molar weight. The correction factor was calculated by running known amounts of the internal standard and synthetic references of (2*S*,3*S*,7*S*)- and (2*S*,3*R*,7*S*)-3,7-dimethylpentadecan-2-ol through the whole method, and comparing the areas in the GC-MS-chromatograms.

No other stereoisomers of 3,7-dimethyltridecan-2-ol or 3,7-dimethylpentadecan-2-ol were detected in the extracts of *D. pini* and *N. sertifer*. The small peaks seen in Figs. 4 and 5 did not exhibit the correct SIM ion ratio for the insect pheromone components.

Discussion

When analyzing the (*S*)-2-acetoxypropionyl esters of 3,7-dimethyltridecan-2-ol, 3,7-dimethyltetradecan-2-ol, and 3,7-dimethylpentadecan-2-ol, six of the eight stereoisomers were separated. However, (2*S*,3*S*,7*R*) and (2*S*,3*S*,7*S*) stereoisomers were not separated. A previous method, with the 3,7-dimethylpentadecan-2-ol as isopropyl carbamate derivatives tested on a chiral XE-60-(*S*)-valine-(*S*)-2-phenylethylamide column, also separated the *(2R*,3S*,7R/S)*-isomers as four peaks and the *(2R*,3R*,7R/S)*-isomers as two peaks (Högberg et al., 1990). However, this method also gave overlapping peaks between the *(2R*,3S*,7R/S)*- and *(2R*,3R*,7R/S)*-isomers. The researchers tried to improve the separation by coupling three different non-chiral columns in series and by converting the alcohol to derivatives of benzoate (Högberg et al., 1990) or pentafluorobenzoate (Wassgren and Bergström, 1995), but despite these efforts the stereoisomers (2*S*,3*S*,7*R*) and (2*S*,3*S*,7*S*) were only partly separated. By using 2-naphthoyl chloride we obtained baseline separation between the peaks of the diastereomeric esters (2*S*,3*S*,7*R*)- and (2*S*,3*S*,7*S*)-3,7-dimethyltridecan-2-ol. (Fig. 3). This also can be applied to 3,7-dimethyltetradecan-2-ol, 3,7-dimethylpentadecan-2-ol, and perhaps, even 3,7,9-trimethyltridecan-2-ol, since they all have similar separation patterns. As this method gives co-elution of other peaks instead, it can be seen as a complement to derivatizing with (*S*)-2-acetoxypropionyl chloride.

As mentioned in the introduction, even very low concentrations of esters of the (2*S*,3*R*,7*R*)-isomer in the female sex pheromone can affect the response behavior of the receiving male to the emitted esters of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol. Thus, we chose to test (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol, with 0.1% of the (2*S*,3*R*,7*S*)-isomer added, as this represents an even more difficult separation compared to the (2*S*,3*S*,7*S*)-isomer with a small amount of (2*S*,3*R*,7*R*)-isomer, since a large peak easily overlaps a closely later eluting and smaller peak

[b]2-tridecanol

[c]2-pentadecanol

(Fig. 2c). Even for this demanding task our method gave excellent separation using the HP-88 column, and the result is shown in Fig. 2d.

An extraordinary result was obtained with our method when the reference mixture of 16 stereoisomers of 3,7,9-trimethyltridecan-2-ol showed, after derivatization with (*S*)-2-acetoxypropionyl chloride, good separation of all the 16 isomers (Fig. 2e). Although, we here just show the elution order and have not assigned each individual peak in the spectra to the corresponding stereoisomer, the results demonstrate that it is possible to efficiently analyze the stereoisomeric composition of the sex pheromone precursor content of females from *M. nemoralis*.

For the derivatized 16 stereoisomeric mixture of 3,7,11-trimethyltridecan-2-ol, the result was only partial separation, with no separation of individual isomers (Fig. 2g). Although the only difference between 3,7,9-trimethyltridecan-2-ol and 3,7,11-trimethyltridecan-2-ol is the positioning of one of the methyl groups, the chromatographic separation is different. It is known that other compounds with one methylene group between two methyl groups, i.e., in our case 3,7,9-trimethyltridecan-2-ol, show unique biological and physical properties when compared to compounds without this structure (i.e., in our case 3,7,11-trimethyltridecan-2-ol) (Hoffmann, 1992).

The quantitative analysis of female extracts from *D. pini* and *N. sertifer* presented herein showed results similar to previous studies, with 8 ng per female of (2*S*,3*R*,7*R*)-3,7-dimethyltridecan-2-ol for *D. pini* (Bergström et al., 1995) and 5–13 ng per female of (2*S*,3*S*,7*S*)-3,7-dimethylpentadecan-2-ol for *N. sertifer* (Wassgren et al., 1992; Wassgren and Bergström, 1995). No other stereoisomers were detected in the extracts. By using MS detection with SIM in our method, the chromatograms showed few co-eluting contaminants in the area of interest and, thereby, the results should be easy to repeat accurately.

The described method is an efficient way to analyze all of the isomers of the secondary pheromone precursor alcohols, 3,7,9-trimethyltridecan-2-ol and 3-methylpentadecan-2-ol, in extracts of female pine sawflies. For 3,7-dimethyltridecan-2-ol, 3,7-dimethyltetradecan-2-ol, and 3,7-dimethylpentadecan-2-ol, baseline separation was obtained for six of the possible eight stereoisomers. To separate the (2*S*,3*S*,7*S*)- and (2*S*,3*S*,7*R*)-isomers, we showed that it is possible by using 2-naphthoyl chloride as the derivatization agent. Another way to obtain good separation between the (2*S*,3*S*,7*S*)- and (2*S*,3*S*,7*R*)-isomers is to use the (*R*)-isomer instead of the (*S*)-isomer of 2-acetoxypropionyl chloride, as the separation then will look like the result obtained with (2*R**,3*R**,7*R*/*S*)- and (2*R**,3*S**,7*R*/*S*)-isomers in Fig. 2a–c. Since (*R*)-2-

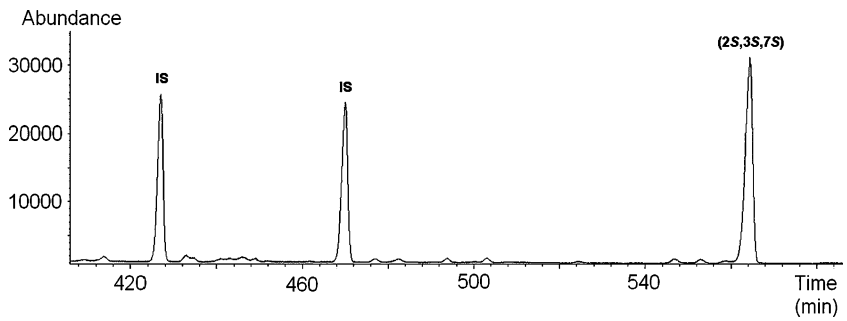

Fig. 5 GC-MS chromatogram of an extract from 90 *Neodiprion sertifer* females (Uppland, Sweden) after derivatization with (*S*)-2-acetoxypropionyl chloride. See Tables 1 and 2 for details

acetoxypropionyl chloride is not commercially available, however, it has to be synthesized in enatiomerically pure form. Until now, although, the (2*S*,3*S*,7*R*)-isomers of 3,7-dimethyltridecan-2-ol, 3,7-dimethyltetradecan-2-ol, and 3,7-dimethylpentadecan-2-ol have not been found in extracts of a female pine sawfly species.

Abstract The citrus pock caterpillar, *Prays endocarpa* (Yponomeutidae; Praydinae), is a pest of pomelo (*Citrus grandis* L.) in Vietnam. Gas chromatography-mass spectrometry analyses of pheromone gland extracts from female moths identified three monoenyl compounds, (*Z*)-7-tetradecenal (Z7-14:Ald), (*Z*)-7-tetradecenyl acetate (tentatively identified, Z7-14:OAc), and (*Z*)-7-tetradecen-1-ol (Z7-14:OH), in a ratio of about 10:3:10. In the field, traps baited with synthetic Z7-14:Ald (0.5 mg) caught male *P. endocarpa*. The other two compounds, either alone or when added to Z7-14:Ald, did not elicit increases in trap catch (relative to the appropriate treatment). Synthetic Z7-14:Ald was used to monitor and control this species in pomelo orchards in Vinh Long Province. Monitoring revealed that adults were present throughout the year with discernible peaks in December, March, and April. A mass-trapping trial, using 20 traps in a 0.1 ha pomelo orchard, effectively suppressed fruit damage to levels similar to that achieved by an insecticide (Karate 2.5EC). Mating disruption trials, using polyethylene-tube dispensers, each filled with 80 mg of Z7-14:Ald at a rate of 200 or 400 dispensers/ha, also controlled damage by this pest to levels below that achieved by an insecticide treatment. This work demonstrates the potential for pheromone-based control of this pest in Vietnam.

Introduction

The citrus pock caterpillar (CPC), *Prays endocarpa* Meyrick (Lepidoptera: Yponomeutidae: Praydinae), is one of the most serious pests of citrus orchards in South and Southeast Asia. While larvae of the congeners, *Prays citri* Milliere and *Prays nephelomima* Meyrick, feed on citrus flowers (the two species are known as citrus flower moths), larvae of CPC attack fruit exclusively, particularly those of pomelo, *Citrus grandis* L. After hatching, the larvae mine into the peel of fruit and feed. Pomelo fruit, attacked by CPC larvae at an early stage of development, will drop from the tree before ripening; fruit attacked at a later stage will develop tumors on the peel, which greatly decrease the commercial value of the fruit. The control of CPC by insecticides is difficult because sprayed insecticide does not directly contact the larvae in the fruit peel. In the Mekong Delta of Vietnam, pomelo trees have two main fruiting seasons: the first from February to May, and the second from September to November; pomelo fruit also is sporadically produced outside of these periods. Since pomelo fruit is expensive, often used as a special gift, control of this pest with no, or minimal, pesticide residue is highly desirable. We decided to identify the sex pheromone of this species in order to develop a control program based on synthetic sex pheromone.

Among species in the genus *Prays*, sex pheromones have been identified from the citrus flower moths, *P. citri* (Nesbitt et al., 1977) and *P. nephelomima* (Gibb et al., 2005), and the olive moth, *P. olea* Bern. (Campion et al.,

1979; Renou et al., 1979). These three species all utilize (*Z*)-7-tetradecenal (Z7-14:Ald) in their pheromonal communication. In this paper, we report the results of studies on chemical identification of compounds produced in the sex pheromone gland of female *P. endocarpa*, field trials testing the ability of these compounds to attract males, as well as the efficacies of mass trapping and mating disruption, using a polyethylene formulation of the synthetic pheromone, to prevent fruit damage by CPC.

Methods and Materials

Insect and Pheromone Extract Pomelo fruit infested with CPC larvae were collected in orchards in My Hoa and Dong Thanh villages, in Vinh Long Province of Vietnam, and brought to Can Tho University. In the laboratory, the fruit was placed in transparent plastic boxes and kept under light and temperature conditions similar to those outside (27°C–30°C, 55%–70% RH, 12L:12D) until larvae pupated. Pupae were collected and placed individually in a small glass tube. Abdominal tips of 2- or 3-d-old adult virgin females were excised 2 hr after the onset of the scotophase and extracted in HPLC-grade hexane (10 μl/female) for 15 min. Abdominal tip extracts [>250 female equivalent (FE)] were sent to Tokyo University of Agriculture and Technology for analysis by gas chromatography-mass spectrometry (GC-MS).

GC-MS Analysis Electron ionization (70 eV) mass spectra of the pheromone components and authentic standards were obtained on a Hewlett-Packard 5973 mass selective detector (Agilent Technologies Inc., Palo Alto, CA, USA), using a DB-23 column (0.25 mm i.d.×30 m, 0.25 μm film, J & W Scientific, Folsom, CA, USA), with helium as carrier gas. The column was programmed from 80°C (held for 1 min) to 220°C at 8°C per min and held for 10 min. To determine the position of a double bond in the compounds, dimethyl disulfide (DMDS) adducts were formed. Briefly, the crude pheromone extract (80 FE) was dissolved in a mixture of DMDS (50 μl) and a diethyl ether solution of iodine (60 mg/ml, 5 μl) and held at 40°C overnight (Buser et al., 1983; Vang et al., 2005). After addition of 10% sodium thiosulfate solution (0.5 ml), crude products were extracted with hexane and analyzed by GC-MS. Adducts were analyzed on the same instrument, using an HP-5 column (0.25 mm i.d.×30 m, 0.25 μm film, Agilent) and the same conditions and temperature program.

Synthesis of (Z)-7-Tetradecenal and Derivatives (*Z*)-7-Tetradecen-1-ol (Z7-14:OH) was synthesized from 1,7-heptanediol. Successive reactions with 3,4-dihydropyrane and pyridinium chlorochromate (PCC) converted the diol to the THP ether of 7-hydroxyheptanal, which was coupled with a phosphorane prepared from 1-bromoheptane and triphenylphosphine. This Wittig reaction produced the THP ether of Z7-14:OH accompanied by a small amount of the (*E*)-isomer. After cleavage of the THP ether, Z7-14:OH (>99% purity) was obtained by column chromatography using silica gel impregnated with 15% $AgNO_3$. Z7-14:Ald and (*Z*)-7-tetradecenyl acetate (Z7-14:OAc) were synthesized by oxidation with PCC and acetylation with acetic anhydride of the alcohol, respectively. For mating disruption, Z7-14:Ald (about 200 g) was prepared from Z7-14:OAc (Shin-Etsu Chemical Company, Tokyo, Japan) by hydrolysis with KOH in methanol, followed by Swern oxidation to the aldehyde.

Field Trapping of Male Moths A synthetic compound(s), dissolved in hexane, was applied to a rubber septum (8 mm o.d., white rubber; Aldrich Chemicals, Milwaukee, WI, USA). After evaporation of the solvent, the lure was placed at the center of a sticky trap (30×27 cm bottom plate, Takeda Chemical Ind., Ltd., Osaka, Japan), which was hung on a pomelo tree approximately 1.5 m from the ground. Captured males were counted weekly. For comparison of trap catches, virgin females (three, 2- or 3-d-old, allowed to feed on 10% sugar water absorbed on a cotton wick) were caged in a small tea sieve and placed in a trap; females were renewed every 2 d.

Field trials for monitoring and mass trapping of *P. endocarpa* males were carried out using the same traps baited with a lure containing 1.0 mg of Z7-14:Ald on a rubber septum. The monitoring experiment was carried out in pomelo orchards of three different villages in Vinh Long Province in 2007, with three traps placed in each pomelo orchard. Traps were checked roughly every second week. The mass trapping experiment was carried out in three 0.1 ha plots in each of My Hoa and Dong Thanh villages, in Vinh Long Province, from April 4 to June 10, 2008. The three plots in each village had different treatments: 20 pheromone-baited traps only, a pyrethroid insecticide (cyhalothrin, Karate 2.5EC) sprayed three times during the test, or no (control) treatment. In the pheromone treatment, trapped males were counted weekly, and each lure was renewed monthly over the course of the experiment. Fruit damaged by CPC larvae in plots of the orchards was determined by inspecting the peel, and was assessed three times, on May 15, May 25, and June 10.

Formulation of Polyethylene Dispensers and Evaluation of Mating Disruption Synthetic Z7-14:Ald and stabilizers (Sumisorb 300 and Sumilizer BHT, 3% each, Sumitomo Chemical Co., Ltd., Osaka, Japan) were poured into 20-cm-long red polyethylene tubes, which were used for "Hamaki-con®" (Shin Etsu Chemical Co). Each tube contained about 80 mg of the

aldehyde and was suspended by twisting it around a small branch of a pomelo tree, approximately 1.5–2.0 m high above the ground. The efficacy of mating disruption was evaluated over two consecutive pomelo fruiting seasons in Vinh Long Province. The first trial was carried out from August 15 to September 30, 2008, in plots of three separate orchards located >500 m from each other: a 0.75-ha plot using 300 tubes (400 tubes/ha), a 0.6-ha plot using 120 tubes (200 tubes/ha), and a 0.5-ha plot using no tubes (control). Insecticides were not sprayed in the orchards during the trial. The second trial was carried out from August 11 to October 30, 2009 in plots of four separate orchards: a 1.1-ha plot using 440 tubes (400 tubes/ha), a 0.8-ha plot using 160 tubes (200 tubes/ha), and 0.3-ha and 0.6-ha plots using no tubes (control). In the last plot, a pyrethroid insecticide (cyhalothrin, Karate 2.5EC®) was sprayed three times during the trial; no insecticides were sprayed in the other orchards. The trial areas used were mostly square, with pomelo trees planted at a density of 400–500 trees/ha.

The efficacy of mating disruption was assessed by counting trapped males and damaged fruit in the orchards. Three traps, baited with a lure (Z7-14:Ald, 1.0 mg/septum), were hung in the middle of each orchard, with the lures renewed monthly. Captured males were counted biweekly in 2008 and weekly in 2009. Fruit damaged by CPC larvae was assessed as for the mass trapping experiment. In each orchard, 24 trees in peripheral plots and 18 trees in central plots were marked with a red stripe. CPC infestation was examined for all the fruit developed during the test term on the marked trees.

Data Analysis Data obtained from the experiments were analyzed by one-way ANOVA and Tukey-Kramer's HSD test. Means were standardized using log(x+0.5) and arcsine {SQRT(x)} transformation, in order to homogenize the variance.

Results

GC-MS Analysis of Female Extract Extracts of CPC were analyzed by GC-MS (Fig. 1). While the extract included many unknown compounds (Fig. 1a), the mass chromatogram of *m/z* 192 ($[M\text{-}H_2O]^+$, Fig. 1c) suggested the occurrence of a tetradecenal at 11.45 min. The retention time (Rt) and mass spectrum of this compound was the same as that for authentic Z7-14:Ald. In addition to the aldehyde, a mass chromatogram of *m/z* 194 (Fig. 1b), suggested two (Rts of 12.68 and 12.89 min) other candidates for pheromone components. The Rts and mass spectra of these compounds were coincident with those of authentic Z7-14:OAc and Z7-14:OH, respectively. GC-MS analysis of the extract treated with DMDS confirmed the positions of the double bonds for Z7-14:Ald and Z7-14:OH. The DMDS adduct derived from the aldehyde component (Rt 22.45 min) showed M^+ at *m/z* 304 and fragment ions at *m/z* 145 and 159, while the DMDS adduct derived from the alcohol component (Rt 23.99 min), showed M^+ at *m/z* 306 and fragment ions at *m/z* 145 and 161. As the concentration of the acetate component was low, the mass spectrum of the DMDS adduct could not be identified. The *cis*-geometry of these compounds was confirmed by the respective retention times of the *E*-isomers on the DB-23 column: E7-14:Ald (11.30 min), E7-14:OAc (12.54 min), and E7-14:OH (12.73 min). A

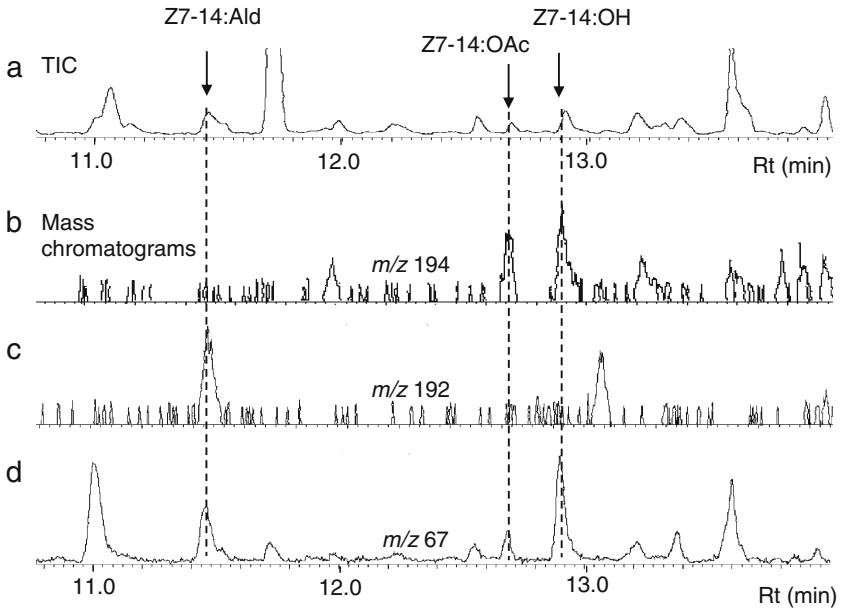

Fig. 1 Gas chromatography-mass spectrometry analysis of a pheromone gland extract from 30 female moths of the citrus pock caterpillar, *Prays endocarpa*. Total ion chromatogram (**a**), mass chromatograms at *m/z* 194 (**b**), 192 (**c**), and 67 (**d**)

mass chromatogram of *m/z* 67, a common fragment ion of tetradecenyl compounds, revealed no traces of *E*-isomers of any of the compounds (Fig. 1d). Mass spectral analysis of several extracts showed the ratio of Z7-14:Ald: Z7-14:OAc: Z7-14:OH to be about 10:3:10.

Optimization of the Synthetic Lure The three compounds, Z7-14:Ald, Z7-14:OH, and Z7-14:OAc were tested in field trials in pomelo orchards in My Hoa village from 2006 to 2009 (Table 1). Traps baited with Z7-14:Ald alone caught CPC males, while traps baited with other single-component lures, 1:1 binary blends, or a ternary blend did not (Table 1a). Addition of small amounts of Z7-14:OAc to Z7-14:Ald did not affect the catch of male CPC, relative to that caught by Z7-14:Ald alone. However, addition of a small amount of Z7-14:OH to Z7-14:Ald resulted in a drop in catch (relative to Z7-14:Ald alone), suggesting that Z7-14:OH inhibits the activity of Z7-14:Ald to CPC males (Table 1b). Increasing ratios of Z7-14:OAc to Z7-14:Ald in the blend resulted in decreased trap catches, although whether this was (at least in part) due to decreases of Z7-14:Ald amount was not investigated (Table 1c).

In general, increasing dosages of Z7-14:Ald yielded increased catches of CPC males (Table 2). The catches of male CPC in traps baited with any of the dosages of Z7-14: Ald tested were greater than those in traps baited with virgin females (Table 2).

Monitoring by the Pheromone Trap Figure 2 shows the catches of CPC males in the pheromone-baited traps in pomelo orchards of three different villages in Vinh Long Province in 2007. The numbers of captured males in My Hoa village generally were greater than those in Dong Thanh and Vinh Xuan villages. While adults were caught throughout the year, relatively lower numbers of males were caught from May to September, the rainy season in the Mekong Delta of Vietnam.

Mass Trapping by the Synthetic Pheromone The efficacy of mass trapping on reduction of CPC damage is shown in Table 3. In My Hoa village, over a thousand males were caught in the pheromone-treatment plot. Damage in this plot was less than in the untreated plot, but higher than in the insecticide-treated plot (Table 3a). In Dong Thanh village, in the pheromone-treated plot, fewer males (716) were caught and damage levels were similar to the plot with the insecticide but less than that in the untreated plot (Table 3b).

Disruption of Mating Communication by the Synthetic Pheromone Results of the mating disruption experiments are shown in Table 4. In 2008, pheromone traps in areas treated with dispensers, either at a rate of 200 or 400 dispensers/ha, captured no males over one and half months, while three traps in the untreated orchard (control) captured

a total of 211 males, indicating 100% disruption of male catch (Table 4a). A similar result was observed in 2009 (Table 4b), with only one and two males caught in the plots treated with the dispensers at 400 tubes/ha and 200 tubes/ha, respectively, over two and half months, compared to the 291 males caught in the untreated plot. The number of fruit damaged by CPC larvae was also reduced in pheromone-treated orchards. In 2008, about one half of the fruit examined in the control plot was damaged, compared to roughly only 3% in the center of the treated plots (for both densities of dispensers). A reduction in damage also was observed at the periphery of the pheromone-treated plots (Table 4a). While damage generally was lower in 2009 (compared to 2008) in the control area, damage again was lower at both the center and periphery of the pheromone-treated plots (Table 4b). In the pesticide-treated plot (in 2009), fewer males were caught in pheromone traps than in the untreated plots. Damaged fruit occurred at a similar frequency to that found in the untreated plot, and at a greater frequency than in the pheromone-treated plots.

Discussion

Chemical analysis of the pheromone gland of female CPC showed Z7-14:Ald, Z7-14:OAc (tentatively identified), and Z7-14:OH. In field trials, synthetic Z7-14:Ald alone attracted male moths. No synergistic effect of the other two compounds was demonstrated, although increasing proportions of Z7-14:OAc in a two-component blend (with concomitant decreases in the dosage of Z7-14:Ald) resulted in decreased trap catches. Z7-14:Ald previously has been identified as a pheromone component of four species of moths (Ando, 2010; El-Sayed, 2010), including three in the genus *Prays*, the citrus flower moths (*P. citri* and *P. nephelomima*) and the olive moth (*P. oleae*). CPC differs from these congeners morphologically as well as in host range and feeding behavior. All four *Prays* species appear to be attracted to Z7-14:Ald. However, pheromone traps baited with Z7-14:Ald caught only CPC males in our field tests, suggesting that only CPC is found in the Mekong Delta. We will investigate whether CPC is sympatric with *P. citri* and *P. nephelomima* in other areas of Vietnam.

Field evaluations of synthetic pheromone found that a rubber septum loaded with 1.0 mg of Z7-14:Ald was an

[a] Experiments were carried out in Vinh Long Province from April 4 to June 10, 2008. Damaged fruit were counted on May 15, May 25, and June 10. In (a), F=330.1, DF=9; in (b), F=20.1, DF=8

[b] Mean ± SE. Values within each test followed by a different letter are significantly different at $P<0.05$ by Tukey-Kramer Test

[c] Each pheromone treatment used 20 traps baited with synthetic (*Z*)-7-tetradecenal (1 mg/septum). Each lure was renewed monthly and trapped males were counted weekly. Mean trap captures were 54.4±25.4 and 35.8±18.0 of *Prays* sp. in My Hoa and Dong Thanh, respectively

[d] A pyrethroid insecticide (cyhalothrin, Karate 2.5EC) was sprayed three times during the trial

effective tool for monitoring CPC. Our monitoring with pheromone traps showed that adult populations of CPC were high during the dry season and in the early and latter parts of the rainy season. These periods are coincident with the main fruit-bearing stages of pomelo in the Mekong Delta of Vietnam, from February to May, and from September to November. Additionally, CPC males were captured in greater numbers in My Hoa village, than in the two other villages of Dong Thanh and Vinh Xuan. The farming system in My Hoa is a monoculture of pomelo, while in Dong Thanh and Vinh Xuan, pomelo is only one of a number of crops planted, including other fruits, rice, and vegetables. Together, these data suggest that the population density of CPC may be governed by the phenology and density of pomelo fruit.

After identifying an attractive pheromone component, we utilized synthetic pheromone for suppression of damage by CPC in pomelo orchards. In lemon orchards in Israel, pheromone-based mass trapping at a density of 120 traps/ha successfully controlled the citrus flower moth, *P. citri*

[c] Three traps baited with synthetic (Z)-7-tetradecenal (1.0 mg/septum) were set on the first day of the experiments in each area. Each lure was renewed monthly and trapped males were counted biweekly for the 2008 trial and weekly for the 2009 trial

[d] Disruption (%) was calculated as $(N_c - N_t)/N_c \times 100$, where N_c and N_t are the numbers of males trapped in a control orchard and an area treated with dispensers

[e] Pyrethroid insecticide (cyhalothrin, Karate 2.5EC) was sprayed three times during the trial

(Sternlicht et al., 1990). In our work, mass trapping of CPC in pomelo orchards at a density of 200 traps/ha resulted in decreased damage to fruit, although the efficacy of this appeared to be dependent upon population density of CPC. This approach could be useful in areas with low densities of CPC damage. In addition to mass trapping, we also attempted mating disruption using polyethylene tubes filled with synthetic Z7-14:Ald, similar to that used for mating disruption of several leaf-roller moths in tea and apple orchards in Japan (Wakamura, 1992; Ando et al., 2004). Mating disruption has been used successfully for the control of a number of moth pests of crop fields, orchards, and forests (Cardé and Minks, 1995), including *P. oleae* in Greece and Egypt (Mazomenos et al., 1999; Hegazi et al., 2009). We found that both densities of tubes used (200 and 400/ha) resulted in virtually complete suppression of trap capture of male CPC. Moreover, the number of fruit damaged by larvae decreased, even in areas treated at 200 tubes/ha, indicating the efficacy of this approach for control of CPC.

This work is a first step in establishing new, sustainable Integrated Pest Management programs in Vietnam. In further work, we plan to establish the minimum density and longevity of dispensers for effective control of CPC throughout the year.

Acknowledgements The authors are grateful to Shin-Etsu Chemical Company (Japan) for supplying Z7-14:OAc and formulating the synthetic pheromone.

RAPID COMMUNICATION

Constraints of Simultaneous Resistance to a Fungal Pathogen and an Insect Herbivore in Lima Bean (*Phaseolus lunatus* L.)

Daniel J. Ballhorn

Received: 27 October 2010 / Revised: 8 December 2010 / Accepted: 21 December 2010 / Published online: 11 January 2011
© Springer Science+Business Media, LLC 2011

Abstract The existence of tradeoffs among plant defenses is commonly accepted, however, actual evidence for these tradeoffs is scarce. In this study, I analyzed effects of different direct defenses of wild lima bean plants (*Phaseolus lunatus*) that were simultaneously exposed to a fungal pathogen (*Colletotrichum lindemuthianum*) and an insect herbivore, the Mexican bean beetle (*Epilachna varivestis*). Although plants were derived from spatially widely separated populations, I observed a common tradeoff between resistance to pathogens and herbivores. Plants with high levels of anti-herbivore defense (cyanogenesis) showed low levels of resistance to pathogens (polyphenol oxidase activity and phenolic compounds), and *vice versa*. Competition for resources generally is considered to be the basis for tradeoffs. However, I report direct inhibition of polyphenol oxidase by cyanide, making simultaneous expression of both defenses at high levels impossible. I argue that populations composed of individuals investing in one type of defense have an advantage in environments that periodically favor either pathogen or herbivore plant antagonists.

Key Words Tradeoff · Plant defense · *Colletotrichum lindemuthianum* · *Epilachna varivestis* · *Phaseolus lunatus* · Defense syndrome · Cyanogenesis · Polyphenol oxidase · Phenolics

Introduction

In their natural environment, plants are exposed to multiple antagonists simultaneously, including pathogens as well as herbivores. Consistent with the broad range of attackers, plants generally do not rely on a single defense mechanism, but express multiple defenses (Walling 2000). Theory predicts that constraints on resource allocation produce negative genetic correlations (tradeoffs) between individual traits (Agrawal et al., 2010). In theory, tradeoffs occur where multiple traits are favored by natural selection and compete for shared resources (Thaler et al., 1999), but in practice tradeoffs are rarely found (Agrawal et al., 2010). Such discrepancies between the theory and evidence are difficult to explain without a mechanistic understanding of how tradeoffs affect plant interactions in ecological networks.

Tradeoffs may reflect physiological interference among defensive traits instead of direct resource competition. In lima bean for example, extensive cyanogenesis (anti-herbivore defense) inhibits the activity of polyphenol oxidases (PPO), which are mainly targeted against pathogens. Cyanide binds to the metal-containing active site of PPO (Lieberei et al., 1989). Cyanide-resistant defensive enzymes such as lipoxygenases (LOX) have been demonstrated in some plant species (Tscharntke et al., 2001), but PPOs in lima bean are cyanide-sensitive (Ballhorn et al., 2010a).

I asked how two traits that act against different types of antagonists (Ballhorn et al., 2010a,b) functionally interact when lima bean plants are under simultaneous attack by fungal pathogens and insect herbivores. Under experimental greenhouse conditions, I used wild lima bean plants derived from three different populations in North America, Central America, and the Caribbean to test the concerted effects of cyanogenesis and PPO activity on resistance to a fungal bean pathogen (*Colletotrichum lindemuthianum*) and

a specialist insect herbivore, the Mexican bean beetle (*Epilachna varivestis*).

Methods and Materials

Plants Lima bean plants were grown from seeds collected at natural sites from a Mexican (near Puerto Escondido, Pacific coast of Oaxaca 15°55′31.80″N, 97°9′4.68″W, 8 m a.s.l.), a Costa Rican (near Asserri, San Jose 9°51′48.02″N, 84°5′42.07″W, 1900 m a.s.l.), and a Cuban (Montecristo, Guantanamo 20°7′12.15″N, 74°14′58.01″W, 168 m a.s.l.) population. Plants were cultivated under greenhouse conditions as described in Ballhorn et al., (2007) for 5 wk prior the experiments.

Pathogens and Insects The anthracnose-causing fungal bean pathogen *Colletotrichum lindemuthianum* (strain 12250 purchased from the DSMZ, Braunschweig, Germany), was maintained on oat flake medium (30 g oat flakes, 15 g agar, 1000 ml H_2O) according to DSMZ instructions. To induce sporulation, sterile young snap bean pods (*Phaseolus vulgaris*) were inoculated with a suspension of *C. lindemuthianum* mycelia and incubated at 22±1°C for 14 d in the dark. From these cultures, conidial suspensions were prepared by filtering the homogenate through 3 cm cotton in a 60 ml syringe to remove mycelial fragments. Spore concentration in pooled solutions was adjusted to 10^5 conidia ml^{-1} with sterile distilled water using an Improved-Double-Neubauer counting-chamber. Mexican bean beetles (MBB) were maintained on snap bean as described in Ballhorn et al., (2010b). Freshly molted third-instar larvae were used for the experiments.

Experimental Setup Twenty-four plants (in blocks of 6×4 plants) from each population were used for the experiment in growth chambers under conditions similar to those used for greenhouse cultivation (Ballhorn et al., 2007). Plants of the same block (= population) had contact with each other, whereas the different blocks did not. At the end of the light period, every plant was sprayed from the lower side with 5 ml spore suspension. On the following day, one MBB larva was placed on each plant. Third-instars are relatively mobile and move between contacting plants searching for suitable hosts but do not leave their food plants completely.

Data Collection and Chemical Analysis After an experimental period of 8 d, the number of fungal lesions was counted, and feeding damage was quantified for every plant. Missing leaf area was quantified with a LICOR LI-3100 Area Meter (Walz GmbH, Effeltrich, Germany). Every leaf was scanned three times, and the mean was used for further analysis. To characterize defensive features of plants, leaf discs from undamaged areas of young leaves (Ballhorn et al., 2010c) were analyzed chemically. Leaf cyanogenic potential was analyzed by complete enzymatic degradation of cyanogenic glycosides in leaf extracts followed by 20 min of incubation at 30°C in gas-tight glass vessels (Thunberg-vessels) and spectrophotometric measurement at 585 nm using the Spectroquant® cyanide test (Merck, Darmstadt, Germany) (Ballhorn et al., 2011). Enzymatic activity of PPO was determined polarographically, using the Clark electrode system (Yellow Springs Instruments, Yellow Springs, OH, USA) to measure O_2−consumption during the oxidation of polyphenols and their derivates to quinones (Ballhorn et al., 2010a). Total phenolics were determined in aqueous acetone extracts of leaves with the Folin method using epicatechin (Sigma, Deisenhofen, Germany) as the standard.

Statistical Analyses One-way ANOVAs were applied to test for significant differences of chemical traits, number of lesions, and consumed leaf area among populations. *Pearson's correlations* were used to test for co-variation of variables. Analyses were carried out with PASW Statistics 18.

Results and Discussion

Lima bean plants varied by a factor of 5.15 between the lowest and highest values measured for cyanogenic potential (HCNp, total amount of cyanogenic precursors in leaf tissue). There also was variation in PPO activity (factor of 16.01), and in concentration of total phenolics (factor of 2.76). As I observed no significant differences of traits among lima bean plants from the different origins (HCNp: $F_{2,69}$=0.670, P=0.515; PPO activity: $F_{2,69}$=0.048, P=0.953; total phenolics: $F_{2,69}$=2.469, P=0.092; according to *one-way ANOVA*), data were pooled for further analyses. Cyanogenic potential of plants was correlated negatively with PPO activity and concentration of total phenolics, whereas PPO activity and phenolics showed a positive correlation (according to *Pearson's correlation*; Fig. 1a–c). Consumed leaf area was correlated negatively with HCNp but showed a significantly positive correlation to PPO activity and phenolics (Fig. 1d–f). The number of lesions showed a positive correlation to HCNp (Fig. 1g) but was correlated negatively to PPO activity and concentration of phenolics (Fig. 1h,i). The observed defensive effects of cyanide on the insect herbivore as well as of PPO activity on the fungal pathogen are in line with previous studies (Gleadow and Woodrow 2002; Ballhorn et al., 2010a,b). However, the positive correlation between consumed leaf area and PPO activity (Fig. 1e) or total phenolics (Fig. 1f) is more likely due to negative effects of HCN on insects than to

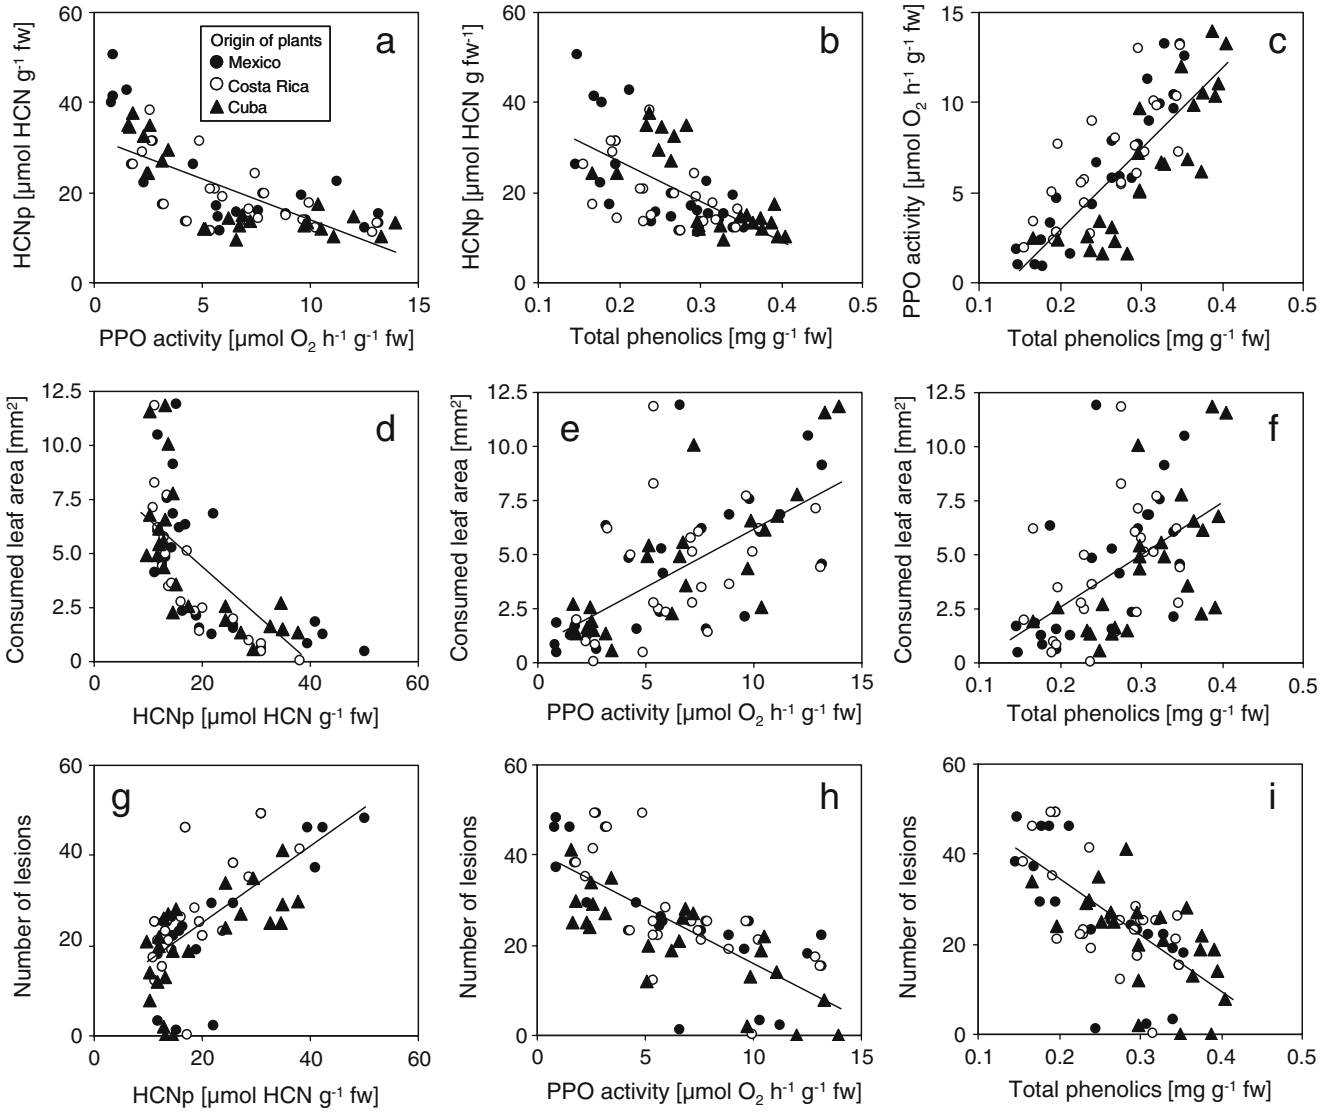

Fig. 1 Correlations between plant traits and plant resistance to fungal and herbivore antagonists. Lima bean plants from three different populations (Mexico, Costa Rica, and Cuba) were analyzed for cyanogenic potential (HCNp; total amount of cyanogenic precursors in leaf tissue), polyphenol oxidase (PPO) activity and concentration of total phenolics. In experiments in which plants were simultaneously exposed to a fungal pathogen (*Colletotrichum lindemuthianum*) and a specialist insect herbivore (Mexican bean beetle; *Epilachna varivestis*), damage caused by each plant antagonist was quantified. To search for potential tradeoffs among plant traits and resistance to fungal pathogens and insect herbivores, the following *Pearson's correlation* were conducted (**a**: $r=-0.716$, $P<0.001$; **b**: $r=-0.604$, $P<0.001$; **c**: $r=0.710$, $P<0.001$; **d**: $r=-0.682$, $P<0.001$; **e**: $r=0.646$, $P<0.001$; **f**: $r=0.534$, $P<0.001$; **g**: $r=0.659$, $P<0.001$; **h**: $r=-0.732$, $P<0.001$; **i**: $r=-0.558$, $P<0.001$)

positive effects of PPOs and phenolics (Ballhorn et al., 2010a). It also is likely that the negative correlations between HCNp and PPO activity as well as between HCNp and phenolic content are the underlying cause of the positive correlation obtained here between the number of pathogen lesions and HCNp (Fig. 1g).The complex interdependence of various chemical plant traits and the resulting effects on different plant antagonists shows that correlations have to be interpreted with care—in particular when only one trait and one corresponding effect is analyzed—as some correlations might not be of functional importance.

The present study on wild lima beans demonstrates that tradeoffs between cyanogenesis and PPO activity as well as cyanogenesis and phenolics occur in natural bean populations distributed over large spatial scales. More importantly, the work shows that these tradeoffs actually result in an ecologically important tradeoff between resistance to pathogens and herbivores when plants were exposed to both antagonists simultaneously. Among all plants, feeding damage and lesion number showed a highly significant negative correlation ($r=-0.600$, $P<0.001$ according to *Pearson's correlation*). From the ecological and population-genetics

perspective, the expression of either anti-fungal or anti-herbivore defenses may be interpreted as an adaptation to variable environmental conditions, which either favor the occurrence of pathogens (humid conditions) or enhance the pressure by herbivores (dry periods) in the natural habitats of lima bean (pers. observation). Thus, variability of defensive traits allows populations to overcome periodically changing environmental conditions not only on the seasonal level but also over longer periods for example due to El Niño climate episodes. In evolutionary terms, periodically changing environmental conditions may represent a stabilizing factor for maintaining this tradeoff between anti-pathogen and anti-herbivore defenses in natural lima bean populations.

Acknowledgements I thank José Rodriguez for providing seeds of Costa Rican and Caribbean bean populations as well as Martin Heil and Ralph Krüger for providing seeds from Mexico. I thank Corrie S. Moreau and Stefanie Kautz for helpful comments on earlier versions of the manuscript. Financial support by the DFG (Ba 3966/1-1) is gratefully acknowledged.

Why Feed on Fungi? The Nutritional Content of Sporocarps Consumed by Buffy-Headed Marmosets, *Callithrix flaviceps* (Primates: Callitrichidae), in Southeastern Brazil

Renato R. Hilário · Stephen Francis Ferrari

Abstract The typical diet of *Callithrix* marmosets is based on gums, although fungi are the dietary staple of a single group of *Callithrix flaviceps* studied in the Augusto Ruschi Biological Reserve, in southeastern Brazil. Here, we present the nutritional composition of two species of *Mycocitrus* fungi consumed by *C. flaviceps*, and discuss possible determinants of the preference of the marmosets for fungi over gums. The fungi were high in sugar/fiber and poor in proteins, and were similar in composition to the gums exploited by other marmosets and to the fungi consumed by *Callimico goeldii*. The reduced protein content of the fungi may be offset by the arthropod component of the diet of the *Callithrix flaviceps* study group. The low relative metabolic rate and enlarged cecum of *Callithrix* enable these marmosets to exploit foods with a high fiber content. In addition, the greater digestibility of chitin in comparison with plant fiber may make fungi a nutritionally more valuable resource to marmosets than gums. Marmosets, thus, may prefer to feed on fungi when an adequate supply of this resource is available in the environment.

Key Words Mycophagy · Atlantic forest · *Mycocitrus* · Diet · Feeding choices · Primate · Callitrichidae

Introduction

Primates exploit a wide range of resources, including reproductive and non-reproductive plant parts and animal prey (Chapman et al., 2002). Despite this, fungi constitute an unusual resource for primates, and mycophagy has been recorded only to date in 23 of the more than 400 recognized species (Hanson et al., 2006; Hilário and Ferrari, 2010). In most cases, fungi are an occasional food used to complement the diet as and when available, although for some species, such as the black snub-nosed monkey (*Rhinopithecus bieti*) and Goeldi's monkey (*Callimico goeldii*), fungi are a dietary staple (Kirkpatrick et al., 1998; Porter, 2001).

Food quality is an important factor influencing foraging decisions (Chapman and Fedigan, 1990). In addition to nutrients such as carbohydrates, proteins, and lipids, which provide essential substances for bodily functions (Maynard and Loosli, 1974), fiber is an important digestive aid (NRC, 2003). While they vary considerably in their composition, fungi tend to be a relatively rich source of carbohydrates, although much of this component may be present in the form of fiber, which requires specializations for efficient digestion (Claridge and Cork, 1994; Claridge et al., 1999).

Atlantic Forest marmosets (genus *Callithrix*) are small-bodied monkeys specialized for the dietary exploitation of plant exudates (gums), which are relatively rich in polysaccharides and minerals such as calcium. Their primary feeding specializations are their chisel-like lower incisors, which allow them to gouge the bark of gum-producing plants to provoke the flow of exudates (Rosenberger, 1978),

and an enlarged cecum, in which the gums are probably fermented for digestion (Coimbra-Filho et al., 1980).

Two cases of mycophagy are known in *Callithrix*, in populations that inhabit montane coastal forests in southeastern Brazil (Corrêa, 1995; Hilário and Ferrari, 2010). In the case of buffy-headed marmosets, *Callithrix flaviceps*, which is reported here, fungi were a staple food, and largely have substituted both gum and fruit in the group's diet. In this research, samples of sporocarps consumed by these marmosets were analyzed to establish their nutritional content for comparisons with other fungi consumed by mammals, and with gums exploited by *Callithrix* marmosets, in an attempt to evaluate the factors that determine the preference for fungi over gum in the *C. flaviceps* study group.

Methods and Materials

Study Site and Group Ecological data were collected at the Augusto Ruschi Biological Reserve (RBAR—19°52′ S, 40°33′W), a 3589 ha fragment of montane Atlantic Forest, located in the Brazilian state of Espírito Santo. The vegetation within the study group's home range varied from primary to early successional forest, with dense stands of *Merostachys* bamboo in many areas. The composition of the diet of a free-ranging group of *C. flaviceps* was estimated by using scan sampling records (Altmann, 1974) collected between January and December, 2008. Data were collected on 6 to 9 days per month, with a 1-min scan being conducted at 5-min intervals throughout the daily activity period on a total of 91 days (Hilário and Ferrari, 2010).

Nutritional Analysis The marmosets consumed two species of *Mycocitrus* (Ascomycetes) fungi, *Mycocitrus* sp. 1 and *Mycocitrus* sp. 2 (Fig. 1), the sporocarps of which were invariably attached to the stems of bamboos of the genus *Merosthachys*. Samples of sporocarps were collected between July and December, 2008. Approximately 200 g of sporocarps of *Mycocitrus* sp. 1 and 130 g of *Mycocitrus* sp. 2 were collected for analysis. Samples initially were dried in a plant specimen drier under an incandescent lamp, triturated in a Wiley mill, sieved through a size 42 mesh, and then stored in tightly-sealed glass flasks at room temperature until processing. The sporocarps were triturated together to produce a single homogeneous sample for each species. Three sub-samples were analyzed for each species, and the results are presented as simple means, given the negligible variation among them. During processing, the samples were first dried in a laboratory oven at 100–105°C, following Cuniff (1995), to determine the humidity level by weighing the material before and after drying. The ash content was determined by heating the material, initially over a Bunsen burner, and then in a muffle furnace at 550°C, until it had turned into lightly-colored ash.

Nitrogen content was determined using the Kjeldahl method and multiplied by a Nitrogen/protein factor of 6.25, following the procedure recommended by Cuniff (1995). Lipid content was determined through hot extraction in ethyl ether, by the Soxhlet method, using QUIMIS-Q-308 G26 as the extractor. An attempt was made to determine the gross fiber content of the sample by acid digestion with citric, acetic, and trichloroacetic acids, as recommended by Diemair (1963), but during processing, the material became gelatinized, possibly due to the presence of complex carbohydrates. As this can compromise the digestion and filtering process, and affect the reliability of the results, we opted to estimate the fiber and sugar content as a single value, by subtracting the weight of the other substances (protein, lipid, and ash) from that of the sample. Caloric value of the fungi, per gram, was calculated by multiplying the proportion of protein by 4.80, carbohydrates by 4.10, and lipids by 9.45, according to Paine (1971).

Results

Diet of the C. flaviceps Study Group During the 12 months of the study period, a total of 2278 records of feeding behavior were collected, and in 1673 of these, the item being ingested was identified. Hilário and Ferrari (2010) proposed that most of the unidentified records probably

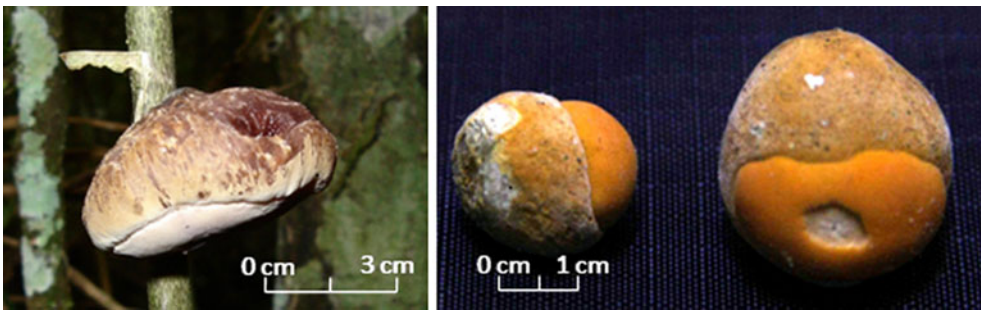

Fig. 1 The two *Mycocitrus* morphospecies exploited by the *Callithrix flaviceps* group in the RBAR, Espírito Santo, Brazil. Photographs: Frederico Pereira. Reproduced with permission from Hilário and Ferrari, 2010

were related to the ingestion of fungi, in which case, the contribution of this item to the diet would have been underestimated. Even so, fungi contributed 64.6% of feeding records for identified items on average over the study period, and never contributed less than 54.0% in any 1 month. In addition to being the most mycophagous diet recorded for any platyrrhine species, including *Callimico goeldii* (Porter, 2001; Porter et al., 2007), the animals appeared to ignore other plant resources (fruit and exudates). In other words, they fed preferentially on fungi, even when the resources typically exploited by other marmosets were available in the environment.

The role of fungi as a dietary staple throughout the year for the *C. flaviceps* study group is comparable to that of plant exudates in the diets of other *Callithrix* marmosets. This includes a second *C. flaviceps* group studied at a site where edible fungi were apparently rare (Ferrari, 1991; Guimarães, 1998).

Nutrient Content of the Sporocarps Moisture represented 11.49±0.03% of the composition of *Mycocitrus* sp. 1 and 9.78±0.03% for *Mycocitrus* sp. 2. These values are not necessarily comparable with those from other studies, however, due primarily to the fact that the sporocarps were partly dried, rather than fresh.

The two species of fungi analyzed here were relatively poor in protein, in comparison with other fungi and most gums (Table 1), although lipid content was similar to that of other fungi. Fiber/sugar content was relatively high in comparison with other fungi, by contrast, and more compatible with that of the gums. The ash content of *Mycocitrus* also was more similar to that of gums than to other fungi.

The two *Mycocitrus* species also were highly similar in their energy content, with 4.18 kcal per gram for species 1, and 4.12 kcal/g for species 2. These values are slightly higher than those obtained for *Auricularia auricula* (4.10 kcal/g) and *A. delicata* (4.01 kcal/g) by applying Paine's (1971) formula to the proportions of nutrients provided by Hanson et al. (2006)—see Table 1. Practically all these values also are within the range for gums—4.02–4.28 kcal/g—provided by Passamani (1996) and Melo et al. (1997).

There are considerable disparities in some values—in particular, the two analyses of *Acacia paniculata*—which may reflect either methodological differences or real variation in the composition of the samples. Despite this variation, one other clear pattern apparent from the data is the greater similarity of the composition of *Mycocitrus* to that of *Ascopolyporus* and *Auricularia* (the bamboo fungi

consumed by *Callimico*) in comparison with the hypogeal species, especially in relation to proteins and fibers/sugars.

Discussion

Overall, the nutritional composition of the fungi consumed by *Callithrix flaviceps* is similar to that of both the fungi consumed by *Callimico goeldii* (Hanson et al., 2006) and to the gums exploited by other *Callithrix* species (Melo et al., 1997; Passamani, 1996—see Table 1). As fungi contributed to the diet of the *C. flaviceps* study group in a proportion similar to that of gum in other *Callithrix* studies (see Hilário and Ferrari, 2010), it seems reasonable to conclude that the fungus-rich diet recorded in the present study had a nutritional balance similar to that of other marmosets.

A small, but potentially important difference is the smaller protein content of the *Mycocitrus* fungi in comparison with gums (Table 1). The values for the fungi may even be overestimated given that they were determined via the nitrogen content, which includes the proportion present in the carbohydrate chitin molecules of the fungus. While the protein content of the fungus may be lower than the daily requirement for marmosets (6.6% dry matter for *Callithrix jacchus*: NRC, 2003), this may not be a limiting factor, given that 25.8% of the study group's diet was made up of animal prey, primarily arthropods, which are an excellent source of protein (Sterling et al., 1994; Baker et al., 1998).

Based on the results of Hanson et al. (2006), it seems reasonable to conclude that the carbohydrates in *Mycocitrus* are composed primarily of fiber, which slows the transit time of food through the gut (Power and Oftedal, 1996), and may thus impose ecological constraints on small-bodied animals such as marmosets (adult body weight 300–400 g), given their relatively higher metabolic rates (Milton, 1984). However, marmosets have a lower metabolic rate than predicted by their body weight (Ross, 1992), and an enlarged cecum, which is thought to aid in the digestion of fiber through bacterial fermentation (Coimbra-Filho et al., 1980).

The fiber of fungi is mainly chitin (Martin, 1979), which is also the primary component of the arthropod exoskeleton. Some insectivorous mammals produce chitinase (Jeuniaux, 1961; Cornelius et al., 1975) and, while this has not been confirmed in marmosets, chitin is more easily digested by these primates than plant fiber (Krombach et al., 1984). In this case, fungi may represent a more nutritionally valuable resource for marmosets than gums, in which the fiber content is composed primarily of heteropolysaccharides, with a predominance of arabinose, galactose, rhamnose, and aldobiouronic acids (Bearder and Martin, 1980). The higher nutritional quality of fungi in comparison with exudates could thus account for the preference of fungi over exudates, and explain why these marmosets appeared to ignore fruit during their foraging activities.

Fungi nevertheless pose other challenges. Edible species are rare in most forests and have slow rates of regeneration (Hanson, 2000; Hanson et al., 2003), which may impose a need for relatively large home range, given the need to ensure access to a number of feeding patches sufficient to maintain an adequate diet over the course of the year. The *C. flaviceps* study group occupied a home range approximately four times larger than the next largest recorded to date for any marmoset group (Hilário, 2009). Relatively large home ranges are also characteristic of a second callitrichid, *Callimico goeldii* (Porter et al., 2007), a characteristic which also has been attributed to the importance of mycophagy in the ecology of this species (Porter and Garber, 2010). In the marmosets, this large home range problem may nevertheless be partly offset by other benefits, such as the avoidance of bark gouging, which is necessary to maintain a regular supply of gum exudates (Digby et al., 2011). Given the findings of the present study, the predominance of gum in the diets of other marmosets may be primarily a consequence of the relative lack of edible fungi at most study sites. Future studies should target the understanding of the relationship between the consumption of fungi and their availability within the environment. Systematic analyses of the nutritional content of other marmoset foods will provide more definitive insights into the factors that determine feeding and foraging choices.

Acknowledgments We extend special thanks to Professor José Virgílio Coelho, who dosed the nutrient content of the fungi. We are also grateful to Tatiana Gibertoni and Jadergudson Pereira for identification of the fungi. We thank Eduardo Mignone, director of the Augusto Ruschi Reserve, Flávio Rodrigues, Adriano Chiarello, Kátia Corrêa, Milene Martins, Sérgio Mendes, Ítalo Mourthé, Waldney Martins, and Frederico Pereira. The project was supported by Idea Wild and US Fish and Wildlife Service, RRH by FAPEMIG and CAPES, and SFF by CNPq (process no. 302747/2008-7).

Abstract In response to herbivory by arthropods, plants emit herbivory-induced volatiles that attract carnivorous enemies of the inducing herbivores. Here, we compared the attractiveness of eight cucumber varieties (*Cucumis sativus* L.) to *Phytoseiulus persimilis* predatory mites after infestation of the plants with herbivorous spider mites (*Tetranychus urticae*) under greenhouse conditions. Attractiveness differed considerably, with the most attractive variety attracting twice as many predators as the least attractive variety. Chemical analysis of the volatiles released by the infested plants revealed significant differences among varieties, both in quantity and quality of the emitted blends. Comparison of the attractiveness of the varieties with the amounts of volatiles emitted indicated that the quality (composition) of the blend is more important for attraction than the amount of volatiles emitted. The amount of (*E*)-β-ocimene, (*E,E*)-TMTT, and two other, yet unidentified compounds correlated positively with the attraction of predatory mites. Quantities of four compounds negatively correlated with carnivore attraction, among them methyl salicylate, which is known to attract the predatory mite *P. persimilis*. The emission of methyl salicylate correlated with an unknown compound that had a negative correlation with carnivore attraction and hence could be masking the attractiveness of methyl salicylate. The results imply that the foraging success of natural enemies of pests can be enhanced by breeding for crop varieties that release specific volatiles.

Key Words Cucumber · *Tetranychus urticae* · *Phytoseiulus persimilis* · Induced plant volatiles · Jasmonic acid · Volatile variability

Introduction

In nature, plants are challenged by a wide range of herbivorous arthropods. Herbivory can severely reduce reproductive success of native plants, and in crops herbivore infestation can result in severe yield losses (Schoonhoven et al., 2005). Plants have developed a multitude of survival strategies, which include constitutive physical and chemical barriers, tolerance mechanisms, and induced defenses that are activated upon attack, such as herbivore-induced plant volatiles (HIPV) that attract natural enemies of the herbivores.

Natural plant odors usually are blends of many different compounds. Upon infestation by herbivores, the composition of the emitted plant volatile blends changes (Arimura et al., 2005). It is widely recognized that these HIPV play an important role in host/prey searching behavior of predators and parasitoids of herbivorous arthropods (Vet and Dicke, 1992; Dicke, 1999; Heil, 2008; Dicke and

Baldwin, 2010). The release of these attractants also can be achieved by wounding the plants in combination with the application of herbivore regurgitant to the damaged sites or by exposing the plant to phytohormones such as jasmonic acid (JA) (Turlings et al., 1993; Hopke et al., 1994; Dicke et al., 1999; Halitschke et al., 2001).

The two-spotted spider mite, *Tetranychus urticae* Koch, is a common pest of many glasshouse vegetables, including cucumber. *Tetranychus urticae* feeds on individual leaf cells, causing the reduction of total chlorophyll content and net photosynthetic rate of leaves (Bondada et al., 1995; Iatrou et al., 1995). Such leaf cell and tissue injury alters carbon allocation patterns of plant organs (Wyman et al., 1979), often causing deformation of plants (Campbell et al., 1990), and finally often results in a decrease of the productivity of the crop or in death of the plant (Park and Lee, 2005). Previous studies have shown that *T. urticae* infestation or JA treatment induced the emission of volatiles in cucumber plants that attract the predatory mite *Phytoseiulus persimilis* (Bouwmeester et al., 1999; Dicke et al., 1999; Gols et al., 1999; Agrawal et al., 2002; Kappers et al., 2010), a major natural enemy of the spider mites (Sabelis and Dicke, 1985). Predatory mites are blind and rely on odors to locate distant prey patches (Sabelis and Van De Baan, 1983). Arrestment of predatory mites on plants can be influenced not only by the presence of prey, but also by leaf surface characteristics (Krips et al., 1999), and by HIPV (Sabelis et al., 1984).

The quantitative and qualitative HIPV emission varies among plant species (Van Den Boom et al., 2004) and within plant species among varieties (Loughrin et al., 1995; Takabayashi and Dicke, 1996; Krips et al., 2001; Hoballah et al., 2002; Degen et al., 2004; Bukovinszky et al., 2005; Kappers et al., 2010), which may result in differences in attractiveness to the natural enemies of herbivores. However, little to nothing is known about the consequences of these differences among plant genotypes for the effectiveness of the natural enemies under field or greenhouse conditions.

The attractiveness of typical spider mite-induced plant volatiles has been reported for (*E*)-β-ocimene, methyl salicylate, linalool, nerolidol, (*E*)-4,8-dimethyl-1,3,7-nonatriene [(*E*)-DMNT], and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene [(*E,E*)-TMTT] (Dicke et al., 1990a; De Boer and Dicke, 2004a,b; De Boer et al., 2004; Kappers et al., 2005). Furthermore, results obtained by de Boer and Dicke (2004a) suggest that *P. persimilis* is attracted by methyl salicylate after the mites have been exposed to a methyl salicylate-containing odor blend.

Studies that address the attraction to herbivory-induced plant volatiles have been performed mostly under standardized experimental conditions, such as two-choice Y-tube set-ups (but see De Moraes et al., 1998; Kessler and Baldwin, 2001; Heil, 2004). In this study, we analyzed the attraction of the predatory mite *P. persimilis* to the volatiles of eight cucumber varieties upon spider-mite infestation under realistic greenhouse conditions. In addition, we analyzed the volatile blends emitted by plants of the cucumber varieties in response to spider-mite infestation or JA-treatment, and analyzed the correlation between these volatiles and predatory mite attraction.

Material en Methods

Plant and Mite Material Eight *Cucumis sativus* L. varieties were used. We obtained the varieties from the Centre for Genetic Resources, The Netherlands (CGN19656), and two Dutch Seed Companies (Table 1). Seeds were germinated in vermiculite, and after 7 d transplanted to 6 L pots with potting compost and nutrient solution. Plants were cultivated in a greenhouse at 23±2°C, 60±10% relative humidity (RH), under a natural daylight photoperiod (April–September). Four-wk-old plants with eleven leaves were used for experiments.

The herbivore *Tetranychus urticae* Koch, the two-spotted spider mite, was reared on bean plants (*Phaseolus vulgaris*) in a greenhouse. Predatory mites, *Phytoseiulus persimilis,* were reared on spider-mite infested bean plants.

Predator Attraction Setup Plants were infested with *T. urticae* to induce herbivore feeding under similar conditions as described above. Per cucumber variety, ten healthy plants were placed in a line with approx. 0.45 m between two neighboring plants. The ten plants were enveloped by a gauze cage (3×6×2.5 m). The 3rd plant was infested with approx. 500 spider mites that were distributed equally over the 7th and 8th leaf. After 3 d, the inoculated infested leaves showed visual signs of damage. Spider mites did not move between leaves, i.e., no mites were found on uninoculated leaves. Three days later, 150 predatory mites, *P. persimilis,* were released on plants 5, 6, and 7 in the row, 50 predators on each plant. The number of walking predatory mites and predator eggs that were found on spider-mite infested plants was counted after 48 and 96 hr after the introduction of the

Table 1 Origins of cucumber varieties used in this study

Code	Varieties & Genetic background

B	F1 Hybrid, long European type
C	F1 Hybrid, long European type
D	F1 Hybrid
E	F1 Hybrid
F	F1 Hybrid, long European type
G	F1 Hybrid, long European type
H	F1 Hybrid, mini type

predators. All varieties were included six times, randomly distributed over eight experimental runs, with six varieties per run. The six gauze cages were positioned next to each other in a greenhouse with 1 m between two cages. In each run, an accession had different accessions as neighbors. Per accession, the average number of mobile *P. persimilis* adults on spider-mite infested plants (plant nr. 3) was determined for each time point. Furthermore, we counted the number of *P. persimilis* eggs on these plants, as well as the number of spider-mite adults on these plants.

Headspace Collection To analyze the quantity and composition of herbivory-induced cucumber volatiles, dynamic headspace collection was used in the greenhouse setup. In the dynamic sampling procedure, the volatiles were collected on 200 mg Tenax TA (20/35 mesh; Grace-Alltech, Deerfield, MI, USA) in stainless steel cartridges (Markes, Llantrisant, UK). Headspace air was drawn through the cartridges for 1 hr using a portable battery-operated air sampler with a constant flow of 100±5 ml min^{-1} (Ametek / du Pont de Nemours & Co., type Alpha-2, DEHA International, Huizen, The Netherlands).

For comparison of herbivory-induced cucumber volatiles among varieties, we also used the plant hormone jasmonic acid (JA) to standardize the level of induction. Jasmonic acid induces a similar, though not identical, blend of volatiles as spider-mite infestation (Bouwmeester et al., 1999; Dicke et al., 1999; Gols et al., 1999; Bruinsma et al., 2009; Kappers et al., 2010; Snoeren et al., 2010b). Two healthy 3-wk-old plants of each accession were enclosed in a 2.5 L glass jar and sprayed with 1.0 mM (±) jasmonic acid (Sigma-Aldrich) in 0.01% Tween-20. In total, 20 ml were used to spray 16 plants (8 varieties, 2 plants each). Control plants were sprayed with water with 0.01% Tween-20. Dynamic headspace sampling was carried out in a climate room (20±2°C, 70% RH; L8:D16h photoperiod and 150–170 μmol photons m^{-2} s^{-1} PPFD at the level of the plants). Twenty-four hours after JA treatment, just before headspace collection, jars with plants were closed with a Viton-lined glass lid having an inlet and outlet. Inlet air was filtered by passing it through stainless steel cartridges filled with 200 mg Tenax TA. Volatiles were trapped by sucking air through the jar at a rate of 100 ml min^{-1} through a similar cartridge filled with 200 mg Tenax TA. Headspace volatiles for all treatments were collected for a period of 3.5 hr. Fresh weights of shoots were determined immediately after the experiments. On each experimental day, headspace samples of eight varieties were collected simultaneously. For each accession, the headspace was collected and analyzed for three replicate sets of two plants.

Analysis of Headspace Volatiles Headspace samples were analyzed with a Thermo Trace GC Ultra (Thermo Fisher Scientific, Waltham, MA, USA) connected to a Thermo Trace DSQ (Thermo Fisher Scientific, Waltham, MA, USA) quadrupole mass spectrometer. Before desorption of the volatiles, the Tenax cartridges were dry-purged with nitrogen at 30 ml min^{-1} for 30 min at ambient temperature to remove water. Volatiles were desorbed from the cartridges by using a thermal desorption system at 250°C for 3 min (Model Ultra Markes Llantrisant, UK) with a helium flow of 30 ml min^{-1}. Analytes were focused at 3°C on an electronically-cooled sorbent trap (Unity, Markes, Llantrisant, UK). Volatiles were transferred in splitless mode to the analytical column (Rtx-5 ms, 30 m, 0.25 mm i.d., 1.0 μm film thickness, Restek, Bellefonte, PA, USA) by rapid heating of the cold trap to 250°C. The GC was held at an initial temperature of 40°C for 3.5 min followed by a linear thermal gradient of 10°C min^{-1} to 280°C, and held for 2.5 min with a column flow of 1 ml min^{-1}. The column effluent was ionized by electron impact ionization at 70 eV. Mass spectra were acquired by scanning from 45–400 m/z with a scan rate of 3 scans s^{-1}. Compounds were identified by using the deconvolution software AMDIS (version 2.64, NIST, USA) in combination with NIST 98 and Wiley 7th edition spectral libraries and by comparing their retention indices with those from the literature (Adams, 1995). The identification of (*E*)-β-ocimene, (*E,E*)-TMTT, methyl salicylate, and geranyl isovalerate was confirmed by comparison with authentic standards. For quantification, characteristic quantifier ions were selected for each compound. Metalign software (PRI-Rikilt, Wageningen, the Netherlands) was used to align peaks of chromatograms of all samples and to integrate peak areas for the quantifier ions.

Statistics Individual volatiles were analyzed for significant changes among varieties for the treatments using one-way ANOVA followed by a LSD *post-hoc* analysis (SPSS 15.0, Chicago, Il, USA). The emitted quantities of individual volatile components were analyzed for significant differences among plant treatments by using a *t*-test (SPSS 15.0). Varieties were analyzed for significant differences in the attraction of predatory mites using one-way ANOVA followed by a LSD *post-hoc* analysis (SPSS 15.0).

Overall volatile profiles were analyzed by using Principal Component Analysis (GeneMath XT 2.0) after $\log_{10}$ transformation of the data and subtracting the average value of all treatments to normalize the data (Hendriks et al., 2005). The first few principal components (PCs) explain most of the variance in the original data, and we used it to visualize differences of the total volatile profile among varieties.

Multivariate mass spectra reconstruction (MMSR, Plant Research International, Wageningen, The Netherlands) as developed by Tikunov et al. (2005) was used to reduce the MetAlign dataset of 33.800 mass fragments. By using MMSR, clusters of related metabolite fragments that show

similar patterns over different samples can be recognized as so-called centrotypes on the basis of their overlapping patterns throughout the different samples, and the corresponding metabolites can be subsequently identified.

Results

Eight varieties of *C. sativus* were compared for their attractiveness to *P. persimilis* predatory mites after herbivory by *T. urticae* spider mites (Fig. 1). Twenty-one to 40% of the predatory mites that were released at a distance of 90, 135, and 180 cm from the spider-mite infested plants were retrieved on these infested plants within 96 hr, ranging from 30.8±2 predatory mites retrieved on hybrid D to 59.5±3 on landrace A (Fig. 1a). The number of *P. persimilis* eggs retrieved on these plants was lowest on hybrid D (21.3±2 eggs), and highest on landrace A (34.5±3 eggs) (Fig. 1b).

The total emission of volatiles by plants of each accession after damage by spider mites was estimated by summing all peak areas. All varieties, except accession B had significantly higher emission rates of volatiles than the surrounding non-infested cucumber plants (Fig. 2a). Hybrid B had the lowest emission rate of total volatiles after 96 hr of spider-mite infestation, whereas hybrid G had the highest emission rate. Differences in emission rates were not caused by differences in the numbers of spider mites on the infested plants. The number of spider mites retrieved on plants after 96 hr was lowest on landrace A and highest on hybrid H (Fig. 2b). There was no relation between the numbers of spider mites and the total amount of volatiles emitted across the eight varieties.

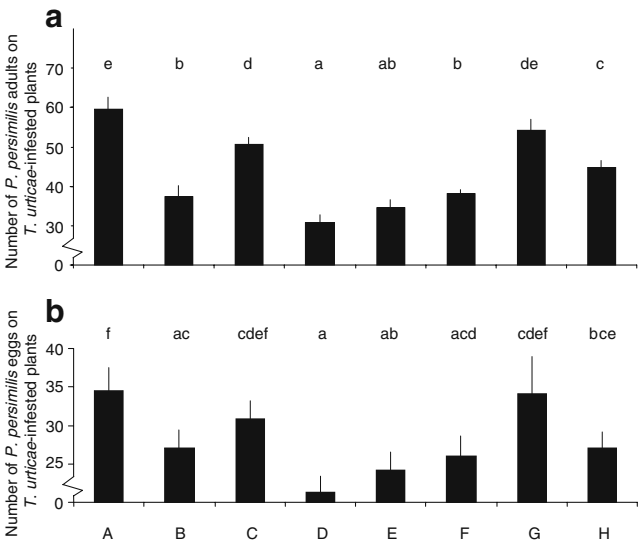

Fig. 1 Mean (± SE) of *Phytoseiulus persimilis* adults (**a**) and eggs (**b**) retrieved on spider-mite infested plants on eight cucumber varieties. *N*= 6 plants. Data were statistically analysed by using a one-way ANOVA followed by LSD *post-hoc*. Varieties followed by different letters indicate a significant difference ($P<0.05$)

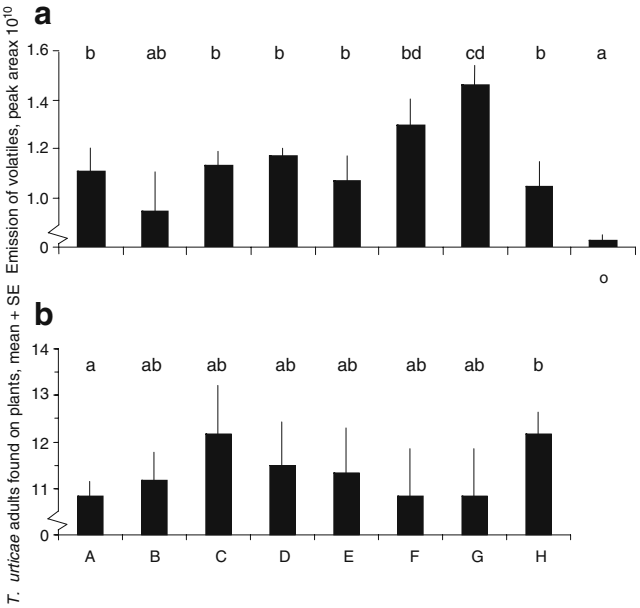

Fig. 2 Total emission of volatiles (mean peak area of all mass fragments ± SE) emitted after 96 hr of spider-mite infestation (**a**) (*N*= 6 plants). Mean number (± SE) of *Tetranychus urticae* adults retrieved on infested plants (**b**) after 96 hr. Different letters indicate significant differences ($P<0.05$) using one-way ANOVA followed by LSD *post-hoc*. The o in Fig. 2a indicates ambient air

To address the question of which volatiles may be responsible for the differences in attractiveness, multivariate exploratory analysis was performed on the headspace compositions by using Principal Component Analysis. The first two principal components of the PCA explained 57% of the variance found in the data set, discriminating the more attractive landrace A and hybrids C, G, and H from the less attractive hybrids B, D, E, and F along vector 1 (47.3%), and the variation among replicates along vector 2 (9.7%) (Fig. 3a). The order of attractiveness of the eight varieties towards predatory mites also is indicated in Fig. 3, with no. 1 representing lowest numbers of predatory mites attracted and no. 8 representing the strongest attraction. This shows that the four most attractive varieties cluster in the left part of the plot, and the four least attractive ones cluster in the right part of the plot (Fig. 3a). The loading plot of the first two principal components is shown in Fig. 3b, and can be used to identify which compounds contribute most to the separation of the varieties in Fig. 3a. However, as hundreds of different volatile compounds can be detected in a headspace sample, quantitative alignment of the different metabolites results in a dataset that comprises almost 34,000 mass fragments (Fig. 3b).

In order to recognize metabolites from those tens of thousands of molecular fragments that constitute a typical GC-MS profile, MMSR was used to assign 363 centro-

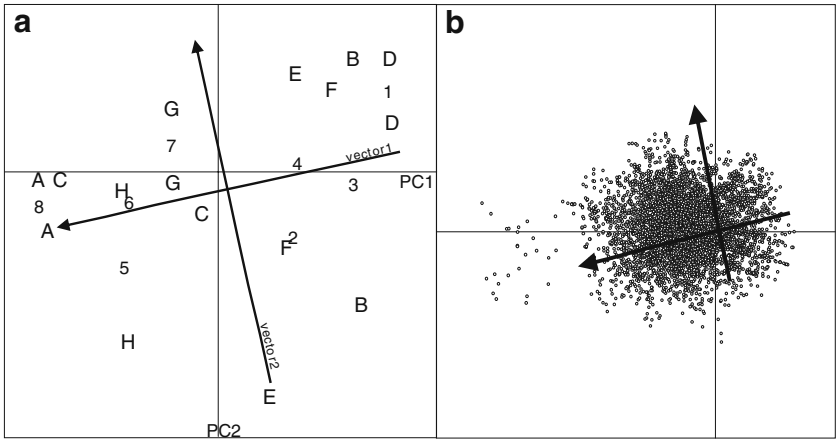

Fig. 3 **a**: Principal Component Analysis of the mass fragments of volatiles emitted by eight cucumber accessions. Accession A (*filled square*, 8), B (*empty square*, 3), C (*empty circle*, 6), D (*filled circle*, 1), E (*empty triangle*, 2), F (*filled triangle*, 4), G (*empty diamond*, 7), H (*filled diamond*, 5). The first PC explains 47.3% of the variation found and the second PC 9.7%. The order of attractiveness of each accession is added along vector 1, with no. 1 representing the accession for which the lowest number of predatory mites was recorded and no. 8 representing the accession for which the highest number of predatory mites was recorded on spider-mite infested plants. The variation between replicates is added along vector 2. **b**: Loading plot with 33.800 mass fragments

types. Pearson correlation coefficients were calculated between the peak areas of each centrotype and the attractiveness data for the whole dataset. In addition, the dataset was subjected to stepwise regression with backward elimination, where the contribution of each predictor was determined one by one by using the *t*-test significance value, and centrotypes that did not contribute to significance were omitted from the model. Supplementary Online

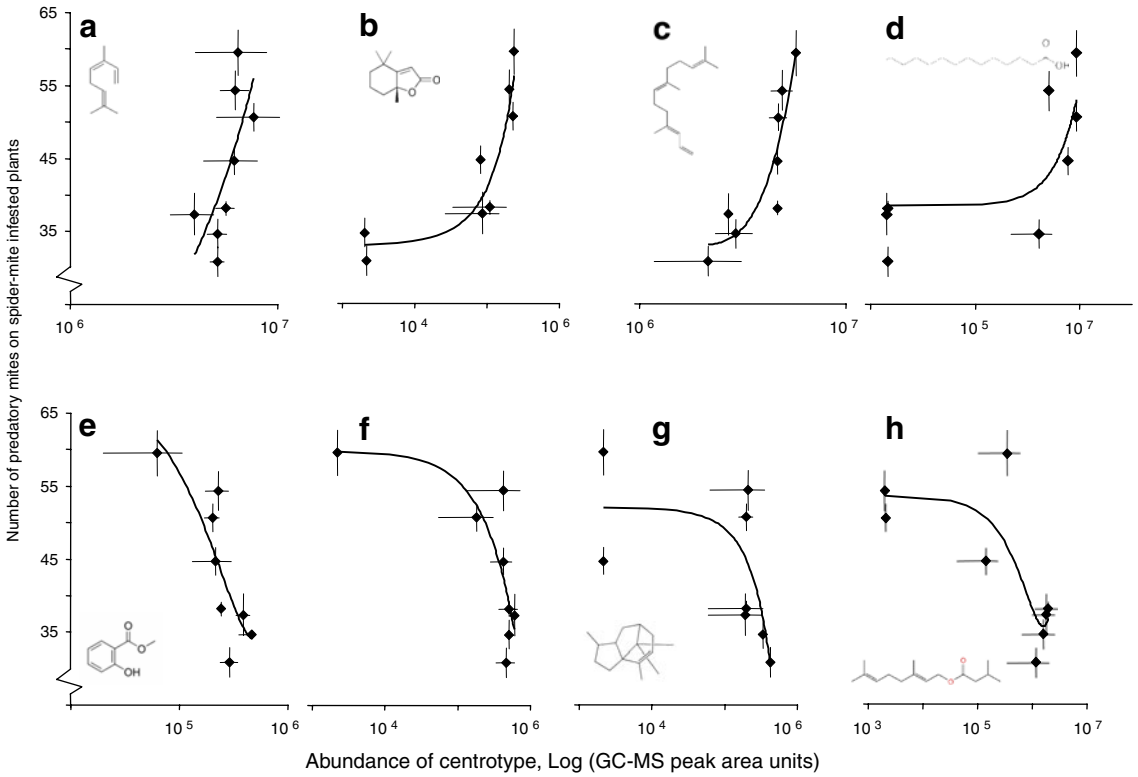

Fig. 4 Correlation of eight selected centrotypes and the number of predatory mites found on each of the varieties included in this study. **a**: Centrotype 9969, (*E*)-β-ocimene, R^2=0.504; **b**: Centrotype 21281, putative dihydoactinidiolide, R^2=0.871; **c**: Centrotype 23191, (*E,E*)-TMTT, R^2=0.830; **d**: Centrotype 26893, putative myristic acid, R^2=0.431; **e**: Centrotype 13780, methyl salicylate, R^2=0.678; **f**: Centrotype 14154, unknown compound, R^2=0.628; **g**: Centrotype 20359, putative α-patchoulene, R^2=0.511; **h**: Centrotype 22546, putative geranyl isovalerate, R^2=0.655

Material Table 1 shows the centrotypes that were assigned as attractive to *P. persimilis*, their putative identity, and statistics (*P*-values of stepwise regression and Pearson coefficients). Fifteen centrotypes were significantly ($P< 0.05$) affecting predator behavior as determined by stepwise regression, either in a positive or negative way. Eight of these centrotypes also had a strong Pearson correlation (>0.5 or <−0.5) with attractiveness, and these are depicted in Fig. 4. Positive correlations were found for (*E*)-β-ocimene (Fig. 4a), (*E,E*)-TMTT (Fig. 4c), and two other centrotypes (Fig. 4b,d). Centrotype 21281 (Fig. 4b) has a retention index of 1489, and its mass spectrum shows homology with that of dihydroactinidiolide (retention index 1483). The mass spectrum of centrotype 26893 depicted in Fig. 4d corresponds well with that of myristic acid, but the retention index (1809) deviates much from the one reported for myristic acid (1720). Pearson correlation analysis showed that the emission of (*E*)-β-ocimene correlated with the emission of 64 other centrotypes. Five of these centrotypes also showed modest positive correlation with predator attraction (Pearson coëfficient between 0.40 and 0.50), among them (*E,E*)-α-farnesene and an unknown sesquiterpenoid (Fig. 5a). There were no centrotypes with a high correlation with both the amount of (*E,E*)-TMTT and predator attraction.

A negative correlation between attractiveness and amount of the compound was recorded for methyl salicylate (Fig. 4e) and three other centrotypes (Fig. 4f–h). The mass spectra and retention indices of two of these centrotypes correspond well with those of α-patchoulene (Fig. 4g) and geranyl isovalerate (Fig. 4h), respectively. The emission of methyl salicylate correlated with that of 11 other centrotypes. Two of these centrotypes also negatively correlated with attractiveness (Pearson coëfficient between −0.30 and −0.40; Fig. 5b).

For direct comparison of variation in herbivory-induced cucumber volatiles, independent of differences in mite feeding damage due to variation in the level of direct defense, plants were treated with JA. As in previous experiments, JA-treated plants emitted higher amounts of volatiles than did non-treated plants (data not shown), with considerable variation among accessions in the relative proportion of individual compounds. Table 2 shows the amounts of individual volatiles emitted 2 d after JA-treatment by plants of the eight varieties included in this study. The total emission of volatiles in JA-treated plants was highest in hybrid C and lowest in hybrid H. Variation in emission rates for individual volatile compounds among varieties varied between 4-fold differences for (*E,E*)-TMTT and up to almost 3000-fold for linalool.

Discussion

Our data show that there is considerable variation among cucumber varieties in HIPV emission rates as well as the attraction of predatory mites under greenhouse conditions. Attraction to and arrestment on spider-mite infested cucumber plants by predatory mites can be influenced by prey density (Toyoshima and Amano, 1998), leaf surface characteristics (Krips et al., 1999), and HIPV (Sabelis et al., 1984). We assume that, just as was shown for Lima bean plants (Gols et al., 2003), within a cucumber variety the attraction of *P. persimilis* is positively related to the amount of spider-mite damage on cucumber leaves. Hence, among plants of the same variety the total amount of damaged leaf area affects the degree of attraction of the predators. However, across varieties, no significant correlation was found between the number of spider mites and the number of *P. persimilis* retrieved (Pearson correlation coefficient

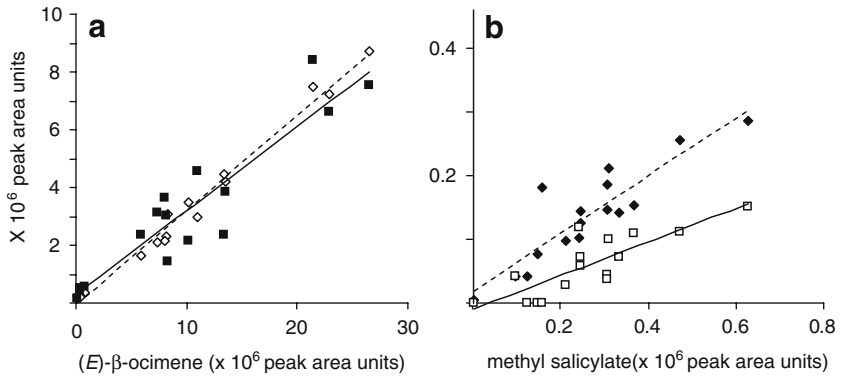

Fig. 5 Correlation between the amounts of selected centrotypes. **a**: between (*E*)-β-ocimene and two other centrotypes, i.e., putative (*E,E*)-α-farnesene (closed squares, solid line, Pearson coefficient with (*E*)-β-ocimene 0.674, Pearson coefficient with attraction of *Phytoseiulus persimilis* 0.384) and an unknown sesquiterpenoid (open diamonds, dotted line, Pearson coefficient with (*E*)-β-ocimene 0.878, Pearson coefficient with attraction of *P. persimilis* 0.441); **b**: between methyl salicylate and two other unknown centrotypes (Pearson coefficient with methyl salicylate 0.640 for closed diamonds and 0.782 for open squares, respectively, Pearson coefficient with attraction of *P. persimilis* −0.421 and −0.346, respectively)

[b] (*Z*)-3-hexen-1-yl acetate

[c] Total emission is estimated by adding all peak areas from the chromatogram

−0.12). Thus, the difference in attraction of predatory mites among varieties was not dependent on the amount of damage. Furthermore, the relative attractiveness of the cucumber varieties to the predatory mites did not correlate with the total amount of volatiles emitted by the spider-mite infested plants of the different varieties (Pearson coefficient 0.29). For example, plants of hybrid G acted as the "loudmouth" in terms of HIPV emission and were very effective in recruiting natural enemies, while hybrid G had the lowest infestation of spider mites compared with the other accessions in this study. In contrast, hybrid D showed a moderate spider-mite infestation and had the third highest HIPV emission, but was not effective in attracting predatory mites in comparison with the other accessions. Thus, when comparing different varieties, it is not just a matter of more damage inflicted by more mites, resulting in higher amounts of volatiles that attract more predatory mites. Rather, certain compounds within the total blend are differentially important for attraction or repellence, and determine total attractiveness of the plants of different varieties to the predatory mites.

To investigate which compounds within the volatile blend correlated to the differences in attraction, we analyzed the headspace of spider-mite-infested cucumber plants under realistic greenhouse conditions and in parallel attractiveness to predatory mites. This implies that headspace was captured at relatively 'dirty' ambient air with a high humidity, which resulted in relatively overcrowded GCMS chromatograms. To avoid technical problems, our GCMS method included dry purging at room temperature and focusing of the samples at temperatures above 0°C, which may have resulted in some loss of highly volatile compounds, such as green leaf aldehydes (Ruther, 2000). We chose to use an untargeted statistical approach to handle the complex GCMS profiles. Using MMSR (Tikunov et al., 2005), more than 360 centrotypes were recognized as metabolites from the tens of thousands of mass fragments, that constitute a typical GCMS profile. No attempt was made to identify all these centrotypes. Instead, we focused on those that had a high Pearson correlation with attractiveness, resulting in a selection of 15 centrotypes that we identified tentatively.

The lowest number of spider mites was retrieved on plants of accessions A, F, and G. Accession A is a land race, and may have enhanced levels of cucurbitacin C compared with the other accessions, which are all hybrids that were selected for non-bitterness. Thus, the level of direct defense could perhaps explain the lower number of spider mites in accession A, although accessions F and G have comparably low numbers of spider mites. Accession A is, however, quite interesting: a low level of herbivory results in the highest attraction of predatory mites, while the amount of HIPV is rather moderate compared to the other accessions. When infested with spider mites, accession A appears to be very sensitive: low numbers of herbivores trigger the induced volatile production cascade in such a way that it results in a volatile blend that is most attractive to the predatory mites and relatively rich in (*E*)-β-ocimene,

(*E,E*)-TMTT, and two other centrotypes that show homology in mass spectrum with dihydroactinidiolide and myristic acid. Furthermore, the volatile blend of accession A contains relatively low levels of methyl salicylate and geranyl isovalerate, and two other repellent centrotypes, of which one shows homology with α-patchoulene. It would be interesting to address how this is regulated genetically and biochemically.

Geranyl isovalerate, dihydroactinidiolide, α-patchoulene, and a putative fatty acid have not been reported previously to be present in the volatile blends of cucumber or other *Cucumis* species (Takabayashi et al., 1994; Agrawal et al., 2002). Dihydroactinidiolide ($C_{11}H_{16}O_2$) occurs naturally in fenugreek (*Trigonella foenum-graecum*), mangos (*Mangifera indica*), and silver vine (*Actinidia polygama*) (Mebazaaa et al., 2009). α-Patchoulene has been reported in *Hypericum* spp., and geranyl isovalerate has been reported to be present in the blend of many plant species (DNP, 2009). The occurrence of myristic acid (or, based on the retention index, probably another fatty acid) has not been previously reported in volatile blends of cucumber, but could likely be present in its blend, because with proceeding spider-mite damage lipoxygenase activity increases and the breakdown of fatty acids occurs.

The responses of carnivores to volatiles have been tested mostly against a minimal odor background in laboratory or simplified greenhouse setups. Several spider-mite induced plant volatiles attract *P. persimilis*, among them linalool (Dicke et al., 1990a), (*E*)-β-ocimene (Dicke et al., 1990a; Krips et al., 2001), (*E*)-DMNT, nerolidol (Dicke et al., 1990a; Kappers et al., 2005), and methyl salicylate (Dicke et al., 1990a; De Boer and Dicke, 2004a,b). Furthermore, (De Boer et al., 2004) reported that, although (*E,E*)-TMTT itself was not attractive to *P. persimilis*, the presence of this compound in the total volatile blend did improve preferences of the predatory mites. Moreover, Van Wijk et al. (2008) suggest that *P. persimilis* does not have an innate preference for (individual) HIPV, but is able to adjust its olfactory response based on experience. An innate preference for specific compounds in combination with the ability to identify these compounds in unfamiliar mixtures could explain how *P. persimilis* prefers, without prior experience, the odor of spider mite-infested plants over that of uninfested conspecifics for several plant species (Van den Boom et al., 2002). We repeatedly found a stronger attraction of predatory mites to cucumber varieties that have higher proportions of (*E*)-β-ocimene, (*E,E*)-TMTT, and putative dihydroactinidiolide and myristic acid in their induced blend, both in laboratory olfactometer experiments (Kappers et al., 2010) as well as in the greenhouse experiments presented here. The predatory mites used in this study were reared on spider-mite infested *Phaseolus vulgaris* plants that are known to emit (*E*)-β-ocimene, (*E*)-DMNT, (*E,E*)-TMTT, and methyl salicylate (Dicke et al., 1990a, 1999). We expect that predatory mites have learned to associate these volatiles with prey.

However, three other compounds have opposite effects: varieties with high proportions of methyl salicylate, geranyl isovalerate, or putative α-patchoulene in their odor profile were less attractive to predatory mites. The negative effect of methyl salicylate on the attraction of predatory mites was unexpected, as this compound is commonly induced after herbivory in many plant species (e.g., Dicke et al., 1990b; Ament et al., 2004; De Boer et al., 2004; Bukovinszky et al., 2005) and has been reported to be an attractive compound to predatory mites (Dicke et al., 1990a; Ament et al., 2004; De Boer and Dicke, 2004a,b). However, in our study, the negative association of methyl salicylate with attractiveness was found within the total HIPV-blend of different cucumber accessions. The presence of methyl salicylate correlated positively with the presence of 11 other centrotypes in the HIPV-blend. Two of these centrotypes also were negatively associated with the attraction of predatory mites. This could imply that one or both of these (unknown) compounds are produced coordinately with methyl salicylate, are repellent towards the predatory mites, and may affect or override the attractiveness of methyl salicylate in the headspace. A repellent effect of methyl salicylate on carnivores also was found for *Diadegma semiclausum*, a parasitoid wasp that preferred the HIPV blend of transgenic *Arabidopsis* lacking methyl salicylate (Snoeren et al., 2010a). Examples of compounds in the HIPV-blend of cucumber with suggested repellent effects to predatory mites are volatile oximes (Takabayashi et al., 1994). Indeed, Agrawal et al. (2002) showed that sweet cucumber plants attracted more predatory mites than bitter, cucurbitacin-containing cucumber plants although the latter plants emitted more volatiles, among them (*E*)-β-ocimene and (*E,E*)-α-farnesene. The explanation for this discrepancy was found in the presence of oximes in the HIPV blend of bitter cucumber plants (Agrawal et al. 2002). Breeding and selection of crops may provide varieties that emit higher amounts of unwanted compounds that have negative effects on attraction of natural enemies. A previous study showed that sweet cucumber plants, lacking cucurbitacins, attracted more predatory mites than plants from bitter varieties that produce constitutive and inducible cucurbitacins. The bitter plants emitted larger amounts of several volatiles that are known attractants of the predatory mite *P. persimilis*, i.e., (*E*)-β-ocimene, (*E*)-DMNT, and methyl salicylate (Agrawal et al., 2002). This also suggests the presence of repellent compounds.

Other examples of repellent compounds present in herbivore-induced plant volatiles blends can be found in systems involving parasitoid wasps. For example, a HIPV fraction of maize containing (*Z*)-3-hexen-1-yl acetate,

linalool, and (*E*)-DMNT was the least attractive compared to other tested fractions of the HIPV blend of maize to the parasitoid *Cotesia marginiventris*; this fraction might even have a repellent or masking effect on other fractions of the HIPV blend (Turlings and Fritzsche, 1999). In addition, isoprenoids also were found to interfere with host finding, as was demonstrated for transgenic *Arabidopsis* plants emitting isoprene (Loivamäki et al., 2008). The function of emitting HIPV that do not lure naïve carnivores but rather repel them may be linked to the compounds' role in other plant defense mechanisms. For example, HIPV that may be involved in microbial resistance can act as repellents towards herbivores (Bruce et al., 2008), which has been demonstrated for methyl salicylate (Snoeren et al., 2010a). However, it is well known that carnivores can learn to respond to HIPV blends, and this also has been demonstrated for the response of predatory mites to prey-associated odor mixtures.

The typical spider-mite induced volatile (*E*)-DMNT (Dicke et al., 1990a; Mercke et al., 2004; Van Den Boom et al., 2004) was emitted by all JA-treated accessions with a 100-fold variation in the range of emission rates (Table 2). Furthermore, linalool was emitted by all accessions in small amounts. No correlation between attractiveness to *P. persimilis* and these HIPV was found in our spider-mite induced plant experiment, although these compounds have been reported for their capacity to attract predatory mites (Dicke et al., 1990a,b; Kappers et al., 2005). In contrast, (De Boer et al., 2004) and (Van Wijk et al., 2008) did not find an attractive effect of (*E*)-DMNT. Linalool was not attractive either in the study by Van Wijk et al. (2008). Our results also indicate that these compounds are not of high importance for prey searching of predatory mites.

All accessions in this study emitted (*E*)- and (*Z*)-β-ocimene. Most accessions have an (*E*)-β-ocimene proportion of the total ocimene amount of more than 70%, except hybrids E and F that have an (*E*)-β-ocimene proportion of less than 50%, and thus a relatively high proportion of (*Z*)-β-ocimene in their blend. Dicke et al. (1990a) reported that (*E*)-β-ocimene is attractive to predatory mites. These authors also assessed the effect of mixtures of (*E*)- and (*Z*)-β-ocimene, and found that only (*E*)-β-ocimene was attractive. However, the response to (*E*)-β-ocimene was attenuated by the addition of (*Z*)-β-ocimene. A racemic mixture of 70% (*E*)-β-ocimene and 30% (*Z*)-β-ocimene was tested by Dicke et al. (1990a) and Van Wijk et al. (2008), and in both studies this blend was not attractive. In contrast, a racemic mixture of 90% (*E*)-β-ocimene and 10% (*Z*)-β-ocimene did attract *P. persimilis* (Dicke et al., 1990a). Thus, the relatively low degree of attraction of the predatory mites to hybrids E and F may be explained (partly) by the relatively high proportion of (*Z*)-β-ocimene in these accessions. Although hybrids C and G do not emit high amounts of (*E*)-β-ocimene in absolute terms, the (*E*)/(Z) ratio is quite high, which agrees with their ranking in attractiveness.

Finally, the emission of (*E*)-β-ocimene is highly correlated with that of (*E,E*)-α-farnesene and an other unknown sesquiterpenoid. The relation between these three compounds was demonstrated previously in cucumber (Kappers et al., 2010), and it suggests that they are products of a single terpene synthase.

Although individual spider mite-induced plant volatiles have no *a priori* function, and predatory mites can learn to associate odors with the presence of prey after a brief learning experience of less than 15 min (Van Wijk et al., 2008), our study demonstrates that the composition of the induced blend matters to the plant. Within a large spatial greenhouse setup with a high three-dimensional complexity, as in this study, predatory mites preferred certain accessions above others. An accession that emits an attractive induced blend at low rates of herbivory during initial infestation, will attract more bodyguards that can quickly build up a population at the location where the herbivore is settling. It is, therefore, worthwhile to select and breed for cucumber varieties that have a strong attraction of natural enemies. This study identified some of the volatiles that affect natural enemy behavior and that could be used as markers in breeding. Furthermore, we demonstrated that highly correlated compounds in the emitted volatile blend may have opposite effects on attractiveness. The introduction of varieties that improve the foraging success of natural enemies could be one of the critical factors that can further enhance the success rate of biological control.

Acknowledgements The authors thank the Centre for Genetic Resources The Netherlands (CGN), Wageningen, The Netherlands and two anonymous Dutch seed companies, for seeds of various cucumber varieties. Two anonymous reviewers are acknowledged for valuable comments on a previous version of this manuscript. The Netherlands Organization for Scientific Research (NWO) is acknowledged for a Technology Foundation grant STW 5479 to I.F.K. and NWO-VICI grants to M.D. and H.J.B.

Pheromone Communication in *Nasonia vitripennis*: Abdominal Sex Attractant Mediates Site Fidelity of Releasing Males

Abstract Males of the parasitic wasp *Nasonia vitripennis* (Hymenoptera: Pteromalidae) use a substrate-borne sex pheromone to attract virgin females. The pheromone is synthesized in the rectal vesicle and deposited via the anus by dabbing movements of the abdominal tip. The chemicals attracting the females are composed of a mixture (4*R*,5*R*- and (4*R*,5*S*)-5-hydroxy-4-decanolides (HDL) being synergized by the trace component 4-methylquinazoline (4-MeQ) which is not attractive for females when offered alone. Here we show that male pheromone deposits are not only attractive to virgin females but also for the releasing males themselves. In an olfactometer bioassay, males were strongly attracted by their own pheromone markings but were unable to discriminate between their own markings and those deposited by other males. Polar fractions of pheromone gland extracts containing the HDLs and 4-MeQ were also highly attractive for males. Bioassays using synthetic pheromones in natural doses revealed that combinations of HDL/4-MeQ and 4-MeQ alone attracted males whereas the HDLs alone were behaviorally inactive. Furthermore, males did not discriminate between HDL/4-MeQ and 4-MeQ alone. We conclude that the trace component 4-MeQ mediates site fidelity of *N. vitripennis* males at sites previously marked with the abdominal sex pheromone. The use of 4-MeQ to stay at and to return to scent-marked patches rather than marking new ones might be a strategy to economize semiochemical use in *N. vitripennis* males.

Key Words Sex pheromone · Abdomen dipping · Site fidelity · Mate finding · Pteromalidae · Parasitic wasp

Introduction

The use of pheromones for sexual communication is often associated with costs for the releasing gender. These comprise physiological costs if the attractive chemicals are biosynthesized from limited resources and ecological costs if the signal not only attracts potential mates but also natural enemies and intraspecific competitors (Wyatt, 2003; Wertheim et al., 2005). Hence, sex pheromone release has to be economical in space and time, i.e. restricted to sites and situations in which receptive mates are likely to occur. For species depositing the attractive chemicals on substrates rather than releasing them directly from the producing gland, site fidelity is of crucial importance for successful mate attraction (Raw, 1975; Kroiss et al., 2010). If scent-marked areas attract also opportunistic conspecifics of the same sex, site-fidelity might pass into territoriality, i.e. scent-marked holdings are defended aggressively against the intruders (Baker, 1983). The mechanisms involved in chemically mediated site fidelity and territoriality in insects are often not fully understood, although it is self-evident that individuals may use the same chemicals they deposited for mate attraction to recognize and defend their holdings.

The Jewel wasp *Nasonia vitripennis* (Walker) (Hymenoptera: Pteromalidae) is a gregarious ectoparasitoid parasitizing pupae of numerous cyclorrhaphous flies (Whiting, 1967). The species is found worldwide in nests of hole-breeding birds. Males of *N. vitripennis* are protandrous and remain on or near the host they emerged from to mate with the females emerging shortly after. Females of *N. vitripennis* typically mate only once, and males compete for them aggressively. Dominant males defend the escape hole against their competitors (van den Assem et al., 1980a; van den Assem, 1986; Leonard and Boake, 2006). Subordinate other males (so-called satellite males) often wait in the vicinity of the host puparium for females leaving the natal site without being inseminated by the dominant male (van den Assem, 1986). Attraction and arrestment of virgin females is achieved by an abdominal sex attractant produced in the abdomen of males. It consists of a mixture of (4*R*,5*R*)- and (4*R*,5*S*)-5-hydroxy-4-decanolides (HDL) (Ruther et al., 2007) being synergized by the trace component 4-methyquinazoline (4-MeQ). In contrast to the HDLs, 4-MeQ is not attractive to females when offered alone (Ruther et al., 2008). The pheromone is synthesized in the rectal vesicle (Abdel-latief et al., 2008) and deposited on the ground by dabbing movements ("abdomen dipping") of the abdominal tip (see supplementary online material) (Barrass, 1969; van den Assem et al., 1980b; Steiner and Ruther, 2009). Pheromone deposits remain attractive for about 2 hrs and the range of activity is about 5 cm (Steiner and Ruther, 2009). Marking behavior is shown increasingly by males after mating or mere contact with a receptive female (van den Assem et al., 1980b; Steiner and Ruther, 2009). This suggests that males economize the use of the pheromone by releasing it specifically if the target is present. Van den Assem et al. (1980b) observed that males were arrested for days on areas scent-marked by themselves suggesting that they use the substrate borne sex pheromone not only to attract virgin females but also to recognize their territorial holdings. In the present paper we investigate the chemical basis of the site fidelity in *N. vitripennis* males. We identify the responsible chemical and study whether males are able to discriminate their own markings from those deposited by other males. We discuss the results with respect to the biology and the mating system of *N. vitripennis.*

Methods and Materials

Insects and General Methods Parasitoids used in this study originated from the same *N. vitripennis* strain used in our previous pheromone studies (Ruther et al., 2007, 2008, 2009; Steiner and Ruther, 2009). Starter individuals were collected from a bird's nest in Hamburg, Germany. Parasitoids were reared on pupae of the green bottle fly *Lucilia caesar* (Diptera: Calliphoridae) at 25°C, 60% RH, and a photoperiod of 16:8 (L/D) (for details see Ruther et al., 2007). Virgin parasitoids of either sex were obtained by excising pupae from host puparia 1–2 d prior to eclosion and keeping them in 1.5 ml microcentrifuge tubes (Brand GmbH, Wertheim, Germany). Male wasps used in the bioassays were 2 d old and were generally of equal size (660–700 μm) to control for size-dependent differences in the pheromone titers (Ruther et al., 2007). Size was determined by measuring the head width of fully melanized pupae. One hr prior to the experiments, parasitoids were held at room temperature (20–22°C) for acclimatization. Handling of the parasitoids was done using a fine artist's paint brush. Each parasitoid was used only once.

Bioassays The response of males to naturally deposited pheromone markings, fractionated pheromone gland extracts and synthetic pheromone components was investigated by using a still air 4-cavity olfactometer made from acrylic glass (Steiner and Ruther, 2009). It consisted of a round walking arena (9 cm diameter, 8 mm thick) with four symmetrically arranged spherical cavities (1 cm diameter, 4 mm deep), a low rim (2 mm high) and a glass lid to cover the arena. Only two opposite cavities of the olfactometer were used to offer the stimuli to be compared. After application of the stimuli, males were introduced singly into the centre of the olfactometer which then was covered by the glass lid. Subsequently, the residence time of the test males in the cavities to be compared was recorded for 5 min using The Observer 3.0 observational software (Noldus, Wageningen, The Netherlands) (N=20 for all bioassays). After each experiment, the male was removed and the olfactometer was cleaned with ethanol and demineralized water. To avoid bias due to optical stimuli, the olfactometer was placed into a white plastic bowl (30 cm length x 30 cm width x 15 cm height) and illuminated from above with a 60 W bulb. Additionally, the olfactometer was turned clockwise by 90° after every run.

In the first experiment, we tested the response of males to their own naturally deposited pheromone markings. Previous studies have demonstrated that males show a clearly increased pheromone marking activity after mating (Steiner and Ruther, 2009). Thus males were allowed to mate with a virgin female prior to the experiment. For this purpose a couple was introduced into the cavity which was covered by a microscope cover slip. After observation of the copulation, the female was removed and the male was allowed to mark the cavity for 5 min. After marking, males were removed from the olfactometer and kept isolated for 3 min in a clean glass dish. After this time, the male was re-transferred to the olfactometer and the behavior was observed as described above. The second experiment was performed following the same protocol but the pheromone

deposits offered originated from a foreign male. Then, we exposed males simultaneously to their own pheromone deposits and to those from a foreign male. Both markings were deposited at the same time. Furthermore, we tested whether the arrestment of males is in fact mediated by components of the known pheromone gland (rectal vesicle). For this purpose, we offered to males in one cavity one individual equivalent of a fractionated pheromone gland extract (methanol fraction applied to filter paper, see below) and the pure solvent in the other.

Finally, we tested the response of males to synthetic analogues of the known pheromone compounds (4*R*,5*R*)-HDL, (4*R*,5*S*)-HDL, and 4-MeQ, respectively. We tested a combination of 100 ng HDL [1:1 mixture of (4*R*,5*R*)-HDL and (4*R*,5*S*)-HDL] plus 1 ng 4-MeQ. The pheromone dose represents about one third of a male abdomen equivalent and the ratio of approximately 100:1 for HDL and 4-MeQ was found in the male abdomen in a previous study (Ruther et al., 2008). We also tested equal doses of HDL and 4-MeQ alone and investigated whether the combination of 100 ng HDL and 1 ng 4-MeQ is more attractive than 4-MeQ alone. (4*R*,5*R*)-HDL was synthesized as described by Garbe and Tressl (2003) by Sharpless asymmetric dihydroxylation of ethyl (4*E*)-decenoate. After oxidation of the hydroxyl group using Dess-Martin periodinane, the resulting (4*R*)-5-oxo-4-decanolide was reduced by sodium borohydride to obtain a 1:1 mixture of (4*R*,5*R*)-HDL and (4*R*,5*S*)-HDL (Garbe and Tressl, 2003). 4-MeQ was synthesized following the protocol of Bergmann et al. (1986) by reaction of 2-aminobenzonitrile with methyl magnesium iodide and subsequent treatment with ethyl formate.

Fractionation of Pheromone Gland Extract The rectal vesicles of 30 freeze-killed males were dissected under a stereo microscope as described elsewhere (Abdel-latief et al., 2008). The glands were transferred to an autosampler vial with micro insert and extracted for 30 min with 100 µl dichloromethane. The extract was carefully concentrated under nitrogen to a volume of 10 µl and diluted with 70 µl hexane. The extract was applied to a conditioned 100 mg silica gel cartridge (IST, Mid-Glamorgan, UK) and eluted with 500 µl each of hexane, dichloromethane, and methanol. The methanol fraction containing the pheromone components was carefully dried under a gentle stream of nitrogen and the residue was re-solved with 30 µl of dichloromethane. This extract was used for bioassay as described above. The presence of the *N. vitripennis* sex pheromone components was verified by GC-MS using the instrumentation and conditions described elsewhere (Ruther et al., 2007).

Statistical Analyses Statistical analyses were performed using Statistica 4.5 scientific software (StatSoft, Tulsa, OK,

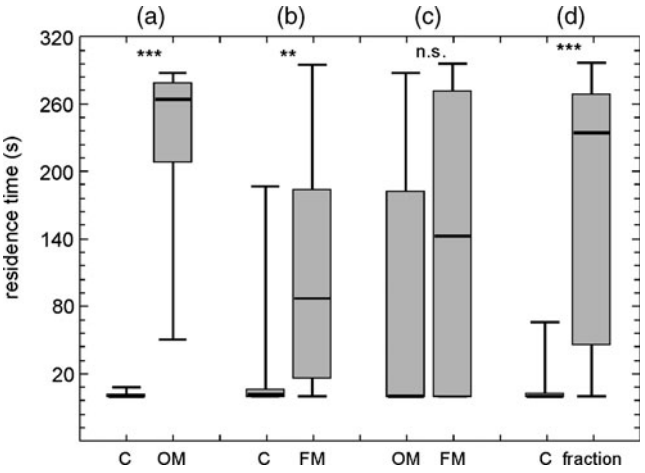

Fig. 1 a–d. Residence times of *N. vitripennis* males in a still air olfactometer during a 5 min observation period. Prior to the experiment, the test cavities were marked for 5 min with the abdominal sex attractant by the test male itself (own marking, OM) or by another male (foreign marking, FM) (**a**–**c**) or were treated with 1 individual equivalent of a fractionated pheromone gland extract (**d**). Control cavities (C) remained untreated (**a**–**c**) or were treated with pure solvent (**d**), respectively. Box and whisker plots indicate the median (horizontal line) with 25th and 75th percentiles (*boxes*) and maximal/minimal values (whiskers). Asterisks indicate significant differences between the test and the control cavities at $P<0.01$ (**) or $P<0.001$ (***) (one-sample Wilcoxon test, n.s. = not significant, $N=20$)

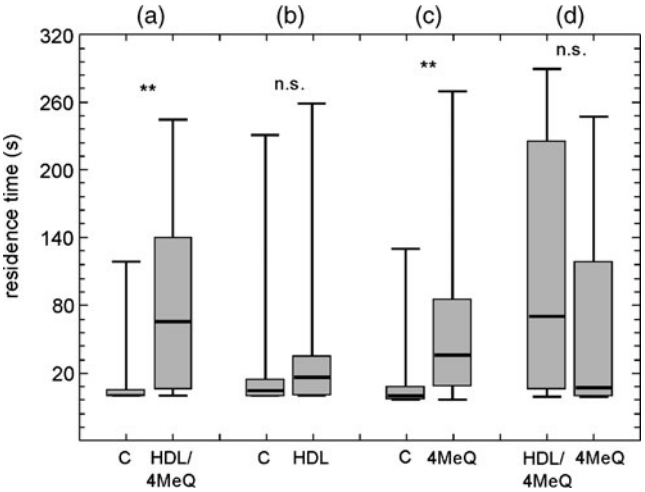

Fig. 2 a–d. Residence times of *N. vitripennis* males in a still-air olfactometer during a 5 min observation period. Prior to the experiment, the cavities were equipped with disks of filter paper treated with the synthetic sex pheromone components HDL and/or 4-MeQ, respectively. Control cavities (C) were treated with pure solvent. Box and whisker plots indicate the median (*horizontal line*) with 25th and 75th percentiles (*boxes*) and maximal/minimal values (*whiskers*). U.S.A). Residence time of males spent in the cavities to be compared was analyzed by a one-sample Wilcoxon test.

Results

Males of *N. vitripennis* spent significantly more time in the pheromone-marked cavity of the olfactometer than in the control cavities irrespective of whether the pheromone deposits originated from themselves (Z=3.92, P<0.001, Fig. 1a) or from foreign males (Z=2.688, P<0.01, Fig. 1b). When offered simultaneously, males were not able to discriminate their own pheromone markings from foreign ones (Z=1.248, P=0.212, Fig. 1c). Polar fractions of the male sex pheromone glands containing the HDLs and 4-MeQ were also attractive to males (Z= 4.124, P< 0.001, Fig. 1d). Males spent significantly more time in cavities treated with a synthetic mixture of (4*R*,5*R*)-HDL, (4*R*,5*S*)-HDL and 4-MeQ (Z=2.931, P=0.0034, Fig. 2a) and with 4-MeQ alone (Z=3.034, P=0.0024, Fig. 2c) whereas the HDLs were behaviorally inactive, when tested alone (F= 0.977, P=0.329, Fig. 2b). When offered simultaneously, the combination of HDLs/4-MeQ was not more attractive to males than 4-MeQ alone (Z=1.471, P=0.141, Fig. 2d).

Discussion

The present study demonstrates that site fidelity of *N. vitripennis* males at scent-marked areas is mediated by 4-MeQ, the minor component of their abdominal sex pheromone. In contrast, the HDLs which have been shown to be the primary attractants of virgin females did not contribute to the response of males to their own pheromone deposits. Sex pheromones should be honest signals and thus, the biosynthesis typically causes physiological costs (Johansson and Jones, 2007). In the case of the HDLs, these costs may arise from the pheromone precursor linoleic acid (J. R., unpublished data) which is an essential nutrient and a limited resource for most animals (Wathes et al., 2007, but see Borgeson et al., 1991; Weinert et al., 1993). Male pheromone markings remain attractive for virgin females for at least 2 hrs (Steiner and Ruther, 2009). Hence, using 4-MeQ to stay at scent-marked patches rather than dispersing and marking new ones might be a strategy of *N. vitripennis* males to save costly resources. 4-MeQ allows them to stay where attracted females arrive and helps them to return to the scent-marked areas which they often leave when chasing females over some distance during courtship or when chasing male competitors away from their territorial holdings (van den Assem et al., 1980a, b). Pheromone mediated site fidelity might be part of the mating strategy of both the dominant male and the subordinate satellite males. The dominant male may minimize the number of females dispersing unfertilized and the satellite males may compete in a kind of chemical contest for those females that nevertheless leave the natal site without immediate attention of the dominant male (van den Assem et al. 1980a). The chemical contest scenario is supported by the fact that virgin females orientate along concentration gradients of the male sex pheromone and are able to discriminate even subtle concentration differences (Ruther et al., 2009). Hence, males being able to deposit the sex attractant in higher doses than their competitors might get their mating opportunities without getting involved in aggressive interactions with dominant males at the eclosion holes of host puparia. However, the fact that males do not discriminate between their own pheromone deposits and those from other males, suggests that, apart from the physiological costs of pheromone biosynthesis, males have to face also ecological costs by attracting opportunistic males. These might compete for the attracted females without releasing pheromone themselves. Detailed behavioral observations under controlled near-natural conditions are necessary to unravel the exact role of scent-mark mediated site fidelity in the mating strategies of dominant and subordinate *N. vitripennis* males.

Abstract The absolute configuration of the sex pheromone of the citrophilous mealybug, *Pseudococcus calceolariae*, was determined to be (*1R,3R*)-[2,2-dimethyl-3-(2-methylprop-1-enyl)cyclopropyl]methyl (*R*)-2-acetoxy-3-methylbutanoate. NMR, derivatization reactions, chiral gas chromatography-mass spectrometry, and comparison with synthetic chiral reference compounds, were used to determine the absolute configuration of this compound. This activity of this compound was further confirmed by testing synthetic stereoisomers of the compound as lures in traps for adult male mealybugs. Traps baited with 1,000 μg of the pheromone compound caught 36 times more males than traps baited with virgin females. A mixture of stereoisomers of the pheromone compound can be used for field trapping without adverse effects on trap catch. A comparison with the structures of other sex pheromones of mealybugs is presented.

Key Words (*R,R,R*)-Chrysanthemyl 2-acetoxy-3-methylbutanoate · (*R,R,R*)-chrysanthemyl 2-hydroxy-3-methylbutanoate · Chrysanthemol · Mealybug pheromone · *Pseudococcus calceolariae*

Introduction

The citrophilous mealybug, *Pseudococcus calceolariae* (Maskell, Hemiptera: Pseudococcidae), is a pest of numerous economically important crops, such as orange, lemon, avocado, and other vegetable, fruit and floricultural plants (Bartlett, 1978). The insect is a problem for agricultural crops in a number of ways, including vectoring of viruses, such as the *Grapevine Leafroll-associated Virus 3* (GLRaV-3), through causing direct damage to plants by its piercing-sucking feeding habit, which can lead to malformation of fruits, shoots, or leaves, and transmission of other diseases, and through the excretion of honeydew, which facilitates the development of fungi affecting fruit quality. Furthermore, the insect is responsible for additional economic loss to Chilean agriculture through the quarantine restrictions imposed by a number of fruit-importing countries.

The sex pheromone of *P. calceolariae* recently was identified as chrysanthemyl 2-acetoxy-3-methylbutanoate (**1**) (El-Sayed et al., 2010). This paper reports the determination of the absolute configuration of the insect-produced compound, and the results of field trials testing the attractiveness of stereoisomers of the pheromone to adult males.

1

Methods and Materials

Insects Adult and immature stages of *P. calceolariae* were collected from vineyards in Hawke's Bay, New Zealand, and from raspberry plantations near Quillota, Chile, and reared on sprouted seed potatoes or butternut squash. Virgin females were obtained as described earlier (El-Sayed et al., 2010).

Volatile Collection Mature virgin females were transferred into glass air-entrainment chambers, and headspace chemicals trapped on Tenax (50 mg) or activated charcoal (150 mg). Glass chambers, containing clean rearing substrate or rearing substrate infested with mixed-sex colonies, were used as controls. The trapped volatiles were eluted with 1 ml hexane every 4–7 day, and the extracts stored at −20°C until further use.

Chemical Analyses ^{1}H-NMR and ^{13}C-NMR spectra were recorded on a Bruker AMX 400 instrument. Chemical shifts are expressed in ppm relative to tetramethylsilane. Analyses of female headspace volatiles and synthetic chemicals were carried out by coupled gas chromatography/mass spectrometry, (GC/MS), generally with a Saturn 2200 instrument (Varian Walnut Creek, CA, USA) in electron impact mode at 70 eV. The following capillary columns were used for the analyses: 1) a 30 m×0.25 mm i.d.×0.25 μm film thickness VF-5 ms, non-polar column (Varian); 2) a 30 m×0.25 mm i.d.×0.25 μm VF-23 ms, polar column (Varian); 3) a 30 m×0.25 mm i.d.×0.25 μm CycloSil-β chiral column (J&W Scientific); 4) a 30 m×0.25 mm i.d.×0.25 μm RT-γ-DEXsa column (Restek). The injectors were held at 220°C and the injections were splitless for 0.6 min. The oven was programmed from 40°C (held for 2 min) to 220°C at 4°C.min^{-1}. Helium was used as carrier gas at a flow rate of 1 ml.min^{-1}. A Shimadzu GC-17A/GCMS-QP5050A combination, equipped with a 30 m x 0.25 mm HP-5 fused silica capillary column, was used for some analyses.

Chemical Syntheses Reagents and solvents were purchased from Sigma-Aldrich (St Louis, MO, USA) and Merck (Gibbtown, NJ, USA) and used without further purification. Column chromatography was carried out on silica gel 60 (0.040–0.063 mm, Merck) using mixtures of hexane and ethyl acetate as eluents.

(1R,3R)-Chrysanthemol (1*R*,3*R*)-Chrysanthemol was obtained by reducing commercially available (1*R*,3*R*)-chrysanthemic acid with $LiAlH_4$ in dry Et_2O at room temperature under standard conditions.

^{1}H NMR (400 MHz, $CDCl_3$): δ 4.89 (1 H, m), 3.80 (1 H, dd *J* =11.4, 6.5 Hz), 3.59 (1 H, dd *J* =11.4, 8.5 Hz), 1.72 (3 H, s), 1.69 (3 H, d *J* =1.1 Hz), 1.17 (3 H, s), 1.14 (1 H, dd *J* =8.0, 5.2 Hz), 1.08 (3 H, s), 0.86 (1 H, ddd *J* =8.5, 6.5, 5.3 Hz) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ 133.16, 123.38, 63.72, 35.19, 28.68, 25.61, 22.68, 22.33, 21.37, 18.26 ppm.

(1R,3R)-Chrysanthemyl (R)-2-acetoxy-3-methylbutanoate (1*R*,3*R*)-Chrysanthemyl (*R*)-2-acetoxy-3-methylbutanoate was prepared following the procedure previously described for the isomeric mixture (El-Sayed et al., 2010). (*R*)-2-Hydroxy-3-methylbutanoic acid was acetylated using acetic anhydride in pyridine and a catalytic amount of DMAP. The resulting product was transformed to the acid chloride [$(COCl)_2$, DMF, benzene], which was esterified with (1*R*,3*R*)-chrysanthemol, giving the target compound in 49% overall yield. Chemical purity: 93% (GC).

^{1}H NMR (400 MHz, $CDCl_3$): δ 4.86 (1 H, m), 4.84 (1 H, d J=4.6 Hz), 4.48 (1 H, dd J=11.7, 6.7 Hz), 3.97 (1 H, dd J=11.7, 9.0 Hz), 2.24 (1 H, dhept J=6.9, 4.6 Hz), 2.15 (3 H, s), 1.71 (3 H, s), 1.67 (3 H, m), 1.19 (1 H, dd J=7.8, 5.3 Hz), 1.15 (3 H, s), 1.05 (3 H, s), 1.02 (3 H, d J=6.9 Hz), 1.00 (3 H, d J=6.9 Hz), 0.90 (1 H, ddd J=9.0, 6.7, 5.3 Hz) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ 170.69, 169.81, 133.69, 122.74, 76.86, 66.36, 30.88, 30.05, 29.19, 25.56, 22.46, 22.29 21.54, 20.59, 18.63, 18.26, 17.26 ppm.

Ethyl (R)- and (S)-2-hydroxy-3-methylbutanoate Commercial (*R*)- or (*S*)-2-hydroxy-3-methyl-butanoic acid (8 mg, 0.068 mmol) was dissolved in ethanol (2.5 ml), and a drop of conc. H_2SO_4 added. After stirring overnight, the reaction mixture was partitioned between a water layer and a hexane layer. The hexane layer was dried ($MgSO_4$), filtered, concentrated, and analyzed by GC/MS.

MS (70 eV): *m/z* (rel. intensity)=(*R*-isomer): 147 (32), 119 (12), 104 (18), 76 (38), 73 (100), 58 (14), 55 (56), 41 (12), and 39 (20). (*S*-isomer): 147 (33), 119 (12), 104 (18),

76 (39), 73 (100), 58 (16), 55 (55), 54 (18), 41 (12), and 39 (23).

Transesterification of the Mealybug Pheromone Extract A sample containing 4,000 female day equivalents of mealybug pheromone extract was concentrated under a stream of argon to near dryness. One milliliter of calcium ethoxide solution [prepared from 10% CaH_2/ethanol (w/v)] was added, and the mixture left to react overnight. Dichloromethane and water were added, and the organic layer dried ($MgSO_4$), filtered, and submitted to analysis.

Field Trapping Two experiments were carried out to test the activity of various isomers of chrysanthemyl 2-acetoxy-3-methylbutanoate for the attraction of *P. calceolariae*.

Experiment 1: Treatments were: 10 μg of a mixture of the four stereoisomers of chrysanthemyl (*R*)-2-acetoxy-3-methylbutanoate, 10 μg of a mixture of the four stereoisomers of chrysanthemyl (*S*)-2-acetoxy-3-methylbutanoate, and 10 μg of an 8-component mixture of the stereoisomers. Five virgin females were used as positive controls, and a blank trap was used as a negative control. The experiment was carried out in February 2009 (New Zealand) and April 2009 (Chile).

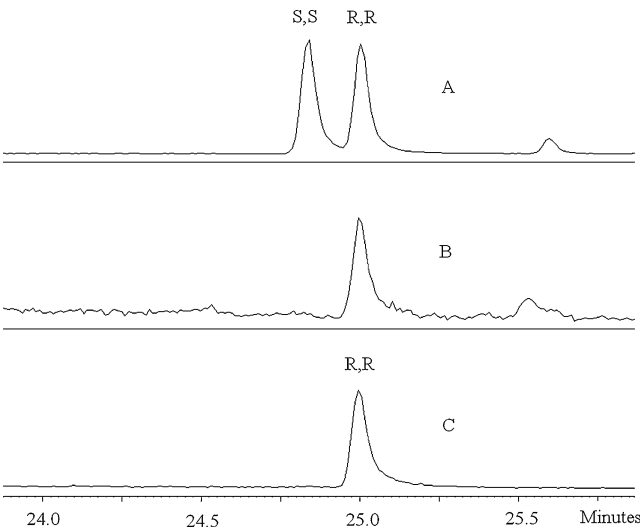
Experiment 2: Treatments were five doses of pure (1*R*,3*R*)-chrysanthemyl (*R*)-2-acetoxy-3-methylbutanoate (0, 0.1, 1, 10, 100, and 1,000 μg), and a 1,000 μg dose of the 8-stereoisomers mixture. The amount of the *RRR*-isomer in this mixture was ≈210 μg. Traps baited with 5 virgin females were used as positive controls. Experiments were carried out in March 2009 (New Zealand) and late April/early May 2009 (Chile).

The experiments were carried out in vineyards in Hawke's Bay, New Zealand (39°65′S 176°83′E) and in a raspberry plantation near Quillota, Chile (32°43′S 71°11′ W). For preparation of lures, rubber septa were treated with the compounds dissolved in 200 μl hexane, with the solvent allowed to evaporate in a fume hood. Septa were stored at −20°C until use. Septa were placed in the center of the white sticky base of the trap. Adopting a randomized block design, traps were placed in five rows, with five replicates per treatment, with 15-m spacing between trapping stations and treatment rows. Each of the treatments tested was randomly assigned to a trap in a row of vines. The effect of treatment on the mean number of males captured was tested using ANOVA (SAS Institute Inc. 1998) after variances were stabilized using the $\sqrt{x+1}$ transformation. Significantly different treatment means were identified using Fisher's Protected Least Significant Difference Test (Statview, SAS Institute Inc., Cary, NC, USA).

Results

Chemical Analyses Headspace volatiles from mature virgin females contained three compounds that were not found in control samples. These compounds have been previously identified as [2,2-dimethyl-3-(2-methylprop-1-enyl)cyclopropyl]methanol (chrysanthemol), chrysanthemyl 2-hydroxy-3-methyl-butanoate, and chrysanthemyl 2-acetoxy-3-methylbutanoate (**1**) (El-Sayed et al., 2010).

Mealybug-produced chrysanthemyl 2-acetoxy-3-methylbutanoate showed only one GC peak on each of the non-polar, polar, and two chiral columns (β- and γ-cyclodextrin). In order to determine the relative configuration of the alcohol part of the compound, a commercial sample of chrysanthemol, containing a mixture of *cis* and *trans* isomers, was analyzed by NMR and GC/MS; this revealed that the mixture had a 1:2 ratio of diastereomers. The proportion of the signals of the C-1 ring proton at 0.83 (*trans*) and 1.38 (*cis*) ppm, and of the olefinic proton at 4.86 (*trans*) and 4.96 (*cis*), in the NMR spectrum showed that the smaller peak on the GC/MS trace corresponded to the *cis* isomer (Bramwell et al., 1969; Takano et al., 1985). Analysis of a hydrolyzed (KOH, EtOH) mealybug headspace extract on non-polar and polar columns showed that the insect-produced



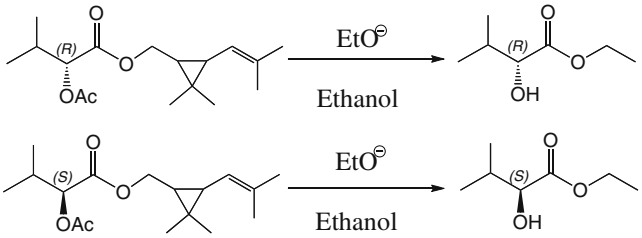


Fig. 1 Gas chromatograms of **a** synthetic racemic chrysanthemol (90% *trans* and 10% *cis*), **b**, natural chrysanthemol from the hydrolyzed extracts of headspace volatiles collected from sexually mature female citrophilous mealybugs, and **c**, synthetic *R,R*-chrysanthemol

Scheme 1 Solvolysis of the mealybug pheromone stereoisomers by ethoxide/ethanol

chrysanthemol matched the retention time of the *trans* isomer, showing that the compound possessed either the (1*R,*3*R*) or the (1*S,*3*S*) configuration on the alcohol part of the ester.

To determine the absolute configuration of the alcohol part, an isomeric mixture of chrysanthemol [racemates of *trans* (90%) and *cis* (10%)] was analyzed by GC/MS on the β-cyclodextrin column; both *trans* enantiomers separated from each other (Fig. 1a). The chrysanthemol isomer found in the hydrolyzed mealybug extract eluted at the same retention time as the second peak of *trans*-chrysanthemol (Fig. 1b). Synthetic (1*R,*3*R*)-chrysanthemol also matched the retention time of the second peak (Fig. 1c), proving that the absolute configuration of the alcohol part of the pheromone was *RR*. Additionally, the retention time of (1*R*,3*R*)-chrysanthemol matched that of the mealybug-produced compound on a second chiral column (γ-cyclodextrin, data not shown).

To determine the configuration of the acid part of the pheromone compound, commercially available (*R*)- and (*S*)-2-hydroxy-3-methylbutanoic acids were converted to their corresponding ethyl esters. These esters separated well

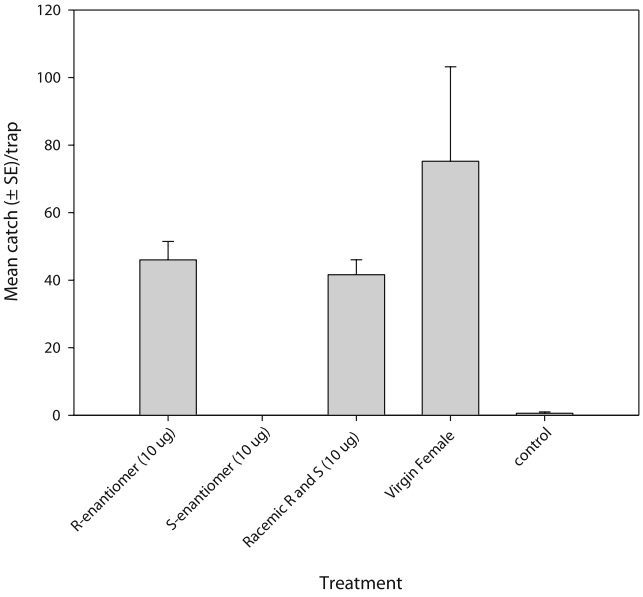

Fig. 3 Mean catch (± SE) of male citrophilous mealybugs in red delta traps baited with the following chemicals: 10 μg of a mixture of the four esters synthesized from *R*-acetate and *cis/trans* chrysanthemol (1:2 mixture of geometric isomers), 10 μg of a mixture of the four esters synthesized from the *S*-acetate and *cis/trans* chrysanthemol (1:2 mixture of geometric isomers), a mixture of all eight esters (from R- and S-acetates), virgin females, and a blank (control) trap. Different letters atop columns indicate significant differences (FPLS Test, $\alpha = 0.05$)

on the chiral columns. Subsequently, the mealybug headspace extract was subjected to a transesterification reaction (calcium ethoxide in ethanol) to convert the insect-produced chrysanthemyl 2-acetoxy-3-methylbutanoate to ethyl 2-hydroxy-3-methylbutanoate (Scheme 1). Gas chro-

matographic analysis on the chiral columns showed a single isomer that co-eluted with ethyl (*R*)-2-hydroxy-3-methylbutanoate (Fig. 2).

Field Trapping In the first experiment, 10 μg of the 4-component mixture, that contained the stereoisomers with *R* configuration in the acid part of the molecule (amount of *RRR* stereoisomer, ca. 3 μg), or of a mixture of all eight stereoisomers (amount of *RRR* stereoisomer, ca. 1.5 μg) both attracted males (relative to the control). The mean numbers of males captured by these traps did not differ from that caught in traps baited with virgin females. The stereoisomeric 4-component mixture with *S* configuration in the acid part of the ester did not attract males (Fig. 3).

In the second experiment, traps baited with doses of 10 μg or greater of the pure *RRR* stereoisomer, caught more males than the control or virgin female traps. In general, the number of males caught in traps increased with increasing dose (up to 1,000 μg) of the pure *RRR* stereoisomer. A 1,000 μg dose of the mixture of the 8 stereoisomers (containing ca. 210 μg *RRR* isomer) attracted a number of males similar to the 100 μg dose of the pure *RRR* isomer (Fig. 4).

Discussion

Chemical analysis and field tests showed conclusively that virgin females of the citrophilous mealybug produce (1*R*,3*R*)-chrysanthemyl (*R*)-2-acetoxy-3-methylbutanoate, and that this compound is highly attractive to conspecific males. Further, field experiments demonstrated that traps baited with relatively low doses of the *RRR* isomer caught as many males as traps baited with virgin females. This is in

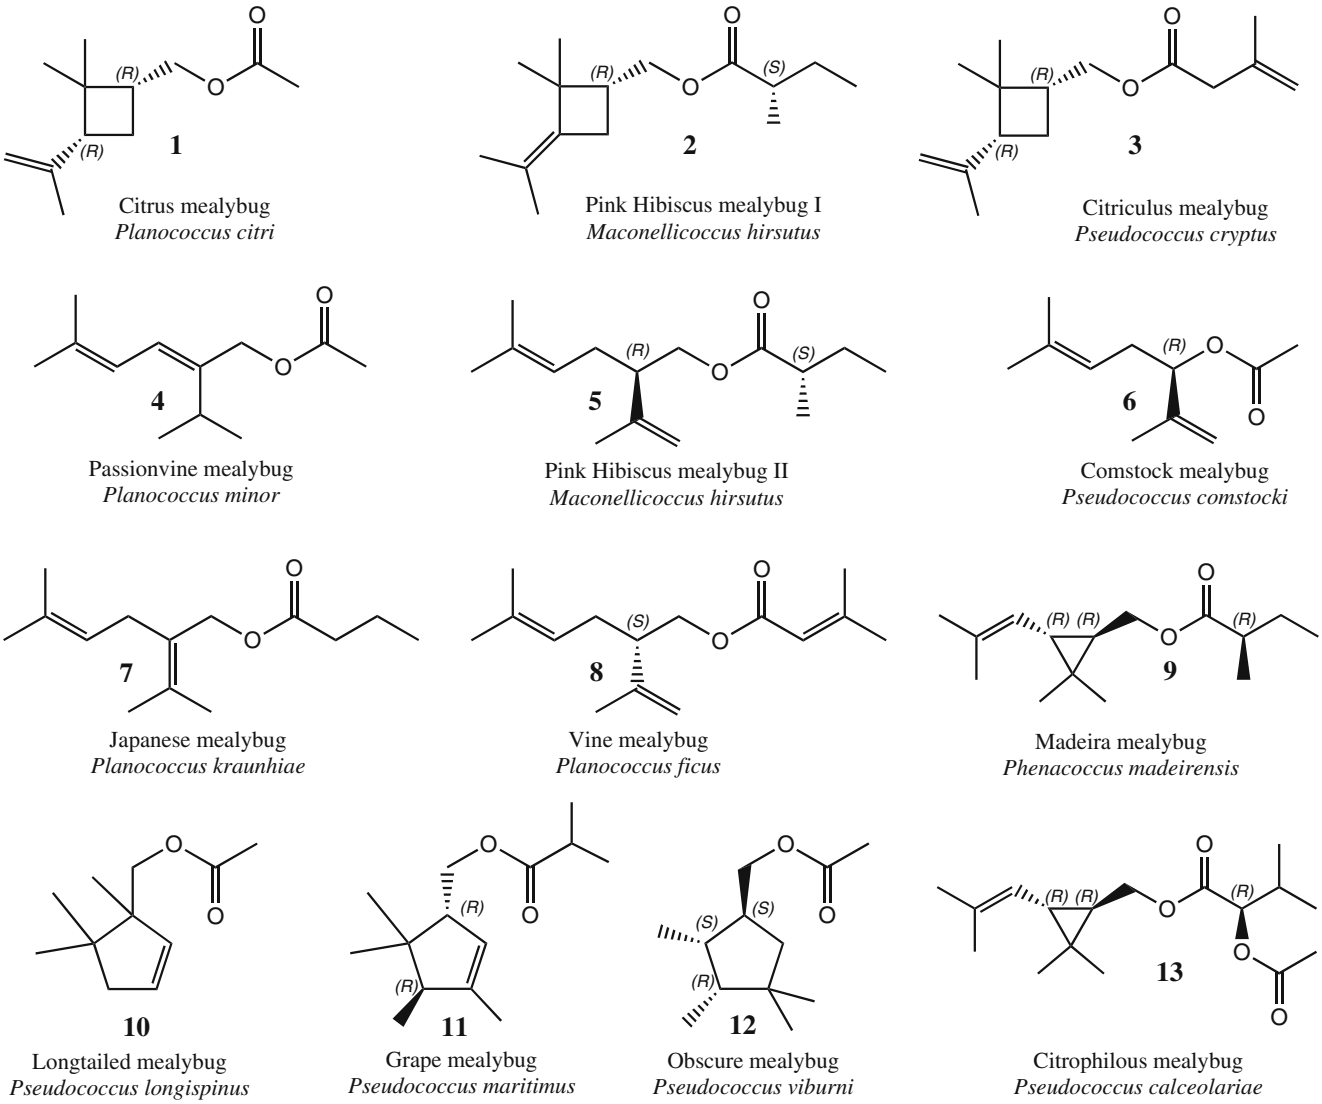

Fig. 5 The known mealybug pheromone compounds (El-Sayed, 2009; Millar et al., 2005a)

accord with the high sensitivity of male mealybugs to female pheromone reported for other species (e.g., Zhang and Amalin, 2005). This compound is the second example of a chrysanthemol derivative produced by an insect: a component of the sex pheromone of the Madeira mealybug, *Phenacoccus madeirensis*, is (1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate (Ho et al., 2009). It is noteworthy that the chrysanthemol part has the same absolute configuration as in the *P. calceolariae* compound, but is linked to a different chiral acid.

When we tested various mixtures of stereoisomers in field trials, results showed that the *R* configuration in the acid part of the ester was necessary for activity, and that stereoisomers with the *S* configuration in the acid were not attractive on their own, or were inhibitory in a mixture with the active stereoisomer. Additionally, traps baited with 1,000 μg of a mixture of all 8 stereoisomers (containing ca. 210 μg of the *RRR* isomer) captured a number of males similar to traps baited with 100 μg of pure *RRR* isomer, also suggesting that the non-natural stereoisomers are not, or at most only slightly, inhibitory. That isomeric mixtures of the pheromone can be used for monitoring the citrophilous mealybug is important, as the relatively inexpensive racemic chrysanthemol can be used for the synthesis of the pheromone rather than the enantiomerically pure and expensive precursor (1*R*,3*R*)-chrysanthemic acid.

In general, mealybugs do not seem to use mixtures of stereoisomers in their pheromones, either for behavioral synergism or antagonism (against sibling species). Instead, mealybug pheromones appear to differ from sibling species by structural isomerism. Sex pheromones now have been identified for twelve mealybug species, including the citrophilous mealybug pheromone. The core structures for all are irregular, non-head-to-tail, monoterpenols, esterified to a C2-C5 acid (Fig. 5). Five of the hitherto-known mealybug pheromones consist of compounds with a C5 isoprenic acid part, four are acetates, and two are butanoates. Four of the pheromone compounds (2,5,9,13; Fig. 5), have a stereogenic center in the acid part. The alcohol part of the pheromone compounds is a monoterpenol (or, as in the case of *P. comstocki*, a norterpenol), and it is related to maconelliol (compounds 1–3, Fig. 5; Bierl-Leonhardt et al., 1981; Arai et al., 2003; Nakahata et al., 2003; Zhang et al., 2004a, b, 2006; Zhang and Amalin, 2005), lavandulol (compounds 4-8; Negishi et al., 1980; Hinkens et al., 2001; Zhang et al., 2004a, b, 2006; Zhang and Amalin, 2005; Ho et al., 2007; Sugie et al., 2008), cyclopentylmethanol (compounds 10–12; Millar et al., 2005b, 2009; Figadere et al., 2007), or chrysanthemol (9,13; Ho et al., 2009 and the present paper).

Future work will investigate the role of structural- and stereo- isomerism in the specificity of the pheromone signals of mealybugs.

Abstract We report the identification, synthesis, and field bioassays of a female-produced sex attractant pheromone component of the cerambycid beetle *Ortholeptura valida* (LeConte). Headspace volatiles from females contained a female-specific compound, (*Z*)-11-octadecen-1-yl acetate, which elicited a strong response from antennae of adult males in coupled gas chromatography-electroantennogram analyses. In field bioassays, significant numbers of males were collected by traps baited with this compound. The pheromone represents a new structural class of cerambycid pheromones, and is the first pheromone identified for a cerambycid species in the subfamily Lepturinae.

Introduction

Cerambycid beetles of the subfamily Lepturinae (*sensu* Napp, 1994) are primarily Holarctic in distribution (Linsley, 1959; Švácha and Danilevsky, 1986), and the larvae typically develop in decaying wood (Linsley, 1959; Linsley and Chemsak, 1972; Švácha and Danilevsky, 1988). The adults of many species are diurnal and feed on the pollen or nectar of flowers (Linsley, 1961; Linsley and Chemsak, 1972). Other than those general habits, however, little is known of the behavior of most lepturine species (e.g., Swaine and Hopping, 1928; Michelsen, 1963; Linsley and Chemsak, 1972; Švácha and Danilevsky, 1988). We previously have suggested that mate location in lepturines is mediated by host plant volatiles (e.g., see Hanks, 1999; Ray, 2009). To our knowledge, long-range pheromones have not been reported for any species in the subfamily. Adult males of some lepturine species mate with females only after contacting them with their antennae (Michelsen, 1963), suggesting that mate recognition is mediated by contact pheromones (Millar et al., 2009).

We report here the identification, synthesis, and field bioassays of a female-produced sex attractant pheromone component of the lepturine *Ortholeptura valida* (LeConte). The active compound, (*Z*)-11-octadecen-1-yl acetate, represents the first example of a new structural class of pheromones within the Cerambycidae. *Ortholeptura valida* is endemic to the Pacific coast of North America, and

occurs from British Columbia to southern California along the Cascade, Sierra Nevada, Transverse, and Peninsular mountain ranges (Linsley and Chemsak, 1976; Švácha and Danilevsky, 1986, 1988). The larvae develop in the decaying trunks of conifers of many species (Craighead, 1923; Linsley and Chemsak, 1976; Cope, 1984; MacRae and Rice, 2007). Adults emerge from late June to August, and mate and oviposit on trees that are stressed, moribund, or have recently died (RLA, pers. obs.; Linsley and Chemsak, 1976). *Ortholeptura valida* is unusual among lepturines in that the adults are nocturnal (Linsley and Chemsak, 1976), and apparently do not feed on flowers (e.g., Švácha and Danilevsky, 1988). Adults often are collected at lights at night (Linsley and Chemsak, 1976).

Methods and Materials

Source of Beetles We collected prepupal larvae of *O. valida* on 3 June 2010 from downed *Abies concolor* Lind. & Gord. in the Barton Flats region of the San Bernardino National Forest (along California State Route 38, Mountaintop Ranger District, San Bernardino Co., CA, USA; N 34° 10′ 6″ W 116° 53′ 31″, 1940 m elevation). Dominant vegetation included mature *A. concolor*, *Pinus jeffreyi* Grev. & Balf., *P. ponderosa* Dougl. ex P. & C. Lawson, and *Quercus kelloggii* Newb. We extracted larvae from decomposing wood with an axe, and placed them in 25-ml plastic vials. In the laboratory, artificial pupation chambers were constructed from newsprint that was rolled into tubes (~7 cm long, ~2 cm diam). We placed a single larva in each tube, plugged the ends with tissue paper, misted them with water, and stored tubes together in a 4 l plastic bag at room temperature. Tubes were examined 2–3 times per week to monitor development.

The beetles eclosed during 20 June–5 July 2010. Teneral adults were returned to their paper tubes and temporarily stored at 4°C. Beetles were sexed using the sexually-dimorphic characters of antennal length and shape of the terminal abdominal sternite (Linsley and Chemsak, 1976). Two beetles of each sex were prepared for aeration by transferring them into individual vials (20 ml), and leaving them under ambient room conditions for 24 hr. The adults were virgins, and their cuticles were not fully sclerotized at the time that they were aerated.

Collection of Volatiles We collected headspace odors of adult male and female *O. valida* in an environmentally controlled room (26°C, 65% RH). Individual beetles were placed in modified 250 ml Ball® Mason-style canning jars that contained a glass vial (~2 ml) of 10% sucrose solution plugged with cotton, as nourishment. The jar lids were fitted with a Teflon® liner and two brass bulkhead unions (pipe thread, ~0.64 cm to 0.32 cm; Swagelok®, San Diego Valve and Fitting Co., San Diego CA, USA), one of which was connected to a flow meter-controlled vacuum source, and the other to a charcoal scrubber. Collectors were 6-mm OD by 41 mm long glass tubes containing a 5 mm long bed of thermally-desorbed activated charcoal (200 mesh; Fisher Scientific, Pittsburgh, PA, USA) held in place by Soxhlet-extracted (ether) glass wool plugs. The collectors were attached to jar lids with brass fittings (0.64 cm) with Teflon® ferrules (Swagelok®). Charcoal-filtered air was pulled through the chamber and collector at ~160 ml/min. Aerations were run for 4 days, after which the collectors were extracted with dichloromethane (3 rinses, for a total volume of 500 µl). Extracts were stored in a freezer (−4°C).

Coupled Gas Chromatography-Electroantennogram Detection (GC-EAD) and Gas Chromatography–Mass Spectrometry (GC-MS) Analyses GC-EAD analyses were performed using DB-5 and DB-Wax columns (both 30 m× 0.25 mm i.d., 0.25 µm film; J&W Scientific, Folsom, CA, USA). The carrier and makeup gas was helium. The GC oven was programmed from 40°C for 1 min, 10°C (5°C for calculation of Kovat's indices [KI] on DB-Wax) per min to 275°C for DB-5 and 250°C for DB-Wax, hold for 45 min. Solvent extracts (1 µl aliquots) were analyzed in splitless mode. The effluent from the columns was split with half of the sample going to the FID detector and the other half to the EAD. The portion directed to the EAD was diluted in a humidified air stream that was directed over the antennal preparation that consisted of the excised terminal 4–5 antennal segments of a male beetle, with the distal tip cut off with a razor blade, placed between two saline-filled glass capillary electrodes (7.5 g NaCl, 0.21 g $CaCl_2$, 0.35 g KCl, and 0.20 g $NaHCO_3$ in 1 l Milli-Q® purified water). The glass electrodes were fitted with 0.2 mm diam gold wires that connected to the amplifier, with the amplifier gain set at 100X amplification. A single antennal preparation was used for as many as ten runs. GC-MS analyses were carried out with an Agilent 6890 N GC interfaced to a 5975 C mass selective detector (Agilent, Santa Clara, CA, USA). The GC was fitted with an HP5-MS column (30 m×0.25 mm i.d., 0.25 µm film), and the same temperature program and injection conditions were used as described above. KI were calculated for unknowns and standards relative to blends of straight-chain hydrocarbons. For increased precision, KI values on the DB-Wax column were obtained using a GC oven program rate of 5 rather than 10°C/min.

Epoxidation of the Unknown Approximately half of an aeration extract from a female beetle was treated with 20 µl of a solution of *m*-chloroperbenzoic acid in methylene chloride (2 mg/ml), and the solution was held at room temperature for 1 hr, swirling occasionally. The mixture was then concentrated just to dryness under a stream of

nitrogen, the residue was taken up in pentane, and loaded onto a small column of silica gel (2 cm×3 mm ID). The column was eluted successively with pentane (400 µl) and 2×300 µl 7.5% EtOAc in pentane. The resulting fractions were concentrated to ~25 µl and analyzed by GC-MS as described above. The epoxidized pheromone was in the third fraction.

Synthesis of (Z)*-11-Octadecen-1-yl acetate* Lithium aluminum hydride ($LiAlH_4$, 150 mg, 4 mmol) was added to 10 ml of dry THF under argon, and the mixture was cooled in an ice bath while a solution of *cis*-vaccenic acid (300 mg, 1.06 mmol; Sigma Chemical Co., St. Louis, MO, USA) in 3 ml THF was added dropwise. When the addition was complete, the ice bath was removed and the mixture was stirred overnight. The mixture was cooled in an ice bath and quenched by cautious addition of water (0.16 ml; foams!), 2 M NaOH (0.12 ml), and water (0.56 ml). The resulting slurry was stirred 15 min, during which time the inorganic salts precipitated out as a gummy white solid. The mixture was filtered through a short pad of Celite® (Fisher Scientific, Fairlawn, NJ, USA), rinsing the solids well with ether. The filtrate was dried over anhydrous Na_2SO_4, and then concentrated on a rotary evaporator. The resulting alcohol was taken up in a solution of 25 ml dry ether, and pyridine (160 µl, 2 mmol) and acetyl chloride (145 µl, 2 mmol) were added. The solution was stirred overnight at ~22°C, then poured into water and extracted with ether. The ether extract was washed with brine, dried over anhydrous Na_2SO_4, concentrated, and Kugelrohr distilled (oven temp. to 110°C, 0.05 mm), yielding (*Z*)-11-octadecen-1-yl acetate (270 mg, >99% pure by GC). The proton NMR spectrum was in agreement with that previously reported (Vig et al., 1988).

Field Bioassays of Synthetic Compounds We tested the response of adult *O. valida* to the female-specific component of the aeration, (*Z*)-11-octadecen-1-yl acetate, in field bioassays. We used black flight-intercept panel traps (1.2 high×0.3 m wide, model PT Intercept™, APTIV, Portland, OR, USA). Internal surfaces of traps were treated with Fluon®, which renders traps more slippery and can greatly improve trap catch of cerambycid beetles (Graham et al., 2010). To capture beetles alive, traps were modified by replacing the collection basin with a 1.9 l plastic funnel that was attached to a clear plastic jar (1.9 l, General Bottle Supply Company, Los Angeles, CA, USA). The funnel spout was cut off, leaving a 3.5-cm-diam hole at the bottom, a ~10 cm hole was cut into the threaded lid of the jar, and the funnel spout was hot-melt glued to the lid so that the spout was inside the jar. We hung traps from tree branches or from L-shaped hangers constructed of PVC pipe (as in Graham et al., 2010) with the trap bases ~30 cm above the ground. Pheromone lures were clear low-density polyethylene press-seal bags ("Zipper" seal sample bags, 2"×3", 51 µm wall thickness, #01-816-1A; Fisher Scientific, Pittsburgh, PA, USA) loaded with 25 mg of (*Z*)-11-octadecen-1-yl acetate in 475 µl of absolute ethanol (500 µl total volume) and sealed. Control lures contained 500 µl of absolute ethanol. Lures were suspended with wire in the central open area of traps.

We monitored flight activity of *O. valida* with two pheromone-baited sentinel traps at the Barton Flats study site. The sentinel traps were set up on 28 July 2010, within the seasonal activity period of the species (Linsley and Chemsak, 1976). Seven adult male *O. valida* were captured by sentinel traps within 2 days, and the field bioassay then was set up and run until 25 August 2010 (clear skies, no precipitation, air temperatures 10–33°C, maximum wind speed 11 km/h). We set up three replicates of the two treatments at the Barton Flats site, and two replicates at another site ~4 km to the southwest (along West Jenks Lake Road; N 34° 9′ 47″ W 116° 53′ 57″, 2020 m elevation). At both sites, traps were positioned in a southerly transect and separated by ~10 m, with pheromone and control treatments assigned randomly to traps.

Traps were checked for beetles at intervals of 4–6 days, and were shifted along transects every 7 days to control for location effects, at which time lures were replaced. Captured beetles were sexed using the sexually-dimorphic characters listed above. Differences between trap treatments in the number of beetles captured per trap per time interval were tested with the nonparametric Friedman's test (blocked by date and site; PROC FREQ with CMH option; SAS Institute, 1999) because assumptions of analysis of variance were violated by heteroscedasticity (Sokal and Rohlf, 1995). We excluded from the analysis one date on which no beetles were captured.

Voucher specimens of *O. valida* have been deposited at the Entomology Research Museum at the University of California, Riverside (museum voucher numbers: UCRC ENT 00282753, 00282754, 00282755, 00282756, 00282757, 00282758).

Results

Identification of the Pheromone Analyses of the extracts of volatiles released by female *O. valida* showed that a single sex-specific trace component in the extracts elicited a strong and reproducible response from antennae of male beetles (Fig. 1), with a KI on the relatively nonpolar DB-5 column of 2192 and a KI on the polar DB-Wax column of 2512. The EI mass spectrum showed a series of regularly spaced ion clusters separated by ~14 mass units, suggestive of a long hydrocarbon chain (Fig. 2, top). The values of the

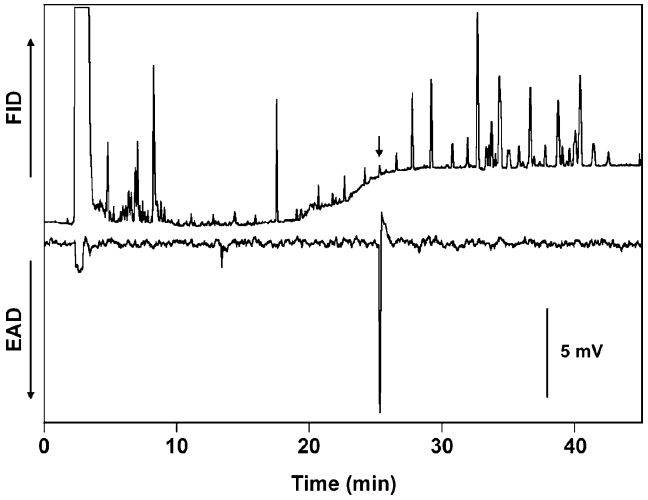

Fig. 1 Coupled gas chromatography-electroantennogram analysis of an extract of headspace odors from a female *Ortholeptura valida*. Upper trace is the chromatogram; lower inverted trace is the electroantennogram signal from the antenna of a male beetle. DB-5 column, 40°C/1 min, then 10°C/min to 275°C, hold 40 min. Scale bar represents 5 mV for the amplified antennal response (gain 100X)

most prominent ions in each cluster (*m/z* 69, 82, 96, 109, 123, etc.) suggested that the compound was unsaturated, or that it had a functional group that was readily lost as a neutral fragment to leave an unsaturated ion that fragmented further. A prominent fragment at *m/z* 61 suggested the presence of an acetate. The highest mass ion observed was at *m/z* 250 (possible formula, $C_{18}H_{34}$), which could reasonably be derived from the loss of acetic acid from a monounsaturated 18 carbon acetate ester.

GC-MS analyses of the model compound (*Z*)-9-octadecen-1-ol (oleyl alcohol) revealed that its mass spectrum was quite similar to that of the unknown, but the Kovats index (2062) on the DB-5 column was 130 units less than that of the unknown. However, a standard of (*Z*)-9-octadecen-1-yl acetate gave a retention index (2186) and a mass spectrum that was similar, but not an exact match to that of the unknown, indicating that the unknown was probably one of the other octadecenyl acetate isomers. The double bond position and geometry were determined by epoxidation of an extract, followed by GC-MS analysis. The resulting derivative gave enhanced fragments at *m/z* 127 ($C_8H_{15}O^+$) and 241 ($C_{14}H_{25}O_3^+$) from cleavage on either side of the epoxide, identifying the double bond in the parent compound as being in the 11 position (Fig. 3, top). An exact retention time match of the derivative with an epoxidized standard of (*Z*)-11-octadecen-1-yl acetate (vaccenyl acetate, Z11-18:Ac) indicated that the double bond in the unknown had the *Z*-configuration (*cis*- and *trans*-epoxides from *cis*- and *trans*-alkenes, respectively, have different retention times; Attygalle, 1998). This was confirmed by the presence of a trace amount of the corresponding *trans*-epoxide in the synthetic standard; the *cis*- and *trans*-epoxides were separated to baseline on the DB-5 column (*cis*: retention time 22.70 min; *trans*: 22.56 min). The epoxidized insect extract showed a peak only at 22.70 min, indicating that the insect produced only the *Z*-stereoisomer. The identification was confirmed by exact matches in retention times between the unknown and Z11-18:Ac on both the DB-5 and DB-WAX columns, and matching mass spectra (Fig. 3). Thus, the highest mass ion at *m/z* 250 observed in EI mass spectrum of the parent compound did indeed correspond to loss of acetic acid from the molecular ion (*m/z* 310), as commonly occurs with long-chain acetates under 70 eV electron impact ionization conditions.

Field Bioassays of Synthetic Compounds Traps baited with pheromone lures captured 139 and 41 male *O. valida* (a total of 180 beetles) at the Barton Flats and Jenks Road sites, respectively, but no beetles were captured by control traps. As many as 46 male beetles were captured per

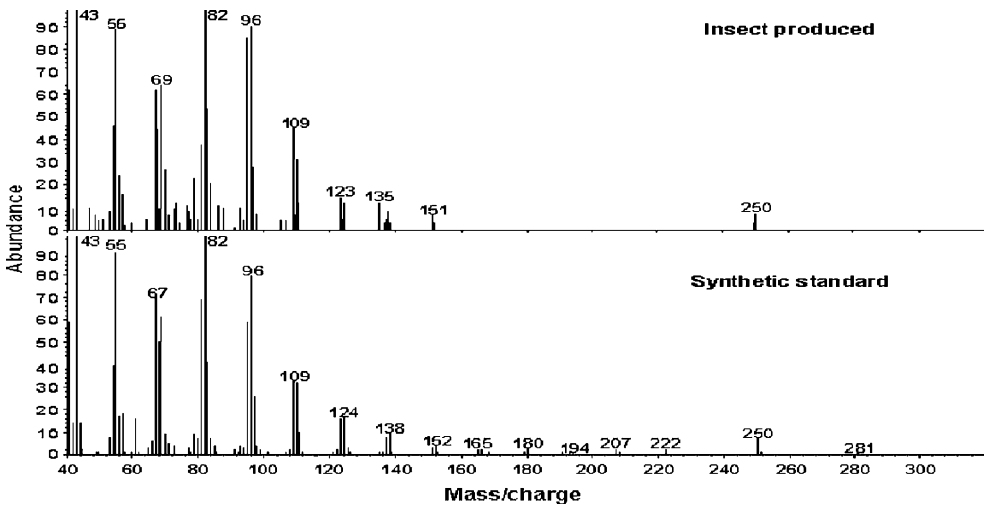

Fig. 2 EI mass spectra (70 eV) of the compound that elicited a strong electroantennogram response in Fig. 1 (top) and of an authentic standard of (*Z*)-11-octadecen-1-yl acetate

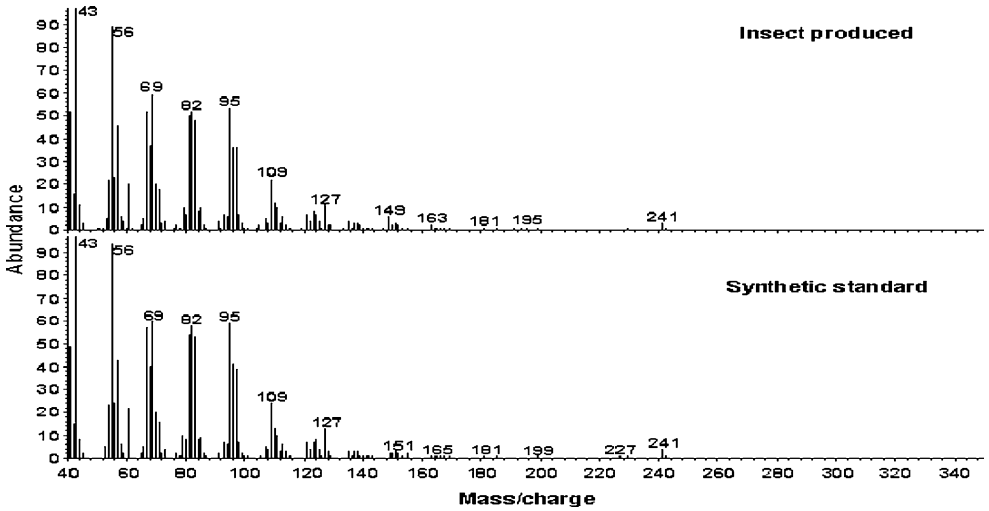

Fig. 3 EI mass spectra (70 eV) of the epoxide of the compound that elicited a strong EAD response in Fig. 1 (top) and of epoxidized authentic (*Z*)-11-octadecen-1-yl acetate

pheromone trap per date, with a mean of 7.5±1.9 beetles (SE; significantly different from the 0 mean for controls; Friedman's $Q_{1,48}$=28.7, P<0.001). Traps baited with the synthetic pheromone did not capture any other insect species.

Discussion

Exclusive attraction of *O. valida* males to lures baited with synthetic (*Z*)-11-octadecen-1-yl acetate indicates that this compound is a sex pheromone for this species. The strong attraction in field bioassays, coupled with the lack of any other significant responses from antennae of male beetles in GC-EAD analyses of aeration extracts of females, strongly suggests that the pheromone consists of only this single component. Female-produced pheromones also have been found in species of the cerambycid subfamily Prioninae (Rodstein et al., 2011), and species that apparently are related to the Cerambycidae, including *Migdolus fryanus* Westwood (Anoplodermatinae; Leal et al., 1994) and *Vesperus xatarti* Dufour (Vesperidae; Boyer et al., 1997; for phylogenetic relationships, see Švácha and Danilevsky, 1986; Napp, 1994). Females of those species generally are larger than males and sedentary, being incapable of flight until after they have oviposited, permanently incapable of flight, or at least characteristically reluctant to fly (Linsley, 1959). The sedentary behavior of the females is consistent with the persistent nature of the larval hosts: living roots of perennial grasses, shrubs, or trees (e.g., Leal et al., 1994; Barbour et al., 2006). Individual hosts, therefore, can support many generations, and females need not disperse to locate appropriate new hosts (Hanks, 1999). Newly eclosed females of these species may remain concealed in the soil, or within tissues of the larval host, and release pheromones that attract their mates (Leal et al., 1994; Hanks, 1999; Barbour et al., 2006). The early release of pheromone by females, and strong response of males, suggests an urgency that is consistent with limited energy reserves due to the fact that the adults likely do not feed (Linsley, 1959; Hanks, 1999; Barbour et al., 2006).

In contrast to other species that have female-produced pheromones, the larvae of *O. valida* develop in hosts that are dying, or have recently died. Such hosts are unpredictable and ephemeral resources, since their tissues degrade rapidly (reviewed by Hanks, 1999). Therefore, adult females must be capable of dispersing to locate appropriate hosts, which is consistent with reports that they take flight readily (Linsley and Chemsak, 1976). This relationship between larval host condition and dispersal ability in adults is more consistent with species in the subfamilies Cerambycinae, Lamiinae, and Spondylidinae in which males produce pheromones that attract both sexes (Silk et al., 2007; Millar et al., 2009; Ray et al., 2009; Fonseca et al., 2010; Pajares et al., 2010). Larvae of those species also develop in highly stressed or moribund woody plants, and the pheromones apparently serve to expedite location of hosts (Hanks, 1999).

The structure of the *O. valida* pheromone is unprecedented among the cerambycid pheromones that have been reported to date, and completely unlike the diol/hydroxyketone motif of the volatile pheromones produced by species in the subfamily Cerambycinae (Millar et al., 2009), the terpene motif of the pheromones produced by males of species in the subfamily Spondylidinae (Silk et al., 2007), or the carboxylic acid motif of species in the genus *Prionus* (subfamily Prioninae; Rodstein et al., 2011). (*Z*)-11-Octadecen-1-yl acetate also is an aggregation pheromone produced by male fruit flies (*Drosophila* spp.; Bartelt et al., 1985), but when transferred to females during mating it subsequently discourages courtship of other males (Jallon et al., 1981). This compound also has been reported as a minor

component in the defensive secretions of larvae of the chrysomelid beetle *Linaeidea aenea* (L.) (Sugawara et al., 1979). In addition, (*Z*)-11-octadecen-1-yl acetate is similar in structure to the monounsaturated acetate compounds that are pheromone components of many lepidopterans (El-Sayed, 2011).

Acknowledgments We thank Tom Coleman, USDA Forest Service, for information about field sites and for support of this work, Ian Swift for discussions on taxonomy and natural history, assistance with the literature, and for comments on an early version of this work, and Rebeccah Waterworth for assistance with field work and GC-EAD. We are grateful for financial support from the Alphawood Foundation (to LMH), and the National Research Initiative of the USDA Cooperative State Research, Education and Extension Service, grant number #2009-35302-05047 (to JGM and LMH).

Abstract Within the complex network of chemical signals used by termites, trail pheromones and sex pheromones are among the best known. Numerous recent papers map the chemical identity and glandular origin of these pheromones in nearly all major isopteran taxa. In this study, we aimed to describe the sex pheromone and the trail pheromone of a poorly known sand termite, *Psammotermes hybostoma*. We identified (3*Z*,6*Z*,8*E*)-dodeca-3,6,8-trien-1-ol (dodecatrienol) as the sex pheromone released by tergal and sternal glands of female imagos and, at the same time, as the trail pheromone secreted from the sternal gland of workers. We conclude that chemical communication in *Psammotermes* does not differ from that of most other Rhinotermitidae, such as *Reticulitermes*, despite the presence of a diterpene as a major component of the trail pheromone of *Prorhinotermes* to which *Psammotermes* is presumed to be phylogenetically close. Our findings underline once again the conservative nature of chemical communication in termites, with dodecatrienol being a frequent component of pheromonal signals in trail following and sex attraction and, at the same time, a tight evolutionary relationship between the trail following of working castes and the sex attraction of imagos.

Introduction

Devoid of visual orientation, termites have reached a high level of social and functional complexity, with semiochemicals being involved in many aspects of their life. Within the network of chemical signals used by termites, the trail pheromones and the sex pheromones are among the best known. Numerous recent papers map the chemical identity and glandular origin of these pheromones in all but one (Serritermitidae) of the extant isopteran families using modern methods of chemical extraction (solid phase microextraction) and electrophysiological experiments (Sillam-Dussès et al., 2009; reviewed in Bordereau and Pasteels, 2011).

This progress in chemical ecology allows us to discern several particularities of termite trail and sex pheromones, contrasting with the situation in social hymenopterans. First, only a few glands are involved in the trail-following communication and sexual attraction in termites. Trail pheromones are always produced by the same homologous gland, the sternal gland of workers (but the gland is present in all castes and developmental stages) (Quennedey et al., 2008). The sex pheromones are secreted from the sternal gland and/or the tergal glands and/or the posterior sternal glands of female, or rarely from male imagoes or both sexes (reviewed in Pasteels and Bordereau, 1998; Bordereau and Pasteels, 2011). Second, the chemical diversity of pheromonal components is surprisingly low, with only 8 compounds being identified as trail pheromones in more than 60 species studied, and only 9 compounds confirmed so far to participate in sexual attraction in 25 species studied

(Bordereau and Pasteels, 2011). Third, along with the low diversity in anatomy and chemistry, there is striking parsimony in the pheromones of the many species observed, with the same compound acting as trail and sex pheromone though in different concentrations and in different contexts (reviewed in Pasteels and Bordereau, 1998; Bordereau and Pasteels, 2011). Fourth, both trail and sex pheromones most often consist of a single compound, not blends of compounds as in numerous other insects. However, some recent studies demonstrated the presence of minor components in addition to these major compounds (Sillam-Dussès et al., 2009, 2010; Bordereau et al., 2010; Anani Kotoklo et al., 2010), suggesting that minor active components could have been overlooked in the past.

Nevertheless, despite the conservative nature of both trail and sex pheromones and their glandular origins, their chemical ecology still represents a useful comparative tool at higher taxonomical levels. It is particularly true for the situation within the paraphyletic family Rhinotermitidae, within which both Serritermitidae and Termitidae probably evolved (see recent molecular phylogenetic studies, e.g., Lo et al., 2004; Ohkuma et al., 2004; Inward et al., 2007; Legendre et al., 2008). Most rhinotermitids studied so far use the unsaturated alcohol (3*Z*,6*Z*,8*E*)-dodeca-3,6,8-trien-1-ol (dodecatrienol) as their trail pheromone (e.g., Matsumura et al., 1968; Tai et al., 1969; Tokoro et al., 1989, 1991; Wobst et al., 1999; Sillam-Dussès, 2004), and also as the sex pheromone produced by the sternal or tergal glands of females (Laduguie et al., 1994a,b; Hanus et al., 2009). However, the subfamily Prorhinotermitinae displays another combination of glands and compounds, similar to the situation in Termitidae (Bordereau et al., 2002, 2010; Sillam-Dussès et al., 2010): the trail pheromone consists of the diterpene neocembrene (major component) and dodecatrienol (Sillam-Dussès et al., 2009); the sex pheromone is once again dodecatrienol, but it is secreted by female tergal glands (Hanus et al., 2009). This striking singularity of *Prorhinotermes* promoted our interest in the chemistry of sex and trail pheromones in other basal rhinotermitid genera, namely *Psammotermes*, which is suggested to be a sister clade to *Prorhinotermes* in several recent phylogenies (Austin et al., 2004; Lo et al., 2004; Ohkuma et al., 2004; Inward et al., 2007).

Species in the genus *Psammotermes*, Desneux, 1902, which are important timber pests, inhabit arid areas of the Old World, namely Sahara and Arabia (*P. hybostoma* Desneux, 1902), South Africa (*P. allocerus* Silvestri, 1908), Madagascar (*P. voeltzkowi* Wasmann, 1910), and South-West Asia (*P. rajasthanicus* Roonwal & Bose, 1960). However, the most basic aspects of *Psammotermes* biology remain unknown, such as the caste system (only a pronounced size polymorphism of workers and soldiers has been noted; Clément, 1952; Roonwal, 1988) or the chemistry of the defensive frontal gland of soldiers. Together with Stylotermitinae and Termitogetoninae, Psammotermitinae is among the last rhinotermitid subfamilies that have not yet been studied with respect to the trail and sex pheromones. In this study, we report the results of our investigations on the source and chemical identity of the trail pheromone and the sex pheromone in the sand termite *Psammotermes hybostoma*.

Methods and Materials

Insects Large portions of *Psammotermes hybostoma* colonies were collected from tamarisk wood at the periphery of Sohag, Egypt and brought to Prague, Czech Republic. The colonies were held under laboratory conditions in their original wood at 26°C and a low relative humidity. Some of the colonies contained alate imagos of both sexes waiting for their dispersal flight. These were kept in the colonies and used in the study of the sex pheromone. Males were eventually dealated prior to behavioral experiments. The readiness of males to respond to female sex pheromone has been tested by observation of tandem behavior. Within the polymorphic worker caste, the "large workers" represented a minority of individuals, their number being insufficient for the purpose of this study. Moreover, Clément (1952) questioned the participation of "large workers" in colony tasks. Therefore, only individuals that could be classified as "minor workers" were included in trail pheromone analysis.

Histology of Exocrine Glands Semithin resin sections were prepared with male and female dealate imagos and with workers (see Šobotník et al. (2010) for details of fixation procedure). Sections (1 μm) were cut using an Ultracut Reichert-Jung, stained with Azur II solution, and studied using a Carl Zeiss Amplival optical microscope combined with a Canon EOS 500D camera.

Pheromone Standard (3*Z*,6*Z*,8*E*)-Dodeca-3,6,8-trien-1-ol (dodecatrienol) was kindly supplied by Christian Bordereau (Dijon, France).

Glandular Extracts The following hexane extracts were prepared after dissection of females and workers: 250 sternal glands of workers, 500 sternal glands and 500 tergal glands of female imagos, 500 female bodies devoid of the sternal and tergal glands. Extracts were diluted with hexane to two concentrations, i.e., 1 and 10 gland equivalents per 10 μl. These extracts were used in the sex attraction bioassays, and trail-following bioassays. Concentrated glandular extracts were used for electrophysiological experiments and gas chromatography (GC).

Electrophysiological Experiments Electroantennographic bioassays (EAG) and gas chromatography coupled with electroantennographic detection (GC-EAD) were performed with antennae of males and workers as described in Sillam-Dussès et al. (2009). Concentrated extracts of sternal and tergal glands of female imagos, concentrated extracts of sternal glands of workers, and a solution of a standard of dodecatrienol were used in GC-EAD. The applied solutions were co-eluted with a series of *n*-alkanes (C8-C22) in order to calculate the linear retention indices (LRI) of particular compounds. A DB-5 column (30 m×20.25 mm i.d., 0.25 μm film; J&WScientific, Folsom, CA, USA) was used, programmed from 40°C (2 min) to 270°C (10 min) at 50°C/min. Injector and detector temperatures were 220°C and 250°C, respectively. Glandular extracts and dodecatrienol (0.1–100 pg per stimulation) were tested in EAG, with hexane and air being used as controls.

Gas Chromatography The extract of tergal and sternal glands of females, and sternal glands of workers were analyzed by two-dimensional GC with mass spectrometric time of flight detection (GC × GC/TOF-MS, Pegasus 3D, Leco, St. Joseph, MI, USA). A nonpolar DB-5 column as above was used in the first column, and a polar BPX-50 column (2 m×0.1 mm i.d, 0.1 μm film; SGE, Melbourne, Australia) was used as the second column. The first GC was programmed from 40°C (1 min) to 320°C at 7°C/min, and the second column was set at 340°C. 1 μl Samples were injected in a splitless mode; injector temperature was 250°C; and helium (1.0 ml/min) was used as carrier gas. Separation time in the second dimension was 4 sec with a 0.6 sec hot pulse. Detector conditions: The EI source for the TOF-MS operated at temperature 220°C using 70 eV ionization, and an acquisition rate 50 spectra/s.

Sex Attraction Choice Bioassays Two dealate male imagos were introduced at the same time in a 15 cm Petri dish lined with Whatman No. 1 filter paper. The dish contained two folded pieces of filter paper (1 cm^2), treated with 10 μl of hexane extract of female bodies (devoid of sternal and tergal glands) or sternal and/or tergal glands extracts of females (always 1 female equivalent per paper) or various concentrations of dodecatrienol standard or 10 μl of hexane as control. Two males were used because a single male deprived of tactile communication displays an unstable behavior. The time spent by one or two males in contact with particular pieces of paper was measured during 5 min. Results obtained from 15 replicates for each treatment combination were statistically analyzed by using Mann-Whitney *U* test.

Trail-following Choice Bioassays Trail-following bioassays were performed to test the orientation activity of hexane extracts of sternal glands. Sternal gland extracts of females were used in tests with males, worker sternal gland extracts in tests with workers, and dodecatrienol standard solutions. Solutions were tested with a 'Y open field' bioassay on Whatman No.1 filter paper discs (15 cm diam), with a 120° angle between each branch. On the stem (3 cm) and one of the branches (7 cm), an artificial trail was drawn with a syringe containing 10 μl of sternal gland extract (1 μl/cm of the trail, i.e., 0.1 or 1 gland equivalent per cm of the trail). Ten μl of hexane were deposited on the stem and the other branch of the Y. One termite was placed inside a holding chamber (55 mm Petri dish), with a 2-mm opening located at the base of the Y. The distance travelled by the insect on the trail was measured. The activity threshold was defined as the minimum concentration that elicited termites to travel a mean distance of more than 3 cm, the maximum response being 10 cm. Each experiment was repeated with 15 or 30 individual termites. Choice tests were performed with the same experimental setup to compare the preference of termites between gland extracts and dodecatrienol. Each of the compared stimuli was deposited on the stem and on one of the Y branches of the experimental arena. This test was repeated with 30 individual termites, and results were evaluated using χ^2-test.

Results

Origin of the Female Sex Pheromone – Microscopy Semi-thin sections of *P. hybostoma* female imagos revealed the presence of three well developed tergal glands in the anterior parts of the 8th, 9th, and 10th tergites, and of one sternal gland in the anterior part of the 5th sternite (Fig. 1). Tergal glands consist of two common cell types, and these are probably class 1 and class 3 secretory cells (*sensu* Noirot and Quennedey, 1974, 1991). Tergal glands are between 130 and 180 μm long, and up to 50 μm thick. We did not observe the tergal glands in *P. hybostoma* males. The sternal gland of imagos is about 250 μm long and 35 μm thick, and its external reservoir is quite large (see Fig. 1).

Origin of the Female Sex Pheromone – Behavior Calling behavior was not observed in either sex in the field or the laboratory, but tandems (a female followed by a male) were formed immediately after encountering the opposite sex (Fig. 2). In sex attraction bioassays, males preferred the mixed extract of sternal and tergal glands of females to the extracts of whole female body devoid of these glands (63± 16 sec vs. 3±1 sec, $P<10^{-5}$). Males clearly preferred the extract of sternal glands and, even more, the extract of tergal glands of females to hexane controls (Table 1). No significant preference was observed when the extract of

tergal glands and the mixed extract of tergal and sternal glands were exposed to the males (72±18 sec vs. 54±9 sec, N=15, P=0.56). In addition, trail-following bioassays showed that males were able to consistently follow the trails made with sternal gland extract of females (Table 2). All these results indicate that the components of the female sex pheromone are located in both the sternal gland and the tergal glands of female imagos.

Chemical Nature of the Female Sex Pheromone In GC-EAD experiments, injections of extracts of 6 female tergal glands elicited a single significant and reproducible major antennal response in males to a compound eluting at 7.21 min (Fig. 3a). Co-injection of the extract with a series of hydrocarbons revealed that the LRI of the putative active compound was approximately 1525. The retention index was characteristic for dodecatrienol. Indeed, the injection of 10 ng of dodecatrienol resulted in a clear FID peak at the same retention time, and a corresponding antennal response (Fig. 3c). Subsequently, the presence of dodecatrienol in the tergal glands was confirmed by an analysis of the extract (25 gland equivalents) by GC × GC/TOF-MS.

The extract of female sternal glands elicited a single antennal response of males at the retention time identical to that observed for the tergal gland extract and dodecatrienol standard (Fig. 3b). Analysis of this extract (25 gland equivalents) by GC × GC/TOF-MS confirmed the presence of the dodecatrienol in the sample. We concluded that dodecatrienol is a component of the female sex pheromone of *P. hybostoma*, secreted by sternal and tergal glands.

[a] The time spent by two dealate male imagos on papers impregnated with hexane, female tergal gland extract, female sternal gland extract, or dodecatrienol at 6 different concentrations was measured (mean in sec ± *S.E.M.*). TGE – tergal gland equivalent, SGE – sternal gland equivalent, *N* – number of repetitions, *P* value (Mann-Whitney *U* test), *NS* – non-significant.

choice test, males preferred dodecatrienol at 100 pg/paper and higher to tergal glands extract; this indicates that approximately 10 pg of dodecatrienol are present in the tergal glands of one female (Table 1).

In trail-following bioassays, the trail-following activity of males was elicited by dodecatrienol at a concentration 10 pg/cm and higher (Table 2). In the choice trail-following test, males preferred to follow the trail made with dodecatrienol at 100 pg/cm and higher to the extracts of sternal gland (1 gland equivalent per cm). This indicates that between 10 and 100 pg of dodecatrienol are present in the sternal gland of one female (Table 3).

Quantification of the Female Sex Pheromone In addition to the sex attraction and trail-following bioassays (see above), the dose-response relationship of the EAG response to dodecatrienol standard solutions compared to glandular extracts was used to estimate the quantity of dodecatrienol in sternal and tergal glands of females. EAG amplitude increased with increasing concentrations of dodecatrienol; dodecatrienol was estimated to be approximately 1 pg in the sternal gland, and 10 pg in tergal glands of one female (Fig. 4). The results for the two methods used are summarized and compared in Table 5.

Origin of the Trail Pheromone of Workers – Microscopy The presence of a single sternal gland located at the anterior part of the 5th sternite of worker was confirmed, as in all Rhinotermitidae studied so far (Fig. 1). The gland is approximately 170 μm long and 50 μm thick. It does not differ in overall size from the gland of female imagos, but its shape is bilobed, as in workers of other rhinotermitids (see Ampion and Quennedey, 1981).

Origin of the Trail Pheromone of Workers – Behavior - Workers followed trails made of the sternal gland extract of workers at both concentrations tested (5.1±1 cm at 10^{-1} gland equivalent/cm, *N*=15; 6.9±0.7 cm at 1 gland

Table 2 Trail-following bioassays with dodecatrienol or female sternal gland extracts[a]

Hexane	Sternal gland extract (SGE/cm)		Dodecatrienol (pg/cm)				*N*

0	–	–	–	–	–	9.7±0.3	30

[a] The distance travelled by one dealate male imago on trails made of sternal gland extract or dodecatrienol was measured (mean in cm ± *S.E.M.*). SGE – sternal gland equivalent, *N* – number of repetitions.

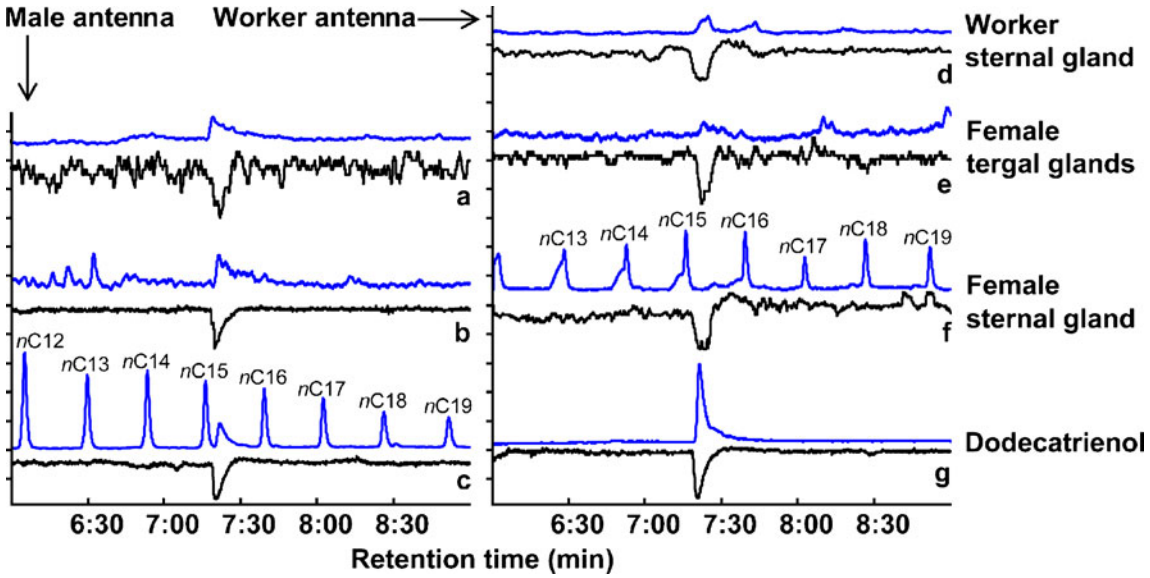

Fig. 3 Electroantennographic recordings of male (left) and worker (right) antennae exposed to the extracts of female tergal and sternal glands, worker sternal glands, and dodecatrienol standard solution. Upper curve (blue) – FID, lower curve (black) – EAD. Note the antennal response of both, males and workers, at the retention time 7.21 in all experiments. In c and f, the tested solutions are co-eluted with *n*-alkane standards (C8–22). *Y* scale (mV per division): a – EAD=0.1, FID=4; b – EAD=1, FID=3; c – EAD=1, FID=25; d – EAD=1, FID=5; e – EAD=0.1, FID=4; f – EAD=0.5, FID=4; g – EAD=1, FID=10

equivalent/cm, N=30). Therefore, we concluded that the trail pheromone of workers is secreted by their sternal gland.

Chemical Nature of the Trail Pheromone of Workers Injection of concentrated extract of sternal glands from 5 workers into the GC-EAD setup resulted in a single antennal response of workers, matching the retention characteristics of dodecatrienol as described above (Fig. 3d, g). The workers responded identically to the extracts of the female sternal and tergal glands, suggesting the presence of the same active component, dodecatrienol, in the glands (Fig. 3e, f). In addition, workers followed trails made of the tergal gland extract of female imagos (10^{-1} female tergal gland equivalent per cm), which confirms the identity of the female sex pheromone and the worker trail pheromone. The presence of dodecatrienol in the sternal gland extract of workers was confirmed using GC × GC/TOF-MS (50 gland equivalents injected). Thus, we concluded that dodecatrienol is a component of the trail pheromone of *P. hybostoma* workers.

Table 3 Trail-following choice bioassays to female sternal gland extract and dodecatrienol[a]

6	–	–	24	30	$< 10^{-3}$

[a] Values indicate the number of choices made by one dealate male imago when given a choice between a trail made of female sternal gland extract or dodecatrienol. SGE – sternal gland equivalent, *N* – number of repetitions, *P* value (χ^2-test).

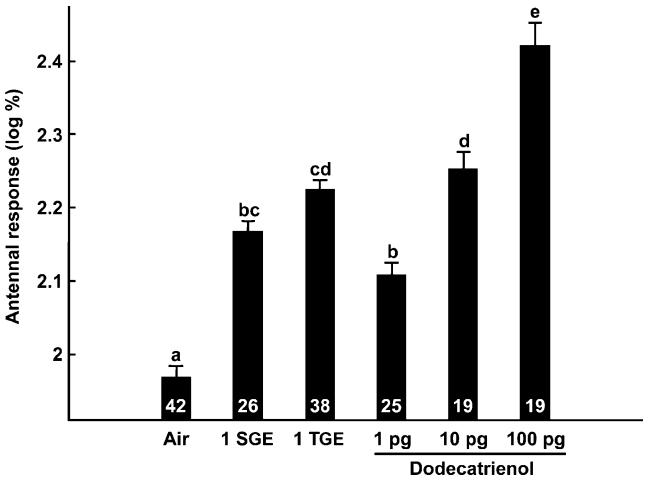

Fig. 4 EAG responses of males to air control, glandular extracts of females, and various concentrations of dodecatrienol (mean ± *S.E.M.*). Data were normalized to hexane stimulations and log transformed to reduce heteroscedasceity. Data normality was controlled using Levene's test (P=0.09). Bars marked with different letters indicate significant differences (P<0.05) among treatments, calculated by means of ANOVA ($F_{(5,169)}$=74.5, $P<10^{-4}$) with subsequent post-hoc comparison using HSD for unequal *N*. Numbers at the base of each bar represent the number of observations for each treatment. SGE = sternal gland equivalent; TGE = tergal gland equivalent

Table 4 Trail-following bioassays with dodecatrienol[a]

Dodecatrienol (pg/cm)					*N*
10^{-1}	1	10	100	1000	
1.1±0.2	–	–	–	–	30
–	3.8±0.4	–	–	–	30
–	–	5.8±0.6	–	–	30
–	–	–	3.4±0.6	–	30
–	–	–	–	2.9±0.5	30

[a] The distance travelled by one worker on trails made of dodecatrienol is measured. Another trail, made of hexane, is used as a control and is never followed. *N* – number of repetitions.

Biological Activity of Dodecatrienol Dodecatrienol was highly active in eliciting the trail-following of workers; the activity threshold being 1 pg/cm, with maximum activity observed at 10 pg/cm. A decrease in the trail-following activity was observed at 100 pg/cm and higher (Table 4). In the choice trail-following test, workers preferred dodecatrienol at a concentration 100 pg/cm to sternal gland extract (1 gland equivalent per cm), which suggests that approximately 10 pg are present in one gland.

Quantification of the Trail Pheromone of Workers In addition to the trail-following choice bioassays (see above), the EAG dose-response experiments were performed to estimate the quantity of dodecatrienol in sternal glands of workers. The threshold activity was observed at 1 pg of dodecatrienol; the quantity of dodecatrienol in the sternal gland of one worker was estimated to be between 1 and 10 pg (Fig. 5). The results of the two approaches are compared in Table 5.

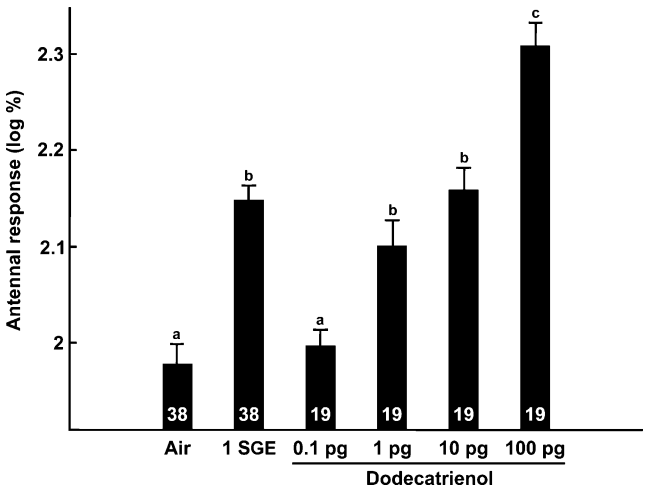

Fig. 5 EAG responses of workers to air control, sternal gland extract of workers, and various concentrations of dodecatrienol (mean ± *S.E.M.*). Data were normalized to hexane stimulations and log transformed to reduce heteroscedasceity. Data normality was controlled using Levene's test (P=0.075). Bars marked with different letters indicate significant differences (P<0.05) among treatments, calculated by means of ANOVA ($F_{(5,\ 152)}$=30.8, $P<10^{-4}$) with subsequent post-hoc comparison using HSD for unequal *N*. Numbers at the base of each bar represent the number of observations for each treatment. SGE = sternal gland equivalent

Discussion

Our study demonstrates that (3*Z*,6*Z*,8*E*)-dodeca-3,6,8-trien-1-ol (dodecatrienol) is the major component of the sex pheromone of female imagos and of the trail pheromone of workers in the sand termite *Psammotermes hybostoma*. The female sex pheromone is produced by the tergal glands and the sternal gland, and the trail pheromone is secreted by the sternal gland of workers. The identity of the two pheromones has been studied and confirmed using a combination of behavioral bioassays, electrophysiology, and chemical analysis.

For the first time, a termite sex pheromone secreted by two different glandular sources, the tergal glands and the sternal gland, has been chemically characterized. Previous studies implicated multiple glands in termite sexual attraction, such as the sternal gland and the tergal glands in *Trinervitermes bettonianus* (Termitidae: Nasutitermitinae) (Leuthold, 1975, 1977) and *Kalotermes flavicollis* (Kalotermitidae) (Wall, 1971), or the tergal and the posterior sternal glands in *Macrotermes annandalei* and *M. barneyi* (Termitidae: Macrotermitinae) (Peppuy et al., 2004), but the nature of the sex pheromones has not been identified in these species. The participation of the female tergal glands in the sexual attraction was obvious from their occurrence in histological sections; the female imagos being the only caste and sex with these glands present (see also Ampion and Quennedey, 1981). The role of the sternal gland and its secretion was less obvious but also likely, based on their histology: the gland is smaller than in *Reticulitermes* (Rhinotermitidae: Heterotermitinae), in which it is the sole source of the sex pheromone, but at the same time it is significantly larger than in the related *Prorhinotermes*, in which it does not participate in the sexual attraction and is vestigial (Šobotník and Hubert, 2003; Hanus et al., 2009).

Table 5 Comparison of the quantity of dodecatrienol in exocrine glands involved in sex attraction and trail following based on EAG experiments and behavioral bioassays

Caste	Gland	Dodecatrienol (pg)	
		EAG	Behavioral bioassay
Female imago	Tergal	10	10
Female imago	Sternal	1	10–100
Worker	Sternal	1–10	10

What would be the purpose of having two types of glands secreting the same compound for sexual attraction? Courtship in termites usually consists of calling behavior and tandem behavior, both associated with secretion of a sex pheromone. In *Psammotermes*, we did not observe the typical calling posture of females with the tergal glands exposed (see e.g., Hanus et al., 2009). However, the readiness of females to call might have been affected by the laboratory conditions. Alternatively, the females can secrete their sex pheromone without the characteristic calling posture. Nevertheless, the males are attracted by the females, and immediately after an encounter they form the typical tandem following the female tergal region with their heads and antennae. Therefore, we presume that females use their tergal glands to attract males at a short distance and to ensure the tandem cohesion, while they lay an odor trail with their sternal gland that prevents an accidental tandem separation, as described in other termite species (Nutting, 1969; Bordereau and Pasteels, 2011). Thus, interestingly, the same compound, dodecatrienol, would be used as a short-range airborne sex pheromone and as a trail pheromone. Nevertheless, although dodecatrienol was the only active compound identified, we cannot exclude that other, undetected compounds are involved.

Dodecatrienol has been confirmed as the major or only component of the sex pheromone in numerous termite species; it is produced by the tergal glands in Syntermitinae (Bordereau et al., 2002), and by the sternal gland in the macrotermitine *Pseudacanthotermes* (Bordereau et al., 1991) and in the rhinotermitid *Reticulitermes* (Laduguie et al., 1994a). In *Prorhinotermes*, probably the closest relative of *Psammotermes*, we also have recently ascribed the function of sex pheromone to dodecatrienol secreted from the tergal glands of females (but not from the vestigial sternal gland), as evidenced by bioassays and GC-EAD experiments (Hanus et al., 2009). However, we were not able to detect the compound using GC-MS, probably due to its very low concentrations in the tergal glands (units of picograms). In *Psammotermes* females, the content of the compound in the sternal gland and the tergal glands, and its active concentrations, also are very low (picograms) (see Table 5). Such low concentrations of dodecatrienol also have been observed in *Reticulitermes* (Laduguie et al., 1994a), and contrast with usually high concentrations of sex pheromones in other species (see Bordereau and Pasteels, 2011).

We also have demonstrated that dodecatrienol, secreted from the sternal gland of workers, is the trail pheromone used to mark foraging trails. Even though we cannot exclude the presence of multiple components, we observed no GC-EAD evidence of other compounds being involved in trail following. This finding is not surprising given that the sternal gland is a universal source of trail pheromones in termites, and dodecatrienol is used as a trail pheromone in all Rhinotermitidae studied (Sillam-Dussès et al., 2009; Bordereau and Pasteels, 2011). The sternal gland of workers does not differ significantly in size from the sternal gland of females, but it differs in having a bilobed shape, as in workers of other rhinotermitids (Ampion and Quennedey, 1981). The estimated quantity of dodecatrienol in one gland (1–10 pg), and the estimated activity threshold (1 pg/cm), correspond to values observed in some *Reticulitermes* species (see Bordereau and Pasteels, 2011).

The activity threshold appears to be only slightly higher in females than in workers, as well as the content of dodecatrienol in the corresponding glands (Table 5). This is, once again, a similarity with *Reticulitermes*, i.e., *R. santonensis* (Laduguie et al., 1994a,b; Wobst et al., 1999). On the other hand, it contrasts with the dramatic differences between the amounts of dodecatrienol used by workers and females in the termitids *Pseudacanthotermes spiniger* (Bordereau et al., 1991, 1993) and *Cornitermes bequaerti* (Bordereau et al., 2002).

In summary, the chemistry of trail-following and sex attraction in *Psammotermes*, with dodecatrienol being used for both purposes, differs little from that of other subterranean rhinotermitids, despite the extremely different climatic conditions in which *Psammotermes* lives. Probably the most obvious adaptation to arid environment is the unprecedented speed of motion of both workers and imagos, probably to minimize the time spent in hot and arid areas during foraging and imaginal dispersal; their velocity is comparable to that of open-air foraging termites (pers. obs.). Interestingly, workers of *Psammotermes* do not easily follow their own sternal gland extracts. The orientation effect of the trail pheromone is weak in *Psammotermes*, while this is not the case in all other Rhinotermitidae studied, *Prorhinotermes* included. This weak orientation effect may be the due to the unprecedented speed of the individuals tested.

The surprising constancy of pheromonal signaling with ecological conditions has already been noted in distant taxa sharing the same pheromones, such as Kalotermitidae and Macrotermitinae (see Bordereau and Pasteels, 2011). The only singularity of *Psammotermes* within Rhinotermitidae is the production of the sex pheromone by both the sternal and the tergal glands of female imagos. On the other hand, the genus *Prorhinotermes*, supposedly a close relative of *Psammotermes* (Austin et al., 2004; Lo et al., 2004; Ohkuma et al., 2004; Inward et al., 2007), remains the sole genus of Rhinotermitidae with a diterpene (neocembrene) used as the major component of the trail pheromone, in addition to the minor component dodecatrienol (Sillam-Dussès et al., 2005, 2009).

Our findings underline the conservative nature of chemical communication in termites, with dodecatrienol being the most frequent component of pheromonal signals in trail-following and sex attraction in Rhinotermitidae and Termitidae. At the same time, they highlight the tight evolutionary relationship

between the trail following of working castes and the sex attraction of imagos, the ancestral life forms of termites; the former has supposedly developed from the latter during the social evolution of Isoptera (Traniello and Leuthold, 2000, Bordereau and Pasteels, 2011).

Acknowledgments The authors are grateful to Jarmila Titzenthalerová for technical help in experiments. This research was supported by the Czech Science Foundation (No. P506/10/1570) and by the Institute of Organic Chemistry and Biochemistry, Academy of Sciences of the Czech Republic, Prague (project No. Z40550506). We are grateful to two anonymous reviewers for comments on the manuscript.

Abstract Chemoreception in insects is mediated by small odorant-binding proteins (OBPs) that are believed to carry lipophilic stimuli to the olfactory receptor cells through the aqueous sensillar lymph. Binding experiments and recent structural studies of OBPs have illustrated their versatility and ability to accommodate ligands of different shapes and chemical structures. We expressed and purified seven recombinant OBPs (MmedOBP1-MmedOBP7) from the parasitic wasp, *Microplitis mediator* (Hymenoptera: Braconidae) in a prokaryotic expression system. With 4,4′-dianilino-1,1′-binaphthyl-5,5′-sulfonic acid (bis-ANS) as a fluorescent probe, the ligand-binding specificities of these seven MmedOBPs with 50 small organic compounds were investigated *in vitro*. The results revealed that all of the *M. mediator* OBPs can bind a wide variety of odorant molecules with different binding affinities. The best ligand for all seven MmedOBPs was β-ionone. MmedOBP2 showed affinity for some aromatic compounds, whereas MmedOBP4 and MmedOBP6 bound several terpenoids. MmedOBP5 bound β-ionone, but did not bind any of the other potential ligands that we tested.

Key Words Binding specificity · 4,4′-Dianilino-1, 1′-binaphthyl-5,5′-sulfonate acid (bis-ANS) · Fluorescent probe · *Microplitis mediator* · Odorant-binding protein (OBP) · Polymerase chain reaction (PCR) · Protein expression · Hymenoptera · Braconidae

Introduction

Microplitis mediator (Haliday) (Hymenoptera: Braconidae), is a solitary endoparasitoid. It is polyphagous on about 40 species of Lepidoptera, including an important pest of cotton in China, the bollworm, *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctuidae) (Shenefelt, 1973). Generally, *M. mediator* searches and locates its host by relying on olfactory senses that detect specific odorants.

In insects, olfaction is mediated by odorant-binding proteins (OBPs), which are small antennal proteins that have been proposed to play an important role in perceiving and discriminating different odorants. OBPs are water-soluble acidic proteins with a pattern of six conserved cysteine residues. They are thought to carry lipophilic odorants to the olfactory receptor cells through the

hydrophilic environment of the sensillar lymph, and are involved in the initial biochemical step of odor reception (Vogt et al., 1985; Steinbrecht, 1996, 1999; Wang et al., 2003; Xu et al., 2005; Pelosi et al., 2006; Laughlin et al., 2008). There are many *in vitro* assays to explore the binding properties of OBPs to putative ligands. The first OBP was identified by using tritium-labeled pheromone (Vogt and Riddiford, 1981), and this isotope labeling method also was used to study the binding affinities among pheromones and pheromone-binding proteins (PBPs) (Du and Prestwich, 1995; Maida et al., 2000, 2003). However, fluorescent binding assays also have been conducted in many species, with 1-aminoanthracene (1-AMA),1-anilinonaphthalene-8-sulphonic acid (ANS), and N-phenyl-1-naphthylamine (1-NPN) as fluorescent probes (Campanacci et al., 2001; Bette et al., 2002; Calvello et al., 2003; Honson et al., 2003; Riviere et al., 2003). The following are representative examples with 1-NPN as the fluorescent probe. The OBP1 of the migratory locust, *Locusta migratoria* (Orthoptera: Acrididae) does not bind fecal or green leaf volatiles, but shows high affinity to some linear aliphatic compounds, with pentadecanol and 2-pentadecanone binding with the highest affinity (Jiang et al., 2009). The affinity of 12 compounds to three aphid OBPs were measured in competitive binding experiments. Similar behavior was observed for the three proteins towards most ligands, but (*E*)-β-farnesene, the alarm pheromone, and farnesol exhibited clear selectivity to OBP3 (Qiao et al., 2009). The silkworm, *Bombyx mori* (L.) (Lepidoptera: Bombycidae) PBP1, PBP2, GOBP2, and ABPx all bind the sex pheromone component (10*E*, 12*Z*)-hexadecadien-1-ol (bombykol). BmorPBP1, BmorPBP2, and BmorABPx also bind the pheromone component (10*E*,12*Z*)-hexadecadienal (bombykal) equally well, whereas BmorGOBP2 can discriminate between bombykol and bombykal (Zhou et al., 2009). The *Chilo suppressalis* GOBP2 has significant affinity to *cis*-11-hexadecenal (Z11-16: Ald), the main component of the sex pheromone and to laurinaldehyde and benzaldehyde, two general plant volatiles (Gong et al., 2009). By using a fluorescent displacement assay, Inkster et al. (2005) found that disparlure analogs all bound the gypsy moth, *Lymantria dispar* PBP1 with similar affinity to (−)-disparlure.

In previous research, we identified several putative OBPs in *M. mediator*, only four of which were found to be antennal specific. The remaining genes are expressed either ubiquitously or strictly regulated in specialized tissues or during different developmental stages. Some OBP genes are sex specific (Zhang et al., 2009). In order to further study the properties of these OBPs and their relationships with volatiles of host plants, we investigated the binding of 50 diverse small organic compounds to seven recombinant OBPs (MmedOBPs) from *M. mediator*. In these assays, 4,4′-dianilino-1,1′-binaphthyl-5,5′-sulfonate acid (bis-ANS) was used as the fluorescent probe.

Methods and Materials

Insects A colony of *M. mediator* was obtained from the Institute of Plant Protection, Hebei Academy of Agriculture and Forestry, China. The parasitoids emerged from the host as mature larvae and spun silk cocoons for pupation. Emerged adult parasitoids were fed on a 10% honey solution and mated in culture cages (20×20×10 cm) at 26±1°C, 14L:10D (Wang et al., 1984). Antennae were dissected from

1- to 3-d-old females or males and immediately frozen in liquid nitrogen, and then stored at −70°C until use.

RNA Manipulation and cDNA Synthesis Total RNA was extracted by homogenizing antennae in Trizol™ reagent (Invitrogen, Carlsbad, CA, USA) following the manufacturer's instructions, then reverse transcribed into single strand cDNA by using oligodT18 primers and MMLV reverse transcriptase (Promega, Madison,WI, USA). The reverse transcription reaction was performed at 42°C for 30 min, and the reaction was stopped by heating at 95°C for 5 min.

Recombinant Protein Expression and Purification The *M. mediator* OBPs (MmedOBP1–MmedOBP7) were obtained by prokaryotic expression in BL-21 *Escherichia coli* cells. Briefly, specific primers (Table 1) were used to amplify the coding sequence of MmedOBP genes with the cDNA as the template. The PCR product was first cloned into a pGEM-T simplevector (Takara, Dalian, Liaoning, China) and then excised and cloned into an expression vector pGEX-4T-1 for over-expression in prokaryotic cells BL21(DE3). The pGEX-4T-1 vector allows the expression of a recombinant product tagged with a glutathione *S*-transferase (GST) sequence at its N-terminus.

Clones containing the appropriate OBP sequence were chosen and incubated. When the optical density of the culture had reached a value of OD_{600}=0.6–0.8, protein expression was induced by addition of isopropyl-β-D-1-thiogalactopyranoside (IPTG) to a final concentration of 0.1 mM. Cells were incubated for an additional 8 hr at 30°C; harvested by centrifugation at 5000×*g* for 15 min at 4°C; and cells were lysed by sonication (60×5 sec pulses of 400W) on ice. The recombinant OBPs both were present in the supernatant of the lysate and the pellet as inclusion bodies. Recombinant proteins in the supernatant were purified by GSTrap FF (GE Healthcare, Piscataway, NJ, USA). GST tags were cleaved from the recombinant proteins by thrombin on-column (GE Healthcare), then desalted by using HiTrap Desalting (GE Healthcare).

Fluorescence Binding Assay Emission fluorescence spectra were recorded on a fluorescence spectrometer (Lengguang F96, Shanghai, China) with a 1 cm light path quartz cuvette and 10 nm slits for both excitation and emission. The fluorescent probe 4,4′-dianilino-1,1′-binaphthyl-5, 5′-sulfonate (bis-ANS, Sigma, Riedstr, Steinheim, Germany) was excited at 365 nm and emission spectra were recorded from 435 to 580 nm. To measure the affinity of bis-ANS to each protein, a 2 μM solution of the protein in 50 mM Tris–HCl, pH 7.4, was titrated with aliquots of 1 μM of each potential ligand in methanol to final concentrations of 2–20 μM. The affinities of each OBP for 50 potential ligands (all purchased from Sigma-Aldrich, St. Louis, MO, USA, Supplementary Data Table 1) were measured in competitive binding assays by using both protein and bis-ANS at 2 μM in the presence of 1–50 μM of each competing ligand

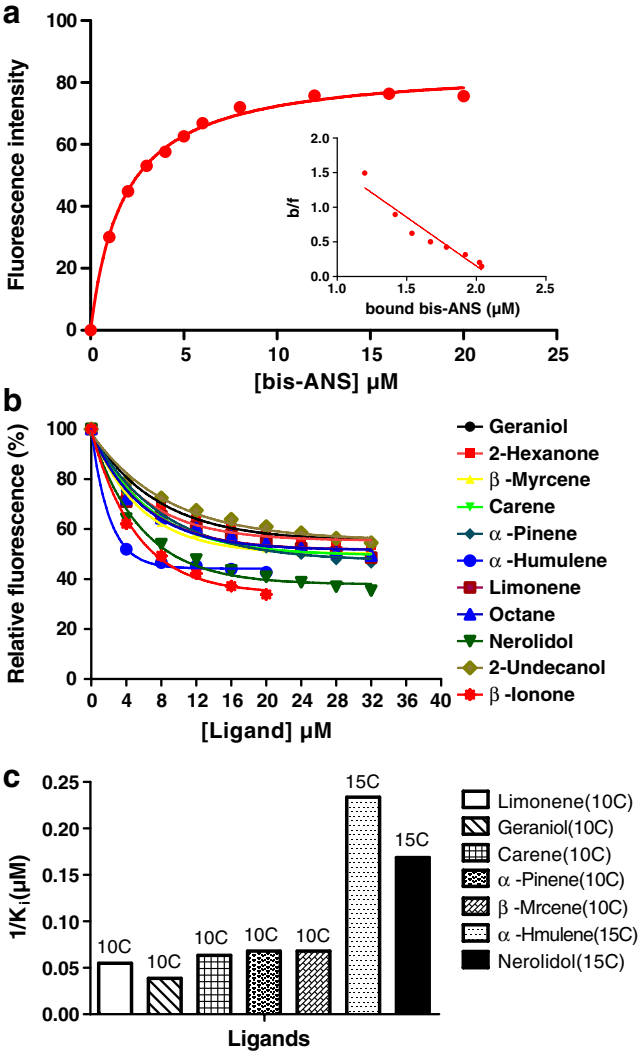

Fig. 1 Binding curve for 4,4′-dianilino-1,1′-binaphthyl-5,5′-sulfonate acid (bis-ANS) to recombinant *Microplitis mediator* OBP4 (**a**) and Scatchard plot (inset). A 2 mM solution of the protein in Tris buffer was titrated with a 1 mM solution of bis-ANS in methanol to final concentrations of 2–20 μM. Binding curves also were measured for the other OBPS (data not shown) and dissociation constants (mean of three replicates) were: OBP1: 3.10±0.23 μM, OBP2: 3.70±0.37 μM, OBP3: 2.48±0.18 μM, OBP4: 1.99±0.14 μM, OBP5: 2.29±0.62 μM, OBP6: 5.63±1.02 μM, and OBP7: 3.54±0.16 μM. Competitive binding of selected ligands to *M. mediator* OBP4 (**b**). A mixture of the protein and bis-ANS in Tris, both at the concentration of 2 μM, was titrated with a 1 mM solution of each competing ligand to final concentrations of 2–32 μM. Fluorescence intensities are reported as percent of the values in the absence of competitor. The same potential ligands were also used with other OBPs (data not shown). Relationship between ligand size and K_i of terpenoids (**c**)

Data Analysis To determine the binding constants of bis-ANS to each OBP, the intensity values corresponding to the maximum of fluorescence emission were plotted against free ligand concentrations. Bound ligand was evaluated from the values of fluorescence intensity by assuming that the protein was 100% active, with a stoichiometry of 1:1 (protein:ligand) at saturation. The curves were linearized by using a Scatchard plot program (Campanacci et al., 2001). Dissociation constants of the competitors were calculated from the corresponding IC_{50} values, by using the equation: Ki = [IC50]/1 + [bis-ANS]/$K_{bis\text{-}ANS}$, where [bis-ANS] is the free concentration of bis-ANS and $K_{bis\text{-}ANS}$ is the dissociation constant of the protein/bis-ANS complex (Wei et al., 2008).

Results

Binding Specificity of MmedOBPs The seven purified proteins were used in competitive binding assays with the fluorescent probe bis-ANS as a reporter and the 50 potential ligands as competitors. First, we measured the dissociation constants between MmedOBPs and bis-ANS. Values ranged from 1.99 μM to 5.64 μM (Fig. 1a, b).

Competitive binding experiments revealed different specificities for the seven proteins (Table 2). MmedOBP1 bound 6 ligands, but only 2-Ethylhexanol (K_i=59.30 μM) and β-ionone (K_i=40.69 μM) effectively replaced bis-ANS from MmedOBP1. MmedOBP2 bound 7 ligands, whereas MmedOBP3-MmedOBP7 bound 3, 11, 1, 11, and 5

Table 2 Binding affinities of *Microplitis mediator* odorant-binding proteins for experimental ligands in a binding assay with the fluorescent probe 4,4′-dianilino-1,1′-binaphthyl-5,5′-sulfonate acid (bis-ANS)

Affinities (mean ± SD) measured in μM

[a] More potential ligands were tested, but the remaining 23 potential ligands did not bind any of the OBPs. These compounds were 3-hexanone, *Z*-hex-3-en-1-ol, ethylheptanoate, decanal, *E*-2-*Z*-6-nonadienal, *Z*-3-hexenyl acetate, 2-nonanone, *Z*-3-nonen-1-ol, 2-octanone, nonanal, 2-octanol, ethylphenylacetate, benzoic acid, methyl salicylate, methyl phenylacetate, ethyllaurate, *S*-(−)-limonene, β-citronellol, nerol, β-*E,E*-farnesol, (−)-carveol, carvacrol, and indole

[b] N.D. is an abbreviation for not determined, which means that no significant binding was detected in the assay

ligands, respectively. All MmedOBPs bound β-ionone, as well as some aliphatic compounds. Otherwise, the *M. mediator* OBPs exhibited some degree of broad selectivity towards the ligands tested. Although all seven OBPs bound β-ionone, the binding affinities were different. MmedOBP4 had the highest binding affinity (4.37 μM), whereas MmedOBP5 had the lowest (>100 μM). Both MmedOBP4 and MmedOBP6 bound 11 ligands, but MmedOBP4 had a higher binding affinity than MmedOBP6.

Discussion

We explored the ligand binding specificity of seven MmedOBPs to 50 compounds including green leaf volatiles, aliphatic alcohols, aromatic compounds, terpenoids, and heterocyclic compounds. *Microplitis mediator* is polyphagous on hosts that include important agricultural pests for maize, cotton, and tobacco, such as *Helicoverpa armigera*, *Helicoverpa assulta*, *Heliothis virescens*, and *Spodoptera exigua* (Shenefelt, 1973). Successful parasitization requires a series of successive steps. These include host habitat location, host location, host acceptance, host suitability and host regulation. In the first three steps, volatiles have been reported to play important roles (Vet and Dicke, 1992). Such compounds may come directly from the host, as well as from host by-products, host food plants, host damaged food plants, or organisms closely associated with the host (Tumlinson et al., 1992; Steiner et al., 2007).

Of the 50 compounds examined, 14 were from cotton, healthy or damaged by *H. armigera* (Yu et al., 2007); ten were from maize, healthy or damaged by *Spodoptera frugiperda*, *S. exigua*, *H. virescens*, or *H. zea* (Alborn et al., 1997; De Moraes et al., 1998; Carroll et al., 2006); and seven were from tobacco, healthy or damaged by *H. armigera*, *H. assulta*, *H. virescens*, or *H. zea* (De Moraes et al., 1998; Yan et al., 2005). Therefore, most compounds used in our experiments were typical volatiles from the host plants. In this study, we used bis-ANS as a fluorescent probe, and bis-ANS emits a strong fluorescence in hydrophobic environments, but almost no fluorescence in water (Rosen and Weber, 1969). There is a central hydrophobic cavity in the conserved domain of the OBPs that can bind and transport hydrophobic molecules, including odorants. We showed that bis-ANS binds to all seven MmedOBPs, and emits fluorescence strongly. This suggests that bis-ANS may bind in the hydrophobic cavity of MmedOBPs.

de Bruyne and Baker (2008) reported that OBPs can be selected to detect key odorants with high sensitivity and to perceive a wide variety of general odorants at higher doses. Nonanal, decanal, and (*Z*)-3-hexenyl acetate elicited electroantennogram (EAG) responses from *M. mediator* (Yu et al., 2010), but they did not bind to all seven MmedOBPs in the test. This suggests that there may be other OBPs in *M. mediator* antennae. In contrast, octanal bound to MmedOBP1 and MmedOBP6 in our experiment, but it did not elicit behavioral responses from *M. mediator* in a previous study (Yu et al., 2010).

MmedOBP1, MmedOBP3, and MmedOBP7 showed weaker binding ability to all ligands, whereas MmedOBP5 only bound β-ionone. Similarly, in *Apis mellifera*, general odorant-binding protein (GOBP) ASP2 has the ability to bind ligands of different structures and properties (Lescop et al., 2009), and these authors propose that the broad ligand specificity of GOBPs compared with PBPs is conferred by the cumulative effects of weak nonspecific protein–ligand interactions and of enhanced protein internal dynamics at the ligand entry site.

We presumed that MmedOBPs can recognize the chemical conformation and functional groups of ligands. MmedOBP1, MmedOBP2, MmedOBP3, MmedOBP4 and MmedOBP7 can distinguish citral and nerolidol, respectively. Three MmedOBPs (MmedOBP2, MmedOBP4, and MmedOBP6) can bind to terpenoids effectively. MmedOBP4 mainly expressed in female antennae, about 99.6% in female antennae and 0.4% in male antennae. MmedOBP6 was expressed almost equally in female and male antennae. The expression level of MmedOBP2 was higher in male antennae than in female antennae (Zhang et al., 2009). Due to the function of terpenoids in parasitoid finding hosts, we concluded that those proteins may play important roles for *M. mediator* to search and locate the hosts. When MmedOBP4 and MmedOBP6 bind to terpenoids, they have stronger binding affinity to C15 terpenoids than C10 terpenoids (Fig. 1c).

In this study, we successfully expressed seven MmedOBPs in *E. coli* and purified them by affinity chromatography. We further characterized the ligand-binding specificities of those OBPs to 50 diverse small organic compounds by using bis-ANS as probe. The results could help us to understand the mechanism of olfactory recognition when parasitoids search for and locate their hosts.

Abstract Larvae of *Chrysomela lapponica* (Coleoptera: Chrysomelidae) sequester characteristic *O*-glucosides from the leaves of their food plants, namely *Betula* and/or *Salix* The present study focuses on birch-feeding larvae of *C. lapponica* from the Altai region in East Kazakhstan. As in other sequestering leaf beetle larvae, the compounds are transported intact *via* different membrane barriers into the defensive system, followed by glucoside cleavage and subsequent transformations of the plant-derived aglycones. Unlike previous studies with model compounds, we studied the sequestration of phytogenic precursors by analyzing the complex pattern of glucosides present in food plant *Betula rotundifolia* (39 compounds) and compared this composition with the aglycones present as butyrate esters in the defensive secretion. In addition to the analytic approach, the insect's ability, to transport individual glucosides was tested by using hydrolysis-resistant thioglucoside analogs, applied onto the leaf surface. The test compounds reach the defensive system intact and without intermediate transformation. No significant difference of the transport capacity and selectivity was observed between larvae of birch-feeding population from Kazakhstan, and previous results for larvae of birch-feeding population from the Czech Republic or willow-feeding populations. Overall, the transport of the phytogenic glucosides is highly selective and highly efficient, since only minor compounds of the spectrum of phytogenic glucoside precursors contribute to the limited number of aglycones utilized in the defensive secretion. Interestingly, salicortin **44** and tremulacin **60** were found in the leaves, but no aldehyde or esters of salicylalcohol. Surprisingly, we observed large amounts of free glucose, together with small amounts of 6-*O*-butyrate esters of glucose (**27a/b** and **28a/b**).

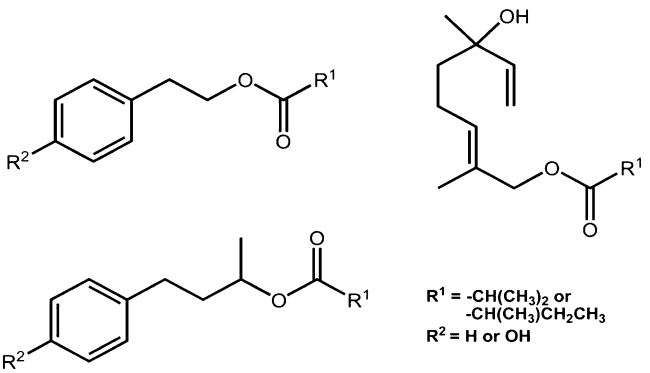
Introduction

Larvae of the leaf beetles (Chrysomelina) possess nine pairs of dorsal exocrine glands from which secretions emerge as small droplets when a predator appears. As soon as the disturbance is over, the droplets are resorbed into a large reservoir into which glandular cells open. The anti-predatory effect of the secretion is based either on *de novo* production of repellents or on compounds derived from sequestered, plant-derived glucosides. The major components, which are secreted by leaf beetle larvae belonging to the taxa *Phaedon*, *Gastrophysa*, *Hydrothassa*, *Prasocuris Plagiodera*, *Linaeidea*, and *Phratora* (in part) are iridoid



monoterpenes (Meinwald et al. 1977; Blum et al. 1978; Pasteels et al. 1982; Soe et al. 2004). According to (Termonia et al. 2001) the *de novo* production of iridoids is considered the ancestral strategy. Recent studies have demonstrated, however, that the whole group also is able to sequester early precursors from plants (Feld et al. 2001; Kuhn et al. 2004; Kunert et al. 2008). A more advanced and resource saving strategy to produce chemical defenses, is the sequestration of plant-derived precursors. The sequestration of phenol glucosides, especially salicin, has been developed and optimized by species feeding on Salicaceae, i.e., *Phratora vitellinae* and *Chrysomela* (Pavan 1953; Pasteels et al. 1983). In these species, the plant-derived glucosides serve as precursors for the repellent salicylaldehyde; a concomitant *de novo* biosynthesis does not seem to play a significant role.

The most derived Chrysomelina species, the interrupta group *sensu* (Termonia and Pasteels 1999), which includes *Chrysomela lapponica* do not sequester single glucosides, but import a broad spectrum of glucosidically bound plant-derived alcohols (Kuhn et al. 2007). After import into the reservoir, which functions as a bioreactor containing all necessary enzymes for the transformation of the sequestered precursors, the glucose moiety is removed, and the aglycones are esterified with isobutyric acid, 2-methylbutyric acid, and benzoic acid generated from the insects' internal pools of amino acids. This type of "combinatorial biosynthesis" can generate a cocktail of more than 70 secretion ingredients, as has been shown for a larval secretion of *C. lapponica* from Bavaria, Queyras, Czech Republic, and related North American species (Hilker and Schulz 1994; Schulz et al. 1997; Termonia and Pasteels 1999; Kuhn et al. 2007). Bioassays have demonstrated the protective function of these blends against predators (Hilker and Schulz 1994). For several defensive secretions of leaf beetle larvae, antimicrobial effects also have been demonstrated and discussed (Gross et al. 2002).

The sequestration of glucosides as pro-toxins is advantageous. The compounds often occur in high abundancy in the food plants. The polar glycosides are not able to pass membranes unless functional transport systems mediate their passage, which assures safe guidance of the compounds to their destination through the larval body. The leaf beetle larvae possess an interconnected network of transport systems for uptake and excretion of surplus glucosides (Discher et al. 2009).

According to model experiments with selected (thio) glucoside mixtures, the phytogenic precursors are imported via the gut membrane with low selectivity, followed by a specific import of only a few compounds from the hemolymph into the reservoir. Model studies were based on test compounds, comprising a glucoside precursor of iridoid biosynthesis, salicin for salicylaldehyde production, and phenylethanolglucoside that is converted into the corresponding (iso)butyrate (Scheme 1). Uptake into the glandular reservoir was highly specific, and only the phytogenic precursors for the genuine defenses accumulated in the reservoir. For example, only salicin was imported into the reservoir of *Chrysomela populi* and converted to salicylaldehyde. In contrast, the iridoid-producing larvae of *Phaedon cochleariae* accumulated only the glucoside of 8-hydroxy-geraniol, which is converted into the iridoid chrysomelidial (Discher et al. 2009). This is different in the case of the defensive secretion of *C. lapponica* feeding on birch. Their defensive secretion is a rather complex mixture composed of butyrate esters of very different and most likely plant-derived aglycones released from sequestered glucosides (Hilker and Schulz 1994; Schulz et al. 1997; Kuhn et al. 2007). This implies that larvae of *C. lapponica* possess either several different transport systems, each of them specifically tuned to the imported glucoside, or that the larvae possess a transport system of low selectivity that allows the import of a broad range of glucosides, as demonstrated by Kuhn et al. 2007 with *C. lapponica* from Queyras feeding on willow by using thioglucosides as probes.

In this study, we focused on birch feeding *C. lapponica* from Kazakhstan, which also produce butyrate esters, but lack the production of salicylaldehyde, as will be shown. To investigate the capacity and the "filter characteristics" of the transport systems that operate in larvae of birch feeding *C. lapponica*, we compared the spectrum of the glucosides present in the leaves of the host plant *Betula rotundifolia* with the spectrum of butyrate esters in the defensive secretion of the larvae. Here, we demonstrated that the defensive secretions and the glucoside spectrum of *B. rotundifolia* share only a small number of aglycones that are sequestered and utilized by the insect. Moreover, the defensive secretion of *C. lapponica* contains large amounts of glucose and certain glucose esters (butyrates), which may serve as cryoprotection.

Scheme 1 Butyrate esters from the defensive secretion of larvae of birch-feeding larvae of *Chrysomela lapponica* endemic to the Altai region, East Kazakhstan

Methods and Materials

Leaf Beetle Larvae and Host Plant Leaves Larvae of *C. lapponica* feeding on leaves of *Betula rotundifolia* were collected in the Altai mountains (East Kazakhstan) near the Burkhat Pass (2130 m altitude, 49°07,438'N, 86°01,365'E) in early August 2008. Larvae were reared for 1 week with leaves from *Betula rotundifolia* from the Burkhat Pass. Freshly harvested *Betula* twigs were kept alive for several days in tap water. Additional plant material was sun dried and stored for phytochemical analysis. Field conditions did not allow for extraction of fresh plant material.

Collection of Defensive Secretion Larvae were gently squeezed by forceps and forced to protrude their mesothoracal glands. The emerging droplets were collected with glass capillaries (Hirschmann Laborgeräte, diam: 0.28 mm, length: 100 mm). The capillaries were sealed by melting with a micro gas torch and stored at −20°C.

Analytical Procedures Analysis of defensive secretions. An aliquot of the secretion (1-3 μg) was dissolved in 20 μl dichloromethane. After vortexing and centrifuging, 1 μl was subjected to GC-EIMS analysis (ThermoQuest Finnigan Trace GC-MS 2000 (Quadrupole) equipped with Alltech EC 5-column, 15 m×0.25 mm, film thickness 0.25 μm). Substances were separated using helium as carrier (1 ml/min); conditions: 45°C (2 min), then at 10°C min^{-1} to 280°C (5 min).

Highly concentrated samples were appropriately diluted. For quantification, external standards at different concentrations were used. Polar components were analyzed after derivatization with MSTFA. The defensive secretion (5 μl solution in dichloromethane) was mixed with *N*-methyltrimethylsilyltrifluoroacetamide (MSTFA) (10 μl) and pyridine (5 μl). After heating to 70°C for 1 h, an aliquot (1 μl) of the solution was analyzed directly by GC-EIMS. Free fatty acids were derivatized with pentafluorobenzylbromide (PFBB) prior to analysis (Attygalle et al. 1991). For esterification, the secretion (0.5 μl) was dissolved in triethylamine (10 μl) containing PFBB (5 μl). The solution was kept at 25°C for 3 h and hydrolyzed with water (30 μl). After extraction with *n*-hexane (20 μl), the solution was analyzed by GC-EIMS (conditions see above). All compounds were identified by comparison with authentic references and sample chromatograms, respectively. Secretion analysis was carried out against external standards (N=3). No replicates were measured owing to the restricted availability of secretion.

Transport Analysis with Thioglucosides Leaves from *Betula pendula* (used instead of *B. rotundifolia* because of the larger surface area for the transport experiments) were painted on the upper side with 0.5 ml of MeOH/H_2O (1:1, v/v) containing the test compound at a concentration of 25 mM. After evaporation of the solvent with an air stream, third instars (four larvae per ca. 3.5 cm^{-2} leaf segment) were allowed to feed on the treated leaves for 48 h, followed by sampling of defensive secretion. The defensive secretion was withdrawn with a small capillary from the everted glands of the larvae. The secretion was stored and transported in sealed capillaries. The thioglucosides transported into the glandular system were analyzed and quantified as described (Kuhn et al. 2007).

Statistics To obtain valid data, feeding experiments with thioglucosides were repeated several times. *Chrysomela lapponica* (Kazakhstan): compounds **1** to **6** (N=6), *C. lapponica* (Czech Republic): compound **1** (N=5), compounds **2**, **4**, and **6** (N=4). Variances between groups were not homogeneous according to Levene's test. Hence, Mann-Whitney test was used to evaluate significant differences. Statistics were calculated with SPSS Statistics 17.0.

Analysis of Leaf Glycosides Air dried leaves (3 g) of *B. rotundifolia* were pestled in liquid nitrogen and extracted with 20 ml 80% aqueous methanol using an Ultra-Turrax homogenizer for 3 min. Extraction was continued by shaking for 1 h at ambient temperature. Solids were removed by filtration and re-extracted with methanol (20 ml) for another 1 h at ambient temperature. The combined extracts were evaporated to dryness, re-dissolved in methanol (10 mg/ml), and after filtration (0.45 μm pore size) the glycosides were determined by HPLC using a Thermoquest LCQ (Thermoquest, D-63329 Egelsbach, Germany) in the APCI mode (vaporizer temperature: 560°C) connected to an Agilent HP1100 HPLC-system equipped with an RP18 column, (Purosphere 4×250 mm (5 μm). Samples (10 μl) were analyzed by using gradient elution at 0.65 ml min^{-1}. Solvent A: 0.5% acetic acid in water; solvent B: 0.5% acetic acid in acetonitrile. Compounds were eluted according to the following protocol: 0-10 min, 10% of B in A; 10–50 min 10–60% of B in A. UV-detection at 254, 266, and 360 nm prior to the mass spectrometer allowed us to gain further information on the analytes. Commercially unavailable compounds were isolated and identified based on data from HR-ESI-MS, ^{1}H- and HSQC-NMR spectroscopy, and literature data. Known compounds were compared by their retention times and UV-Vis and MS data with authentic references. Myricetin derivatives were identified after hydrolysis of the crude extract of *B. rotundifolia* (1.2 M HCl for 4 h at 100°C) by HPLC using an authentic reference. In addition, the aglycones were determined after enzymatic hydrolysis (Schulz et al. 1997) of the raw extracts followed by GC-EIMS. Compounds were identified using authentic standards.

Table 1 Identification and quantification of defensive substances in the birch-feeding population of *Chrysomela lapponica* from the Burkhat Pass, East Kazakhstan

Peak number	Substance	Compounds [nmol/mg secretion]
	Acetic acid	3.6[a]
	Isobutyric acid	1.1[a]
	2-Methylbutyric acid	0.3[a]
1	Benzyl alcohol	0.3
2	(*Z*)-3-Hexenylisobutyrate	2.2
3	Hexylisobutyrate	1.2
4	5-Hexenyl isobutyrate	Not quantified[b]
5	Benzoic acid	trace
6	(*Z*)-3-Hexenyl-2-methylbutyrate	5.3
7	Hexyl-2-methylbutyrate	1.5
8	5-Hexenyl-2-methylbutyrate	Not quantified[b]
9	Benzylisobutyrate	8.7
10	Benzyl-2-methylbutyrate	4.6
11	Phenylethylisobutyrate	1.5
12	Phenylethyl-2-methylbutyrate	1.8
13	1,3-Hexandiyl-1,3-diisobutyrate	Not quantified[b]
14	(*Z*)-3-Hexenylbenzoate	trace
15	8-OH-Geranylisobutyrate	Not quantified[b]
16	8-OH-Linalylisobutyrate	0.1
17	mixture of 1,3-Hexandiyl-1-isobutyrate-3-(2-methylbutyrate), 1,3-Hexandiyl-1-(2-methylbutyrate)-3-isobutyrate	Not quantified[b]
18	8-OH-Geranyl-2-methylbutyrate	Not quantified[b]
19	*p*-OH-Phenylethylisobutyrate	13.0
20	8-OH-Linalyl-2-methylbutyrate	0.2
21	1,3-Hexandiyl-1,3-di-2-methylbutyrate	Not quantified[b]
22	*p*-OH-Phenylethyl-2-methylbutyrate	25.0
23	Betuligenolisobutyrate	4.2
24	Betuligenol-2-methylbutyrate	4.3
25	Linolenic acid methylester	1.6
26a–e	Glucose	468.7
27a,b	Glucose-6-*O*-isobutyrate	17.2
28a,b	Glucose-6-*O*-2-methylbutyrate	26.8

Quantification was carried out using external standards (N=3), [a] quantified after derivatization with PFBB (Attygalle et al. 1991), [b] determined by spectral data comparison. Numbering in Table 1 corresponds peak numbering of Fig. 1.

Synthesis of Glucose Esters Acylation was carried out according to a modified method from Woudenberg (Woudenberg-van Oosterom et al. 1995). The procedure was conducted under an inert atmosphere. 100 mg glucose were dissolved in 10 ml *t*-butanol. 1 g molecular sieve 4 Å was added. 10 ml 12.5% ethylisobutyrate and ethyl-2-CH_3-butyrate, respectively, in *t*-butanol then were added. The reaction was started by adding 100 mg *Candida antarctica* lipase B. The suspension was stirred for 72 h at 50°C. The molecular sieve and the immobilized enzyme were separated by filtration, and the solvent was evaporated. The raw product was fractionated by column chromatography ($CHCl_3$/MeOH/H_2O=75/22/3) to yield the acylated glucoses. The described procedure produced an anomeric mixture. Hence, multiple signals were observed. Assignment of peaks was carried out using 2D-NMR-experiments (HSQC and HMBC).

Spectral Data of 6-O-isobutyryl-a/b-D-glucopyranoside ^{1}H NMR ($MeOD_4$) [ppm]: 5.01 (d, J=3.67 Hz, 0.5 H), 4.41 (d, J=7.74 Hz, 0.5 H), 4.30 (ddd, J=19.13 Hz, J=11.88 Hz, J=2.15 Hz, 1 H), 4.15-4.08 (m, 1 H), 3.89 (ddd, J=10.17 Hz, J=5.48 Hz, J=2.17 Hz, 0.5 H), 3.60 (t, J=9.29 Hz, 0.5 H), 3.43-3.38 (m, 1 H), 3.30-3.20 (m, 1 H), 3.17 (masked by

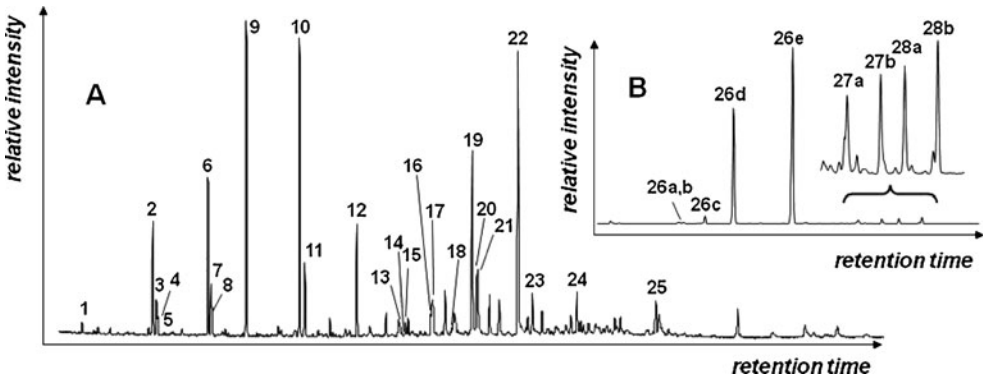
Results

The defensive secretion of the larvae of *C. lapponica* mainly comprised 2-methylbutyric and isobutyric acid esters of aglycones, which occur as glucosides in the leaves of the host plant (Table 1). Major compounds are the butyrate esters of hexanol (**3** and **7**), (*Z*)-3-hexenol (**2** and **6**), benzyl alcohol (**9** and **10**), phenylethanol (**11** and **12**), *p*-OH-phenylethanol (**19** and **22**), and betuligenol (**23** and **24**). While the concentration of free alcohols in the secretion was low, significant amounts of free 2-methylbutyric- and isobutyric acids along with acetic acid and traces of benzoic acid were found after derivatization with pentafluorobenzylbromide (Table 1). In addition, the secretion contained large amounts of free glucose (**26a-e**) along with glucose-6-*O*-butyrates (**27a/b** and **28a/b**), which are identified for the first time in leaf beetle defenses. Glucose and the two 6-*O*-glucose esters **27a/b** and **28a/b** were identified after derivatization with MSTFA by GC-EIMS using synthetic references. Identified compounds are compiled in Table 1 according to the elution order shown in Fig. 1.

The presence of large amounts of glucose was unexpected. Even more remarkable was the presence of C(6) glucose esters, indicating that the easily accessible primary hydroxy group of glucose can serve as a substrate for the acyl transferase(s) that catalyze the acylation of the plant-derived aglucones. Only the 6-*O*-butyrates **27a/b** and **28a/b** (a and b refer to α- and β-anomers of the butyrates) were detected (Scheme 2). Esters linked to a secondary hydroxyl group of the glucose moiety were not observed.

Glycosides in Leaves of B. rotundifolia We addressed the full spectrum of glycosides from dry leaves of the food



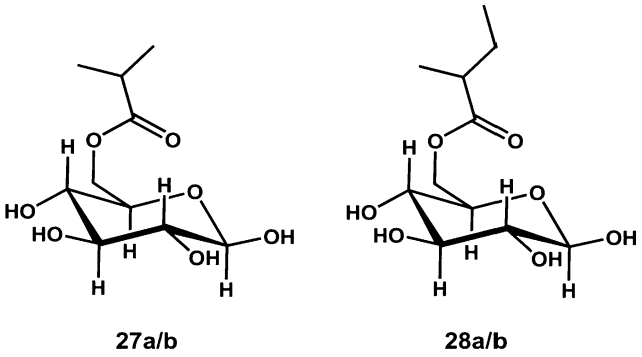


Fig. 1 Gaschromatographic profile of the defensive secretion of birch-feeding larvae of *Chrysomela lapponica* from the Altai Mountains, East Kazakhstan. Numbering and identification of the peaks corresponds to Table 1. **a** GC-EIMS analysis of the volatile esters of the secretion **b** GC-EIMS analysis of the polar constituents of the defensive secretion after derivatization with MSTFA. Low boiling silyl-derivatives are not shown. The four signals for **27a/b** and **28a/b** correspond to the α- and β-enantiomers of the silylated glucose esters. Silylated glucose is represented by the signals **26a-e**

Scheme 2 Butyrate esters (**27a/b**) and (**28a/b**) of glucose

plant *B. rotundifolia* by exhaustive extraction and analysis by HPLC-MS, LC-UV, and NMR of isolated compounds. The LC-profile (Fig. 2) of the polar extract of *B. rotundifolia* displayed a rich pattern of glycosylated flavonoids (**45**), (**46**), (**49**), (**53**) derived from quercetin (**58**), kaempferol (**62**), and the 3′,5′-trihydroxy-6,7,4′-trimethoxyflavones (**55**), and (**66**) (Table 2). To our knowledge, santin-7-*O*-glucoside (**59**) is isolated for the first time. The presence of tremulacin (**60**) and salicortin (**44**), which can ultimately serve for the production of salicylaldehyde after hydrolysis in the gut (Julkunen-Tiitto and Meier 1992), is noteworthy, since no butyrate esters of saligenin or free salicylaldehyde were found in the larval secretion. In general, comparison of the host plant chemistry with secretion revealed that the glycoside pattern of the host plant dramatically differed from the aglycone pattern found in the larval secretion. The predominant flavonoid glycosides were completely absent in the larval secretion, while the low molecular weight aromatic/phenolic esters and aliphatic hexenyl esters, which are minor or even trace components of the plant-extracted glycosides, dominated the larval secretions. Nevertheless, the aglycones of several plant-produced precursors like betuloside (**37**), phenylethyl-Glc (**42**), salidroside (**29**), and 8-OH-linaloyl-Glc (**39**) matched the aglycones present in the secretion. The identities of the 39 identified compounds are given in Table 2.

Since not all aglycones present in the defensive secretion were found as glucosides, we hydrolyzed the total extract with a mixture of glucosidases and galactosidases according to (Schulz et al. 1997). Analysis of the released compounds indeed revealed the presence of (*Z*)-3-hexenol, and benzyl-alcohol, which for unknown reasons were not found among the leaf-derived glycosides.

Hemolymph Transport of the Phytogenic Glycosides After uptake into the digestive system, the gut epithelial cells constitute the first membranes that the glycosides have to pass. Previously, we tested this passage in birch-feeding larvae from the Czech Republic and willow-feeding larvae of *C. lapponica* from Queyras by using hydrolysis-resistant thioglucosides (Kuhn et al. 2007). After application of the compounds to the leaf surface, larvae of the birch-feeding *C. lapponica* were allowed to feed on the treated leaves, and the amount of thioglucosides transported through the insect into the glandular reservoir was determined by HPLC-MS.

As shown (Fig. 3), the birch-feeding populations of *C. lapponica* from Kazakhstan and also from the Czech Republic (Kuhn 2005) show similar transport characteristics. No significant differences could be evaluated for thiosalicin (**1**), *o*-kresolthioglucoside (**2**), or 8-OH-geraniolthioglucoside (**6**). Only the uptake of phenylethylthioglucoside (**4**) differed significantly between the birch-feeding populations. Common to both population (birch and willow feeders) (Kuhn et al. 2007), is the selective import of only thioglucosides; galactosides were not taken up. Moreover, the birch-feeding

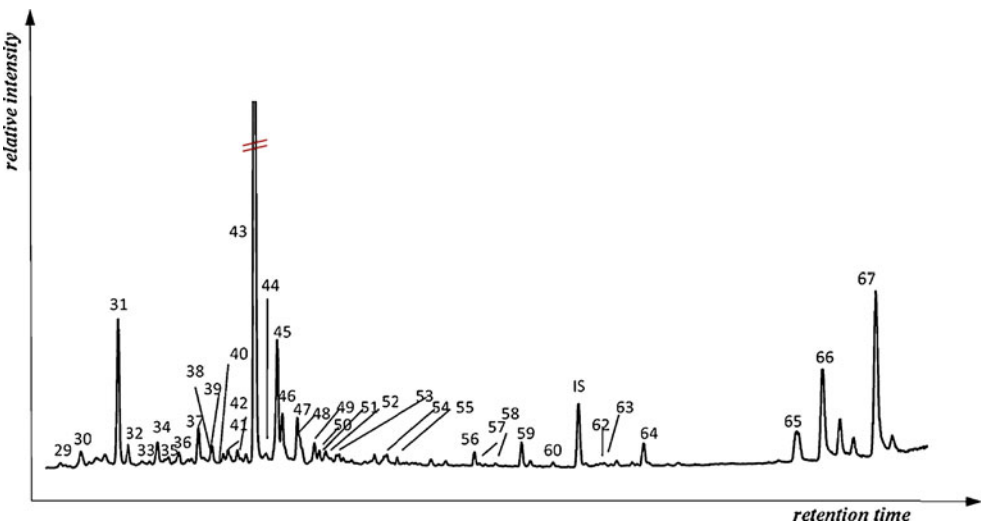

Fig. 2 HPLC-MS chromatogram of the methanolic extract of *Betula rotundifolia*. Compounds of the methanolic extract were separated and monitored by HPLC-MS on Purosphere RP18, 5 μm, 4×250 mm (Merck) using an isocratic solvent system 10% of B (10 min) and linear gradient from 10% B to 60% B (50 min). Solvent A: 0.5% CH_3COOH in H_2O, solvent B: 0.5% CH_3COOH in CH_3CN. Flow rate 0.65 ml/min. Numbering and identification of the peaks correspond to Table 2

Table 2 Identification and quantification of glucosides and other compounds from the polar extract of *Betula rotundifolia*

Peak	Molecular formula	$[M+H]^+$ *m/z*	Compound
29	$C_{14}H_{20}O_7$	301	Salidroside[a]

Compounds were identified using authentic reference substances, by isolation, or by release of the aglycones by enzymatic hydrolysis (see Experimental). Numbering in Table 2 corresponds peak numbering of Fig. 2. [a] compared with reference substances, [b] isolated and compared [1] H and HSQC-NMR and UV, HR-ESI MS spectroscopic data with literature, [c] identification based on the APCI-MS and compared the aglycone with reference substances after hydrolysis, [d] identification based on the APCI-MS and HR-ESI-MS.

larvae were able to sequester salicin from the food plants. Thus, a defect in the transport system does not account for the total lack of salicylaldehyde or other aldehydes (e.g., benzaldehyde from benzylalcohol; see Table 1). Fig. 3 also demonstrates that the thioanalogs of (*Z*)-3-hexenylglucoside, phenylethylglucoside (**42**), and 8-OH-geraniolglucoside (**39**) are easily imported with a similar efficiency. In general, almost identical transport characteristics and capacities were observed for willow- and birch-feeding larvae of *C. lapponica*.

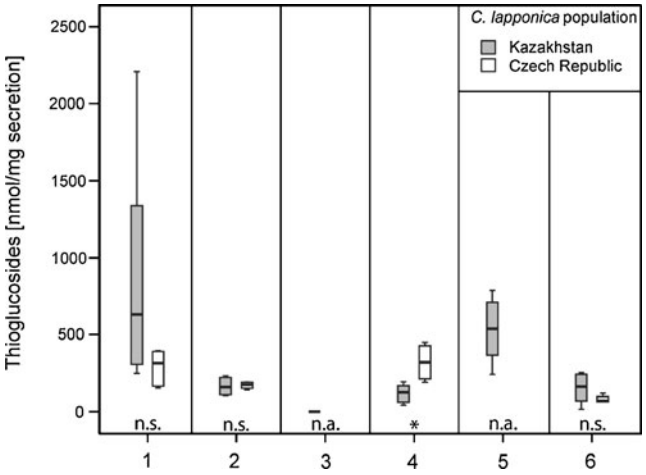

Fig. 3 Accumulation of the thioglucosides **1** to **6** in the defensive secretion of the birch-feeding larvae of *Chrysomela lapponica*. Test compounds: **1**: thiosalicin, **2**: *o*-kresolthioglucoside, **3**: salicylthiogalactoside, **4**: phenylethylthioglucoside, **5**: (*Z*)-3-hexenylthioglucoside, **6**: 8-OH-geraniolthioglucoside. Compounds were determined and quantified by HPLC-MS (see Experimental). Boxplots represent median, 25% and 75% percentile and inner fences show lowest and highest value. Data for larvae collected in the Czech Republic are taken from (Kuhn et al. 2004). According to Mann-Whitney test significant differences were only observed for **4** (P=0.019). No significant differences (n.s.) were observed for **1** (P=0.126), **2** (P=0.914) and **6** (P=0.257). Statistics were not applicable (n.a.) to **3** and **5**

Discussion

Sequestering leaf beetle larvae or those using a mixed-mode biosynthesis (sequestration and *de novo* biosynthesis) have developed an efficient network of transporters in their guts and glandular systems to channel phytogenic precursors into their reservoirs (Kunert et al. 2008; Discher et al. 2009). In general, only the glucoside precursor of the genuine chemical defense (e.g., salicylaldehyde or iridoid) is imported and channeled *via* hemolymph transport through the larval body to the glandular reservoir for the final toxification reactions. For example, larvae of *Chrysomela populi* and *Phratora vitellinae* specifically import salicin (Kuhn et al. 2004) and almost no related compounds. The *de novo* producers *Phratora laticollis*, *Hydrotassa marginella*, *Phaedon cochleariae*, *Gastrophysa viridula*, and *Plagiodera versicolora* also possess the ability to selectively uptake glucosidically bound 8-hydroxygeraniol (Feld et al. 2001; Kuhn et al. 2004) provided that the compound is present in the food plant (Kunert et al. 2008). In all cases, the imported glucosides coincided with the biosynthetic precursors of the final chemical defenses of the defensive cocktail that is based mostly on a single or only a few compounds.

In contrast, *C. lapponica* should possess transport systems of lower selectivity, thus allowing the sequestration of a range of plant-derived glucosides that is reflected in the remarkable pattern of substances within the secretion. Their principal ability to sequester structurally different glucosides was shown previously in *Salix*-feeders from Queyras using hydrolysis-resistant thioglucosides, which remain intact all the way from the leave to the defensive gland (Kuhn et al. 2007). By direct inspection of Tables 1 and 2, which compare the spectrum of glucosides present in the food plant (Fig. 2, Table 2) and the enzymatically released aglycones with the components of the defensive secretion, the selectivity of the sequestration process becomes obvious. For example, neither the dominant flavanoids, nor any of their ester derivatives, accumulate in the defensive secretion. Instead, the aglycones of (*Z*)-3-hexenol, phenylethanol, *p*-OH-phenylethanol, and betuligenol are present as major constituents in the blend of 2-methylbutyryl- and isobutyryl esters. The aglycones are imported into the reservoir as their glucosides, as demonstrated by the successful import of thioglucosides (Fig. 3, similar to the results shown for the Queyras population, (Kuhn et al. 2007). After import into the gland, the sugar moiety is hydrolyzed, followed by acylation of the resulting aglucone with the butyrates. Interestingly, all glucoside precursors of the defensive compounds were present only as minor components in the leaf extract (Fig. 2) suggesting a selective and highly efficient transport process in the larvae.

The complete lack of derivatives of salicortin (**44**) and tremulacin (**60**) in the defensive secretion is striking, although they are present in small amounts in the birch extract. Unspecific esterases, generally occurring in the enzymatic inventory of a gut, could remove the cyclohexenoic acid moiety (Lindroth 1988; Julkunen-Tiitto and Meier 1992), thus generating salicin, which would be readily sequestered into the glandular reservoir (Fig. 3). After hydrolytic cleavage in the reservoir, the released aglycone could be converted into a butyrate or oxidized to salicylaldehyde. Neither reaction was observed. However, the lack of salicylaldehyde or benzaldehyde is readily explained since the birch-feeding population of *C. lapponica* from Kazakhstan has no functional salicylalcohol oxidase (unpublished data).

Additionally, striking is the presence of high amounts of glucose (469 nmol mg^{-1} secretion) and minor amounts of the two glucose-6-*O*-butyrates **27a/b** and **28a/b** in the secretion (44 nmol mg^{-1} secretion). Apparently, glucose not only acts as a carrier for import of plant-derived aglycones into the glandular system, but also may serve as a scaffold for acylation reactions. The same compounds are known from trichomes of tomato (Neal et al. 1990), and an insecticidal activity has been demonstrated (Juvik et al. 1994).

The biological relevance of the high amounts of glucose in the larvae of the Altai populations is not clearly understood, but the sugar apparently does not interfere with the repellent function of the esters, as has been demonstrated (Hilker and Schulz 1994); probably the volatile esters form a repellent plume around the larvae, thus

preventing the necessity of a direct contact, which has been shown previously for *Phratora vitellinae* and *Phaedon cochleariae* (Gross et al. 2008; Gross and Schmidtberg 2009).

On the other hand, since the larvae experience rather low temperatures that go well beyond 0°C at night during the season (July, August), the high amount of glucose may function as a cryoprotectant (Calderon et al. 2009). Moreover, since the defensive secretion is an emulsion of organic esters and water, the actual concentration of free glucose in the aqueous phase, and hence its cryoprotective effect, might be even higher than calculated from the molar concentration (ca. 1.1°C at ca. 470 nmol mg^{-1} secretion). Since in the Altai region predators seem to be rare compared to other habitats of *C. lapponica* (personal observations), the selective pressure on adaptation to climate may be higher than to predation. The risk of infections by microorganism that utilize the "sweet secretion", particularly by entomophagous fungi (e.g., *Beauveria bassiana*) might be reduced by the presence of a few antimicrobially active constituents, such as *p*-OH-phenylethyl-isobutyrate (**19**), *p*-OH-phenylethyl-2-methylbutyrate (**22**), and betuligenoliso-butyrate (**23**) in the secretion (Tolzin-Banasch 2009).

By studying the selective import from the whole spectrum of glucosides that occur in the leaves of the food plant (*B. rotundifolia*), instead of a limited set of model compounds (Discher et al. 2009), we were able to better evaluate the selectivity and efficiency of transport. Although the larvae import several compounds (e.g., **37** or **42**), this corresponds only to a minor fraction of glycosides present in the food plants (Fig. 2). Moreover, the imported compounds do not belong to the major constituents of the plant, thus demonstrating a high enrichment capacity of the transport system. However, *de novo* biosynthesis of certain aglycones, especially phenylethanol and benzylalcohol from phenylalanine (unpublished results) in addition to sequestration cannot be excluded.

Whether or not the transport systems in the two membrane barriers (gut epithelial cells, glandular system) indeed have different selectivities (Discher et al. 2009) remains to be established.

Task Group Differences in Cuticular Lipids in the Honey Bee *Apis mellifera*

Abstract Social insects are defined by their ability to divide labor among their numerous nestmates. This is achieved via a complex system of chemical communication that allows colonies to organize task activity so as to maximize the productivity of the colony. However, the mechanism by which social insects distinguish task groups among morphologically identical individuals remains unknown. Using the honey bee, *Apis mellifera*, as our model species, we investigated the presence of task-specific patterns in the cuticular lipids (*n*-alkanes, fatty acids, and alkenes) of bees. Cuticular lipids are known to play an essential role in the recognition processes of insects. We found task-specific features in the *n*-alkane and alkene profiles of bees, but no task-specific patterns in the fatty acid profile. Foragers, in particular, had elevated levels of *n*-alkanes relative to nurse and newly emerged bees, suggesting increased waterproofing. Newly emerged bees had low levels of cuticular lipids, supporting the Blank Slate theory and potentially explaining their acceptance into foreign colonies.

Key Words Cuticular lipids · Recognition · Task · *Apis mellifera*

Introduction

Social insects owe much of their success to their ability to divide labor, and to their highly sophisticated communication systems. Division of labor requires a high level of colony organization and integration (Hölldobler and Wilson, 1990; Seeley and Seeley, 1995); these processes are underpinned by a multi-layered chemical communication system (Wyatt, 2003).

Cuticular lipids form the waxy layer on an insect's cuticle and are an integral part of an insect's physiology (Lockey, 1988). They typically are composed of esters, alcohols, free fatty acids, and hydrocarbons (*n*-alkanes, alkenes, and branched alkanes), with hydrocarbons often the dominant group. These lipids protect the insect from external influences, such as trans-cuticular water movement and pathogens, but some are also used in communication. As cuticular lipids vary in both quantity and quality (type) among species, age classes, genders, and colonies (Howard and Blomquist, 2005), they have the potential to convey information about an individual's biology.

Even though division of labor is essential to a colony's life, the mechanism by which workers that perform different tasks distinguish each other, especially when they are morphologically similar, as in the honeybee, remains poorly understood. In many social insects, workers performing different tasks have been shown to vary in lipid composition (Howard et al., 1982; Bonavitacougourdan et al., 1993; Wagner et al., 1998; Sevala et al., 2000; Nunes et al., 2009); such studies generally have used multivariate statistics (e.g., Discrimant Analysis and Principal Components Analysis) to show differences. There are two drawbacks to using only multivariate statistics to analyze differences in cuticular lipids among workers performing different tasks. First, such

methods render it difficult to identify task-specific chemical patterns, an important first step for illuminating the precise function of individual compounds. Second, they treat each compound as an independent variable and seek statistical patterns, thus maximizing the variance explained or the among-group component of variation, without reference to chemical relationship or biological function among compounds (Martin and Drijfhout, 2009a). The last point is particularly important, as social insects discriminate and "learn" some lipids more readily than others (Châline et al., 2005; Dani et al., 2005). This implies that lipid profiles revealed by the chemical analysis and those detected by the insects may not be congruent, as not all compounds may be used in communication, but instead serve other functions, such as waterproofing.

Here, we tested the hypothesis that there are differences in cuticular lipids of workers of the European honeybee, *Apis mellifera* L, that perform different tasks. For this, we quantified and compared compounds of the same lipid class, identified task-specific patterns related to these lipid classes, and then tested the potential of these patterns to separate tasks by using multi-variate statistics. We investigated the honeybees' two major cuticular lipid classes, namely *n*-alkanes and alkenes, which consistently occur in the honey bee from emergence onwards and make up the vast majority of the lipid profile (Blomquist et al., 1980). We also included fatty acids, which seem to play a role in the recognition process of the honey bee (Breed, 1998), but have not been quantified on an individual task basis. We compared three task groups: newly emerged bees, foragers, and nurse bees. Although newly emerged bees, strictly speaking, do not form a task group, they allowed us to follow the changes of the lipid profile with age, since a worker's task is age dependent. Choosing three groups had two advantages. First, it allowed us to look at age-dependent changes in cuticular profile from emergence onwards and, second, we were able to quantify changes in cuticular profile when workers experienced environmental conditions different from their hive environment, as in the case of nurse vs. forager bees.

Methods and Materials

Study Organism In October 2007, bees were collected from five queen-right *A. mellifera* colonies. From each colony, 15 newly emerged bees, 15 nurses, and 15 foragers were collected. Since task groups are morphologically indistinguishable, foragers were caught when entering the hive entrance, often with bags of pollen attached to their hind legs, whereas nurses were collected directly from a brood frame containing a high proportion of open brood. Collecting bees at the nest entrance or on the brood frame increased the probability that the majority of bees collected were foragers or nurses, respectively, although a few guard bees waiting at the entrance, or a small number of foragers and young bees sitting on the brood frame, might have been caught as well. Newly emerged bees were collected from a brood frame containing mature sealed brood that was kept in an incubator at 37°C. Newly emerged bees (≤24-h-old) were collected daily. All bees were killed by freezing at −20°C. In total, 196 bees were collected, including 75 foragers, 75 nurses, and 46 newly emerged bees. The lower number of newly emerged bees was because of a lack of sealed brood in two colonies.

Chemical Extraction Cuticular lipids were extracted by immersing each bee in 0.5 ml of HPLC-grade hexane, and then shaking the vial gently at ambient temperature for 2 min. Pollen, if present, was removed from foragers before immersion. After 2 min., the bee was removed from the solvent, and 50 µl of the extract were transferred to a glass insert and left for the solvent to evaporate.

Immediately before analysis, 30 µl BSTFA [N, O-bis (trimethylsilyl) trifluoroacetamide] were added to each sample and left to react at 70°C for 20 min. After silylation, products were extracted in 30 µl hexane and analyzed on an HP 6890GC, equipped with an HP-5MS column (length 30 m, ID: 0.25 mm, film thickness: 0.25 µm; Agilent Technologies Inc., Santa Clara, CA, USA) connected to an HP5973 Mass Selective Detector (electron impact ionization; 70 eV). Samples were injected in the splitless mode. The column oven was programmed from 70°C to 200°C at $40°C.min^{-1}$, and to 320°C at $25°C.min^{-1}$. Helium, at a constant flow rate of 1.0 ml min^{-1}, was the carrier gas.

Compounds were tentatively identified by using standard mass spectral databases, key diagnostic ions, and Kovats indices. Double bond position and geometry was not identified but was assumed to be as in the literature (Blomquist et al., 1980; Breed, 1998). The notation for each compound is based on chain length (e.g., tricosane = C_{23}), and number of double bonds (e.g., pentacosene = $C_{25:1}$).

Statistical Analysis The peak area of each compound was determined by manual integration of each total ion chromatogram (TIC). Compounds that, on average, contributed less than 1% to the overall chemical profile (i.e., *n*-alkanes + alkenes + fatty acids) were excluded from the analysis. Six samples were excluded due to poor chromatography. For each individual, *n*-alkane, fatty acid profile, and alkene profiles were quantified by dividing the peak area of each compound by the total compound abundance of that chemical class per individual; these profiles were compared among the three task groups. A preliminary

analysis indicated that the chemical profile of some individuals in one task group was more similar to that of another task group, and this was consistent across all three chemical classes, presumably because individuals could not be identified as belonging to a particular task group with complete reliability (see above).

All significance tests were performed using the statistical software R (v 2.81). A one-way *ANOVA* was used to test for task group differences in total compound quantity for each compound class, and a two-way *MANOVA*, with *Pillai test* and *post-hoc Tukey test*, was carried out to test for task group differences in chemical profile for each chemical class separately. Data were transformed to log-contrasts and standardized to meet the *MANOVA* assumptions of independence, equal variance, and normal error distribution (Aitchison, 1986). For each chemical class, the least variable compound was used as a reference peak for the log-contrast transformation. C_{27}, $C_{18:1}$, and $C_{29:1}$ were used as reference peaks for *n*-alkanes, fatty acids, and alkenes, respectively. From here on, compounds will be referred to by their names even though the analysis was carried out on each compound relative to the respective reference peak of its chemical class. The newly emerged group was excluded from the *MANOVA* test on the alkenes, as many alkenes were absent or below the detection threshold in this group, rendering the test unstable.

To determine what compound class produced the clearest separation of task groups, a discrimant analysis (DA) was performed for each chemical class using SPSS 13.0. For this, the proportion of each compound (relative to the total compound abundance of that chemical class per individual) was transformed before the multivariate analysis according to the formula (Aitchison, 1986), $Z = ln[A_p/g(A_p)]$ (where A_p is the proportion of the compound and $g(A_p)$ is the geometric mean of all compounds to be included in the multi-variate analysis), so as to avoid complications arising from analyzing compositional data. Each of the 13 task-colony groups (3 newly emerged, 5 nurse, and 5 forager) was treated as a separate group during the DA, so as to investigate the relative separation of task groups and colonies.

Results

Chemical Analysis Five *n*-alkanes, five fatty acids, and six alkenes were identified (Fig. 1). The combination of *n*-alkanes, fatty acids, and alkenes found in this study agreed with previous studies (Blomquist et al., 1980; Carlson, 1988; Dani et al., 2004). All *n*-alkanes and alkenes had an odd number of carbons in the chain, with lengths ranging from 23 to 33. In contrast, fatty acids had an even number of carbons in the chain, from 16 to 28.

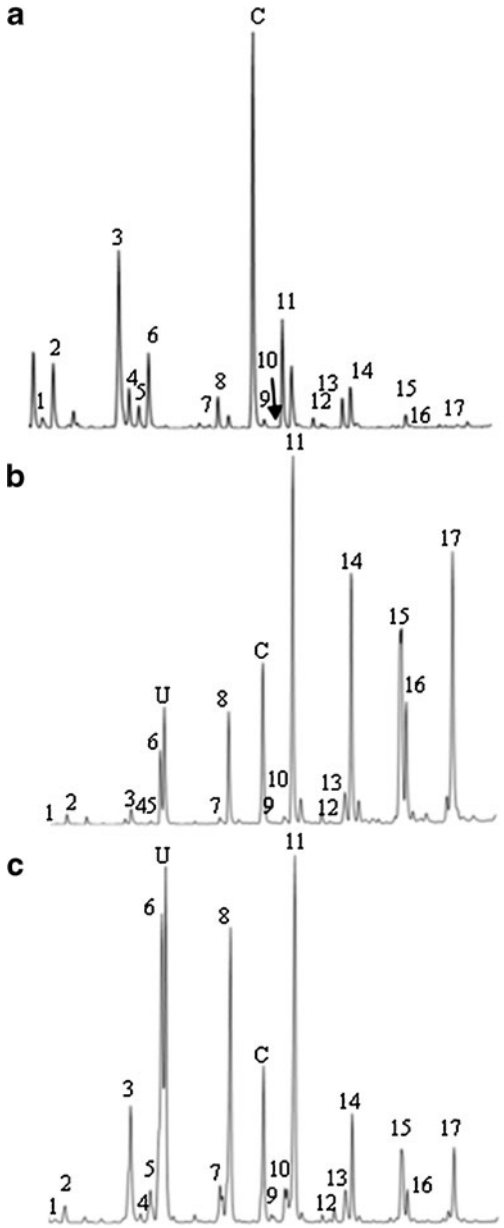

Fig. 1 Gas chromatogram of **a**) newly emerged, **b**) nurse, and **c**) forager honey bee. 1 = palmitoleic acid ($C_{16:1}$); 2 = palmitic acid ($C_{16:0}$); 3 = oleic acid ($C_{18:1}$); 4 = stearic acid ($C_{18:0}$); 5 = tricosene ($C_{23:1}$); 6 = tricosane (C_{23}); U = eicosenol, 7 = pentacosene ($C_{25:1}$); 8 = pentacosane (C_{25}); C = contaminating phalate; 9 = docosanoic acid ($C_{22:0}$); 10 = heptacosene ($C_{27:1}$); 11 = heptacosane ($C_{27:0}$); 12 = lignoceric acid ($C_{24:0}$); 13 = nonacosene ($C_{29:1}$); 14 = nonacosane ($C_{29:0}$), 15 = hentriacosene ($C_{31:1}$); 16 = hentriacosane (C_{31}); 17 = tritriacosene ($C_{33:1}$)

Although there was a significant overall colony effect of the *n*-alkanes (*MANOVA*, F=9.92, *d.f.*=16, 147, P< 0.001, *Pillai*), fatty acids (*MANOVA*: F=6.05, *d.f.*=16, 147, P<0.001), and alkenes (*MANOVA*: F=10.11, *d.f.*= 16, 147, P<0.001, *Pillai*), further analysis using Tukey multiple comparison tests indicated that this arose due to one or two colonies having a chemically distinct group of

newly emerged forager, or nurse bees, e.g., when analyzing $C_{25:1}$, foragers of colony 1 differed from foragers of colony 2 ($P<0.001$) and colony 3 ($P<0.001$), although there was no significant difference ($P>0.08$ in all cases) among foragers of colonies 2, 3, 4, and 5. However, the nurses of colony 1 were not different ($P>0.8$) from nurses of any other colony, while nurses of colony 4 were different from nurses of colonies 2, 3, and 5 ($P<0.01$). This inconsistent pattern was found across almost all of the 16 compounds analyzed (Fig. 1), and is not indicative of a colony signal that one would expect to be consistent across all nurses and foragers from the same hive. We found that in the majority of cases, different age groups (task groups) of the same colony were different (*Tukey test*: $P<0.01$ in all cases), whereas groups of the same age, but from different colonies, were not (*Tukey test*: $P>0.05$). Therefore, we concluded that there was no consistent colony effect for any of the three chemical classes.

Differences in Quantity The three task groups differed considerably (*ANOVA*: *d.f.*=2, $P<0.001$) in amount of *n*-alkane produced, with the amount increasing with age (Fig. 2a). Foragers produced around 70% more *n*-alkane compared to nurses, and 1,000% more than newly emerged bees. Fatty acid quantity also increased (*ANOVA*: *d.f.*=2, $P<0.01$) from newly emerged to nurse bees (Fig. 2b), but there was no difference (*ANOVA*: *d.f.*=2, $P=0.90$) between nurse bees and foragers. Task groups also differed (*ANOVA*: *d.f.*=2, $P<0.001$) in the amount of alkene produced. Alkene quantity was extremely low in newly emerged bees, increased by 1,300% at the nurse stage, and then dropped by 40% for foragers (Fig. 2c).

Differences in Chemical Profile The three task groups varied in overall chemical profile (Fig. 1). By considering the three chemical classes separately, it can be seen that *n*-alkanes effected the clearest separation of task groups (Fig. 3a). Newly emerged bees, nurses, and foragers clustered into distinct groups, independent of colony origin, with little overlap among them (Fig. 3a). In contrast, according to fatty acid profiles, bees formed a single cluster with no task group separation (Fig. 3b). Nurses and foragers also could be separated on alkene profiles (Fig. 3c). The newly emerged group was removed from this analysis because many alkenes were not detected in members of this group (Fig. 3c).

A clear task group separation also was found in the actual chemical profiles of bees when based on *n*-alkanes and alkenes, as opposed to fatty acids (Fig. 4). The three age groups varied little in fatty acid profile (Fig. 4a–c), leading to the poor group separation of Fig. 3b. All groups were dominated by palmitic ($C_{16:0}$) and oleic ($C_{18:1}$) acids. The increased amount of lignoceric acid ($C_{24:0}$) observed in the nurse profile was evident only in two of five colonies and, thus, the overall task group effect was not significant (*MANOVA*: $F=14.06$, *d.f.*=12, 147, $P=0.08$). Groups differed, however, in their *n*-alkane and alkene profiles. The clearest difference among groups was in the profiles of compounds within a chemical class. Newly emerged bees and nurses (Fig. 4a, b) showed similar *n*-alkane and alkene profiles, with the main difference being that newly emerged bees had relatively higher levels of $C_{23}/C_{23:1}$, whereas nurses produced relatively more C_{31}/C_{29} and $C_{30:1}$ and $C_{33:1}$ (Tukey multiple comparison test, $P<0.001$). The high $C_{23:1}$ peak observed in the newly emerged bee profile is an artifact of the absence of other alkenes in many of the young bees, and this was only observed at this extreme in one colony. The *n*-alkane and alkene profiles of foragers did not show similar (to the other groups) patterns (Fig. 4c). The relative increase of C_{23}/C_{25} and decrease in C_{29}/C_{31} rendered foragers chemically distinct (*Tukey test*, $P<0.001$) from nurses and newly emerged bees. At the same time, the increase (*Tukey test*, $P<0.001$) of $C_{23:1}/C_{25:1}$ and decrease of $C_{30:1}$ and $C_{33:1}$ lead to a relatively even abundance profile of alkenes in foragers.

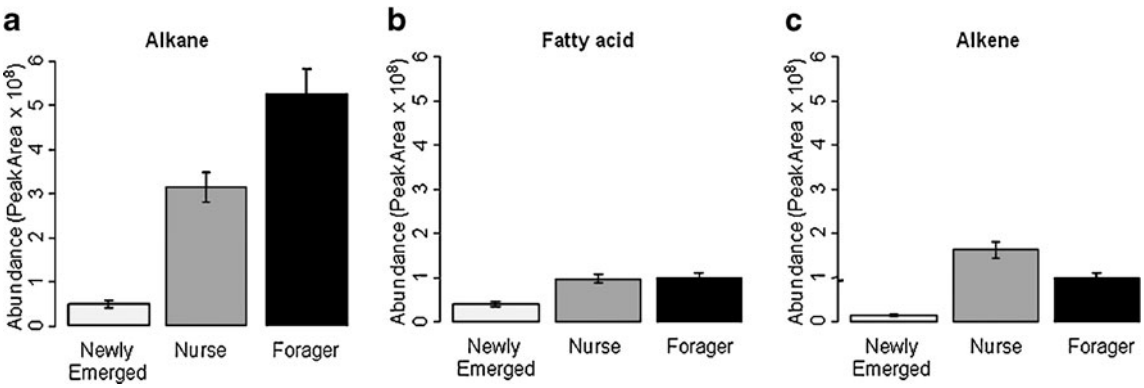

Fig. 2 Total abundance of: **a**) *n*-alkane, **b**) fatty acid and **c**) alkene produced by newly emerged honey bees (light grey bars), nurses (dark grey bars), and foragers (black bars). Error bars are standard errors

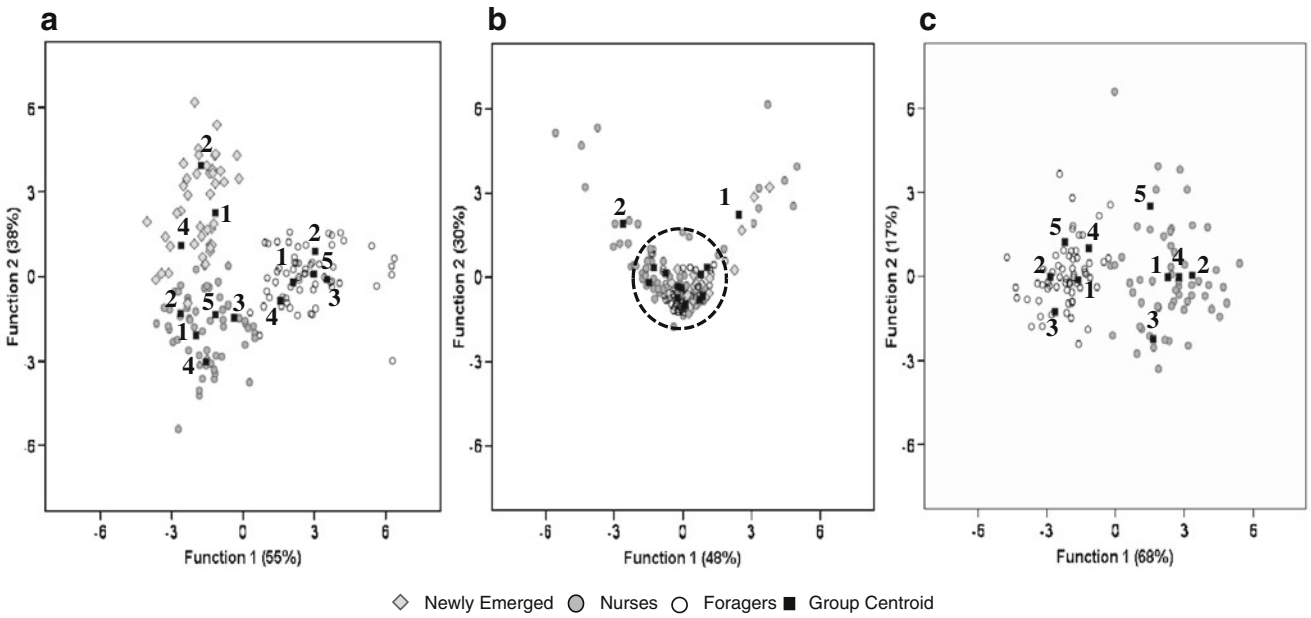

Fig. 3 Caste separation based on discriminant analysis (DA) of a honey bee's **a**) *n*-alkane, **b**) fatty acid, and **c**) alkene profiles. For clarity, the centroid of each group was given its colony number (1 to 5) to show colony separation as well as caste separation. In the fatty acid DA (3b), all groups except the nurses of colony 2 and 1 are contained in the dashed circle. The proportion of variance explained by each function is given in brackets

Discussion

We demonstrated that *A. mellifera* task groups differed in their chemical profiles in at least two of the three compound classes investigated, namely *n*-alkanes and alkenes. Changes in cuticular chemical profiles of insects can occur during development, for example, such as reaching sexual maturity (Nelson et al., 1981), or can be affected by changes in temperature and humidity (Gibbs et al., 1991; Wagner et al., 2001). The most dramatic change we observed in the *n*-alkane profile of *A. mellifera* occurred during the transition from nurse to forager, as has been previously reported (Dani et al., 2004; Del Piccolo et al., 2010). During this transition, a honey bee's duty changes from working within, to foraging outside, of the hive. We found that this change was accompanied by a distinct increase in *n*-alkane quantity and a change in the *n*-alkane profile. This change in hydrocarbon profile could be a response to the change in temperature and humidity levels that the bee is exposed to when leaving the hive and may provide better waterproofing under more variable conditions.

In general, high levels of cuticular *n*-alkanes typically are associated with species living in hot, arid habitats (e.g., Hadley and Schultz, 1987). *n*-Alkanes are thought to be the best class of hydrocarbon for providing cuticle waterproofing, because of their high melting point and shape (Gibbs and Pomonis, 1995; Gibbs, 1998). In several species of ants, foragers produce significantly higher amounts of the *n*-alkanes C_{25} and C_{27} than do nest-maintenance workers (Wagner et al., 1998; Martin and Drijfhout, 2009b). The red harvester ant (*Pogonomyrmex barbatus*) uses this difference to distinguish workers performing different tasks (Greene and Gordon, 2003). Wagner et al. (2001) showed that the increase in *n*-alkane quantity is caused by exposing a nest-maintenance worker for just 50 min to a higher temperature (>27°C) and lower humidity (<43%) than conditions found in the nest. Furthermore, several species of flies, including *Sargophala bullata*, *Musca domestica*, and *Pteronarcys californica,* increase levels of alkanes in response to dry and warm conditions (Armold et al., 1969; Noorman and Den Otter, 2002).

To what extent, if at all, honeybees use *n*-alkane dimorphism to distinguish between nurses and foragers remains to be tested. Châline et al. (2005) found that honey bees detect and remember alkenes more readily than they do *n*-alkanes. Dani et al. (2005) and Breed (1998) showed that changes in a bee's *n*-alkane profile did not change how the bee was treated by nest mates, supporting the theory that *n*-alkanes are probably used more for waterproofing than communication. In contrast to this, changes in a bee's alkene (Breed et al., 1998; Dani et al., 2005) and fatty acid profiles (Breed et al., 1998) resulted in a bee being attacked by its own nestmates, implying that these compounds may serve in communication, especially as alkenes are believed to be poor waterproofing agents (Gibbs, 1995). Dani et al. (2005) and Breed and Stiller (1992) suggested that alkenes and fatty acids may be used by bees to recognize nestmates. In our study, task groups varied in alkene profile, suggesting

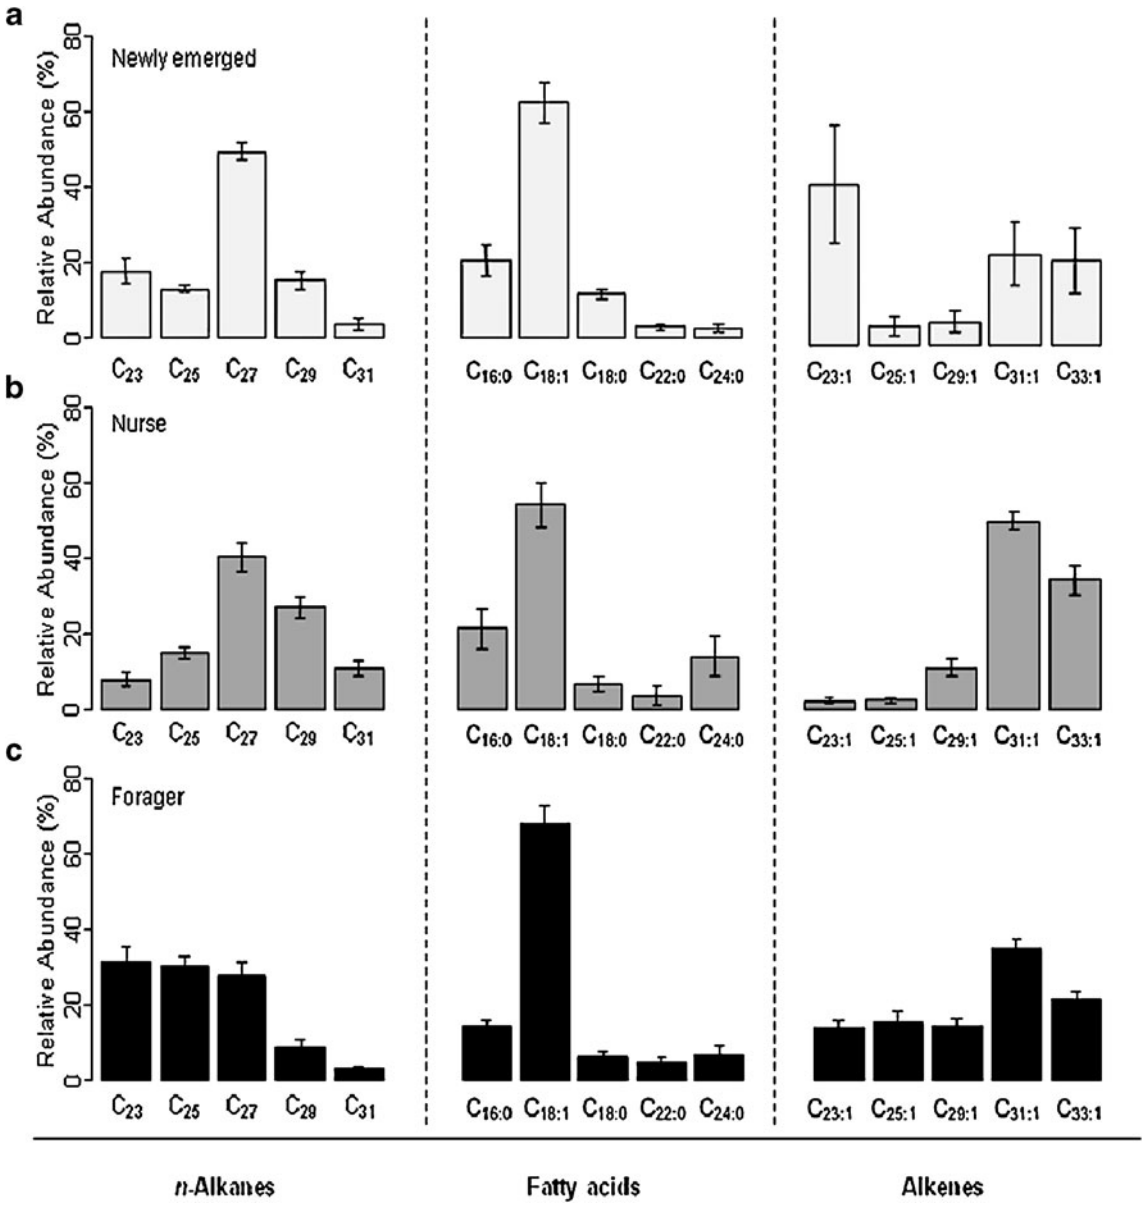

Fig. 4 Differences in chemical profiles of different task groups [newly emerged = light grey bars; nurses = dark grey bars; foragers = black bars] of honey bees. Relative abundance of **a**) *n*-alkanes (C_{23} = tricosane; C_{25} = pentacosane; C_{27} = heptacosane; C_{29} = noncacosane; C_{31} = heintriacontane), **b**) fatty acids ($C_{16:0}$ = palmitic acid; $C_{18:1}$ = oleic acid; $C_{18:0}$ = stearic acid; $C_{22:0}$ = docosanoic acid; $C_{24:0}$ = lignoceric acid), and **c**) alkenes ($C_{23:1}$ = tricosene; $C_{25:1}$ = pentacosene; $C_{29:1}$ = nonacosene; $C_{31:1}$ = hentriacosene; $C_{33:1}$ = tritriacosene). Error bars are standard errors

that bees could use these alkenes to distinguish task groups; this will need to be investigated. However, we did not find a difference in alkene profile among colonies, contradicting the hypothesis of Dani et al. (2005). Fatty acids, also, did not contain sufficient variation to separate task groups or colonies, suggesting that these acids do not function in task group or colony recognition; the latter contradicts the findings of Breed and Stiller (1992).

Nevertheless, there are two explanations for a lack of colony effect of alkenes and fatty acids. First, queens of the colonies used in this study may have been related, which could result in reduced chemical variation among colonies. Second, alkenes and fatty acids contain another level of information in the form of isomers. In *A. mellifera*, alkenes of a similar chain-length contain several isomers with double bonds at carbons 7, 8, 9, 10, or 12 (Dani et al., 2004). Breed et al. (2004) reported only one isomer of octadecenoic (with a double-bond at carbon 9; i.e., oleic) acid, but reported two polyunsaturated fatty acids, (*Z*, *Z*)-9,12-octadecenoic acid and (*Z*,*Z*,*Z*)-9,12,15-octadecatrienoic acid; these polyunsaturated acids were present in quantities below the detection limit of our method. These

alkene and fatty acid isomers may contain sufficient variation to separate colonies. A recent study (Martin et al., 2010) found that bumblebees have a high diversity of alkene isomers, of which some are mimicked by bumblebee parasites, thereby enabling them to integrate into the host colony. Furthermore, newly emerged bees are readily accepted into colonies if they lack essential nestmate recognition compounds; this is known as the Blank Slate Theory proposed by Breed et al. (2004). A lower amount of cuticular lipids at this early developmental stage appears to be common in bees (Breed et al., 1988, 2004), wasps (Panek et al., 2001), and ants (Lenoir et al., 2001). In our study, the class of compounds found in the lowest quantities was alkenes, followed by fatty acids, and then *n*-alkanes. This suggests that alkenes may be the most likely compound group to function as colony recognition compounds. However, this needs investigation.

In light of our results, it remains to be tested whether the task-group differences in *n*-alkane profiles are indeed adaptations to outside conditions and whether or not honey bees use these compounds to distinguish task groups. Further investigations are also needed into the role of alkenes as task- and colony-recognition compounds, and into any role fatty acids may play in these processes.

Alkaloids in the Mite *Scheloribates laevigatus*: Further Alkaloids Common to Oribatid Mites and Poison Frogs

Abstract Poison frogs are chemically defended from predators by diverse alkaloids, almost all of which are sequestered unchanged from alkaloid-containing arthropods in the frog diet. Oribatid mites recently have been proposed as a major dietary source of poison frog alkaloids. Here, we report on alkaloids common to an oribatid mite and poison frogs. Gas chromatographic-mass spectrometric analysis of methanol extracts of adult *Scheloribates laevigatus* (Oribatida: Scheloribatidae) revealed nine alkaloids. Five of these have been detected previously in the skin glands of poison frogs: two isomers of the pumiliotoxin **291G**, two isomers of the 5,6,8-trisubstituted indolizidine **209C**, and the 5,6,8-trisubstituted indolizidine **195G**. The other four alkaloids, a pumiliotoxin, a tricyclic (coccinelline-like), and two isomers of an izidine, were not previously known, but are similar in structure to alkaloids found in poison frogs. Alkaloids were not detected in immature *S. laevigatus*, suggesting that they are adult-specific and possibly the result of mite biosynthesis. Although most of the alkaloids detected in *S. laevigatus* are common to poison frogs, the geographic distributions of these organisms are not sympatric. The findings of this study indicate that oribatid mites, and in particular, members of the genus *Scheloribates*, represent a relatively unexplored arthropod repository for alkaloids and a significant dietary source of alkaloids in poison frogs.

Key Words Chemical defense · Dendrobatids · Indolizidines · Oil glands · Opisthonotal glands · Pumiliotoxins · Scheloribatidae · Tricyclic alkaloids · Poison frog

Introduction

The term ‘poison frog’ refers to the four known evolutionary lineages of anurans characterized by the ability to sequester alkaloid-based chemical defenses from dietary arthropods. They include certain dendrobatids from Central and South America, mantellids from Madagascar (*Mantella*), bufonids from South America (*Melanophryniscus*), and myobatrachids from Australia (*Pseudophryne*). Over the past 40 years, more than 850 lipophilic alkaloids, organized into over 20 structural classes, have been detected in the skin glands of poison frogs, apparently reflecting the diversity of alkaloids present in arthropod prey (Daly et al., 2005; Saporito et al., 2009). Most of these alkaloids are pumiliotoxins, indolizidines, and coccinelline-like tricyclics (Saporito et al., 2009), and have molecular weights of less than 400 atomic mass units (Daly et al., 2005). A large number of alkaloids have been identified in arthropods (Jones and Blum, 1983; Braekman et al., 1998), and insofar as is currently known, most poison frog alkaloids are sequestered from alkaloid-containing mites, ants, beetles, and millipedes in the diet (Saporito et al., 2009).

Oribatid mites are among the most abundant and diverse arthropods in soil and leaf-litter, both in temperate and tropical regions (Maraun and Scheu, 2000; Franklin et al., 2004), but they also are found frequently in arboreal microhabitats, both on exposed surfaces and in "suspended soil" (Lindo and Winchester, 2006). Their food generally consists of decaying higher plant material and saprophytic fungi (Schneider and Maraun, 2005), although stable isotope studies indicate that necrophagy or predation on small invertebrates also is common, especially in tropical soils (Illig et al., 2005). Consistent with low rates of secondary production and relatively long lives (1–5 years or more), these mites have multiple defenses, especially as adults (Norton, 1994). These defenses include cuticular sclerotization or mineralization, specialized cuticular outgrowths, special defensive body forms and behaviors, and defensive chemicals (Sanders and Norton, 2004; Schneider and Maraun, 2009). Chemical defenses probably are derived from paired exocrine glands (Raspotnig et al., 2003) called opisthonotal or oil glands. These glands secrete a wide range of organic compounds including monoterpenes, sesquiterpenes, aromatics, aliphatic aldehydes, a ketone, fatty acids, fatty acid esters, an alkyl formate, and hydrocarbons (Kuwuhara, 2004; Raspotnig, 2009).

Recently, alkaloids have been identified in oribatid mites, representing a repository of these natural products in animals as well as a major dietary source for these compounds in poison frogs (Takada et al., 2005; Saporito et al., 2007a, 2009). More than 80 alkaloids, representing 11 structural classes, have been identified in oribatids, including pumiliotoxins, a homopumiliotoxin, 5,8-disubstituted- and 5,6,8-trisubstituted indolizidines, dehydro-5,8-disubstituted indolizidines, coccinelline-like tricyclics, a 1,4-disubstituted quinolizidine, a 4,6-disubstituted quinolizidine, a 3,5-disubstituted indolizidine, two pyrrolidines, a spiropyrrolizidine, and several that could not be assigned to a specific structural class (Saporito et al., 2009). These alkaloids have been reported in the scheloribatid mites *Scheloribates azumaensis* and *Scheloribates* sp. from Japan (Takada et al., 2005), and in oribatid mites from Costa Rica and Panama, including numerous scheloribatid mites (Saporito et al., 2007a). The full extent of the diversity and taxonomic distribution of alkaloids in oribatid mites is unknown, but initial studies indicate that they are common in the widespread family Scheloribatidae.

As part of a large, ongoing study on the taxonomic distribution of alkaloids in oribatid mites, we analyzed extracts from adult and immature specimens of the soil mite *Scheloribates laevigatus* (C. Koch) (Acari: Oribatida: Scheloribatidae). This mite is a generalist feeder on fungi, algae, and litter (Woodring and Cook, 1962; Hubert et al., 2001) and is common and abundant in Europe and in anthropogenic habitats in North America, where it appears to be an introduced species (Marshall et al., 1987; Weigmann, 2006; R. Norton, unpublished). Here, we report the presence of pumiliotoxins, indolizidines, and a coccinelline-like tricyclic alkaloid in adults of this species. Most of these alkaloids have been detected previously in the skins of poison frogs, lending support to suggestions that scheloribatid mites are an important dietary source of alkaloids in poison frogs.

Methods and Materials

Mite Collection and Sample Preparation Adult mites were extracted with Berlese-funnels from soil and leaf-litter samples collected near Syracuse, NY, USA. Individuals were maintained at room temperature in small glass jars containing a plaster-charcoal substrate, and were provided with alga-covered tree bark and small amounts of leaf-litter and woody debris. Reproduction in the cultures provided a source of immature mites. For chemical analysis, adult or immature mites (10–25 individuals) were extracted for 24 hr in glass vials with 20 µl of methanol.

Alkaloid Identification When possible, alkaloids were identified by comparison of mass spectra, vapor-phase FTIR spectra, and GC retention times to those of previously reported poison frog alkaloids (Daly et al., 2005). Poison frog alkaloids are assigned code names consisting of a bold-faced number corresponding to the nominal mass (molecular weight) and a bold-faced letter to distinguish alkaloids with the same nominal mass (Daly et al., 2005).

Alkaloids in *S. laevigatus* were quantitated by extracting 25 adult mites with 20 µl of methanol containing 100 ng of nicotine [(-)-nicotine ≥99%, Sigma-Aldrich, Milwaukee, WI, USA] as an internal standard. Nicotine was used because its retention time is outside of the typical values for most mite alkaloids. All alkaloids were quantitated by comparing peak areas to that of the nicotine internal standard in the total ion current (TIC) gas-chromatogram (see *Chemical Analysis*) with the ICIS peak detection function in Xcalibur © version 1.4 SR1 (Thermo Electron Corporation, 1998–2003). Although a flame ionization detector (FID) may provide better dynamic range linearity, the moderate precision reported in this paper can be achieved with either TIC or FID if an internal standard is used to account for losses due to instrument behavior and sample manipulation. A similar analysis was done for immature mites, but without the internal standard, which could interfere with the determination of low levels of alkaloids. The analyses were repeated on three independent extracts.

Chemical Analysis GC-MS data were obtained on a Thermo-Electron Polaris-Q instrument coupled to a Focus GC with a 30 m×0.25 mm i.d. Restek-5MS fused silica column. GC separation of alkaloids was achieved using a temperature program from 100 to 280°C at a rate of 10°C per min with He as carrier gas (flow rate: 1 ml/min.). Each extract was analyzed with both electron impact-mass spectrometry (EI-MS) and chemical ionization-mass spectrometry (CI-MS) with NH_3 as the reagent gas. High resolution GC-MS analysis was obtained using a Waters GCT instrument coupled to a Hewlett-Packard model 6890 GC, with a column, temperature program, and carrier gas conditions identical to those listed above. GC-FTIR data were obtained with a Hewlett-Packard model 5890 gas chromatograph fitted with a 30 m×0.32 mm i.d. Phenomenex Zebron ZB-5 capillary column (same temperature program as above), interfaced with a Hewlett-Packard model 5971 Mass Selective Detector and a Model 5965B IRD with a narrow range (4000–750 cm^{-1}) infrared detector.

Results and Discussion

GC-MS analysis of adult *Scheloribates laevigatus* extracts detected nine alkaloids (including isomers), representing five structural classes (Figs. 1 and 2a; Table 1). Five of these have been identified previously in the skin of poison frogs: the 5,6,8-trisubstituted indolizidines (5,6,8-I) **195G** and **209C** (two isomers) and pumiliotoxin (PTX) **291G** (two isomers). The 5,6,8-I **195G** also has been previously detected in an unidentified oribatid mite species in the family Scheloribatidae from Bocas del Toro, Panama

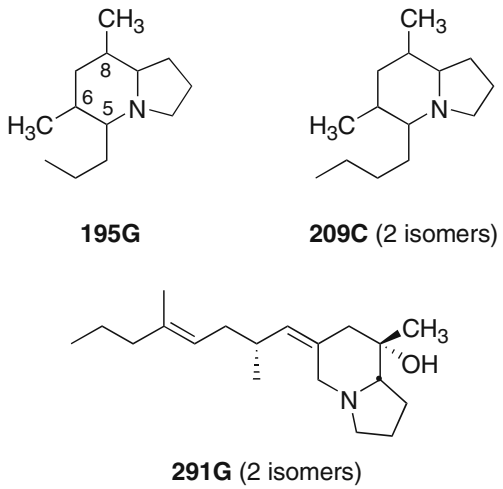

Fig. 1 Structures of alkaloids identified in *Scheloribates laevigatus* that have been previously identified from the skins of certain poison frogs

(Saporito et al., 2007a). The remaining four alkaloids have not been observed previously, but are similar in structure to other alkaloids identified in poison frogs: a pumiliotoxin of molecular weight (MW) 307, a tricyclic (Tri) of MW 247, and an izidine (two isomers) of MW 275 (Table 1; see Supplementary Material for vapor-phase FTIR). Tricyclics represent a large alkaloid group of varied structural types, characterized by mass spectra with many intense peaks, often homologous, but without any dominant alpha-substituent cleavages, probably having three aliphatic rings, and are typified by the coccinelline alkaloids (Daly et al., 2005). Izidines also are a large alkaloid group of varied structural types that are generally characterized as bicyclic izidines with either one or two substituents readily lost by alpha-cleavage during mass spectrometric analysis, but without fragmentation patterns corresponding to any of the currently known pyrrolizidine, indolizidine, or quinolizidine classes (Daly et al., 2005). The chemical properties (MW, empirical formulae, GC retention times, mass spectral data, vapor-phase FTIR spectral data, and other data) of these previously unreported alkaloids are found in Table 1. Additional physicochemical characterizations (e.g., ^{1}H and ^{13}C NMR) will be necessary in order to assign definitive structures to these alkaloids.

Nine frog-skin alkaloids of MW 275 are currently known with the empirical formula assigned to the two new MW 275 mite alkaloids. They are assigned codes of **275A-G**, **275I**, and **275K** and are found in dendrobatid, mantellid, or bufonid species. None has a mass spectrum similar to the ones from the two mite MW 275 isomers. Nine dendrobatid or mantellid frog alkaloids, **247B-247J,** have MW 247 and the same empirical formula calculated for the mite MW 247 alkaloid. Only one of the frog compounds is a tricyclic, and it has a significantly different mass spectrum from that of the mite alkaloid.

Individual *S. laevigatus* adults (average wet mass 29 μg) contained approximately 17±2 ng (mean ± SD) of alkaloids, about 0.06% of the mite's body weight. The most abundant alkaloid was PTX **291G** (two isomers), accounting for approximately 9 ng (50%) of the total alkaloid quantity per mite. Takada et al. (2005) reported that individual *S. azumaensis* contained about 10 ng of PTX **251D**. The next most abundant alkaloids in *S. laevigatus* were the novel alkaloids PTX of MW 307, Tri of MW 247, and the two izidines of MW 275 (all of them present in approximately equal amounts), followed by the 5,6,8-Is **195G** and **209C** (two isomers). Figure 2a is a representative chromatogram illustrating the relative alkaloid quantities for adult *S. laevigatus*.

All of the alkaloids identified in *S. laevigatus* contain branch points in their carbon skeleton (Fig. 1), which appears to be the most common alkaloid structural characteristic seen in oribatid mites (Saporito et al., 2009).

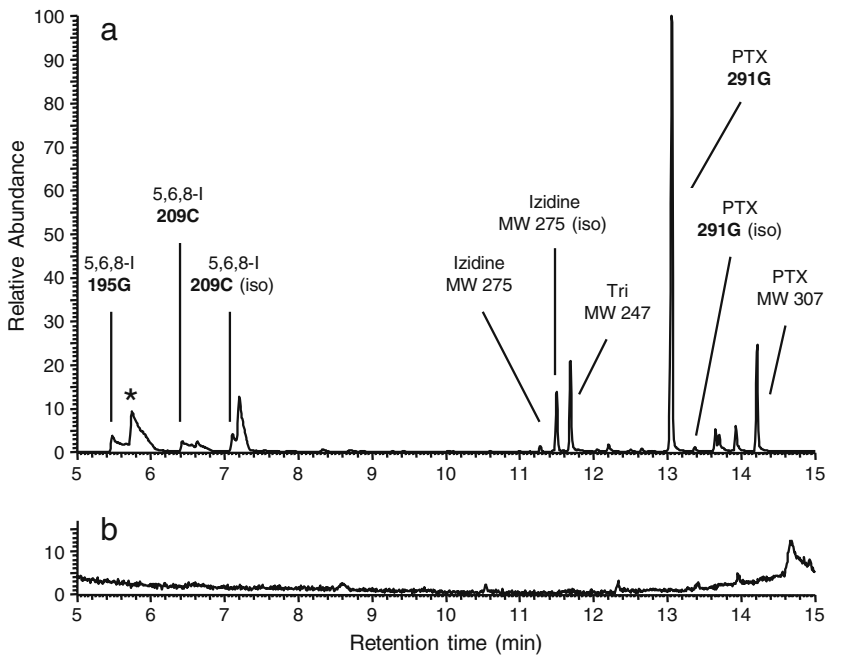

Fig. 2 Gas chromatogram of *Scheloribates laevigatus* extracts in adults (**a**) and immature mites (**b**). The unlabeled peaks in chromatogram a and b are not alkaloids. 5,6,8-I=5,6,8-trisubstituted indolizidine; PTX = pumiliotoxin; Tri = coccinelline-like tricyclic. An *asterisk* (*) indicates the nicotine internal standard in the adult extracts. The term (*iso*) refers to an alkaloid isomer

Numerous branched-chain alkaloids (including pumiliotoxins, 5,6,8-trisubstituted indolizidines, and tricyclics) have been identified previously in oribatid mites, including other members of the genus *Scheloribates* (Saporito et al., 2009). Takada et al. (2005) identified the branched-chain alkaloids PTX **251D**, Tri **193C** (precoccinelline), and an unidentified Tri in *Scheloribates azumaensis*, and the branched-chain PTX **237A**, deoxy-pumiliotoxin **193H**, 5,6,8-I **223A**, and the 1,4-disubstituted quinolizidine (1,4-Q) **231A** in an unidentified *Scheloribates* sp. from Japan. Saporito et al. (2007a) identified mainly branched-chain alkaloids in several different species of oribatid mites (including *Scheloribates*) from Costa Rica and Panama, which included pumiliotoxins, a homopumiliotoxin, 5,6,8-trisubstituted indolizidines, 5,8-disubstituted indolizidines (5,8-Is), dehydro-5,8-disubstituted indolizidines, a 1,4-disubstituted quinolizidine, tricyclics (including precoccinelline), and a spiropyrrolizidine (see Tables 1 and 2 in Saporito et al. 2007a, 2008). A smaller number of unbranched alkaloids also have been identified in oribatid mites (Saporito et al., 2007a). Branched-chain alkaloids also represent the most common alkaloid structural type found in poison frogs worldwide, accounting for approximately 70% of all classified alkaloids, the majority of which are pumiliotoxins, 5,6,8-Is, 5,8-Is, and tricyclics (Saporito et al., 2009).

GC-MS analysis indicated that immature *S. laevigatus* contained no detectable alkaloids (Fig. 2b), which suggests that alkaloids are adult-specific and possibly biosynthesized by the mites. Under culture conditions, both adults and immature mites had the same food choices, and therefore it is unlikely that adult *S. laevigatus* acquire alkaloids or precursor(s) from a dietary source. The culture substrates provided to the mites—tree bark with *Protococcus* alga and secondary fungal growth—are not known to contain the alkaloids in question. However, it remains possible that: (1) adults contained alkaloids that were sequestered from a natural diet, whereas immature mites, which bred in culture, did not have an opportunity to sequester such alkaloids from a natural diet; (2) adults and immature mites had unobserved dietary differences within the cultures; and/or (3) immature mites lack an ability to acquire alkaloids or precursor(s) from their diet. Takada et al. (2005) similarly

Table 1 Chemical properties of previously unreported alkaloids from oribatid mites. These alkaloids have not been found in poison frogs

247. Tri. $C_{17}H_{29}N$. Rt 12.24. MS: *m/z* 247 (18), 232 (5), 218 (12), 204 (22), 190 (100), 176 (78), 162 (52), 148 (36), 137 (50), 136 (35), 124 (16), 96 (22), 70 (20). Vapor phase FTIR (cm^{-1}): 3015 (cis double bond), 2968, 2938 (s), 2866, 2791 (strong Bohlmann band), 984. DBE = 4.

275. Izidine. $C_{19}H_{33}N$. Rt 11.84. MS: *m/z* 275 (22), 246 (5), 190 (48), 178 (22), 150 (100), 136 (20), 70 (8). DBE = 4.

275. Izidine (Isomer). $C_{19}H_{33}N$. Rt 12.06. MS: *m/z* 275 (20), 246 (5), 190 (55), 178 (24), 150 (100), 136 (18), 70 (10). Vapor phase FTIR (cm^{-1}): 2967(s), 2901, 2789. DBE = 4.

307. PTX. $C_{19}H_{33}NO_2$. Rt 14.78. MS: *m/z* 307 (<1), 291 (15), 206 (38), 194 (12), 193 (14), 176 (16), 166 (100), 70 (35). Vapor phase FTIR (cm^{-1}): 3543 (H-bonded OH), 2969 (s), 2888, 2799 (strong Bohlmann band), complex fingerprint region typical of PTXs. DBE = 4.

The tabulation of alkaloids and format of properties, including the Rt values which were proportionally corrected to the known value, follow those of the Appendix in Supporting Information of Daly et al. (2005)

reported that alkaloids occur only in adults of *S. azumaensis* and *Scheloribates* sp., and suggested that alkaloids may be biosynthesized by adult oribatid mites. Our study supports the hypothesis that adult oribatids synthesize alkaloids, but the possibility of a microsymbiont cannot be excluded. Microsymbionts are the source of chemical defenses and/or natural products in a variety of organisms, including vertebrates and invertebrates (Piel, 2002; Daly, 2004).

Some of the alkaloids (and alkaloid classes) found in oribatid mites have been identified in other arthropods. These include some pumiliotoxins, which have been detected in formicine ants of the genera *Brachymyrmex* and *Paratrechina*; some tricyclics (including precoccinelline), detected in coccinellid beetles; a spiropyrrolizidine, detected in polyzoniid millipedes in the genera *Rhinotus* and *Kiusiozonium*; and a number of unbranched-chain alkaloids that were originally considered to be exclusively of myrmicine ant origin: a 3,5-disubstituted indolizidine, two 4,6-disubsituted quinolizidines, and two pyrrolidines (Saporito et al., 2009).

The occurrence of identical alkaloids in both oribatids and other arthropods raises the possibility that some may be transferred among different arthropod groups, possibly through trophic interactions (Takada et al., 2005; Saporito et al., 2009). Certain myrmicine ants in the genera *Myrmecina*, *Pheidole*, and *Oligomyrmex*, and several families of small beetles (Ptiliidae, Staphylinidae, and especially Scydmaenidae) are predators of oribatid mites (Ito and Takaku, 1994; Sanders and Norton, 2004; Wilson, 2005). Furthermore, oribatid mites can be found in ant nests as specialized or unspecialized myrmecophiles (Ito and Takaku, 1994). Although it is not known if alkaloids are present in arthropod predators of oribatid mites, it is conceivable that predation and sequestration could explain the presence of identical alkaloids in at least some of these evolutionarily distinct arthropod lineages. However, it is also possible that different lineages of arthropods synthesize identical alkaloids, and/or that there is a yet unknown, widespread alkaloid-containing microsymbiont present among different arthropod groups.

The biological function of alkaloids in *S. laevigatus* and other oribatid mites is unknown. However, the pumiliotoxins, which comprise the most abundant alkaloids in *S. laevigatus*, are highly toxic (Weldon et al., 2006) and may defend oribatid mites against predation. In poison frogs, alkaloids serve as a chemical defense against potential invertebrate and vertebrate predators (Saporito et al., 2007b), microorganisms (Macfoy et al., 2005), and possibly ectoparasites (Weldon et al., 2006). The functions of other compounds identified in oribatid mites have not been fully studied, but include alarm signals and chemical defenses (Shimano et al., 2002; Raspotnig et al., 2003). In the better-studied and closely related mite group Astigmata, organic compounds also function as aggregation signals and sex pheromones (Kuwuhara, 2004). Alkaloids most likely comprise part of the defensive "tool box" of adult *S. laevigatus*, similar to the non-alkaloid secretions present in immature mites of this species and in many other oribatid mites (Raspotnig, 2009). Research is needed to identify the specific role of alkaloids in oribatids, and to determine why there is such a marked ontogenetic shift in scheloribatid mite gland chemistry, if indeed the alkaloids are housed there.

It has been established from analysis of stomach contents that mites constitute a major prey item for many poison frogs (Simon and Toft, 1991; Valderrama-Vernaza et al., 2009). It is evident that some oribatid mites contain a relatively high diversity and quantity of alkaloids, and that many of these are in the skin of poison frogs. We think oribatid mites may constitute the most important dietary source of alkaloids in poison frogs, more so than ants, which have long been considered to be the principal source (Saporito et al., 2004). Furthermore, since members of the widespread genus *Scheloribates* contain the greatest diversity of alkaloids known from oribatids to date, scheloribatids may be an especially important dietary item for poison frogs worldwide. Additional studies of poison frog diet through stomach content analysis, in which mites are taxonomically identified, coupled with information on the distribution and availability of scheloribatids, will be necessary to understand the importance of scheloribatid mites to the alkaloid defenses of poison frogs.

Although oribatids are a significant proximate source, the ultimate biological source of these alkaloids remains unknown. To more conclusively understand the origin of alkaloids in mites (and therefore in poison frogs), we propose three general research themes: (1) a series of feeding experiments in which cultured mites, raised through multiple generations, are provided a diet with and without alkaloids and/or precursors; (2) identification of the location of alkaloids within adult mites (e.g., are they located in the opisthonotal glands?); and (3) an attempt to culture the microbes (e.g., bacteria, fungi, etc.) present in mites in search for a possible alkaloid-producing microsymbiont.

A Multi-Component Species Identifying Pheromone in the Goldfish

Abstract Although it has been established that sexually-immature goldfish and their relatives recognize members of their own species by using chemicals that they release, the identity of this cue(s) and whether it might be produced and used by other life stages is not yet known. To address this question, this study tested the behavioral responses of sexually immature and mature goldfish to each other's body washings, their sensitivity to this cue, the role of the olfactory sense in detecting it, and whether it is comprised of either polar and/or non-polar compounds. Tests that used two-choice mazes discovered that juvenile, immature, mature male, and mature female goldfish all release and respond to a common chemical cue(s). Dilution studies next demonstrated that this cue is active when diluted over 10 times and thus capable of functioning as a short range attractant/identifier. Olfactory occlusion demonstrated that it is detected by the olfactory sense. Finally, chemical fractionation demonstrated that it is comprised of both polar and non-polar components but likely does not include bile acids. Together, these results suggest that all life stages of goldfish use a complex multicomponent pheromonal odor to discern species identity, and that this odor has the potential to function with hormonal metabolites to identify sexual condition in behaviorally active fish of many species.

Introduction

Pheromones have been defined as chemical cues that convey information among individuals of the same species (Karlson and Lüscher, 1959; Wyatt, 2003, 2009). Cues that fit this definition are commonly used by teleost ('bony') fishes to mediate alarm, aggregation, and reproductive synchrony in the vast expanses of dark and/or turbid waters that they inhabit (Liley, 1982; Stacey et al., 1986; Stacey and Sorensen, 2009). All fish pheromones identified to date are body metabolite(s), a likely consequence of life in water (Sorensen and Hoye, 2010). Studies of the biological activity and identity of pheromonal odors in fish have taken two approaches. Several dozen studies have tested the actions of unpurified whole odors of immature and mature fish (body washings) and found that when tested, they generally elicit behavioral activity in a species-specific manner (Liley, 1982; Stacey et al., 1986; Baker and Montgomery, 2001; Sisler and Sorensen, 2008). Another set of studies has tested the activity of key hormonal metabolites ('hormonal pheromones') commonly produced by fishes, and found that they frequently stimulate olfactory and behavioral activity among closely related taxa (Stacey and Sorensen, 2005, 2009; Olsen et al., 2006). One possible explanation for these seemingly divergent results is that fish pheromones may function naturally as complex mixtures of metabolites, some of which identify species identity, while others (e.g., hormonal pheromones) change with maturity and time, thus adding information about physiological state.

The goldfish, *Carassius auratus*, is an excellent model to address whether and how a fish might use a species-

identifying pheromone because it is easily studied, well-understood, and seemingly typical of many other fishes (Stacey and Sorensen, 2009). Behavioral studies of immature (sexually-regressed) goldfish and the closely related common carp (*Cyprinus carpio*) show that these species both recognize their own species (Saglio and le Martret, 1982; le Martret and Saglio, 1982) and readily distinguish between each other and many other species by using waterborne chemicals that do not appear to be learned (Sisler and Sorensen, 2008). Further, a laboratory spawning study suggests that goldfish and carp do not readily hybridize (Sorensen et al., 1992) despite the fact that they use a common set of five hormonal compounds that mediate pre-spawning hormonal surges and reproductive behavior (Kobayashi et al., 2002; Stacey and Sorensen, 2009). Comparisons of the olfactory sensitivity and reproductive physiology of these species have yet to show any differences (Sorensen and Stacey, 2004). Intriguingly, a single study also has demonstrated that while male goldfish respond behaviorally to a metabolite of prostaglandin $F_{2\alpha}$ when it is added to goldfish holding water, males of another species (the blue gourami, *Trichogaster trichopterus*) do not become sexually aroused when the prostaglandin metabolite is added to their holding water (Sorensen et al., 2000, unpublished data). Although these data suggest that common goldfish body metabolites are perceived as a species-identifying cue, it has not yet been tested directly whether all life stages of any fish release a common subset of odorous compounds that might serve this function. This is an especially relevant question because physiological (reproductive) condition is known to modify many aspects of fish metabolism, sex hormonal pheromone release, and behavior (Stacey and Sorensen, 2009).

The chemical identity and biological significance of the compounds employed by goldfish to identify species also await resolution. Unique mixtures of bile acids may serve this role, as many fishes, including goldfish and related carps, are known to release and detect these relatively distinctive compounds with high sensitivity and specificity (Døving et al., 1980; Sorensen et al., 1987; Li and Sorensen, 1997; Derby and Sorensen, 2008). Complex mixtures of amino acids also could contribute because they too are released in quantity, and are detected with high sensitivity and specificity (Saglio and Blanc, 1989). Of course, other types of metabolites could also be involved. Notably, it has yet to be resolved whether the body washings (metabolites) of fishes are detected by the olfactory sense at concentrations low enough that they could function as pheromones in open waters.

The present study tested the possibility that all life stages of goldfish produce and perceive a common species-identifying pheromone by addressing five questions: 1) Does responsiveness of goldfish to conspecific washings remain constant with time as might be expected of a pheromone?; 2) Do all maturational stages of goldfish produce and respond to conspecific washings in the same manner?; 3) Are conspecific washings recognized by the sense of smell?; 4) Is the cue detected at low-enough concentrations for it to function as a pheromone?; and 5) Is this cue comprised of a single or multiple components, and might either bile acids and/or amino acids be involved?

Methods and Materials

Fish and Fish Care Goldfish were obtained from outdoor ponds (Hunting Creek Fish Farm, PA, USA) and shipped to the laboratory where they were held in 1000-l flow-through holding tanks supplied with well water (3-l/min; 17°C) on a 16:8 hr (L:D) photoperiod. Fish were fed a mixture of flake food (Aquatic Ecosystems, Apopka, FL, USA) and brine shrimp (San Francisco Bay Brand, CA, USA). Four groups of fish were used (Table 1). Briefly, juvenile fish were 3–6-mo-old and sexually undifferentiated. Sexually-immature fish were sexually regressed (previously mature) individuals that had been held in the laboratory for several years and had been previously used by Sisler and Sorensen (2008). Sexually-mature male and female fish were obtained from ponds several weeks prior to spawning, and were held in the laboratory as single sex groups to prevent them from stimulating each other (recent reproductive behavior or exposure to pheromones strongly enhances sexual receptivity and pheromone release; see Table 1 for more details on fish conditions). With the exception of the olfactory occlusion experiments, all fish were tested only once. Odor donors came from the same groups as the behavioral subjects.

Behavioral Assay Responses of goldfish were studied in the same circular mazes employed (and described) by Sisler and Sorensen (2008). Briefly, these mazes were 1.5 m diam and divided into two semi-circular sections that were connected by a 35 cm long central drained region. Each maze was illuminated by a set of dim (<1 lux) overhead incandescent bulbs and infrared light sources. A low-light overhead camera with a DVD recorder also was placed overhead. Well water (100 ml/min, 18°C) entered the central region of each maze and was maintained at a depth of 20 cm by using a drain. When appropriate (see below), odor stimuli were added to the semi-circular test sections through silicon tubes attached to air stones (to evoke mixing) using a peristaltic pump (10 ml/ min; Gilson, France). Control experiments have shown these mazes to be without bias (Sisler and Sorensen, 2008; Levesque, unpublished data). The day before each test, groups of 5 goldfish were moved into the mazes and allowed to acclimate.

Table 1 Characteristics of experimental fish

Life stages	Weight (g) N=4	GSI (%) N=4	Age	Time in laboratory	Notes
Juvenile	3.7±0.2	<0.42	3 mo	1 mo	Sexually undifferentiated
Immature	45.1±9.5	1.7±0.2	3–4 yr	3 yr	Regressed (nonvitellogenic oocytes, no sperm); Sexually non-responsive
Mature male	34.4±5.1	4.0±0.4	2 yr	3 mo	Presence of tubercles on pectoral fins and spermiated; Sexually responsive but not immediately receptive; Modest source of male sex pheromone[a]
Mature female	39.9±4.6	13.6±3.4	2 yr	3 mo	Distended abdomen with vitellogenic eggs; Sexually non-receptive; Modest source of steroidal pheromones[b]

Mean±Standard error

GSI = Gonadosomatic index (gonad weight /body weight body weight x 100)

[a] based on data from Sorensen et al. (2005)

[b] based on data from Scott and Sorensen (1994)

Experimental trials were conducted one at a time and started the next morning when the inflowing well water was turned off, and then 1 hr later, a 15-min pretest was conducted during which time blank well water (10 ml/min) was pumped into both sides of each maze. Pretests were followed by 15-min tests during which time either well water (control) or test odor (see below) were added to opposite sides of each maze while fish distribution was monitored. Test odor was added to the side that had been used least during the pretest to minimize possible bias. Trials concluded with a food odor control in which food odor (see below) was added to the least-used side for 15-min to confirm that fish were responsive to odors. All experiments were conducted 10 times with different groups of fish.

For data analysis, the numbers of fish on each side of each maze were counted at 15-sec intervals across each 15-min test period (pilot studies showed this to give a good representation of fish distribution). The total number of fish on each side was then summed for each test period and divided by the total number of times fish were seen on both sides after which the difference between the percent time fish spent on the test side during the pre-test period was subtracted from the percent time they spent during the test period to yield 'relative attraction'. Data then were summed for each experiment, evaluated for normality (Kolmogorov Smirnov test), transformed if appropriate (data for experiment 3 were arc-sin transformed), and then analyzed with one-way ANOVA (Instat, Graphpad Software, CA, USA). If significance was indicated (P<0.05), individual values were compared with the control in that experiment using Tukey Kramer *post-hoc* tests. In addition, well water and food odor controls within each experiment were compared to an expected value of zero using Student *t*-tests (Instat, Graphpad Software, CA) to ensure that there was no bias.

Test Odor Preparation Odor stimuli were prepared fresh each day following established protocols (Sisler and Sorensen, 2008). Briefly, approximately 100 g of goldfish (a value previously deemed to reflect that of a dense shoal of fish (Saglio and Blanc, 1989)) were carefully captured by hand net, weighed, and placed into clean plastic buckets containing 5- l of well water, and aerated by using a silicon air stone for 1-h. Blank control was prepared the same way without fish. Food odor was prepared by placing 1 g of fish food (tropical flake food, Aquatic Ecosystems Inc., Apopka, FL, USA) into 100 ml of well water for 1-h and then filtering it through filter paper (Grade 3,Whatman, International Ltd, Maidstone, England). Stimuli were used within 5 hr.

Experiment 1: Does Responsiveness of Juvenile Goldfish to Conspecific Washings Change with Time? This initial experiment sought to determine whether juvenile goldfish exhibit the same responses to conspecific washings as the sexually-immature goldfish that had been held for over a year in the laboratory. Not only did this question address whether this cue is a pheromone, but it allowed us to address whether we could use immature and juvenile fish interchangeably. Responses of both juvenile and regressed immature goldfish were tested to each other's body washings and blank water control in a randomized order. In a final test, juvenile goldfish were offered simultaneously the choice of juvenile and immature washings to confirm that they were equally attractive (thus reducing the possibility that fish may simply have appeared to have been equally attracted because these odors had been tested against a blank (a very weak competing stimulus).

Experiment 2: Do All Maturational Stages of Goldfish Produce and Respond to Conspecific Washings in the Same

Manner? Experiment 1 indicated that immature and juvenile goldfish release and respond to the same chemical stimuli; this experiment extended this approach to include sexually-mature males and females. All combinations of mature and juvenile fish and their body washings were tested. In addition, mature female goldfish were offered a choice of mature male vs. immature washings in one experiment, and mature male vs. mature female washings in another. The later experiments sought to confirm that these odors were perceived as being the same.

Experiment 3: Are Conspecific Body Washings Detected by the Olfactory Sense? To test the role of the olfactory sense in conspecific recognition, responses of immature goldfish were tested to body washing after their nares had been occluded, and then again after their occlusions had been removed. Immature fish were used because their large size made them easier to handle. For occlusion, fish were anesthetized in MS222® (tricaine methanesulfonate; 1 g/ 10 l), placed onto a wet paper, and an inert dental impression material (3M Express vinyl polysiloxane, St. Paul, MN, USA) was injected carefully into their nares following protocols previously shown not to affect fish swimming behavior or health (Maniak et al., 2000). Fish were tested with goldfish body washings within a day of occlusion, then anesthetized to remove their nasal occlusions using forceps, and given 3 week to recover before being re-tested.

Experiment 4: How Potent Is the Species-identifying Cue? Different groups of juvenile goldfish fish were tested to full strength body washings (20 g/ l), a 10-fold dilution of the former, and then a 100-fold dilution. The order of testing was randomized, and a well water control was included in the test matrix.

Experiment 5: Is this Cue Comprised of a Single or Multiple Components, and Might Either Bile and/or Amino Acids Be Involved? This experiment proceeded in two steps. The first tested whether the cue was polar and/or non-polar, while the second tested the role of bile acids found in the non-polar fraction. For the first step, 1-l aliquots of juvenile goldfish holding water (20 g/ l) were filtered (Whatman Grade 3, International Ltd, Maidstone, England), passed through activated reversed-phase C18 columns (Sep-pak Plus, Waters Corp., Milford, MA, USA), and eluted with 5 ml of methanol following established protocols (Polkinghorne et al., 2001). The eluate (i.e., the non-polar fraction) then was dried under a stream of nitrogen, reconstituted in well water to its original concentration, and its behavioral activity tested with juveniles. The filtrate (polar fraction) was tested directly in the maze. A mixture of the two then was tested to confirm that activity had not been lost. Pilot studies using C18 resins have shown that they do not release unknown compounds that influence fish behavior.

For the second step, the bile acid composition of goldfish holding water was examined following established protocols (Polkinghorne et al., 2001), and the bile acids found therein were tested for behavioral activity. Briefly, three 1-l aliquots of goldfish holding water were extracted as described above, dried, spiked with standards, injected onto a reversed-phase C18 column (Nova-pak C18, 4 μm column; Waters Corp., Milford, MA, USA) eluted with a gradient of acetonitrile and ammonium dihydrogen phosphate, and treated with 3α-hydroxysteroid dehydrogenase while fluorescence was monitored. Bile acids were identi-

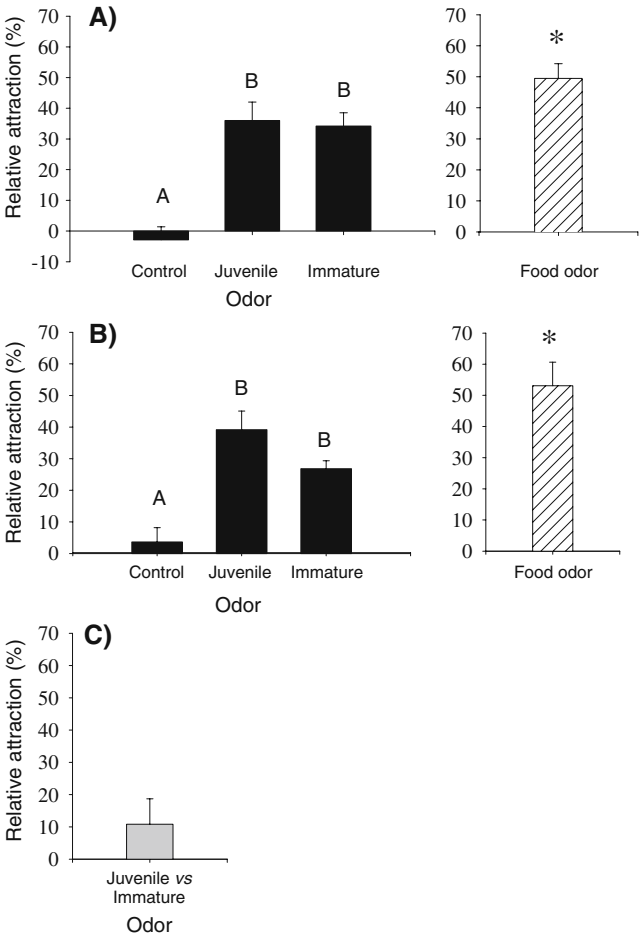

Fig. 1 **a** Changes in the distribution ('Relative attraction') of immature goldfish after the addition of either well water control, juvenile goldfish washings, or immature goldfish washings (mean percent change ± Standard error [SE]; N=10 groups of 5 fish in each case). Different letters denote statistical differences between treatments (P<0.05 by ANOVA). A summation of all food odor control experiments is shown to the right (*P<0.01 vs. 0 by paired t-test). **b** Relative attraction (mean percent change) of juvenile after addition of well water control, juvenile and immature goldfish washings (N=10). A summation of all food odor control experiments is shown to the right (*P<0.01 vs. 0.0 by paired t-test). **c** Changes in the relative distribution of immature goldfish offered a choice between juvenile and immature goldfish washings (N=10 groups of 5 fish)

fied based on retention times and mass spectrometry (Fine and Sorensen, 2008). The available compound (taurocholic acid) was purchased (Sigma Chemical Co, MO, USA), while the unavailable compound (cyprinol sulfate) was isolated and purified (99% purity by LC-MS) from goldfish gall bladders. These bile acids then were tested in our maze (in methanol carrier) at the concentration (10^{-10} Molar) estimated to be present in body washings.

Results

Experiment 1 found that while immature goldfish were not attracted to well water control ($P>0.10$), they were attracted to the body washings of both immature goldfish ($P<0.01$) and juvenile goldfish ($P<0.01$) (Fig. 1a). Similarly, juvenile goldfish were not attracted to well water ($P>0.10$) but were attracted to both washings of immature ($P<0.01$) and juvenile goldfish ($P<0.01$) (Fig. 1b). When juvenile goldfish were offered the choice of juvenile and immature body washings, they did not choose between them ($P>0.10$) (Fig. 1c). Food odor control was highly attractive to both groups ($P<0.01$) (Figs. 1a, b).

Experiment 2 demonstrated that all life stages of goldfish produced and discerned similar conspecific aromas. Juvenile goldfish were not influenced by well water control ($P>0.10$) but were highly attracted to washings of mature males ($P<0.01$) and mature females ($P<0.01$) (Fig. 2a). Mature females also were not attracted to the well water control but were attracted to washings of juveniles ($P<0.01$), mature females ($P<0.01$), and mature males ($P<0.01$). Further, when females were offered the choice of mature male vs. immature washings, and mature male vs. mature female washings, they showed no preference for either ($P>0.10$; Fig. 2c). Finally, mature males were attracted to the washings of juveniles ($P<0.01$), mature females ($P<0.01$) and mature males ($P<0.01$) (Fig. 2d).

Experiment 3 demonstrated that immature goldfish are attracted to conspecific washings because of their odor; they were not attracted to this stimuli when their nares were occluded ($P>0.10$), but they were attracted when occlusions were removed ($P<0.01$; Fig. 3). Experiment 4 showed this cue to be fully potent when diluted 10 times ($P<0.01$) but not 100 times (Fig. 4). The food odor control was attractive for all groups ($P<0.01$).

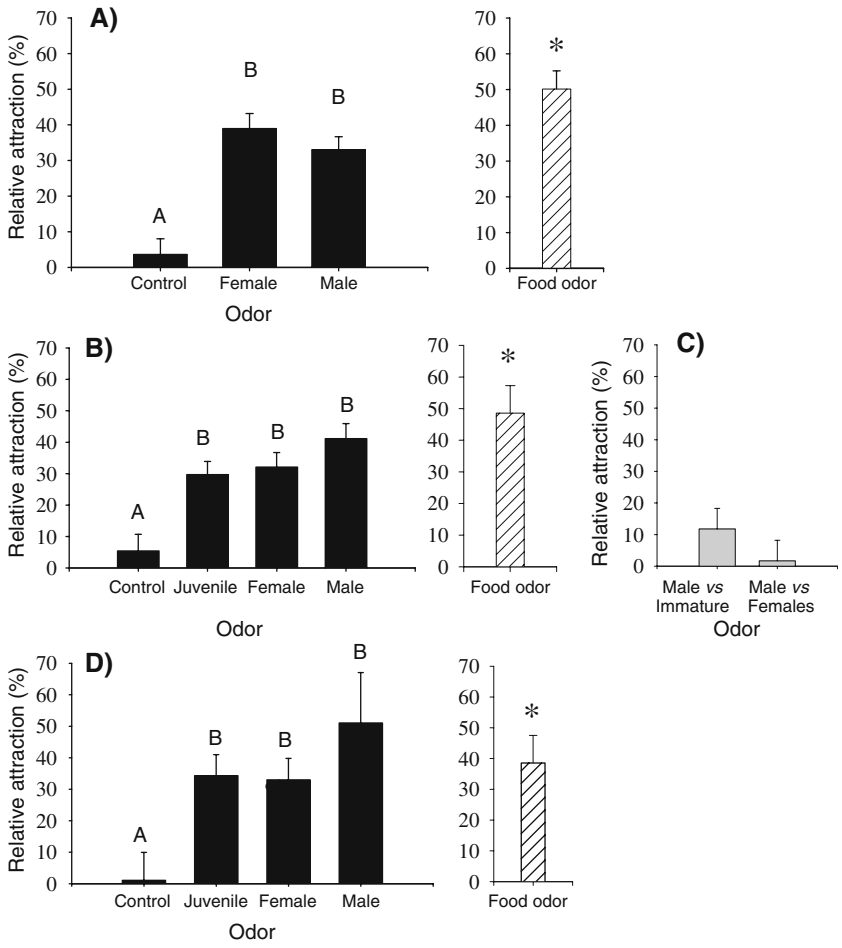

Fig. 2 **a** Relative attraction (mean percent change ± Standard error [SE]) of juvenile goldfish after the addition of either well water control, mature female, or mature male washings ($N=10$ groups of 5 fish; letters denote differences between treatments at $p<0.05$); A summated food odor experiment is shown to the right (*$P<0.01$ vs. 0.0 by paired t-test). **b** Relative attraction of mature female goldfish to well water control, juvenile, mature female, or mature male goldfish washings ($N=10$; $P<0.05$). The summated food odor control experiment is shown to the right (*$P<0.01$); **c** Changes in the relative distribution of mature female goldfish offered a choice between mature male and immature goldfish washings, and between mature male and mature female washings ($N=10$ for each; $P<0.05$); **d** Relative attraction of mature male goldfish to well water control, juvenile, mature females, or mature male washings ($N=10$ groups of 5, $P<0.05$). The food odor control is shown to the right (*$P<0.05$)

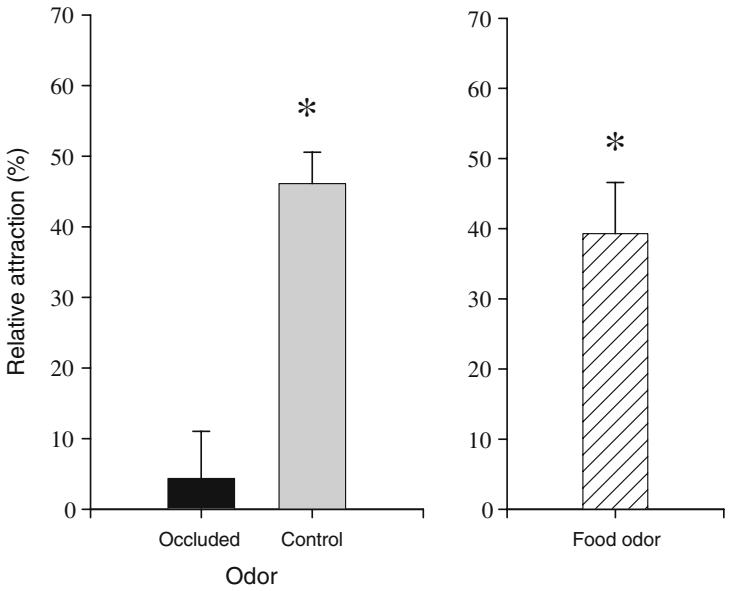

Fig. 3 Changes (mean percent change ± Standard error [SE]) in the relative distribution of immature goldfish with occluded nostrils (black bar) and the same fish after their occlusions had been removed (clear bar) to immature goldfish body washings (N=5 groups of 10; *P< 0.01 vs. 0 for both treatments). The food odor control for the post-occluded group (*P<0.05 vs. 0) is shown to the right

Finally, experiment 5 showed that both the non-polar C18 eluate and the polar filtrate of juvenile holding water were attractive to juvenile goldfish (P<0.05; Fig. 5). A combination of the eluate and filtrate had potency equivalent to untreated juvenile holding water (P>0.10), and also was more attractive than either the filtrate or eluate alone (P<0.05; Fig. 5). HPLC analysis of goldfish water found large quantities of two identifiable bile acids, cyprinol sulfate (CS) and taurocholic acid (TCA) (Fig. 6a). The former was released at a rate of 4.2 μg / l / 20 g body weight of goldfish for CS and the later at a rate of 0.085 μg / l / 20 g. A mixture of these bile acids had no measurable effect on the behavior of juvenile goldfish (P>0.10; Fig. 6b).

Discussion

This study confirms the existence of a species-identifying cue in immature goldfish body washings (Saglio and le Martret, 1982; Sisler and Sorensen, 2008), while demonstrating that juveniles, mature males, and mature females all produce and respond to a similar conspecific cue. The fact that neither juvenile nor female goldfish distinguished between mature or juvenile fish washings in head-to-head behavioral tests, argues strongly that maturity does not influence the production or discrimination of this cue, whose specificity has already been described in some detail by Sisler and Sorensen (2008). Because the species-identifying cue is active at low concentrations and it is detected by the olfaction, it should be considered a pheromone. Fractionation suggests that it has multiple non-polar and polar components. This appears to be the first systematic description of the ability of a fish species to identify all life history stages of conspecifics by using odor alone. Previous work allows us to apply this finding to the closely-related common carp (Sisler and Sorensen, 2008).

This species-identifying pheromone should be adaptive to the goldfish and its relatives that live in turbid waters, and forage and spawn in groups (McCrimmon, 1968). Our dilution experiments suggest that the primary role of the pheromone may be as a close range identifier for shoaling and spawning. Although the present study did not examine the full range or complexity of pheromonal compounds released by goldfish (the specific role of sexual cues was not examined), it nevertheless does demonstrate that different life history stages consistently release common compounds that are consistently perceived as a distinctive species-specific entity by all life stages. The presence of a species-specific odor could explain previous observations that goldfish and carp do not readily hybridize despite the fact that

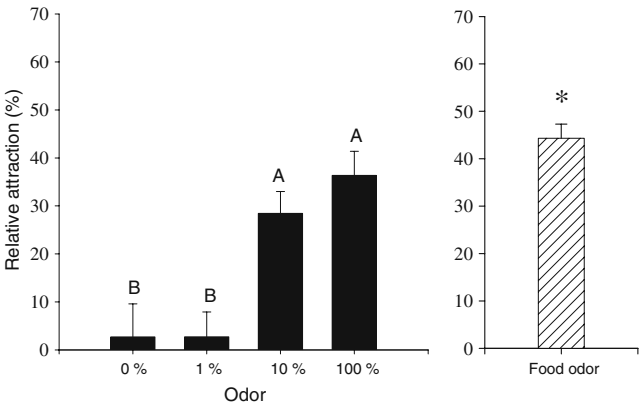

Fig. 4 Relative attraction (mean percent change ± Standard error [SE]) of juvenile goldfish to well water control, a 1% dilution of juvenile washings, 10% juvenile washings, juvenile odor (100%) odor, and then food control (N=10 groups of 5; different letters indicate differences; P<0.01)

they share the same hormonal pheromones (Sorensen et al., 1992), and that altering body odor background could alter the function of hormonal >pheromones (Sorensen et al., 2000; Sorensen and Levesque, unpublished data). If true, this phenomenon would answer the paradox of how various fish species can employ common hormonal products as species-specific sex pheromones (Sorensen and Stacey, 1999; Stacey and Sorensen, 2005, 2009). A similar scenario can be envisaged for the fish alarm cue, which some suggest to be a simple purine (Brown et al., 2000), but which detailed cross-species comparisons using whole odors often show to be species-specific (Smith, 1992). The sophisticated neural architecture of the fish olfactory system appears capable of discriminating odor complexes (Friedrich and Korsching, 1998; Michel, 2006; Derby and Sorensen, 2008). Further study of pheromone mixtures would be timely.

The present study demonstrates that the species-identifying pheromone recognized by the goldfish is comprised of both non-polar and polar components, and all components need to be present for full activity. Somewhat surprisingly, the two bile acids we isolated from goldfish waters, cyprinol sulfate (a bile acid novel to the cyprinid minnows; Tammar, 1974) and taurocholic acid, seemed unable to explain the biological activity of the non-polar fraction although both are detected by the goldfish with picomolar sensitivity (Sorensen et al., 1987; Sorensen and Stacey, 2004; Sorensen, unpublished data). However, while bile acids and related compounds have been shown to exhibit pheromonal activity in an ancient cartilaginous fish, the sea lamprey (*Petromyzon marinus;* Li et al., 2002; Fine and Sorensen, 2008), their roles as behavioral stimuli have to date been equivocal in bony fishes (Baker et al., 2006). More detailed tests are needed. Although our study did not

address the chemical identity of the active component(s) in the polar fraction, it remains possible that it is comprised of mixtures of amino acids as suggested by Saglio and Blanc (1989). Future work should fully fractionate goldfish and carp body washings to determine the identity of these pheromones.

In summary, this study has demonstrated that all life stages of goldfish produce and use a common species-specific pheromone. The pheromone awaits identification although pilot data suggest that bile acids may not play a prominent role. Because the goldfish has proven to be a good model for many fish, it seems likely that that other fish species use similar cues. It will be especially interesting to test directly how this species-identifying pheromone influences perception and function of hormonal pheromones.

New Synthesis. Thirty five years have passed since the Journal of Chemical Ecology (JCE) was first published. A glance through the contents of that inaugural volume reveals the zeitgeist of our field in 1975: papers on pheromone identification, defensive secretions, chemical attraction (or repellence), and the methods required to study these subjects, primarily by using insects and terrestrial plants as model systems. Although these themes remain current, recent issues of JCE have featured studies of cuticular hydrocarbons (especially in social insects), tri-trophic interactions, phenotypic plasticity, metabolomics, genomics and other informatics approaches, with a growing number of such studies using marine and/or microbial systems. These changes are symptomatic of a genomics-age "new synthesis" in the biological sciences, in which researchers working at levels of organization as different as coral reefs and insect guts increasingly use similar analytical tools to understand how complex interactions mediate the generation and maintenance of biological diversity.

Here, we initiate a new feature for JCE, entitled "New Synthesis", in which short essays will highlight exciting new conceptual and/or technological trends in Chemical Ecology. Chemical Ecology has always played a prominent role in the development and testing of theory in the fields of sexual selection, plant-herbivore interactions and integrated pest management. In "New Synthesis", we will trumpet the growing impact of Chemical Ecology on the study of symbiosis and mutualism, molecular ecology, community genetics and ecosystem-level biogeochemistry, among other fields.

Our goal is for these "essays" to appear monthly and to obtain contributions from important labs worldwide. Their appearance in all likelihood will be somewhat sporadic at first. For now, we are targeting individuals who have expressed interest and who are willing to write. We hope for a variety of perspectives. The thoughts of both innovators and those with mature vantage points are desired. These contributions will be subject to editorial but not peer review. We envision them to focus on a single or small group of papers and to be no longer than 500 words. We hope this will become a useful feature, and we encourage your participation.

COMMENTARY

New Synthesis—Trade-offs in Chemical Ecology

Anurag A. Agrawal

Published online: 12 March 2011

Although many chemical ecologists may not consider themselves evolutionary biologists first and foremost, evolutionary thinking pervades much of our science. Indeed, the concept of trade-offs is central to nearly all arguments about adaptation—what else would limit organisms from being perfectly adapted to all predators, changing climates, and sundry other life challenges? And such trade-offs (aka costs) often are held as a holy grail for those trying to explain variation in investment in traits, including chemical compounds, assumed to be adaptive. Nonetheless, we still lack a taxonomy for the causes and types of trade-offs. Trade-offs in chemical ecology may be caused by resource limitation, direct chemical interference, suppression of genes or biosynthetic pathways, or even divergent natural selection on a single trait. New papers, discussed below, contribute to the discourse working towards this needed taxonomy.

Because chemical compounds intertwine within organisms and biosynthetic pathways intersect during expression, there is great potential for trade-offs in chemical ecology. Recently, Ballhorn (2011) and Ballhorn et al. (2010) demonstrated the *direct chemical interference* of one plant defense by another and its ecological consequence. Using cultivated and wild lima bean (*Phaseolus lunatus*), they first report a pattern: insect resistant, high cyanide (HCN) bean accessions were susceptible to a fungal pathogen. Indeed, this pattern also was reported for clover by Rodolfo Dirzo in the early 1980s. But what is the mechanism? Ballhorn et al. (2010) show that HCN directly disrupts the enzymatic activity of polyphenol oxidase (PPO), a likely mechanism of resistance to fungi. Thus, a direct chemical trade-off results in a dilemma for plants: to resist insects or pathogens? A similar ecological pattern could, however, occur via an *ecological trade-off*. In this case, a single compound may be deterrent to some herbivores and attractive to others, as has been well-documented for cucurbitacins and some glucosinolates.

Of course, historically, and even predating Darwin, *resource-based trade-offs* were presumed to be the rule—that is, resources allocated to one trait simply cannot be allocated to another trait. Although resource-limitation clearly is important at the level of the whole organism, resource-based trade-offs are unlikely to be the direct drivers of most negative correlations between two traits. In fact, we realize now that some negative associations between traits may be *adaptive negative correlations*. Take, for example, the oft cited trade-off between chemical resistance and tolerance. Tolerance is the ability of plants to withstand and regrow following herbivory. Theory and some evidence has suggested that highly resistant plants, need not tolerate damage (and *vice versa*, highly tolerant plants do not experience selection for resistance to herbivory). If these traits are, indeed, ecologically redundant and even a little energetically costly, then a "trade-off" may occur because selection has favored it. Current mechanistic work is showing how tolerance mechanisms can be induced following herbivory. Nonetheless, we know little about the mechanistic basis of variation in tolerance, and its relation to chemical resistance among plant genotypes or species.

Finally, neither the mechanistic nor evolutionary basis of some trade-offs may be known, even if quite general. *Negative hormonal cross-talk* between jasmonate and salicylate in plant defense signaling appears to be nearly ubiquitous. Is this a resource-based trade-off? Or does it make sense for plants—when one is employed the other is not needed? It seems unlikely to be direct chemical interference. Whatever the case, all sorts of organisms manipulate these pathways to their benefit and perhaps to the decrement of plants. The latest case is the induction of salicylate by insect eggs, which reduces jasmonate-induction following egg hatch, and thereby benefits caterpillars (Bruessow et al., 2010). Isn't chemical ecology wonderful!

But remember, nearly all trade-offs can be overcome by natural selection—they just have to be important enough. Thus, an important next step is understanding the evolutionary context of trade-offs among compounds that mediate ecological interactions.

Release of Hydrogen Cyanide via a Post-secretion Schotten-Baumann Reaction in Defensive Fluids of Polydesmoid Millipedes

Yasumasa Kuwahara · Nobuhiro Shimizu · Tsutomu Tanabe

Received: 20 September 2010 / Revised: 15 January 2011 / Accepted: 7 February 2011 / Published online: 23 February 2011

Abstract Mandelonitrile benzoate, a minor defense component produced by polydesmoid millipedes, is produced in large amounts together with hydrogen cyanide following shake-disturbances administered to individuals of *Nedyopus tambanus tambanus*, *Parafontaria tonominea*, *Epanerchodus* sp., and *Epanerchodus fulvus.* These species commonly produce mandelonitrile and benzoyl cyanide (the oxidized product after discharge). The newly generated mandelonitrile benzoate was identified as a product of post secretion Schotten-Baumann reaction under basic conditions of bled bodily fluids (pH ca. 9.0), and was not an enzymatic reaction product. The reaction occurred *in vitro* even under less basic conditions [1*M* Tris-HCl buffer (pH 8.0)], and could be defined as a new mechanism of hydrogen cyanide release occurring in roughly half of polydesmoid millipedes. Species possessing no benzoyl cyanide, such as *Oxidus gracilis* and *Cryptocorypha* sp., could also produce mandelonitrile benzoate under conditions in which benzoyl cyanide was exogenously provided.

Introduction

Hydrogen cyanide is a toxic component widely distributed by arthropods and plants. It is believed to function as a defensive agent against predators or as a toxin to herbivores (Zagrobeiny et al., 2008). With the exception of a few non-cyanogenic Polydesmida such as *Niponia nodulosa* Verhoeff (Ômura et al., 2002a), *Eutrichodesmus elegans* Miyosi (Kuwahara et al., 2002), and *Eutrichodesmus armatus* Miyosi (Kuwahara et al., 2003), the majority of polydesmoid millipedes are cyanogenic, and generally are identified as containing mandelonitrile {**3**, benzaldehyde (**1**) cyanohydrine} (Mori et al., 1994; Kuwahara, 1999). Benzoyl cyanide (**2**) also is recognized as one of the major defense components of three polydesmoid millipedes (Conner et al., 1977) and of twelve species belonging to Xystodesmidae (Duffey et al., 1977).

The major constituents in the hexane rinse of *Nedyopus tambanus tambanus* are a mixture of **2** and **3**, whereas its gland's reservoir has been shown to only contain **3** (Kuwahara et al., 2008). To obtain substantial amounts of endogenous **3**, a live millipede contained in a glass vial was shaken vigorously (shake-disturbance) and then extracted by hexane. Unexpectedly, the resulting extracts contained large amounts of mandelonitrile benzoate (**4**, reaction product of **2** and **3**). The formation of **4** as a major component also was demonstrated from shake-disturbance in the three other Polydesmida.

In this study, the unusual mandelonitrile benzoate (**4**) formation was identified as the result of a Schotten-Baumann reaction between **2** and **3** (Scheme 1); a new mechanism that produces rapid emission of hydrogen cyanide. The distribution of this reaction also is discussed among related polydesmoid millipedes together with their defensive functions.

Scheme 1 Hydrogen cyanide release mechanisms evidenced in cyanogenic polydesmoid millipedes

Methods and Materials

Millipede Species The following six millipedes were used: *Nedyopus tambanus tambanus* (Attem) 1901 (Polydesmida: Paradoxomatidae); *Parafontaria tonominea* Attems, 1899 (Polydesmida: Xystodesmidae); *Epanerchodus fulvus* Haga 1956 (Polydesmida: Polydesmidae); *Oxidus gracilis* C. L. Koch (Polydesmida: Paradoxosomatiae); *Cryptocorypha* sp. (Polydesmida: Pyrgodesmidae); and *Epanerchodus* sp. (Polydesmida: Polydesmidae). *Nedyopus tambanus tambanus*, *P. tonominea* and *Ep. fulvus* were collected around the campus of Kyoto Gakuen University in Kameoka in the Kyoto Prefecture. *Cryptocorypha* sp. was obtained from litters in the Osaka prefecture, as well as on the campus of Kyoto Gakuen University. *Oxidus gracilis* was collected from litters in Kyoto city, and *Epanerchodus* sp. (at the 7th stage, examined by T. Tanabe) from litters at Lake Usui in the Gunma Prefecture. Individuals were maintained by feeding rotten plant material. Specimens of unidentified millipedes, *Cryptocorypha* sp. and *Epanerchodus* sp., were deposited in the Kumamoto University (Kumamoto Japan 860-8555) millipede collections (T. Tanabe, accession number D5120 and D5121, respectively).

Chemicals Mandelonitrile (**3**, tech. grade), benzoyl cyanide (**2**, 98%), and n-tetradecane (99+%) were obtained from Sigma-Aldrich Co, Japan. Benzaldehyde (**1**, reagent grade, Wako Pure Chem. Co. Ltd. Japan), n-hexane (reagent grade, Wako Pure Chem. Co. Ltd. Japan), and others were commercially available. Mandelonitrile benzoate (**4**) was prepared by a Schotten-Baumann reaction as described below.

Chemical Analysis Gas chromatography-mass spectrometry (GC-MS) analysis was conducted using a Network GC System (6890N; Agilent Technologies Inc.) coupled with a mass selective detector (5975 Inert XL; Agilent Technologies Inc.) operated at 70 eV, using an HP-5MS capillary column (0.25 mm i.d.×29 m, 0.25 μm film thickness; Agilent Technologies Inc.). Helium was used as the carrier gas at a flow rate of 1.00 ml/min, with a split-less mode at a temperature programmed to change from 60°C (2 min) to 290°C at a rate of 10°C/min. This temperature was maintained for 5 min. GC and GC-MS data were obtained by Chemstation (Hewlett Packard Co.), with reference to an MS database (Wiley275 library; Hewlett Packard Co.).

pH of Millipede Body Fluids The pH of two species, *Ne. tambanus tambanus* and *O. gracilis* were measured by pH indicator paper (pH 1–14; Johnson Test Papers Ltd.).

Detection of Hydrogen Cyanide A piece of sodium picrate paper was exposed to the atmosphere of a test vial containing a millipede to determine the presence of hydrogen cyanide.

Conventional Hexane Extraction of Millipedes (Total Six Species) Each adult (or immature) millipede was submerged alive in a screw-capped glass vial (10 ml, 5 ml, or 1 ml in volume, depending upon the body size of the millipede species) that contained the following amounts of hexane; 0.5 ml for *Ne. tambanus tambanus*; 2 ml for *P. tonominea*; 0.3 ml for *Epanerchodus* sp.; 0.1 ml for *Ep. fulvus*; 1 ml for *O. gracilis*; and 0.05 ml for *Cryptocorypha* sp. The resulting hexane extracts, collected by decantation, then were analyzed by GC-MS.

Hexane Extraction of Shake-disturbed Millipedes (Total Six Species) Before extraction, each live millipede was shaken vigorously in a glass vial by hand for 2 min. Hexane (volume for each species, as above) was then added, and vials were kept for 3 min at room temperature. Secretions smeared on the inner wall of the vial were simultaneously extracted and recovered. The extract was collected by decantation followed by GC-MS analysis.

*Hexane Extraction of Shake-disturbed Millipedes Kept in Vials with Exogenously Provided Benzoyl Cyanide (**2**) (Total Two Species)* The following procedure was applied to the species *O. gracilis* and *Cryptocorypha* sp. Either 100 μg (*O. gracilis*) or 30 μg (*Cryptocorypha* sp.) of authentic benzoyl cyanide (**2**, dissolved in hexane) was exogenously introduced into each vial. The millipede then was added and shake-disturbed following evaporation of the solvent. The millipede and inner wall of the vial were extracted for 3 min by hexane as above, and extracts then were analyzed by GC-MS as described.

*Incubation of **2** and **3** Mixtures with Macerated Millipede* To explore the possibility of an enzymatic reaction, a macerated *Ne. tambanus tambanus* (as the "crude enzyme") was incubated in hexane (0.1 ml) containing a mixture of **2** (100 μg) and **3** (100 μg), together with n-tetradecane (100 μg) as an internal standard. The "crude enzyme" was prepared by crushing a millipede with a glass rod, followed by subsequent washing (twice) with hexane to remove non-

polar components and any secreted defense compounds. Following incubation, organic layers were analyzed by GC-MS at intervals of 3, 40, and 85 min, respectively, to monitor reaction during the hexane incubation period. As a control, a macerated millipede body subjected to a treatment of 100°C for 30 min in a small, sealed glass tube (heat denatured) was incubated similarly at room temperature.

Schotten-Baumann Reaction Between **2** *and* **3** *Using Tris-HCl Buffer (pH 8.0)* A neat stock mixture was prepared by dissolving compounds **2** (131 mg, 1 mmol) into compound **3** (133 mg, 1 mmol) without a solvent. A drop of 1 *M* Tris-HCl buffer (pH 8.0) was added to a portion of the stock mixture (**2** and **3**, less than 10 mg) in a test tube (5 cm length × 0.7 cm o.d.). After 1 min, the reaction mixture was extracted with hexane. After appropriate dilution, this extract was analyzed by GC-MS.

As a control, one drop of distilled water was similarly added to the stock (**2** and **3**, less than 10 mg). After 1 min, the resulting mixture was extracted similarly, diluted by hexane, and analyzed by GC-MS.

Results and Discussion

The defense secretion of *Ne. tambanus tambanus* was directly sampled by using a glass capillary and was found to contain solely mandelonitrile **(3)**, whereas the conventional solvent extracts contained a mixture of benzoyl cyanide (**2**, 23.1±9.5 μg in males and 13.8±2.7 μg in females) and mandelonitrile (**3**, 34.6±5.6 μg in males and 30.9±5.6 μg in females) (Kuwahara et al., 2008). The content of **3** was calculated from that of benzaldehyde (**1**, a thermally decomposed product from **3** during GC-MS analysis, Mori et al., 1995).

As discussed earlier, endogenous **3** was not obtained by shaking (shake-disturbance) and subsequent hexane rinse. The GC profile of the hexane extracts, unexpectedly, showed a major peak at t_R 18.18 min for mandelonitrile benzoate (**4**) as the most abundant component (Fig. 1b), together with two small peaks at t_R 5.67 min (artifact from **3**) and 7.80 min for **1** and **2**, respectively. Although the ester (**4**) is commonly distributed among Polydesmoid millipedes as a minor component (Duffey et al., 1977; Eisner et al., 1978), the shake-disturbance of *Ne. tambanus tambanus* increased its production by 50 fold, although **2** and **1** (artifact from **3**) decreased, respectively, to 1/10 and 1/4 of the control (undisturbed and conventional solvent extraction) (Fig. 1a). Hydrogen cyanide release upon shake-disturbance also was confirmed by the development of dark orange color on sodium picrate paper. During shaking, the inner surface of the vial became wet from smeared defense secretions and/or bodily fluids that bled out.

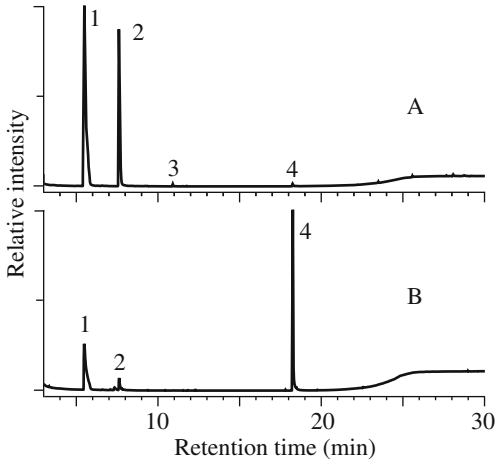

Fig. 1 A typical GLC of the defense secretion from *Nedyopus tambanus tambanus*. **a** Conventional hexane extracts; **b** Shake-disturbed extracts. **1**, benzaldehyde; **2**, benzoyl cyanide; **3**, mandelonitrile; and **4**, mandelonitrile benzoate

This effect of shake-disturbance similarly was examined in *O. gracilis*, whose defense secretions consisted only of **3** (detected as **1** by GC) as cyanogen together with non-cyanogenic minor components (Taira et al., 2003). No difference was observed between GC chromatograms of the conventional extract (Fig. 2a) and extracts post

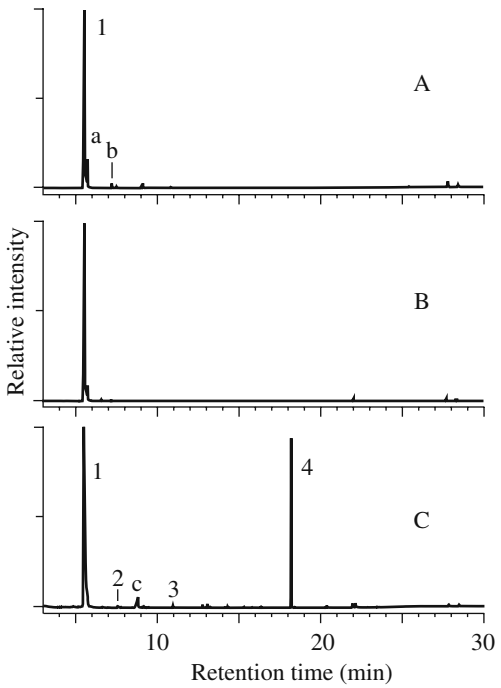

Fig. 2 A typical GLC of the defense secretion from *Oxidus gracilis*. **a** Conventional hexane extracts; **b** Shake-disturbed extracts; **c** Shake-disturbed extracts upon addition of benzoyl cyanide. **1**, benzaldehyde; **2**, benzoyl cyanide; **3**, mandelonitrile; **4**, mandelonitrile benzoate; a, phenol; b, *p*-cresol; and c, benzoic acid

shake-disturbance (Fig. 2b), while shake-disturbance with exogenously introduced **2** (100 μg) produced **4**, as summarized in Fig. 2c. Based on these observations, it is clear that the production of **4** is dependent on the occurrence of **2** and **3**.

Among eleven Japanese cyanogenic Polydesmida (Table 1), the following six species contained **1** (as **3**), **2**, and **4** together with sporadic detection of **3** by GC: *Ne. tambanus tambanus* (Kuwahara et al., 2008), *P. tonominea* (Ômura et al., 2002b), *Epanerchodes sp*., *Ep. fulvus*, *Chamberlinius hauliensis* (Noguchi et al., 1997a), and *P. laminata armigera* (Mori et al., 1995). In addition to *Ne. tambanus tambanus*, the following three species demonstrated the effect of shake-disturbance to produce large amounts of **4**, as summarized in Fig. 3: *P. tonominea*, *Epanerchodes* sp., and *Ep. fulvus*. In the case of *P. tonominea*, **4** increased 21 fold, with a decrease of **2** to 1/46 and a 1.6 fold increase of **1**. In the case of *Epanerchodus* sp., **4** increased 94 fold, with a decrease of **1** and **2** to 3/16 and 17/48, respectively. In the case of *Ep. fulvus*, **4** increased sevenfold, with an unchanged level of **2** and a decrease of **1** to 3/19. Shake-disturbance, therefore, promoted significant production of **4**, with a corresponding decrease in production of **1** and **2**.

In contrast, the following five species release compound **3** (detected as **1** by GC) as only one cyanogen together with non-cyanogenic minor components: *O. gracilis* (Taira et al., 2003), *Cryptocorypha* sp., *Ep. japonicus* Carl. (Mori et al., 1994), *Riukiaria semicircularis semicircularis* (Ômura et al., 2002b), and *Ne. patrioticus patrioticus* (Noguchi et al., 1997b). Neither **2** nor **4** were detected in these species, except in cases of exogenously introduced **2** (100 μg) to *O. gracilis*, as described earlier. The same shake-disturbance effects were reproduced in *Cryptocorypha* sp. in the presence of exogenously introduced **2** (30 μg), as summarized in Fig. 3 and Table 1.

The ester (**4**) formation was hypothesized to occur through the process of enzyme(s) reaction; the possibility of this process was explored with *Ne. tambanus tambanus*. An entire hexane-washed millipede body submerged in the substrate (hexane solution of **2** and **3**) did not generate **4**, although a macerated body catalyzed the production of **4**. However, even after heat treatment, the reactivity to **4** did not decrease, and **4** was similarly produced during 85 min incubation at room temperature together with decreased production of **2** and **3** (as **1**) (Fig. 4). Therefore, enzyme(s) reaction is excluded as a possibility for the demonstrated formation of **4**.

This result, although puzzling at first, led us to discover a new mechanism of hydrogen cyanide release (cyanogenesis) distributed among cyanogenic millipedes. Based on the following evidence, formation of **4** was inferred as the Schotten-Baumann reaction (Kuerti and Czako, 2005) between **2** and **3** under alkaline body fluids conditions: 1) the reaction occurs in the presence of body fluids that may bleed from shake-disturbance; 2) the body fluids are basic

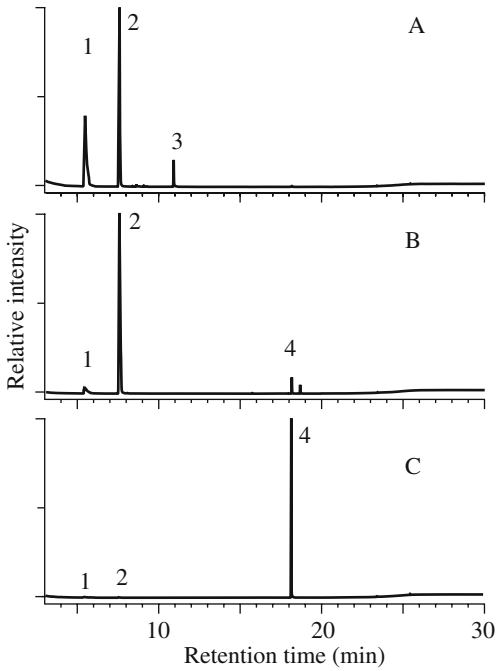

Fig. 5 A reaction between benzoyl cyanide **2** and mandelonitrile **3** under Schotten-Baumann conditions. **a** Control (mixture of benzoyl cyanide **2** and mandelonitrile **3**); **b** reaction after addition of a drop of water; **c** reaction after addition of a drop of pH 8 buffer (1*M* Tris-HCl buffer). **4**, mandelonitrile benzoate

(pHs of *Ne. tambanus tambanus* and *O. gracilis* were ca. 9.0); and 3) cyanide (**2**) is a potent reagent, equivalent to acid halide or acid anhydride, to produce esters or amides with alcohols or amines under basic conditions.

As a trial, one drop of pH 8.0 buffers was added to the neat mixture (less than 10 mg, transparent oil) of **2** and **3**. The mixture instantly turned milky-white, and produced **4** as a major product with no remaining trace of **2** or **3** (as **1**) (Fig. 5c). No reaction occurred with the addition of a drop of water to the same mixture, and a large amount of unreacted **2** was obtained together with a small amount of **4** (Fig. 5b, the nitrile (**3**, as **1**) appeared to be largely lost due to its solubility in water). In contrast, the mixture of **2** and **3** did not begin to react without alkaline conditions, even during both neat and heated conditions, whereas a dilute mixture in hexane seemed to react gradually during storage. As a whole, formation of **4** by shake-disturbance occurred as a result of the Schotten-Baumann reaction between **2** and **3** under basic conditions of bled bodily-fluids to release hydrogen cyanide instantly (Scheme 1).

The nitrile **3** is biosynthesized from phenylalanine (Duffey et al., 1974), and the directly sampled defensive secretion from a gland's orifice of *Ne. tambanus tambanus* by a glass capillary is composed only of **3** (Kuwahara et al., 2008). The cyanide (**2**, an oxidation product from **3** and extractable by hexane) is not involved in the biosynthetic sequence, thus suggesting transformation during or after discharge from the defensive gland. Similarly, the oxidized compound 2-methyl-3,4-methylenedioxyphenol (considered to be a reaction product between 2-methoxy-3-methyl-1, 4-benzoquinone and its hydroquinone), has been reported in a millipede *Acladocricus setigerus* (Diplopoda:Spirobolidida) (Wu et al., 2007). Although its production is explained chemically (Wu et al., 2007), it is reasonable to suggest the involvement of oxidation/reduction enzyme(s). In fact, previously we have demonstrated similar dehydrogenase (oxidase) activity in Astigmatid mite bodies suspended in hexane. It operates reversely to change citral (a mixture of neral and geranial) to its alcohols (Kuwahara et al., 1983), and has been characterized from *Carpoglyphus lactis* as a new class of dehydrogenase, with almost no homogeneity to currently known groups (Noge et al., 2008). Although the origin of **2** in millipedes remains unclear, the Schotten-Baumann reaction between **2** and **3** is concluded to be a new mechanism of instantaneous hydrogen cyanide release against enemy attack, emitting defensive secretions together with bled bodily fluids.

In Japan, a total of 14 polydesmoid millipedes have been studied based on their defensive secretions, among which eleven species are cyanogenic (listed in Table 1), with the remaining three, *Ni. nodulosa* Verhoeff (Ômura et al., 2002a), *Eu. elegans* Miyosi (Kuwahara et al., 2002), and *Eu. armatus* Miyosi (Kuwahara et al., 2003), identified as non-cyanogenic. The eleven cyanogenic species now are divided into two groups, with one group denoted by the first six species in Table 1, in which either the Schotten-Baumann reaction has been demonstrated to produce **4** together with hydrogen cyanide release, or its production is indicated by the presence of **2** and a detectable amount of **4** in the solvent extract. These millipedes belong either to Paradoxosomatidae, Xystodesmidae, or Polydesmidae.

The second group corresponds to the latter five species in Table 1. Although their defense secretions are composed of only **3**, a detectable amount of **4** is produced when a millipede is shake-disturbed with exogenously added benzoyl cyanide (**2**), as demonstrated in *O. gracilis* and *Cryptocorypha* sp. (Fig. 3 and Table 1). The millipedes from this second group belong either to Paradoxosomatidae, Xystodesmidae, Polydesmidae, or Pyrgodesmidae. Based solely on Japanese cyanogens millipedes, instantaneous hydrogen cyanide release by the Schotten-Baumann reaction, as a whole, might be distributed among roughly half the cyanogen millipedes that belong either to Paradoxosomatidae, Xystodesmidae, or Polydesmidae. Other than these species, defensive secretions **2** and **4** are known in millipedes belonging to three polydesmoid (Conner et al., 1977), as well as to twelve species that belong to Xystodesmidae (Duffey et al., 1977), whereas involvement of the present post-secretion Schotten-Baumann reaction has not been previously identified as a hydrogen cyanide release mechanism by millipedes. At present, no taxonomic evidence is available in the literature to support an evolutionary trend. However, the defensive mechanism might be a more advanced and evolved chemical defense than the natural or lyase-catalyzed dissociation of labile **3** to hydrogen cyanide and benzaldehyde (**1**), as in the case of *Harpaphe haydeniana* (Xystodesmidae: Polydesmida) (Duffey and Towers, 1978) (Scheme 1).

Abstract We considered the effects of plant secondary metabolites on the immune response, a key physiological defense of herbivores against pathogens and parasitoids. We tested the effect of host plant species and ingested iridoid glycosides on the immune response of the grazing, polyphagous caterpillar, *Grammia incorrupta* (Arctiidae). Individuals of *G. incorrupta* were fed either one of three plant diets with varying secondary metabolites, or an artificial diet with high or low concentrations of iridoid glycosides. An immune challenge was presented, followed by measurement of the encapsulation response. We failed to detect a significant difference in the immune response of *G. incorrupta* feeding on diets with varying concentrations of iridoid glycosides, or feeding on different host plants. However, the immune response was lower in caterpillars consuming the artificial diet compared to those consuming the plant diets. When caterpillar performance was measured, pupal weights were lower when caterpillars ingested high concentrations of iridoid glycosides due to a decrease in feeding efficiency. Overall, individuals of *G. incorrupta* that consumed different plant diets exhibited a high immune response with low variation. We conclude that the immune response of *G. incorrupta* is adapted to feeding on a variety of plants, which may contribute to the maintenance of this caterpillar's polyphagous habit.

Introduction

Insect herbivores rely on host plants to meet daily nutritional requirements needed for proper metabolism and growth. Beyond these basic physiological functions, host plant secondary metabolites may help structure herbivore interactions with natural enemies (Turlings et al., 1990; Dyer, 1995; Smilanich et al., 2009a). Detoxification or accumulation of these metabolites may incur physiological costs (Camara, 1997; Despres et al., 2007), leading to ecological and evolutionary consequences (Bowers, 1992; Nishida, 2002). A variety of studies have demonstrated that ingestion and sequestration of secondary metabolites renders herbivores unpalatable to predators such as birds, wasps, and ants (e.g., Bowers, 1992; Dyer, 1997; Vencl et al., 2005), thus providing protection from predators. However, ingestion of secondary metabolites also can increase susceptibility to natural enemies such as parasitoids because (1) chemically-defended herbivore hosts provide enemy-free space for parasitoid development (Gentry and Dyer, 2002), or (2) sequestration and/or detoxification of secondary metabolites alters herbivore immune responses (Smilanich et al., 2009a).

The insect immune response is an effective defense against parasitoids and pathogens (Beckage, 2008; Smilanich et al., 2009b). In this paper, we investigated

whether diet causes variation in the immune response, which could lead to vulnerability to parasitism. In particular, we presented an immune challenge to polyphagous, sequestering caterpillars that were consuming different levels of secondary metabolites.

The immune response consists of three main components: phagocytosis, nodule formation, and encapsulation (Carton et al., 2008). Encapsulation is the concerted action in which specialized immune cells (hemocytes) adhere to a large foreign body, such as a parasitoid or parasitoid egg, and build layers of cells that eventually are melanized. The cytotoxic effect of melanization and asphyxiation from encapsulation both contribute to killing the pathogen (Carton et al., 2008). Host plant chemistry can have negative, positive, or neutral effects on the immune response (Klemola et al., 2007, 2008; Bukovinszky et al., 2009; Smilanich et al., 2009a). Plant nutrients (e.g., protein) can enhance encapsulation and lysozyme-like antibacterial activity, but may have little effect on other immune system components like phenoloxidase activity (Lee et al., 2008; Povey et al., 2009). Ingestion and sequestration of some plant secondary metabolites (e.g., iridoid glycosides) can weaken the immune response by directly interfering with the melanization component of immunity (Smilanich et al., 2009a), whereas other metabolites (e.g., hydrolyzable tannins) may act indirectly on immunity via reductions in herbivore performance (Haviola et al., 2007; Yang et al., 2008). In contrast, carotenoids, flavonoids, and synthetic chemicals may enhance immunity, perhaps by quenching harmful oxygen species (Babin et al., 2010).

Given the possibility that plant chemistry may have a negative effect on the immune response, herbivores face the dual challenge of digesting and assimilating plants of variable quality and at the same time maintaining the immune response in order to evade parasitoids. Here, we used experiments with the grazing generalist caterpillar, *Grammia incorrupta* Hy. Edwards (Arctiidae), to address the following questions: (1) what are the effects of three host plant species with different nutrient and secondary chemical profiles on the immune response, and (2) what are the effects of iridoid glycosides (IGs) added at different levels to a standard diet on the immune response? *Grammia incorrupta* larvae sequester pyrrolizidine alkaloids (0.3 to 2.7 mg/g dry wgt, Hartmann et al., 2005) and low levels of IGs (Bowers, 2009).

To address these questions, larvae were reared on three different host plants: *Plantago major* (Plantaginaceae), which has low concentrations of one IG, aucubin (Barton and Bowers, 2006); *P. lanceolata*, which has high concentrations of two IGs, aucubin and catalpol (Bowers and Stamp, 1992), and *Taraxacum officinale* (Asteraceae), which has no IGs, but does contain flavonoids, phenolics, and sesquiterpenes (Schutz et al., 2006). Larvae were presented with an immune challenge and the immune response was analyzed. To more specifically examine the effects of IGs, larvae were fed artificial diets that contained extracted IGs (aucubin and catalpol) and were then presented with an immune challenge. For the artificial diet experiment, we also measured feeding efficiency in order to test for a relationship between food utilization and the immune response. Based upon previous work (Smilanich et al., 2009a), we predicted that ingestion of IGs would negatively affect the immune response, and that host plants with the highest content of IGs would be detrimental to the immune response.

Methods and Materials

Experimental Overview Experiments with *G. incorrupta* were performed at Tulane University, New Orleans, LA, USA during fall 2006, and at University of Colorado, Boulder, CO, USA during fall 2008. Egg masses were obtained from an established lab colony at Wesleyan University, Middletown, CT, USA (courtesy of M.S. Singer). The first experiment tested the effects of host plant species on the immune response. The second experiment tested the effects of high and low concentrations of IGs on the immune response and feeding efficiency by using an artificial diet with added IG extract.

Immune Assay To measure the immune response, *G. incorrupta* caterpillars were injected with Sephadex beads as a proxy for parasitization (Lavine and Beckage, 1996; Rantala and Roff, 2007; Smilanich et al., 2009a,b). The beads (Sigma-Aldrich, Sephadex A25, 40–120 μm) were dyed red using 0.1% Congo red and were suspended in Ringer's solution so that 5–10 beads could be injected into the base of the third proleg (Lavine and Beckage, 1996). Caterpillars then were returned to their test diets and after 24 hr were freeze-killed. Caterpillars were dissected in 95% methanol, and beads were photographed with a camera mounted on a dissection microscope focused at 80× magnification (Carl Zeiss Discovery V.8, AxioVision software). Since the beads were dyed red before injecting them into the caterpillars, we quantitated melanization by measuring the red value (r-value, Adobe Photoshop ver. 6.0), a scale ranging from 0–255, where 0 = pure gray, and 255 = pure red, for each bead. The mean r-value for all the beads from each caterpillar was statistically compared between treatments, using ANOVA with r-value as the dependent variable and treatment as the independent variable. The r-value was transformed into percent melanization [1−(r-value/maximum r-value)] where the maximum r-value is 255 for a non-injected, unmelanized bead.

Experiments with Three Host Plants Caterpillars were randomly assigned to one of three diets: *T. officinale*, *P. lanceolata,* or *P. major*. *Plantago major* contains only one iridoid glycoside, aucubin, at relatively low levels (0.2–1.0% dry weight) (Barton and Bowers, 2006), while *P. lanceolata* contains both aucubin and its derivative catalpol at much higher concentrations, ranging from 5–12% dry weight (Bowers and Stamp, 1992). *Taraxacum officinale* does not contain iridoid glycosides, but does contain flavonoids generally considered less toxic to herbivores (Harborne, 1991; Schutz et al., 2006). Newly hatched larvae were reared in groups of five in plastic rearing cups in growth chambers with 16:8 h L:D control, and 25°C daytime, 20°C nighttime temperatures. Plants were collected from Boulder County, CO, USA, soaked in dilute bleach solution for approximately 10 min, rinsed three times, and spun dry in a salad spinner before they were offered to caterpillars *ad libitum*. After molting to the 6th instar, 25 caterpillars feeding on each of the three host plants were removed in order to test the immune response. An additional 20 *G. incorrupta* caterpillars from each of the *Plantago* treatments were removed, injected, and immediately frozen for assessment of IG sequestration. Ten individuals from each host plant were dissected in methanol, and 10 were left intact in order to determine whether the dissection procedure affected IG sequestration. Five subsets of leaves of *P. major* and *P. lanceolata* from the material fed to caterpillars were dried at 50°C to a constant weight, ground to a fine powder, and subsampled to quantify IGs.

Chemical Analysis Iridoid glycosides in plant material and caterpillars reared on *P. major* and *P. lanceolata* were quantified by gas chromatography. Frozen caterpillars were ground in 5 ml of 95% methanol and extracted overnight. Those caterpillars that had been previously dissected were extracted overnight in the methanol solution utilized for the dissection. A subsample (25 mg) of dried plant material was extracted in 5 ml of 95% methanol overnight. Caterpillar and leaf samples were filtered, and the methanol was removed by evaporation. An internal standard (phenyl-β-D-glucose, Sigma-Aldrich, St. Louis, MO, USA) was added, and the sample was partitioned between water and ether in order to remove hydrophobic compounds. The water phase was collected, evaporated to dryness, and the residue was dissolved in 1 ml methanol. An aliquot of 100 μl was dried overnight, derivitized with 100 μl Tri-Sil-Z (Pierce Chemical Company, Rockford, IL, USA) and injected (1 μl) into a Hewlett Packard 5890A gas chromatograph equipped with a FID detector for separation as described by Bowers and Stamp (1992). The two iridoid glycosides, aucubin and catalpol, were identified by comparison with standards of the pure compounds that were extracted and isolated from plant material (Camara, 1996) and quantified using Agilent Chem Station software.

Artificial Diet Experiment This experiment was designed to measure the effects of IGs on the immune response while holding all other diet variables equal. Thus, we used an artificial diet (Lei and Camara, 1999) to which we added known concentrations of IGs. Iridoid glycosides were extracted and purified from *P. lanceolata* collected from Southern Alabama (Camara, 1996). The crude extract comprised 8% IG making it impossible to adjust the artificial diet to 12% IG, which is the upper limit found in natural plant populations. Crude extract was dissolved in water and added to the artificial diet mix to yield a 1% (low concentration) and a 5% (high concentration) IG diet. Newly hatched caterpillars were assigned randomly to high or low diets and placed in individual plastic rearing cups (30 per treatment) with food. Rearing cups were kept in a walk-in growth chamber with environmental conditions set at 12:12 h L:D at 23°C. The immune response was tested at the beginning of 6th instar.

Feeding Efficiency Experiments For the artificial diet experiment, feeding efficiency was calculated using the standard gravimetric method (Waldbauer, 1968). All measurements were obtained over a standardized time interval starting at third instar and ending when caterpillars molted into 6th instar. Measurements included food mass, body mass, and fecal mass each day. In addition, samples of larvae and diet were dried and weighed at the beginning and the end of the experiment. Growth rate and feeding efficiency measures were analyzed using MANOVA where measurements at each instar were considered separate response variables (i.e., multivariate repeated measures). The following indices were calculated for each caterpillar:

Efficiency of conversion of ingested food (**ECI**) = larval dry weight gain/dry weight of food consumed
Approximate digestibility (**AD**) = (dry weight of food consumed − dry weight of frass)/dry weight of food consumed
Efficiency of conversion of digested food (**ECD**) = larval dry weight gain/(dry weight of food consumed − dry weight of frass)
Growth Rate (**GR**) = larval dry weight gain/(duration of feeding period*mean weight during growth interval).

(1)

Results

Three Host Plants Individuals of *G. incorrupta* that fed on the three different host plants did not significantly differ in their immune response ($F_{2,4}$=2.69, N=42, P=0.081) (Fig. 1a). Within each species, the iridoid glycoside content was quite variable but overall *P. lanceolata* had a higher IG content than *P. major* (*t*-test, P=0.015) (Fig. 2). *Grammia incorrupta* larvae sequestered very low levels of IGs (Fig. 2) and fewer than 40% of the larvae tested contained detectable amounts. To determine whether dissection of larvae affected IG content by promoting breakdown of the IGs, we performed a two-way ANOVA on the arcsine square root transformed proportion of total IGs in larvae, with host plant and dissection as the main effects. For this analysis, we used only those larvae in which IGs were detected (only aucubin for larvae reared on *P. major* and both aucubin and catalpol for larvae reared on *P. lanceolata*). The amount sequestered was not affected by host plant species ($F_{1,10}$=2.52, P=0.143) or by dissection ($F_{1,10}$=3.84, P=0.079), although there was a trend for dissected larvae to contain higher levels of IGs (Fig. 2), nor was there an interaction ($F_{1,10}$=0.220, P=0.649).

Artificial Diet When individuals of *G. incorrupta* were fed IGs in an artificial diet at 5% and 1% concentrations, there was no significant difference in the melanization response ($F_{1,70}$=0.01, N=71, P=0.907) (Fig. 1b). Pupal weights were higher on the 1% iridoid diet compared to the 5% iridoid diet ($F_{1,37}$=10.76, N=38, P=0.002). There were no significant differences in growth rates across all instars (Table 1), indicating that the higher pupal weights on the 1% diet were not a result of slower growth, which could allow more time to feed. The difference in pupal weights may be due to significant differences in the digestion indices. The ECI and ECD differed significantly between diets (Table 1). For both indices, the mean consumption (dry weight of food consumed / average larval dry weight during interval) for caterpillars feeding on the 1% IG diet were higher. However, AD did not significantly differ between caterpillars feeding on the 1% and the 5% diets (Table 1). These results indicate that while caterpillars may be assimilating nutrients from food (AD) efficiently on both diets, they are less efficient at converting the assimilated nutrients into caterpillar biomass on the 5% iridoid diet, thus resulting in lower pupal weights.

Discussion

Our initial hypothesis that ingestion and sequestration of iridoid glycosides would cause significant decreases in the immune response was not supported. Sequestration was a poor predictor of variation in the immune response, since overall sequestration was low, and many individuals had undetectable levels of IGs. Poor sequestration ability also was found in another generalist arctiid, *Estigmene acrea* (Lampert and Bowers, 2010). Individuals feeding on diets with high and low concentrations of IGs exhibited almost identical immune responses. The overall high levels of melanization on the plant diets, and the low amount of variation among all diets suggest that individuals of *G. incorrupta* have a reliably strong immune response.

There was, however, a 37% difference in melanization score between caterpillars feeding on the artificial diet and caterpillars feeding on the plant diets. The relatively lower degree of melanization in larvae fed on the artificial diets may be due to the lack of essential substrates necessary for the phenoloxidase cascade to occur. The phenoloxidase cascade promotes the melanization process that darkens the cells encapsulating a foreign object (Beckage, 2008). The artificial diet contains only essential nutrients so that caterpillars are not ingesting pigments or other plant components that may be required for melanization.

Immune responses can be highly variable in insects (Rolff and Siva-Jothy, 2003). This variation is attributed to environmental stress (van Ooik et al., 2008), diet (Smilanich et al., 2009a), genetic variation (Lazzaro et al., 2004), or predation pressure (Slos et al., 2009). In our study, the only variation in the melanization response was associated with artificial diets vs. leaf diets. The results with

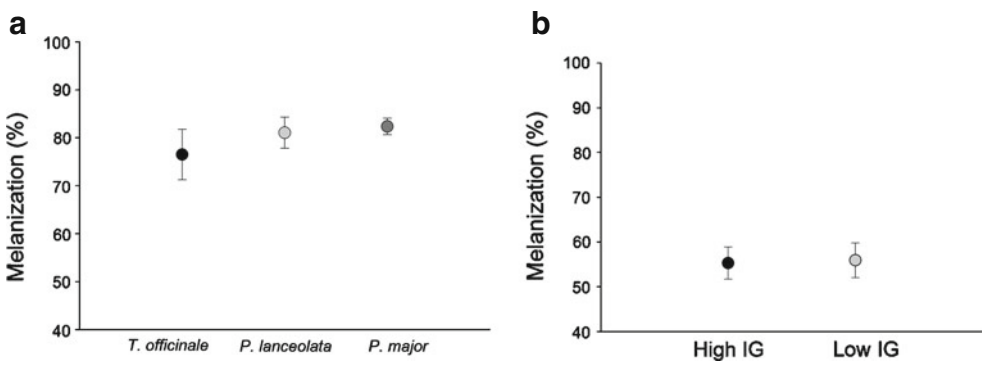

Fig. 1 Response to immune challenge for *Grammia incorrupta* consuming plant diets (*Taraxacum officinale, Plantago lanceolata*, or *Plantago major*) (**a**) or iridoid glycoside (IG)-containing artificial diets (**b**). The immune response was measured as % melanization of injected particles

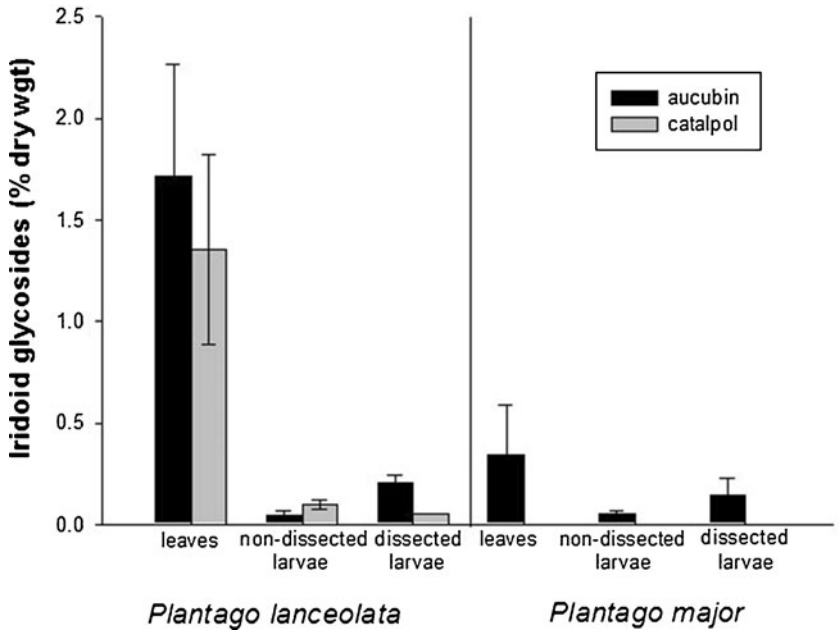

Fig. 2 Level of iridoid glycosides in *Plantago lanceolata* and *P. major*, and in intact or dissected *Grammia incorrupta* fed on either *P. lanceolata* or *P. major*

leaf diets suggest that high concentrations of IGs in the diet are not directly toxic to the immune system in this species. One reason for the low variation among diets in this study may be because this species is not efficient at sequestering IGs. In a previous study, we found that the specialist buckeye caterpillar, *Junonia coenia* (Nymphalidae), which can sequester IGs in concentrations as high as 25% dry weight (Bowers and Stamp, 1997), had a significantly lower melanization response when sequestering high concentrations of IGs (Smilanich et al., 2009a). Since *G. incorrupta* inefficiently sequesters IGs, the impact of the compounds on the immune response is probably minimal, thus leading to the small effect observed in our study.

Consumption of the 5% IG diet caused a significant decrease in pupal weights compared to the 1% IG diet. This effect most likely was driven by differences in the consumption indices, ECI and ECD, which were dramatically lower (36%) on the high IG diet. In our study of immune-challenged insects, feeding efficiency can give an approximation of the metabolic costs of feeding on diets with high concentrations of secondary metabolites coupled with mounting an immune response. The ECI measures the overall efficiency with which the caterpillar assimilates food into biomass. This measurement is broken down into the AD and ECD, where AD measures the proportion of nutrients that are assimilated from the ingested food (predigestion), and ECD measures the proportion of assimilated food that is turned into caterpillar biomass. If individuals on the high IG diet are consuming less and converting less of the digested food to biomass, then a decrease in pupal weights is expected. This difference in pupal weights was not correlated with growth rate or development time since there was no significant difference between diets for these variables. Instead, the increase of IG concentration in the caterpillar's diet negatively affected pupal weights by interference with consumption and post-digestive ability. Since pupal weights are correlated with adult fecundity (Gilbert et al., 1984), *G. incorrupta* fecundity may be lower when

MANOVA was used to analyze GR, growth rate; ECI, efficiency of conversion of ingested food; AD, approximate digestibility; ECD efficiency of conversion of digested food. Mean values are reported (standard error of the mean, *SEM;* sample size, *n*). *F* is reported as Wilks' Lambda

feeding on plants with high concentrations of secondary metabolites. However, if individuals of *G. incorrupta* are able to switch hosts easily, then continued feeding on a nutritionally poor plant is unlikely unless individuals are parasitized (Singer et al., 2009).

The ability to switch host plants and feed on plants with suboptimal quality can be an asset for an insect challenged by a parasitoid (Karban and English-Loeb, 1997; Singer et al., 2009). Switching hosts as a defense against parasitoids may outweigh any developmental costs suffered by feeding on an inferior host. Our study provides further support that being a polyphagous feeder is advantageous by demonstrating that the immune response did not vary among three plant species, which are likely to have different nutritional qualities as well as differences in secondary metabolite contents.

The evolution of herbivore diet breadth is complex and influenced by many variables (Singer and Stireman, 2005). Here, we found that the immune response, which is one of the most effective defenses against parasitoids, did not vary among a select set of host plant species and was not affected by one group of secondary metabolites, iridioid glycosides. This lack of variability may allow individuals to feed on a variety of plants without detrimental effects on the immune response. Recent work has demonstrated that pyrrolizidine alkaloids, which are actively sequestered by *G. incorrupta*, also do not affect the immune response (Smilanich et al., 2011). In light of these results, we suggest that this polyphagous caterpillar is well adapted to feeding on host plants of variable quality with no detrimental effect on its immune response.

Acknowledgments This work was funded by NSF grants DEB 0614883 and CHE 0718732 as well as EarthWatch Institute funding. Thanks to Michael S. Singer (Wesleyan University) for providing caterpillars and Evan Lampert, Jeff Chambers, and Grant Gentry for providing comments on earlier versions of the manuscript. Excellent technical assistance was provided by EarthWatch volunteers and students in the Chemical Ecology Laboratory at Tulane University.

Abstract Epicuticular lipids are contact cues in intraspecific chemical communication in insects, both for aggregation and sexual behavior. Triatomine bugs are vectors of the parasite *Trypanosoma cruzi*, the cause of Chagas disease. In *Triatoma infestans*, the major epicuticular lipids are hydrocarbons, fatty alcohols, and free and esterified fatty acids. Previously, we found that epicuticular lipid extracts, or selected fatty acid components, trigger aggregation and arrestment behavior in this bug. Using headspace solid phase microextraction, we found no sexual dimorphism in epicuticular hydrocarbons, but found female-specific fatty alcohols (eicosanol and docosanol). The role of epicuticular lipids in *T. infestans* copulation behavior was tested by observing male responses to live or various treatments of freeze-killed females. We report that hexane-soluble contact cues on females trigger copulation by males. Freeze-killed intact females were attractive to males, but no response was observed when males were exposed to hexane-washed females. Responses were partially recovered when epicuticular extract was applied to the dorsal surface of dead, hexane-washed females. One female equivalent of docosanol, evoked similar responses.

Key Words Contact sex pheromone · Mating behavior · Fatty alcohols · Hydrocarbons · Chagas disease vectors · Hemiptera · Reduviidae

Introduction

Triatoma infestans (Hemiptera: Reduviidae) is a major vector of Chagas disease in South America, especially in the 1.3 million km^2 Gran Chaco geographic region, which has a mostly rural human population (Schofield and Kabayo, 2008). Late nymphs and adults are the major targets in vector control strategies, as they are more likely to transmit the disease. Attractants for this bug could help in the development of new control methods by using these chemicals as components of traps that monitor or "attract and kill". Recently, a "trap and kill" device that used entomopathogenic fungi, was shown to be successful against *T. infestans* (Pedrini et al., 2009).

Epicuticular lipids are known to mediate mate recognition in many insect species (Schal et al., 1990; Ferveur et al., 1996; Ginzel et al., 2006; Barbour et al., 2007; Rutledge et al., 2009). *Triatoma infestans* and other triatomines exhibit characteristic aggregation (Juárez et al., 2008; Lorenzo Figueiras et al., 2009), although no evidence for a contact sex or aggregation pheromone has been described. The epicuticular lipids of *T. infestans* are a complex mixture of long-chain hydrocarbons and oxygenated components, mostly fatty alcohols, waxes, and free and esterified fatty acids, which protect insects against chemical and biological attack (Juárez, 1994, 1995; Juárez and Calderón-Fernández, 2007; Pedrini et al., 2009). Epicuticular hydrocarbons are

sexual dimorphic in *Triatoma sordida*, although no sex difference was found in *T. infestans* (Juárez and Calderón-Fernández, 2007).

Here, we tested the hypothesis that contact pheromones mediate mate recognition in *T. infestans*. We examined the behavioral role of epicuticular lipids and show, for the first time, that these lipids elicit male mating attempts. We also report the identification of a female-specific fatty alcohol component that is capable of eliciting this behavior.

Methods and Materials

Insects Triatoma infestans were from a colony at the INIBIOLP, reared at 28°C, 50–60% RH. Adults from a small field colony were collected and used in one experiment. Virgin adults were collected daily and maintained separately. Insects were fed on domestic chickens 2–3 d after last molt, and used 10–12 d thereafter. Chickens were housed and managed under standard laboratory conditions approved by INIBIOLP's Animal Care and Use Committee.

Solvent Extraction and Head Space Solid Phase Microextraction (HS-SPME) Sampling Epicuticular lipids were extracted from single-sex groups of three bugs in redistilled hexane (6 ml g^{-1}, 3 times 5 min. each). The extract was concentrated under a stream of nitrogen. Hydrocarbons were fractionated by silica gel column chromatography, as described (Calderón-Fernández et al., 2011), using hexane as eluent.

For HS-SPME, hexane extracts of epicuticular lipids were deposited inside 10 ml crimp top vials (Supelco, Bellefonte, PA, USA), and the solvent was evaporated by a nitrogen stream. Vials were sealed and the residual lipids sampled at 150°C by HS-SPME for 20 min., using a 65 μm polydimethylsiloxane/divinylbenzene fiber (PDMS/DVB) (Supelco) inserted through the septum.

Chemical Analysis Both hydrocarbon and epicuticular lipid samples were analyzed by coupled gas chromatography–mass spectrometry (GC-MS) using electron impact ionization (70 eV). A Hewlett-Packard 6890 GC, equipped with a DB-5MS capillary column (30 m×0.25 mm×0.25 μm film; J&W Scientific, Folsom, CA, USA), interfaced to an Agilent 5975 mass selective detector, was used for the analyses. Samples were injected either splitlessly or directly (SPME), with helium as carrier gas. The column oven was programmed from 50–180°C (at 20°C.min^{-1}), then to 310°C (at 3°C.min^{-1}). Transfer line and quadrupole were held at 320°C and 150°C, respectively. Peak areas were calculated and expressed as a percentage of total peak area. Interpretation of hydrocarbon mass spectra was performed as described in Juárez et al. (2001). Spectra of other lipids were compared to data from MS libraries (NIST/EPA/NIH, NIST 05 and ADAMS 07). Fatty alcohols were identified by interpretation of their mass spectral fragmentation and by a close match of their mass spectra and retention times with those of authentic standards. Absolute amounts of fatty alcohols were quantified by flame ionization detection and calculated relative to eicosanol as an external standard; response was linear in the concentration range tested.

Bioassays Bioassays were performed in the late evening in plastic Petri dishes (13 cm diam.×12 cm height), generally using paired virgin males and females (alive or dead). Live males and females (N=68 each sex) were used to characterize the mating behavior of adults. A further experiment, using live females, tested the role of antennal contact in mating by covering the antennae of males with eyelash gel.

To test whether a contact pheromone was involved in mate recognition, females were freeze-killed (−20°C, 30 min) and allowed to warm to room temperature. These dead females were tested to determine whether recognition cues remained unchanged after killing, and therefore independent of female behavior. Next, epicuticular lipids were extracted from a dead female, as above, and the female was air-dried for ~30 min. The responses of individual males, were tested to the solvent-washed female. Finally, we loaded 1 or 3 female equivalents (FE) of lipid extract (in 20 μl hexane) onto a dead female. Each dead female was presented to 1–5 males (N=84 males and 48 females). The response of a male was observed by eye or recorded with a video camera over 30 min. A trial was scored as a "positive response" if the male, after antennal contact, stopped walking (arrest behavior), aligned with the female, and mounted and grasped her (copulation attempt). If the male showed no response after antennal contact, it was scored as "no response". Male responses were tested to live females, dead and intact females, dead and hexane-washed females, and dead, washed and lipid-reconstituted females.

To test the role of female-specific components in mate recognition, hexane solutions of 1 FE of docosanol and eicosanol (Sigma Aldrich, St. Louis, MO, USA) either individually, or combined, were placed on 2 cm long, polypropylene half cylinders, cut from 1 ml micropipette tips. Males were exposed to treated tips or control tips (hexane), in a arena similar to that described. A positive response was scored when a male mounted the tip.

The responses to treatments were tested by Fisher's exact test (Sokal and Rohlf, 2001). Differences were considered to be significant if the probability of their occurrence by chance was less than 5%.

Results

Hexane-extracts of epicuticular lipids of mature virgin *T. infestans* sampled by HS-SPME had a high abundance of saturated hydrocarbon components, mostly straight chain from 21 to 33 carbons, together with straight chain fatty alcohols of 20–30 carbons. Other minor components were fatty acids and fatty aldehydes (Fig. 1 and Table 1). No evident sexual dimorphism was observed for these components, except female extracts contained more than 7% of eicosanol and docosanol, whereas male extract had only trace amounts of these compounds. One equivalent of docosanol and eicosanol in a female corresponded to 14.1±3.9 ng and 6.1±0.8 ng, respectively. Females also had higher proportions of tetracosanol, which coeluted with *n*- heptacosane (Fig. 1 and Table 1).

Male *T. infestans* only attempted to mate (57.6% of total males tested attempted mating, N=66) with live females after contacting them with their antennae. After initial wandering in the container, males stopped, turned their antennae toward the female and contacted her with them, usually on the abdominal dorsal surface and the thorax (step 1). As described (Manrique and Lazzari, 1994), males aligned their body to the female, mounted and grasped her (step 2). After a male assumed a dorsolateral position and exposed his genitalia, copulation commenced (step 3). Most

Peak numbers correspond to peaks in Fig. 1

Males and females were analyzed separately

[a] Means of four groups of three individuals each

[b] Tetracosanol amount is roughly 50% and 26% of the overlapping peaks in females and males, respectively

(98.5%) males that reached step 2 also completed copulation. The time to first antennal contact, varied from 0.16 to 5 min (mean = 1.25 ± 1.31 min, N=13), and to mating attempt, from 0.33 to 12 min (4.27±4.63 min, N=10). The percentage of mating attempts by previously mated males (62.5%, N=8, unmated for 2 d) was not different from that of virgin males. No males (N=10) that had their antennae covered with an eyelash gel attempted mating

Freeze-killed females elicited 61.0% of males to attempt mating (N=41) (Fig. 2), not different (P=0.836) to the percentage elicited by live females, suggesting that active female behavioral cues were not involved. Hexane-washed female bodies (N=42) elicited no response from males, different from that elicited by intact, freeze-killed females (P<0.001). When epicuticular lipids (1FE) were loaded onto dead, washed females, 41.2% of males responded, differently (P=0.001, N=17) from that to dead, washed females only. At a higher dose (3 FE) of extract, 53.8% (N=26) of males responded, not different (P=0.536) from the percentage that responded to the lower dose (Fig. 2). Responses to dead and intact or reconstituted freeze-killed females were not different at either of the 2 doses tested (3 FE, P=0.246; 1 FE, P=0.616).

Triatoma infestans from a small field colony were also tested. Freeze-killed females elicited mating attempts from 100% of males tested (N=10), solvent-washed females evoked no males (N=9) to respond, and epicuticular lipid-reconstituted females (1 FE) elicited mating attempts from 57.1% of males (N=14). One FE of docosanol elicited 46.7% of males (N=30) to attempt copulation with the treated pipette tip. This percentage was different (P=0.025) from that observed by using 1 FE of eicosanol (16.7% of males, N=30) (Fig. 3). The percentage responses of males to docosanol (1 FE) were similar to those to docosanol plus eicosanol (1 FE each), either on a polypropylene tip (50%, P=0.811, N=38) (Fig. 3), or on hexane-washed females (61.1%, P=0.334, N=18). Control tips elicited no response from males, differing from responses to eicosanol (P=0.008), docosanol (P<0.001), and eicosanol plus docosanol (P<0.001).

Fig. 2 Responses of *Triatoma infestans* males to females with different treatments: freeze-killed, extracted with solvent, or addition of 1 (*white*) or 3 female equivalents (FE; *gray*) of epicuticular lipid extract following extraction with solvent (reconsitution). Forty one males and 27 females were used both in the freeze-killed and solvent-extracted treatments, and 43 males and 21 females in the reconstitution treatment. Different letters indicate differences (P≤0.05) among treatments by Fisher's exact test. The letter atop the reconstitution bar applies to both 1 and 3 FE

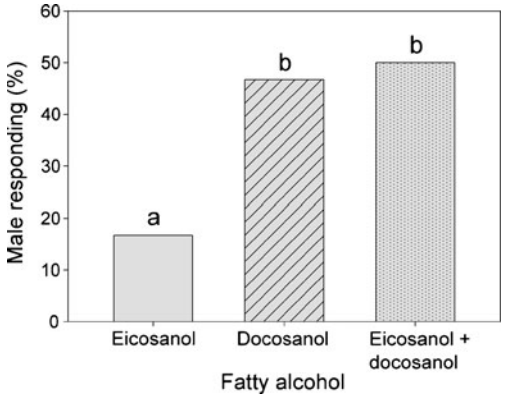

Fig. 3 Responses of *Triatoma infestans* males to polypropylene pipette tips treated with 1 female equivalent of eicosanol (*plain*), docosanol (*lines*), or 1 equivalent each of eicosanol plus docosanol (*dots*). Thirty males were tested to each individual alcohol treatment and 38 to the mixture. Different letters indicate differences (P≤0.05) among treatments by Fisher's exact test

Discussion

Previous analyses of cuticular hydrocarbons of *T. infestans* found saturated, mostly odd-numbered, straight chain compounds of 23–33 carbons, together with methyl-branched compounds of 29 or more carbons (Juárez and Blomquist, 1993). No evident sexual dimorphism in epicuticular hydrocarbons was detected in bugs of unknown mating status (Juárez and Brenner, 1985). In the present study, our analyses of extracts of virgin males and females of the same age also found no sexual dimorphism in the hydrocarbon fraction. However, our HS-SPME sampling allowed us to detect various oxygenated compounds in the epicuticular lipid extracts of *T. infestans*. A whole series of even-numbered fatty aldehydes of 22 to 30 carbons were novel, and present in both sexes. Of particular note were two female-specific fatty alcohols, docosanol and eicosanol. Previous studies, using solvent extracts, showed that triacontanol and dotriacontanol were the major fatty alcohol components in both females and males (Juárez and Calderón-Fernández, 2007).

Free fatty alcohols are not commonly found in epicuticular lipids of insects, although high molecular weight alcohols have been reported in honeybees (Blomquist et al., 1980) and triatomines (Juárez and Calderón-Fernández, 2007). High molecular weight alcohols also have been reported in the defensive secretions of scale insects (Buckner, 1993; Byrne and Hardley, 1988). Typically, insects more commonly produce lower molecular weight alcohols. Honeybees produce alcohols of 17–22 carbons, which induce arrestment in parasitic varroa mites (Donze et al., 1998). A mixture of short chain alcohols, their acetate derivatives, and (*Z*)-11-eicosenol are components of bee alarm pheromones (Pickett et al., 1982). In moths, a major class of female sex pheromone is unsaturated compounds of

10–18 carbons with oxygenated functional groups, mostly alcohols, their acetate esters or aldehydes (Bjostad et al., 1987; Arn et al., 1998).

There have been no previous reports of eicosanol and docosanol being involved in insect sexual communication. Although eicosanol was found in the sex pheromone blend of the grapevine moth *Lobesia botrana*, the actual pheromone components are unsaturated acetates of 12-carbon alcohols (Witzgall et al., 2005). Although volatile chemicals, which elicit electroantennogram responses, are released by *T. infestans,* this occurs during, and not before, copulation (Gonzales Audino et al., 2007; Crespo and Manrique, 2007). Our results show that mating attempts by a *T. infestans* male requires contact of the male's antennae with the female, and that epicuticular lipids trigger this response. Female-specific docosanol seems to be an important chemical that mediates this behavior. The characteristic triatomine aggregation behavior in small nests probably facilitates contact, and consequently recognition, of mates. Further studies on pheromone components may help the development of new control tools (Juárez et al., 2008; Pedrini et al., 2009) against Chagas disease vectors.

Acknowledgements We thank Raúl Stariolo for providing insects, and Facundo Bozzolo and Cecilia Fuse for rearing insects. The research was supported in part by grants from the Agencia Nacional para la Promocion de la Ciencia y Tecnología, Argentina (PICT 2004–25479 and PICT 2007–01503) to MPJ. Abstract The relationship among physiological stress responses, fecal marking behavior, and reproduction in male and female European pine martens was investigated. Between July 2004 and June 2007, 145 fresh fecal samples were collected in a protected area of northwest Spain. Fecal DNA was used for specific identification by using the polymerase chain reaction-restriction fragment length polymorphism technique. Glucocorticoids (cortisol) and sex steroid hormones (P, progesterone; E, estradiol; T, testosterone) were quantified by enzyme immunoassays. Sex was assigned according to concentrations of T+P+E and the T/P ratio. Fecal cortisol concentrations were higher in males than in females. Feces with a presumptive marking function (on conspicuous substrates, above ground level, and/or in latrines) had higher mean levels of cortisol than those that were on inconspicuous substrates and/or at ground level, for both males and females. Fecal mark density was highest in spring, when mean levels of fecal cortisol were more elevated. Therefore, the higher physiological stress levels in females could be due to female physiological state (late-term pregnancy and lactation), competition for resources connected to birth, or food resources for offspring rearing. In males, the increase could be due to higher male competition for access to females during pro-estrus and estrus. Our results suggest that scent marking in European pine martens is related to reproduction and is involved in intersexual and intrasexual communication.

Key Words Feces · Glucocorticoids · *Martes martes* · Reproduction · Scent marking · Sex hormones

Introduction

Chemical communication plays an important role in carnivore social and reproductive behavior. Many species use olfactory signals for information about reproductive state, territory defense, identity, group membership, and social status (Gorman and Trowbridge, 1989). Many species of mustelids use feces, urine, and the secretions of specialized glands as visual and scent marks for chemical communication (Pulliainen, 1982; Hutchings and White, 2000; Barja, 2005). In carnivores, the function of these marks is a matter of debate, but several studies have indicated that scent-marking behavior is related to reproduction, and is involved in basic functions such as defense of territory, intrasexual competition, and mate choice (Macdonald, 1985; Gosling and McKay, 1990; Gosling and Roberts, 2001). Scent marking in territories is best understood in terms of competitor assessment theory (Parker, 1974). Resource holders scent mark to provide opponents with a means of competitor assessment, thus reducing the costs of resource defense (Gosling and McKay, 1990).

Behavior can determine or modify the production and blood concentration of hormones (Mazur et al., 1992). However, little is known about the behavioral factors that cause an increase in glucocorticoid levels (e.g., scent marking, Barja et al., 2008a). When environmental, social, and physiological conditions are favorable, hormones coor-

dinate the physiological and behavioral changes associated with reproduction (Alcock, 1998). Sex steroid hormones (SSH) act on sexual organs, thus contributing to the development of reproductive processes, and are crucial in regulating patterns of reproductive behavior (Nelson, 2005). Studies on different carnivores indicate that concentrations of these hormones increase during the reproductive season (Velloso et al., 1998; Soto et al., 2004; Barja et al., 2007).

Cortisol is the primary glucocorticoid produced and secreted by the adrenal cortex. It is often referred to as a "stress hormone", as it is involved in the response to stress, affecting blood pressure, blood sugar levels, and other actions of stress adaptation (Axelrod and Reisine, 1984). Short-term glucocorticoid secretions have been related to adaptive responses of animals to stresses, and are considered beneficial for the organism (Möstl and Palme, 2002). An increase in glucocorticoid secretion is the front-line endocrine mechanism to defend an organism against stressful conditions. Additionally, glucocorticoids are released in response to situations not normally regarded as stressful, including courtship, copulation, and hunting. Moreover, during short-term stress, glucocorticoids improve fitness by mobilizing energy, and causing changes in behavior (Möstl and Palme, 2002). Nevertheless, prolonged periods of high cortisol levels can lead to pathologies (e.g., reproductive and/or endocrine disruption, immune suppression, and gastrointestinal ulcerations) that can reduce overall fitness (Dobson and Smith, 1995).

The quantification of glucocorticoids and SSHs in blood and urine requires capture and manipulation of animals which, in itself, can modify hormonal concentrations and lead to increases in physiological stress (Young et al., 2001). Quantification of these hormones in feces is a non-invasive method that is increasingly used in carnivore studies (e.g., Goymann et al., 2001; Soto et al., 2004; Creel, 2005; Barja et al., 2008a, b).

The European pine marten is an elusive, nocturnal carnivore that is difficult to study in the field. Relationships among glucocorticoid levels, fecal marking behavior, and SSH are not known for this mustelid. The only study on its reproductive behavior was performed using captive animals (Mead, 1994). The aims of the present study were: 1) to establish the relationship among fecal glucocorticoid levels, fecal marking frequencies and SSH concentrations in males and females of free-ranging European pine martens; and 2) to use these results to test current theories on the function of scent marking in territories.

Methods and Materials

Collection of Fecal Samples The study was conducted from July 2004 to June 2007 in Montes do Invernadeiro Natural Park, a mountainous area of 5,722 ha located in Northwest Spain. European pine martens use forest roads and deposit feces with visual and scent-marking functions (Pulliainen, 1982; Barja, 2005). To collect fresh fecal samples and study the fecal marking of this species, we surveyed forest roads, consisting of between 26 and 33 400 m-long transects, in 26 Universal Transverse Mercator cells of 1 km^2 each, in each season. The mean territory size of the European pine marten is 1.3 km^2 for males and 1.0 km^2 for females (O. Berdión, unpublished data). Thus, in order to increase the likelihood of obtaining fecal samples from different individuals and to minimize pseudoreplication, we collected from four zones of the study area, set far apart from one another and, in each zone, the 400 m transects were separated by a distance of 1 km. During the study we located 239 European pine marten scats, of which 145 were fresh. Of these 145, 90 were used in the DNA analyses and all for the hormonal analyses.

To quantify cortisol and SSH levels, samples of fresh feces were collected, from sunrise to 3 h after, thus ensuring that exposure time to environmental conditions and microbial action was minimized (Millspaugh and Washburn, 2004). We collected all samples from the fine end of the scat to standardize sampling. Feces were considered fresh when they had a layer of mucus, a high level of hydration, and a strong odor. From each fresh scat, 10 g of sample were gathered and the date recorded. In the field, the fecal samples were placed in a portable refrigerator loaded with ice. Because freezing of such samples is considered the best method of preserving hormone content (Millspaugh and Washburn, 2004), all samples were frozen within 5 h of collection and maintained at −20°C until assayed.

Specific Identification of Feces Based on morphology, pine marten feces are difficult to distinguish from those of medium-size carnivores such as red fox (*Vulpes vulpes*), wildcat (*Felis silvestris*), and stone marten (*Martes foina*) (Davison et al., 2002). Therefore, we analyzed fecal DNA, from the first 90 fresh samples collected, by polymerase chain reaction–restriction fragment length polymorphism analysis (Ruiz-González et al., 2008). This showed that 80 of the samples were from European pine marten. The remaining ten samples were not amplified by PCR. The DNA results were consistent with our morphological identification of feces in the field. Therefore, the remaining (55) samples used in this study were identified by morphological characteristics.

Fecal Marking For fecal marking behavior, the following information was recorded for feces found in transects: "conspicuousness of substrate", height of substrate, and location in latrines (Barja, 2005). In order to analyze the

variable conspicuousness of substrate, we established two categories: inconspicuous and conspicuous. Conspicuous substrates were those that, for a human observer, stood out from the surrounding substrates (e.g., mound of soil, plants, stones). All others were regarded as inconspicuous. When a scat was on the ground, but less than 10 cm from a conspicuous substrate, we surveyed the substrate to check whether there were remains of scat or not; in this case, we considered that scat had a presumptive marking function. For the variable height, feces were considered as being above ground level or at ground level. We considered feces to be in latrines when two or more scats were concentrated at a defecation point. Feces were assumed to have a presumptive scent-marking function only when they were placed on a conspicuous substrate, above ground level, and/or in latrines. However, we do not exclude the possibility of scats placed on the ground and out of a latrine also serving a marking function.

Quantification of Glucocorticoids and Sex Steroid Hormones Fecal samples were analyzed for levels of cortisol, testosterone (T), progesterone (P), and estradiol (E). Hormones were extracted using methods for similar carnivore species (Brown et al., 1994) and for European pine martens (Barja et al., 2007). The efficiency of extraction was tested by the addition of radiolabeled hormones (^{3}H-cortisol, ^{3}H-testosterone, ^{3}H-progesterone, and ^{3}H-estradiol; 4,000–8,000 dpm; ICN, California, USA) prior to extraction of a parallel set of fecal samples.

SSH and cortisol concentrations were determined from fecal extracts by an enzyme immunoassay developed in our laboratory, and previously validated for the European pine marten (see assay protocol in Barja et al., 2007). Hormone concentrations were calculated by means of software developed for this technique (ELISA-AID, Eurogenetic, Belgium). Standard-dose response curves were constructed by plotting the binding percentage (B/B×100) against the standard hormone concentrations added.

The mean recovery of ^{3}H-steroids from fecal extracts was as follows: ^{3}H-cortisol, 81.5%; ^{3}H-testosterone, 85.4%; ^{3}H-progesterone, 85.5%; and ^{3}H-estradiol, 92.8%. Parallel displacement curves were obtained for each hormone by comparing serial dilutions of pooled fecal extracts and standard curves. The results showed that both curves were parallel in all cases. Intra- and inter-assay coefficients of variation were calculated by assaying 10 replicates of a pooled fecal sample in the same assay and 10 replicates of the same sample in 10 consecutive assays. The percentages recovered were, respectively, as follows: cortisol, 6.4 and 9.5%; testosterone, 5.5 and 8.9%; progesterone, 4.5 and 6.9%; estradiol, 4.9 and 7.5%. For each sample, SSH and cortisol concentrations are expressed in ng/g of dry feces.

Origin of the Fecal Samples Previous studies on carnivores showed that the concentration of T+P+E and the relation of T/P were higher in males than in females (Velloso et al., 1998; Soto et al., 2004). Therefore, to assign sex to the depositors of particular fecal samples, we carried out a k-means conglomerate analysis, using the concentrations of T+P+E and the T/P ratio of each sample (Barja et al., 2008b). This analysis pooled the samples in groups, or conglomerates, so that each group was as homogeneous as possible, and different from the other groups, for the variables analyzed.

Data Analysis We used one-way ANOVA, with year as a fixed factor and cortisol levels as a response variable. We used two-way ANOVA to test whether cortisol levels vary in relation to two factors: sex and fecal marking. The differences in cortisol concentrations between seasons were analyzed using one-way ANOVA. We used Games-Howell tests for *post-hoc* testing. A χ^2 test was used to verify if there were seasonal differences in the number of deposited feces with a presumptive marking function or not. For seasonal analysis, the months were grouped as follows: spring (April–June), summer (July–September), autumn (October–December), and winter (January–March). We consider this grouping appropriate because the months in each season have temperatures similar to each other in the study area. The relationship between seasonal fecal marking frequencies and SSH levels was analyzed using Spearman's correlation coefficient. Pearson's correlation coefficient also was used to determine the relationship between concentrations of fecal glucocorticoids and SSH. Fecal sex hormone and cortisol concentrations are given as mean ± SE. A p value$\leq$0.05 was considered significant. All analyses were carried out using SPSS version 15.0 for Windows (SPSS Inc, Chicago, IL, USA).

Results

Sex Assignment in Relation to Sex Hormone Concentrations Hormone concentrations (cortisol, T, P, and E) were analyzed for 145 fresh fecal samples of European pine marten. The k-means conglomerate analysis for the variables T+P+E and T/P revealed that the samples belonged to two different groups. Group 1 comprised the greater number of samples (83.4%) and had concentrations of T+P+E of 133.9±13.6 ng/g of dry feces (range to 697.61) and a T/P ratio of 0.30±0.03 ng/g of dry feces (range to 2.49) that were lower than those of group 2. Group 2 comprised 16.6% of the fecal samples, all with a high concentration of T+P+E (1399.0±97.1 ng/g of dry feces) and a high T/P ratio (0.90±0.1 ng/g of dry

feces; range 3.28). The differences between both groups for T+P+E and T/P were significant (T+P+E: ANOVA, $F_{1,\ 145}$= 580.23, P<0.001; T/P: ANOVA, $F_{1,\ 145}$=29.12, P<0.001). Therefore, the fecal samples of group 1 belonged to females and those of group 2 to males (Velloso et al., 1998; Soto et al., 2004).

Fecal Glucocorticoid Levels and Fecal Marking The differences in fecal cortisol levels between years were not significant (one-way ANOVA: $F_{4,145}$=0.109, P=0.955). Therefore, the results of both years were pooled for further statistical analysis. The fecal cortisol levels in European pine marten were dependent on sex (males, 58.9±10.1 ng/g of dry feces; females: 22.6±4.9 ng/g of dry feces) (two-way ANOVA: $F_{1,\ 145}$=46.6, P=0.014) and fecal marking (with a presumptive marking function, 36.4±10.6 ng/g of dry feces; no presumptive marking function, 25.7±5.0 ng/g of dry feces) (two-way ANOVA: $F_{1,\ 145}$=9.72, P=0.051). The interaction between fecal marking and sex was not significant (two-way ANOVA: $F_{1,\ 145}$=3.43, P=0.187). In males and females, cortisol levels were higher in feces that had a presumptive marking function than those that did not. In both feces with a presumptive marking function and those with no presumptive marking function, males had higher cortisol levels higher than females (Fig. 1).

Seasonal Variation in Fecal Marking Frequencies and Sex Hormone Levels The spatial location of 239 scats was categorized for fecal marking. A presumptive marking function was evident in 23.4% of scats, as they were deposited on conspicuous substrates, above ground level, and/or in latrines. Density of feces with a presumptive marking function was highest in spring and lowest in winter. Fecal marking densities were similar in summer and autumn (Fig. 2). There were seasonal differences in fecal marking frequencies (χ_3^2=30.54, P<0.001). Mean fecal glucocorticoid levels were higher in spring than in summer, winter, and autumn (one-way ANOVA: $F_{3,\ 145}$=2.30, P= 0.080; *post-hoc* Games-Howell test: P=0.025 for spring and autumn, and P>0.05 for comparisons among the other seasons; Fig. 2).

We found a positive correlation between fecal testosterone concentrations and seasonal fecal marking (Spearman correlation: r=0.223, N=4, P=0.007). However, the concentrations of progesterone (Spearman correlation: r=0.0911, N=4, P=0 .275) and estradiol (Spearman correlation: r=0.064, N= 4, P=0.444) were not associated with fecal marking frequency. In addition, fecal cortisol levels were positively associated with the three SSHs examined, as follows: T (Pearson correlation: r=0.372, N=145, P<0.001), P (Pearson correlation: r=0.544, N=145, P<0.001), and E (Pearson correlation: r=0.564, N=145, P<0.001).

Discussion

In the present study, the highest density of feces with an evident marking function occurred in spring; these spring feces also had the highest concentrations of fecal cortisol. This result is consistent with a previous study in the same study area, which showed that fecal concentrations of T, P, and E were higher in spring than in other seasons (Barja et al., 2007). Given that scent marking is important for mustelids in sexual communication (Pulliainen, 1982; Hutchings and White, 2000; Barja, 2005), and that SSHs regulate sexual behavior in mammals (Velloso et al., 1998; Nelson, 2005), it appears that SSHs may play a key role in modulating fecal marking behavior in mustelids, such as the European pine marten. The low density of feces with a presumptive marking function in autumn coincided with the non-reproductive period (delayed implantation) of the

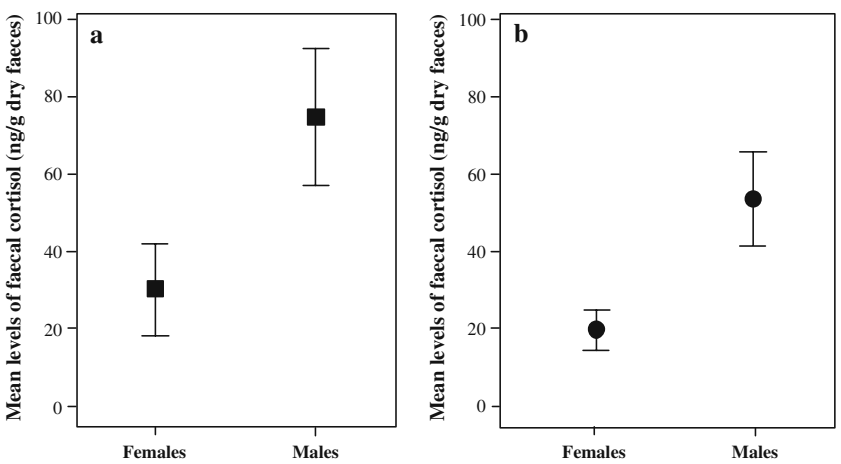

Fig. 1 Comparison of fecal cortisol levels (mean ± SE) of male and female European pine marten, according to presumptive fecal marking. **a** Feces with a presumptive marking function, and **b** feces with no presumptive marking function

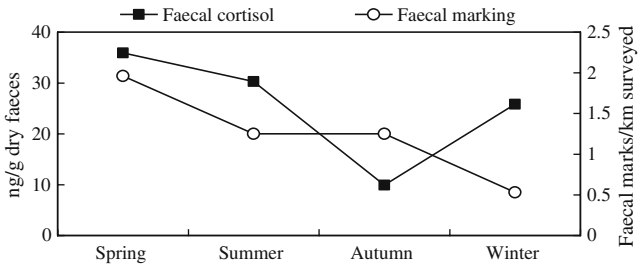

Fig. 2 Seasonal variation in the density of European pine marten feces with a presumptive marking function, and fecal cortisol levels

species (Mead, 1994). This is consistent with European pine martens having low SSH levels in this season (Barja et al., 2007).

In our study, the increase in fecal cortisol levels and in density of feces with a presumptive marking function during the spring and, to a lesser extent, in summer (when births and estrus occur; Mead, 1994), likely reflects the sex-biased cost of reproduction. Short-term activation of adrenocortical hormone secretion, associated with a low degree of physiological stress, seems to be beneficial for reproduction by maintaining the animal's level of responsiveness to socio-sexual stimuli necessary for sexual arousal and reproductive activation (Carlstead and Shepherdson, 1994). However, long-term elevation of glucocorticoid levels can disrupt reproductive behavior and the reproductive hormone axis, causing decreases in an animal's chances of finding mates, initiating pair formation, and copulating, as well as possibly arresting ovulation (Pierce et al., 2008). We do not know whether or not the fecal cortisol levels observed in this study are indicative of decreased fitness.

Females could be maximally stressed in spring by their physiological state (i.e., late-term pregnancy and lactation; Mead, 1994), as reported in other mammals, such as the ring-tailed lemur (Starling et al., 2010). This would indicate that female martens experience increasing physiological costs as pregnancy progresses and throughout the period of exclusive infant nursing. In addition, the increase in cortisol levels in females could be due to intrasexual competition for resources connected to birth (nest sites) and food resources for offspring rearing. Changes in glucocorticoid levels also have been linked to food availability in wild olive baboons (Sapolsky, 1986). In males, the highest physiological stress levels may be due to territory defense and to intrasexual competition over females during pro-estrus and estrus. Scent marks may allow intruders to assess the identity of the territory owner, and thus avoid the high cost of territory defense (Gosling and McKay, 1990). Studies should be carried out to confirm this, because the sample size of males in our study was small.

In our study population, cortisol levels were higher in feces that had a presumptive marking function than in those that did not, both for males and females. Similar results have been observed in other carnivores, such as the Iberian wolf (Barja et al., 2008a). Higher cortisol levels in prominent fecal marks support the idea of scent marking as part of competition between males and females. The costs that lead to higher stress are likely to be costs of competition (including injury), which a signaler risks when its marks are more conspicuous to competitors. Scent marks also may be condition-dependent signals of quality and competitive ability, thus providing a means of assessment about the signaler's quality (Roberts and Gosling, 2001). Competitors could identify resource holders by investigating fecal scent marks from a given area, and match these with the owner's odor when they meet, a mechanism known as the scent-matching hypothesis (Gosling, 1982). European pine martens are solitary animals that are territorial toward members of their own sex. The territory of a male often overlaps extensively with those of several females (Macdonald, 2001). Territories within a sex can overlap, but every individual uses parts of the shared area exclusively (Blanco, 1998). As the chance of invading occupied locations in these overlapping areas is probably higher than in a strict territorial system, scent matching could modulate intrasexual aggression among females and males in non-exclusive areas, as reported for male snow voles (Luque-Larena et al., 2001).

Testosterone concentrations were higher when presumptive fecal marking was more frequent, suggesting that this is associated with aggressiveness of males and the defense of territories. When females are in estrus, there is intense competition between males for territories that determine priority of access to mates (Pulliainen, 1982; Mead, 1994; Schroepfer et al., 1997). Several studies indicate that testosterone plays a key role in the modulation of aggression (Lincoln et al., 1972; Alcock, 1998) and that in mammals males have higher levels of testosterone and are more aggressive than females (Lincoln et al., 1972; Barja et al., 2008b). Higher levels of aggressive behavior are associated with estrus and with defense of territory in ungulates and primates (Bouissou, 1983). Therefore, our results indicate that fecal testosterone in European pine martens may play a key role in the regulation and modulation of fecal marking by males in relation to reproduction and intrasexual competition.

Quantification of fecal steroid hormone levels is a useful method for detecting and monitoring reproduction in threatened and endangered carnivores, because quantification of fecal hormone levels is a non-invasive method for evaluating gonadal function (Young et al., 2004). In addition, fecal hormone quantification avoids additional stresses that can be caused by animal capture, handling, sedation and/or transport (Brown and Wildt, 1997). A better understanding of carnivore reproductive physiology, in conjunction with

behavioral studies, could facilitate breeding, management, and conservation activities, of endangered species.

RAPID COMMUNICATION

The Effect of Elevated Steroids Released by Reproductive Male Round Gobies, *Neogobius melanostomus*, on Olfactory Responses in Females

Alyson J. Laframboise · Yogesh Katare · Alexander P. Scott · Barbara S. Zielinski

Received: 20 November 2010 / Revised: 14 February 2011 / Accepted: 16 February 2011 / Published online: 2 March 2011
© Springer Science+Business Media, LLC 2011

Abstract The round goby, *Neogobius melanostomus*, is a highly successful invasive species in the Laurentian Great Lakes. Previous behavioral studies implied that females are attracted by pheromones to the nests of reproductive males, and that males release putative steroidal pheromones—unconjugated as well as conjugated forms of 3α-hydroxy-5β-androstane-11,17-dione (11-O-ETIO)—following stimulation of the hypothalamic-gonadal axis with salmon gonadotropin releasing hormone analog (sGnRHa). In this study, we tested the olfactory system of females in response to extracts containing these released steroids. We compared electrical field potential responses from the olfactory epithelium (electro-olfactogram, EOG) of non-reproductive females to methanol extracts of water that previously held males, collected before and after injection of the males with sGnRHa or saline. The females showed increased EOG responses to the post-injection extracts when males were treated with sGnRHa but not saline. This finding provides further evidence for interactions between male and female *N. melanostomus* via steroidal reproductive pheromones.

Introduction

Many fishes use hormonal products released into the water as reproductive pheromones (Stacey et al., 2003). Gonadotropin releasing hormone (GnRH) is an important factor in the production and release of steroidal hormones, as it stimulates the release of luteinizing hormone, which is responsible for stimulating gonadal steroid release (reviewed by Zohar et al., 2010). GnRH is known to increase plasma steroid levels, but it is less clear whether GnRH can lead to an altered chemical signal, or whether this signal could in turn affect the response of opposite-sex conspecifics. Serrano et al. (2008) showed that treating male peacock blennies, *Salaria pavo*, with 11-ketotestosterone increases female olfactory responses to extracts of the gonads and anal glands. The olfactory system of the round goby, *Neogobius melanostomus* Pallas, responds to steroidal compounds (Murphy et al., 2001), and reproductive females show increased olfactory and behavioral responses to water from reproductive males vs. non-reproductive males (Belanger et al., 2004; Gammon et al., 2005). Katare et al. (2011) observed that following injection with salmon GnRH analog (sGnRHa), male *N. melanostomus* increase the release of several steroids into the water, including 11-oxo-etiocholanolone (11-O-ETIO) and 11-O-ETIO-3-sulfate (11-O-ETIO-3-s), which are novel fish steroids and putative pheromones in this species. We used electro-olfactogram (EOG) recordings of female *N. melanostomus* to determine how a surge of sGnRHa would affect the olfactory signal released by males.

Methods and Materials

Experimental Animals Neogobius melanostomus were angled from the Detroit River and Lake Erie in Windsor and

Leamington, Ontario, respectively. Fish were separated by sex and held in the animal facilities at the University of Windsor in flow-through aquaria with dechlorinated municipal tap water at ambient temperatures (~20°C) on a 16:8 h photoperiod. Fish were fed commercial food once daily (Aquatic Eco-systems, Apopka, FL, USA). All experimental procedures conformed to guidelines of the Canadian Council for Animal Care.

Generation of Methanol Extracted Male Water The procedure for generating methanol extracts of water that held reproductive males (RM) has been described elsewhere (Katare et al., 2011). Each RM (chosen on the basis of secondary sexual characters; Belanger et al. 2004) was isolated in 1 l of dechlorinated water, which was collected after 4 h ("pre-injection"). The RMs were given an intramuscular injection of either 20 μg/kg sGnRHa (Ova-RH, Syndel Laboratories, Qualicum Beach, BC, Canada; N=6) dissolved in 0.9% saline at 4 μg/ml, or 0. 9% saline (N=3). RMs then were immersed into fresh dechlorinated water (1 l) for 16 h, and this water was collected ("post-injection"). Steroids were extracted from the water (1 l) by passing it through activated, rinsed C18 cartridges (Sep-Pak, Waters, Milford, MA, USA) and eluting with 5 ml of methanol, a 200-fold concentration. C18 cartridges were used only once and then discarded. Stock solutions of methanol extracted steroids were produced by diluting 100 μl of extract into 10 ml of dechlorinated water (a 100-fold dilution). Individual stocks were diluted 100× further in dechlorinated water for EOG testing; thus, tested concentrations of extracted compounds were all below the original concentrations produced by the RMs. We used a custom immunoassay to measure the amount of released immunoreactive unconjugated and conjugated 11-O-ETIO in the methanol extracts (Katare et al., 2011). The release rate of immunoreactive 11-O-ETIO was 2.13±0.64 ng/ml/h in methanol extracts prepared prior to injection. The release rate was 0.95±0.57 ng/ml/h (N=3) for saline-treated RMs and 8.08±2.12 ng/ml/h for sGnRH-treated fish (N=6).

Electro-olfactogram (EOG) Recordings We recorded summed generator potentials from the surface of the olfactory epithelium by using a recording procedure adapted from Murphy et al. (2001) and Belanger et al. (2004). Non-reproductive female *N. melanostomus* were used for all recordings (N=7). Fish were anesthetized by submersion in a bath containing tricaine methanesulfonate (MS-222; Finquel®, Argent Chemical Laboratories, Redmond, WA, USA) at 100 mg/l. Dechlorinated municipal tap water (used as background water) was dripped constantly over the olfactory epithelium via a tube positioned over the posterior naris (nostril). Odors were introduced into this water flow via a solenoid-driven switching mechanism to avoid mechanical stimulation. The standard odor, 10^{-5} M L-alanine (Sigma-Aldrich, Oakville, ON, Canada), was delivered periodically to monitor the stability of the recording. We recorded responses to pre- and post-injection extracts. EOG responses were recorded in millivolts (mV) and normalized by dividing them by the mean response to L-alanine. When more than one female was exposed to the methanol extract of a particular male, those females' responses were averaged together to obtain one mean response value for each individual extract. We used a data acquisition system (PowerLab, ADInstruments, Colorado Springs, CO, USA) and computer to record and analyze the data. Data were analyzed with SigmaStat 3.5 (Systat, San Jose, CA, USA) by using a paired t-test to analyze for differences in EOG response to pre-injection vs. post-injection extracts (from sGnRHa- and saline-treated fish).

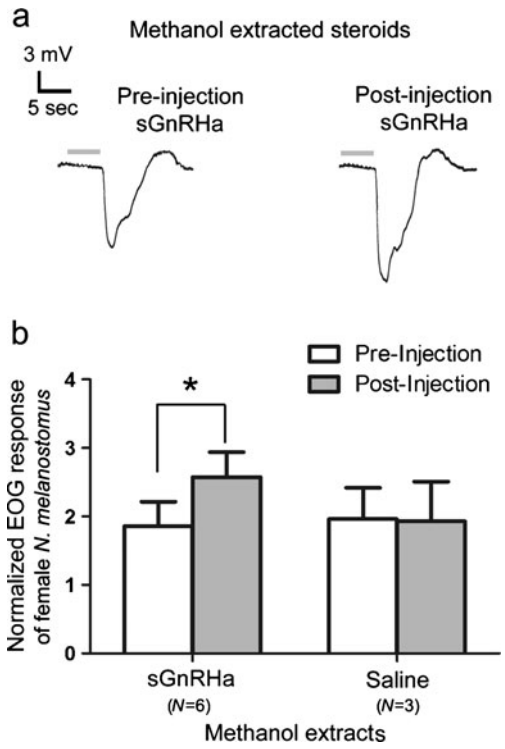

Fig. 1 Electro-olfactogram (EOG) responses to methanol-extracted conditioned water from reproductive male (RM) *Neogobius melanostomus* before and after injection with either sGnRHa or saline. **a** Typical EOG trace from female *N. melanostomus* to pre-injection and post-injection (with sGnRHa) methanol extracts from an RM; **b** female *N. melanostomus* show an increased and significant (*, P= 0.02) EOG response to the post-injection methanol extract of conditioned water when the RM was treated with sGnRHa, but not when it was treated with saline

Results

Methanol extracts of RM *N. melanostomus*-conditioned water elicited robust olfactory responses from female *N. melanostomus* (Fig. 1a). Females had a greater EOG response to the methanol extracts following treatment of males with sGnRHa (t=3.23, P=0.02, df=6); the response did not differ following treatment of males with saline (t= 0.24, P= 0.83, df= 2; Fig. 1b).

Discussion

We observed that olfactory responses by female *N. melanostomus* to odors from the male were greater after the male had been treated with sGnRHa—a treatment known to increase the male's release of putative pheromones (Katare et al., 2011). This finding indicates that females may be attuned to, and subsequently stimulated by, endocrine changes in the male through release of chemical signals, and it provides additional evidence for the use of sex pheromones by *N. melanostomus*. While Belanger et al. (2004) observed an increased EOG response from reproductive female *N. melanostomus* to water that held RMs, our findings indicate that even non reproductive females are capable of responding to changes in the endocrine status of the male, and that compounds that elicit this olfactory response have the properties of steroids. Although immunoreactive 11-O-ETIO was quantified in the RM water extracts (Katare et al., 2011), other steroids also captured by the C18 columns may have contributed to the increased olfactory responses. This increased olfactory response may translate to behavioral effects in the female, as responses to urine from sGnRHa-treated males have been observed (Kereliuk, 2009). In order to synchronize spawning between the sexes, many fish species have evolved the use of hormonal products as pheromones, as these signals are indicative of the reproductive status of the sender. In goldfish, *Carassius auratus* (with the best characterized reproductive system involving identified pheromones), females experience a surge in gonadotropin II in response to environmental factors, which in turn induces the females to release 17α,20β-dihydroxy-4-pregnen-3-one (17,20β-P) (Stacey et al., 1989). Release of 17,20β-P in turn stimulates a gonadotropin increase in the males (Stacey et al., 1989), and leads to the initiation of reproductive behavior (DeFraipont and Sorensen, 1993). Thus, increasing the titer of GnRH is the necessary first step leading to spawning in both male and female *C. auratus*.

Acknowledgments The authors wish to acknowledge the contribution of Zena Alyasha'e with the preparation of the methanol extracts, and the efforts of many students with animal collection.

We also acknowledge our funding sources: NSERC Strategic Grants STPGP 322317–05 and 3814161 to BZ; the Ontario Ministry of Research and Innovation PDF Program (YK); the Ontario Ministry of Training, Colleges and Universities Ontario Graduate Scholarship award (AL); and the University of Windsor Faculty of Graduate Studies. Finally, we also appreciate the support of the Ontario Ministry of Natural Resources, and in particular helpful discussions with Dr. Timothy Johnson.

RAPID COMMUNICATION

Low Concentrations of Salicylic Acid Stimulate Insect Elicitor Responses in *Zea mays* Seedlings

Abstract Salicylic acid (SA) generally is thought to suppress jasmonic acid (JA) related signaling events. However, when we treated the roots of corn seedlings overnight with low physiological concentrations of SA (50 μM), we found a priming effect of this pretreatment on typical insect elicitor (IE)-induced responses in the leaves of these plants. IE-induced JA was more than 2-fold up regulated in SA-pretreated plants. Consequently, IE-induced volatile organic compounds (VOC) release also was significantly increased. In contrast, when corn seedlings were treated with SA overnight and then mechanically damaged, we found no significant differences in JA accumulation. We also found that the application of even lower concentrations of SA (5 μM) had no significant effect on IE-induced responses, while higher concentrations (500 μM) inhibited IE-induced JA accumulation. Likewise, shorter exposure to SA did not affect subsequent JA accumulation induced by IE or mechanical wounding. These results provide evidence for the existence of non-compatible defense priming by signaling molecules that usually are involved in a conflictive defense signaling pathway and suggests common elements in the regulation of priming plant defense responses.

Introduction

In the plant defense responses to pests and pathogens, two major hormones are responsible for regulating specific countermeasures, salicylic acid (SA) and jasmonic acid (JA). Salicylic acid is an important signal in the plant response against pathogen or viral infections, while JA is the major regulator in insect-herbivore response, including the production of proteinase inhibitors, toxic secondary metabolites, and the production and release of volatile organic compounds (VOC). The latter may serve as important signals in tritrophic interactions by attracting predators and parasites of attacking insect herbivores and they have been demonstrated to be quite effective (Kessler and Baldwin, 2001). Besides causing significant mechanical damage to the plant, insect herbivores also apply compounds abundant in their saliva to the wounding site. These elicitors often potentiate the plant's defense responses by causing a significant higher accumulation of JA and producing more VOC, a defensive measure when compared to mechanically damaged control plants (Schmelz et al., 2009).

The interaction of the SA- and JA-pathway in this context is of particular interest due to the fact that often activation of one pathway inhibits the other. Examples for this interaction have been described frequently (Koornneef et al., 2008 and refs. therein). However, other reports indicate that SA also may have a stimulatory effect on certain JA-mediated responses. Mur et al. (2006) reported that this interaction depends on the concentration of the hormones involved, and found that lower concentrations of SA, when applied concomitantly with JA, caused a significant increase in certain JA-mediated responses. Similarly, elicitors like alamethicin and inceptin, and also

certain pathogens, activate both signaling pathways concomitantly in corn, cowpea, *Arabidopsis*, and tobacco, respectively (van Wees et al., 2000; Engelberth et al., 2003; Schmelz et al., 2009; Mur et al., 2006). It seemed that in those cases SA did not have any inhibitory effects. High concentrations (500 μM–1 mM) of SA also were used to test for effects of this compound on JA levels and JA-mediated processes. However, when endogenous levels of SA in corn after treatment with alamethicin were calculated, the average concentrations in those plants were much lower (Engelberth et al., 2003). Therefore, we decided to use these lower, more physiological amounts to test for the effects of SA on induced JA accumulation. We found that treatment with a low concentration of SA significantly increased IE-induced JA production and VOC release when applied to the root system of the plant. To our knowledge, this is the first report on a priming effect of SA on insect herbivore-related and JA-mediated defense responses in plants.

Methods and Material

Salicylic acid was purchased from Sigma chemicals (St. Louis, MO, USA). Corn [*Zea mays* cv. Kandy Korn; Jung Seed Company (www.jungseed.com)] was grown in plastic pots (size appr. 10×10×8 cm) filled with approximately 400 cm^3 soil (Ready Earth Plug & Seed, SunGro, MA, USA) at 26°C, 12:12 h, L:D conditions. Light intensity was set at app. 150 μmol m^2 s^{-1}.

SA was applied at a 5, 50, or 500 μM by watering 14-d-old corn seedlings (V2 stage, 3rd leaf already well developed) with 100 ml of the respective solution in water/methanol (99:1 vol/vol) per pot overnight for 15 h prior to treatment with insect elicitor (IE; here: *N*-linolenoyl-glutamine) or with mechanical wounding (MW). Controls were treated with the water/methanol mixture alone. IE was applied as described previously (Engelberth et al., 2004). In brief, an area of about 2×10 mm on the second leaf of each plant was scratched with a razor blade and 10 μl of the IE solution (100 pmol/μl in 50 mM KPi buffer, pH 8) immediately added to the wounded site. Mechanical wounding was done similarly without adding buffer. Leaf segments (about 2.5 cm in length) comprising the IE or MW application site were cut 1 and 2 h after treatment, and analyzed for JA and SA accumulation. Control segments without damage were taken from SA- and water-treated plants.

Jasmonic acid and SA were extracted and quantified by vapor phase extraction (Engelberth et al., 2004). In brief, frozen plant tissues were extracted with a mixture of 1-propanol:H_20:HCl (2:1:0.002) and dichloromethane. After phase separation, the organic phase was transferred and evaporated under a constant air stream, re-dissolved in 100 μl of diethyl ether: methanol (9:1, vol:vol), and subsequently methylated by diazomethane. Thus, volatilized metabolites were separated from the complex mixture by vapor phase extraction and analyzed by GC/MS.

To test for the effects of SA on IE-induced VOC, intact corn plants were incubated with SA overnight. The next morning, plants were treated with IE, and 5 h later were cut at the root base, wrapped in wet tissue paper, and transferred to 200 ml glass cylinders, where VOC were collected for 1 h as described (Engelberth et al., 2004), and analyzed by GC/MS with 3-octen-2-one as internal standard. At least three biological replicates of all experiments were

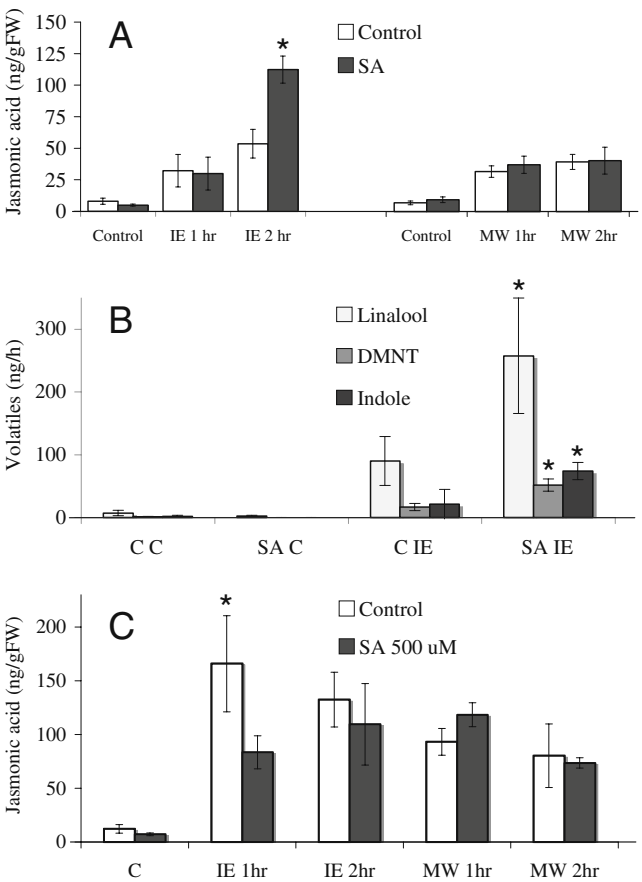

Fig. 1 Effects of salicylic acid (SA) on wound (MW)- and insect elicitor (IE)-induced total jasmonic acid accumulation and volatile release in *Zea mays*. **a**: Jasmonic acid accumulation measured 60 and 120 min after treatment with insect elicitors or mechanical wounding in SA pretreated and control plants. **b**: Volatile release of SA-pretreated and control plants 5 hr after induction with insect elicitors. For both experiments (**a** and **b**), roots of corn seedling were watered with 100 ml of a 50 μM SA aqueous solution overnight (15 hr). DMNT, (*3E*)-4,8-dimethyl-1,3,7-nonatriene; C C, untreated control; SA C, SA pretreated control. **c**: A higher concentration of SA (500 μM) inhibits IE-induced JA accumulation at 1 h. A *t*-test was used to test for significance (*, $P \leq 0.05$) compared to the respective control. Data represent mean ± standard error ($n \geq 3$)

performed. Data were analyzed for significance with *t*-test ($P<0.05$). Treatments were compared to appropriate controls.

Results and Discussion

We tested SA for its effect on IE- and MW-induced JA accumulation and VOC release. When roots of corn seedlings were pretreated with 50 μM SA for 15 h and then the leaves induced by application of IE, we found a significant increase in JA production (112.4 ng/g FW) compared to IE-induced control plants (53.5 ng/g FW) 2 h after IE application. Mechanical wound-induced JA was not affected in SA treated plants (Fig. 1a). We also did not detect any increases in free or conjugated SA over control plants (data not shown). While even lower (5 μM) concentrations of SA had no significant effect on MW- or IE-induced JA accumulation (data not shown), we observed a significant reduction in IE-induced JA accumulation 1 h after elicitation in plants treated with 500 μM SA (Fig. 1c). Shorter treatment periods (4 and 8 h) with SA had no effects on JA accumulation (data not shown).

Consequently, 15 h SA pre-treated plants produced significantly more VOC when induced by IE (Fig. 1b). Most affected were linalool, (3E)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and indole, while no increases in sesquiterpenes were observed. Overall, a 3-fold increase for combined volatiles was found for SA-pretreated plants. It is noted that no MeSA emission as a consequence of the pre-treatment of corn seedling with SA was observed.

The priming effect of SA on JA and VOC release after induction with IE in *Zea mays*, as described herein, bears close resemblance to those observed for corn plants exposed to green leaf volatiles (GLV) (Engelberth et al., 2004). When corn seedlings were exposed to physiological concentrations of GLV overnight and subsequently induced with IE, they also exhibited a stronger response with regard to JA accumulation and VOC release when compared to appropriate controls. As for SA treatment, MW-induced JA accumulation was not affected.

Defense "priming" describes a process in which a response to a certain challenge (i.e., pathogen infection or herbivore infestation) is accelerated and/or enhanced by challenge-specific prior stimulation. A requirement for priming is for the plant to be either previously challenged by either nonpathogenic strains of potential pathogens, or treated with compatible chemicals or analogs of those compatible chemicals that are usually also involved in direct defense signaling (Prime-A-Plant Group, 2006; Frost et al., 2008). For example, SA as a major direct defense signal primes defense responses against pathogen attack at low concentrations. Likewise, priming against insect herbivory is mostly signaled by methyljasmonate and/or green leaf volatiles (GLV), compounds that are also involved in direct anti-herbivore defense signaling. However, the data presented herein are in contrast to those forms of compatible priming. Corn seedlings appear to be capable of utilizing signals from a conflicting pathway to prime anti-herbivore defenses, when those signals are recognized at appropriate concentrations. Mur et al. (2006) described a comparable stimulatory effect of SA on typical JA responses. However, both compounds were applied exogenously, and no treatment was tested for its effect on endogenously induced responses, for example JA accumulation after mechanical wounding or pathogen infection. In our study, only SA was applied exogenously, while JA accumulation was induced *in planta* by treatment with IE and MW. Furthermore, SA exhibited its priming effects only when applied for 15 h, and was specific towards IE-induced JA accumulation, whereas MW-induced JA was not affected. It is well known that mechanical damage and insect herbivory exhibit certain differences, which can be attributed to IE like volicitin, *N*-linolenoyl-glutamine, and other fatty acid-amino acid conjugates abundant in the spit of the attacking insect herbivore (Engelberth et al., 2007; Schmelz et al., 2009). In corn, major differences between MW and IE application were found with regard to the spatial distribution of major jasmonates (Engelberth et al., 2007), and it appears that this context-dependent accumulation of jasmonates is a critical factor for the initiation and effectiveness of GLV- and SA-induced anti herbivore defense priming. The similarities between GLV- and SA-induced priming also further suggest that common mechanisms may exist, which govern the primed state of the plant. Work is currently in progress to identify elements that regulate this response.

Abstract Females of the gregarious endoparasitoid *Cotesia kariyai* were attracted to a blend of volatiles released from corn plants infested with larvae of their host, the common armyworm (*Mythimna separata*). We investigated the effects of time after the last infestation (1–168 h) on the attractiveness of corn plants infested by host larvae by using a wind tunnel under laboratory conditions. Immediately after the removal of the larvae, parasitoids were attracted more to plants that had been infested with the larvae than to intact plants (control). This attractiveness gradually decreased with time after the last infestation. The attractiveness of the infested plants was significantly higher than that of intact plants when the time after the last infestation was within 1 day. Fifteen herbivore-induced volatiles were recorded in the headspace of infested corn plants irrespective of time. The amounts of some compounds including (*Z*)-3-hexen-1-yl acetate, which have already been reported to attract *C. kariyai*, correlated with the attractiveness. The ecological meaning of the duration of production of *C. kariyai* attractants is discussed.

Introduction

Plants respond to herbivore attack and defend themselves against herbivores either directly or indirectly (Karban and Baldwin, 1997; Arimura et al., 2009). These plant responses are called induced direct defenses and induced indirect defenses. For induced direct defense, plants produce chemical weapons such as toxins, repellents, and digestibility reducers that target the herbivores preference and performance (Karban and Baldwin, 1997). One of the well known induced indirect defenses is the attraction of carnivorous natural enemies of the herbivores by emission of herbivore induced plant volatiles (HIPVs) (Takabayashi and Dicke, 1996; Arimura et al., 2009).

Mythimna separata (Walker) (Lepidoptera: Noctuidae) is a pest of various gramineous crops in Australia, New Zealand, and the tropic and temperate zones of Asia (Kanda, 1991). One dominant natural enemy of *M. separata* larvae is *Cotesia kariyai* Watanabe (Hymenoptera: Braconidae) (Hirai, 1984), a gregarious endoparasitoid. Females of *C. kariyai* prefer to oviposit in the 3rd to early 6th larval instar of *M. separata* (Sato and Tanaka, 1984). Takabayashi et al. (1995) reported that *C. kariyai* was attracted to HIPVs emitted from corn plants infested by early instars of *M. separata* larvae. The flight response of *C. kariyai* also was affected by host plant species, leaf age, and wasp experience (Fujiwara et al., 2000a, b; Fukushima et al., 2001; Hou et al., 2005).

From the viewpoint of carnivorous natural enemies, HIPVs emitted by herbivore-infested plants are useful

information for indicating the presence of host/prey (Vet and Dicke, 1992). Thus, HIPVs released by plants also are expected to influence the fitness of natural enemies. It would be adaptive for carnivores to find a plant that is currently infested by enough suitable prey/hosts. However, in a field, there are host/prey-infested plants with various histories of herbivory (i.e., number of host/prey, their developmental stages, time after the last infestation, etc.). Until recently, most chemical and behavioral studies on HIPVs have been on plants currently infested by herbivores or plants immediately after infestation. Here, we focused on the effects of time after the last infestation on the attractiveness of HIPVs in a tritrophic system consisting of corn plants, *M. separata* larvae, and *C. kariyai*.

Methods and Materials

Plants and Insects Corn plants (*Zea mays* L., Honey Peter 619, Sakata Seed Co., Kanagawa, Japan) were grown separately in small, transparent plastic pots (5.5 cm diam., 7 cm in height) in an incubator (25±1°C, 50–60% relative humidity (RH)) under fluorescent lights (15,000 *lx*, 16 L: 8D photoperiod). Plants were observed daily and watered when needed. In all experiments, 14-d-old corn plants (ca. 30 cm in height) were used.

Both *M. separata* and *C. kariyai* were reared in the Laboratory of Applied Entomology and Zoology, University of Tsukuba, Japan, from cultures obtained from the Center of Ecological Research, Kyoto University in 2001. *Mythimna separata* was reared on an artificial diet (Silkmate® 2(s), Nosan Corporation) under laboratory conditions (25±2°C, 16 L: 8D photoperiod, and 60-70% RH).

The *C. kariyai* population was maintained under the same conditions used for rearing *M. separata*. Individual fourth instars *M. separata* were offered to 2-3-d-old *C. kariyai* females in small Petri dishes (5 cm diam.) for parasitization. Soon after attack, the host larvae were collected and reared with Silkmate® in plastic boxes (10 cm diam., 6 cm in height). These cages were checked daily to provide sufficient artificial diet until egression, which occurred approx. 10 days after parasitoid oviposition into host larvae. A cluster of cocoons of *C. kariyai* was collected and placed in a transparent plastic cage (16×28×17 cm) until emergence of adults, which occurred 5 days after egression from host larvae. Honey droplets on moist cotton wool were provided as food for the parasitic wasps. Mating occurred immediately after emergence. Unless otherwise stated, all experimental parasitoid females were 3-d-old, mated, and well-fed individuals.

Wind Tunnel Bioassay The flight responses of *C. kariyai* to corn plants previously infested with *M. separata* larvae were observed in a wind tunnel (30×30×150 cm; 25–30 cm/s wind velocity; 25±1°C; 60–70% R.H. and 800 *lx* light intensity) (Fukushima et al., 2001). A metal platform (15 cm in height) was placed 50 cm downwind of the test corn plant as a release point for the parasitoid females. Wasps were selected without bias from the cage and individually placed into a Petri dish (4.5 cm diam., 1.5 cm in height) containing small droplets of honey and water 1 h prior to the experiment and then transferred to the bioassay room. The Petri dish was opened, and a parasitoid female was given 5 min to leave the dish, otherwise it was discarded. Females that did not take off within 5 min or did not land on the plant within 5 min from take off were considered as not having been attracted to the test plant. Each female was used once and then discarded. Wind tunnel tests were performed primarily between 10:00 am and 3:00 pm.

We investigated the effect of time after the removal of host larvae from corn plants on the attraction of *C. kariyai* with a wind tunnel. For control, we used uninfested plants. Twenty 4th-instars of *Mythimna separata* were introduced into a plastic cage with a potted corn plant (14-d-old, ca. 30 cm in height). Larvae were allowed to feed until the damaged area reached approximately 30% of the total surface area (feeding period was ca. 30–45 min). Each pot was covered with aluminum foil during the feeding period to prevent feces from falling on the soil. *M. separata* larvae and their associated products then were removed from the plant with a fine camel hair brush. The plant was washed with tap water and used for wind tunnel bioassays.

Flight responses of *C. kariyai* were examined at different time intervals of 0, 3, 6, 24, 48, 72, 96, 120, 144, and 168 h after removal of larvae. After each test, corn plants were placed inside plastic cages (30×30 cm, 50 cm in height) and kept indoors under conditions of 25±1°C; 60-70% R. H. and a 16 L: 8D photoperiod. Plants were watered regularly during the experimental period. For each plant, 5 *C. kariyai* females were tested for each time interval, and the bioassay was replicated 8 times on different days (a total of 40 wasps for each time interval).

Chemical Analyses Headspace volatiles of corn plants were collected at the different times (0, 6, 24, 48, 96, and 144 h) after removal of the host larvae. Six corn plants were grown in a plastic pot (12 cm diam., 10 cm in height) under the same rearing conditions for 14 days. Before volatile collection, corn pots were covered with aluminum foil to eliminate possible volatiles from the pot.

Prior to headspace collection, each plant was placed in a 3 l glass bottle (13 cm diam., 30 cm in height). Plant volatiles were collected on the adsorbent 'HayeSep-Q' (60-80 mesh) (Restek Corporation, USA) for 2 h at a flow rate of 1,000 ml /min. Each treatment was repeated 4 times with fresh

batches of corn plants. The methods used for the collection of volatiles were the same as reported earlier by Takabayashi et al. (1991). Volatile collections were conducted during daytime (from 10:00 to 15:00). After the 2-hr-collection period, traps were rinsed with 200 µl redistilled hexane, and 100 ng of tridecane were added to the extract as an internal standard. After concentrating the extract under a nitrogen stream, aliquots of the extract were injected into a gas chromatograph-mass spectrometer (GC-MS). Identification and quantification of the trapped volatiles were performed using GC-MS (GC; Hewlett Packard 6890) with an HP-5MS capillary column: 0.25 mm i.d., 30 m length, 0.25 µm film thickness, MS: Hewlett Packard 5973 mass selective detector, ion source 70 eV). The GC oven temperature was programmed to increase from 40°C (5 min hold) to 280°C at 15°C/min. The chemical structure of each compound was determined by comparison with the mass spectra and the retention time of authentic chemical samples or by comparison with the Wiley databases (Wiley 7 N and Wiley275) and the database of the National Institute of Advanced Industrial Science and Technology (SDBS compounds and spectral search) (http://riodb01.ibase.aist.go.jp/sdbs/cgi-bin/direct_frame_top.cgi).

Statistics The effect of time after removal of *M. separata* larvae from infested corn plants on the percentage of *C. kariyai* that landed on the plants was analyzed with a mixed model using the restricted maximum likelihood (REML) and individual plants as a random effect. Tukey's HSD test was used to analyze the differences in the percentages of *C. kariyai* that landed on each treatment plant (infested plants) and control plant (intact plants). Proportional data were transformed by arcsine square root before analysis. Linear regression analysis was performed to examine the relationship between the amounts of each compound and the mean percentage of *C. kariyai* females that were attracted to the *M. separata*-infested plants using the least squares method. All analyses were performed with the JMP statistical software (SAS Institute, 2003).

Results and Discussion

Olfactory Responses of Cotesia kariyai to Host-infested Plants The percentage of naive *C. kariyai* females that were attracted to *M. separata*-infested plants (flight response) gradually decreased with an increase in time after the last infestation (Fig. 1). The effects of time after the last infestation were significant (Mixed model; $df=9$, $F=4.462$, $P<0.001$).

When the flight responses were tested within a day (0, 3, 6, 24 h), the percentage of wasps that were attracted to *M. separata*-infested plants was significantly higher than the one attracted to the controls (Fig. 1; Tukey's HSD test, $P=0.05$). Two d after the last infestation and later (48 to 144 h), the flight responses to previously infested plants were not significantly different from those to the uninfested controls or the responses within a day after the last infestation (Fig. 1; Tukey's HSD test, $P=0.05$). When 168 h had passed after the last infestation, the flight response to infested plants was not significantly different from that to the uninfested controls and from responses to plants that experienced the last infestation 48 to 144 h. However, 168 h past infestation, the parasitoids´ response to the previously infested plants was significantly lower than the one observed within a day after the last infestation (Fig. 1; Tukey's HSD test, $P=0.05$). The olfactory responses of *C. kariyai* females to previously infested plants decreased significantly with time only 24 h after termination of infestation; this was the time point of change in attractiveness. Similar results have been reported in a tritrophic system of corn plants, *M. separata* larvae, and the tachnid fly *Exorista japonica* with significantly higher responses of the parasitic fly observed only within 1 day (Hanyu et al., 2009). Kugimiya et al. (2010) showed that *Cotesia vestalis*, a larval parasitoid of diamondback moth (*Plutella xylostella*), preferred Japanese mustard spinach 1 and 2 days after herbivory (formerly infested plants) over intact plants, and freshly infested plants over formerly infested plants.

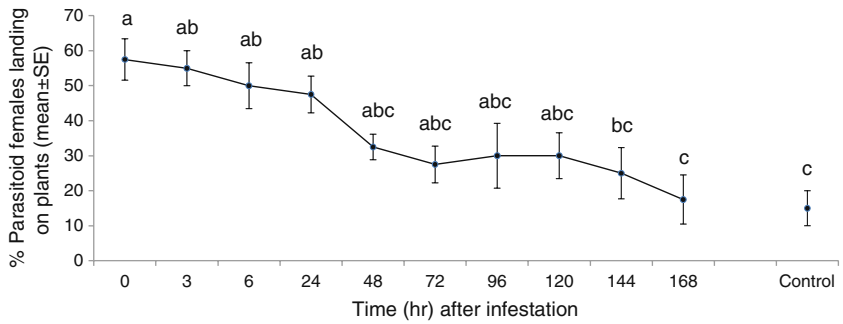

Fig. 1 Wind tunnel bioassay. Percentage of *Cotesia kariyai* females (mean±SE) landing on corn plants previously infested with *Mythimna separata* host larvae. Controls: uninfested corn plants. The same letter indicates no significant difference (Tukey-Kramer HSD test $P=0.05$). $N=40=100\%$ wasps were tested for each time interval

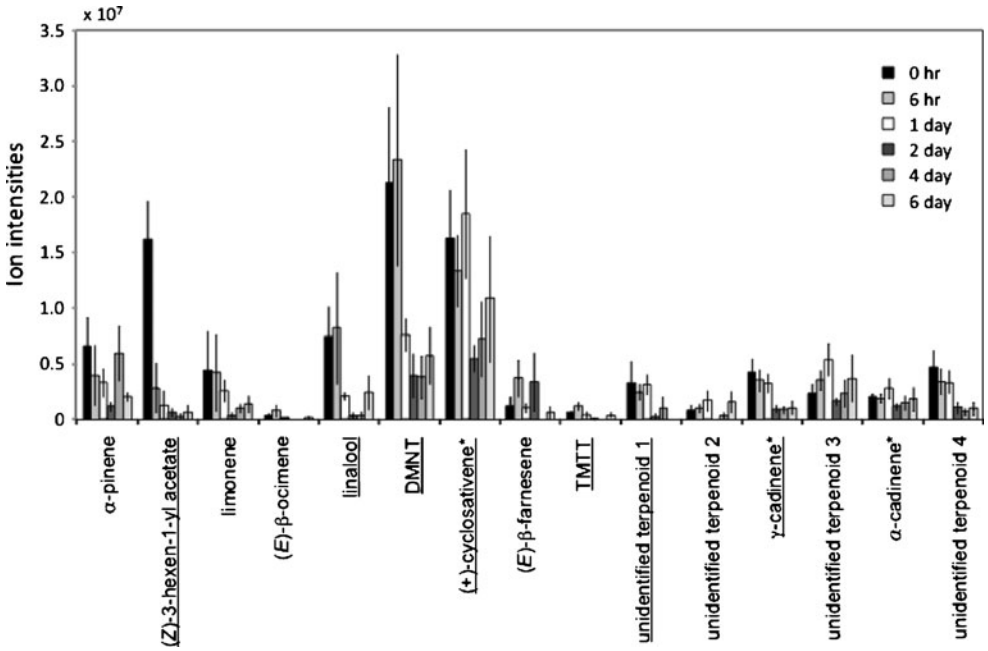

Fig. 2 Volatile compounds identified from the headspace of corn plants previously infested with *Mythimna separata* larvae. Mean±SE ion intensities (N=4). DMNT: (*E*)-4,8-dimethyl-1,3,7-nonatriene. TMTT: (*E, E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. Quantities of underlined compounds correlate with attractiveness shown in Fig. 1 (regression analyses). Compounds with * were tentatively identified by comparison with mass spectra from databases

Chemical Analyses In total, 15 compounds were recorded in the headspace of corn plants infested by *M. separata* (Fig. 2). α-Pinene, (*Z*)-3-hexen-1-yl acetate, limonene, (*E*)-β-ocimene, linalool, DMNT ((*E*)-4,8-dimethyl-1,3,7-nonatriene), (*E*)-β-farnesene, (+)-cyclosativene, and TMTT ((*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene) were identified based on the comparisons of the mass spectra and the retention times with authentic samples by GC-MS. γ-Cadinene and α-cadinene were tentatively identified from mass spectra databases. Four compounds remain unidentified. The induced compounds listed in Fig. 2 were not exactly the same as those detected in our previous study (Takabayashi et al., 1995), probably due to a difference in the cultivar (Royal Dent corn in Takabayashi et al., 1995).

The attractiveness of infested corn plants with different times after the last infestation was positively correlated with the total amount of volatiles in the time course (regression analysis, P=0.003). We then tested the correlation of the attractiveness of the plants and the amounts of each volatile compound in the time course. Among 15 compounds, (*Z*)-3-hexen-1-yl acetate, linalool, DMNT, (+)-cyclosativene, TMTT, unidentified compound 1, γ-cadinene, and 4 unidentified compounds showed significant correlations with plant attractiveness (regression analysis) (Table 1). These compounds may cause the differences in attractiveness of plants at different times after infestation. By using this approach, we should be able to select candidates from a herbivore-induced plant volatile blend that are involved in the attraction of natural enemies (Kugimiya et al., 2010).

Previously, we reported that *C. kariyai* females were attracted to (*Z*)-3-hexen-1-yl acetate and α-pinene (Ozawa et al., 2008). The production of α-pinene by the infested plants does not match the change in attractiveness in time (regression analysis; Table 1). The amounts of (*Z*)-3-hexen-1-yl acetate released by the infested plants were significantly different 0 and 24 h after the last infestation, but did not significantly differ 24 and 168 h after stop of infestation (Tukey's HSD test, P<0.001), thus indicating that the change in the production of (*Z*)-3-hexen-1-yl acetate alone does not explain the changes in the attractiveness shown in Fig. 1. Ozawa et al. (2008) reported that *C. kariyai* responded to a mixture of volatiles but that the wasps did not respond to single compounds in the blend. Thus, the

Table 1 Linear regression analysis of the amounts of each compound and the mean percentage of *C. kariyai* females attracted to *M. separata*-infested plants

Compound	r^2 value	t value	P value
α-Pinene	0.0672	1.26	0.2212

Unidentified compound 4	0.3277	3.27	0.0035
Total	0.3421	3.38	0.0027

changes in the attractiveness may be explained by changes in the blend of volatiles released by corn plants in the course of time after infestation. Turlings et al. (1990) reported that corn seedlings infested by the beet armyworm *Spodoptera exigua* for 2 h released terpenoids only in minute amounts immediately after infestation, but that larger amounts of the compounds were detected after 16 h (following day). In our study, (*E*)-β-ocimene, (*E*)-β-farnesene, and the 3 unidentified compounds showed a similar trend (Fig. 2).

The host larvae *M. separata* are nocturnal and thus feed on host plants mainly during the night, except for the early instars (Sato et al., 1983). By contrast, *C. kariyai* females search for host larvae during the daytime when the larvae are hiding (Sato et al., 1983; Shiojiri et al., 2006). Under these conditions, the host searching wasps likely use *M. separata*-induced corn plant volatiles induced by the larvae during the previous night. Thus, it would be adaptive for *C. kariyai* to respond not only to volatiles from corn plants freshly damaged by hosts but also to plants with damage caused within a 24-h-period. From the plant's viewpoint, continuing to produce higher amounts of *C. kariyai* attractants for 24 h after the last damage by the host larvae during the previous night also would be adaptive because the plants are likely to be damaged by herbivores in the forthcoming night. However, the metabolic costs of induced volatile production in corn plants is expected to be costly (Hobrallah et al., 2004). Currently undamaged corn plants with a history of previous infestation should stop producing *C. kariyai* attractants at some time. The recorded time period (24 h) after the last infestation during which previously infested corn plants keep on attracting may be counterbalanced by the benefits for the plants and *C. kariyai*. Further, herbivore-induced plant volatiles also may be used by other sympatric herbivore species to search for food plants (Hilker and Meiners, 2006), thus causing additional ecological costs/benefits in the production of herbivore-induced plant volatiles for plants. The ecological relevance of timing of the production of herbivore-induced plant volatiles also has been discussed with respect to egg parasitoids (Hilker and Meiners, 2006). Further studies that clarify the mechanisms involved in timing HIPV production will shed light on the relative costs/benefits of the members of tritrophic interactions.

Abstract Several studies have shown that herbivore-induced plant volatiles act directly on herbivores and indirectly on their natural enemies. However, little is known about the effect of herbivore damage on resistant and susceptible plant cultivars and its effect on their natural enemies. Thus, the aim of this study was to evaluate the attraction of the herbivorous pentatomid bug *Euschistus heros* and its egg parasitoid *Telenomus podisi* to two resistant and one susceptible soybean cultivars with different types of damage (herbivory, herbivory+oviposition, and oviposition). In a Y-tube olfactometer, the parasitoids were attracted to herbivory and herbivory+oviposition damaged soybean plants when compared to undamaged soybean plants for the resistant cultivars, but did not show preference for the susceptible cultivar Silvânia in any of the damage treatments. The plant volatiles emitted by oviposition-damaged plants in the three cultivars did not attract the egg parasitoid. In four-arm-olfactometer bioassays, *E. heros* females did not show preference for odors of damaged or undamaged soybean plants of the three cultivars studied. The Principal Response Curves (PRC) analysis showed consistent variability over time in the chemical profile of volatiles between treatments for the resistant cultivar Dowling. The compounds that most contributed to the divergence between damaged soybean plants compared to undamaged plants were (*E,E*)-α-farnesene, methyl salicylate, (*Z*)-3-hexenyl acetate, and (*E*)-2-octen-1-ol.

Introduction

Plants are equipped with several mechanisms to defend themselves against herbivores, microbial pathogens, or abiotic stress. One of the mechanisms of damage-induced plant defense is the production of plant volatile organic compounds (VOCs) that serve as repellents to herbivores or as attractants to parasitoids and predators (Price, 1997; De Moraes et al., 2001; Hilker and Meiners, 2006; Chen, 2008; Heil, 2008).

Plants change the blend of VOCs in response to damage either qualitatively or quantitatively (Dicke, 1999), depending mainly on plant traits that vary among species or genotypes and on the different herbivore species causing the damage (Lin et al., 2008; Rasmann and Turlings, 2008). This change can be responsible for differential attraction of parasitoids and predators (Fritzsche Hoballah and Turlings, 2001). Soybean plants, *Glycine max* L. (Fabales: Fabaceae)

and pigeon pea, *Cajanus cajan* (Valder) (Fabales: Fabaceae) damaged by *Euschistus heros* (Fabricius) (Hemiptera: Pentatomidae) released similar chemical profiles of volatiles that attracted the egg parasitoid *Telenomus podisi* (Ashmead) (Hymenoptera: Scelionidae). However, when soybean was damaged by feeding *Anticarsia gemmatalis* Hübner (Lepidoptera: Noctuidae) larvae, the chemical profile was different and did not attract *T. podisi* (Moraes et al., 2005).

The identification of chemicals responsible for plant defense and their role in the interactions with natural enemies could be used to attract and retain parasitoids in crops (Gatehouse, 2002) and help breeders in the development of cultivars resistant to pests (Piubelli et al., 2005). Therefore, it is important that hostplant resistance interacts positively with the action of natural enemies. However, this association does not always result in positive interactions. Chemical and morphological plant traits can directly influence survival, fecundity, and foraging success of natural enemies on hosts or prey. These traits also can have indirect effects on the quality of herbivores that in turn affects the physiology, behavior, or development of their natural enemies (Cortesero et al., 2000). In a study investigating the effects of chemical plant resistance against herbivores and of predators on plant fitness, Bartlett (2008) observed a negative interaction between the predator *Podisus maculiventris* (Say) (Hemiptera: Pentatomidae) and soybean resistance against *Epilachna varivestis* Mulsant (Coleoptera: Coccinellidae).

Studies on resistance of soybean cultivars primarily involve direct defense against herbivory during the reproductive stage of soybean (Piubelli et al., 2005; Li et al., 2004, 2008). Carrão-Panizzi and Kitamura (1995) reported that the cultivar IAC100 contains high quantities of isoflavones compared to other soybean cultivars studied and showed high resistance to herbivorous stink bugs. The resistance of IAC100 to stink bugs and lepidopteran larvae was confirmed by McPherson and Buss (2007) and Piubelli et al. (2005) who proposed an antibiotic effect of this cultivar on velvetbean caterpillars, *A. gemmatalis*. The soybean cultivar Dowling shows antixenotic and antibiotic effects against aphids, which stop feeding and cause death after 48 hr (Li et al., 2004, 2008).

However, except for these studies of direct effects of soybean cultivar resistance on herbivores, no study has yet addressed the question how resistant traits of the vegetative stages of soybean cultivars affect the plant's indirect defense against herbivores. For Integrated Pest Management in soybean crops, it has been proposed that natural enemies could be released or attracted to the field before herbivorous stink bugs arrive (Borges et al., 1998). Therefore, it is important that the development of resistant cultivars does not alter plant responses to herbivore damage and the release of herbivory-induced volatiles that attract natural enemies.

In this study, we tested the hypothesis that the level of indirect defense in response to damage by herbivores in resistant soybean cultivars is different from that of susceptible cultivars. Hence, we compared chemically the blend of herbivore-induced volatiles in resistant and susceptible cultivars during the vegetative stages. In addition, we compared the behavioral response of both herbivores and their parasitoids to induced volatiles released by the different cultivars. We chose two different cultivars that are known to display resistance against herbivores (IAC100 and Dowling) and one cultivar that shows high susceptibility to stink bugs (Silvânia) (Laumann et al., 2008). The studied herbivorous insect was the stinkbug *E. heros* and its egg parasitoid *T. podisi*.

Specifically, we studied the following questions: (a) Does *T. podisi* respond differently to resistant and susceptible cultivars when exposed to undamaged plants or plants damaged by herbivory and oviposition by *E. heros*? (b) Are *E. heros* females attracted to the volatiles of undamaged or damaged soybean cultivars? (c) Do resistant and susceptible soybean cultivars release a different chemical profile of volatiles when submitted to herbivory, herbivory+oviposition, or oviposition damage by *E. heros*? (d) Does attraction of *T. podisi* depend on the extent of herbivore damage?

Methods and Materials

Plant and Insect Rearing Soybean (cultivars Dowling, IAC100 and Silvânia) seeds were obtained from the Embrapa Cerrados Research Center (Brasília, DF, Brazil). Seeds were germinated on damp paper, and after 3 day they were transplanted to pots with a mixture of soil and organic substrate (in a proportion of 1:1 *w*/*w*). Plants were kept in a controlled environment room at L14:D10 photoperiod, 27± 1°C and 65±10% r.h. All plants used were in the V3 physiological stage (Fehr et al., 1971).

Euschistus heros individuals were obtained from a laboratory colony started from adults collected in soybean fields near Embrapa Genetic Resources and Biotechnology, Brasília, Brazil (15°47′ S, 47°55′ W). Bugs were reared in 8 l plastic containers, on a diet of soybeans, sunflower seeds (*Helianthus annus*), raw peanuts (*Arachis hypogaea*), fresh green beans (*Phaseolus vulgaris*), and water. The food supply was renewed twice a week. To provide oviposition substrate and shelter for the bugs, a piece of a nylon mesh screen (15 cm^2) was placed inside the cages. To obtain virgin females, insects were sexed after their imaginal molt and cuticular hardening, and maintained isolated from males until their use in experiments.

The egg parasitoid *T. podisi* was obtained from a laboratory colony raised on eggs of *E. heros*. The wasps were maintained in acrylic cages (25 cm^2 tissue culture flask, angled neck; ICN Biomedicals, Irvine, CA, USA), and fed with a drop of honey, supplied twice a week. Once parasitoids hatched from eggs, they were transferred to an egg-free acrylic cage where they could mate for a period of 24 hr. *Euschistus heros* and *T. podisi* were maintained in separate environmental rooms at 27±1°C, 65±10% r.h., and a 14 hr photoperiod.

Preparation of Plants for Bioassays We studied the attraction of *T. podisi* to the three soybean cultivars (cv) that had been subjected to following treatments: (1) herbivory damaged soybean (Herb): five virgin, sexually immature *E. heros* females (2–4 day-old) were placed on the plant; (2) herbivory+oviposition damaged soybean (HerbOvi): five mated *E. heros* females (12–15 day-old) were placed on the plant; (3) oviposition damaged soybean (Ovi): five mated *E. heros* females, with their stylet removed using dissection scissors, were placed on the plant; (4) control: undamaged soybean (UD). For treatments, each plant was kept in a micropore plastic bag (bread bag) where the insects were introduced. Plants were used 24, 48, 72, 96, and 120 hr after damage, with 60 replicates for each time/treatment combination. All insects were removed from the plants a few minutes before the bioassays.

We studied the preference behavior of *E. heros* females by using soybean plants that had been submitted to the same treatments as described above. All bioassays were carried out using plants on the 4th d of damage, because preliminary results showed that natural enemies respond to damaged plants only on the 4th d, and the chemical analysis of the extracts collected from the air-entrainment also showed higher levels of volatiles released on the 4th d

Olfactometer Bioassays with Egg Parasitoids To determine if herbivory- or oviposition-induced volatiles have an effect on the foraging behavior of parasitoids, individual naïve female parasitoids were offered a choice between odors in a Y-shaped olfactometer. A square acrylic block (19×19 cm) with a Y-shaped cavity (1 cm thickness) sandwiched between two glass plates was used as the bioassay arena (Moraes et al., 2005). The trunk of the apparatus measured 8 cm, and each arm 7 cm. Damaged or undamaged plants were placed in glass chambers that were connected to the olfactometer via silicon tubing. Filtered (activated charcoal) and humidified air was pushed through the system at 0.6 l/min, and pulled through at 0.2 l/min, in a push-pull system. The behavior of the insect was monitored by a camera (CCD camera Sony SPT M324CE; Sony, Minato-Ku, Tokyo, Japan fitted with a 12.5–75.0 mm/F1.8 zoom lens) coupled to SACAM software (Jorge et al., 2005) to register behavioral parameters. A single *T. podisi* female was introduced at the base of the Y-tube and observed for 600 sec, and the first choice in each arm was recorded by the software. The first choice was considered to have been made when the insect entered an arm and remained there for at least 20 sec. Each individual was used only once, and the plants were replaced after every five repetitions. The position of the arms of the olfactometer was changed after every five bioassays in order to avoid any bias in the parasitoid response. The response of the parasitoid females was tested for each combination as follows: (1) Herb vs. UD (N=60); (2) HerbOvi vs. UD (N=60), and (3) Ovi vs. UD (N=60). The bioassays were carried out for each soybean cultivar 24, 48, 72, 96, and 120 hr after the start of damage. The damaged and undamaged plants were kept under the same conditions, but in different rooms to avoid plant–plant signalling, until used in the bioassays.

Olfactometer Bioassays with Herbivore Females A four-arm-olfactometer modified from Vet et al. (1983) was used with *E. heros* females. The olfactometer consisted of a square acrylic block (44×44 cm) with an X-shaped cavity (1.5 cm) sandwiched between two glass plates, and it was used as the bioassay arena. The "X" of the apparatus measured 37 cm, and length of the active area for each arm was 25 cm. The length of each arm considered for a positive response of the insects was 15 cm, measured from the upwind end towards the center of the olfactometer. The bioassay procedure was the same as described for the Y-olfactometer above. The first choice was considered to have been made when the insect entered an arm and remained there for at least 60 sec. The responses of 70 stink bug females were tested for each combination: (1) Herb vs. HerbOvi vs. Ovi vs. UD for each soybean cultivar (cv) with 96 hr of damage and (2) UD of cv Dowling vs. UD cv IAC100 vs. UD cv Silvânia vs. air. For each combination, we tested females in different physiological conditions: (a) starved virgin females (the diet was removed 24 hr before the bioassay); (b) fed virgin females; and (c) fed mated females.

Volatile Analysis Herb-, HerbOvi-, Ovi-, and UD-plants were placed individually in cylindrical glass chambers (internal volume 10 l). Volatiles were collected for 24 hr, during seven consecutive days (N=11 replicates for each treatment). In an attempt to minimize contamination by volatiles from the soil, pots were wrapped in aluminium foil. A glass tube containing the adsorbent Super Q (100 mg, 80-100mesh, Alltech PA, USA) was connected via a PTFE tube to a vacuum pump at a flow of 0.6 l/min, and the air entrance was connected to a flow of air filtered with activated charcoal (1.0 l/min) creating a positive push-

pull system (Moraes et al., 2008). The trapped volatiles were eluted from the adsorbent using 500 µl *n*-hexane and pre-concentrated to 200 µl under a N_2 flow. Extracts were stored at −20°C until analysis by gas chromatography (GC) and GC coupled to mass-spectrometry (GC-MS).

The extracts obtained by air entrainment were analyzed by GC (Shimadzu 17A, DB-5 column, 30 m×0.25 mm ID, 0.25 µm film, J&W Scientific, Folsom, CA, USA), using a temperature program of 50°C/1 min, 15°C/min to 250°C/20 min. The column effluent was analyzed with a flame ionization detector (FID) at 270°C. For the GC analyses, 50 µl of each extract were separated, and 1 µl of 1-octen-3-ol was added as internal standard (IS), for a final concentration of 9.8 µg/ml of the IS. One microliter of each sample was injected in splitless mode with helium as carrier gas. Amounts released by the plant in each 24 hr period were calculated in relation to the area of the internal standard. Data were collected with ClassGC software and were handled using Excel Software (Microsoft Corporation 2003).

For qualitative analysis, selected extracts were analyzed using a Shimadzu QP2010 instrument equipped with a quadrupole analyzer, a non-polar DB-5 column (30 m× 0.25 mm ID, 0.25 µm film, J&W Scientific, Folsom, CA, USA) and a splitless injector, with helium as the carrier gas. Ionization was by electron impact (70-eV, source temperature 200°C). Data were collected and analyzed with GC-MS Solutions 2.4 Software (Shimadzu Corporation, Japan). Identifications were made by comparison of spectra with library databases (NIST 2005) or with published spectra and confirmed by using authentic standards when available.

Chemicals Super Q (80/100 mesh) was purchased from Alltech (PA, USA). n-Hexane (95% pesticide residue) was purchased from Fisher Scientific (Loughborough, Leicestershire, UK). (*E*)-2-Hexenal and (*Z*)-3-hexen-1-ol were purchased from Sigma Aldrich (Gillinghan, Dorset, UK). (*Z*)-3-Hexenyl acetate was purchased from Alfa Aesar (Heysham, UK) and (*E*)-ocimene from Botanix (Paddock Wood, Kent, UK). Limonene and linalool were purchased from TCI America (Portland, OR, USA). Methyl salicylate, β-caryophyllene, benzothiazole, β-myrcene, geranyl acetone, and (*E*)-2-hexenyl acetate were purchased from Sigma Aldrich (Steinheim, Germany). (*E*,*E*)-α-Farnesene was provided by Jeffrey Aldrich (USDA-ARS, USA) and (*E*)-4,8-dimethylnona-1,3,7-triene (DMNT) and (*E*,*E*)-4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT) were provided by Michael Birkett (Rothamsted Research, UK).

Statistical Analysis The null hypothesis of equal preference (P=0.05) of parasitoids for the volatiles from damaged plants vs. undamaged plants was tested at each sampling time (24, 48, 72, 96, and 120 hr), using *chi-square* tests with the Yates correction for continuity (Zar, 1998).

Since the volatile sampling was carried out on the same plant at several time points, repeated measures analysis of variance was used to avoid the problem of pseudo-replication during the times analyzed (Hurlbert, 1984; Green, 1993). Therefore, the total amounts of volatiles released in each treatment over time were compared by MANOVA (PROC ANOVA with the PROFILE statement; SAS Institute, 2001), using the subsequent sampling times as repeated measures of the same experimental unit, as suggested by von Ende (1993). Significant data by MANOVA were subjected to *post-hoc* mean comparisons in individual sampling time using the Tukey's test (significance level 5%).

The change in the chemical profile of damaged and undamaged soybean plants over time was assessed using Principal Response Curves (PRC) analysis. PRC models the effect of the treatment d at a determined time t in a species k. The statistical model for compound concentration is: $(y_{d(j)tk}=y_{\underline{0}k}+b_k\ c_{dt}+\varepsilon_{d(j)tk})$, where, $y_{d(j)tk}$ is the concentration of the compound k in replicate j of treatment d at time t, $y_{\underline{0}tk}$ is the mean concentration of the compound k in time t in the control (untreated plant, d = 0), c_{dt} is a basic response pattern for every treatment d, and time t, b_k is the weight of each compound with this basic response pattern, and $\varepsilon_{d(j)tk}$ is an error term with mean zero and variance σ_k^2. These parameters were generated through redundancy analysis (RDA) least-squares estimates from reduced-rank regression with concomitant variables (van den Brink and ter Braak, 1999), with N=11 replicates for each sampling time and treatment.

The values of c_{dt} for the treatment (treatment effect) were plotted as vertical axis (first principal component, PRC1) over sampling time generating a PRC diagram, with a curve for each treatment, that describes the dynamic changes in the blend of volatiles released by the plant. We compared the variation in volatile composition in damaged and undamaged soybean, the latter being our standard (c_{dt} = 0). The response variable weights (displayed on the right side of each diagram) allow evaluation of the contribution of each compound to the overall blend composition. The higher the values of the weight of the variable, the higher the contribution of the compound to the actual response pattern of the PRC.

PRC analysis was applied separately to each soybean cultivar, comparing the damaged and undamaged soybean. For each set of analyses, the significance of each PRC diagram was tested using an F-type test obtained by permutating (Monte Carlo permutation tests; 999 permutations) whole time series in the partial RDA from which the PRC was obtained. A second series of permutation tests (individual contrasts) was performed within each sampling date to determine if differences indicated by the PRC diagram between treatments were statistically significant.

These analyses were carried out using the software CANOCO 4.5 for Windows (ter Braak and Šmilauer, 2002). The data from the main volatile compounds responsible for the treatment differences in PRC diagram were individually submitted to repeated measures MANOVA followed by contrasts formed within sampling time to compare induction treatments against the control, using the *t* test (significance level 5%).

Results

Olfactometer Bioassays with Egg Parasitoids When testing the resistant soybean cultivar Dowling, the egg parasitoid *T. podisi* responded preferentially to the odor of plants with herbivory (Herb; χ^2=7.67, *P*=0.005; χ^2=8.06, *P*=0.005) and herbivory plus egg deposition (HerbOvi; χ^2=9.60, *P*=0.002; χ^2=8.06, *P*=0.005) when compared to undamaged plants (UD) after a 72 and 96 hr treatment-period, respectively (Fig. 1). *Telenomus podisi* preferred volatiles from the resistant soybean cultivar IAC100 when these have been treated for 96 hr by herbivory (Herb, χ^2=11.26, *P*=0.001) and herbivory plus egg deposition (HerbOvi, χ^2=8.06, *P*=0.005) to volatiles from undamaged (UD) plants. No preference was observed to the odors of cv IAC100 with other treatments at the different times evaluated (Fig. 2). For the susceptible cultivar Silvânia, *T. podisi* did not discriminate between odors emitted by undamaged plants and damaged plants regardless of the treatments and duration of treatment (*P*>0.05) (Fig. 3).

Olfactometer Bioassays with Herbivore Females In the four-arm-olfactometer bioassays, *E. heros* females did not show a preference for the Herb-, HerbOvi-, Ovi-, or UD-plants (χ^2, *P*>0.05) of any the three cultivars Silvânia, IAC100 and Dowling, or for undamaged plants of the three cultivars tested against air. This result was independent of the physiological state of the females (virgin starved, virgin fed, and mated fed).

Volatile Analysis The total amount of volatiles released by the soybean cultivar Dowling differed between treatments throughout the sampling times (treatment: *F*=9.89; *d.f.*=3, 56; *P*=0.001; interaction: *Wilk's* λ=0.383; *d.f.*=18, 145; *F*=3.25; *P*=0.001) (Fig. 4). The chemical profile of Dowling plants treated by herbivory (Herb), herbivory plus egg deposition (HerbOvi), egg deposition only (Ovi) differed when compared to undamaged plants (UD) at 48 hr of treatment and at longer treatment periods (*post-hoc* pairwise comparisons by Tukey test, *P*<0.05). No difference was observed for treatment effects or its interaction with time for the cv IAC100 (treatment: *F*=1.82; *d.f.*=3, 56; *P*=0.15; interaction: *Wilk's* λ=0.583; *d.f.*=18, 145; *F*=1.61; *P*=0.06) or cv Silvânia (treatment: *F*=2.63; *d.f.*=3, 56; *P*=0.06; interaction: *Wilk's* λ=0.607; *d.f.*=18, 145; *F*=1.55; *P*=0.08) (Fig. 4).

The chemical profile of the extracts obtained from the treatments Herb, HerbOvi, Ovi, and UD differed between the three cultivars Dowling, IAC100, and Silvânia. The compounds (*Z*)-2-octen-1-ol and (*E*)-2-octen-1-ol were identified only in cv Dowling; (*E*)-2-hexenyl acetate, and indole were identified in cv IAC100, while DMNT was

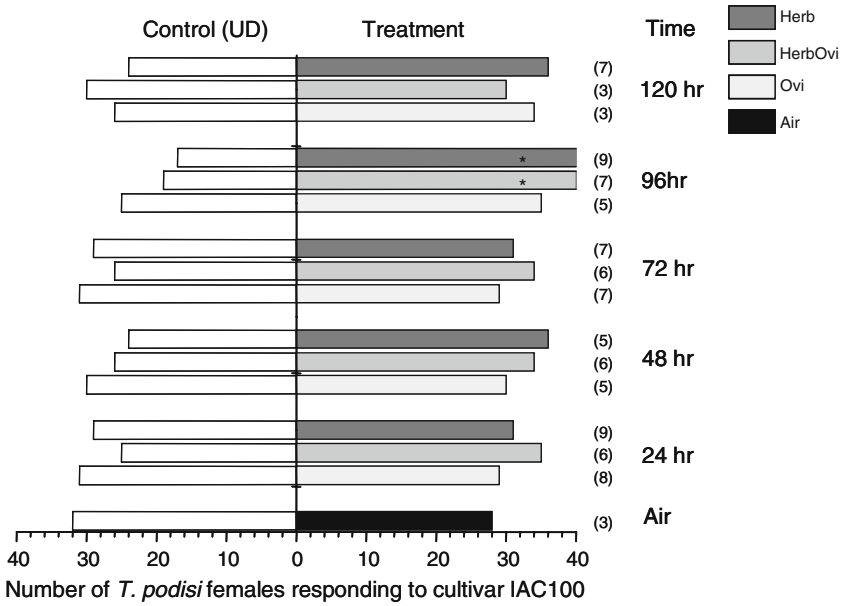

Fig. 2 Responses of the egg parasitoid *Telenomus podisi* in a Y-tube olfactometer to volatiles from soybean cultivar IAC100 subjected to different treatments. *UD* undamaged soybean, *Ovi* soybean plant with oviposition damage, *HerbOvi* soybean plant with herbivory+oviposition damage, *Herb* soybean plant with herbivory damage. 24, 48, 72, 96 and 120 hr: time of plant treatment (induction time). *Asterisks* indicate significant differences ($P<0.05$) between parasitoid responses to volatiles from different treatments: χ^2 test on the proportion responding. *Numbers in brackets* represent the number of insects that did not respond to either of the treatments tested

identified only in cv Silvânia (Table 1). The cultivars also emitted common compounds, such as the green leaf volatile (*Z*)-3-hexenyl acetate; the terpenoids camphene, limonene, α-humulene, β-caryophyllene, (*E,E*)-α-farnesene, TMTT, and the shikimic acid derivatives benzothiazole, benzaldehyde, and methyl salicylate. In addition, some compounds were released in higher quantities by damaged soybean when compared to undamaged soybean (Table 1).

Soybean Cultivar Dowling The PRC analysis of the plant volatiles released showed that cv Dowling had a consistent variability over time between treatments. Of the total variance in the blend composition of volatiles released, 8.6% is explained by sampling times and 12% is explained by induction treatments. The variance exhibited in the first PRC axis was highly significant (Monte Carlo permutation test $F=35.0$, $P=0.001$), and explained 63.0% of the variation in the blend composition due to interactions between sampling times and induction treatments (Fig. 5). At 24 hr after damage, the analysis did not show a significant difference, indicating that the blends of the four treatments were similar. From 48 hr onward, PRC showed a

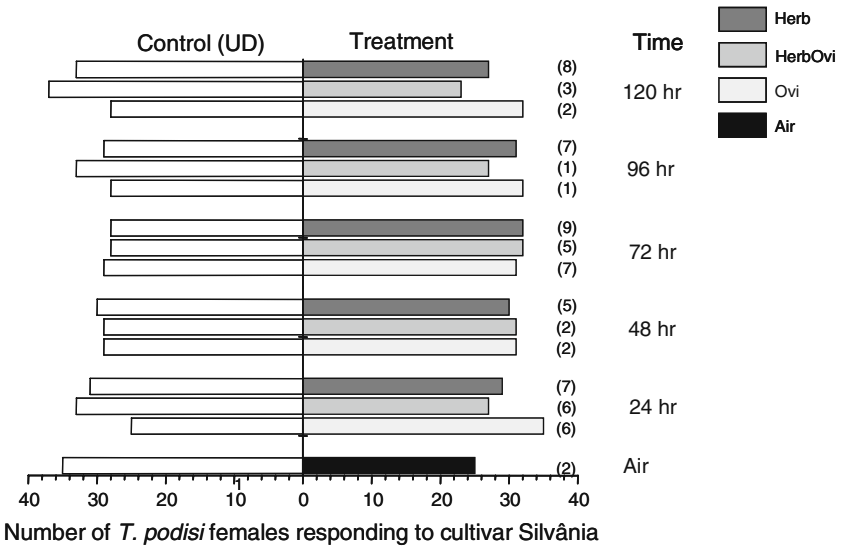

Fig. 3 Responses of the egg parasitoid *Telenomus podisi* in a Y-tube olfactometer to volatiles from soybean cultivar Silvânia subjected to different treatments. *UD* undamaged soybean, *Ovi* soybean plant with oviposition damage, *HerbOvi* soybean plant with herbivory +oviposition damage, *Herb* soybean plant with herbivory damage. 24, 48, 72, 96 and 120 hr: time of plant treatment (induction time). *Asterisks* indicate significant differences ($P<0.05$) between parasitoid responses to volatiles from different treatments: χ^2 test on the proportion responding. *Numbers in brackets* represent the number of insects that did not respond to either of the treatments tested

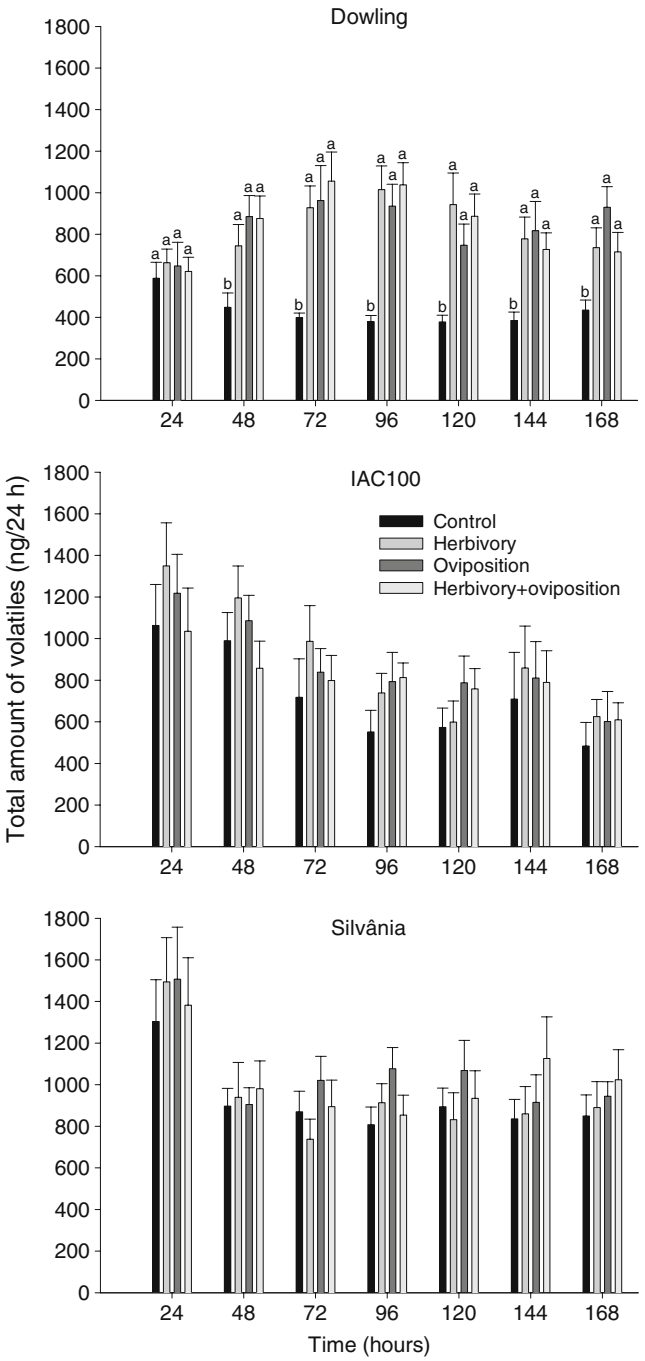

Fig. 4 Total amount of volatiles (mean + SEM) obtained from undamaged plants (control) and plants submitted to the treatments herbivory, oviposition, and herbivory+oviposition for soybean cultivars Dowling, IAC100, and Silvânia. The increase in the amount of volatiles released by damaged plants of cultivar Dowling was significant after 48 hr. For cultivars IAC100 and Silvânia there was no significant difference between treatments and its interactions with time (MANOVA for repeated measures, $P>0.05$). Means followed by the same letter within each sampling date are not significantly different by the Tukey's test at $P>0.05$

clear divergence in curves of the treatments when compared to the undamaged soybean (Fig. 5).

All variable weights (b_k) showed on the right side of the PRC diagram were positive (Fig. 5), which means that all compounds were positively associated with the pattern of changes in the volatile blend. Compounds with weight values higher than 0.5 contribute to the overall volatile blend response (van den Brink and ter Braak, 1999) and the greater the b_k value, the higher the influence on the blend response. Thus, (*E*,*E*)-α-farnesene, methyl salicylate, (*Z*)-3-hexenyl acetate, and (*E*)-2-octen-1-ol were the main compounds that contributed (b_k absolute values >1.0) to the divergence between treatments and control for the cv Dowling (Fig. 5).

A significant interaction between treatment and time (MANOVA for repeated measures, $P<0.05$) was found when data for the main compounds of cultivar Dowling were analyzed individually (Fig. 6). Plants with the treatments Herb and HerbOvi differed from UD plants (contrasts within sampling date; *t* test, $P<0.05$), releasing significantly higher quantities of the same compounds as indicated by PRC analysis (Fig. 6).

Soybean Cultivars IAC100 and Silvânia No significant treatment effect on the volatile blend composition was observed in PRC analysis for the cultivars IAC100 ($F=1.9$, $P=0.073$; Fig. 7, Table 1) and Silvânia ($F=10.4$, $P=0.104$; Fig. 8, Table 1). The variable weights (b_k) displayed in the PRC diagrams showed low values, ranging between −0.5 and 0.5, for all compounds sampled (Figs. 7 and 8).

Although no differences were observed by PRC for IAC100, some compounds were released in higher quantities by plants with the treatments Herb and HerbOvi when compared to UD and Ovi (Table 1). When we analyzed the compounds individually (MANOVA for repeated measures, $P<0.05$), (*Z*)-3-hexenyl acetate ($t_{59,3}=2.031$. $P=0.055$), methyl salicylate ($t_{59,3}=2.159$, $P=0.035$), and (*E*,*E*)-α-farnesene ($t_{48,3}=1.909$, $P=0.061$) were released in significantly or marginally non-significantly higher amounts from plants subjected to 72-hr herbivory (Herb) when compared to undamaged plants (UD). (*Z*)-3-Hexenyl acetate ($t_{59,3}=2.071$, $P=0.043$), methyl salicylate ($t_{59,3}=1.834$, $P=0.072$) and (*E*,*E*) α-farnesene ($t_{55,3}=2.820$, $P=0.006$) were released in significantly or marginally non significantly higher amounts from plants subjected to 96 hr herbivory-plus-oviposition (HerbOvi) when compared to undamaged ones (UD). (*E*,*E*)-α-farnesene ($t_{55,3}=2.322$, $P=0.023$) was released in significantly higher amounts from plants after 96 hr herbivory (Herb) when compared to undamaged plants (UD). The quantities of compounds released by Silvânia also were analyzed by MANOVA for repeated measures, but they did not differ among treatments.

Discussion

In this study, by comparing the susceptible cultivar Silvânia and the resistant cultivars Dowling and IAC100, it is apparent that each cultivar has a different response to herbivore damage, eliciting different responses by the egg parasitoid. The results support our hypothesis that the level of indirect defense in response to damage by herbivores in resistant soybean cultivars is different from that of susceptible cultivars. We could show that the resistant cultivars (here Dowling and IAC100) showed stronger induction of indirect defense; they show a higher production of volatile compounds in response to herbivore attack and a stronger response by the egg parasitoid, *T. podisi*, to volatiles released from plants with herbivory and herbivory+oviposition when compared to undamaged plants. In addition, the results obtained in this study agree with those presented by previous work on induced plant responses to oviposition by Pentatomidae (Colazza et al., 2004a, b; Moraes et al., 2008), where oviposition itself (without herbivory) did not induce changes of plant odors that are attractive to the egg parasitoids.

However, egg-laying by the pentatomid *E. heros* on the cultivars Dowling and IAC100 changes the plant volatile profile; we have detected differences in the

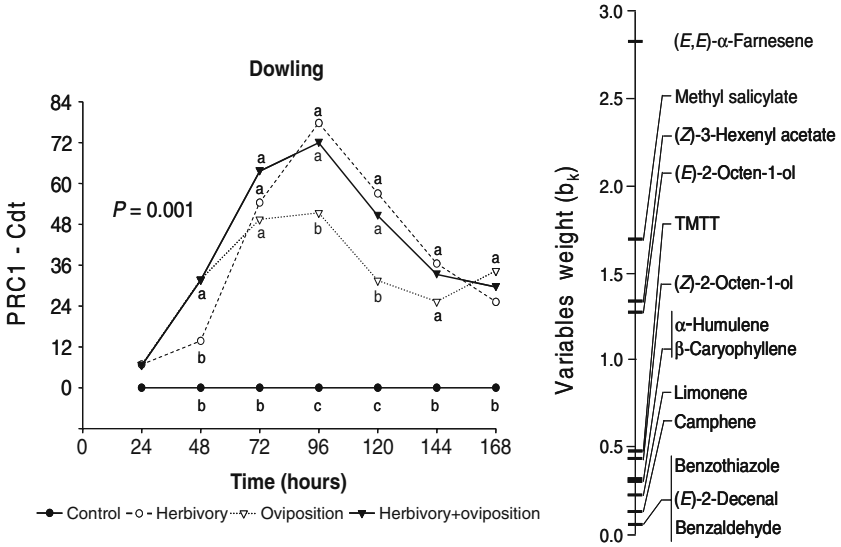

Fig. 5 PRC diagram and variables weights (b_k) based on volatile blends released by soybean plants of the cultivar Dowling, on seven sampling days. The lines represent the response pattern of soybean plants to different treatments in time. The *P*-value indicates significance of the PRC diagram over all sampling times based on *F*-type permutation test. On each date, values of C_{dt} differ significantly between treatments that do not share the same letter code (*a*–*c*); shared or omitted letter codes denote contrasts that do not differ significantly by the Monte Carlo permutation tests at $P<0.05$. The higher (absolute values) the variable weight, the more closely the compound response pattern follows the deviation pattern (from the control, $C_{dt} = 0$ line) indicated on the PRC

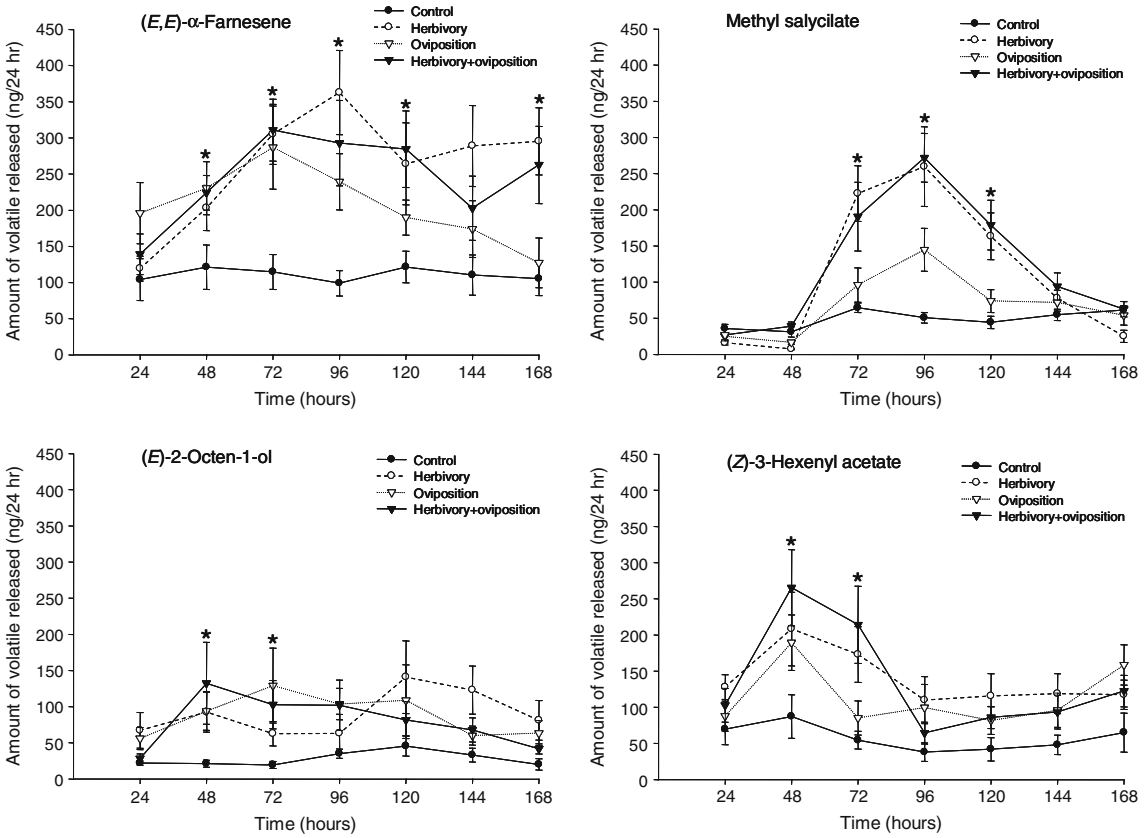

Fig. 6 Amounts (mean ± SEM) of principal volatile compounds released by undamaged soybean (control) and soybean plants submitted to herbivory, oviposition and herbivory+oviposition damage, for cultivar Dowling. *Bars* represent the standard error of the mean. Means marked with an *asterisk* indicate significant differences ($P<0.05$) between induction treatments and control (within a sampling date), *t* test

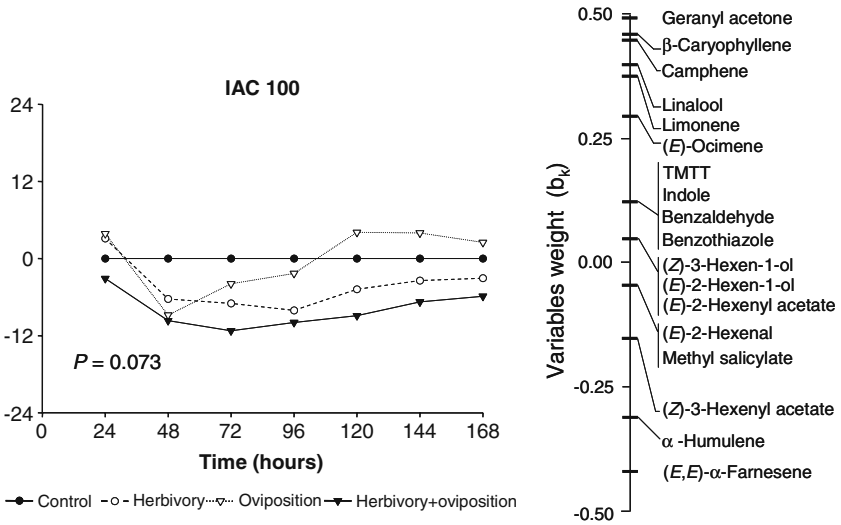

Fig. 7 PRC diagram and variables weights (b_k) based on volatile blends released by soybean plants of the cultivar IAC 100, on seven sampling occasions. The *lines* represent the response pattern of soybean plants to different treatments in time. The *P*-value indicates significance of the PRC diagram over all sampling times based on *F*-type permutation test. The first PRC did not display a significant part of the treatment variance (Monte Carlo permutation test, $P>0.05$), indicating that no significant induction treatment effect on the volatile blend composition was detected. All compounds showed low values for the variables weights ($b_k<0.5$)

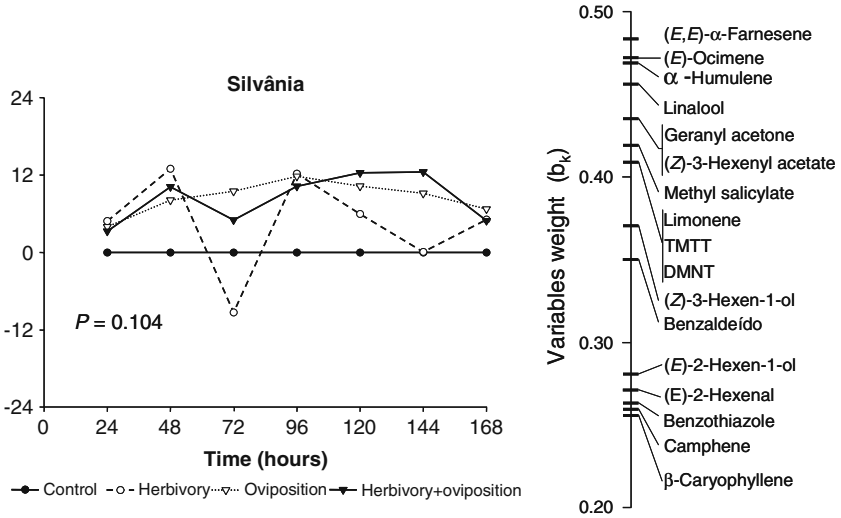

Fig. 8 PRC diagram and variables weights (b_k) based on volatile blends released by soybean plants of the cultivar Silvânia, on seven sampling occasions. The lines represent the response pattern of soybean plants to different treatments in time. The *P*-value indicates significance of the PRC diagram over all sampling times based on *F*-type permutation test. The first PRC did not display a significant part of the treatment variance (Monte Carlo permutation test, $P>0.05$), indicating that no significant induction treatment effect on the volatile blend composition was detected. All compounds showed low values for the variables weights ($b_k<0.5$)

volatile blends of these cultivars between undamaged, herbivory- and herbivory+oviposition-damaged soybean plants. Moraes et al. (2008) suggested that the egg parasitoid *T. podisi* was not attracted to the blend of volatiles produced by herbivory+oviposition and oviposition damaged soybean (cv BR-16), probably due the switching-off of jasmonate signaling caused by oviposition damage. In contrast, the results presented here suggest that oviposition did not switch off jasmonic acid-dependent plant defense because herbivory+oviposition-damaged soybean plants also attracted the natural enemy.

The lack of attraction of the egg parasitoid to oviposition-damaged plants could be explained if the response of the plant is not systemic. When the stink bug lays eggs on the leaves, there is a localized necrosis below and around the eggs (personal observation), which suggests a hypersensitive response (HR) by the plant, isolating the damaged area in a way similar to plant-pathogen responses (Walling, 2000; Kaloshian and Walling, 2005). What induces soybean plants to respond with necrosis to oviposition needs further study, but could be due to microorganisms or chemicals from the oviposition secretion that induce the HR. We are trying to elucidate this phenomenon by studying the chemistry of the saliva and the oviposition secretions.

The PRC analysis used in this work showed the main compounds induced by herbivore damage and the interaction between the damage time and the volatiles released by the soybean plant. The PRC analysis is a multivariate method that is commonly used to aid in impact assessments of pollutant stress on aquatic and terrestrial biological communities in ecotoxicological studies (van den Brink and ter Braak, 1999; van den Brink et al., 2003), and application to other ecological aspects (Torres and Ruberson, 2005; Poelman et al., 2010) has proceeded rapidly. The great advantage of the PRC compared to other multivariate analysis is that it is possible to evaluate the variation of the compounds over time and the importance of each compound in a blend. Furthermore, there is no limitation on the number of variables and normality of the data is unnecessary.

The PRC results suggest that the increase of (*E*,*E*)-α-farnesene, methyl salicylate, (*Z*)-3-hexenyl acetate, and (*E*)-2-octen-1-ol in the total blend have an effect on parasitoid behavior, but the role of these compounds, individually, on the attraction of the egg parasitoid *T. podisi* needs to be evaluated. The attraction of parasitoids and predators to herbivore induced volatiles is often attributed to the relative contribution of each compound in the blend (D'Alessandro et al., 2006, 2009; Pareja et al., 2009), and not all herbivore-induced compounds are important for changing insect behavior. For example, two important compounds in the herbivore-induced volatile blend, indole in maize, *Zea mays*, and methyl salicylate in *Arabidopsis* sp, were not the key compounds responsible for the attraction of the parasitoids tested (D'Alessandro et al., 2006, 2009; Snoeren et al., 2010).

Telenomus podisi did not distinguish among the odors of damaged and undamaged plants for any treatment in cv Silvânia, probably because the volatile compounds released by undamaged and damaged Silvânia soybean are too similar for a discrimination. Vet et al. (1998) suggested that

an insect does not discriminate between odor sources because it is not able to do so, or because the odor is not in the right conditions for the discrimination, i.e., the compounds released by the plant are not in the correct concentration or proportion to be perceived by the natural enemies as a cue indicating the presence of the host. The egg parasitoid *T. podisi* discriminated between volatiles released from differently treated cv Dowling and IAC100, respectively. However, no preference for odor of any treatment of the susceptible Silvânia cultivar was detected; thus, we suggest that the susceptible cultivar was not induced by herbivore damage.

Herbivory-induced plant volatiles are important cues for host foraging behavior of parasitoids. Therefore, maintaining and even enhancing the attractiveness of crop plants to natural enemies should be considered an important trait when breeding new crop varieties. However, these possibilities may sometimes be constrained by the effect of these changes on the attractiveness of the plant to herbivorous pests, as volatiles that attract more natural enemies could also attract more herbivores (Cortesero et al., 2000). Thaler (1999) mentioned that it is advantageous for herbivores to avoid laying eggs on induced plants because such plants are likely to host other herbivores, which are potential competitors for second offspring herbivores, and can also attract a population of natural enemies. The results obtained in this work showed that *E. heros* does not use herbivore-induced volatiles as cues to distinguish between damaged and undamaged plants, or to distinguish between cultivars, but *E. heros* females responded preferentially to undamaged soybean (χ^2, P=0.002) compared to air, suggesting that *E. heros* uses the volatiles from soybean plants to locate its host-plant (results not shown).

The cv Dowling and IAC100 are known to have in their reproductive stage an antixenotic and antibiotic effect against aphids and stink bugs, respectively (Carrão-Panizzi and Kitamura, 1995; Li et al., 2004, 2008). Recently, field experiments showed that population levels of stink bugs colonizing cv Dowling and cv IAC100 were lower than on cv Silvânia suggesting a differential resistance/susceptibility (Laumann et al., 2008). Different studies suggested that the resistance during the reproductive stage of soybean could be related to the amount of isoflavonoids (Rao et al., 1990; Hoffmann-Campo et al., 2001; Piubelli et al., 2003, 2005). Experiments are needed to determine the amount of isoflavonoids during the different physiological stages of soybean plants to evaluate if there is a relation between direct and indirect defense and the quantities of volatile organic compounds.

In summary, the results suggest that the herbivorous stink bug *E. heros* induces the indirect defense of the resistant soybean cultivars Dowling and IAC100, and that the egg parasitoid *T. podisi* is attracted to the volatiles released by herbivory- and herbivory+oviposition-damaged plants of these cultivars. In olfactometer bioassays, *E. heros* did not distinguish between damaged and undamaged soybean nor between resistant and susceptible cultivars. In addition, the resistant cultivar Dowling and IAC100 showed consistency in the main volatile compounds induced: (*E*,*E*)-α-farnesene, methyl salicylate, (*Z*)-3-hexenyl acetate. Further laboratory studies are necessary to investigate the importance of these compounds for attraction of the egg parasitoid *T. podisi*. Once understood, these volatile compounds could help to develop new strategies for control of *E. heros* using natural enemies in soybean crops.

Acknowledgements We thank H. Santos and D. Tiburcio for helping with laboratory rearing of the insects, and Jeffrey Aldrich and Michael Birkett for providing synthetic standards. We are grateful to Dr. Mark Horn International Consultant at Embrapa Genetic Resources and Biotechnology, to Monika Hilker and Martin Pareja for comments that improved the manuscript and for revising the English. We also thank the Post-Graduate Animal Biology program of University of Brasília (UnB) for use of their facility. This work received financial support from the Brazilian Council for Scientific and Technological Development (CNPq) through a grant to Mirian F.F. Michereff, International Foundation for Science IFS, Distrito Federal Research Foundation (FAP-DF) and Brazilian Corporation of Agricultural Research (EMBRAPA).

Abstract Individual *Eucalyptus* trees in south-eastern Australia vary considerably in susceptibility to herbivores. On the one hand, studies with insect herbivores have suggested that variation in the concentrations of foliar monoterpenes is related to variation in susceptibility. On the other, studies with marsupial folivores have suggested that variation in the concentrations of sideroxylonals (a group of formylated phloroglucinol compounds) is responsible for variation in susceptibility. We examined relative importance of sideroxylonals and 1,8-cineole (a dominant monoterpene) in host tree selection by Christmas beetles (*Anoplognathus* species: Coleoptera: Scarabaeidae) by using no-choice experiments, choice/no-choice experiments, and manipulative experiments in which concentrations of sideroxylonals or 1,8-cineole were altered. We used two species of host *Eucalyptus*, one species of non-host *Eucalyptus*, and three species of non-host non-*Eucalyptus* trees. Leaf consumption by Christmas beetles was negatively correlated with the concentrations of sideroxylonals and 1,8-cineole. Artificial increases in the concentration of sideroxylonals or 1,8-cineole reduced leaf consumption by Christmas beetles. An artificial reduction in foliar monoterpenes had no effect on leaf consumption by the beetles when leaves contained high or very low concentrations of sideroxylonals. However, when the concentration of sideroxylonals was moderate, a reduction in the foliar monoterpenes increased leaf consumption by the beetles. Therefore, monoterpenes such as 1,8-cineole may be used as a negative cue by Christmas beetles. The pattern of food consumption on non-host *Eucalyptus* species and non-host non-*Eucalyptus* species suggest that both positive and negative cues may be used by Christmas beetles to select host trees.

Key Words *Anoplognathus* · Cineole · *Eucalyptus melliodora* · *Eucalyptus polyanthemos* · *Eucalyptus sideroxylon* · Formylated phloroglucinol compounds · Plant-herbivore interactions · Sideroxylonals

Introduction

Plant secondary metabolites play important roles in host selection by herbivores. Some of these compounds may act as positive (attractants) or negative cues (deterrents) that signal the quality of plants as food, while other compounds may act as toxins that reduce performance of insects. At least some specialist insect herbivores choose host plants upon which to oviposit on the basis of plant secondary metabolites (e.g., Steinbauer et al., 2004; Östrand et al., 2008), and many studies have documented negative

relationships between performance of herbivores and concentrations or types of secondary metabolites (e.g., Feeny, 1968; Matsuki and MacLean, 1994 and references therein; Osier et al., 2000). When specialist insect herbivores include a new host species, the new host species is likely to be taxonomically close to, or share at least some secondary metabolites with, the original host species (Futuyma and McCafferty, 1990; Janz and Nylin, 1998; Janz et al., 2001).

The importance of intra-specific variation in secondary metabolites to plant—herbivore interactions is widely accepted (Denno and McClure, 1983; Fritz and Simms, 1992; Hunter, 1997). For feeding or egg-laying, specialist insect herbivores must select not only the right host species but also the right individual of the host species.

Some *Eucalyptus* (Myrtaceae) species show striking intra-specific variation in concentrations of secondary metabolites and susceptibility to herbivores. For example, trees growing in close proximity may show marked variation in susceptibility to Christmas beetles (*Anoplognathus* species: Coleoptera: Scarabaeidae) (Edwards et al., 1993), and occasionally, there are some showing within tree variation in susceptibility. One branch of a particular study tree of *E. melliodora* suffered only 5% defoliation, while the rest of the tree suffered 85% defoliation (Edwards et al., 1990). There were negative correlations between herbivory by Christmas beetles and the proportion of 1,8-cineole (a monoterpene) in six species of *Eucalyptus* (Edwards et al., 1993). 1,8-Cineole and other components of essential oils in leaves of eucalypts are considered to play important defensive roles against other insect herbivores (e.g., Morrow and Fox, 1980; Ohmart and Larsson, 1989; Stone and Bacon, 1994; Southwell et al., 2003).

Studies of arboreal marsupial folivores on *Eucalyptus* have shown that consumption is negatively affected by a group of compounds called formylated phloroglucinol compounds (FPCs) (Pass et al., 1998; Lawler et al., 2000; Wallis et al., 2002; Moore et al., 2004a). Formylated phloroglucinol compounds are found only in some species in Myrtaceae, and leaves of many *Eucalyptus* species contain one to several different FPCs (Ghisalberti, 1996; Eschler et al., 2000).

Sideroxylonals (a class of FPCs) show strong antifeedant activity against marsupial folivores, and these animals can adjust food intake to regulate the amounts of sideroxylonals being ingested (Lawler et al., 1998; Wallis et al., 2002). Sideroxylonals appear to cause emetic responses in animals that have ingested the chemical (Lawler et al., 1998; DeGabriel et al., 2010). However, because sideroxylonals are not volatile, animals have to ingest some leaves to detect concentrations in foliage. It has been hypothesized that volatile monoterpenes might act as pre-ingestive cues to marsupial folivores (Lawler et al., 1999), and subsequently, it has been shown that concentrations of sideroxylonals and some monoterpenes are positively correlated (Moore et al., 2004b). Following studies with marsupial folivores, it was shown that performance of Christmas beetles and some Lepidopterans are negatively affected by sideroxylonals (Steinbauer and Matsuki, 2004; Andrew et al., 2007; Matsuki et al., 2010).

The purpose of this study was to examine roles of sideroxylonals and 1,8-cineole in host selection and food consumption by Christmas beetles. These beetles are particularly suited to examining roles of the two secondary metabolites. Some of the host species of Christmas beetles (*E. melliodora* and *E. sideroxylon*) show strong within-species variation in concentrations of both sideroxylonals and 1,8-cineole (Watson, 1998; Moore et al., 2004a). As noted, Christmas beetles show strong preference for some individuals of the host species over other individuals (Edwards et al., 1993; Andrew et al., 2007). They chew through leaves, and thus, must ingest sideroxylonals. In this study, laboratory experiments were carried out to examine effects of sideroxylonals and 1,8-cineole on food consumption by Christmas beetles.

Methods and Materials

Study Organisms We examined leaf consumption by 6 species of Christmas beetles that are commonly found in south-eastern Australia (*Anoplognathus chloropyrus*, *A. hirsutus*, *A. montanus*, *A. pallidicollis*, A. *suturalis*, and *A. viriditarsis*). Larvae feed on roots of grasses and crops. Adult beetles preferentially feed on young leaves of *Eucalyptus* that are nearly or completely expanded (Carne et al., 1974). Leaves of less than 3 yr-old also are eaten when young leaves are not available. In south-eastern Australia, Christmas beetles feed on at least 12 species of *Eucalyptus* (Edwards et al., 1993; M. Matsuki, pers. obs.).

We used *E. melliodora*, *E. polyanthemos*, and *E. sideroxylon*. Sideroxylonals (a mixture of three isomers A, B, and C) are the major class of FPCs found in these species (Eschler et al., 2000). *Eucalyptus melliodora* and *E. sideroxylon* are typical hosts of Christmas beetles, while leaves of *E. polyanthemos* trees are rarely eaten (M. Matsuki, pers. obs.; R. Andrew, pers. comm.). Cyanogenic glycosides are in leaves of *E. polyanthemos* but not in leaves of *E. melliodora* or *E. sideroxylon* (Gleadow et al., 2008). The three *Eucalyptus* species grow naturally in woodlands throughout south-eastern Australia and are similar in many aspects of their natural history (Boland et al., 1984). We also used *Betula* sp. (Betulaceae), *Quercus* sp. (Fagaceae), and *Populus tremuloides* (Salicaceae) as non-host species that are only distantly related to the host species. These are exotic ornamental trees in Australia and are not known to contain sideroxylonals or to store monoterpenes.

Choice of Trees Trees (m1–m3, s1–s3, & p1–p3) were chosen on the basis of variation in leaf consumption by marsupial folivores. Among 8 *E. melliodora* trees tested, leaf consumption by koala (*Phascolarctos cinereus*: Moore et al., 2004a) and common brushtail possum (*Trichosurus vulpecula*: Watson, 1998) was highest on m3, intermediate on m2, and lowest on m1. Among 12 *E. sideroxylon* trees tested, leaf consumption by common brushtail possum (Watson, 1998) and common ringtail possum (*Pseudocheirus peregrinus*: Lawler et al., 2000) was highest on s3, intermediate on s2, and lowest on s1. Among 36 *E. polyanthemos* trees tested, leaf consumption by common ringtail possum (Lawler et al., 2000) was highest on p3, intermediate on p2, and lowest on p1. We also chose some susceptible (m6, m7, s6, and s7) and resistant (m4, m5, s4, and s5) trees of *E. melliodora* (m4–m7) and *E. sideroxylon* (s4–s7) on the basis of the records of herbivory by Christmas beetles (mostly *A. montanus*) in the field (P. B. Edwards and W. J. Wanjura, unpubl.). These were some of the trees studied by Edwards et al. (1993). Trees s8–s11 (*E. sideroxylon*) had never been used in studies with vertebrates or insects. During the study period, the trees used in this study suffered only minor defoliation by herbivores. Trees m4–m7 were located in Yeoval, New South Wales (32°44′S, 148°39′E), and s4–s7 were located in Cumnock, New South Wales (32°55′S, 148°44′E). All other trees were located in Canberra, Australian Capital Territory (35°16′S, 149°7′E). The tree numbers indicate unique trees. For example, m1 indicates the same tree throughout this paper.

Physical and Chemical Characteristics of Leaves We measured leaf water content and specific leaf weight. *Eucalyptus* leaves contain volatile terpenes, and leaves were dried at 40°C for 2 d so as not to lose these compounds. Specific leaf weight was measured by weighing a small disk of a known area cut from the leaf blade.

In 1997–99, concentrations of monoterpenes were determined by gas chromatography (GC) using the method described in Edwards et al. (1993). Two leaves per tree were analyzed for monoterpenes. The concentration of sideroxylonals was determined by high performance liquid chromatography (HPLC) using the method described in Lawler et al. (2000). A mixture of the three isomers of sideroxylonal was extracted and purified as described elsewhere (Eschler and Foley, 1999). Concentrations of leaf nitrogen in 1997–98 and those of 1,8-cineole and sideroxylonals in 1999–2000 were estimated by using near-infrared reflectance spectroscopy, NIRS (Lawler et al., 2000).

The calibration equation for the concentration of leaf nitrogen was developed with a set of NIRS spectra and measured nitrogen content of 226 pre-existing samples of various *Eucalyptus* species by using a modified partial least square regression (ASTM 1995). We validated the calibration equation with 3 samples of *E. melliodora* and 6 samples of *E. sideroxylon* that were not used in the calibration equation. The calibration equations for sideroxylonals and 1,8-cineole were developed from a set of NIRS spectra and measured sideroxylonals and 1,8-cineole concentrations of 49 *E. melliodora* samples by using partial least square regressions. We used a cross-validation procedure (Infrasoft International, 1996; Brown, 1993) to validate calibration equations for total sideroxylonals and 1,8-cineole.

We classified leaves into three broad categories of concentrations of sideroxylonals or 1,8-cineole: low concentrations (<5 mg sideroxylonals or 1,8-cineole g^{-1} leaf dry matter); intermediate concentrations (5–20 mg sideroxylonals g^{-1} leaf dry matter or 5–10 mg 1,8-cineole g^{-1} leaf dry matter); and high concentrations (>20 mg sideroxylonals g^{-1} leaf dry matter or >10 mg 1,8-cineole g^{-1} leaf dry matter).

Consumption Trials We conducted five types of experiments in the three consecutive Austral summers between 1997 and 2000: (1) no-choice experiments; (2) choice/no-choice experiments; (3) experiments where the foliar concentration of sideroxylonals was enhanced; (4) an experiment where the foliar concentration of cineole was reduced via steaming; and (5) experiments where the foliar concentration of cineole was enhanced (see below for details).

For each experiment, several small branches were taken from each experimental tree so that leaves used were representative of leaves on experimental trees. Size and age of leaves in a given season were standardized visually in order to minimize these effects on leaf consumption. In the summer of 1997–1998, we used leaves of 1.5–2.5 yearr of age because leaves less than 1 yr-old were rare. However, the study trees produced new leaves in the autumn—spring of 1998, and by late December 1998, almost all old leaves had abscised. Therefore, we used leaves of 6- to 8-mo-old in the summer of 1998–1999. We used leaves that were approximately 1.5 yr-old in the summer of 1999–2000.

Adult beetles were collected in the field around Canberra. *Anoplognathus chloropyrus* also was collected from three other locations: Ginninderra, (35°09′S, 149°03′E); Gunning (34°47′S, 149°16′E); and Boorowa (34°26′S, 148°43′E), New South Wales.

To estimate the dry weight of leaf consumed by each beetle, we used two leaves for each insect. Each leaf was weighed and placed individually in clear plastic screw-top vials (250 ml) with moist plaster of Paris to maintain leaf turgor. At the beginning of an experiment, each beetle was weighed and placed in one of the two vials. Vials for each beetle were kept together during an experiment. Experiments were terminated after 5–15 h when some leaves were

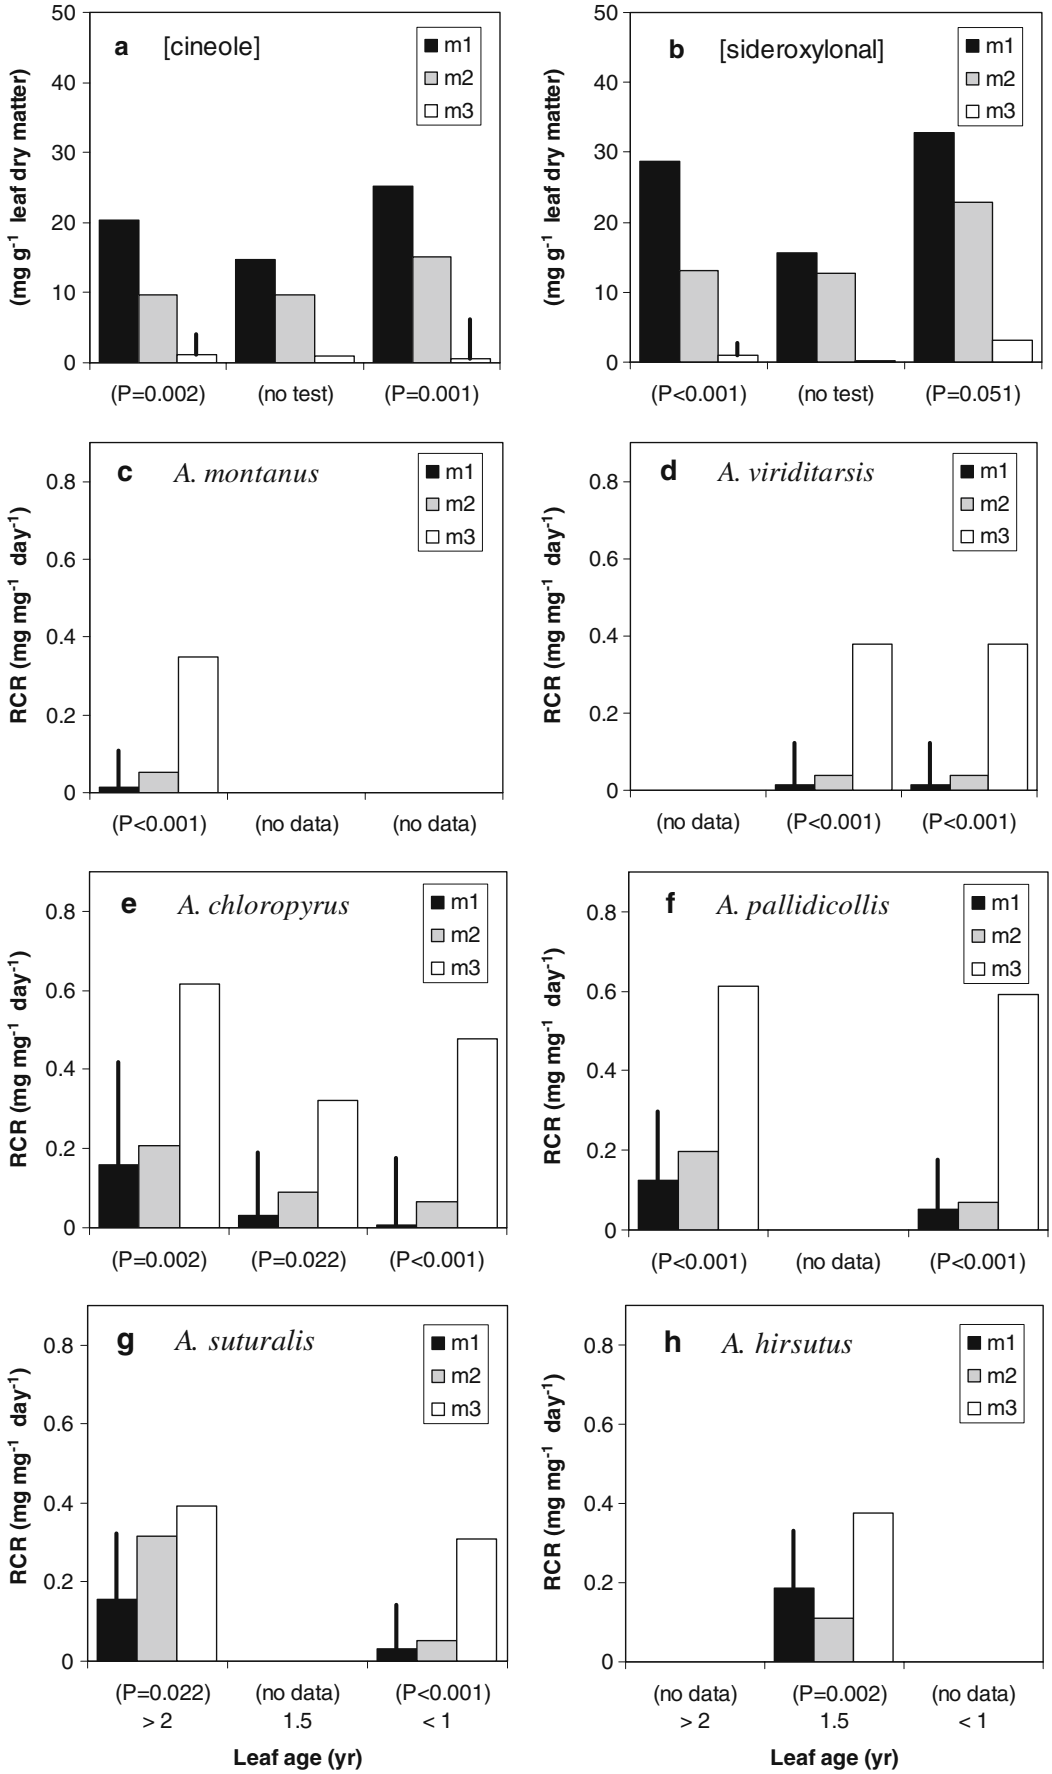
nearly completely consumed. All experiments were started in the morning and terminated in the evening of the same day. Each beetle was weighed again at the end of each experiment. Each leaf was placed in a small envelope and dried at 40°C for 2 day. The water content of the leaf that had not been offered to insects (control leaf) was used to estimate the water content of the leaf that had been offered to an insect (trial leaf). The dry weight of leaf consumed by each insect was estimated as described elsewhere (Ayres and MacLean, 1987; Matsuki et al., 1994). There was no difference in relative consumption rates between male and female beetles for a given tree, and we used the pooled data for analyses.

No-choice and Choice/no-choice Experiments For no-choice and choice/no-choice tests, separate experiments were carried out for each *Eucalyptus* species, each leaf age, and each *Anoplognathus* species. In each no-choice experiment, the experimental design was 1 *Eucalyptus* species × 1 leaf age × 1 *Anoplognathus* species × 5 blocks × 3–4 treatments (trees) × 3 replicates. In choice/no-choice experiments, the experimental design was 1 *Eucalyptus* species × 1 leaf age × 1 *Anoplognathus* species × 5 blocks × 6 treatments (tree combinations) × 3 replicates. Blocks in the experiments represented rooms in three different buildings; however, the same five rooms were used in all experiments.

In no-choice experiments, one fresh leaf was placed in each vial. In choice/no-choice experiments, two fresh leaves were placed in each vial. For each *Eucalyptus* species, three trees were used in each choice/no-choice experiment: the susceptible, the resistant, and an intermediate tree (as defined above). We used all six pair-wise combinations of trees, i.e., susceptible-susceptible, susceptible-intermediate, susceptible-resistant, intermediate-intermediate, intermediate-resistant, and resistant-resistant. For example using *E. melliodora*, six pair-wise combinations of trees were m3-m3, m3-m2, m3-m1, m2-m2, m2-m1, and m1-m1, respectively.

We calculated relative consumption rates of leaves by Christmas beetles using a dry matter based method (Waldbauer, 1968). Using a subset of beetles, dry mass of beetles was estimated from the ratio of wet mass to dry mass for each beetle species/sex combination.

To examine preference of a tree i in choice/no-choice experiments, we used the index D (Jacobs, 1974):



$$D_i = \frac{DR_i - RA_i}{RA_i + DR_i + 2RA_iDR_i},$$

Where DR_i is the dietary ratio, defined as the ratio between dry matter consumption of a leaf of tree i (DMC_i) and the total dry matter consumption of leaves from tree i and tree j (DMC_t): $DR_i=DMC_i/DMC_t$. RA_i is the relative amounts of leaf matter of tree i offered to a beetle during an experiment and is defined as the ratio between dry matter of a leaf of tree i offered (DMO_i) and the total dry matter of leaves of tree i and tree j (DMO_t): $RA_i=DMO_i/DMO_t$. Negative values of the index D indicate avoidance, while positive values indicate preference. For each experiment, the mean D_is were calculated, and 95% confidence intervals were used to detect whether the mean preference was significantly positive or negative. We used the index D because it met all three criteria for a good index of diet preference proposed by Cock (1978) and is sensitive to small changes in preference (Kam et al., 1997).

Manipulating the Foliar Concentration of Sideroxylonals We manipulated the foliar concentration of sideroxylonals by painting leaves with solutions of purified compounds. We used leaves of an *E. melliodora* tree that was most susceptible to marsupial folivores (m3) and another that was most resistant to marsupial folivores (m1). Purified sideroxylonals were dissolved in 10% methanol: 90% dichloromethane. We painted solutions of sideroxylonals onto leaves of m3 so that the treatment leaves would have approximately 20, 40, or 80 mg sideroxylonals per g leaf dry matter. In *E. sideroxylon* and *E. melliodora* in the field, only a small number of trees have greater than 40 mg sideroxylonals per g leaf dry matter (Watson, 1998; Wallis et al., 2002). We also painted leaves with solvent only as controls. Solutions of sideroxylonals were prepared in 3 different concentrations so that approximately the same amount of the solutions was applied to each leaf. The experimental design of the sideroxylonal manipulation experiments was 1 *Anoplognathus* species × 5 blocks × 7 treatments (2 trees × no solvent or solvent control + 3 concentrations of sideroxylonals) × 3 replicates. Blocks were as in no-choice and choice/no-choice experiments. Separate experiments were carried out for four *Anoplognathus* species.

Cineole Addition Experiments We also artificially increased the concentration of 1,8-cineole by painting leaves with purified compound. Approximately 0.1 ml of purified 1,8-cineole was applied to leaves of the most susceptible *E.*

Fig. 1 Mean concentrations of sideroxylonals and 1,8-cineole and mean relative consumption rates (RCR) of Christmas beetles. **a**–**h** *Eucalyptus melliodora* trees (m1–m3) and **i**–**p** *Eucalyptus sideroxylon* trees (s1–s3) with records of susceptibility to marsupial folivores. N=15 beetles per tree. *Grey bars* and *open bars* represent intermediate and susceptible trees, respectively, to marsupial folivores. *Solid bars* represent a resistant tree to marsupial folivores. The P-value for the differences among three trees for each leaf age is shown in parentheses. When $P<0.05$, the LSD for comparing the means is shown as the vertical line. No statistical test was carried out for concentrations of sideroxylonal and 1,8-cineole in 1.5 yr-old leaves because the concentration for each tree was estimated from ground material of multiple leaves per estimate using NIRS

melliodora tree (m3). We used meshed screw-caps to avoid the build-up of vapor pressure inside the vials due to evaporation of 1,8-cineole. The design of the cineole addition experiments was 1 *Anoplognathus* species × 1 block × 2 treatments (cineole addition or control) × 1 tree × 10 replicates. Separate experiments were carried out for five *Anoplognathus* species.

Manipulating the Foliar Concentration of 1,8-Cineole by Steaming We reduced the foliar concentration of 1,8-cineole by placing leaves in a stream of steam. In this experiment, we used leaves of the two *E. melliodora* trees used in the sideroxylonal manipulation experiments (i.e., m1 and m3) and an *E. sideroxylon* tree (s9) with an intermediate concentration of sideroxylonals and a high concentration of 1,8-cineole. Leaves were steamed for 1 min. Fresh (i.e., unsteamed) leaves of the 3 trees were used as controls. Examination of the steamed leaves by GC revealed that steaming resulted in approximately 50% reduction in all monoterpenes, including 1,8-cineole (data not shown). The experimental design of the cineole reduction experiment was 5 blocks × 2 treatments (steaming or control) × 3 trees × 3 replicates. Blocks were as in no-choice and choice/no-choice experiments. This experiment was carried out with *A. chlorophyrus* only.

Experiment with Exotic Species To examine leaf consumption of species without sideroxylonals or monoterpenes, we used 3 species of exotic ornamental trees (*Betula* sp., *Quercus* sp., and *Populus tremuloides*) in a no-choice experiment. Leaves of the exotic species were collected from ornamental trees around the laboratory at CSIRO in Canberra. We included the most susceptible tree of *E. melliodora* (m3) as the standard in the experiment. The experimental design of the exotic species experiment was 5 blocks × 4 treatments (tree species) × 3 replicates. Blocks were as in no-choice and choice/no-choice experiments. This experiment was carried out with *A. chlorophyrus* only.

Statistical Analyses We analyzed data on leaf physical and chemical characteristics and consumption using ANOVAs (when the data set was balanced) or restricted maximum likelihood analyses (when the data set was unbalanced). When we examined differences among species, populations, and individual trees in leaf physical and chemical traits, we treated species, populations, and trees as fixed factors in nested ANOVAs. Since we used only 3 individuals of *E. polyanthemos* from 1 population in this study, we excluded *E. polyanthemos* from the analysis of differences between species.

In this study, we did not statistically examine effects of host plant population/beetle species on leaf consumption by beetles. The reasons for this are: (1) separate experiments were conducted for each beetle/host population combination; and (2) leaf consumption by beetles decreased gradually as the season progressed. Therefore, if a particular species of Christmas beetle shows lower consumption in an experiment conducted late in the season with a host population when compared with its consumption in an experiment conducted early in the season with another host population, the difference in consumption is likely due to combined effects of season and differences in host plant leaf chemistry.

However, we were able to examine relationships between the reduction in the mean relative consumption rates (RCRs) and changes in leaf traits, (specific leaf weight and concentrations of sideroxylonals and 1,8-cineole) in *E. melliodora* and *E. sideroxylon*. For each no-choice experiment, we calculated differences in the mean RCRs and the three leaf traits between a pair of trees: (1) resistant – susceptible; (2) resistant – intermediate; and (3) intermediate – susceptible. For each beetle species, the changes in the mean RCRs and leaf traits between pairs of trees from different experiments were pooled. *Anoplognathus montanus* and *A. chloropyrus* were the only species with more than five comparisons per tree pair, and other beetle species were not used in this analysis. For each beetle species and each of the three pairs of trees, we then examined the slope of the regressions between the changes in the mean RCRs (response variable) and the changes in each of the tree leaf traits (explanatory variable). Because the three leaf traits sometimes showed significant correlations (i.e., multicollinearity), we were not able to compare relative strength of the three leaf traits by using multiple regressions. We used GENSTAT (Genstat 5 Committee, 1993) and SAS (SAS Institute, 1989) for the statistical analyses.

Results

Host Eucalyptus Species Under no-choice situations, leaf consumption by all six species of Christmas beetles showed marked variation among three trees of *E. melliodora* (m1–m3) and three trees of *E. sideroxylon* (s1–s3), and all six species of beetles showed qualitatively consistent pattern of leaf consumption (Fig. 1). The Christmas beetles consumed more leaves from trees with markedly lower concentrations of sideroxylonals and 1,8-cineole than trees with high concentrations of sideroxylonals and 1,8-cineole. Leaves of the resistant trees (with high concentrations of sideroxylonals and 1,8-cineole) tended to contain higher concentrations of some other monoterpenes such as α-pinene, limonene, and terpineol but lower concentrations of *p*-cymene and α-phellandrene than leaves of susceptible trees (with low concentrations of sideroxylonals and 1,8-cineole) (Table 1).

Table 1 Differences in physical and chemical characteristics of leaves (>2 yr-old) among species, populations, and trees of *Eucalyptus melliodora* and *Eucalyptus sideroxylon* and differences between resistant and susceptible trees of the two *Eucalyptus* species

[c] SLW=Specific Leaf weight

However, 1,8-cineole was the dominant component of the *Eucalyptus* oils. The concentration of 1,8-cineole ranged from 0 to 27 mg g^{-1} leaf dry matter, while the maximum concentration of any one monoterpene other than 1,8-cineole was 3.5 mg g^{-1} leaf dry matter. Leaf nitrogen concentration, leaf water content, and specific leaf weight did not differ significantly between the resistant and susceptible trees (Table 1). When we examined relationships between changes in leaf consumption and changes in leaf traits between pairs of trees (resistant – susceptible, resistant – intermediate, and intermediate – susceptible), the decreases in relative consumption rates in *A. montanus* and *A. chloropyrus* tended to be more strongly associated with the increases in concentrations of sideroxylonals and 1,8-cineole than the changes in specific leaf weights (Table 2).

The same qualitative pattern of difference in leaf consumption of the same six trees (m1–m3 and s1–s3) was observed between years and between young (<1 yr-old) and old leaves (>2 yr-old). The same qualitative pattern also was observed in three different populations of *A. chloropyrus* (the only species examined) in the same year (Fig. 2). Moreover, for at least two species of Christmas beetles (*A. montanus* and *A. chloropyrus*) the same qualitative pattern of tree discrimination associated with the same pattern of leaf chemical composition was observed in trees from Yeoval (m4–m7) and Cumnock (s4–s7) (Fig. 3). For these trees, leaf consumption in the laboratory was correlated directly with the historical record of defoliation by Christmas beetles (mostly *A. montanus*).

There was a striking difference in the behavior of Christmas beetles depending on the leaves offered. The entire leaf, except mid vein and leaf margins, was consumed when leaves with low concentrations of sideroxylonals and 1,8-cineole were offered. In contrast, when leaves with high concentrations were offered, beetles either did not feed at all or took one to several

Table 2 Relationships between reduction in relative consumption rates (ΔRCRs) by *Anoplognathus montanus* and *Anoplognathus chloropyrus* and increases in concentrations of sideroxylonals (Δsideroxylonals) or 1,8-cineole (Δ1,8-cineole), or changes in specific leaf weight (ΔSLW)

bites at a number of locations along the leaf margins but never continued feeding. Leaves of some trees (e.g., s9) either were consumed nearly entirely (as leaves of the susceptible trees) or not touched at all. Leaves of s9 contained an intermediate concentration of sideroxylonals and a high concentration of 1,8-cineole (Fig. 3). Some leaves of s9 were never chewed. These observations lead to the hypothesis that trees with low to moderate concentrations of sideroxylonals might be avoided by Christmas beetles due to presence of strong negative cues (e.g., high concentrations of 1,8-cineole). This hypothesis was tested by artificially manipulating the concentrations of sideroxylonals and 1,8-cineole (see below).

When beetles were given a choice between leaves from two different trees of *E. melliodora*, they always preferred the susceptible to the resistant or the intermediate tree (Table 3). The intermediate tree always was preferred to the resistant tree. When leaves from two trees of *E. sideroxylon* were offered together, beetles also always preferred the susceptible to the resistant or the intermediate tree (Table 3). The intermediate tree was preferred to the resistant tree by three species of Christmas beetles, but not by *A. chloropyrus*. Differences in preference among the three *E. sideroxylon* trees were not as large as those among the three *E. melliodora* trees.

Non-host Eucalyptus Species Leaf water content and specific leaf weight of *E. polyanthemos*, which was not a preferred host of Christmas beetles, did not differ from those of either *E. melliodora* or *E. sideroxylon* (data not shown). In terms of leaf chemistry, *E. polyanthemos* differed from the other two species by having generally low values and little between-individual variation in

Table 3 Between-tree feeding preference by *Anoplognathus* species with three species of *Eucalyptus* species

Trees compared	*E. melliodora*[a]	*E. sideroxylon*[a]	*E. polyanthemos*[b]

[e] Sample size

concentrations of α-phellandrene (0.19–0.53 mg g^{-1} leaf dry matter) and *p*-cymene (0 mg g^{-1} leaf dry matter). In contrast, like *E. melliodora* and *E. sideroxylon*, concentrations of sideroxylonals and 1,8-cineole in the three *E. polyanthemos* trees differed markedly (Fig. 4). Leaf consumption by Christmas beetles, however, did not show corresponding differences (Fig. 4). *Anoplognathus suturalis* consumed as much leaf material of *E. polyanthemos* as that of *E. melliodora* and *E. sideroxylon*, while five other species of Christmas beetles consumed much less leaf material of *E. polyanthemos* compared with the other *Eucalyptus* species.

Effects of Sideroxylonals and 1,8-Cineole on Leaf Consumption There was a negative dosage-dependent effect of sideroxylonals on leaf consumption in all four species of Christmas beetles tested (Fig. 5). Relative consumption rates (RCR) were reduced to approximately one third of those in the control when concentrations of sideroxylonals were high (40 and 80 mg g^{-1} leaf dry matter). In *A. chloropyrus* and *A. pallidicollis*, there was no effect of increased concentrations of sideroxylonals at least up to one half of the maximum concentration found naturally in leaves of *E. sideroxylon* and *E. melliodora* (i.e., 20 mg g^{-1} leaf dry matter).

When pure 1,8-cineole was painted onto leaves of *Eucalyptus* branches, Christmas beetles immediately ceased feeding and quickly moved far away from the painted 1,8-cineole. An artificial increase in the concentration of 1,8-cineole reduced leaf consumption by all five species of Christmas beetles tested (Fig. 5). The beetles did not feed on leaves painted with 1,8-cineole until the 1,8-cineole had evaporated. Once that happened, the treatment leaves were consumed just as the control leaves. Therefore, the observed reduction in consumption is due to effective reduction in feeding time caused by evaporating 1,8-cineole.

An artificial 50% reduction in the concentration of 1,8-cineole by steaming leaves increased leaf consumption by *A. chloropyrus* on s9 with the moderate natural concentration of sideroxylonals and high natural concentration of 1,8-cineole (Fig. 6: see s9 in Fig. 3a and b for natural concentrations of sideroxylonal and 1,8-cineole). However, steaming leaves did not affect the consumption of leaves when the natural concentrations of both sideroxylonals and 1,8-cineole were high (m1) or low (m3).

Exotic Species The mean relative consumption rates (RCRs) by *A. chloropyrus* varied among species of exotic ornamental trees: very low in *Populus tremuloides* (0.014 mg mg^{-1} day^{-1}) and moderately high in *Betula* sp. (0.20 mg mg^{-1} day^{-1}) and *Quercus* sp. (0.32 mg mg^{-1} day^{-1}). The mean RCR on *Quercus* sp. was not different from the mean RCR on m3 (0.45 mg mg^{-1} day^{-1}) (LSD=0.14 for comparing the means). Monoterpenes were not detected in leaves of these species.

Discussion

New findings from this study are: (i) high concentrations of sideroxylonals or 1,8-cineole alone reduce leaf consumption by Christmas beetles, and (ii) sideroxylonals may act as post-ingestive deterrents, while 1,8-cineole may act as a pre-ingestive deterrent in host selection by Christmas beetles. Consistent with previous studies, we also found that: (i) there were positive correlations between concentrations of 1,8-cineole and sideroxylonals in *Eucalyptus melliodora* (as in Moore et al., 2004a), *E. sideroxylon*, and *E. polyanthemos*, and (ii) trees with low concentrations of sideroxylonals (as in Andrew et al., 2007) and 1,8-cineole (as in Edwards et al., 1990, 1993) suffered greater leaf consumption by beetles than trees with high concentrations

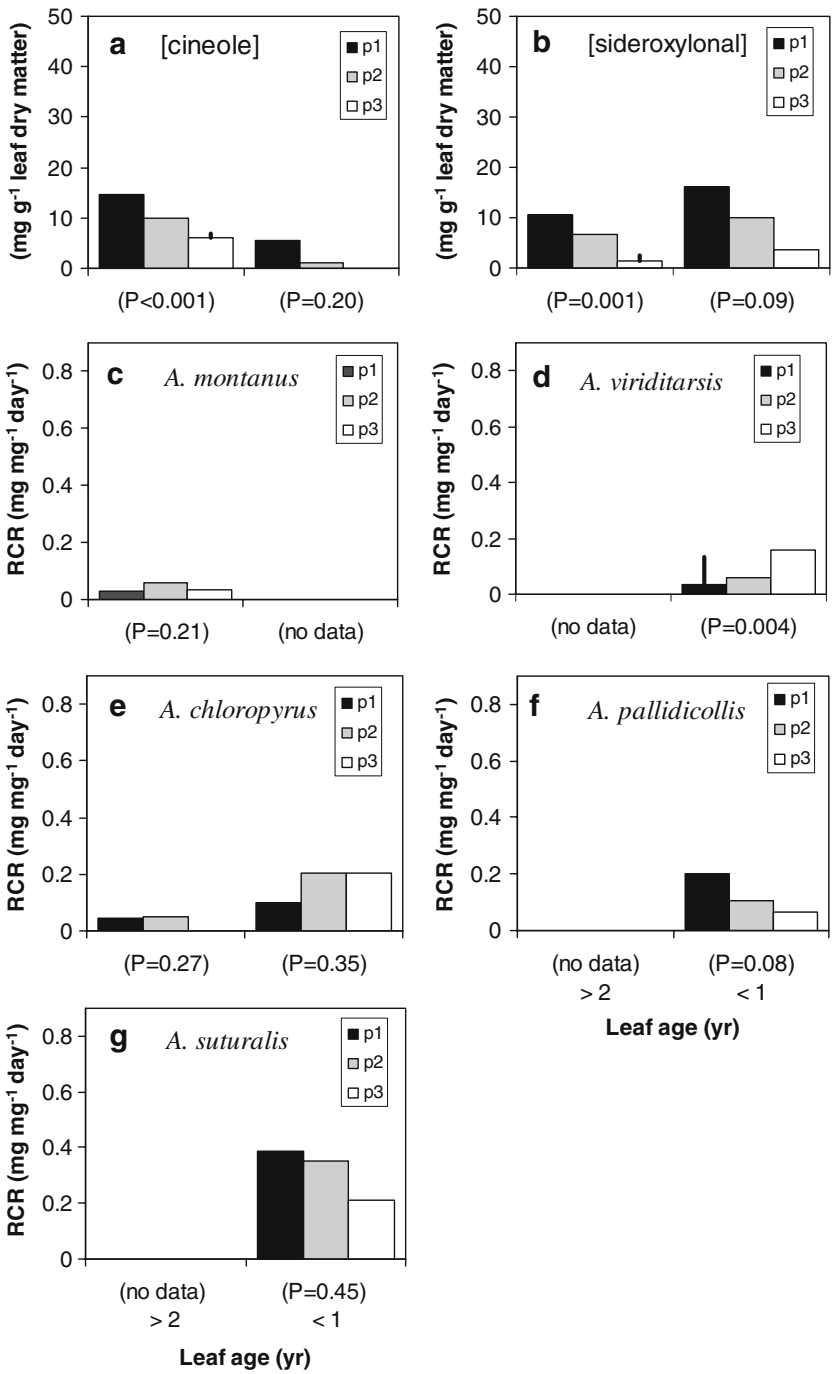

Fig. 4 Mean concentrations of **a** 1,8-cineole and **b** sideroxylonals of *Eucalyptus polyanthemos* trees and **c**–**g** mean relative consumption rates (RCR) of Christmas beetles. N=15 beetles per tree. The P-value for the differences among three trees for each leaf age is shown in parentheses. When $P<0.05$, the LSD for comparing the means is shown as the vertical line. *Solid bars* represent a resistant tree to common ringtail possum. *Grey bars* and *open bars* represent intermediate and susceptible trees, respectively, to common ringtail possums

of the two metabolites. Andrew et al. (2007) suggested that high concentrations of sideroxylonals conferred resistance of some individual trees of *E. melliodora* to Christmas beetles. However, by examining and manipulating multiple compounds in host and non-host species, we found that beetles might select host trees by detecting more than one plant secondary metabolite.

When leaves with high concentrations of sideroxylonals were offered, Christmas beetles took only one to several bites that were spread along the margin of leaves (M. Matsuki, pers. obs.). Thus, they appeared to detect the presence of sideroxylonals using sensory organs in their mouthparts. However, when leaves with moderate concentrations were offered, beetles continued feeding for some time but never consumed entire leaves. Thus, it appears that, even when sideroxylonals are ingested at low concentrations, there is another mechanism which stops Christmas beetles from ingesting large amounts of sideroxylonals. Marsupial folivores also regulate intake of sideroxylonals and some other FPCs (Lawler et al., 1998; Stapley et al., 2000; Wallis et al., 2002).

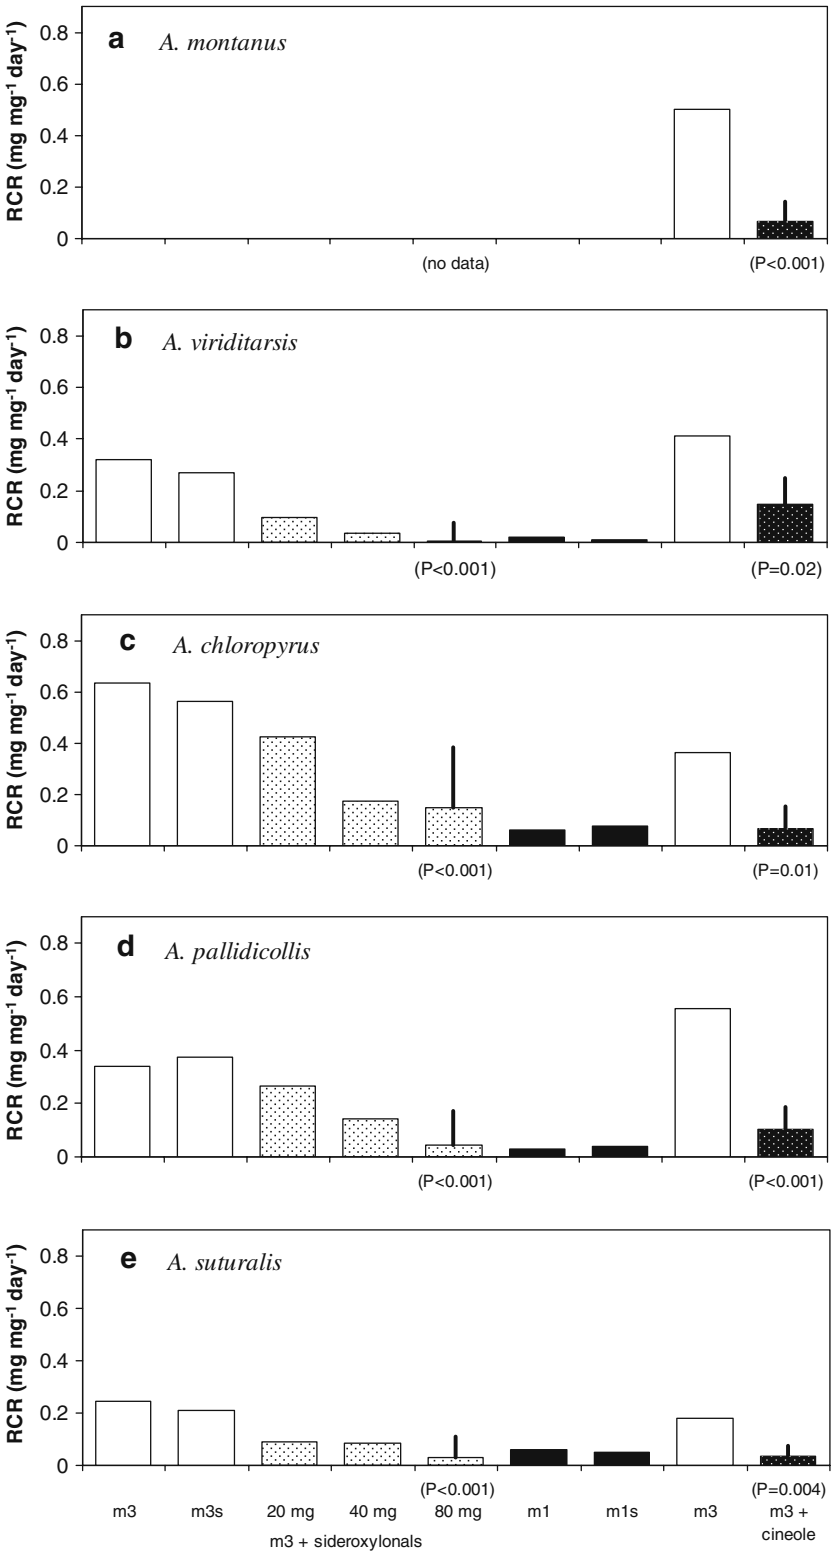

Fig. 5 Effects of artificially increased concentration of sideroxylonals and 1,8-cineole on relative consumption rate (RCR) of *Eucalyptus melliodora* leaves by five species of Christmas beetles. Data present means of $N=11–15$ beetles per tree. The P-value for the differences among the treatment is shown in parentheses. When $P<0.05$, the LSD for comparing the means is shown as the vertical line. Separate P-values and LSDs are shown for the sideroxylonal addition experiement (*seven bars on the left*) and the cineole addition experiment (*two bars on the right*). *Open bars* represent the susceptible tree (m3), and *closed bars* represent the resistant tree (m1). Solvent controls are represented as m1s and m3s. Trees m1 and m3 were also shown in Figs. 1, 2 and 6. > 2 yr-old leaves were used with *Anoplognathus chloropyrus* and *Anoplognathus pallidicollis,* while <1 yr-old leaves were used with *Anoplognathus montanus, Anoplognathus viriditarsis,* and *Anoplognathus suturalis*

Monoterpenes (e.g., 1,8-cineole) also can have harmful effects on insects post-ingestively (Rose, 1985). However, *A. montanus* and *Paropsis atomaria* (Coleoptera: Chrysomelidae) feeding on *Eucalyptus* leaves may simply "tolerate" (Morrow and Fox, 1980) or "avoid" (Edwards et al., 1993) monoterpenes.

Results of the experiment with steamed leaves suggest that Christmas beetles may use 1,8-cineole, or other volatile

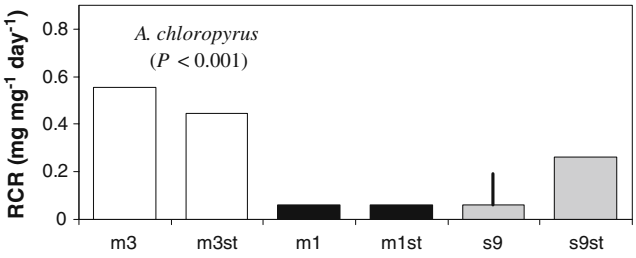

Fig. 6 Effects of artificially decreased concentration of 1,8-cineole by steaming leaves on relative consumption rate (RCR) of *Eucalyptus* leaves by *Anoplognathus chloropyrus*. Data present means of $N=15$ beetles per tree. The *P*-value for the differences among the treatment is shown in parentheses. The LSD for comparing the means is shown as the vertical line. *Open bars* represent the susceptible tree (m3), and the *closed bars* represent the resistant tree (m1). Trees m1 and m3 were also shown in Figs. 1, 2 and 5. Leaves of tree s9 (*grey bars*) contain high concentration of 1,8-cineole but only moderate concentration of sideroxylonals (cf. Fig. 3a & b). Leaf consumption on steamed leaves is indicated as m3st, m1st and s9st. >2 yr-old leaves were used in the experiment

compounds in *Eucalyptus* oils, as a pre-ingestive deterrent for selecting host trees. In the field, Christmas beetles fly around the canopy at close range. If a tree had high concentrations of sideroxylonals and 1,8-cineole, many beetles flew away without landing on a leaf or landed on a leaf but took off without feeding (M. Matsuki, pers. obs.). Since Christmas beetles seem to detect high concentrations of sideroxylonals with sensory organs in their mouthparts, the observed host selection behavior in the field is not likely driven by sideroxylonals in leaves. Christmas beetles may detect high concentrations of volatile terpenes in the atmosphere immediately surrounding resistant trees.

Guilford and Cuthill (1991) have suggested that evolution of unpalatability is not a likely result of selection on individuals that share the same phenotype (i.e., synergistic selection) because, unlike aposematic coloration in animals, palatable and unpalatable plants appear identical except for the difference in palatability. However, volatile compounds such as 1,8-cineole may act as a signal for the presence and the concentration of compounds such as sideroxylonals (this study; Lawler et al., 1999: for the debate on whether one plant secondary metabolite can serve as a signal for another, see Dethier and Post, 1979; Eisner and Grant, 1981; Launchbaugh and Provenza, 1993; Augner, 1994; Augner and Bernays, 1998).

Tuomi and Augner (1993) and Leimar and Tuomi (1998) showed that evolution of plant unpalatability might result from synergistic selection, even without a cue, if herbivores took samples from a population of plants and made generalizations about the population. *Eucalyptus melliodora* and *E. sideroxylon* showed striking variation in leaf chemistry among neighboring individuals (Edwards et al. 1993). Therefore, if synergistic selection has been involved in evolution of chemical defenses using sideroxylonals, the presence of volatile compounds such as 1,8-cineole, which can be used as a cue (Guilford and Cuthill 1991), is a more likely mechanism than leaf sampling and subsequent generalization by herbivores (Tuomi and Augner 1993; Leimar and Tuomi 1998).

An interesting twist in the *Eucalyptus*—herbivore system is that some trees of *E. sideroxylon* seem to have only low to intermediate concentrations of sideroxylonals but high concentrations of 1,8-cineole (e.g., s8–s11 in this study). If these trees suffer low levels of herbivory in the field, as is observed in the laboratory experiments, then it may be possible that high concentrations of 1,8-cineole in these trees act as a false signal.

So far, we have focused on the role of sideroxylonals and 1,8-cineole as negative cues in host selection, but host selection by Christmas beetles may involve negative and positive cues. Under natural conditions, Christmas beetles encounter four types of plants: (1) host *Eucalyptus* species that contain sideroxylonals and monoterpenes; (2) non-host *Eucalyptus* species that also contain sideroxylonals and monoterpenes; (3) non-host species that contain monoterpenes (but no sideroxylonals); and (4) non-host species that do not contain sideroxylonals or monoterpenes. Moreover, within the host *Eucalyptus* species, only a small proportion of individuals contain low concentrations of sideroxylonals (Lawler et al., 2000; Wallis et al., 2002). If negative cues (i.e., high concentrations of sideroxylonals and 1,8-cineole) alone were used to locate a small number of suitable host trees in the field, Christmas beetles may have to spend great amounts of time and energy before starting to feed.

Christmas beetles readily consumed leaves of some exotic species in captivity. Yet, they rarely consume leaves of these exotic plant species in the field. Leaves of the exotic species do not contain sideroxylonals or 1,8-cineole. Therefore, lack of feeding by beetles on those exotic species under natural conditions cannot be explained by high concentrations of sideroxylonals or 1,8-cineole in the leaves. Christmas beetles did not feed on *Populus tremuloides*. This is possibly because *P. tremuloides* have phenolic glycosides in their leaves (e.g., Osier et al., 2000).

Steinbauer and Wanjura (2002) suggested that Christmas beetles mistook *Schinus molle* (Anacardiaceae) for eucalypts because leaves of this exotic species contained monoterpenes. Other specialist insect herbivores also are attracted to non-host species that have similar secondary metabolites to the hosts (e.g., Murphy and Freeland, 2006; Östrand et al., 2008). However, presence of monoterpenes in general does not seem to signal the suitability as host plants because many *Eucalyptus* species are non-hosts for Christmas beetles. For example, leaves of most trees of *E. polyanthemos* are not consumed by Christmas beetles in the field even when beetles consume leaves on trees of *E.*

melliodora and *E. sideroxylon* in the same area (M. Matsuki, pers. obs.). Since three species of Christmas beetles consumed moderate amounts of *E. polyanthemos* leaves in captivity, it is more likely that *E. polyanthemos* leaves lack positive cues than that the leaves have negative cues. Concentrations of α-phellandrene and *p*-cymene generally were low and showed little between-individual variation in *E. polyanthemos*. In contrast, concentrations of these monoterpenes are negatively correlated with concentrations of 1,8-cineole in *E. sideroxylon and E. melliodora*. Thus, Christmas beetles may be using α-phellandrene or *p*-cymene as a positive cue for host plants. In noctuid moth species, positive and negative cues in a blend of odor are distinguished and processed separately in the brain (Vickers et al., 1998). Thus, to select trees, Christmas beetles may use both positive and negative cues. Alternatively, the ratio of various monoterpenes may be used to select host species by Christmas beetles (Edwards et al., 1993).

Acknowledgements We thank J. Dowse, R. Sutherland, M. Ebbers, W. Wanjura, G. Farrell, B. Clarke, B. Eschler, I. Lawler, and M. Michie for technical advice, assistance, and discussions. B. Eschler provided purified sideroxylonals. Comments by R. Andrew, S. Cunningham, P. Gullan, P. Edwards, T. Heard, A. Keszei, M. Steinbauer, and anonymous reviewers improved the manuscript. We also thank the late K. Barker, the late H. Healey, and S. Dwyer for granting permission to collect leaves on their properties. P. Edwards provided the historical record of Christmas beetle defoliation. M. Watson, B. Moore, and I. Lawler shared their knowledge of the susceptibility of some *Eucalyptus* trees to marsupial folivores. Financial support was provided by Rural Industries Research & Development Corporation and Agriculture, Fisheries, and Forestry—Australia. This paper is dedicated to the late Kevin Barker who has noticed a mosaic tree.

Abstract Observational studies on foliage avoidance by the polyphagous thrips species *Frankliniella occidentalis* (Pergande) and *Heliothrips haemorrhoidalis* (Bouché) (Thysanoptera: Thripidae) identified six non-host species (*Allagopappus dichotomus* (Asteraceae), *Gardenia posoquerioides* (Rubiaceae), *Plectranthus aff. barbatus*, *Plectranthus strigosus*, *Plectranthus zuluensis* (Lamiaceae), and *Sclerochiton harveyanus* (Acanthaceae) among plants growing within a major glasshouse botanical collection. The effects of sequentially obtained acetone and aqueous methanol leaf extracts on mortality in first instar *Frankliniella occidentalis* were assessed. The acetone leaf extract of *Sclerochiton harveyanus,* which had the highest activity against the thrips, yielded four new iridoids, sclerochitonosides A–C, and sclerochitonoside B 4′-methyl ether. Mortality of *F. occidentalis* was increased on exposure to all four iridoids, and the most active iridoid was sclerochitonoside A (8-epiloganic acid 4′-hydroxyphenylethyl ester). Choice experiments demonstrated that this compound did not significantly deter *H. haemorrhoidalis* from treated leaf surfaces. The significance of iridoids in the defense mechanism of plants against thrips is discussed.

Key Words *Frankliniella occidentalis* · Glasshouse thrips · *Heliothrips haemorrhoidalis* · Iridoids · Plant defense · Plant resistance · *Sclerochiton harveyanus* · Western flower thrips

Introduction

Rapid expansion in the distribution range of several invasive species of thrips and their associated tospoviruses has contributed to pressure on agricultural economies and food production in both developed and developing countries (Lewis, 1997a). The polyphagous nature of these invading species has expanded plant host records at a rate that currently exceeds the accumulation of knowledge on host selection, the efficacy of current biological and chemical controls for specific crop plants, and the development of new control agents or control strategies that aim to eliminate or contain emerging populations. Western flower thrips *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae) is a key species that continues to elude the controls available for use on protected crops in North America, Europe, Australia, Asia, and Africa. The success of *F. occidentalis* as a pest species has been attributed to a range of factors, from human assisted transmission to pesticide resistance (Kirk and Terry, 2003), in conjunction with its ability to feed and rapidly reproduce on a wide variety of hosts (Lewis, 1997b). Damage can be extensive because feeding and oviposition on young leaves, buds, and flowers causes leaf and petal discoloration, desiccation, and distortion of developing fruit. In addition, *F. occidentalis* is a vector for several species of tospoviruses such as tomato spotted wilt virus (TSWV) and impatiens necrotic spot virus (INVS) (Ullman et al., 1997, 2002). Another species; *Heliothrips haemorrhoidalis* (Bouché) (Thysanoptera: Thripidae), is a pest of a wide range of plantation crops such as avocado, tea, and citrus (Goodall et al., 1987; Holt, 1989; Dennill and Erasmus, 1992), and also damages ornamental crops and botanical collections held under glass in temperate regions. The pest status of this species is exacerbated by the fact that it reproduces parthenogeneti-

cally resulting in rapid fluctuations in populations over a relatively short period of time when conditions are optimal. Unlike *F. occidentalis*, *H. haemorrhoidalis* tend to feed on older leaves and do not transmit tospoviruses, although the high numbers achieved on foliage can cause complete defoliation of some crop species.

Frankliniella occidentalis and *H. haemorrhoidalis* discriminate among species of plants when selecting suitable hosts for feeding and reproduction from the diverse botanic collections held in the Temperate House, Royal Botanic Gardens, Kew, UK (Scott Brown, 2002). Variations in plant and foliage morphology, flower/foliage color and hue, volatile constituents and leaf chemistry of cultivated hosts influence the thrips. However, factors that prevent thrips from infesting certain species of plants from exotic glasshouse collections have not been widely reported. Plants from the Temperate House collections that both species of thrips avoid belong to families such as Acanthaceae, Asteraceae, Hyacinthaceae, Lamiaceae, Malvaceae, and Rubiaceae. Previous studies by Scott Brown (2002) examined the performance and preference of *H. haemorrhoidalis* on cut leaves of several of the non-hosts from the Temperate House under laboratory conditions and observed varying levels of disruption to the development and longevity of this insect. *Sclerochiton harveyanus* Nees (Acanthaceae), a large (>2 m) evergreen shrub native to southeastern Africa (Hyde and Wursten, 2010), appeared to be highly toxic to *H. haemorrhoidalis* (Scott Brown, 2002).

Plant secondary metabolites apparently influence the host selection behavior of polyphagous thrips (Mollema and Cole, 1996; Kim et al., 1998; Koschier et al., 2000, 2002), as does the availability of nutrients such as carbon and nitrogen (Bernays and Chapman, 1994; Brodbeck et al., 2001; Scott Brown et al., 2002). However, there is little relevant chemical data on the role of specific metabolites in determining whether plants are hosts or non-hosts for *F. occidentalis* and *H. haemorrhoidalis*.

The objectives of this study were to examine the relationships, if any, between the non-host plants in the glasshouses at the Royal Botanic Gardens (RBG), Kew and chemical constituents present in their foliage. Whole-leaf extracts from six species of non-host plants were toxic to *F. occidentalis*. Extracts that were most toxic to thrips were fractionated in an attempt to isolate and identify the active components.

Methods and Materials

Plant Material and Thrips Non-host plant species selected for these investigations were i) observed to remain free from thrips damage during monitoring studies carried out between 1994 and 2003 in the Temperate House, RBG, Kew, and ii) unable to support thrips on excised leaves under laboratory conditions (Scott Brown, 2002). Leaves from 6 non-host species of plants were collected from the Kew Temperate House, in 2004 (Table 1) and freeze-dried immediately. First instar *F. occidentalis* were collected from a stock culture reared on pods of *Phaseolus vulgaris* L. on a thin layer of vermiculite in sealed plastic containers (23 L× 12 W×7.5 H mm) (Stewart Plastics, UK). Cultures were reared in an incubator maintained at 25°C ± 1°C, with a photoperiod of L16:D8 hr. Adult and pupal stages of *H. haemorrhoidalis* were collected from infestations on *Hibbertia scandens* (Willd.) Dryand. (Dilleniaceae) in the Temperate House.

Preparation of Leaf Extracts Freeze dried leaf material was ground with mortar and pestle into a fine powder and extracted with acetone (100 ml per 10 g leaf powder) for 24 hr before filtering through Whatman 1 filter paper. Leaf residue was re-extracted in aqueous methanol (methanol: water, 80:20, v/v; 100 ml per 10 g leaf residue) for 48 hr and filtered. Aliquots (1 ml) of the acetone and aqueous methanol extracts were filtered through nylon acrodisc filters prior to analytical HPLC. The remaining extracts were taken to dryness by rotary evaporation (aqueous methanol extracts) or under nitrogen (acetone extracts).

HPLC Analysis of Leaf Extracts HPLC coupled to diode array detection was carried out using a Waters system (LC600 pump and controller, 996 photodiode array detector and 717 Plus autosampler) with a Merck LiChrospher 100RP-18 column (250 mm×4.0 mm i.d.; 5 μm particle size) operating at 30°C and a flow rate of 1.0 ml/min. The gradient elution program was based on A = methanol:acetic

Table 1 Six species of plants selected from the Temperate House (RBG, Kew) collection because they remained free from infestations of *Frankliniella occidentalis* or *Heliothrips haemorrhoidalis*

Species	Family	Kew Accession No.
Allagopappus dichotomus Cass.	Asteraceae	1988-4128
Gardenia posoquerioides S.Moore	Rubiaceae	1979-5490
Plectranthus aff. *barbatus* Andrews	Lamiaceae	1992-2021
Plectranthus strigosus Benth. ex E.Mey.	Lamiaceae	1967-41108
Plectranthus zuluensis T.Cooke	Lamiaceae	1992-2850
Sclerochiton harveyanus Nees	Acanthaceae	1978-4494

acid:water (18:1:1) and B = acetic acid:water (2:98) with A=25% at t=0 min; A=100% at t=20 min; A=100% at t=25 min; A=25% at t=26 min (return to initial conditions). In standard analyses, 20 μl of extract were injected.

Bioactivity Guided Fractionation of Sclerochiton harveyanus Leaf Extracts The residues from the acetone extraction (1.92 g; A) or aqueous methanol extraction (2.04 g; M) from 10 g of *S. harveyanus* were dissolved in petroleum ether (50 ml) and subjected to silica gel column chromatography (Silica 60 Å,; 40 cm×2.5 cm i.d.; particle size 40–63 μm, Fisher Scientific UK) with stepwise elution first with petroleum ether:ethyl acetate (1:0, 2:1, 1:2, 0:1; 50 ml each) followed by ethyl acetate:methanol (2:1, 1:2; 50 ml each) and methanol (200 ml). The first 50 ml were discarded, and the remaining eluate was collected as 20 ml fractions from the original acetone extract, A.1–A.25, or the original methanol extract, M.1–M.25, and evaporated to dryness. Each fraction was redissolved in 2 ml methanol and evaluated by analytical HPLC and insect bioassay. The fractions of interest included two from the acetone extract (A.15 and A.19) and one from the aqueous methanol extract (M.15). Chemical constituents of the latter were purified by repetitive isolation using semi-preparative HPLC (Waters system as above) with a Merck LiChrospher 100RP-18 column (250×10.0 mm i.d.; 5 μm particle size). Operating conditions were 30°C, a flow rate of 4.5 ml/min, and an elution program based on A = methanol and B = water, with A=25% at t=0 min; A=100% at t=20 min; A=100% at t=25 min; A=25% at t=26 min (return to initial conditions).

NMR spectra were acquired in CD_3OD at 30°C on either Bruker Avance 400 MHz or Varian 500 MHz instruments using standard pulse sequences and referencing the chemical shift to TMS at 0.00 ppm. Mass spectra were obtained with a Bruker Daltonics microTOF^{TM} mass spectrometer operating in positive ESI mode. LC-APCI-MS analysis was performed using a Thermo-Finnigan system consisting of 'Surveyor' autosampler, pumps and PDA connected to an 'LCQ Classic' quadrupole ion-trap mass spectrometer fitted with an APCI source. Chromatography of 10 μl injections was performed on a Phenomenex Luna C18(2) column (150 mm×4.6 mm i.d., 5 μm particle size) using a 1 ml/min linear mobile phase gradient of water:methanol:5% acetic acid in methanol, 80:0:20 to 0:80:20 in 20 min followed by a methanol wash. Concentrated ammonia was added post column at 2 μl/min and positive ion first-order APCI-MS were recorded using the source settings: vaporizer temperature 550°C; sheath and auxiliary nitrogen gas pressures of 80 and 20 psi, a needle current of 5 μA and a heated capillary temperature of 150°C. Source induced dissociation (sidMS) was achieved by applying a collision energy of 45% in the octapole ion optics (Grayer et al., 2000).

Leaf Extract Bioactivity To evaluate toxicity of leaf extracts to *F. occidentalis*, aliquots (0.5 ml) of the acetone or 80% methanol extracts, at concentrations of 1, 10, 100, 1000 ppm, were distributed around small glass vials (2 ml) with lids in position for 2 min (N=10 for each concentration). The lids were removed and excess extract poured off, and the vials then were air dried for 20 min, thus providing a uniform coating (residue) of extract on the internal surface. Five first instars of *F. occidentalis* were placed in each vial, and mortality was recorded after 2 hr. Controls for each species of plant consisted of two sets of 10 vials rinsed with either acetone or 80% methanol.

Statistical Analysis The Shapiro-Wilk test (Field, 2005) demonstrated that the majority of the data were not from a normally distributed population, and thus non-parametric analyses were used. The differences between all controls were examined using the Kruskal-Wallis analysis of variance test (*KW*). The Mann-Whitney U test (*MW*) was carried out on each of the concentration datasets for each plant species, adjusting the significance level depending on the number of comparisons each time (Bonferroni correction). To determine whether mortality levels differed between species at each concentration the data sets were initially analyzed with the *KW* test, followed by *MW* on each of the concentration data sets to determine where the differences lay, again employing the Bonferroni correction. Differences between mortality levels achieved on exposure to acetone and 80% methanol extracts of each treatment were also examined using *MW* with the Bonferroni correction.

Activity Tests with Fractions and Isolated Compounds Fractions were tested for activity against *F. occidentalis* at concentrations of 1 to 10 ppm. Thin sections of the bean pods of *P. vulgaris* were dipped in the test solutions for several sec, in addition to rinsing the 2 ml glass vials and lids as before. Vials and cut bean sections were left to air dry for 30 min. Five first instars *F. occidentalis* were introduced into each vial (N=15) and allowed to feed on bean sections for 2 hr before assessing mortality. Control treatment vials (N=15) and cut bean sections were rinsed with acetone only. The mortality levels of thrips exposed to each of the test solutions were compared with controls, and differences between them were determined using *KW* and *MW* with the Bonferroni correction. Iridoids **1**–**4** isolated from active fractions from extracts of *S. harveyanus* were tested at a concentration of 100 ppm (N=15). The most active of the iridoids obtained from *S. harveyanus* was tested at concentrations ranging from 1 to 1000 ppm.

Choice Experiments Heliothrips haemorrhoidalis pupae were collected from the host *H. scandens* growing in the Temperate House, Kew. Uninfested leaves of *H. scandens*

were collected, rinsed in distilled water, dried, and cut into sections (2×2 cm) that were dipped in either 100 ppm acetone leaf extract of *S. harveyanus* (treatment 1; T1), 100 ppm iridoid **1** (treatment 2; T2), or acetone only (control). Three leaf discs; one from each treatment and a control, were equally spaced at the sides of a Petri-dish (9 cm) on top of filter paper dampened with distilled water. Five thrips pupae were placed in the center of the Petri dish, the lid was sealed with parafilm (N=15). The locations of the thrips were recorded after 24 and 144 hr (18L:6D) and the distribution of thrips between the treated leaf-discs (T1, T2), acetone only disc (control), and filter paper arena (center) were examined using *KW*. All pupae had eclosed prior to the 24 hr assessment. Dead thrips were not included in the final analysis.

Results

Leaf Extract Activity Test The toxicities of acetone and 80% methanol leaf extracts of the six plant species listed in Table 1 were evaluated for *F. occidentalis* (Fig. 1). Mortality varied among plant species at concentrations of 100 ppm (*KW* $P<0.05$) and 1000 ppm (*KW* $P<0.001$) (acetone extracts), and 10 ppm (*KW* $P<0.01$) and 1000 ppm (*KW* $P<0.05$) (80% methanol extracts). The acetone extract of *S. harveyanus* was more toxic than extracts of the other species at 1000 ppm (*MW*, $P<0.001$ in each case). Dose-relationships generated using Probit analysis were used to determine the bioactivity of dried *S. harveyanus* acetone extracts (LD_{50}=154 ppm). Extracts of *Plectranthus aff. barbatus* (acetone: *MW*, $P<0.005$) and *Plectranthus strigosus* (methanol: *MW*, $P<0.01$) increased the mortality of *F. occidentalis* at concentrations as low as 1 ppm when compared with controls. Overall there was little difference between the activity of acetone and methanol extracts, although in some cases the acetone extracts were more toxic (*KW*, *S. harveyanus*, $P<0.005$; *Plectranthus zuluensis*, $P<0.05$; *P. aff. barbatus*, $P<0.05$). However, only the methanol extracts of *Allagopappus dichotomus*, *Gardenia posoquerioides* and *P. strigosus* were active (Fig. 1). In contrast, the activity of *P. zuluensis* resided in the acetone extracts.

Chemical Composition of Whole Leaf Extracts of Sclerochiton harveyanus Column chromatography of acetone and aqueous methanol leaf extracts of *S. harveyanus* followed by semi-preparative HPLC of the most active fractions afforded four iridoids (Fig. 2). Fraction A.19 (14.2 mg) yielded **1** (3.8 mg, t_R 12.2 min); A.15 (44.6 mg) yielded **2** (7.0 mg, t_R 13.5 min) and **3** (2.0 mg, t_R 16.7 min). Fraction M.15 (69.2 mg) afforded **1** (1.4 mg, t_R 12.2 min) and **4** (3.8 mg; t_R 16.2 min).

Compound **1**, a white amorphous solid, had a molecular formula of $C_{24}H_{32}O_{11}$ by HRESIMS. Analysis of 1D (^{1}H, ^{13}C) and 2D NMR (COSY, HSQC, HMBC) datasets indicated that it was an ester of the iridoid, 8-epiloganic acid (HMBC connectivities are given in Table S1, Supplementary Material). The ^{1}H and ^{13}C resonance assignments for the iridoid moiety of **1** showed an excellent match to those of 8-epiloganin (the methyl ester of 8-epiloganic acid) recorded in CD_3OD (Junior, 1985). The ester group in **1** was readily identified as a 4-hydroxyphenylethyl moiety from NMR and MS data. Thus, in the ^{1}H NMR spectrum, characteristic resonances were observed at δ 4.25 (2H, td, J=6.8, 0.8 Hz, CH_2-8′), 2.85 (2H, t, J=6.8 Hz, CH_2-7′), 7.05 (2H, d, J= 8.6 Hz, H-2′/6′) and 6.72 (2H, d, J=8.6 Hz, H-3′/5′). The site of esterification was determined from a correlation in the HMBC spectrum between the 2H multiplet at δ 4.25 (CH_2-8′) and C-11 at δ 168.9. In LC-APCI-MS analyses conducted using a high cone voltage (source fragmentation), the most abundant fragment ion, at *m/z* 121, corresponded to protonated (4-hydroxyphenyl)ethylene. Compound **1**, therefore, therefore 8-epiloganic acid 4′-hydroxyphenylethyl ester (sclerochitonoside A). The ^{1}H NMR spectrum of the major component of **2** (sclerochitonoside B) was similar to that of **1**, but lacked the resonances corresponding to the glucosyl moiety. It also was noted that H-1, H-5, and H-9 of the iridoid aglycone were upfield shifted by –0.25, –0.05, and –0.34 ppm, respectively, compared to **1**. Use of correlations detected in 2D NMR experiments confirmed that sclerochitonoside B was the aglycone of sclerochitonoside A (**1**). However, the configuration at C-1 could not be determined as H-1 appeared as a broad multiplet in the ^{1}H NMR spectrum of **2**. As expected, LC-APCI-MS analysis (high cone voltage) of **2** revealed a prominent fragment ion at *m/z* 121 corresponding to protonated (4-hydroxyphenyl)ethylene. A further isolate (**3**) was obtained only in small amounts, but preliminary analysis showed that it mainly comprised an iridoid aglycone. The ^{1}H NMR spectrum of the latter was similar to that of **2**, but included an additional 3H singlet resonance at δ 3.76 typical of an aromatic methoxy group. The resonances of H-2′/6′ and H-3′/5′ were downfield shifted by +0.10 and +0.14 ppm, respectively, indicating that the site of methylation was 4′-OH. In LC-APCI-MS, the *m/z* value of 366 recorded for $[M+NH_4]^+$ of **3** was 14 amu greater than that of the corresponding ion of **2**. A prominent fragment ion was recorded at *m/z* 135, consistent with protonated (4-methoxyphenyl)ethylene. These data suggested that **3** was the 4′-methyl ether of **2**, i.e., sclerochitonoside B 4′-methyl ether. Analysis of NMR data acquired for **4** indicated that two subsets of resonances were present, corresponding to iridoid and secoiridoid moieties. The first subset was equivalent to that of 8-epiloganic acid 4′-hydroxyphenylethyl ester (**1**, sclerochitonoside A), except that in the ^{13}C NMR spectrum, C-7 was downfield shifted (+3.7 ppm), and both

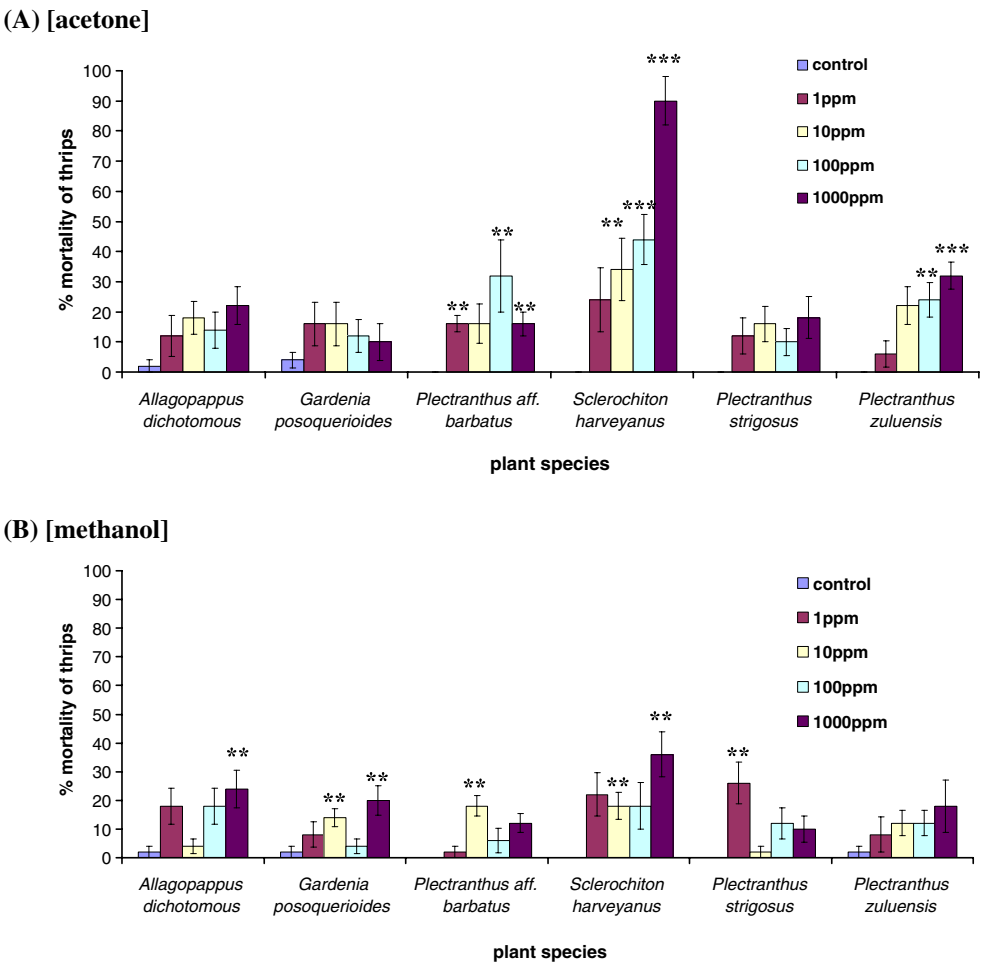

Fig. 1 Mortality of immature *Frankliniella occidentalis* (%±sem) exposed for 2 hr to materials extracted from leaves of six non-host species with acetone (**a**) or 80% methanol (**b**). Each extract was compared to the appropriate solvent control $^{**}P<0.01$, $^{***}P<0.001$, $n=10$

C-6 (– 2.2 ppm) and C-8 (–2.3 ppm) were upfield shifted. Similarly, in the ^{1}H NMR spectrum, H-7 was downfield shifted (+0.98 ppm) compared to the corresponding resonance in **1**. The second subset of resonances were those of the corresponding secoiridoid 4′-hydroxyphenylethyl ester, the structure of which was confirmed from long-range connectivities in an HMBC experiment (Table S2, Supplementary Material). Thus **4** was characterized as a dimer comprising 4′-hydroxyphenylethyl esters of iridoid and secoiridoid subunits, with 8-epiloganic acid as the parent iridoid structure, as in **1**. The linkage between the dimer subunits was defined from a correlation observed between H-7 of the iridoid moiety (subunit a) and C-7 of the secoiridoid moiety (subunit B), in an HMBC experiment. The *m/z* value of 1006 recorded for $[M+NH_4]^+$ of **4** by LC-APCI-MS was consistent with a dimeric structure. Thus, **4** was confirmed to be a dimer of sclerochitonoside A and its secoiridoid analogue, and given the trivial name, sclerochitonoside C.

8-Epiloganic acid 4′-hydroxyphenylethyl ester (sclerochitonoside A) (**1**) ^{1}H NMR (400 MHz, CD_3OD, 30°C): δ (ppm) 5.49 (1H, d, J=4.2 Hz, H-1), 7.35 (1H, d, J=1.3 Hz, H-3), 3.02 (1H, m, H-5), 2.02 (1H, ddd, J=14.0, 8.7, 4.4 Hz, CH_2-6a), 1.77 (1H, dt, J=14.0, 6.3 Hz, CH_2-6b), 3.80 (1H, ‘q’, J=5.4 Hz, H-7), 2.11 (1H, m, H-8), 2.57 (1H, m, H-9), 1.04 (3H, d, J=7.3 Hz, CH_3-10), 7.05 (2H, d, J=8.6 Hz, H-2′/6′), 6.72 (2H, d, J=8.6 Hz, H-3′/5′), 2.85 (2H, t, J=6.8 Hz, CH_2-7′), 4.25 (2H, td, J=6.8, 0.8 Hz, CH_2-8′), 4.64 (1H, d, J=7.8 Hz, H-1″), 3.18 (1H, dd, J=9.2, 7.9 Hz, H-2″), 3.36 (1H, dd, J=9.2, 8.6 Hz, H-3″), 3.24 (1H, dd, J=9.7, 8.6 Hz, H-4″), 3.30 (1H, ddd, J=9.7, 6.1, 2.2 Hz, H-5″), 3.90 (1H, dd, J=11.9, 2.2 Hz, CH_2-6″a), 3.64 (1H, dd, J=11.9, 6.2 Hz, CH_2-6″b). ^{13}C NMR (100 MHz, CD_3OD, 30°C): δ (ppm) 96.3 (C-1), 152.4 (C-3), 114.2 (C-4), 31.1 (C-5), 41.2 (C-6), 79.3 (C-7), 45.3 (C-8), 43.1 (C-9), 14.4 (C-10), 168.9 (C-11), 130.3 (C-1′), 131.0 (C-2′/6′), 116.4 (C-3′/5′), 157.1 (C-4′), 35.4 (C-7′), 66.2 (C-8′), 99.8 (C-1″), 74.8 (C-2″), 78.1 (C-3″), 71.8 (C-4″), 78.5 (C-5″), 63.0 (C-6″). LC-APCI-MS *m/z*: 514 $[M+NH_4]^+$, 335 $[((M+NH_4)–NH_3)–162]^+$, 121 $[C_8H_9O]^+$. HRESIMS *m/z*: 519.1842 $[M+Na]^+$ (calc. for $C_{24}H_{32}O_{11}Na$, 519.1837).

Sclerochitonoside B (**2**) ^{1}H NMR (400 MHz, CD_3OD, 30°C): δ (ppm) 5.24 (1H, br s, H-1), 7.36 (1H, d, J=1.1 Hz, H-3), 2.97 (1H, m, H-5), 2.01 (1H, ddd, J=13.8, 9.6, 4.0 Hz, CH_2-6a), 1.86 (1H, br m, CH_2-6b), 3.91 (1H, br m, H-7),

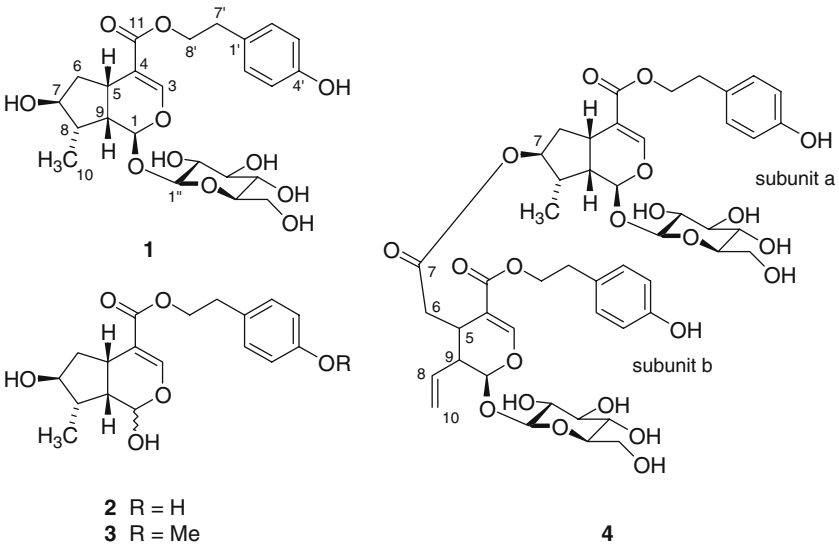

Fig. 2 Structures of four new iridoids identified in the foliage of *Sclerochiton harveyanus*: (**1**) sclerochitonoside A, (**2**) sclerochitonoside B, (**3**) sclerochitonoside B 4′-methyl ether, (**4**) sclerochitonoside C

2.12 (1H, m, H-8), 2.23 (1H, m, H-9), 1.14 (3H, d, *J*=7.1 Hz, CH_3-10), 7.05 (2H, d, *J*=8.7 Hz, H-2′/6′), 6.71 (2H, d, *J*=8.6 Hz, H-3′/5′), 2.85 (2H, t, *J*=7.0 Hz, CH_2-7′), 4.25 (2H, m, CH_2-8′). ^{13}C NMR (100 MHz, CD_3OD, 30°C): δ (ppm) 95.2 (C-1), 153.4 (C-3), 112.4 (C-4), 33.0 (C-5), 42.7 (C-6), 79.9 (C-7), 46.6 (C-8), 45.2 (C-9), 14.2 (C-10), 169.5 (C-11), 130.3 (C-1′), 131.0 (C-2′/6′), 116.3 (C-3′/5′), 157.1 (C-4′), 35.5 (C-7′), 66.2 (C-8′). LC-APCI-MS *m/z*: 352 $[M+NH_4]^+$, 121 $[C_8H_9O]^+$.

Sclerochitonoside B 4′-methyl ether (**3**) ^{1}H NMR (400 MHz, CD_3OD, 30°C): δ (ppm) 7.36 (1H, d, *J*=1.1 Hz, H-3), 2.97 (1H, m, H-5), 2.01 (1H, m, CH_2-6a), 1.88 (1H, br m, CH_2-6b), 3.89 (1H, br m, H-7), 2.13 (1H, m, H-8), 2.23 (1H, m, H-9), 1.14 (3H, d, *J*=7.1 Hz, CH_3-10), 7.15 (2H, d, *J*=8.7 Hz, H-2′/6′), 6.85 (2H, d, *J*=8.7 Hz, H-3′/5′), 2.88 (2H, t, *J*=6.9 Hz, CH_2-7′), 4.26 (2H, m, CH_2-8′) (H-1 was present as a very broad singlet at circa 5.2 ppm). LC-APCI-MS *m/z*: 366 $[M+NH_4]^+$, 135 $[C_9H_{11}O]^+$.

Sclerochitonoside C (**4**) ^{1}H NMR (400 MHz, CD_3OD, 30°C): Subunit a: δ (ppm) 5.51 (1H, d, *J*=4.6 Hz, H-1), 7.37 (1H, d, *J*=1.1 Hz, H-3), 3.02 (1H, m, H-5), 2.16 (1H, ddd, *J*=14.7, 8.7, 2.9 Hz, CH_2-6a), 1.83 (1H, m, CH_2-6b), 4.78 (1H, m, H-7), 2.34 (1H, m, H-8), 2.52 (1H, m, H-9), 1.06 (3H, d, *J*=7.4 Hz, CH_3-10), 7.04 (2H, d, *J*=8.7 Hz, H-2′/6′), 6.71 (2H, d, *J*=8.6 Hz, H-3′/5′), 2.84 (2H, t, *J*=6.9 Hz, CH_2-7′), 4.25 (2H, m, CH_2-8′), 4.67 (1H, d, *J*=7.9 Hz, H-1″), 3.21/3.20 (1H, dd, *J*=9.1, 7.9 Hz, H-2″), 3.36 (1H, m, H-3″), 3.27 (1H, m, H-4″), 3.31 (1H, m, H-5″), 3.90 (1H, dd, *J*=11.9, 2.2 Hz, CH_2-6″a), 3.64 (1H, dd, *J*=11.9, 6.3 Hz, CH_2-6″b). ^{13}C NMR (100 MHz, CD_3OD, 30°C): δ (ppm) 96.0 (C-1), 152.4 (C-3), 113.8 (C-4), 31.6 (C-5), 39.0 (C-6), 82.8 (C-7), 43.0 (C-8), 43.0 (C-9), 14.3 (C-10), 168.8 (C-11), 130.3 (C-1′), 130.8 (C-2′/6′), 116.2 (C-3′/5′), 157.1 (C-4′), 35.3 (C-7′), 66.2 (C-8′), 99.9 (C-1″), 74.6 (C-2″), 78.0 (C-3″), 71.6 (C-4″), 78.3 (C-5″), 62.8 (C-6″). Subunit b: δ (ppm) 5.47 (1H, d, *J*=4.6 Hz, H-1), 7.41 (1H, d, *J*=1.7 Hz, H-3), 3.29 (1H, m, H-5), 2.78 (1H, dd, *J*=16.3, 5.2 Hz, CH_2-6a), 2.30 (1H, dd, *J*=16.3, 8.8 Hz, CH_2-6b), 5.63 (1H, ddd, *J*=17.3, 10.3, 9.3 Hz, H-8), 2.72 (1H, m, H-9), 5.24 (1H, dd, *J*=17.2, 1.5 Hz, CH_2-10a), 5.22 (1H, dd, *J*=10.2, 1.6 Hz, CH_2-10b), 7.04 (2H, d, *J*=8.7 Hz, H-2′/6′), 6.71 (2H, d, *J*=8.6 Hz, H-3′/5′), 2.84 (2H, t, *J*=6.9 Hz, CH_2-7′), 4.25 (2H, m, CH_2-8′), 4.66 (1H, d, *J*=7.9 Hz, H-1″), 3.21/3.20 (1H, dd, *J*=9.1, 7.9 Hz, H-2″), 3.36 (1H, m, H-3″), 3.27 (1H, m, H-4″), 3.31 (1H, m, H-5″), 3.89 (1H, dd, *J*=12.0, 2.1Hz, CH_2-6″a), 3.66 (1H, dd, *J*=11.8, 5.7 Hz, CH_2-6″b). ^{13}C NMR (100 MHz, CD_3OD, 30°C): δ (ppm) 97.5 (C-1), 153.5 (C-3), 110.2 (C-4), 29.3 (C-5), 35.8 (C-6), 174.1 (C-7), 134.5 (C-8), 45.4 (C-9), 120.5 (C-10), 168.4 (C-11), 130.3 (C-1′), 130.8 (C-2′/6′), 116.2 (C-3′/5′), 157.1 (C-4′), 35.3 (C-7′), 66.2 (C-8′), 99.9 (C-1″), 74.6 (C-2″), 78.0 (C-3″), 71.6 (C-4″), 78.3 (C-5″), 62.8 (C-6″). LC-APCI-MS *m/z*: 1006 $[M+NH_4]^+$.

Sclerochitonoside A (**1**), sclerochitonoside B (**2**), sclerochitonoside B 4′-methyl ether (**3**), and sclerochitonoside C (**4**), have not been reported previously. Each compound had the common feature of esterification of the iridoid aglycone by a C-11 phenylethyl moiety (Fig. 2). Both sclerochitonoside B (**2**) and sclerochitonoside B 4′-methyl ether (**3**) lacked a glucosyl moiety at C-1. The dimer, sclerochitonoside C (**4**), comprised subunits based on the 4′-hydroxyphenylethyl esters of 8-epiloganic acid and its secoiridoid analogue. These were linked from O7 of the iridoid to C-7 of the secoiridoid. Similarly linked dimers of iridoids and their corresponding secoiridoid are uncommon, but have been reported as tricoloroside from *Loasa tricolor* (Loasaceae) (Nicoletti et al., 1991) and tricoloroside methyl ester from *Loasa acerifolia* (Müller and Weigend, 1998). In the latter examples, the iridoid subunits were loganic acid and loganin (loganic acid methyl ester), respectively.

Iridoid Activity Tests Against Thrips Exposure of *F. occidentalis* to the four iridoid compounds for 2 hr resulted in varying levels of mortality (*KW*, $P<0.05$). The two compounds which significantly increased mortality of *F. occidentalis* were sclerochitonoside A (**1**) and sclerochitonoside C (**4**) (both *MW*, $P<0.01$, applying Bonferroni correction) when compared with acetone controls ($N=15$) (Fig. 3). Increasing the concentration of sclerochitonoside A (**1**) may result in increased mortality, however, concentrations of 1 and 10 ppm were not found to result in significantly higher levels of thrips mortality when compared with the control mortality levels (Fig. 4) (*MW*, $P>0.01$ (Bonferroni correction) in both cases).

Choice experiments with *Heliothrips haemorrhoidalis* showed little evidence that these thrips were deterred by the presence of residues of crude leaf extracts of *S. harveyanus* (T1) or the iridoid sclerochitonoside A (T2) at a concentration of 100 ppm. *H. haemorrhoidalis* were equally distributed between treated and untreated leaves of *H. scandens* after 24 hr (*KW*, $P>0.05$) and 144 hr (*KW*, $P>0.05$), although after a period of 144 hr the thrips tended to be found on the control leaves rather than those treated with either the crude extract or sclerochitonoside A (Fig. 5).

Discussion

The basis of our study was to examine what effects compounds present in the leaves of 'thrips-resistant' species had on the behavior of thrips. Six species of plants located in the Temperate House, Royal Botanic Garden, Kew, which consistently remained free from thrips infestations, provided leaf extracts that demonstrated varying levels of toxicity against *F. occidentalis*. Extracts with the highest level of activity were those of *S. harveyanus*, and four novel iridoids (**1**–**4**) were isolated from these. Although iridoids were present in both acetone and methanol extracts, the most active and abundant compound, sclerochitonoside A, was more concentrated in the acetone extracts than in the aqueous methanol extracts. The relatively high activity of the acetone whole-leaf extracts of *S. harveyanus* against *F. occidentalis* may be the result of the proportionally higher concentration of sclerochitonoside A in these extracts.

Iridoid glycosides have been reported previously in the leaves, fruit, seeds, bark, and roots of many plant families including Acanthaceae (Bernays and De Luca, 1981). These compounds are frequently described as bitter tasting monoterpenoids, and have a range of activity against herbivorous insect species. Bowers (1984) recognized that iridoids were feeding and oviposition stimulants for certain specialist insects, such as the buckeye butterfly,

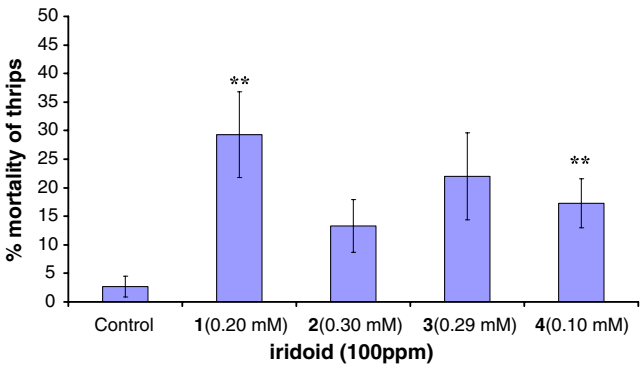

Fig. 3 Mortality of immature *Frankliniella occidentalis* (%±sem) exposed to dried residues of 100 ppm solution of iridoid isolated from leaves of *Sclerochiton harveyanus* on cut bean sections after a 2 hr period. Numbers in parentheses are mM concentrations of the compounds (**1**) sclerochitonoside A, (**2**) sclerochitonoside B, (**3**) sclerochitonoside B 4′-methyl ether, (**4**) sclerochitonoside C. Thrips mortality after exposure to iridoids was compared to the solvent control $^{**}P<0.01$, $N=15$ (**1**, **2** and **4**), $N=10$ (**3**)

Junonia coenia Hübner. Other studies have focused on the activities of iridoid glycosides against insects such as gypsy moth, *Lymantria dispar* L. and the southern armyworm, *Spodoptera eridania* (Cramer) (Bernays and De Luca, 1981; Bowers and Puttick, 1988; Fajer et al., 1992). Biere et al. (2004) concluded that the iridoid glycosides in ribwort plantain, *Plantago lanceolata* L., serve as broad-spectrum defenses against generalist insect herbivores. The iridoid-containing fractions from leaf extracts of *S. harveyanus* were highly toxic to *F. occidentalis* at relatively low concentrations, but were not conclusively deterrent to *H. haemorrhoidalis* when tested in their isolated forms.

There is little or no information on the chemistry of the foliage of the plants included in this study, with the exception of the genus *Plectranthus*, which has ethnobotanical uses (Abdel-Mogib et al., 2002; Lukhoba et al., 2006; Wellsow et al., 2006). In addition, previous studies by Scott Brown (2002) showed that cut leaves of *P. barbatus* have a deterrent effect on adult *H. haemorrhoidalis*. Phytochemical studies of *Plectranthus* have identified monoterpenoid, sesquiterpenoid, diterpenoid, and phenolic compounds (Ascensão et al., 1998; Grayer et al., 2003; Lukhoba et al., 2006; Gaspar-Marques et al., 2008). Wellsow et al. (2006) showed that diterpenoids from *Plectranthus*, including coleon A, had antifeedant activity against the generalist *Spodoptera littoralis* (Boisduval). Another diterpenoid, plectrin, isolated and characterized by Kubo et al. (1984) from leaves of *P. barbatus,* was an active antifeedant against *Schizaphis graminum* and *Pectrinophora gossypiella*. In contrast, a caffeic acid derivative, nepetoidin B, present in foliage extracts of *P. strigosus* was a phagostimulant when presented to *S. littoralis* (Grayer et al., 2003). Although the present study demonstrated that the whole-leaf extracts of the three species of *Plectranthus* are toxic against thrips, further fractionation of extracts and subsequent bioassays will be required to gain a better understanding of all the chemical constituents in these species that are responsible for the activity against *F. occidentalis* and *H. haemorrhoidalis*.

Interpreting the activity of leaf extracts of the remaining plant species included in this study against thrips is more challenging, as the phytochemistry of these plants has not been reported in detail. Novel sesquiterpene lactones and thymol derivatives have been isolated from the aerial parts of *A. dichotomus* (Gonzalez et al., 1995). Thymol has significant activity against stored-product pests (Rozman et al., 2007; Sahaf et al., 2007). Chlorogenic acid, identified in the leaf-extracts of *A. dichotomus,* is active against herbivorous insects (Bernays et al., 2000; Ikonen et al., 2001; Simmonds and Stevenson, 2001; Cipollini et al., 2008) and has been identified as a key component in chrysanthemum cultivars that are thrips-resistant (Leiss et al., 2009). Kaempferol derivatives are found in *A. dichotomus* (Gonzalez et al., 1995), and we tentatively identified a methyl ether of the flavonol, kaempferol, in the leaf extracts of *G. posoquerioides* (Scott Brown et al. unpublished data).

The leaves of the non-hosts selected for this study, with the exception of *G. posoquerioides*, are coated with sparse peltate glandular trichomes (Scott Brown and Simmonds, 2006). Such structures may provide a physical barrier against herbivorous insects and could also contain compounds that modulate thrips behavior (Wagner, 1991; Bisio et al., 1999; Roda et al., 2003). Terpenoids that have antifeedant properties occur in trichomes (Harborne, 1977; Kelsey et al., 1984). However, the lack of trichomes on the surfaces of leaves of *G. posoquerioides*, in addition to activity exclusively in the methanol extracts suggests that a different compound or compound group is key to the anti-thrips activity in this latter species. Comparing the activity levels of leaf-surface wash extracts with whole-leaf extracts could provide a valuable insight into the location of active compounds in the leaves of non-host species.

The actual role of the sclerochitonosides from *S. harveyanus* in host selection by thrips among the diverse plant collections contained within the Kew glasshouses is still unclear due to the complexity of chemically and non-chemically mediated interactions that are involved. This study indicated that crude leaf extracts of *S. harveyanus* were more toxic to *F. occidentalis* than the purified active iridoid components applied individually, thus suggesting that other components have a role in the activity against *F. occidentalis*. The presence of these compounds in the foliage of *S. harveyanus* may contribute to its observed non-host status in the glasshouses at Kew, preventing both *F. occidentalis* and *H. haemorrhoidalis* from alighting and feeding on this plant species, particularly when there are other preferred species in close proximity. Further studies are necessary in order to confirm whether the sclerochitonosides alone are responsible for the disrupted development previously observed in *H. haemorrhoidalis* when exposed to leaves of *S. harveyanus* (Scott Brown, 2002). In addition, a detailed investigation into mechanisms of the active iridoids against *F. occidentalis* may contribute towards the knowledge and subsequent development of successful control techniques against pest thrips species of high economic importance.

Acknowledgements We are grateful to Dr. Renée Grayer and Dr. Geoffrey Kite (RBG, Kew) for guidance on phytochemical analysis, and staff in the Sustainable Uses of Plants Group, Jodrell Laboratory (RBG, Kew) for technical help. We also thank David Cooke, Temperate House (RBG Kew), for providing the plant material and the Medical Research Council Biomedical NMR Centre, National Institute for Medical Research (Mill Hill, London, UK) for access to high-field NMR facilities.

Abstract We examined how tannin structure influences reactivity in tannin assays and carbon and nitrogen mineralization. Condensed tannins from the foliage of ten tree and shrub species and from pecan shells (*Carya illinoensis*) had different proportions of: (a) epicatechin (*cis)* and catechin *(trans)* isomers, (b) procyanidin (PC) and prodelphinidin (PD) monomers, and (c) different chain lengths. The response of each tannin to several widely used tannin assays was determined. Although there was some variation in response to proanthocyanidin (butanol/HCl) and Folin Ciocalteu assays, we did not deduce any predictable relationship between tannin structure and response to either assay. There was little variation in protein precipitation among the different tannins. To assess biological activity, six of the tannins were incubated with forest humus for 22 days. We determined that, while PC-based tannins remained at least partly extractable for the duration of the incubation, tannins with a high proportion of PD subunits rapidly became unextractable from soil. There was a positive correlation between net nitrogen mineralization and *cis* chemical structure. Carbon mineralization was enhanced initially by the addition of tannins to humus, but after 22 days, a negative correlation between the proportion of *cis* subunits and respiration was determined. Overall, we were not able to demonstrate consistent effects of structure on either microbial mineralization or reactivity to chemical assays; such relationships remain elusive.

Key Words Condensed tannin · Proanthocyanidin · Tannin structure · ^{13}C NMR · Protein binding · Acid butanol assay · Folin assay · Carbon mineralization · Nitrogen mineralization

Introduction

Tannin is an abundant polyphenolic plant biopolymer, constituting 10–25% of foliar mass for woody species (Kraus et al., 2003a). Tannins are classified as either hydrolyzable, based on phenolic esters of a central sugar, or condensed (CT), which comprise carbon-carbon linked flavan-3-ols. Gymnosperms can synthesize only CT, but angiosperm dicots can produce both CT and hydrolyzable tannins (Bate-Smith, 1977; Hernes and Hedges, 2004). Structural categorization of CT is based on the stereochemistry at the C2 and C3 bonds, with the B ring either *trans* to the C3 hydroxyl (catechin) or *cis* (epicatechin); the number of hydroxyl groups on the B ring, with two for procyanidin (PC) and three for prodelphinidin (PD); the number of monomers in the polymers (Fig. 1) (Ayres et al., 1997; Czochanska et al., 1980; Kraus et al., 2003b; Nierop et al., 2005). Other structural variations include propelargonidin units that have one hydroxyl group on the B ring, branches formed by C4→C6 linkages, and A-type linkages based on a C2-B hydroxyl ether bond.

Tannins interact with proteins and thus play a role in forest ecosystems through their impact on herbivory (Ayres et al., 1997), allelopathy (MacKenzie and DeLuca, 2006), and carbon and nitrogen cycling (Kraus et al., 2003a). Ericaceous shrubs contain tannins that negatively affect

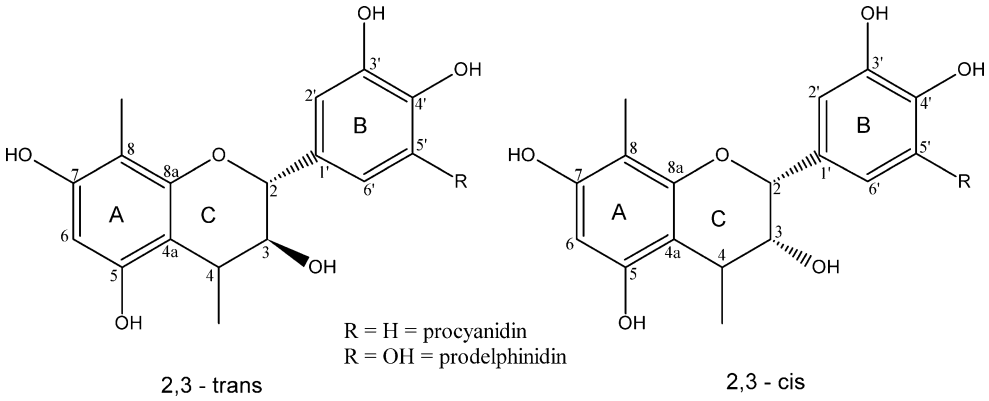

Fig. 1 Structural units of condensed tannins. Catechin type units are 2,3 *trans* (left) and epicatechin are 2,3 *cis* (right). Procyanidin (PC) subunits have two B-ring hydroxyl groups, prodelphinidin (PD) subunits have three

nutrient cycling, as demonstrated for sheep laurel (*Kalmia angustifolia* L.) in the black spruce (*Picea mariana* (Mill.) BSP) forests of Quebec and Newfoundland (Bradley et al., 2000; Joannisse et al., 2007). Wurzburger and Hendrick (2007) described similar effects of *Rhododendron maximum L.* in Appalachian hardwood forests. Negative impacts on nutrient availability also have been suggested for tannin-rich salal (*Gaultheria shallon* Pursch) (Preston, 1999) although in the redcedar (*Thuja plicata* Donn) hemlock (*Tsuga heterophylla* (Raf.) Sarg.) forests of Vancouver Island tannin-rich salal was not a primary cause of poor tree growth, but rather an indicator of poor nutrient availability, especially N limitation (Prescott and Sajedi, 2008). In addition to ericaceous shrubs, CT from other species such as *Populus* impact nutrient cycling (Schweitzer et al., 2008).

Addition of sheep laurel and balsam fir CT to humus decreased mineral nitrogen cycling (Bradley et al., 2000), but the role of CT structure was not considered. Scots pine (*Pinus sylvestris* L.) and Norway spruce (*Picea abies* (L.) Karst) tannins added to humus from Scots pine and Norway spruce stands, or from birch (*Betula pendula* Roth) groves, decreased C respiration and increased net N mineralization (Kanerva et al., 2006; Kanerva and Smolander, 2008). Although Scots pine tannins are predominantly PD-based and Norway spruce are PC, the mineralization results could not be correlated to B-ring substitution (Kanerva and Smolander, 2008). Kraus et al. (2004) compared five purified tannins and found that tannin addition to mineral soil increased cumulative CO_2 production while net N mineralization decreased compared to the control. There was some indication that tannins with a higher proportion of PC units were less labile than those with predominantly PD units, a result supported in subsequent studies (Nierop et al., 2006a, b).

The responses of CT to different analytical methods are not consistent, therefore it has been suggested that for quantitative studies, CT standards should be purified from the species of interest (Schofield et al., 2001; Kraus et al., 2003b). However, there has been little investigation of this variability by using well-characterized purified tannins. Kraus et al. (2003b) extracted tannins from nine species and reported that increased percentage of PC units was positively correlated with the Folin-Ciocalteu (FC) and proanthocyanidin (PA) assays. Chain length had no significant effect on these assays or on protein precipitation, possibly because a relatively small range of chain lengths was investigated.

This study explores three hypotheses about the relationship between CT structure, reactivity in assays, and biological activity. The first hypothesis is that there is a structure-response relationship such that: (a) PA and FC responses increase with increasing PC (%), and (b) protein precipitation (PP) and PA responses increase with increasing CT chain length. The second hypothesis is that CT comprising high PC (%) decrease overall C mineralization. The third hypothesis is that CT containing high PD (%) decrease N mineralization. Specifically, we purified ten condensed tannins from the foliage of tree and shrub species (sheep laurel, black spruce, hemlock, redcedar, salal, balsam fir, Scots pine, jack pine (*Pinus banksiana* Lamb.), blueberry (*Vaccinnium ovalifolium)*, and Douglas fir [*Pseudotsuga menziesii* (Mirb.) Franco)] and from pecan shells (*Carya illinoensis*). The purified CT were structurally characterized using NMR, and were analyzed with three standard tannin assays (PA, FC, and PP). Ecological processes were assessed by quantifying microbial respiration and N mineralization by using humus from the forest floor of a Douglas-fir stand amended with six of the tannins.

Methods and Materials

Sample Origins Composite needle samples of jack pine and black spruce were collected from sites along the Boreal Forest Transect Case Study (BFTCS; Preston et al., 2006) in Saskatchewan and Manitoba in 2003. Oval-leaf blueberry and salal leaves were collected from research plots near Jordan River, British Columbia (BC) in 2002 and from Port McNeill, BC in 2000, respectively. Needles of western hemlock, western redcedar, and Douglas fir were collected

in Victoria, BC in 2002 and Scots pine, the only species growing in an exotic location, also was collected in Victoria in 2001. As reported previously (Preston et al., 1997), balsam fir branch tips and sheep laurel leaves were collected in 1995 in Newfoundland, and pecan tannins were extracted from bulk broken nutshells (1990 harvest) kindly supplied by Dr. S. Kays, University of Georgia, Athens, GA, USA.

Preparation and Purification of Tannins Oven dried (40°C) leaves or freeze dried needles were ground to 2 mm in a Wiley mill (Thomas Scientific, Swedesboro, NJ, USA) and stored at room temperature. Tannins were extracted and purified according to the methods in Lorenz and Preston (2002) and Nierop et al. (2005). For pecan tannins, the hexane pre-extraction and solvent washing steps were omitted, as the dark red powder (packing tissue) found on the inner surfaces of the shells is almost pure condensed tannin (Preston and Sayer, 1992).

Tannin Characterization Carbon and nitrogen analysis of purified tannins was carried out by dry combustion on a LECO CNS 2000 (LECO, St. Joseph, MI, USA). Chemical structures were determined by solution-state ^{13}C nuclear magnetic resonance spectroscopy (NMR) as reported previously (Kraus et al., 2003b; Nierop et al., 2005), using 150–175 mg of tannin dissolved in 3 ml of 1:1 acetone and D_2O. Spectra were obtained at 75.47 Hz on a Bruker MSL 300 spectrometer (Bruker Instruments Inc., Karlsruhe, Germany) using a 10 mm sample tube, inverse-gated decoupling, 45° pulse, 0.5 sec acquisition time, and relaxation delays from 3.6 sec to 10 sec. In some cases, spectra were run with two delay times, and the results were averaged as no consistent differences were apparent above 3.6 sec. The free induction decays (FIDs) were processed with baseline correction and a low line-broadening of 8 Hz to optimize resolution, and chemical shifts were reported relative to tetramethylsilane at 0 ppm using the acetone peak at 30.7 ppm as a secondary standard. Three structural parameters (Fig. 1) were determined by integration of specific regions. Percentages of (a) C2-C3 *cis* vs. *trans* stereochemistry were determined by comparing the integrated areas between 75–80 and 80–85 ppm, (b) procyanidin vs. prodelphinidin B-ring structure (reported as PC%), was determined by integrating peaks at 145 and 146 ppm, and (c) average chain lengths were determined by integrating signals at 67 ppm (terminal unit) and 72 ppm (extender units). Our NMR methods are unable to detect other structural features, such as C4→C6 branching or lower levels of B-ring hydroxylation.

Tannin Assays The eleven tannins were assessed with the FC method for total phenolics, the PA method for proanthocyanidin, and the radial diffusion PP assay. Results were reported as response curves for FC and PA assays by plotting the absorbance as a function of mass of tannin. A response curve also was generated for PP by plotting the diameter of the precipitation ring against the mass of tannin.

For the FC assay (Scalbert, 1992), purified tannin was dissolved in methanol at 0.25 mg ml^{-1}, and aliquots of the solution were dried in 15 ml screw-cap vials using forced air at room temperature to yield between 0.03–0.25 mg of tannin in each vial. Samples were redissolved with 1.0 ml deionized water, 0.5 ml FC reagent (Folin-Ciocalteu phenol reagent, Sigma-Aldrich Inc., St. Louis, MO, USA) and 2.5 ml 20% (w/v) sodium carbonate. Samples were mixed and decanted into disposable cuvettes for analysis at 750 nm on a Milton Roy Spectronic 1001 Plus (Ivyland, PA, USA).

For the PA assay, samples were dispensed and dried in the vials as for the FC assay, and 5 ml of color reagent were added (5% HCl, 0.75 mg ml^{-1} $FeSO_4$, 1.3% H_2O in butanol) (Lorenz et al., 2000). Samples were vortexed prior to, in the middle of, and subsequent to heating for 1 h in a 95°C water bath. Solutions were scanned on the Milton Roy spectrophotometer between 650 nm–450 nm, and absorbances were recorded at the λ_{max} (555±2 nm). The radial diffusion assay was carried out by dispensing 20–80 μl of 12.5 mg ml^{-1} tannin dissolved in 50% aqueous methanol into wells in agarose plates containing 0.050% gelatin type B (Difco Bacto Agar Difco Laboratories, Detroit, MI, USA; Sigma Chemical Co., St. Louis, MO, USA) (Kraus et al., 2003b). The diameters of the resulting rings were measured after the agar plates were inverted and left for 24 h at room temperature.

Tannin Incubation with Humus The top two layers, L and F, of the forest floor were removed, and 300 g of the humus layer were collected from each of three locations in a Douglas fir forest in the Shawnigan Lake Research Forest near Victoria, BC in September 2003. Locations were chosen to avoid salal plants, but otherwise were randomly selected. Samples were bulked, sieved (5 mm), mixed, stored 5 days at 4°C, and conditioned at room temperature for 5 days. The humus had a moisture content of 50%, pH of 5.3 in H_2O, and organic C and N concentrations of 365 and 10.6 mg g^{-1}, respectively, determined by dry combustion (LECO CNS 2000).

Purified tannins from black spruce, balsam fir, western redcedar, jack pine, sheep laurel, or blueberry were used in the incubation. Samples were prepared in 15 ml vials by mixing 1.000 g of fresh humus with 15 mg of tannin (9 mg C g^{-1} soil). Samples were vortexed, capped loosely to maintain aerobic conditions, and incubated at 25°C in the dark.

Respiration was measured in an incremental fashion, with the amount of CO_2 produced between each of 12 time

points (4, 22, 46, 70, 94, 146, 190, 238, 291, 331, 407, and 522 h after the addition of tannin) determined in triplicate. Each replicate comprised four (t=4 or 22 h) or three vials (all other times) that were placed in a larger container at the beginning of the time increment. The container was sealed, and left to incubate at 25°C until the next sampling time, when a syringe was used to collect an aliquot of gas from the headspace of the sealed container through a septum (Bradley et al., 2000). At that time, the next set of vials was placed in a large container to measure CO_2 production during the next increment. The headspace samples were analyzed by gas chromatography with a flame ionization detector (5890 HP Gas Chromatograph, Agilent Technologies, Santa Clara, CA, USA). Carbon dioxide production (mg CO_2 g^{-1} dry soil) was calculated using a standard curve ranging from 0.1 to 5% CO_2.

Ammonium (NH_4-N) and nitrate (NO_3-N) were determined for three vials from each treatment on d 0 and d 22. Samples were extracted with 8.00 ml of 1.00 M KCl, vacuum filtered through pre-washed Whatman #2 filter paper, and frozen for subsequent colorimetric determination of NO_3-N and NH_4-N (Joannisse et al., 2007). Net N mineralization was calculated by subtracting the control value on d 0 (0.11 mg NO_3-N kg^{-1} dry soil and 2.70 mg NH_4-N kg^{-1} dry soil) from mineral N concentration on d 22.

Extractable and residual tannins were determined for triplicate vials from each treatment on d 0, 1, 2, 3, 4, 8, 11, 14, and 22. Each vial was extracted four times by shaking for 45 min with 5.00 ml of 70/30% (v/v) acetone:water and centrifuging at 1,609 x g for 10 min. The extracts were combined for PA analysis as described above. The sample residues were washed by shaking for 10 min with 5 ml methanol, followed by centrifugation, and the residues were dried in a forced-air oven at 70°C. Residues were analyzed by adding 5.00 ml of the PA reagent to each sample, heating, and centrifuging for 20 min at 1,609 x g before reading the absorbance. Concentrations of extractable and residual tannins were determined using the standard curve obtained with pure balsam fir tannins, and were corrected for the variability in response to the PA assay (Table 1). The response correction meant that for some plants, the apparent extractable tannin was >100%, but for each type of tannin the bias due to response correction should be consistent for all measurements, so the trends in tannin extractability can be established from apparent recovery.

Statistical Analysis Responses in the FC, PA, and PP assays, and C and N mineralization, were compared for differences among the different purified tannins. The data were normally distributed and were analyzed using a one-way analysis of variance (ANOVA) with a general linear model procedure followed by a least squares means multiple range test. A forward step-wise regression was used to determine relationships between chemical structure and chemical response or incubation results. All analyses were done using SAS 9.0 (SAS Institute Inc., Cary, NC, USA).

Results

Chemical Structures and Responses of Purified Tannins The ^{13}C NMR spectra were typical of condensed tannins. The 2,3 stereochemistry of the extender units for most of the tannins was dominated by *cis* configuration typical of epicatechin, but tannins from redcedar were dominated by 2,3-*trans* stereochemistry suggesting catechin-based subunits (Table 1). The extent of B-ring hydroxylation varied widely, with lowest PC% for balsam fir, hemlock, jack pine, and pecan, and highest for black spruce and blueberry. Chain lengths ranged from 2.3 to 6.3

but were lower for sheep laurel. Tannins contained small amounts of N (2 to 5 mg g^{-1}) (data not shown).

Results for the response of the tannins to the chemical assays are reported as the slope of the linear response ($r^2>0.90$) (Table 1). There was at most a two-fold difference in response for the 11 different CT types in the PA assay (Table 1), and a three-fold variation in response to the FC assay (Table 1). In contrast, there was little variation in response to the PP assay (Table 1). No significant relationships were observed between any of the chemical assays and the chemical structure (*cis*%, PC%, and chain length) of the tannins ($P>0.05$).

Tannin Incubation with Humus Six purified tannins were chosen based on their variation in chemical structure (*cis*%, PC%, and chain length) for addition to forest floor humus in a 22-day laboratory incubation. Early in the incubation, addition of four of the tannins (spruce, sheep laurel, redcedar, and pine) resulted in significantly higher respiration rates relative to the control (Table 2). After 22 days, the samples amended with sheep laurel tannins had respired significantly more C (5.66 mg g^{-1}) than the control, with 5.7% net mineralization of the added tannin C (Table 3). Addition of jack pine or redcedar did not change soil microbial respiration over the 22-day trial. Addition of balsam fir, black spruce, or blueberry tannins inhibited respiration (Table 2), with blueberry tannins most inhibitory. While chain length and proportion of PC did not affect the cumulative CO_2 production, an increased proportion of *cis* subunits significantly decreased total respiration (P=0.027).

Gross inorganic nitrogen mineralization was significantly higher for humus amended with blueberry or balsam fir tannins compared to the control (Table 3). The increase in N mineralization for balsam fir tannins was due to more ammonium N formation, while for blueberry both ammonium N and nitrate N increased compared to control (Table 3). Net N nitrification was significantly higher for sheep laurel and blueberry treatments compared to the control (Fig. 2). Conversely, there were no significant differences between the control and the tannin treatments for net N ammonification (Fig. 2). As with C mineralization, PC%, and chain length were not significant factors in N mineralization, while the proportion of *cis* subunits was positively correlated with net ammonium (P=0.028) and nitrate (P=0.005) formation.

Quantitation of extractable tannins from humus is influenced by degradation and sorption of tannin. Extractable tannins were not detected in the control samples, but we measured 0.64 mg g^{-1} non-extractable tannins in the control humus. For the amended humus, extractable tannins on d 0 ranged from 34% (sheep laurel) to 121% (black spruce) of the tannin added. In all of the treatments, there was an initial rapid decrease in the amount of extractable tannins, followed by a steady decrease for the remainder of the incubation (Fig. 3). Humus treated with black spruce or blueberry tannins had the highest recoveries of extractable tannins throughout the incubation, with recoveries statistically higher than for the other four treatments on d 22 (Fig. 3). The lowest recovery of tannin initially was from

the sheep laurel tannins treatment, but after 5 days, and for the remainder of the incubation experiment, the lowest recoveries were from the balsam fir treatment. For the amended humus, residual tannin recovery was always less than 2% of the tannin added.

Discussion

Eleven purified condensed tannins were characterized by establishing structural details, responses to chemical assays,

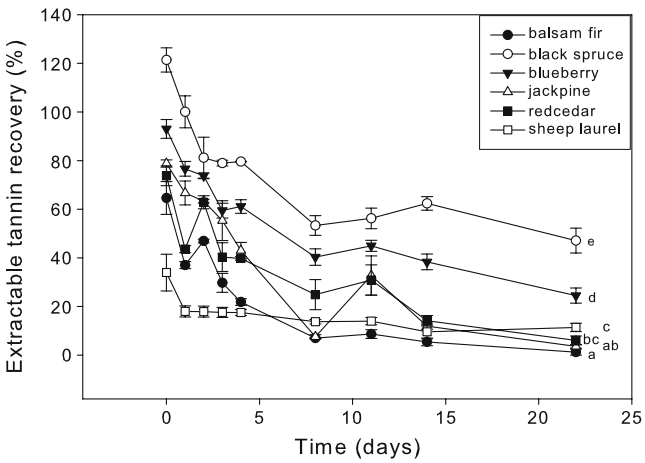

Fig. 3 Percent recovery of added tannin from balsam fir, black spruce, blueberry, jack pine, redcedar, or sheep laurel from forest humus as a function of time. The PA assay was used to determine extractable tannins. Error bars indicate one standard error ($N=3$) and different letters indicate statistical differences between tannin treatments on d 22 ($P<0.05$)

and effects on soil microbial mineralization of C and N. The ^{13}C NMR spectra were similar to those reported in other studies (Czochanska et al., 1980; Ayres et al., 1997; Kraus et al., 2003b), thus confirming that the 11 CTs were essentially free of carboxyl C and extraneous low-molecular-weight contaminants. Structural parameters found in this study (Table 1) are comparable with results from other studies, but some of our NMR data differ slightly from previously published values due to improvements in spectral processing or acquisition of new spectra. The range of values for *cis* configuration, PC%, and chain length is similar to that reported previously for boreal (Ayres et al., 1997) and temperate (Kraus et al., 2003b) forest species. Our structural parameters determined by NMR are generally supported by the characterizations that use techniques such as thermally-assisted hydrolysis and methylation-gas chromatography/mass spectrometry (THM/MS) (Nierop et al., 2005), high-performance liquid chromatography with mass spectrometry (RP- and NP-HPLC/MS) (Kanerva et al., 2006), and direct acid depolymerization (Hernes and Hedges, 2004). However, the NMR determination of chain length may not correctly represent sheep laurel tannins due to incorporation of *p*-coumaric acid units in the polymer (Nierop et al., 2005).

Our set of eleven CTs provided a wide range of chemical structures for evaluating the relationship between chemical structure and chemical reactivity. Blueberry, with the highest proportion of *cis* subunits and PC stereochemistry, had the strongest response to the PA assay, although we found no significant relationship between PA response and the chemical structural parameters that we measured, in agreement with Porter et al. (1986). This was in contrast to Kraus et al. (2003b) who found that tannins with higher percentages of *cis* subunits and PC configurations gave a stronger responses to both the FC and PA analysis. Neither *cis*%, PC%, nor chain length had an effect on PP, confirming previous results (Porter and Woodruffe, 1984; Kawamoto et al., 1990; Kraus et al., 2003b). While we found no relationship between chemical structure and chemical response, the analyses did confirm that different tannins exhibit different responses, leading us to recommend that tannin concentrations in unknown samples be accurately established by using tannin standards that are identical to those found in the sample. A better understanding of the structural factors that affect tannin response to these assays is still required.

Part of the problem in developing better structure-function relationships is that the tannin preparations typically used in this and similar studies are not single pure compounds. Our derived structural parameters were averages, as evidenced by non-integer chain lengths, and not all features were resolved. Plant tannins generally can be purified from extraneous compounds, such as sugars,

lipids, and monomers such as catechin, but may be mixtures of CT and hydrolyzable tannins (e.g., Kraus et al., 2003b), or may contain small amounts of structural units not detected by the basic NMR techniques currently in use, such as C4→C6 branching or monohydroxylation on the B ring. The latter is unlikely to make a significant contribution to structures of CT for temperate shrub and forest species (Hernes and Hedges, 2004), but the contribution of branching units (Newman et al., 1987) should be further investigated. To further elucidate the purified tannin structures other techniques could be used; e.g., THM/MS (Nierop et al., 2005), RP- and NP-HPLC/MS (Kanerva et al., 2006), or matrix-assisted laser deionication-time of flight mass spectrometry (MALDI-TOF/MS) (Li et al., 2010). Additional development of efficient purification, fractionation, or synthetic routes to more homogeneous preparations would be helpful. On the other hand, the rather disperse and heterogeneous tannins that have been widely reported are representative of what plants produce, and therefore are appropriate for ecological studies.

The ecological impact of these heterogeneous tannins can be assessed by monitoring biological activity either in the field, in microcosms, or in laboratory incubations. This study used a laboratory incubation of forest floor humus with six selected CT. After 22 days, there was no significant effect of PC hydroxylation pattern on CO_2 respiration, therefore, our hypothesis that structures with a high proportion of PC would decrease overall C mineralization was not supported. However, the study revealed a negative effect of *cis* stereochemistry on cumulative respiration. The large negative influence of blueberry tannins on C respiration may be due to its high proportion of both *cis* stereochemistry and PC substitution patterns. The results also are generally in keeping with other studies of tannin addition to humus where microbial respiration may be stimulated in the short term but is usually suppressed after 3–4 weeks (Kanerva et al., 2006; Nierop et al., 2006a,b; Nierop and Verstraten, 2006). In contrast, addition of tannins to mineral soil is reported to cause an increase or no change in respiration (Kraus et al., 2004; Madritch et al., 2007; Talbot and Finzi, 2008).

Addition of blueberry CT (94% *cis* and 94% PC) to forest humus resulted in the largest production of ammonium and nitrate in the incubation. While *cis* stereochemistry was positively correlated to net ammonium N and net nitrate N concentration, neither proportions of PC nor chain length were related to N mineralization. In general, we observed little change in N mineralization with the addition of purified tannins to humus (Table 3). Our third hypothesis, that N mineralization would be suppressed with increasing proportions of PD units, was not supported. Other studies have shown a decrease in ammonium N with the addition of tannins to humus (Bradley et al., 2000; Nierop et al., 2006a). Microbial community function is negatively impacted by the addition of tannins (Joannisse et al., 2007; Adamczyk et al., 2009), and Bradley et al. (2000) noted a decrease in microbial biomass when tannins were added to humus. Inhibited or diminished microbial communities may exhibit lower organic matter decomposition and decreased N mineralization, thus leading to the idea that tannins negatively impact nutrient cycling. While not conclusive in terms of N mineralization, our study suggests that tannin structure, particularly *cis* orientation, is important in nutrient cycling.

Analysis of tannins from forest floor is challenging due to lignin interference (Preston et al., 1997; Nierop and Filley, 2008). The few other studies to follow recovery of added condensed tannins to organic horizons were similar to ours, with rapid initial decline in extractable tannins and loss of most or all extractable tannins by 30 days (Nierop et al., 2006a, b; Kraal et al., 2009). We found that there is a negative influence of B-ring hydroxylation on extractable CT, consistent with suggestions that PD substitution may be chemically reactive with organic matter, readily forming quinones and reacting with basic amino acids (Hernes et al., 2001; Hernes and Hedges, 2004). In contrast, PC tannins may be more slowly oxidized and thus may remain extractable and detectable by PA assay. Recovery of the two high-PC tannins, blueberry and black spruce, was high compared to the rapidly declining balsam fir and sheep laurel tannins. The rapid initial loss of sheep laurel tannins may be due to short chain length and *p*-coumaric acid content, which could make it more susceptible to microbial utilization (Kanerva et al., 2006; Nierop et al., 2006a). Reports of high CT concentrations in forest floors of some black spruce stands in Canada (Lorenz et al., 2000; Preston et al., 2006) are consistent with the lower propensity of high-PC tannins to react with organic N. While forest floor tannin concentrations are affected by other factors, such as drainage and rooting, Kanerva et al. (2008) found higher forest floor CT under Norway spruce (high PC tannins) than under Scots pine (high PD tannins).

Apart from enhanced respiration of low-molecular weight fractions (phenolic monomers and tannin dimers) compared to high molecular weight tannins, specific effects of CT structure on soil processes have been difficult to demonstrate. We found that high PC tannins were more extractable than PD tannins, consistent with the greater chemical reactivity of the tri-hydroxylated B ring of PD structures (Hernes et al., 2001; Hernes and Hedges, 2004). Tannins rich in *cis* oriented subunits negatively correlated with respiration but positively related to net N mineralization. Prediction of the effect of CT structure on ecological processes was not achieved, but the results confirm that CT are a heterogeneous group that interact in different ways with ecological processes. Of interest are the long chain,

high PC (%) and high *cis* (%) structures, which seem to have major influences on C and N cycling. Further work to characterize tannin structures and properties may help to elucidate and predict their roles in ecological processes.

Acknowledgements We thank G. D. Joannisse for nitrogen analysis of the lab incubation extracts and three anonymous reviewers for suggestions on an earlier version of the manuscript.

Abstract Volatile monoterpenes such as 1,8-cineole inhibit the growth of *Brassica campestris* seedlings in a dose-dependent manner, and the growth-inhibitory effects are more severe for roots than hypocotyls. The preferential inhibition of root growth may be explained if the compounds inhibit cell proliferation more severely than cell elongation because root growth requires both elongation and proliferation of the constituent cells, whereas hypocotyl growth depends exclusively on elongation of existing cells. In order to examine this possibility, BY-2 suspension-cultured tobacco (*Nicotiana tabacum*) cells were treated with 1,8-cineole, and the inhibitory effects on cell proliferation and on cell elongation were assessed quantitatively. Treatment with 1,8-cineole lowered both the mitotic index and elongation of the cells in a dose-dependent manner, and the half-maximal inhibitory concentration (IC_{50}) for cell elongation was lower than that for cell proliferation. Moreover, 1,8-cineole also inhibited starch synthesis, with IC_{50} lower than that for cell proliferation. Thus, the inhibitory effects of 1,8-cineole were not specific to cell proliferation; rather, 1,8-cineole seemed inhibitory to a variety of physiological activities when it was in direct contact with target cells. Based on these results, possible mechanisms for the mode of action of 1,8-cineole and for its preferential inhibition on root growth are discussed.

Key Words BY-2 · Cell elongation · Cell proliferation · 1,8-cineole · Monoterpene · Protoplast · Starch synthesis

Introduction

Monoterpenes are major components of essential oils, and are wide-spread secondary metabolites in the plant kingdom. Allelopathic interactions due to monoterpenes may be common in nature (e.g., Müller, 1970). They inhibit seed germination and plant growth (Tarayre et al., 1995; Abrahim et al., 2000), causing morphological and physiological changes in plant seedlings (Einhellig and Leather, 1988; Fischer, 1991; Dudai et al., 2000). They inhibit respiration in isolated mitochondria and mitosis, deteriorate membrane integrity of treated cells, interfere with cuticular waxes, enhance transpiration, cause lipid oxidation, and disrupt microtubules (Duke and Oliva, 2004; Dayan et al., 2000; Romagni et al., 2000; Schulz et al., 2007; Zunino and Zygadlo, 2004; Chaimovitsh et al., 2010). Nonetheless, the molecular mechanism (e.g., primary target point) for the allelopathic effects of monoterpenes is still obscure.

Koitabashi et al. (1997) and Nishida et al. (2005) examined the effects of five monoterpenes produced by *S. leucophylla* (camphor, 1,8-cineole, α-pinene, β-pinene, and camphene) on germination and seedling growth of a test plant, *Brassica campestris*. The monoterpenes inhibited growth of *B. campestris* seedlings in a dose-dependent manner, and their inhibitory effects appeared to affect root

growth more severely than hypocotyl growth. The monoterpenes did not alter the sizes of matured cells in roots but effectively inhibited DNA synthesis and cell proliferation in the root apical meristem. These results suggested that monoterpenes preferentially inhibited some physiological processes involved in cell proliferation. Therefore, the observed preferential inhibition of root growth relative to hypocotyl growth might be explained by the preferential inhibition of cell proliferation, because root growth requires both cell proliferation and cell elongation whereas hypocotyl growth only requires elongation of existing cells (Obroucheva, 1999). Thus, the different sensitivities of hypocotyls and roots to monoterpenes could give us a clue towards understanding their mode of action.

In the present study, we examined the effects of a monoterpene, 1,8-cineole, on proliferation and elongation of plant cells by using BY-2 suspension-cultured tobacco (*Nicotiana tabacum*) cells as receiver cells. 1,8-Cineole was chosen because it is easy to handle (it is liquid at room temperature) and has strong inhibitory effects (Nishida et al., 2005). Tobacco BY-2 cells were chosen for the following reasons: (i) In liquid suspension culture, BY-2 cells form small cell clusters composed of several (2–16) cylindrical cells connected in tandem (Sakai et al., 2004). Since most of the surface area of individual cells is exposed directly to culture media, cells are expected to exhibit clear, synchronous, and homogeneous responses to any compound applied to the culture medium; (ii) BY-2 cells can exhibit either a high proliferation rate or drastic elongation, depending on culture conditions. Under conventional culture conditions, BY-2 cells rapidly proliferate and multiply up to 100-fold within a week (Nagata et al., 1992). In contrast, when cultured in an auxin-depleted, cytokinin-containing medium, they elongate drastically and accumulate starch without proliferation (Sakai et al., 1996). Thus, BY-2 cells should provide us with a suitable system for examining the effects of monoterpene on cell proliferation and cell elongation; (iii) A protoplast culture system, in which proliferation and elongation are induced separately depending on culture conditions (Hasezawa and Syono, 1983), is established. Because protoplasts are suspended individually without any protection from a cell wall or neighboring cells (at least initially, i.e., before regeneration of cell wall), a protoplast culture system may provide us with a more sensitive way to examine the effects of monoterpene.

We first examined the effects of 1,8-cineole on growth of tobacco seedlings to check whether the phenomena observed for *B. campestris* were also true for tobacco. Then, appropriate experimental conditions were determined by using the protoplast culture system. Finally, the effects of 1,8-cineole on cell proliferation and cell elongation were assessed quantitatively with BY-2 cell cultures. We also assessed the effects of 1,8-cineole on starch synthesis, as an example of a physiological activity other than cell proliferation and cell elongation. Based on the results, possible mechanisms for the differential inhibition of root growth and hypocotyl growth by monoterpenes as well as the mode of action of monoterpenes at cellular level are discussed.

Methods and Materials

Plant Materials, Chemicals, and Treatment of Seedlings with 1,8-Cineole Seeds of *N. tabacum* (cv. Bright Yellow-2, from which a BY-2 cell line was established) were sown on two layers of filter paper (Whatman No. 3, diam 55 mm) soaked with 3 ml of water in transparent, airtight containers (5.5 cm diam×9.6 cm height, 230 ml volume, 50 seeds per container). 1,8-Cineole, purchased from Aldrich (Milwaukee, WI, USA), was spotted onto a piece of filter paper (3×6 cm) hanging from the cap of the container and allowed to volatilize into the airspace within the container. The doses of 1,8-cineole were expressed as the theoretical concentrations in the airspace within the container, which were calculated assuming that the spotted compounds volatilize completely without adsorption or leakage. For example, spotting of 17 μl of 1,8-cineole solution (f.w.=154, d=0.921) to filter paper hanging within the 230-ml container gives final concentration of 440 μM; zero μM (control) indicates no application of 1,8-cineole liquid. (Note that actual concentrations in the airspace may be lower than those theoretical, calculated values as a result of absorption. See discussion.) The seeds/seedlings in the containers were incubated for several days at 23°C under a 14: 10 h, L:D photoperiod.

Measurement of Seedling and Cell Sizes The lengths of hypocotyls and primary roots were measured with digital calipers. Only individuals that successfully germinated were used for measurements. For determination of cell size, seedlings were fixed, washed, and cleared according to the methods of Yadegari et al. (1994). The cortex cells at the root-hair-forming region (i.e., differentiation/elongation zone in the upper part of the root) of the primary roots were observed with a microscope (BX-60, Olympus, Tokyo, Japan) equipped with Nomarski optics and their sizes measured.

Determination of Mitotic Index in the Root Apical Meristem - Root tips (5 mm long) were excised, fixed with FAA solution (formalin : acetic acid : 50% ethanol=1 : 1 : 18, v/v/v) for 12 h, rinsed with 0.1 M sodium phosphate buffer (pH 7.0), and dialyzed against 0.1 M sodium phosphate buffer containing increasing concentrations of

sucrose (10, 20, and 30%, successively). The samples were immersed finally in O.C.T. compound (Sakura Finetech, Torrance, CA, USA), quickly frozen with liquid nitrogen, and the frozen, serial sections (7 μm thick) were prepared using a cryostat (OTE Cryostat, Bright, UK) at -26°C. Sections were mounted on gelatin-coated slides and air-dried, as described previously (Tamotsu et al., 1994). They were stained with 1 μg/ml 4',6-diamidino-2-phenylindole (DAPI) without removal of the O.C.T. compound, observed with a fluorescence microscope (BX-60, Olympus) under UV irradiation, and the percentages of the cells in a mitotic phase were counted as described in Nishida et al. (2005).

Protoplast Culture and Treatment with 1,8-Cineole Protoplasts were prepared and cultured according to the method of Hasezawa and Syono (1983) with slight modifications. BY-2 cells usually were propagated by inoculating 95 ml of fresh medium with 1.5–2 ml of suspension of stationary-phase cells at weekly intervals and incubating the culture at 26°C in the dark on a gyratory shaker (130 rpm), as described by Yasuda et al. (1988). Four-day-old BY-2 cells were converted to protoplasts by treating them with enzyme solution (0.4 M mannitol, 1% cellulase YC, 0.1% pectolyase Y23, pH 5.5) for 90 min at 30°C. The protoplasts were collected by centrifugation (260*g*, 2 min), suspended in 0.4 M mannitol solution, centrifuged again, and suspended in either 2,4-D medium (LS medium containing 3% sucrose, 0.4 M mannitol, and 0.2 mg/l 2,4-D) or BA-NAA medium (LS medium containing 3% sucrose, 0.4 M mannitol, 1.0 mg/l BA, and 0.1 mg/l NAA) at a density of $0.5–1\times10^5$ cells/ml. The protoplast suspension was dispensed into 50-ml Erlenmeyer flasks (4.6 ml per flask), and cultured at 26°C in the dark without shaking. For treatment with 1,8-cineole, the protoplast-containing flasks were settled, one-by-one, in transparent, airtight containers (5.5 cm diam×9.6 cm height, 230 ml volume). 1,8-Cineole was applied either by spotting appropriate volumes of 1,8-cineole liquid onto a piece of filter paper hanging from the cap of the container (volatilization method) or by adding it directly into the culture medium in the flask (direct-addition method). In both cases, the caps of the containers were closed immediately after the application of 1,8-cineole, and the compound was allowed to volatilize into the airspace within the container. The final concentrations of 1,8-cineole in the airspace were calculated assuming that the compound volatilized completely without adsorption or leakage, as described above.

Cell Culture and Treatment with 1,8-Cineole Seven-day-old (stationary-phase) BY-2 cells were transferred to either fresh D-medium (modified LS medium containing 0.2 mg/l 2,4-D) or fresh B-medium (modified LS medium containing 1 mg/l BA) at a 1:20 dilution, and dispensed into 50-ml Erlenmeyer flasks (9.2 ml per flask). For treatment with 1,8-cineole, the cell suspension-containing flasks were settled, one-by-one, in transparent, airtight containers described above, and were fixed to prepare for shaking-culture. 1,8-Cineole was applied via the direct-addition method only. After the addition of 1,8-cineole, the caps of the containers were closed immediately, and the cells were cultured for 2 days at 26°C in the dark on a gyratory shaker (130 rpm).

Measurements of Mitotic Index, Cell Length, and Starch Content of the Cells/Protoplasts For measurements of mitotic index, protoplasts and cells were fixed with 1% formaldehyde, stained with 1 μg/ml DAPI, and examined with a fluorescence microscope (BX-60) under UV-irradiation. For measurements of the cell (or protoplast) length, samples (with or without fixation with 1% formaldehyde) were observed with a microscope, photographed, and the length measured. The starch content of BY-2 cells was measured according to the method of Sakai et al. (1996). In short, BY-2 cells present in 1 ml of cell suspension were collected by centrifugation, converted to protoplasts by incubation for 1 h at 30°C in enzyme solution (0.4 M mannitol, 1% cellulase YC, 0.1% pectolyase Y23, pH 5.5), and solubilized by adding 1/10 vols of 10% SDS and incubation for additional 30 min at 37°C. Insoluble materials, including starch granules, were collected by centrifugation, re-suspended in 1 ml of hot 80% ethanol, and collected again by centrifugation. The starch was solubilized in hot water, extracted with perchloric acid, and quantified by the phenol-sulfuric acid method (Dubois et al., 1956) using a dilution series of glucose solution as a standard.

Estimation of Half-maximal Inhibitory Concentrations (IC_{50}) We emploied IC_{50} value as the parameter to represent the sensitivities of the biological activities of interest to 1,8-cineole. The IC_{50} values were simply estimated from semi-log graphs of dose–response curves, without any mathematical model-fitting (Belz et al., 2005).

Results

Effects of 1, 8-Cineole on the Growth of Tobacco Seedlings In the absence of 1,8-cineole, germination of tobacco seeds proceeded rapidly and synchronously under our experimental conditions. Almost 100% germination was achieved 5 days after sowing, and the length of hypocotyls and primary roots reached their maximum values by day 10 (data not shown). Thus, the effects of various concentrations of 1,8-cineole were examined on day 10.

Germination of tobacco seeds (Fig. 1, top) was largely unaffected by 1,8-cineole concentrations of 500 μM or less. The germination rate suddenly dropped to 60% at 1,000 μM, and further dropped to 12% at 2,000 μM. The concentration of 1,8-cineole required to lower the germination rate to 50% of the control value (IC_{50}) was about 1,200 μM. Hypocotyl growth (Fig. 1, middle) was not inhibited with 1,8-cineole concentrations up to 200 μM. 1,8-Cineole stimulated hypocotyl growth slightly in a dose-dependent manner within this low-concentration range (rs=0.94, P<0.05), indicating hormesis (Duke et al., 2006; Calabrese et al., 2009). At higher concentration ranges, 1,8-cineole inhibited hypocotyl growth in a dose-dependent manner. The IC_{50} for hypocotyl growth was about 720 μM. Root growth (Fig. 1, bottom) was not stimulated by any concentrations of 1,8-cineole tested; 1,8-cineole shortened root length even in the low concentration range (≤ 200 μM). The IC_{50} value for root growth was 410 μM, indicating that root growth was more sensitive to 1,8-cineole than was hypocotyl growth.

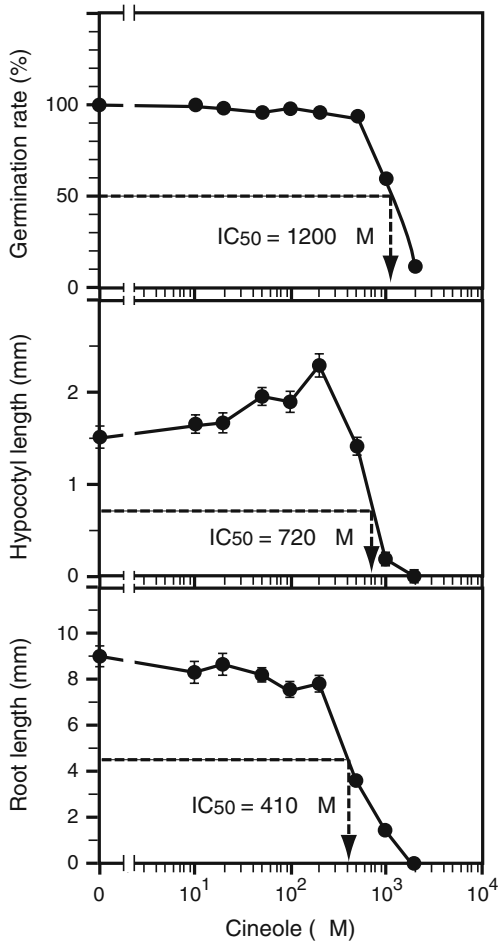

Fig. 1 Effects of various concentrations of 1,8-cineole on *Nicotiana tabacum* seed germination and seedling growth. Germination rate (*top*), hypocotyl length (*middle*), and root length (*bottom*) were measured on day 10. Each data point for germination rate was calculated from the results of all 50 individuals contained in a single container, while each for hypocotyl and root length represents the average value from 30 individuals that successfully germinated. Vertical bars represent standard errors. IC_{50} values calculated from the data are shown in respective graphs

Next, relative contribution of cell elongation and cell proliferation to the root-growth inhibition by 1,8-cineole was examined (Fig. 2). The concentration of 1,8-cineole was set at 440 μM, where hypocotyl length was almost the same as the control value, while root length was reduced by approximately 50% (Fig. 2A). Treatment with 440-μM 1,8-cineole did not reduce the size of cells in the elongation/differentiation zone of tobacco roots, but it lowered the mitotic index in the root apical meristem to less than half the control value (Fig. 2B), indicating that cell proliferation in the root apical meristem was selectively inhibited, while cell expansion in the upper region of the root was largely unaffected with this concentration.

Thus, the results obtained for tobacco seedlings (i.e., preferential inhibition of root growth over hypocotyl growth, relative insensitivity of cell elongation in the upper region of the root as compared to cell proliferation in the root apical meristem) were essentially the same as those obtained previously for *B. campestris* seedlings (Koitabashi et al., 1997; Nishida et al., 2005).

Effects of 1,8-Cineole on the Proliferation and Elongation of Protoplasts Prepared from BY-2 Cultured Tobacco Cells We examined the effects of 1,8-cineole on cell proliferation and cell elongation by using protoplasts prepared from BY-2 cultured tobacco cells. When cultured in 2,4-D medium, BY-2 protoplasts proliferated actively (with mitotic indices of about 3% from day 2 to day 6), but their sizes did not increase significantly during the culture period (Fig. 3A). In contrast, when cultured in BA-NAA medium, they ceased proliferation and elongated drastically by day 7 (Fig. 3B). Thus, BY-2 protoplasts cultured in 2,4-D medium and those cultured in BA-NAA medium were used to examine the effects of 1,8-cineole on cell proliferation and on cell elongation, respectively. In the experiments with protoplast cultures, 1,8-cineole was applied using the two different modes, i.e., the volatilization method and the direct-addition method (Fig. 4A).

Figure 4B shows the mitotic indices of BY-2 protoplasts cultured in the presence of various concentrations of 1,8-cineole in 2,4-D medium for 2 days. In either of the two application modes, relatively high concentrations of 1,8-cineole were necessary to lower the mitotic index. With the protoplast culture system, IC_{50} values of 1,8-cineole for proliferation were estimated to be about 2,000 μM for the volatilization method and 100 μM for the direct-addition method. Figure 4C shows the length of BY-2 cells cultured in the presence of various concentrations of 1,8-cineole in BA-NAA medium for 7 days. Normally, the cell wall should have regenerated by day 7. In either of the two

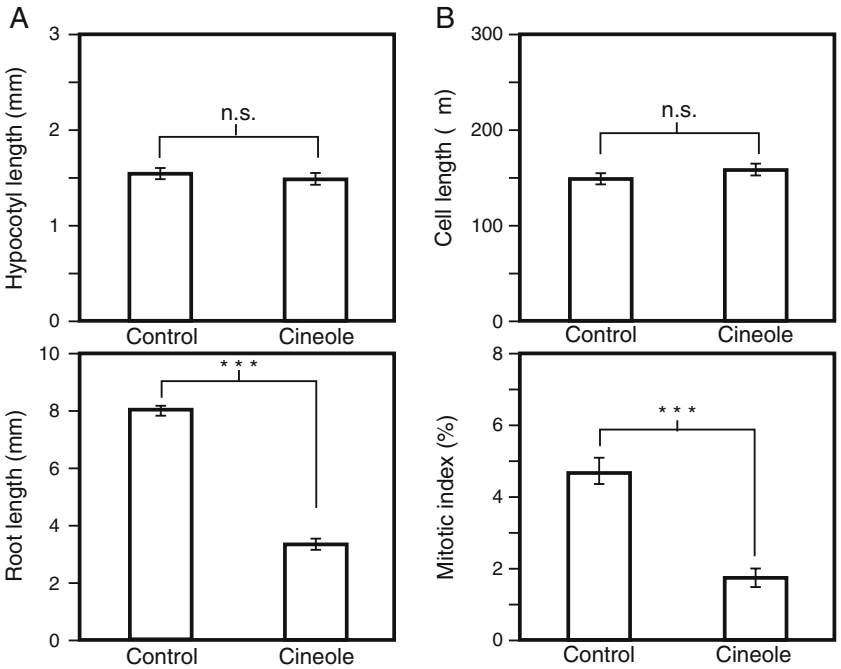

Fig. 2 Effects of 1,8-cineole on growth of *Nicotiana tabacum* seedlings. **A** Effects on hypocotyl length and root length. *N. tabacum* seedlings were grown in the absence (*control*) or presence (*cineole*) of 440 μM of 1,8-cineole for 10 days, and the hypocotyl length (*top*) and root length (*bottom*) were measured. Each datum represents the average of 20 individuals that successfully germinated. Vertical bars represent standard errors. **B** Effects on the cell elongation and cell proliferation in the affected roots. *N. tabacum* seedlings were grown in the absence (*control*) or presence (*cineole*) of 440 μM 1,8-cineole for 10 days, and the sizes of matured cells (*top*) and mitotic index in the root apical meristem (*bottom*) were measured. For cell length (*top*), each datum represents average value of 60 cells derived from more than 4 individuals. Vertical bars represent standard errors. For mitotic index, each datum represents the average value from 8 (*control*) or 7 (*cineole*) individuals. Vertical bars represent standard errors. n.s.; not significant ($P>0.05$), ***; $P<0.001$, Student's *t*-test

application modes, 1,8-cineole lowered cell length in a dose-dependent manner and completely inhibited cell elongation at the highest concentration tested (1,000 μM). IC_{50} values for cell elongation were about 140 μM for the volatilization method and 30 μM for the direct-addition method. These results demonstrate that (i) the direct addition method was more effective than the volatilization method, and (ii) in a BY-2 protoplast culture system, cell elongation was more sensitive to 1,8-cineole than cell proliferation.

Effects of 1,8-Cineole on Proliferation, Elongation, and Starch Accumulation of BY-2 Cells We examined the effects of 1,8-cineole on BY-2 cells that retained intact cell walls. BY-2 cells proliferate actively without significant increase of cell volume when cultured in D-medium that contains 0.2 mg/l 2,4-D, whereas they increase in cell volume (mostly due to cell elongation) and accumulate a large amount of starch without proliferation when cultured in B-medium that contains 1 mg/l BA (Sakai et al., 1996). Accordingly, BY-2 cells cultured in D-medium were used to examine the effects of 1,8-cineole on cell proliferation, while those cultured in B-medium were used to examine the effects on cell elongation and starch accumulation. As the differentiation of cells in the two culture media becomes clear 2 days after transfer (Sakai et al., 1996), measurements were done on d 2. Based on the results of the experiments with the protoplast culture system, only the direct-addition method was used to apply 1,8-cineole.

1,8-Cineole lowered the mitotic index in a dose-dependent manner, and the IC_{50} value for proliferation was about 140 μM (Fig. 5A). 1,8-Cineole also decreased cell length in a dose-dependent manner (Fig. 5B), and at high concentrations (120 or 240 μM), the cell size did not increase as compared to the value at the start of the culture (105 μm). The IC_{50} value for cell elongation was about 30 μM, and was lower than the IC_{50} value for cell proliferation. 1,8-Cineole also lowered starch content in a dose-dependent manner. IC_{50} value for starch accumulation was about 80 μM and was also lower than the IC_{50} value for cell proliferation. These results demonstrate that the inhibition by 1,8-cineole is not specific to cell proliferation.

Discussion

We found here that the effects of 1,8-cineole on *N. tabacum* seedlings were essentially the same as those on *B. campestris* seedlings; 1,8-Cineole preferentially inhibited

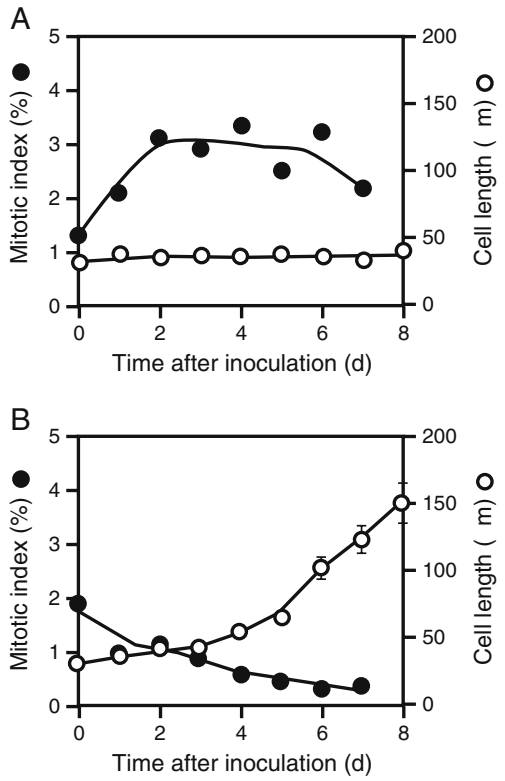

Fig. 3 Behavior of BY-2 protoplasts/cells during culture. Four-day-old BY-2 cells were converted to protoplasts and cultured in either 2,4-D medium **A** or BA-NAA medium **B**, and the changes in the mitotic index (●) and cell length (○) were followed during the culture. Each data point for mitotic index was determined by counting more than 1,000 cells/protoplasts. Each point for the length of cells/protoplasts represents the average value from 30 (for 2,4-D medium) or 60 (for BA-NAA medium) cells/protoplasts. Vertical bars represent standard errors

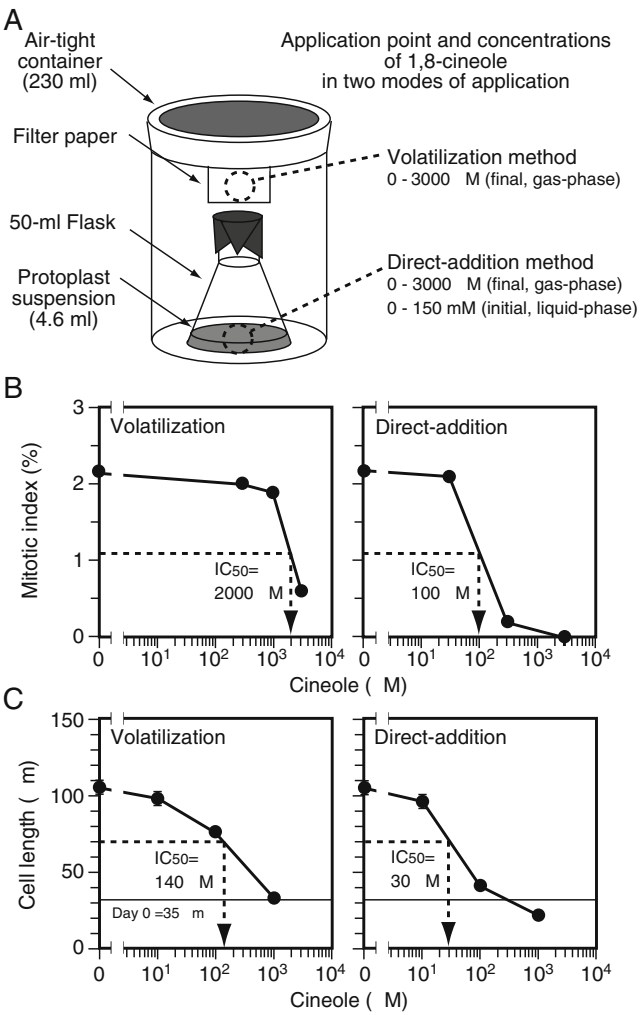

Fig. 4 Effects of 1,8-cineole and its application methods on the proliferation and elongation of BY-2 protoplasts/cells. **A** Schematic representation of the experimental system. 1,8-Cineole was applied to either filter paper hanging from the cap of the air-tight container (volatilization method) or the culture medium in the flask (direct-addition method). The calculated final concentrations of 1,8-cineole in the airspace (gas-phase) were 0 to 3,000 μM. In direct-addition method, the initial concentrations of 1,8-cineole in the culture medium (liquid-phase) were 50 times higher than the calculated final concentrations in the airspace (gas-phase). (**B**) Effects of 1,8-cineole on the proliferation of BY-2 protoplasts grown in 2,4-D medium. Various doses of 1,8-cineole were applied through either the volatilization method (*left*) or the direct-addition method (*right*), and the mitotic index was examined on d 2. Each data point was determined by counting more than 1,000 cells/protoplasts. **C** Effects of 1,8-cineole on the elongation of BY-2 protoplasts grown in BA-NAA medium. Various doses of 1,8-cineole were applied through either the volatilization method (*left*) or the direct-addition method (*right*), and cell length was examined on day 0 and day 7. Each point represents the average value from 200–600 cells/protoplasts. Vertical bars represent standard errors. In **B** and **C**, IC_{50} values estimated from the data are shown in the respective graphs

root growth over hypocotyl growth (Fig. 1). In the affected roots, cell size in the elongation zone (upper region of the root) was largely unaffected, whereas cell proliferation in the root apical region was severely inhibited (Fig. 2). These results indicate that the mode of action of growth inhibition by 1,8-cineole is common within the two plant species. Thus, we consider that tobacco, especially cultured tobacco cells, can be used as experimental material to examine the mode of action of 1,8-cineole at the cellular level.

We compared the effectiveness of two modes of application of 1,8-cineole, i.e., the volatilization method and the direct-addition method, by using a protoplast culture system (Fig. 4), and we found that the direct-addition method was more effective. This result is quite reasonable when the predicted behavior of the applied 1,8-cineole is considered. In the volatilization method, applied 1,8-cineole first volatilizes into air and then dissolves into a liquid phase. Thus, the concentrations of 1,8-cineole that the cells experience should gradually increase and finally reach the highest values determined by equilibrium between the liquid and gas phase. In the direct-addition method, the cells should experience the highest concentrations of 1,8-cineole immediately after application of the compound. Then, concentrations should decline to the lower values determined by the equilibrium. Thus, in the latter method,

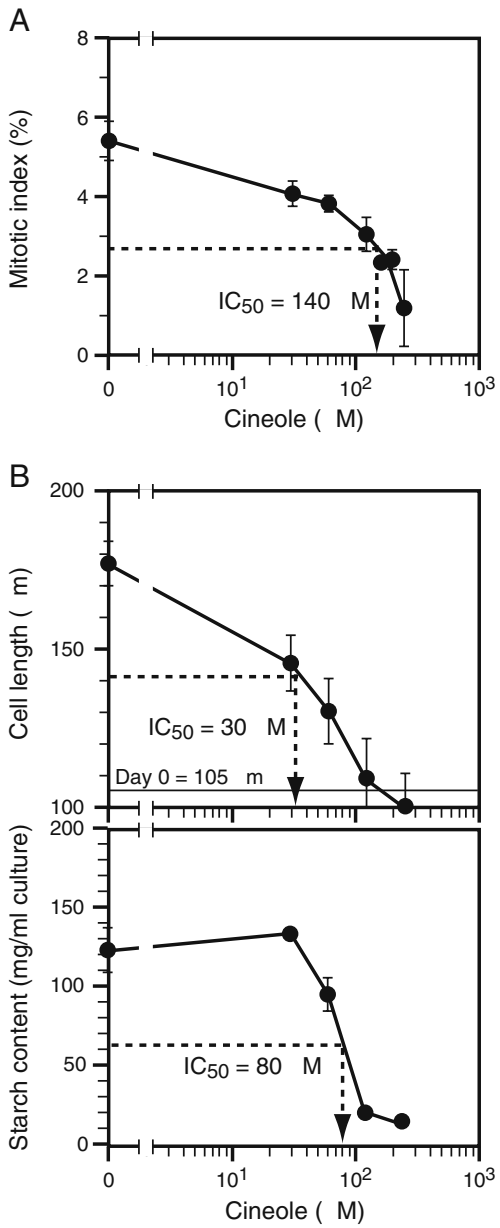

Fig. 5 Effects of 1,8-cineole on the proliferation and elongation of BY-2 cells. **A** The effects of a range of doses of 1,8-cineole on the proliferation of BY-2 cells cultured in D-medium are shown. The mitotic index was examined on d 2. The average values from three independent experiments are shown. Vertical bars represent standard errors. **B** The effects of a range of doses of 1,8-cineole on elongation (*top*) and starch accumulation (*bottom*) in BY-2 cells cultured in B-medium. Cell length and starch content were examined on d 2. The average values from three independent experiments are shown. Vertical bars represent standard errors. In **A** and **B**, 1,8-cineole was applied through the direct-addition method only. The estimated final concentrations of 1,8-cineole in the airspace (gas phase) were 0 to 240 μM, while the initial concentrations in the culture medium (liquid phase) immediately after application were 25 times higher. IC_{50} values estimated from the data are shown in respective graphs

the actual concentration that the cells experience should be higher and the time at which the cells experience the highest concentration should be earlier.

Because protoplasts lose their cell wall and are completely separated from neighboring cells, we expected that they might exhibit higher sensitivity to externally added compounds as compared to cultured cells that have intact cell walls and neighboring cells. For this reason, initially we examined the effects of 1,8-cineole on BY-2 cells using protoplasts (Figs. 3 and 4). However, IC_{50} values obtained for protoplasts and intact cells were essentially the same (compare Figs. 4 and 5), indicating that cell wall and neighboring cells did not function as a barrier to the permeation of 1,8-cineole into the cells.

In contrast to our initial expectation, 1,8-cineole inhibited cell elongation more efficiently than cell proliferation; the IC_{50} value for cell proliferation was always higher than that for cell elongation, irrespective of the application methods (Fig. 4) or the condition (i.e., presence or absence of cell wall) of receiver cells (Figs. 4 and 5). Moreover, 1,8-cineole also inhibited starch accumulation with an IC_{50} value lower than that for cell proliferation (Fig. 5). These results demonstrated clearly that the inhibitory effect of 1,8-cineole was not specific to cell proliferation; rather, 1,8-cineole appeared to affect a wide spectrum of cellular activities in an almost non-specific manner when target cells were efficiently exposed to the compound.

Despite numerous reports on inhibitory effects of monoterpenes, their mechanisms of action remain obscure. Recently, Chaimovitsh et al. (2010) reported that microtubules are an intracellular target of a monoterpene, citral. However, they also reported that the effects of citral and microtubule inhibitor oryzalin on plant seedlings are different from each other, suggesting that there should be additional target(s) of the monoterpene. Our observation that starch accumulation was highly sensitive to 1,8-cineole (Fig. 5) also suggests the presence of additional target(s), as starch accumulation itself does not seem so tightly associated with microtubule function. Then, what is the plausible target of monoterpenes?

A reduction in respiratory oxygen consumption resulting from monoterpene treatment has been reported in a number of studies (e.g., Müller et al., 1968; Peñuelas et al., 1996). Moreover, monoterpenes affect the respiratory activity of isolated mitochondria (Müller et al., 1969; Abrahim et al., 2000, 2003a) via uncoupling of oxidative phosphorylation and inhibition of electron transfer (Abrahim et al., 2003b). The lipophilic property of monoterpenes (Weidenhamer et al., 1993), as well as lipid oxidation and deterioration of membrane integrity in plant cells exposed to monoterpenes (Lorber and Müller, 1976; Fischer, 1986; Zunino and Zygadlo, 2004) suggests that biological membranes,

including mitochondrial membranes, are the primary target of monoterpenes. Among all the possible effects on biological membranes, the deleterious effects on mitochondrial membranes should cause inhibition of mitochondrial energy metabolism and result in disturbances in a wide range of physiological and biochemical processes within the cell.

Our results rule out the possibility that preferential inhibition by 1,8-cineole of root growth is explained by preferential inhibition of cell proliferation; 1,8-cineole inhibited multiple distinct biological processes (cell proliferation, cell elongation, and starch synthesis) in cultured cells, and the sensitivity of cell proliferation to 1,8-cineole was, contrary to our initial expectation, relatively low (Figs. 4 and 5). Then, in plant seedlings, why is root growth more sensitive than hypocotyl growth to 1,8-cineole?

One possibility is that the actual concentration of 1,8-cineole may be higher around roots (liquid/solid phase) than around hypocotyls (gas-phase). In nature, soil colloids adsorb volatile monoterpenes in the atomosphere and exhibit toxicity for several months (Müller and Moral, 1966). Under our experimental conditions for the seedling assay, monoterpenes within an air-tight container might absorb to the wet filter paper wad used as supporting substance, resulting in higher concentrations of the compound around the roots as compared to the concentrations around the aerial tissues. (This also suggests that the actual concentrations of 1,8-cineole in the gas-phase should be lower than the calculated values.) However, root growth was more sensitive to 1,8-cineole than hypocotyl growth even when the seedlings were grown under conditions in which both hypocotyls and roots were in equal contact with the filter paper, and therefore, the concentration of 1,8-cineole surrounding the two organs should have been equal (Nishida et al., 2005). Thus, differences in the actual concentrations around roots and hypocotyls do not seem to play a critical role under our experimental conditions.

Another possible explanation is that root surfaces may have higher permeability to 1,8-cineole as compared to hypocotyl surfaces, resulting in higher doses of the compound within root tissues as compared to those within hypocotyl tissues. The surface of aerial parts of the plant body is covered with a well-developed cuticle layer, while that of roots is not (Bessire et al., 2007). In addition, a permeability assay, based on staining with toluidine blue dye (Bessire et al., 2007), demonstrated differential permeability (and thus differential development of a cuticle layer) within a root; in various plant species, the root tip region that includes the root apical meristem exhibited higher permeability than that of the upper region of the same root, which corresponded to elongation/differentiation zone (unpublished data). Thus, differential permeability due to differential development of a cuticle layer might be involved in not only preferential inhibition of root growth over hypocotyl growth but also preferential inhibition of cell proliferation in the root apical region over cell elongation in the upper region of the same root. The relationship between development of the surface barriers, such as cuticle layer, and sensitivity to monoterpenes is now under further investigation.

Abstract The uropygial secretions of some bird species contain volatile and semivolatile compounds that are hypothesized to serve as chemical signals. The abundance of secretion components varies with age and season, although these effects have not been investigated in many species. We used solid-phase microextraction headspace sampling and solvent extraction coupled with gas chromatography–mass spectrometry to detect and identify volatile and semivolatile chemical compounds in uropygial secretions of gray catbirds (*Dumetella carolinensis*). We identified linear and branched saturated carboxylic acids from acetic (C2) through hexacosanoic (C26); linear alcohols from decanol (C10) through docosanol (C22); one aromatic aldehyde; one monounsaturated carboxylic acid; two methyl ketones; and a C28 ester. We tested for the effect of age on signal strength and found that juvenile birds produced greater amounts of volatile C4 through C7 acids and semivolatile C20 through C26 acids, although the variation among individuals was large. Adult birds displayed small concentrations and minimal individual variation among volatile compounds, but produced significantly higher levels of long-chain linear alcohols than juvenile birds. We tested for the effects of season/location by sampling adult catbirds at their Ohio breeding grounds and at their Florida wintering grounds and found that the heaviest carboxylic acids are significantly more abundant in secretions from birds sampled during winter at the Florida site, whereas methyl ketones are more abundant in birds sampled during summer on the Ohio breeding grounds. We observed no effect of sex on semivolatile compounds, but we found a significant effect of sex on levels of carboxylic acids (C4 through C7) for juvenile birds only.

Key Words Gray catbird · *Dumetella carolinensis* · Solid-phase microextraction · SPME · Gas chromatography–mass spectrometry · GC-MS · Principal component analysis · PCA · Uropygial gland · Preen gland

Introduction

The uropygial, or preen, gland of birds produces a variety of chemical compounds with diverse functions. Among these functions are the water-proofing properties of the secretions' waxy components. In mallards, for example, blocking access to the uropygial gland for 3 months resulted in significant loss in plumage quality and increased water retention (Giraudeau et al., 2010). Volatile compounds, capable of being sensed at a distance, may serve as intraspecific chemical signals. For example, individual odorant signatures have been identified in petrels (Bonadonna et al., 2007), red junglefowl (Karlsson et al., 2010), and dark-eyed juncos (Whittaker et al., 2010). These individual signatures have been associated with mate choice and recognition (Mardon et al., 2010; Whittaker et al., 2010) and with parenting behaviors (Whittaker et al., 2009). Volatile compounds also may serve in interspecific communication or defense. For example, the positive correlation between uropygial gland size and mite abundance in passerines suggests that the gland's secretions are subject to selective pressures from mites (Galván et al., 2008). Antimicrobial compounds found in the uropygial secretions of hoopoes are produced by symbiotic bacteria in the gland (Martín-Vivaldi et al., 2010), suggesting that the origin of

functional compounds in the uropygial secretions of other avian species may be more complex than previously appreciated.

Among the uropygial secretion profiles that have been characterized, several exhibit variation with season. In a study examining 19 sandpiper species, Reneerkens et al. (2002) found that all species switched from lower molecular weight monoesters to higher molecular weight diesters during the period of courtship and incubation. An olfactory-searching dog, used as a proxy for a nest-seeking predator, had greater difficulty sensing the heavier diester compounds than the more volatile monoesters, supporting the hypothesis that the switch to diester waxes enables olfactory crypsis at the nest (Reneerkens et al., 2005). That the diester uropygial secretion is produced by the parent(s) engaged in incubation and not by the non-incubating parent further supports the crypsis hypothesis (Reneerkens et al., 2007). Seasonal variation in volatile compounds has been demonstrated in the dark-eyed junco (Soini et al., 2007). Most notably, linear alcohols were consistently found at higher levels in captive birds maintained under long photoperiod to simulate the breeding season compared with birds reared under short photoperiod, simulating nonbreeding conditions. Such trends also were found among males in some ketones and in linear and branched carboxylic acids, although individual variation in these compounds was large. Whittaker et al. (2010) further investigated seasonally variable compounds and identified a "female-like" volatile profile containing mostly even-numbered carboxylic acids and a "male-like" profile rich in methyl ketones. They also found that secretion compounds provided information about individual identity and could distinguish between two genetically isolated populations of juncos.

Secretion profiles also vary with age. Examination of diol esters from chickens revealed significant shifts in chain length and diastereomer composition as birds matured from 3 to 13 months, after which only minor composition shifts were observed (Kolattukudy and Sawaya, 1974). Sandilands et al. (2004) sampled uropygial secretions from chickens starting at 10 weeks of age and quantified fatty acids derived from ester hydrolysis. They found a significant effect of age on the saturated fatty acids that constituted the majority of the total lipid content. Because secretion profile changed at the onset of laying, they speculated that the shift was a result of changes in sex hormone levels associated with sexual maturity. The significance of hormonal state also was demonstrated in studies of mallards, in which injection of estradiol into male and female birds in the nonmating season induced a shift from short-chain monoesters to long-chain diester compounds (Bohnet et al., 1991).

In a previous study (Whelan et al., 2010), we sampled uropygial secretions from captive gray catbirds and analyzed the chemical composition of the secretions using solid-phase microextraction (SPME) and gas-chromatography mass-spectrometry (GC-MS). We found that linear and branched carboxylic acids were the predominant volatile compounds in the secretions, and that their signal strengths varied significantly with exogenous testosterone and with photoperiod but that sex had no significant effect. As a result of the experimental design, that study focused exclusively on the most volatile components of the secretion samples, those containing up to six carbon atoms, whereas in other bird species uropygial secretions containing linear alcohols and carboxylic acids with much longer aliphatic chains have been identified (Sandilands et al., 2004; Montalti et al., 2005; Bonadonna et al., 2007; Soini et al., 2007; Karlsson et al., 2010; Zhang et al., 2010).

In this study we used a combination of analytical methods (SPME/GC-MS and solvent extraction/GC-MS) to obtain a more complete profile of the volatile and semi-volatile chemical components of gray catbird uropygial secretions. We then tested whether the abundance of these compounds varied with phase of life history in free-ranging birds. Specifically, we examined the effect of age by comparing secretions of adult birds to those of juvenile birds, thus testing the hypothesis that if secretions have important functions, juvenile birds may allocate fewer resources to their production given the competing energetic demands of rapid growth. We also examined the effect of breeding by comparing adult birds captured during the breeding season in Ohio to adult birds captured during the non-breeding season in the winter in Florida. In these experiments, we tested the hypothesis that factors associated with season, such as hormone levels or arthropod pest pressure, or with location, such as diet, temperature/humidity, or pest/predator pressure, are reflected in uropygial secretion composition. Finally we compared the composition of secretions produced by males and females to determine if uropygial secretions differ between the two sexes.

Methods and Materials

Chemical Standards The following chemicals were used as GC-MS standards: acetic acid (glacial) (Acros Organics, Geel, Belgium); benzaldehyde (99%), hexanoic acid (99.5 +%), dodecanoic acid (98%), nonadecanol (99%), tetracosanoic acid (99%) (Aldrich Chemical, Milwaukee, WI, USA); butanoic acid (99 +%), 3-methylbutanoic acid (reagent grade), octanoic acid (98 +%), nonanoic acid (97 +%), 2-tridecanone (99%), 2-pentadecanone (99%), eicosanoic acid (99 +%), docosanol (98%), docosanoic acid (99 +%), hexacosanoic acid (95 +%) (Sigma-Aldrich Chemical, St. Louis, MO, USA); pentanoic acid (technical), dodecanol (98 +%), tetradecanoic acid (98 +%), hexadecanol (99%), octadecanol (99%) (Eastman Chemical,

Kingsport, TN, USA); heptanoic acid (99 +%), decanol (99%), undecanol (98%), tridecanol (99%), tetradecanol (98 +%), pentadecanol (99%), heptadecanol (98 +%), eicosanol (97 +%) (Fluka Chemical, Milwaukee, WI, USA); hexadecanoic acid (Fisher Scientific, Pittsburgh, PA, USA); oleic acid (J.T. Baker, Phillipsburg, NJ,USA); octadecanoic acid (Matheson, Coleman, and Bell, Norwood, OH,USA).

Bird Handling We captured gray catbirds in mist nets from May through August 2009 at Killbuck Marsh Wildlife Area (40°41′N, 81°58′W), in Wayne County, Ohio, and in January 2010 at Archbold Biological Station (27°10′N, 81°21′W) in Highlands County, Florida. Upon capture, we collected 0.1 ml blood via brachial venipuncture into 300 μl of cell lysis solution to determine sex via polymerase chain reaction (PCR) based analysis of sex specific CHD genes (Griffiths et al., 1998). Birds also were weighed, measured, examined for ectoparasites, and banded. Age was determined by plumage according to Pyle (1997).

Sample Collection Uropygial secretions were collected in 1-inch lengths of glass capillary tubing (ID=1.5 mm; OD=1.8 mm; Kimble, Vineland, NJ,USA). Samples were collected by placing one end of the tubing over the gland opening and gently massaging the base of the gland until secretion emerged from the papilla and wicked spontaneously into the capillary. Collection tubes were stored in labeled and pre-weighed 1.8-ml chromatography vials that had been baked at 110°C, along with their caps and Teflon/silicon septa, for at least 8 h. Approximately 5 mg of uropygial secretion were collected from each bird sampled in summer (mean ± SD=0.005±0.001 g, N=64); approximately 3 mg of secretion were collected from birds sampled in winter (mean ± SD=0.0027±0.0008 g, N=18). Samples were stored at −80°C until analyzed.

Sample Analysis All samples first were subjected to static headspace solid-phase microextraction (SPME; volatiles analysis) and then to solvent extraction (semivolatiles analysis). In each case, extraction was followed immediately by GC-MS analysis. Between the two analyses, samples were stored at −80°C.

For analysis of volatile compounds, sealed vials containing secretion were placed into a heating block maintained at 44°C (the body temperature of gray catbirds) to equilibrate volatile chemicals in the headspace. A SPME fiber (75 μm with Carboxen-PDMS coating; Supelco, Bellefonte, PA,USA) was exposed to the headspace for 60 min, after which the fiber was retracted and the adsorbed chemicals were analyzed by GC-MS.

For analysis of semivolatile compounds, secretions were dissolved to a final concentration of 20 mg/ml in dichloromethane (DCM; trace grade; Pharmco-AAPER, Brookfield, CT,USA) containing 0.005% (v/v) benzyl alcohol (≥99%; Aldrich Chemical, Milwaukee, WI,USA) as internal standard. Samples were heated at 44°C for 30 min to dissolve, followed by centrifugation for 2 min at 14,000 × g to pellet any insoluble material.

Chromatographic Methods Separation and identification of compounds from uropygial samples used a Trace GC gas chromatograph equipped with a Polaris Q quadrupole ion trap mass analyzer (Thermo Finnigan, Waltham, MA,USA). Thermogreen LB-2 septa from Supelco were used in the injection port.

For volatiles analysis via SPME, fibers were exposed for 10 s in a 225°C injection port to desorb volatiles. Injection was in splitless mode with a 1-ml/min flow of helium. The gas chromatograph contained a polar AT-WAX column (15 m length, 0.25 mm ID, 0.50 μm film thickness; Alltech, Deerfield, IL,USA.). The column was held at 50°C for 1 min, ramped at 15°C/min to 200°C, then held at 200°C for 2 min. Detection was performed with electron ionization (EI) in full-scan, positive ion mode over a mass-to-charge ratio (m/z) range of 33–350. After each analysis, the SPME fiber was cleaned by exposing it in the heated GC injection port for at least 10 min. Prior to incubation of the fiber with any sample or standard, a blank injection was done to confirm that material from previous analyses was not carried over.

For semivolatiles analysis, 1 μl of dissolved secretion was injected manually in splitless mode with a 1-ml/min flow of helium. The gas chromatograph contained a nonpolar DB-5MS column (30 m length, 0.25 mm ID, 0.25 μm film thickness; Alltech, Deerfield, IL,USA.) Column temperature was initially 50°C followed by a ramp at 4°C/min to 90°C and a second ramp at 30°C/min to 280°C. A final ramp at 1°C/min took the column to 320°C, where it was held for 5 min. Detection of semivolatile compounds was performed in both EI and chemical ionization (CI) modes (in separate runs). EI detection was in full-scan, positive ion mode over a mass-to-charge ratio (m/z) range of 50–650. CI mode used a 1.6-ml/min flow rate of methane as the ionization gas and the same m/z range as EI mode.

Compounds were identified tentatively by searching a NIST library and by examining selected ion current chromatograms generated post-analysis in which ions characteristic of different functional groups were selected (m/z=55 for alcohols; m/z=58 for ketones; m/z=60 for carboxylic acids). Identifications were confirmed by analyzing standard compounds under identical extraction and analysis conditions and comparing retention times and fragmentation patterns.

For quantification of volatiles, use of an internal standard was not practical. Integrated peak areas from total ion chromatograms were subjected directly to the statistical analyses used for inter-group comparisons. We only

compared peak areas of the same compound across different samples, and did not compare quantities of different volatile compounds within the same sample.

For quantification of semivolatiles, integrated peak areas were normalized by dividing them by the peak area of the internal standard (benzyl alcohol) from the same chromatographic run. Normalized peak areas were subjected to the statistical analyses used for inter-group comparisons. In effect, the data were normalized twice, first by preparing secretion samples to the same concentration, and second by dividing each analyte's peak area by the internal standard peak area.

Statistical Analysis We used principal component analysis with an equamax rotation (PCA) to reduce the data to principal components (PCs) that represented correlations of peak areas of compounds found in uropygial secretions as described above. We then used multivariate analysis of variance (MANOVA) to determine the effect of sex, age, and season/location on the generated PCs and a one-way

Table 1 Compounds identified in gray catbird uropygial secretions

Volatiles identified by SPME-GC-MS			
Number	Compound	RT on AT-WAX (min)	Ion (m/z)[a]
1	Acetic acid	4.7	60
2	Benzaldehyde	5.3	77
3	Butanoic acid	6.1	60
4	3-Methylbutanoic acid	6.4	60
5	Pentanoic acid	6.9	60
6	Hexanoic acid	7.7	60
7	Heptanoic acid	8.4	60
8	Octanoic acid	9.1	60
9	Nonanoic acid	9.8	60
Semivolatiles identified by solvent extraction coupled with GC-MS			
Number	Compound	RT on DB5-MS (min)	Ion (m/z)[a]
10	Decanol	12.6	55
11	Undecanol	13.5	55
12	2-Tridecanone	14.0	58
13	Dodecanol	14.1	55
14	Dodecanoic acid	14.2	60
15	Tridecanol	14.3	55
16	Tetradecanol	14.8	55
17	2-Pentadecanone	14.9	58
18	Pentadecanol	15.0	55
19	Tetradecanoic acid	15.1	60
20	Hexadecanol	15.5	55
21	Hexadecanoic acid	15.8	60
22	Heptadecanol	15.9	55
23	Octadecanol	16.2	55
24	Oleic acid	16.3	60
25	Octadecanoic acid	16.4	60
26	Nonadecanol	16.5	55
27	Eicosanol	16.9	55

analysis of variance (ANOVA) to examine the interaction between age and sex. All statistical analyses were performed using PASW Statistics 18 (2009). A *P*-value of ≤0.05 was considered significant.

To test for the effects of sex and age on semivolatiles, only samples collected in Ohio during the summer were compared (HY males *N*=13; HY females *N*=11; AHY males *N*=22; AHY females *N*=17). To test for the effect of season/location and sex on semivolatiles, we compared AHY birds collected in Florida during the winter and in Ohio during the summer (OH males *n*=22; OH females *N*=17; FL males *N*=10; FL females *N*=7).

Similarly, to test for the effects of sex and age on volatiles, only samples collected in Ohio during the summer were compared (HY males *N*=20; HY females *N*=13; AHY males *N*=22; AHY females *N*=19). To test for the effect of season/location on volatiles, we compared AHY birds collected in Florida during the winter and in Ohio during the summer. Males and females were combined for this seasonal analysis because very few females were captured in FL during the winter (OH *N*=41; FL *N*=18).

Results

In total, we identified 34 compounds in gray catbird uropygial secretions. Table 1 lists the identified compounds along with their retention times, type of column used for GC-MS analysis, and characteristic ion used for identification. The compounds we identified were linear and branched saturated carboxylic acids, an unsaturated carboxylic acid, linear saturated alcohols, an aromatic aldehyde, two ketones, and a 28-carbon ester. Compounds containing both odd and even numbers of carbons were identified. We also identified a series of esters at retention times greater than 22 min, but we did not attempt to characterize these esters.

Representative chromatograms from SPME/GC-MS analysis are shown in Fig. 1. We observed that the volatile profile of secretions from adult birds (designated after hatch year or AHY) were qualitatively different from the secretions of juvenile birds (designated hatch year or HY), as shown (Fig. 1a). We also observed that secretions gathered from birds in Ohio during the summer breeding season (designated Ohio or OH) differed from secretions sampled at the Florida wintering grounds (designated Florida or FL); representative chromatograms are shown (Fig. 1b). Figure 2 shows representative total ion chromatograms from DCM/GC-MS analysis. As with the volatile compounds, semivolatile compounds abundance pattern varied with age (Fig. 2a) and season/location (Fig. 2b).

We used PCA to identify sets of compounds that varied together. Table 2 shows the rotated component matrix describing the effect of age on volatile compounds; three principal components accounted for 81% of the variance in these data. The set of principal components describing season/location effects on volatile compounds is shown in Table 3. From this analysis, 82% of the variance is accounted for by three principal components. shows the rotated component matrix for age effects on semivolatile compounds. Here, four principal components account for 59% of the variance in the data, and we note that compounds with similar functional groups tend to load onto PCs together. The compounds in PC1 are long-chain linear carboxylic acids; PC2 contains medium and long-chain alcohols; PC3 contains hexadecanoic acid; methyl ketones load onto PC4. Table 5 shows the rotated component matrix for the effects of season/location on semivolatile compounds; in this analysis the first four PCs account for 65% of the variance. Compounds with similar functional groups are again found to load onto the same PCs. Long-chain carboxylic acids load onto PC1; PC2 contains methyl ketones; PC3 contains linear alcohols; PC4 accounts for octadecanoic acid and C28 ester. Figure 3 shows score plots derived from the four PCAs. In scatter plots in which PC1 is plotted vs. PC2, the individual birds are seen to cluster based on age (Fig. 3a, c) or on season/location (Fig. 3b,d).

Age and season/location influenced levels of both volatile and semivolatile compounds (Tables 6 and 7). We found no effect of sex on signal strength of semivolatile compounds, consistent with our earlier characterization of the uropygial secretions of captive gray catbirds (Whelan et al., 2010). Sex did affect signal strength of volatile PC1. However, because we also found a significant interaction between age and sex, meaning that the effect of sex may be dependent on age, we examined the effect of sex on both AHY and HY birds separately. We found no effect of sex within AHY birds (F=0.47, P=0.499) and a significant effect of sex on HY birds (F=5.85, P=0.022, Fig. 4).

Discussion

General Observations The chemical profile we identified in gray catbird uropygial secretions resembles those reported for two other passerine species in which volatiles and semivolatiles have been characterized, i.e. dark-eyed juncos (Soini et al., 2007) and Bengalese finches (Zhang et al., 2009), in the presence of linear alcohols, carboxylic acids, and methyl ketones. Since the volatile and semivolatile chemical profiles of few passerine species have been described, it is notable that the major compounds found in these three species overlap substantially. Further characterization of the role(s) that these compounds serve for passerine species is needed.

We also note interesting differences in the chemical profile we observed. Soini et al. (2007) identified long-chain branched carboxylic acids, aliphatic aldehydes, alkanes, and alkenes as minor components in secretions of the dark-eyed junco, whereas we did not detect these compounds in gray catbird uropygial secretions. In addition, our results vary from those of Zhang et al. (2009) who identified numerous diesters with retention times between that of hexadecanol and octadecanol in the uropygial secretions of Bengalese finches. These compounds were not present in gray catbird secretions. We acknowledge that these differences may result from differences in analytical methodology. Our extraction method differs from that of Soini et al. (2007) who used sorptive stir-bar extraction, and our GC column choices differ from that of Zhang et al. (2009), who used polar columns exclusively. Inter-lab comparative analyses of samples from the same bird species would help to clarify the roles of these methodological factors. However, the observed differences also may have resulted from interspecific variation or reflect the impact of diet or other environmental factors. In both the junco and finch studies, birds were kept in captivity, whereas the gray catbirds we sampled were free-ranging. Although a more comprehensive study on the differences between captive and free-ranging birds is needed, we suggest that

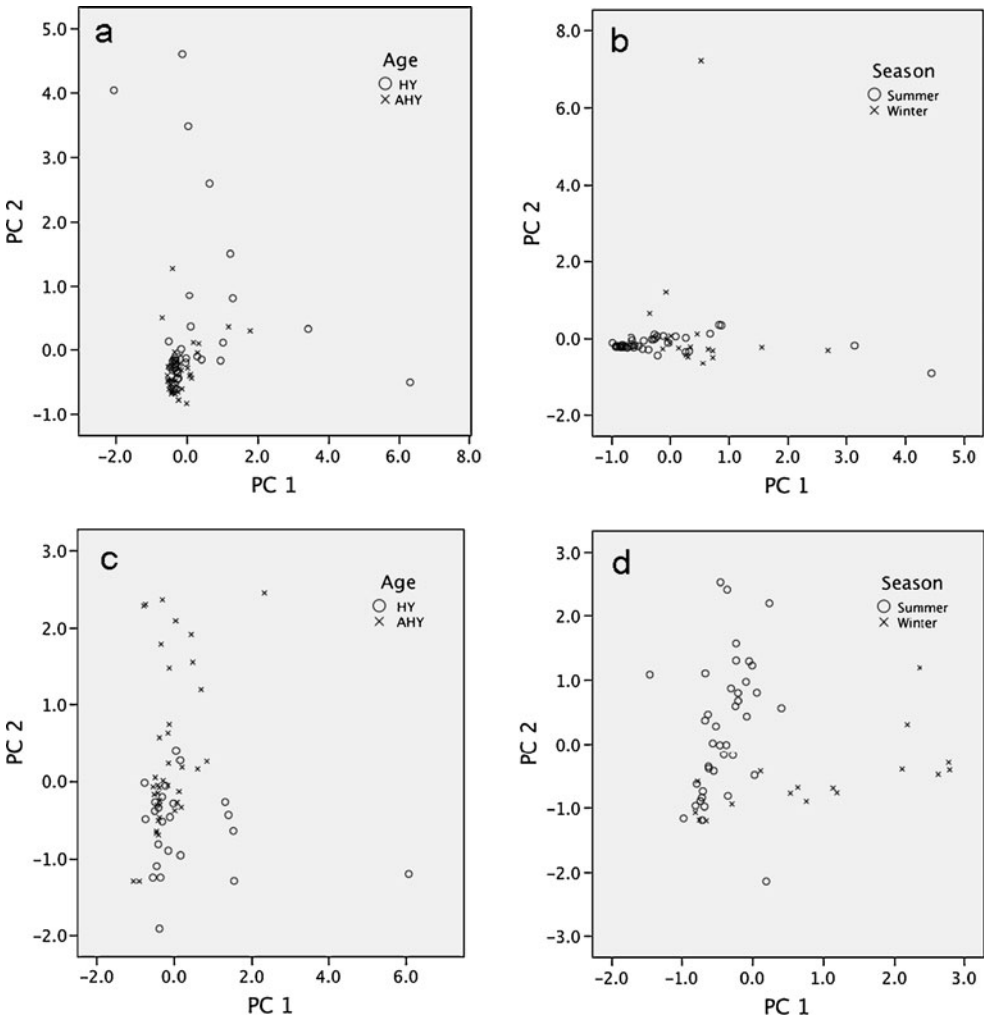

Fig. 3 Score plots resulting from principal component analysis for the effects of: **a** age on volatile compounds, **b** season/location on volatile compounds, **c** age on semivolatile compounds, and (**d**) season/location on semivolatile compounds of uropygial secretions of gray catbirds

meaningful differences in the composition of uropygial secretions may occur between captive and free-ranging birds. For example, compared with the volatile compounds we identified in captive catbirds (Whelan et al., 2010), the chemical profile of free-ranging catbirds includes greater abundance of the carboxylic acids heptanoic, octanoic, and nonanoic, fewer branched carboxylic acids, and the appearance of benzaldehyde.

Volatile Compounds The volatile compounds we identify in gray catbird uropygial secretions are saturated carboxylic acids and benzaldehyde. In the rotated component matrix for age effects on volatiles, the carboxylic acids cluster roughly based on molecular weight, with intermediate weight compounds (linear acids C4 to C7) loading onto PC1 and the heaviest compounds (octanoic and nonanoic acids) loading onto PC3. PC2 contains the lightest acid, acetic, as well as the only branched acid we detected, 3-methylbutanoic acid. The functional significance of these acids in gray catbirds has not been characterized. However, aliphatic carboxylic acids from acetic through dodecanoic have been shown to be potent oviposition repellents for

Culex and *Aedes* mosquitoes (Hwang et al., 1980, 1982; Kramer et al., 1980), consistent with an arthropod defensive function. Adult birds had low score plot values and little variation in both PC1 and in PC2, whereas hatch year birds had higher scores for volatile PC1, corresponding to higher levels of pentanoic acid, hexanoic acid, and heptanoic acid. Moreover, values of both PC1 and PC2 vary greatly among juveniles. We also observed significant interaction of sex and age with volatile PC1 for juvenile birds only (Fig. 4). Perhaps the large variation in volatile compounds among juvenile birds creates an individual olfactory signature of the sex or overall health of young birds for parents. Although our study did not explicitly include nestlings, it is reasonable to expect similar volatile chemical profiles between nestlings and juveniles, considering that some of the juveniles we sampled had only fledged a short time before. Further studies focusing specifically on the uropygial secretions of gray catbird nestlings are ongoing.

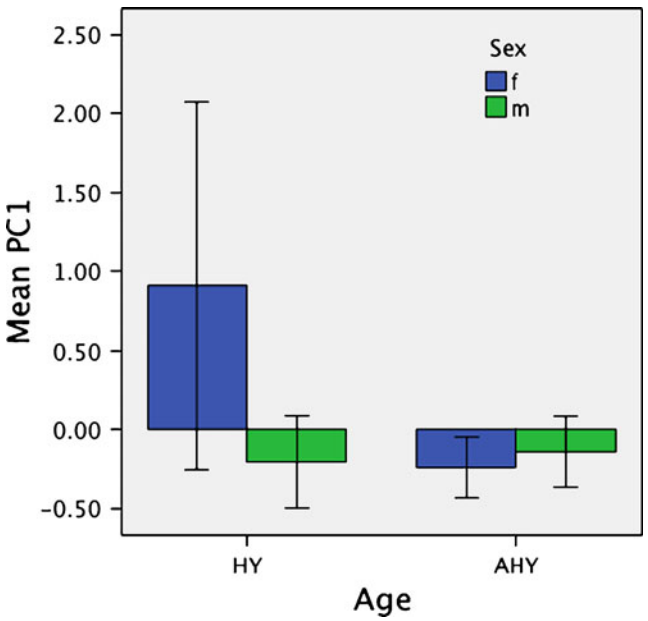

Fig. 4 Mean PC1 volatile compound values for hatch year (HY) female and male catbirds and after hatch year (AHY) female and male birds. All samples were collected in Ohio during summer. Bars indicate standard error

Although benzaldehyde does not load significantly onto any of the PCs, we find it particularly interesting in that we did not detect it in captive gray catbirds (Whelan et al., 2010), and, therefore, predict that it is sequestered from diet. Benzaldehyde is found in stone fruits such as wild black cherries (Cimprich and Moore, 1995), which are abundant at our field site during the study period. Moreover, the pits of this fruit were observed in catbird feces during this study.

In the rotated component matrix for season/location effects on volatiles, the loading onto PCs is again approximately related to molecular weight, with compounds of intermediate weight loading onto PC1, the lightest compounds loading onto PC2, the heaviest compounds loading onto PC3. An interesting exception to this trend is butanoic acid, which loads onto PC1 whereas 3-methylbutanoic acid loads onto PC2. Benzaldehyde loads onto PC2 along with acetic and 3-methylbutanoic acids. Heptanoic acid is exceptional in not loading significantly onto any of the PCs, though with a value of 0.661 it is marginally associated with PC3 and the heaviest and therefore least volatile compounds. A score plot (Fig. 3b) reveals considerable individual variation in PC1 for both winter and summer birds, whereas variation in PC2 is small for birds sampled in the summer and only marginally greater for birds sampled in the winter if the contribution of one exceptional individual is excluded. This difference may reflect variation in food resources between the two sites (see the review by Hagelin and Jones, 2007). Such dietary influences on uropygial secretions are deserving of further exploration. Alternatively, these differences also could reflect population-level genetic variations such as those reported by Whittaker et al. (2010) in dark-eyed juncos.

Semivolatile Compounds Among semivolatile compounds, we found a greater diversity of chemical functional groups, including carboxylic acids, alcohols, methyl ketones and an ester. These classes of chemical compounds have been observed in other passerines (Soini et al., 2007; Zhang et al., 2009). Compounds with similar functional groups tend to load together onto PCs, meaning that their amounts

present in secretions vary together. In the analysis based on age, PC1 contained five compounds with loading scores greater than 0.7, all of which were long-chain linear carboxylic acids; PC2 contains the linear alcohols tetradecanol and nonadecanol; the only major contributor to PC3 is hexadecanoic acid, though oleic acid and two other carboxylic acids are marginal contributors with values greater than 0.6; the ketones 2-tridecanone and 2-pentadecanone load onto PC4. Examination of a score plot (Fig. 3c) shows that values of PC1, and therefore amounts of long-chain carboxylic acids, tend to be greater in juvenile birds whereas values of PC2 (corresponding to linear alcohols) are greater in adult birds. The greater levels of long chain linear carboxylic acids in juvenile birds may assist in the "timed-release" of these less volatile compounds. Given that juvenile birds are still developing adult preening behaviors, a less volatile, more persistent uropygial secretion may be beneficial to young birds. The higher levels of heavier esters observed in hatch-year birds may be similarly important for younger birds. Soini et al. (2007) connected linear alcohol abundance with signaling of reproductive readiness and olfactory crypsis. We found that adult gray catbirds, for whom signaling to conspecifics prior to mating and protection of the nest are of great importance, display greater amounts of these linear alcohols than juveniles. Although this study was not designed to investigate individual variation or the reliability of scent profile as an individual signature, it is interesting to note that both PC1 and PC2 exhibit considerable individual variation.

In the analysis of the effect of season/location on semivolatile compounds, similar functional groups are again found to load onto PCs together. PC1 contains the heaviest linear unsaturated carboxylic acids, and these compounds are significantly more abundant in birds sampled at the Florida wintering grounds (Fig. 3d) than those sampled on Ohio breeding grounds. As suggested for the volatile compounds, perhaps this observation reflects dietary differences or population-level genetic variation. PC2 accounts for two methyl ketones, and these compounds are present at higher levels during the breeding season. Soini et al. (2007) also found that methyl ketones were present at higher levels during long days. In later work Whittaker et al. (2010) found that methyl ketones were more abundant in males and suggested that these compounds contribute to a "male-like" olfactory profile. We did not observe sex differences in semivolatile compounds among gray catbirds. PC3 contains linear alcohols while PC4 contains medium-to-long chain carboxylic acids and the C28 ester.

With the exception of oleic acid, which is monounsaturated, all the compounds we identified contain saturated alkyl chains. Unsaturated lipids rarely are found in uropygial secretions (but see Montalti et al., 2005 and Haribal et al., 2009). Jacob and Ziswiler (1982) attributed the well-documented predominance of saturated lipids to the tendency of unsaturated lipids to spontaneously oxidize under atmospheric conditions, resulting in adverse effects on feathers. Oleic acid was a minor component in the secretions we analyzed and did not load significantly onto any of the principal components, making evaluation of its role difficult. Interestingly, in a comparison of C14 to C24 unsaturated carboxylic acids, oleic acid was the most effective ovipositional repellant in *Culex quinquefasciatus* (Hwang et al., 1984). Oleic acid is sometimes called the "smell of death" because of its role as a molecule that signals death in arthropods thereby eliciting an avoidance behavior (Yao et al., 2009). We suggest that such a signal would be beneficial to catbirds and other songbirds, which are constantly subject to attack by arthropod pests to which they are exposed.

Abstract Parasite loads of animals vary among individuals, but the underlying mechanisms have not been fully identified. Here, we investigated whether health status of hedgehogs (*Erinaceus europaeus*) is correlated with tick burden, and whether chemical cues linked to the health status of the host mediate attraction of the tick *Ixodes hexagonus*. An ecological survey conducted over 10 years, involving 226 wild hedgehogs, revealed a strong association between health status and tick burden of hedgehogs, with healthy animals being less likely to carry ticks than unhealthy ones. Behavioral choice tests demonstrated that ticks display a preference for the fecal odor from sick hedgehogs compared with healthy ones. Chemical analysis of fecal odors using gas chromatography - mass spectrometry showed differences in the odor profile between sick and healthy hedgehogs. Sick animals tended to exhibit raised levels of the volatile aromatic heterocyclic compound indole in their feces. Ticks were attracted to indole when given the choice between indole and a solvent control. However, fecal matter from healthy hosts, with the addition of indole, was not attractive to ticks, suggesting that indole interacts with other, undetected compounds in mediating attraction. This study implies that it is the attraction to fecal odor that causes higher tick burdens in sick hedgehogs. Ticks might benefit from this preference by avoiding possible repulsion mechanisms of healthy hosts. We suggest that ticks potentially choose their host based on odor linked to the host's health status.

Key Words Infochemical · Kairomone · Parasite infestation · Animal health status · Host-parasite interaction

Introduction

Parasites and their hosts are engaged in a co-evolutionary arms race that has resulted in the refinement of specific strategies by both the parasite and its host (Jackson, 2008). Parasites need to target and infest their host species, while the host needs to repel the parasite, particularly if infestation incurs a high cost. This paper addresses the methods used by ticks that selectively target a suitable mammalian host.

Ticks are vectors of human conditions such as Lyme disease (Parola and Didier, 2001) and tick-borne encephalitis (Lindgren and Gustafson, 2001). The tick, *Ixodes hexagonus*, is associated predominantly with hedgehogs, but also is found regularly on mustelid carnivores (Page and Langton, 1996), and occasionally on dogs, cats, and humans (Estrada-Pena and Jongejan, 1999; Ogden et al., 2000). *Ixodes* species are known to cause regenerative anemia in European hedgehogs (*Erinaceus europaeus*), as well as to transmit tick-borne pathogens (Skuballa et al., 2007; Pfäffle et al., 2009).

It is usual for parasites to be aggregated within their host populations. Populations of bank voles (*Myods* (*Clethrionomys*) *glareolus*), hares (*Lepus timidus*), and roe deer (*Capreolus capreolus*) show unequal distribution of ticks (*Ixodes ricinus*) among host individuals of the same species (Tälleklint and Jaenson, 1997). In hedgehogs (*Erinaceus europaeus*), tick (*Ixodes hexagonus*) infestation levels vary among individuals (Bunnell, 2001).

The underlying mechanisms of tick aggregation are not fully understood (Anderson and Gordon, 1982). One possible mechanism of host selection by ticks could be to target animals with reduced immune status, which are less resistant to infestation. There is some evidence to support this hypothesis. For example, cattle have been found to be differentially infested with ticks, an effect attributed to variations in the host's immunological response (Roberts, 1968). Stresses such as lactation or sickness reduce immunological resistance (Seifert, 1971). Ticks that target hosts with reduced immune status are likely to have a selective advantage over those that target hosts irrespective of host resistance. Differential infestation by ticks also could be due to different exposure risk in different habitats (Gregoire et al., 2002), variation in cues emitted by the host (Birkett et al., 2004), or to differences in behavioral (Mooring and Blumstein, 2004) or immunological repulsion by the host (Allen, 1973).

Ticks employ three methods to locate hosts, namely, sitting and waiting in the open, dwelling in host nests or burrows, and active searching (Yoder et al., 1999). *Ixodes hexagonus* is thought to be a nidicolous tick that occupies the nests of hedgehogs. However, dogs and cats show significant levels of attachment by *I. hexagonus* when allowed access to urban parks (Ogden et al., 2000), thus showing that this tick also frequents areas of vegetation away from nests. Here, we focused on the sensory cues leading to attraction of ticks to their hedgehog hosts.

Ticks are attracted to hosts from a distance by using different stimuli including vibrations, body heat, and odor (Parola and Didier, 2001; Donzé et al., 2004). Host odors (kairomones) are the most specific distance stimuli utilized by arthropod parasites (Osterkamp et al., 1999). Ticks possess a cluster of 10 olfactory and gustatory receptors, known as Haller's organ, that are sensitive to vertebrate-associated chemicals including fatty acids and carbon dioxide (Osterkamp et al., 1999). Carbon dioxide, released in the breath, stimulates questing behavior (Waladde and Rice, 1982; Sonenshine et al., 1986; Osterkamp et al., 1999). It also stimulates some species to move towards the source (McMahon and Guerin, 2002). However, carbon dioxide traps have proved largely unsuccessful in attracting *Ixodes* spp. in the field (Schulze et al., 1997), suggesting that other attractants are involved (Crooks and Randolph, 2006). Kairomones that attract ticks may include volatile compounds released by glands (Carroll, 1998) or metabolic residues originating in the gut (Donzé et al., 2004) of the potential host.

Odor cues also can reveal information to a receiver about the health status of the sender (Wyatt, 2003). For example, female screwworm flies (*Cochliomyia hominivorax*) orientate to volatiles produced by a bacterium present in wounds associated with myiasis (flystrike) to find their cattle host (Hammack et al., 1987). Metabolic by-products inadvertently produced by a disease or immune response can result in odor cues that provide a reliable indicator of health and disease (Penn and Potts, 1998). Female mice (*Mus musculus*) discriminate between the odors of parasitized and non-parasitized males (Kavaliers and Colwell, 1992). It has been suggested that the odor of male mice signals infection due to a change in the composition of commensal microbes caused by the infection itself (Penn and Potts, 1998).

We hypothesized that differential tick infestation levels in hedgehogs are linked to the health status of the host, and that this is mediated by odor cues that attract or repel ticks. We tested this hypothesis by employing a multidisciplinary approach that included an ecological survey, behavioral assays, and chemical analysis. In the survey we monitored tick burden of wild hedgehogs in relation to health status. The behavioral bioassay investigated whether fecal odors mediate differential attractiveness of sick and healthy hosts. Analytical techniques complemented by behavioral assays identified a key chemical involved.

Methods and Materials

Ecological Aspects Over a period of 10 years, 226 wild hedgehogs (*Erinaceus europaeus*) were treated at a hedgehog rescue center run by T. Bunnell. Hedgehogs were brought to the center by members of the public from a 25-mile radius around York, North Yorkshire, England, UK. The main reason for them being identified as in need of care was the presence of the normally nocturnal hedgehog in the open during daylight hours. Such animals were either sick or injured and required treatment. Apart from daylight activity the animals were not subject to any selection criteria. Sampled hedgehogs included sick and healthy animals. Hedgehogs were considered sick (N=119) when they suffered from one or more ailments (Table 1) apart from tick infestation. Animals with no apparent ailments, apart from tick infestation, were considered to be healthy (N=107).

Chemical Analysis Fecal samples were collected from 31 sick and 31 healthy hedgehogs ranging in weight from 250 g to 900 g. The ailments suffered by the sick animals were noted (Supplementary Material Table 1). Fecal samples weighed between 1.03 g and 16.34 g and were stored in glass containers at −20°C. Following thawing, 0.5 g feces were placed in a sealed 5 ml glass vial for 20 min to extract head space volatiles. Solid phase microextraction was conducted using a Supelco™ SPME Portable Field Sampler with a 100 μm PDMS (polydimethylsiloxane) fiber. The chemically adsorbent fiber was

Table 1 Ailments observed in sick hedgehogs in relation to tick infestation

Ailment	Diagnosis	Total number of hedgehogs with this ailment	Percentage of hedgehogs with this ailment that were infested	Number of tick-infested hedgehogs with this ailment	Percentage of tick-infested hedgehogs with this ailment	Percentage of uninfested hedgehogs with this ailment	*P*
Crenosoma striatum	microscopic examination of feces	15	53%	8	17%	4%	<0.001
Coccidiosis (Isospora sp.)	microscopic examination of feces	7	29%	2	4%	3%	0.4
Tapeworm	microscopic examination of feces	14	50%	7	15%	4%	<0.001
Diarrhea	liquid feces	29	28%	8	17%	12%	<0.01
Sarcoptic mange	microscopic identification of skin mites	8	0%	0	0%	4%	1.00
Demodectic mange	microscopic identification of skin mites	4	25%	1	2%	2%	0.7
Ringworm	skin lesions	8	25%	2	4%	3%	0.3
Injured	signs of trauma	26	35%	9	19%	10%	<0.001
Breathing difficulties	chest sounds and/or rapid breathing	17	47%	8	17%	5%	<0.001
Malnourished	tapered rear end	54	33%	18	38%	20%	<0.001
Dehydrated	loose skin on abdomen	22	36%	8	17%	8%	<0.001
Hypothermia	abdomen cold to the touch	22	23%	5	10%	10%	<0.07
Hyperactivity	continuous movement during daylight	12	50%	6	13%	3%	<0.001
Collapsed	uncurled and immobile	5	60%	3	6%	1%	<0.02

Diagnoses were confirmed by the Minster Veterinary Practice (York, UK). Microscopic examination of fecal smears were used to identify excessive burdens of internal parasites. Percentages were derived from total numbers of infested hedgehogs (N=48) and uninfested hedgehogs (N=178), respectively. Some animals had more than one ailment. Tick infestation of hedgehogs with an ailment was compared to infestation of healthy hedgehogs using Fisher's exact test (p values were corrected for repeated testing using Hochberg's, 1988, method)

exposed for 15 min to the head space. Exposure time of 15 min was sufficient to reach equilibrium, and is comparable to that used in similar studies (Garner et al., 2007). SPME fibers were analyzed by split-less direct injection using a GC-MS (Agilent 6890 GC/5972) with a 0.25 μm x 30 m HP-5MS capillary column. Helium was the carrier gas with a flow rate of 0.8 L/min. Initial column temperature was 50°C increasing at a rate of 10°C/min to 290°C, which was held for 10 min (inlet temperature 250°C). The MS transfer line was set at 280°C, the electron multiplier voltage at 1788 V, and the energy of ionizing electron was 70 eV. Volatiles were identified tentatively by using the MS Library (NISTO2) supplied with the GC-MS software (Supplementary Material Table 2). The structures were validated with synthetic standards obtained from Sigma-Aldrich Company Ltd. and comparing retention times and MS spectra.

General Procedure for Behavioral Assays On arrival at the rescue center, the weight and health status of the hedgehogs were recorded (Table 1), and all ticks were removed. Ticks were removed by using narrow, curved-ended forceps to grasp the head end and then by turning the forceps swiftly. This caused the tick mouth parts to be removed without incurring damage to the tick or to the spines of the hedgehog. No change in behavior was observed, and all ticks in all bioassays underwent the same procedure. We used ticks removed from hedgehogs rather than collecting them in the field due to the limited availability of free-living ticks in the field.

Individual ticks were selected for testing based on their morphological integrity, such as presence of all appendages and mobility, and the display of questing behavior. Questing refers to a typical posture adopted by ticks whereby the first pair of legs is extended and they wave in response to stimuli that indicate the presence of a host (Osterkamp et al., 1999). Only hungry, questing, adult female ticks were used. Ticks were all identified as *I. hexagonus* by virtue of the positioning of the genital aperture opposite the third coxae (Hillyard, 1996). Inevita-

bly, ticks used in these experiments came from sick hedgehogs as, with the exception of a few individuals, all ticks were removed from sick animals (Fig. 1). Ticks were never tested with the feces of their individual hosts.

Following removal from hosts, the semi-gorged adult female ticks were maintained at ambient temperatures of 20–23°C and humid conditions, and were deprived of a blood meal for at least 1 d prior to being used in a bioassay. The average weight of ticks used was 0.036 g. Choice tests were conducted with a glass T-maze (25 cm trunk and 25 cm arms, internal diam, 0.9 cm) placed horizontally. The two arms of the T-maze, which constituted the top of the 'T', were exposed equally to light to avoid any bias due to negative phototaxis. Odor stimuli were randomly positioned at the end of either the left or right arm of the T-maze. Ticks were placed near the top of the trunk that formed the base of the T-maze, and the tube behind them was blocked. This prevented ticks from returning to the trunk of the maze, thus providing two possible directions of movement (left or right). Each tick was introduced separately into the T-maze, thus avoiding contact with other ticks, and no tick was ever used more than once in any trial in any of the bioassays.

Between trials, the T-maze was cleaned thoroughly with ethanol. A tick was considered to have chosen a particular arm once it had crossed the mid-point on one of the two arms. If a tick had not reached the end of either arm after 10 min, the experiment was discontinued. Ticks began to quest as soon as they were released into the top of the trunk of the maze. All bioassays were conducted within a 2 week period. Ticks were filmed during the bioassays, and their choices were scored by an observer blind with respect to stimulus location.

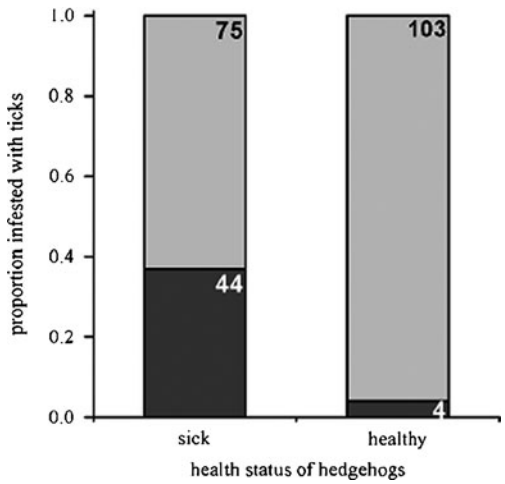

Fig. 1 Proportion of sick and healthy animals infested with ticks. Black bars denote tick-infested animals. Grey bars denote uninfested animals. The numbers of hedgehog individuals are indicated in the corner of each bar. Sick hedgehogs (N=119) were more likely to carry ticks than healthy ones (N=107; Pearson *Chi-square* test, χ^2=37.2, P<0.001)

Bioassay 1 Fecal samples were collected in the morning, having been produced by a hedgehog the previous night. They were mixed immediately with a glass rod to produce a homogenous mix, and were frozen at −20°C and kept at this temperature until needed for chemical analysis or bioassays. A different tick was used in each trial with two different fecal samples, one taken from a sick hedgehog, the other from a healthy one. No fecal sample was used more than once. In no instance were ticks collected from an individual hedgehog used in a bioassay with feces collected from the same animal. Also, in order to avoid a possible family odor signature, fecal samples from related hedgehogs were not used in the same trials.

A freshly thawed fecal pellet (0.1 ml) was placed in a Gilson tip at the end of each of the two arms forming the 'T' of the T maze. One fecal pellet was from a healthy individual, and the other from a sick one. The positioning of the pellets at the different ends of the horizontal arms of the maze was randomly determined by throwing a die. A tick was released to the top of the trunk 10 sec after the pellets were placed in position.

Bioassay 2 The procedure was identical to that used in Bioassay 1 with the exception that the ticks used were obtained from a domestic ferret (*Mustela putorius furo*). Ticks had not been exposed to the odor of sick hedgehogs and could be considered naïve for the purpose of the bioassay.

Bioassay 3 Individual ticks were placed separately at the top of the trunk of the maze. The end of one arm contained 0.04 ml indole (Sigma-Aldrich Company Ltd.) dissolved in a solution of water and ethanol (40 mg in a solution of 98% water and 2% ethanol), and the other arm contained 0.04 ml of the solvent (2% ethanol, 98% water). The concentration of indole used was determined by analyzing fecal samples with the GC-MS (Snellings et al., 2003) and was based on the amount found present in feces from sick hedgehogs.

Bioassay 4 Fecal samples collected from healthy hedgehogs were used. As with all other bioassays, a different tick was used in each trial, and no fecal sample from a particular hedgehog was used more than once for individual trials. In no instance were ticks collected from an individual hedgehog used in a bioassay with feces collected from the same animal. A freshly thawed fecal pellet (0.1 ml) from the same healthy hedgehog was placed in a Gilson tip at the end of each of the two arms forming the 'T' of the maze. The fecal pellet at the end of one arm was spiked with 0.04 ml of indole (Sigma-Aldrich Company Ltd.) dissolved

in a solution of water and ethanol (40 mg in a solution of 98% water and 2% ethanol), and the fecal pellet in the other arm was spiked with 0.04 ml of the solvent (2% ethanol, 98% water). The positioning of the pellets (whether spiked with indole or the solvent) at the different ends of the horizontal arms of the maze was randomly determined by throwing a die. A tick was released to the top of the trunk 10 sec after the pellets were placed in position.

Results

Hedgehogs typically arrived at the rescue center between May and January (Bunnell, 2009). On arrival, 21% (N=48) of all hedgehogs (N=226) were infested with *Ixodes hexagonus* ticks. Of the infested individuals, 44 were sick and 4 were healthy (Fig. 1). Overall, sick hedgehogs were more likely than healthy ones to carry ticks (Pearson *Chi-Square* test, χ^2=37.2, P<0.001; Fig. 1). Hedgehogs suffering from any of 12 different ailments including lungworm (*Crenosoma striatum*), tapeworm, ringworm, breathing difficulties, hypothermia, and injury were more likely to carry ticks than healthy hedgehogs (Pearson *Chi-Square* tests, see Table 1). Only 4 of the hedgehogs carrying ticks displayed no obvious ailments, 3 of these being orphaned nestlings (Fig. 1). Some animals suffered from combinations of ailments (Supplementary Material Table 3).

The association between tick infestation and presence of other ailments could result either from ticks targeting hedgehogs that are already sick or from ticks targeting healthy animals that then become sick due to the tick infestation. However, some of the ailments suffered by sick hedgehogs (Table 1) were not caused by ticks. These include injuries from other animals, machinery, or road traffic, bacterial infections, heavy intestinal parasite burdens resulting from ingestion of certain food sources, and hypothermia caused by prolonged exposure to low temperatures. We tested the hypothesis that ticks are attracted to the feces of hedgehogs that are already sick.

In bioassay 1, more ticks (obtained from hedgehogs) chose the arm in a T-maze containing feces from a sick hedgehog (N=16) than the arm containing feces from a healthy hedgehog (N=4; binomial test, binomial proportion 0.2, P<0.012). In bioassay 2, more ticks (obtained from a ferret) chose the arm in a T-maze containing feces from a sick hedgehog (N=13) than the arm containing feces from a healthy hedgehog (N=4; binomial test, binomial proportion 0.24, P<0.049).

Individual fecal odor profiles of 62 hedgehogs (31 sick, 31 healthy) were analyzed. Out of 7 volatile compounds identified in the odor profiles (Supplementary Material Table 2) only one substance, indole, was present in significantly higher amounts in sick hedgehogs compared with healthy ones (Wilcoxon test, χ^2=19.6, P<0.001; Fig. 2). The presence of indole was confirmed by using a standard and included exact matches of chromatographic and mass spectral data, taken under equivalent concentration under the same operating conditions.

In bioassay 3, ticks were attracted to indole when given a choice between indole and the solvent control (2% ethanol, 98% water). They chose the arm of the T-maze containing indole significantly more times (N=17) than the arm with the control (N=3; binomial test, binomial proportion 0.15, P=0.003). In bioassay 4, ticks displayed no significant preference when given a choice between two samples of healthy feces from the same hedgehog, spiked respectively with indole (approached by 7 ticks) and the solvent (approached by 7 ticks; binomial test, binomial proportion 0.5, P=1.0).

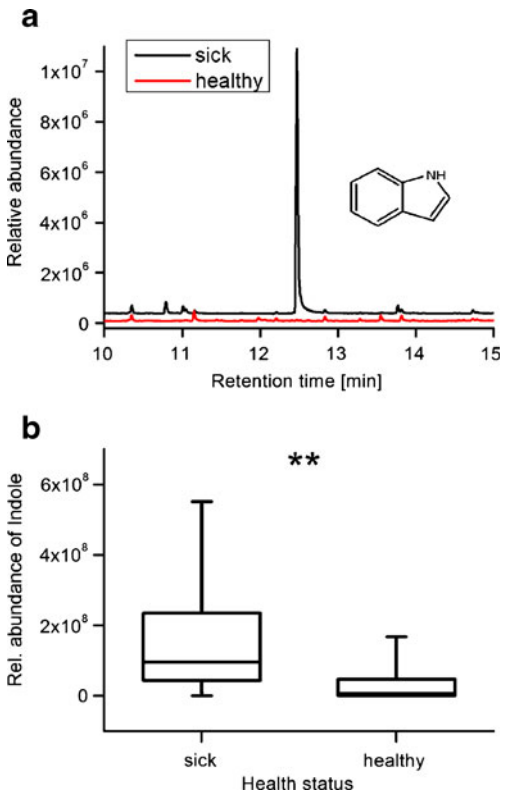

Fig. 2 Abundance of indole in hedgehog fecal odor. Abundance was measured by head space sampling using Solid Phase Microextraction. **a** Examples of gas chromatograms from a typical sick (top line) and a typical healthy (bottom line) individual (Agilent 6890 GC/5972 MS with a 0.25 μm×30 m HP-5MS capillary column; identification by MS Library NISTO2). For clarity, we offset the chromatogram of the sick hedgehog by 300,000 units. The peak represents level of indole in the sick hedgehog. **b** Relative abundance of indole in sick (N=31) and healthy (N=31) hedgehogs. The range indicated by the boxes is from 25 to 75 percentiles and includes the median. Error bars denote 5 and 95 percentiles (error bars) of relative abundance of indole in chromatograms. Asterisks denote significant differences (Wilcoxon test, χ^2=19.6, P<0.001) between the two health states

Discussion

This study sheds light on the mechanisms of parasite host interaction between ticks and hedgehogs. Sick hedgehogs were infested by a significantly higher number of ticks than healthy ones. This initial finding might be due to the preference of ticks for sick hosts. Alternatively, tick infestation could be the cause of illness. Potentially, ticks attached to a hedgehog also might attract more ticks through tick-tick attraction. While we cannot exclude a synergistic effect of these alternative mechanisms, the attraction of ticks to the feces of sick hedgehogs, rather than to the feces of healthy ones suggests that ticks selectively target sick hosts.

By using ticks that had previously infested sick hedgehogs (bioassay 1) we could potentially have biased our sample of experimental animals. These ticks could perhaps show a bias towards sick hosts. However, a second bioassay, using naïve ticks obtained from a domestic ferret, showed that these ticks also displayed a preference for the feces of sick hedgehogs rather than the feces of healthy animals.

The aromatic organic compound indole in the feces (Fig. 2) was the only major odor compound occurring in larger amounts in fecal odor from sick hedgehogs compared to fecal odor from healthy ones. Bioassay 3 showed that ticks are attracted to synthetic indole alone and hence that indole is likely involved in the attraction of ticks to sick hedgehogs.

The lack of preference of ticks for indole when it was used to spike feces from healthy hedgehogs (bioassay 4) might be explained by the masking or repellent compounds in the fecal odor of healthy hedgehogs. A range of other odor compounds was detected in the fecal odor of healthy hedgehogs compared with that of sick ones. These substances potentially could serve to repel ticks, while also masking the effect of any attractive substance such as indole. We cannot exclude the possibility that other minor compounds in the odor of feces of sick hedgehogs also may serve to attract ticks. However, indole was the only substance found present in significantly higher amounts in the feces of the sick hedgehogs compared to healthy ones. Future studies should test such potential synergistic effects.

Why should ticks target sick hedgehogs in preference to healthy ones? Tick infestation triggers a cell-mediated immune response in some host species leading to rejection or to death of the tick (Brown and Askenase, 1985). Acquired resistance of guinea pigs to tick (*Amblyomma americanum*) feeding is mediated by cellular walling off by employing basophils, which obstruct access to blood in the lower dermis (Allen, 1973). Cellular walling off results in reduced tick numbers and weight, or even death of the tick *in situ.* This finding in tick-infested guinea pigs provides some indication of how the mechanism might work in other animals. Mice that are stressed or sick have a depressed immune system making them more susceptible to infection (Kiank et al., 2006). They become more lethargic and less able to protect themselves from mosquitoes (Edman and Day, 1983).

Why would ticks use fecal odor to locate their hedgehog host? Apart from anal glands and sweat glands under the feet, hedgehogs have no specialized skin glands (Reeve, 1994). Odor sources that attract hedgehog antagonists from a distance, therefore, may be limited to footprints and feces. As the tick *I. hexagonus* appears to dwell in open vegetation as well as in nests, fecal deposits could provide a cue that enables ticks to target their hedgehog hosts in areas where hedgehogs are foraging and are either stationary or slow moving. Hedgehogs also tend to use similar routes while away from the nest, and are likely to pass by feces deposited previously. Hence, hedgehog fecal deposits are a good place for ticks to encounter a passing host.

Once near the odor source, some *Ixodes* species ambush their host by waiting on or near the chemical residues left by the host (Rechav et al., 1978; Carroll et al., 1995). Ticks such as *I. scapularis* aggregate in places associated with host presence (Carroll et al., 1995; Carroll and Schmidtmann, 1996; Carroll, 2002), thus increasing their chances of encountering a host that is likely to visit these areas on a regular basis. Near field stimuli such as body heat, vibrations or carbon dioxide that originate from the host facilitate final contact of the tick with the host (Parola and Didier, 2001).

Fecal products can provide information regarding physiological condition of a host, including the general health and the presence of enteroparasites (Patton et al., 1986). Residues from the digestive tract of hosts attract ticks. For example, ungulates release volatile metabolites from the rumen that are carried on the air and attract *Ixodes* spp. from a distance (Donzé et al., 2004).

Indole, identified here in the fecal odor of sick hedgehogs (Fig. 2) is present in odor profiles of other mammals, e.g., the skin and feces of giraffes (Wood and Weldon, 2002) and in the volatile headspace of incubated human sweat (Meijerink et al., 2000). The mosquito (*Anopheles gambiae*) possesses an odorant receptor that is finely tuned to a set of aromatic compounds that includes indole (Carey et al., 2010). Indole is produced in the human gut by bacterial decomposition of the amino acid tryptophan (Jensen et al., 1995). In humans, an abnormal balance of intestinal bacteria is related directly to diseases and immunological disorders, and is indicated by increased levels of indole (Fukuuchi et al., 2002). Future studies will aim to identify the chemical nature of repellent compounds possibly present in odor of feces released by healthy hedgehogs. The combined use of attractants and

repellents could be applied to the environmental management of ticks, as has been shown successfully in insects (Chapman et al., 1998).

Abstract Some birds and mammals roll on or wipe themselves with the fruits or leaves of *Citrus* spp. or other Rutaceae. These anointing behaviors, as with anointing in general, are thought to function in the topical acquisition of chemicals that deter consumers, including hematophagous arthropods. We measured avoidance and other responses by nymphal lone star ticks (*Amblyomma americanum*) and adult female yellow fever mosquitoes (*Aedes aegypti*) to lemon peel exudate and to 24 volatile monoterpenes (racemates and isomers), including hydrocarbons, alcohols, aldehydes, acetates, ketones, and oxides, present in citrus fruits and leaves in order to examine their potential as arthropod deterrents. Ticks allowed to crawl up vertically suspended paper strips onto a chemically treated zone avoided the peel exudate and geraniol, citronellol, citral, carveol, geranyl acetate, α-terpineol, citronellyl acetate, and carvone. Ticks confined in chemically treated paper packets subsequently were impaired in climbing and other behaviors following exposure to the peel exudate and, of the compounds tested, most impaired to carveol. Mosquitoes confined in chambers with chemically treated feeding membranes landed and fed less, and flew more, when exposed to the peel exudate than to controls, and when exposed to aldehydes, oxides, or alcohols versus most hydrocarbons or controls. However, attraction by mosquitoes in an olfactometer was not inhibited by either lemon peel exudate or most of the compounds we tested. Our results support the notion that anointing by vertebrates with citrus-derived chemicals deters ticks. We suggest that some topically applied compounds are converted into more potent arthropod deterrents when oxidized on the integument of anointed animals.

Introduction

Many birds and mammals roll on or wipe themselves with fruits, leaves, or other plant parts (reviewed in Weldon and

Carroll, 2007). Some animals incorporate aromatic leaves or bark in their nests. Phytochemicals appropriated via these anointing and fumigation behaviors are believed to deter consumers, including nuisance arthropods.

Passerine birds, including grackles (*Quiscalus* spp.) (Laskey, 1948; Johnson, 1971; Clayton and Vernon, 1993), starlings (*Sturnus vulgaris*) (Hampe in Stresemann, 1935), and tanagers (e.g., *Tachyphonas coronatus* and *Tangara mexicana*) (Sick, 1993), and mammals, including capuchin (*Cebus* spp.) (Buckley, 1983; Baker, 1996; Leca et al., 2007) and spider monkeys (*Ateles geoffroyi*) (Richard, 1970), wolves (*Canis lupus*) (Zimen, 1981), and coatis (*Nasua* spp.) (C. Cranmore, pers. comm.), anoint with lemons (*Citrus limona*), limes (*Citrus aurantifolia*), or other citrus fruits (Rutaceae), applying the peels, pulp, and/or juice to their integument (Fig. 1). White-faced capuchin monkeys (*Cebus capucinus*) in Costa Rica fur-rub more frequently with citrus fruits, which are introduced in the Americas, than with native plants (Baker, 1996). Spider monkeys in Panama also fur-rub with the leaves of rutaceous trees (*Citrus* and *Zanthoxylum*) (Campbell, 2000).

Humans have long used the Rutaceae as a source of arthropod deterrents. Ancient Europeans placed the fruits and leaves of lemon and other citrus plants among stored garments to deter moths (Arias and Ramón-Laca, 2005). In both the New and Old Worlds, the ethnobotanical uses of the Rutaceae include the topical application of fruit and leaf extracts to repel biting insects (Anaso et al., 1990; Koh and Ong, 1999; Arias and Ramón-Laca, 2005). Sukumar et al. (1991) regard the Rutaceae to be among the most promising of plant families to yield mosquito control agents.

Many volatiles present in citrus tissues possess biocidal and other arthropod-deterrent properties, an observation consistent with the defensive activity hypothesized for these substances in the context of vertebrate anointing. A study of the fumigant activity of 30 citrus peel volatiles against adults of the cowpea weevil (*Callosobruchus maculatus*), a stored product pest, for example, indicated that the chief component, limonene, and 21 other compounds are insecticidal (Don-Pedro, 1996). An investigation of the contact miticidal activity of 30 monoterpenoids against the two-spotted spider mite (*Tetranychus urticae*), a plant-infesting pest, found citronellol, carvone, and geraniol among the most effective compounds (Lee et al., 1997). These or other volatile monoterpenes also repel or kill arthropods that molest tetrapods, including ticks (Chungsamarnyart and Jansawan, 1996; Thorsell et al., 2006; Del Fabbro and Nazzi, 2008; Pälsson et al., 2008), mites (Carroll, 1994; Perrucci et al., 1995), lice (Toloza et al., 2006), fleas (Hink et al., 1988), bugs (Safra et al., 2009), and midges (Logan et al., 2009) and other biting flies (e.g., Zaki et al., 2005; Butler, 2007).

Clayton and Vernon (1993) investigated the potential value of grackles' habit of anointing with limes by conducting experiments with the chewing louse, *Columbicola columbae*, a feather-feeding ectoparasite that impairs host survival and mating success. Lice confined in Petri dishes with lime slices experienced higher mortality than did those confined with water. Lime pulp juice brushed onto lice had little effect, but the peel extract was insecticidal.

We tested nymphs of the lone star tick (*Amblyomma americanum*), a vector of human monocytic ehrlichiosis in the United States, and adult females of the yellow fever mosquito (*Aedes aegypti*), a circumtropical vector of yellow

Fig. 1 Convergence in anointing with citrus fruit by New World vertebrates. (*left*) A tufted capuchin monkey (*Cebus apella*) rubs a lemon slice against its back. (*center*) A boat-tailed grackle (*Quiscalus major*) rubs a lemon slice against its wing and trunk. (*right*) A white-nosed coati (*Nasua narica*) rubs a lemon slice against its tail

fever and dengue viruses, filariasis, and other diseases, for responses to lemon peel exudate and to the chief volatile monoterpenes reported in citrus fruits and leaves. Bioassays were conducted in order to evaluate these substances as ectoparasite deterrents for animals that anoint with them. Both arthropods were tested with 24 monoterpenes (racemates and isomers), including hydrocarbons, alcohols, aldehydes, acetates, ketones, and oxides.

Tick host-finding behavior ranges from ambushing to hunting, depending upon the species (Waladde and Rice, 1982). When stimulated by chemical or other cues, lone star ticks leave ambush sites and crawl toward stationary or slow-moving hosts. After locating a suitable site on the host, they typically feed for days. Mosquitoes, in contrast, swiftly fly toward and land on hosts, imbibing a blood meal within seconds before departing. We tested these distantly related and behaviorally disparate hematophagous arthropods in assays appropriate to their respective methods of host acquisition.

Arthropods in each assay were tested with fresh (unconcentrated) lemon peel exudate and with individual monoterpenes. Ticks in a repellent experiment were tested for their tendency to avoid a substrate treated with peel exudate or monoterpenes in order to assess how they respond when encountering a scent-laden host. Ticks in a toxicity experiment were tested for their motor performances and host-acquisition responses following confinement with these substances, as might occur when they infest a host's integument where the plumage or pelage traps volatiles. Mosquitoes in a feeding experiment were confined in a module with chemically treated membranes to evaluate their landing, feeding, and flying responses to peel exudate or monoterpenes. Finally, mosquitoes in an olfactometer experiment were presented with an airsteam containing these substances in order to assess their anemotactic responses.

Methods and Materials

Chemicals Arthropods in each assay were tested with a fresh exudate of an organically grown lemon, obtained by lacerating a 6×6 cm area of the peel with a razor blade and pressing the exuded fluid against the test medium. Organically grown kale (*Brassica oleracea*) (also lacerated) and blank (untreated) conditions served as controls.

Ticks and mosquitoes were tested for responses to the following compounds, which typically occur in citrus peels and/or leaves (Dugo et al., 2002; Lota et al., 2002): *p*-cymene, bisabolene, (+)-limonene, myrcene, α-pinene, ß-pinene, γ-terpinene, terpinolene, valencene, citral, citronellal, (−)-carveol, citronellol, geraniol, linalool, 4-terpinenol, α-terpineol, (+)-carvone, (−)-carvone, (+)- limonene oxide, (−)-limonene oxide, citronellyl acetate, geranyl acetate, and linalyl acetate. Compounds were dissolved in 0.05 M acetone solutions for feeding membrane tests with mosquitoes and 0.1 M solutions for assays with ticks; acetone alone served as a control. A previous study indicated that the chemical concentrations used in our tests were appropriate to distinguish the effects of different compounds (Kramer et al., 2009); the concentrations of compounds deposited on anointing animals are unknown, but they will vary with the materials used, the duration of anointing, and other factors.

Arthropods Ticks from a colony at the USDA, ARS, Knipling-Bushland U. S. Livestock Insects Laboratory, Kerrville, Texas, were maintained as described by Carroll et al. (2005) and Kramer et al. (2009). At the time of testing, ticks had been in the nymphal stage for 2–6 months.

Mosquitoes for membrane-feeding tests were maintained as described by Weldon et al. (2006). Adult nulliparous female mosquitoes (Liverpool strain), 5–16-d-old, were fed a 10% sucrose solution presented on cotton pads. The sucrose-soaked pads were replaced with water-moistened pads 48 h before testing. Mosquitoes (Orlando strain) for the olfactometer test were maintained as described by Kline et al. (2003). Bioassays were conducted up to four times per day (0700, 0900, 1100, and 1300 h). Female mosquitoes, 6–12-d-old, were a fed a sugar solution on cotton pads that were removed 1 h before testing.

Bioassays with Ticks

Avoidance Test We investigated repellency by exploiting the tendency of ticks to climb, a key host-seeking behavior, inducing them to crawl onto a chemically treated zone on paper strips (Kramer et al., 2009). Ticks were tested on 1× 8 cm strips of recycled bond paper marked at 1–6 cm intervals. In an experiment of the responses of ticks to lemon peel exudate, the paper strips were covered by a piece of tape up to the 2 cm mark. The lacerated area of a lemon peel was applied by manually pressing it against the strip above the 2 cm mark. Kale was applied similarly to paper strips; untreated strips served as an additional control.

In an experiment on the repellency of individual compounds, 12 µl of each solution or plain acetone were evenly applied by a micropipette to paper strips between the 2 and 6 cm marks (4 cm^2). The strips were air-dried for 1 min, and individual ticks confined in a moated Petri dish were touched with an untreated end of the paper strip and allowed to mount. The paper strip was suspended vertically from a bulldog clip positioned 20 cm from a light (275 W) that shone from behind the strip, thus allowing a tick on either side of the paper to be monitored. Ticks were scored for their latencies to cross the 2 cm (Q2), 3 cm (Q3), and

6 cm marks (Q6) on the strip; the number of times they backcrossed and recrossed the 2 cm mark (Qbc); and their latencies to drop off the strip (Qld). In our coding system, Q indicates that a variable is quantitative; all variables described above are quantitative (see Kramer et al., 2009 for details). Most quantitative variables are associated with an indicator variable, 1 if the behavior was performed, and 0 otherwise (in our coding system 'Q' is replaced by 'I' to denote these indicator variables). Sessions were concluded when ticks passed the 6 cm mark, when they dropped from the paper strip or after 10 min had elapsed.

Righting and Climbing (R/C) Test We investigated toxicity by examining the R/C performances of ticks, including their ability to access a human finger, after being confined for 1 h with lemon peel exudate or test compounds (Carroll et al., 2005). A 5×6 cm rectangle of filter paper (Whatman No. 4) was marked with a lead pencil 0.5 cm from the edge. Using a pipettor, 165 μl of a test solution or acetone were applied evenly within the 4×5 cm rectangle bordered by pencil lines. After allowing the paper to air-dry for 10–15 min, it was folded crosswise, and a bulldog clip was attached to each of two margins. Eight ticks were dumped from a centrifuge tube (4 mm inner diam., truncated to 3.5 cm long, inner side coated with Fluon™) into the cavity formed by folding the paper, and another bulldog clip was attached to the open end of the packet to enclose the ticks. The packets were kept for 1 h in a glass desiccator containing water below the shelf to maintain humidity (>95%).

Immediately after a packet was opened, each nymph was placed on its dorsum on a clay substrate, which supported a vertical filter paper cylinder (diam. 3.2 cm; height 3 cm) embedded 3 mm in the clay and encircling the tick. The latencies for each tick to right itself (Qr) and climb to the top of the cylinder (Qt) were recorded. Test sessions ended after 15 min, whereupon the location of each tick (Qloc) on the bottom (recorded as 0), lower side (0.33), upper side (0.67), or on rim or outside the cylinder (1) was noted.

Following these motor performance tests, the ability of ticks to access a host was examined. One of us (J.C.) positioned the tip of his left forefinger 1–2 mm from the anterior of a (motionless or crawling) tick at 45° to its right. The tick was allowed 5 sec to climb onto the fingertip. If it failed to do so, the procedure was repeated with the right finger positioned 45° to the tick's left. If the tick still failed to climb onto the fingertip, the left and right forefingers were again proffered. Each tick had a final opportunity to climb onto the experimenter's left finger, which was placed directly in front of the tick. We scored whether a tick climbed onto a finger (Ih) and the number of trials until a tick climbed onto a finger (Qth).

Morbidity and Mortality Immediately after the R/C test, ticks were placed into a plastic vial and returned to their standard maintenance regime. At 24 h after exposure in the filter paper packet, ticks were observed in a moated Petri dish to assess survivorship. Ticks consistently moving in an uncoordinated manner and a distance of <5 mm were considered moribund. Ticks that failed to move after 5 min in the Petri dish, even when exhaled upon or prodded with forceps, were considered dead. In our analysis, we combined dead and moribund ticks because neither category poses a risk to hosts.

Statistical Methods Data were analyzed as described by Kramer et al. (2009). The basic idea was to use the behavioral differences observed as animals are tested on different compounds to find optimal weightings of these behaviors (i.e., that best discriminate among the compounds) using canonical discriminant analysis. Compounds where animals behave similarly will produce similar composite scores, whereas those compounds that induce different behaviors will produce different scores.

Time variables were square-root transformed. In addition to variables that measure duration or counts of behaviors, indicator variables were created with a value of 1 if the behavior was performed, and 0 if not. This was done so that all variables could be included in the analysis, even if not performed by all individuals. A composite score was created for individual ticks (or, for mosquitoes, a group of five mosquitoes in the chamber, described below). Useful variables to create the score were determined in a stepwise discriminant selection procedure. The composite scores we created used only the first of these canonical discriminant functions, which consisted of the sum of these variables with weights (referred to as 'loadings') from the first axis that best separated the compounds. Because the composite scores for each compound were not normally distributed, we used the non-parametric *a posteriori* Kruskal-Wallis procedure to determine which compounds differed from the acetone control and from each other. We calculated the median score and 16 and 84% quantiles for each compound. This calculation gives 68% percent coverage, so, had the data been normally distributed, these quantiles would be approximately one standard deviation on each side of the mean.

The results of the lemon, kale, and blank tests were included in the data when creating the composite score because we wanted these tests to be on the same scale as that used for the citrus compound scores, but they were analyzed separately for significant differences (i.e., after the composite scores were created, the data were split into two subsets for the Kruskal-Wallis significance tests). The reason for this is that the controls for the two subsets differed; for the lemon exudate, it was kale and blank; for the citrus compounds, it was acetone.

Two sets of analyses were conducted. One set of tick results measured avoidance, i.e., failure to enter and remain in a chemically treated zone. The other measured toxicosis, as reflected in impaired motor performance/host acquisition. The Pearson correlation between these two sets of results was calculated.

Bioassays with Mosquitoes

Membrane-Feeding Test We investigated landing and feeding responses of mosquitoes to chemically treated, artificial feeding membranes, as generally described by Weldon et al. (2006). The test apparatus was a two-piece Plexiglas module. The bottom piece was a 40×7×4 cm hollow platform supporting six circular wells (diam. 3.8 cm, depth 6 mm). Water (40°C) flowed through the central cavity of the platform. The top module piece consisted of six 4.5×4.0×5.0 cm chambers, each with a sliding floor positioned over a circular opening (diam. 3.5 cm).

The wells of the bottom piece were filled with 7 ml of a 10% sucrose solution containing ATP (2.9 mg/ml) to which 75 µl of green dye were added. In an experiment of the responses of mosquitoes to lemon peel exudate (previously reported in Weldon and Carroll 2007), a lacerated peel was pressed against a nylon-reinforced silicone membrane (0.1 mm-thick); kale-treated and blank membranes served as controls. Membranes were placed over the wells. In an experiment with individual compounds, 50 µl of a monoterpene solution or acetone were applied to membranes.

For each test session, five mosquitoes were aspirated into each of 2 or 3 chambers (depending upon the experiment) of the top module piece. The sliding floors of the chambers then were opened, allowing mosquitoes access to the membranes. The number of mosquitoes landing on the membranes, and those flying within the apparatus, were recorded each minute for 5 min. After 5 min, any mosquitoes remaining on the membranes were prodded off with a metal wire, and the sliding floor of each chamber was closed. The top piece of the module was placed into a freezer for 20 min. Mosquitoes were removed from the frozen module, crushed on white paper towels, and examined for the presence of green dye, which indicated that they had fed during a test.

Olfactometer Test We investigated the responses by mosquitoes to citrus volatiles when presented concurrently with an artificial attractant. A stock attractant solution was prepared by dissolving 0.6 g of L-(+)-lactic acid and 100 µl dimethyl disulfide in 250 ml of acetone (Bernier et al., 2007b). Two aliquots of 500 µl of this solution were pipetted into two 1.4 ml plastic vial caps (15 mm i.d. x 9.5 mm height). A 50 µl aliquot of each test compound was delivered by pipet into a smaller vial cap (9 mm i.d.×9 mm height, total capacity 400 µl). Each cap containing the attractant blend was placed on separate aluminum trays (7 x 13 cm) constructed to hold the vials. The vial cap containing the test compound was added to one of the trays.

Mosquitoes were tested in a triple-cage dual-port olfactometer to assess the relative attraction or attraction-inhibition, i.e., "repellency" (Posey et al., 1998). Each cage of the three stacked cages consists of a single unit in which a trial was conducted. In each trial, mosquitoes could remain in the cage or fly into one of the two ports containing the treatments. The test compounds were examined in a competitive bioassay, where two treatment combinations were compared (attractant blend vs. attractant blend+candidate repellent); a "blank" or "control" conditions were not used in this case.

Air for the olfactometer was drawn from outside the laboratory, and filtered, cooled, heated, and humidified or dehumidified to achieve the desired conditions for air temperature and humidity. For experiments, the air flow was 28±1 cm/sec with a temperature of 27±1°C and 60±5% RH. Approximately 75 mosquitoes were transferred to each test cage from a trap after preferential selection of host-seeking females by using a hand-draw box. Mosquitoes were loaded and allowed to acclimate in each cage of the olfactometer for 45–60 min prior to each test. During this period, the port doors were opened slightly to allow a low flow of air to pass through the ports and into the cages.

Treatment order, time of day, and ports and cages used were randomized for these trials. A total of six replicate trials was made for each treatment combination, such that each combination order was tested once in each of the two ports for each of the three cages. At the initiation of a trial, the door was opened to allow mosquitoes access to both ports of a cage. Mosquitoes trapped in each of the ports and those remaining in the cage were counted after each 3-min bioassay.

Statistical Methods For the membrane-feeding tests, data were analyzed using the methods described by Kramer et al. (2009). There were three variables collected from each five-mosquito chamber used to create the composite score. The flying counts (variable 1) were summed [total possible was 25=5 mosquitoes x 5 min (tallied each minute)] and the total count was divided by 25, with the resulting proportion arcsine transformed. The number of mosquitoes landing on the membrane (variable 2) were handled the same way. The number of mosquitoes landing elsewhere in the module at each minute was not used (to preserve independence, since the sum of the three tallies would always yield 25). The proportion of feeding mosquitoes (variable 3) also was arcsine transformed (6 possible proportions). The resulting composite scores (one score per module unit of 5 mosquitoes) were tested for compound

differences using the *a posteriori* Kruskal-Wallis method, and medians and 16 and 84% quantiles were calculated.

For the olfactometer tests, mosquitoes at the 3-min tally were either at one of the two ports or elsewhere in the cage. Thus, the data are multinomial in nature (counts in three categories). These multinomial counts could be affected by several variables, such as which treatment was present in which port, and environmental factors, such as temperature (some of these are rolled into a proxy "day" effect). Preliminary analysis of the data revealed a "day" effect for the number of mosquitoes that did not enter either port. Much of the variability in the proportions of mosquitoes entering one of two ports, based on the total number released into the olfactometer for that trial, could be removed by using instead a proportion based on only those mosquitoes that entered a port rather the total released; this is the proportion used (on the arcsine transformed scale) in the analysis. There also was a significant overall bias toward one of the ports; this was adjusted statistically by estimating the bias and subtracting its effect. Other potential variables did not appear to affect the proportions of interest. To be consistent with the other analyses, we used the Kruskal-Wallis method for determining differences among compounds, based on adjusted arcsine-transformed proportions, with the denominator of each proportion being the sum of the counts of mosquitoes at the two ports (typically between 50 and 80).

Results

Ticks The loadings of individual tick behaviors used in constructing the composite scores, and the mean separations for avoidance and the R/C test data, using all compounds are given in Table 1.

For the avoidance test, nine behaviors were deemed important for constructing the discriminant function (Table 1); the one dimension used captured 83% of the explainable variation. The most salient behavior contributing to the composite score was recrossings (Ibc, partial R^2=0.70); the next two were drop-offs (Ild, partial R^2=0.27) and latency to cross the 3 cm mark (Q3, partial R^2=0.24). Most compounds could be placed into one of two groups, those with low mean scores that were similar to the acetone control, and those with high scores, e.g., geraniol (Fig. 2). A few compounds had intermediate scores, e.g., citronellal and linalool. The axis appears to order compounds by their repellency, as desired.

For the R/C test, six behaviors were used to construct the discriminant function (Table 1). The two most important behaviors were location at end of the session (Qloc, partial R^2=0.30) and righting (Ir, partial R^2=0.20). We used only the first dimension for this score, which captured 57% of the explainable variation (the second axis, which captured about 26% of the explainable variation, separated carveol from all compounds except ß-pinene, but carveol already is well separated in the first axis) (Fig. 3). The compounds overlap considerably on the first axis, from low scores, such as those for ß-pinene and acetone, to those for the most effective compounds, such as geraniol and carveol. Only carveol impaired righting; only one tick righted after exposure to this compound. We interpret this axis to represent the differential effects of the compounds on motor performance.

Most compounds avoided by ticks also had high composite scores on the R/C test (indicating impairment),

Table 1 Loadings for tick behaviors used in constructing composite scores for repellent and righting/climbing bioassays. '*Q*' indicates that the variable is quantitative, '*I*' that it is indicator (0 or 1)

Variable Repellent Bioassay (Code)	Loading
yes/no passed the 2 cm mark (I2)	−3.616
latency to pass the 2 cm mark (Q2)	0.198
yes/no recrossed 2 cm mark (Ibc)	2.302
number recrossings of 2 cm mark (Qbc)	0.461
yes/no passed the 3 cm mark (I3)	−1.286
latency to pass the 3 cm mark (Q3)	0.128
yes/no dropped off filter paper (Ild)	2.356
latency to drop off filter paper (Qld)	−0.099
yes/no passed the 6 cm mark (Ib)	−0.654
Variable Righting/Climbing (Code)	
location (base, upper or lower side, rim) at 15 min (Qloc)	1.161
yes/no righted itself (Ir)	0.102
latency to climb to rim (Qt)	−0.001
yes/no climbed to rim (It)	1.029
yes/no climbed onto fingertip (Ih)	1.316
number of host acquisition attempts (Qth)	−0.251

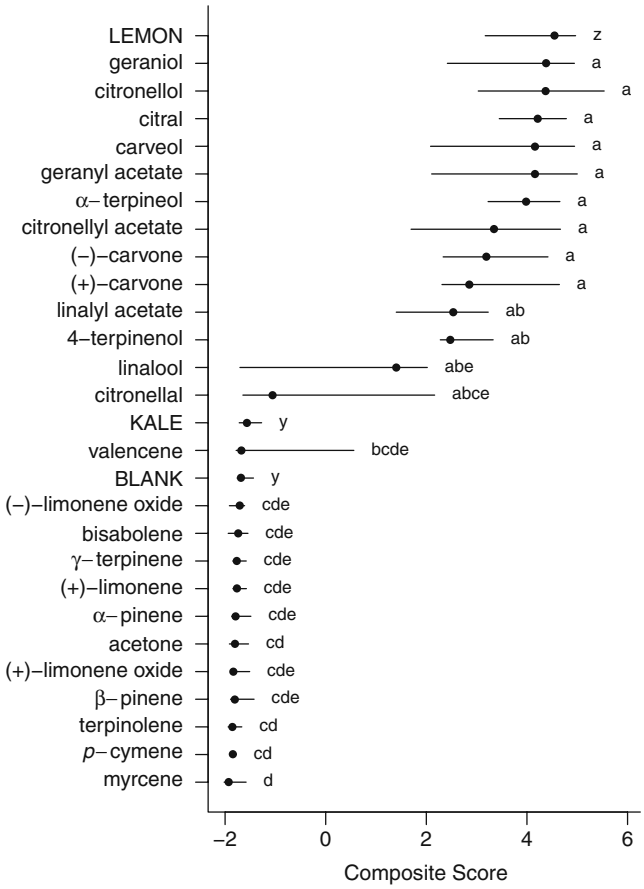

Fig. 2 Rankings of citrus compounds by composite score of five behaviors of lone star ticks to the treated portion of filter paper strips. The median scores and 16% and 84% quantiles (horizontal bars, approximately ± 1 SD) are shown. Compounds with the highest scores most repelled ticks. Note lemon and kale are exudates. Compounds with the same letters (following the horizontal bars) do not differ significantly in their effects on tick behavior. There is a separate set of letters (y and z) for plant exudates and blank

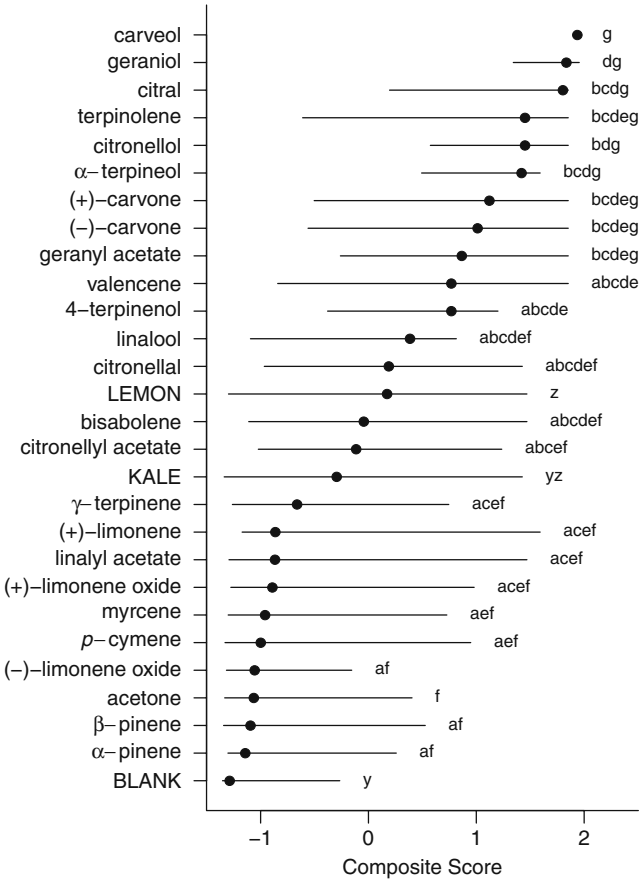

Fig. 3 Rankings of citrus compounds by composite score using righting, climbing, and crawling onto finger by lone star ticks following 1 h confinement in filter paper packet treated with test solution. The median scores and 16% and 84% quantiles (horizontal bars, approximately ± 1 SD) are shown. Compounds with the highest scores most impaired ticks. Note lemon and kale are exudates. Compounds with the same letters (following the horizontal bars) do not differ significantly. There is a separate set of letters (y and z) for plant exudates and blank

as depicted in the scatter plot in Fig. 4; the correlation coefficient of the two sets of composite scores is 0.72 ($P<0.01$). Linalool, linalyl acetate, and citronellyl acetate were avoided but did not impair behavior. Two compounds, terpinolene and valencene, appeared to impair R/C behaviors, but were not avoided. Terpinolene was the only compound for which the impairment of ticks was manifest 24 h after exposure, with 75% of subjects moribund and 17% dead.

Mosquitoes The responses by mosquitoes to nine of the compounds in the membrane-feeding tests were statistically indistinguishable from those to the acetone control. The others had composite scores that differed from the acetone control; 12 compounds/isomers had similar high scores (these are followed by "d" or "de" in Fig. 5). All of the alcohols occurred in this group, as did both isomers of limonene oxide.

In the olfactometer test (Fig. 6), responses only to linalool ("repellent") and two compounds, citronellal and γ-terpinene ("attractants"), differed significantly ($P<0.05$) from each other. Most of the compounds had at least one trial proportion on each side of the 50% (inactive) line, and did not differ ($P>0.05$) from other compounds.

Results from the membrane-feeding test and olfactometer test had essentially no relationship to each other (Fig. 7, Pearson correlation=−0.219, $P=0.28$).

Discussion

Lone star ticks in our study avoided lemon peel exudate and, after confinement with it, exhibited impaired climbing behavior. These responses are consistent with the deterrence of ticks by citrus-derived chemicals applied via anointing, as are our results with a number of compounds we tested.

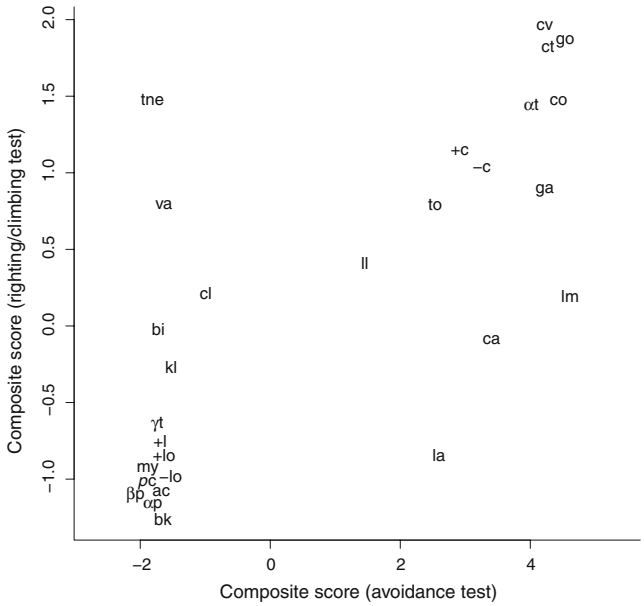

Fig. 4 Scatterplot of composite scores from avoidance (repellent) test and from righting/climbing (motor impairment) test for lone star ticks. Compounds tested were *p*-cymene (*p*c), bisabolene (bi), (+)-limonene (+l), myrcene (my), α-pinene (αp), ß-pinene (βp), γ-terpinene (γt), terpinolene (tne), valencene (va), citral (ct), citronellal (cl), (−)-carveol (cv), citronellol (co), geraniol (go), linalool (ll), 4-terpinenol (to), α-terpineol (αt), (+)- carvone (+c), (−)-carvone (−c), (+)- limonene oxide (+lo), (−)-limonene oxide (−lo), citronellyl acetate (ca), geranyl acetate (ga), and linalyl acetate (la). Most compounds displayed similar rankings in the two tests, with some exceptions (e.g., terpinolene, "tne", impaired motor performance but was not avoided). Note lemon (lm) and kale (kl) are exudates. Compound codes that overlapped were moved slightly apart for readability

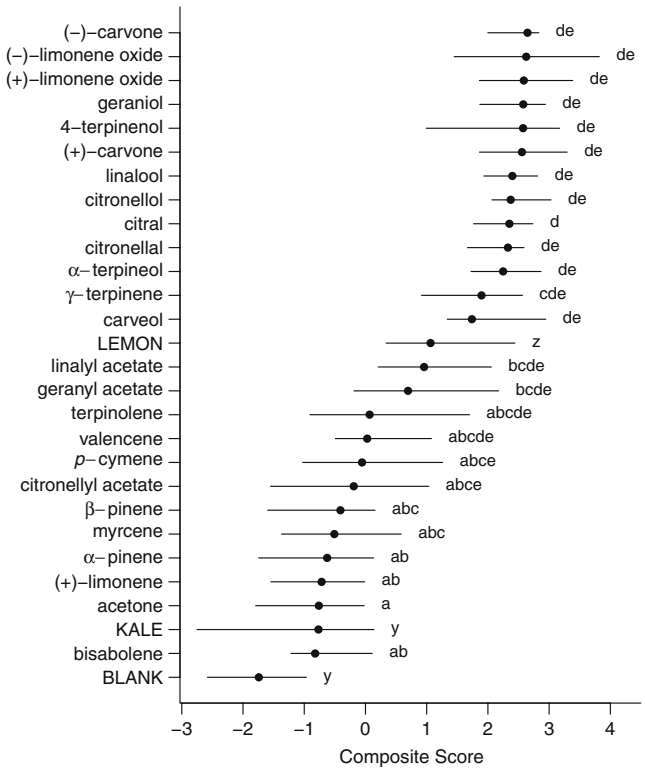

Fig. 5 Rankings of citrus compounds by composite score, using flying, landing, and feeding by yellow fever mosquitoes confined in module containing sucrose solution covered by a membrane treated with test solution. The median scores and 16% and 84% quantiles (horizontal bars, approximately ± 1 SD) are shown. Compounds with the highest scores most inhibited landing and feeding, and elicited flying. Note lemon and kale are exudates. Compounds with the same letters (following the horizontal bars) do not differ significantly in their effects on mosquito behavior. There is a separate set of letters (y and z) for plant exudates and blank

Previous studies on the responses by ectoparasitic acarines to the monoterpenes we examined focus chiefly on mortality. Four monoterpenes tested against the ear mite (*Otodectes cynotis*) exhibited the following order of miticidal potency: geraniol > limonene > *p*-cymene > α-pinene (Traina et al., 2005). A structure-activity study of the contact and fumigation toxicities of 13 monoterpenes against the mange mite (*Psoroptes cuniculi*) indicated mortalities at or near 100% for most doses of geraniol, linalool, α-terpineol, and 4-terpinenol, but failed to indicate limonene, myrcene, or γ-terpinene as toxic; linalyl acetate exhibited intermediate toxicity (Perrucci et al., 1995). The observation of Perrucci et al. (1995) that alcohols are the best miticides against mange mites, and that hydrocarbons are least effective, is consistent with our toxicity results with lone star ticks, where carveol was the most toxic compound, and α- and β-pinene were among the least toxic. Interestingly, a study of the mortality of the southern cattle tick (*Rhipicephalus* [*Boophilus*] *microplus*) to monoterpenes indicated the following order of efficacy: citronellol > α-pinene = β-pinene > linalool (Prates et al., 1998).

The monoterpenes we tested with the lone star tick have been tested as repellents with other tick species. Valencene and 4-terpinenol repelled the blacklegged tick (*Ixodes scapularis*), but not as effectively as did some other terpenes examined (Dietrich et al., 2006). Citronellol, geraniol, α-terpinenol, 4-terpinenol, and α-pinene repelled nymphs of the sheep tick (*Ixodes ricinus*) (Thorsell et al., 2006; Tunón et al., 2006; Pälsson et al., 2008), but linalool was ineffective (Tunón et al., 2006; Del Fabbro and Nazzi, 2008). The cattle tick (*Rhipicephalus appendiculatus*) also was repelled by geraniol and α-terpineol, and, to some extent, myrcene (Ndungu et al., 1995; Lwande et al., 1999). In our study, alcohols—geraniol, citronellol, carveol, and α-terpineol—were among the most potent repellents (see also Kramer et al., 2009). Citral, geranyl acetate, citronellyl acetate, and carvone also were strongly avoided. On the other hand, hydrocarbons, including myrcene and *p*-cymene, were least repellent. Thus, the compounds that most repel our ticks also are most toxic to them, although exceptions

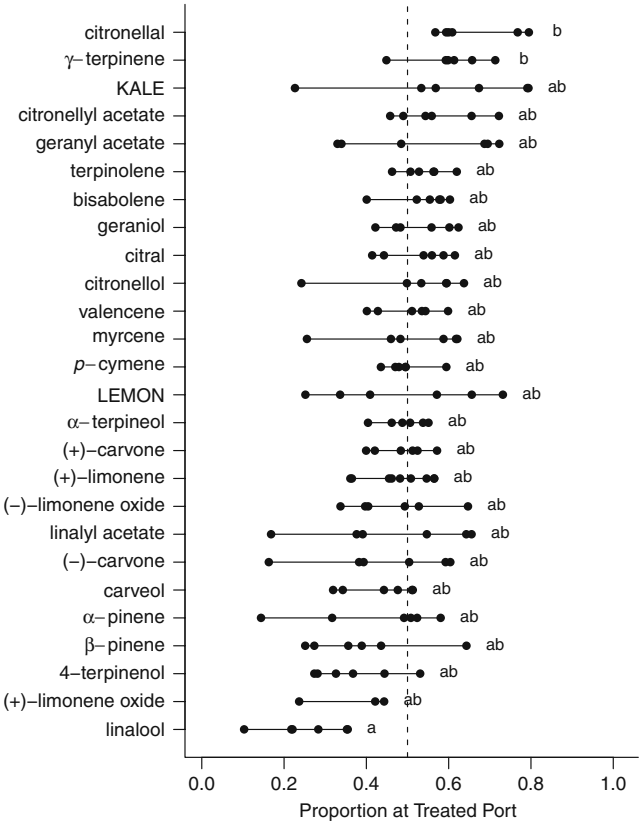

Fig. 6 Proportion of yellow fever mosquitoes at olfactometer port with test compound + attractant blend. Mosquitoes could enter the port with attractant blend only, the port with attractant blend + test compound or remain elsewhere in the olfactometer. The proportions shown are based on only numbers of mosquitoes at the ports at 3 min. Each circle represents the results from one trial. For ease of interpretation, a line connects the results of each of the trials of a compound. Note lemon and kale are exudates. Compounds with the same letters (following the horizontal bars) do not differ significantly in their effects on mosquito behavior. A central dotted line at 0.5 indicates an equal tendency to enter either port. Points further from the line denote greater attractiveness (*right*) or repellency (*left*) of the compounds

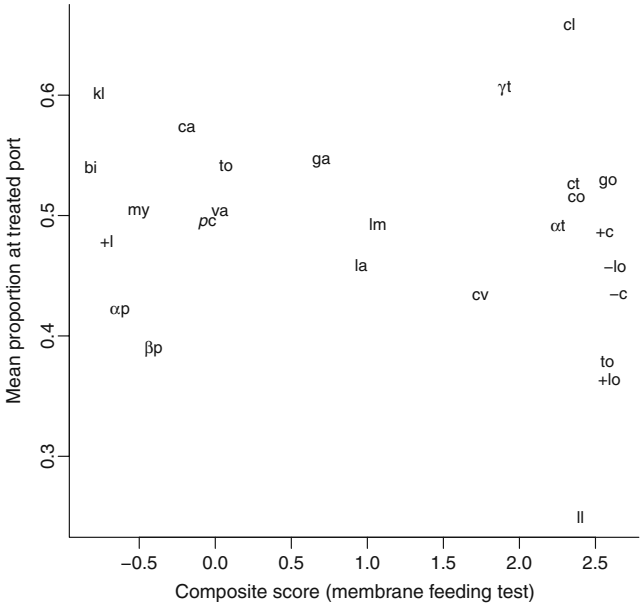

Fig. 7 Scatterplot of composite scores of yellow fever mosquitoes from membrane-feeding test and mean proportion at treatment port from olfactometer test. Results for the two tests appear unrelated. Compounds abbreviated as in Fig. 4. Note lemon and kale are exudates. Compound codes that overlapped were moved slightly apart for readability

occur, e.g., terpinolene, which was not avoided but did impair motor performance.

Mosquitoes in our module tests landed and fed least, and flew most, when confined with lemon peel exudate versus kale and blank controls. These results were interpreted to reflect repellence by lemon peel volatiles (Weldon and Carroll, 2007). In our olfactometer, however, lemon peel exudate did not appear to affect mosquito behavior when the insects were presented concurrently with the artificial attractant solution. Moreover, the application of fresh lemon peel exudate to the arm of a human subject (P.J.W.) failed to deter biting by yellow fever mosquitoes. Buckley (1983), who reported that white-faced capuchin monkeys in Honduras fur-rub with oranges and grapefruit, also failed to sustain fewer bites by deer flies (*Chrysops* sp., Tabanidae) when he applied orange peel exudate to himself.

Some of the monoterpenes we tested, such as *p*-cymene (Choi et al., 2002; Park et al., 2005; Waliwitiya et al., 2009), carvone (Vartak and Sharma, 1993), citral (Hao et al., 2008), citronellal (Waliwitiya et al., 2009), geraniol (Hao et al., 2008; Müller et al., 2009), terpineol (Traboulsi et al., 2005), and linalool (Choi et al., 2002; Park et al., 2005), have been reported to repel adults of some mosquitoes. Tests of yellow fever mosquitoes often have indicated the greater repellency of alcohols, aldehydes, and related compounds compared to hydrocarbons (Hwang et al., 1985; Zaki et al., 2005), thus supporting Bunker and Hirschfelder's (1925) early observation on the greater overall efficacy of oxygenated compounds as mosquito repellents. Our olfactometer results confirmed Kline et al.'s (2003) result that linalool strongly repels yellow fever mosquitoes, but the olfactometer test did not discriminate among compounds as well as did the module assay; there was no correlation between the results of these two assays.

Higher concentrations of volatiles undoubtedly were presented to mosquitoes in the module than in the olfactometer, both in tests with lemon peel exudate and individual compounds. Some of these volatiles, even those that in low doses attract mosquitoes, may repel them at high concentrations (Bernier et al., 2007a; Butler, 2007). Aside from the likely concentration differences of volatiles in the assay systems, the disparity in the results of our mosquito assays may be due to the kind of data collected and how

they were analyzed. The olfactometer test scored only one binary behavior variable, and this behavior is related to anemotaxis toward an attractive odor source; the membrane system measured close-range deterrence, which may reflect "repellency." Moreover, the membrane-feeding test scored three behaviors per unit (five mosquitoes), then combined them into a composite score by a weighted summation, with weights to produce scores that separate the compounds; this more sensitive test demonstrated that mosquitoes discriminated among our compounds.

More fundamentally, it is unclear that the module assay applied to mosquitoes distinguishes between compounds that deter landing (as repellents) and those that elicit sustained flight, as by triggering upwind attraction. To clarify this issue, a range of compounds that have well characterized behavioral effects on mosquitoes needs to be tested in assays that distinguish between repellence and flight stimulation.

Some authors focus on limonene in citrus and other plant extracts as a prime deterrent of ticks (Chungsamarnyart and Jansawan, 1996), mosquitoes (Gillij et al., 2008), or arthropods in general (Ibrahim et al., 2001). Limonene in our study did not emerge as a potent deterrent of either ticks or mosquitoes. Nonetheless, limonene in citrus fruits may contribute to deterring some arthropods by virtue of its abundance; it comprises >90% of the volatiles of some citrus extracts (Dugo et al., 2002). In addition, limonene applied to the integument of anointed animals may be oxidized on the high surface area of the pelage or plumage into more active agents, such as carveol (Karlberg et al., 1992), which was highly repellent and toxic to our ticks. Similar chemical transformations may occur for other components present in citrus and other anointing materials, thus rendering deterrents from ineffective compounds.

Conjecture on the importance of vertebrate anointing as a defense against hematophagous arthropods should consider the availability of anointing materials in nature. *Citrus* spp. originated in Southeast Asia and were transported to America by Portuguese and Spanish conquistadores during the early 1500s (Calabrese, 2002). Citrus trees now are widespread in the New World, but they occur chiefly in cultivated regions, thus they may not be encountered routinely by free-ranging animals. For example, white-faced capuchin monkeys in a region of Honduras devoid of citrus trees were observed to fur-rub only with fruits acquired from humans (Buckley, 1983). The monoterpenes we examined may occur in other materials used for anointing. It is worth noting that some ants, including those used by birds in anointing, such as *Acanthomyops* spp. and *Lasius* spp. (Whitaker, 1957), defensively discharge citral, citronellal, citronellol, and related compounds (Blum, 1981).

Falótico et al. (2007) suggested that tufted capuchin monkeys (*Cebus apella*) anoint with ants in order to acquire formic acid and other topical deterrents of tick nymphs. Similary, DeJoseph et al. (2002) suggested that white-faced capuchin monkeys anoint with plants, including citrus fruits, to combat lice, mites, and ticks. Ticks may be especially vulnerable to topically applied chemicals because they engage in protracted feeding on the integument of hosts (Carroll et al., 2005).

Acknowledgments USDA, ARS, Knipling-Bushland U. S. Livestock Insects Research Laboratory, Kerrville, Texas, provided ticks used in the study. G. Allen, N. Elejalde (Center for Medical and Veterinary Entomology, USDA, ARS, Gainesville, Florida), J. P. Benante, W. Dheranetra, M. Dowler, L. Jones, N. McLean-Cooper, J. R. Murphy, E. Rowton, and J. Williams (Walter Reed Army Institute of Research, Silver Spring, Maryland) assisted with studies of mosquitoes. K. Bagnall (Jungle Friends, Gainesville, Florida), C. F. Cranmore (Tri-Lakes Veterinary Clinic, Mount Pleasant, Texas), and K. Perkowska (Kenner, Louisiana) permitted animals in their care to be photographed. J. Greff (Tonal Vision, LLC, Baltimore, Maryland) prepared Fig. 1. M. P. Fiedler (Gorgas Memorial Library, Walter Reed Army Institute of Research, Silver Spring, Maryland) provided needed references. J. Forbey and D. Strickman commented on the manuscript, and D. Clayton, L. Durden, and J. Weckstein provided valuable discussions. D. Heard and P. and F. Leibe extended numerous courtesies.

RAPID COMMUNICATION

The Biosynthesis of Hexahydrofarnesylacetone in the Butterfly *Pieris brassicae*

Stefan Schulz · Selma Yildizhan · Joop J. A. van Loon

Received: 18 February 2011 / Revised: 18 March 2011 / Accepted: 22 March 2011 / Published online: 5 April 2011
© Springer Science+Business Media, LLC 2011

Abstract Hexahydrofarnesylacetone (6,10,14-trimethylpentadecan-2-one, **1**) is a widespread ketone occurring in plants and insects. Several species use this compound or the respective alcohol as part of their pheromone bouquet. Here, we showed by using deuterium labeled phytol (**3**) and GC-MS experiments that the Large Cabbage White butterfly *Pieris brassicae* can take up phytol in the larval stage and transforms it into **1** by oxidative degradation.

Key Words Biosynthesis · Pheromone · Labeled compounds · Terpenes

Introduction

Hexahydrofarnesylacetone (6,10,14-trimethylpentadecan-2-one, phytone, HHFA, **1**), is a relatively common natural product, occurring in many plants, often as part of the floral odor bouquet, and in several insect species (Schulz et al., 1993; Schulz and Nishida, 1996; Vendilo et al., 1998; Sasaerila et al., 2003; Kalinova et al., 2009). Closely related is the corresponding alcohol, 6,10,14-trimethylpentadecan-2-ol that occurs in the pheromone gland of several Lepidoptera (Mori et al., 1991; Sasaerila et al., 2003; Nieberding et al., 2008). Recently, Eltz et al. (2010) showed that Orchid bees are attracted to the (*R*,*R*)-enantiomer of **1**, produced by many orchids, and store this compound in their tibial fragrance. These authors also established the absolute configuration of insect-derived **1** for the first time. We have found that *Pieris* butterflies use **1** as a component of the aphrodisiac pheromone of the males (Yildizhan et al., 2009). Hexahydrofarnesylacetone is a known degradation product of (*E*)-phytol (**3**), a diterpene alcohol that occurs as a side chain of chlorophyll a in all plants. This degradation proceeds abiotically by oxidative processes. Nevertheless, the biogenic formation of **1** has not been studied before. Different plausible biosynthetic routes exist to this ketone. An enzymatic oxidative cleavage of **3** could lead to **1**. Alternatively, oxidative degradation of the tetraterpene and carotenoid precursor lycopersene or related compounds, and reduction of the respective double bonds also would lead to **1**. Finally, degradation of tocopherol, which is produced by green plants and commonly found in plant feeding insects, could furnish **1** in the end. In this communication, we show that **1** is indeed directly derived from **3,** and is synthesized by the Large Cabbage White, *Pieris brassicae*.

Methods and Materials

Analytical Methods GC/MS analyses were performed as follows: an HP 6890 GC was coupled with an HP 5973 mass selective detector, splitless injection, BPX-5 column (SGE), 60–320°C, 5°C/min. In nuclear magnetic resonance (NMR) experiments, a DRX-400 (400 MHz, Bruker) instrument was used.

Synthesis of Compounds A 3:1 mixture of D-labeled (*E*)- and (*Z*)-**3** was obtained from **1** (Fig. 1a). An H/D exchange

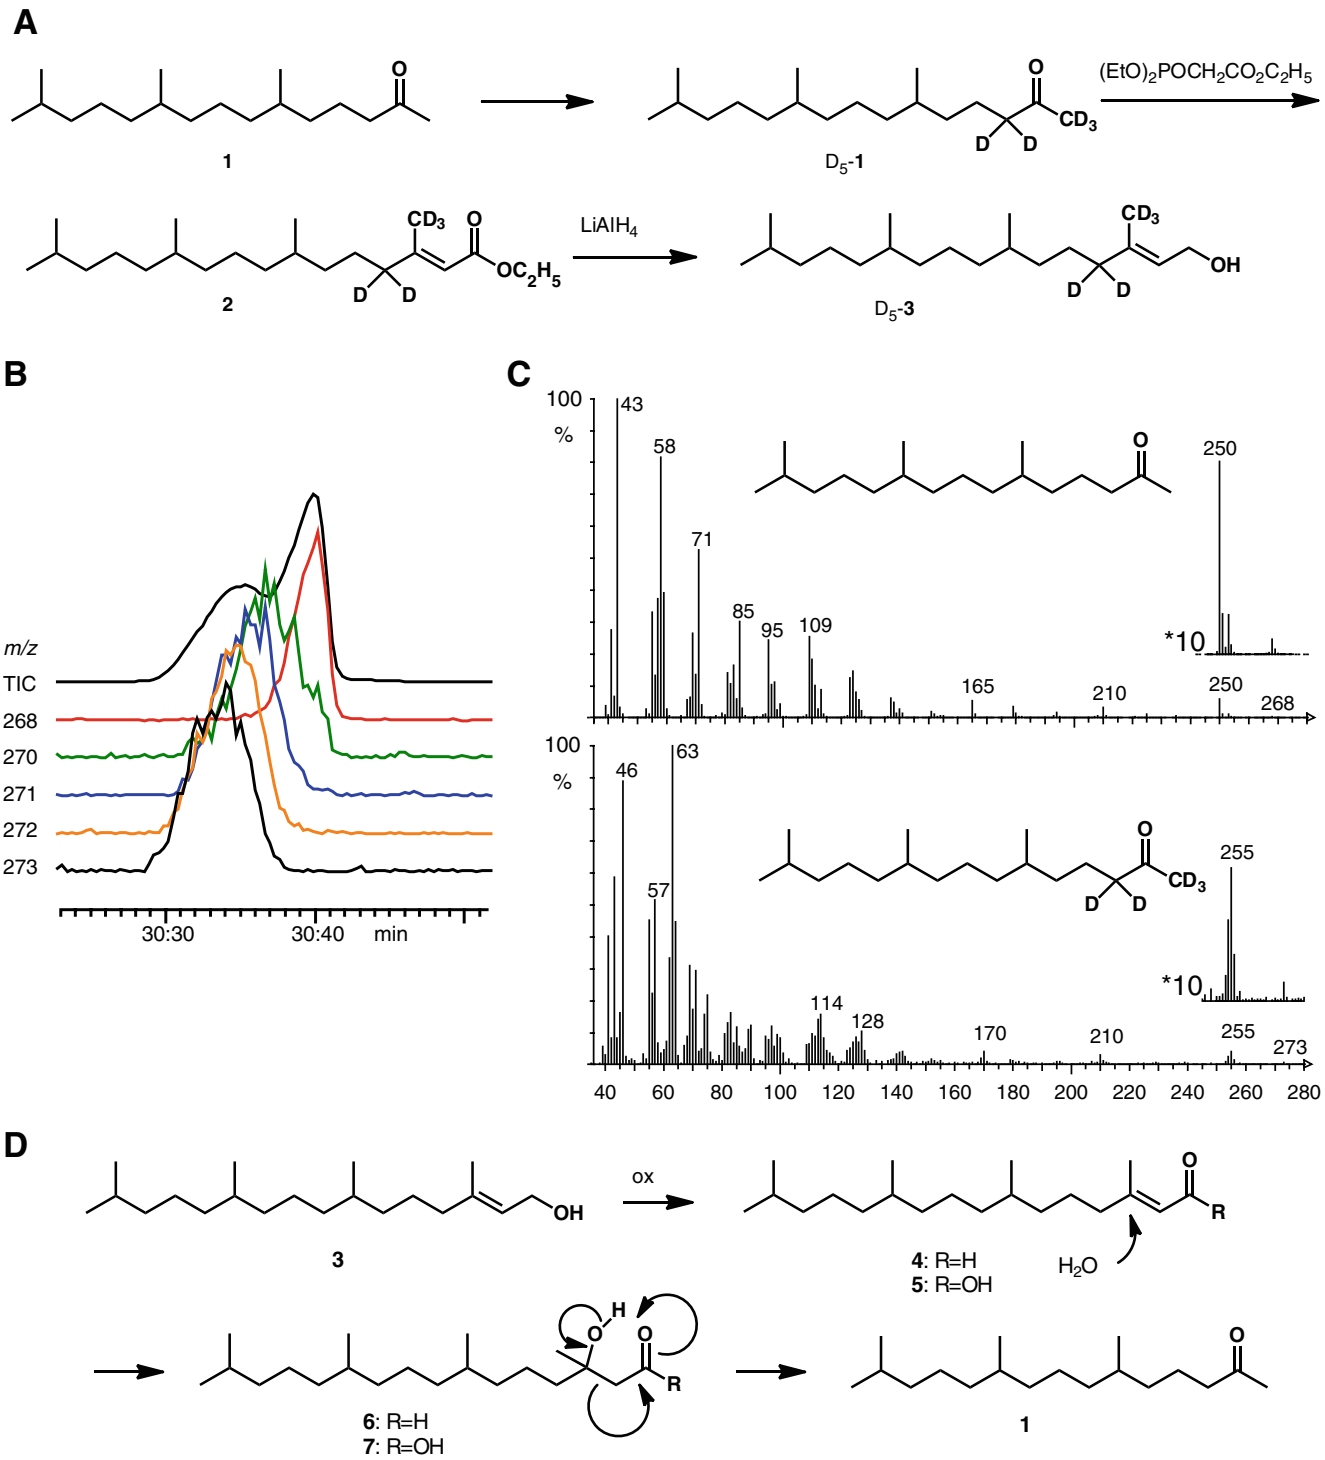

Fig. 1 **A**: Synthesis of deuterated phytol. **B**: Total ion chromatogram with ion traces of molecular ions of the different isotopomers of **1** from an extract of wings of male *Pieris brassicae* after feeding the larvae with D_5-**3**. **C**: Mass spectra of **1** and D_5-**1**, obtained in the feeding experiments. **D**: Proposed biosynthetic pathway from **3** to **1** in *P. brassicae*

at the α-positions next to the carbonyl group was performed under basic conditions with NaH/CH_3OD. The thus obtained 1,1,1,3,3-D_5-**1** was transformed into a mixture of ethyl (*E*)- and (*Z*)-phytoenoate (**2**) by a standard Horner-Wadsworth-Emmons reaction with triethyl phosphonoacetate. This ester was reduced finally with $LiAlH_4$ to give D_5-phytol (**2**), and purified by column chromatography. The analysis of the product revealed that the D-exchange was not complete, but sufficient for our experiments. The ratio of the different isotopomers D_0:D_1:D_2:D_3:

D_4:D_5 was 4:4:8:22:35:27. D-**3**: ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.34 (t, 1H, H-2), 4.08 (d, 0.75H, *E*-H-1), 4.05 (d, 0.25H, *Z*-H-1), 1.0–1.6 (m, 22H), 0.79 (d, 6H), 0.78 (d, 3H), 0.76 (d, 3H).

Feeding Experiments Pieris brassicae fifth instar caterpillars were obtained from a laboratory colony reared on greenhouse-grown *Brassica oleracea* L. var. *gemmifera* cv. Cyrus (Sluijs & Groot, Enkhuizen, The Netherlands), in climate controlled rooms at 22°C ±2°C, 50% RH, 16:8 hL:D. Caterpillars were put singly into Petri dishes when they had reached a body weight of ca. 450 mg, as this indicates that feeding will cease within a few hours to be followed by the wandering phase and formation of the prepupa. Individuals were offered a leaf disk of *B. oleracea* on which a solution of labeled phytol in 5% ethanol in water was surface-applied (1 mg phytol per leaf disk). After the leaf disk was fully consumed, caterpillars were deprived of food and kept in the dish until pupation. Pupae were sexed and male pupae were mounted in a cage for eclosion. Males were kept for 5 d in a cage provided with a 10% solution of sucrose in tap water, after which their wings were dissected and immediately extracted with 100 L dichloromethane for 10 min using stainless steel forceps.

Results

Deuterium-labeled phytol (**3**) was synthesized starting from **1** by H/D-exchange under basic conditions. By this approach, the label is in positions that will not be affected by the proposed transformation of phytol. The labeled **3** then was fed to *P. brassicae* larvae, and the wings of the resultant adult males were extracted. Analysis of the extract by GC-MS showed the presence of deuterium labeled isotopomers of **3** in a roughly 1:1 ratio to the unlabeled compound (Fig. 1). Particulary instructive is the mass spectrum of the earliest eluting isotopomer with the molecular ion at *m/z* 273, indicating the retention of all five D-atoms of the labeled phytol. The ion shifts from *m/z* 43 to 46 and *m/z* 58 to 63 locate the D-atoms in the positions C-1 and C-3, because they are formed either by α-cleavage next to the carbonyl group or by McLafferty-rearrangement typical for methylketones. The degradation of the double bond would lead to this labeling pattern. All D-atoms found in the labeled phytol are present in the product **1** in identical isotopomer distribution.

Discussion

Chlorophyll a is taken up by most chewing insects during feeding on plants, and is degraded during digestion, releasing (*E*)-phytol (**3**) (Matile et al., 1999). The larvae of *P. rapae* is thus taking up **3** and accumulating it in the scent scales of the wings of males. In the males, **3** is at least in part degraded to **1**. This is different from orchid bees that take up **1** from plants (Eltz et al., 2010). The mechanism of this cleavage is unknown, but a plausible explanation is shown in Fig. 1. Phytol can be oxidized to either phytenal (**4**) or even further to phytoenic acid (**5**). The now established α,β-unsaturated carbonyl system can act as a Michael-acceptor and add water as a nucleophile. A retro-aldol-fragmentation of the hydroxycarbonyl compounds **6** or **7** follows that releases hexahydrofarnesylacetone and acetaldehyde or acetate. The intermediate **4** can be found as a trace component in the male wing extracts (Yildizhan et al., 2009). Alternatively, a direct oxidative cleavage of the double bond of **1** is possible, but the dioxygenase enzymes capable of doing this usually act on aromatic systems. The formation of **1** by degradation of tocopherol seems less likely because it would require cleavage of a non-activated C-C bond. The formation from tetraterpenes also is not supported by our data because in that case no deuterium incorporation would be expected. It seems likely that plants synthesize **1** by a similar pathway. In all known cases, natural **1** and **3** share the same absolute (6*R*,10*R*)-configuration in the chain. The described pathway also may be active for other degraded terpenes like sulcatone or geranylacetone, derived from geraniol or farnesol, in addition to the already known formation by direct oxidation of open-chain carotenoids like lycopene (Vogel et al., 2008).

In essence we have shown that male *P. brassicae* synthesize hexahydrofarnesylacetone (**1**) from phytol (**3**), originating from chlorophyll a degradation. This may explain the relatively widespread occurrence of this compound in both plants and insects.

RAPID COMMUNICATION

Risk of Egg Parasitoid Attraction Depends on Anti-aphrodisiac Titre in the Large Cabbage White Butterfly *Pieris brassicae*

Martinus E. Huigens · Erik de Swart · Roland Mumm

Received: 28 December 2010 / Revised: 22 February 2011 / Accepted: 11 March 2011 / Published online: 31 March 2011

Abstract Males of a variety of insects transfer an anti-aphrodisiac pheromone to females during mating that renders them less attractive to conspecific males. In cabbage white butterflies, the transfer of an anti-aphrodisiac can result in the unwanted attraction of tiny egg parasitoid wasps of the genus *Trichogramma* that hitch-hike with mated female butterflies to a host plant where they parasitize the freshly laid butterfly eggs. Here, we show that the anti-aphrodisiac benzyl cyanide (BC) of the large cabbage white *Pieris brassicae* is depleted by frequent display of the mate-refusal posture that signals a female's unreceptivity to mating. This depletion of BC is ecologically important because it results in a reduced risk of attracting the hitch-hiking egg parasitoid *Trichogramma brassicae* to mated female butterflies over time since mating. Our results indicate for the first time that a reduction in anti-aphrodisiac titre in mated females due to frequent adoption of the mate-refusal posture is beneficial to both mated females and males particularly when parasitoid pressure is high.

Key Words Benzyl cyanide · Pheromone · Polygamy · Mate-refusal posture · Chemical espionage · *Trichogramma brassicae*

Introduction

In various butterfly species with female polygamy, the male transfers an anti-aphrodisiac pheromone blend to the female during mating to reinforce monogamy (Andersson et al., 2000, 2003, 2004; Schulz et al., 2008). This not only benefits the male, because it reduces the risk of sperm competition, but also the recently mated female, because a reduced harassment by other males enables her to invest more in offspring production (Forsberg and Wiklund, 1989). However, the use of an anti-aphrodisiac is vulnerable to chemical espionage by natural enemies (Fatouros et al., 2005b; Huigens et al., 2009, 2010).

Males of the large cabbage white butterfly *Pieris brassicae* transfer the anti-aphrodisiac benzyl cyanide (BC) to females during mating, which renders them less attractive to conspecific males, whereas males of the green-veined white *Pieris napi* transfer methyl salicylate (MeSA) (Andersson et al., 2000, 2003, 2004). In *P. napi*, the storage of MeSA in the mated female is depleted over time after mating by frequent adoption of a posture that signals unreceptivity to mating (Andersson et al., 2004). This so called 'mate-refusal' posture with spread wings and elevated abdomen is displayed both at male and female butterflies and is typical for all Pieridae (Obara, 1964).

In this study, we examined whether depletion of an anti-aphrodisiac has ecological consequences for both male and female butterflies. Recently, we discovered how the use of the anti-aphrodisiac BC in *P. brassicae* can be exploited by the tiny egg parasitoid wasps *Trichogramma brassicae* and *T. evanescens*; after the wasps detect BC released by a female butterfly on day 1 after mating, they mount her and hitch a ride to a host plant where they parasitize her freshly laid eggs (Fatouros et al., 2005b; Huigens et al., 2009). Here, we investigated whether the amount of BC released by mated

female *P. brassicae* butterflies a) changes over time since mating, b) is influenced by frequent display of the mate-refusal posture, and c) mediates the risk of attracting the hitch-hiking egg parasitoid *T. brassicae* to mated female butterflies.

Methods and Materials

Butterflies and Wasps *Pieris brassicae* L. (Lepidoptera: Pieridae) butterflies and *Trichogramma brassicae* Bezdenko (Hymenoptera: Trichogrammatidae) wasps (iso-female strain Y175) were reared as described in previous studies (Fatouros et al., 2005a, b; Huigens et al., 2009). We used only mated, 2-d-old female wasps in the experiments. Singly-mated female butterflies were obtained by adding virgin males to virgin females in a cage (50×50×50 cm) 2 days after eclosion. Mating couples were individually isolated in plastic cylinders (15 cm i.d., 30 cm high) covered with a gauze lid. After a couple had separated, the male was removed, and the female was provided daily with fresh honey water (10%). On day 1 after mating, females were kept individually, and volatiles were collected for 1.5 hr (see below). After BC collection, females were either housed individually, or housed together with 6 other mated females. Benzyl cyanide was collected again on day 5 after mating (Andersson et al., 2004). All butterflies were active, but females only (frequently) displayed the mate-refusal posture when housed in a group (Andersson et al., 2004).

Emission of BC A dynamic headspace system was used to collect BC that is released by one singly-mated female butterfly. An individual female was confined in a glass jar (0.5 L, Weck, Germany) that was closed with a Viton-lined glass lid having an inlet and outlet. Inlet air was filtered by passing through a stainless steel cartridge filled with 200 mg of charcoal. Volatiles were trapped by sucking air out of the jar at a rate of 100 ml min^{-1} through a similar cartridge filled with 200 mg Tenax TA (20/35 mesh; Grace-Alltech, USA). Benzyl cyanide was collected for 1.5 hr on day 1 and day 5 after mating. To determine whether a female butterfly releases more BC when it displays the mate-refusal posture, we added a virgin [BC free (Andersson et al., 2003)] female butterfly to the glass jar during volatile trapping. Headspace samples were analyzed with a Thermo Trace GC connected to a DSQ mass spectrometer (Thermo Fisher Scientific, USA). Volatiles were thermally desorbed from Tenax cartridges at 250°C for 3 min (Ultra, Markes Llantrisant, UK) with a helium flow of 30 ml min^{-1}. Analytes were focused at 0°C on an electronically-cooled sorbent trap (Unity, Markes, Llantrisant, UK) and were then transferred in splitless mode to the analytical column (ZB-5Msi, 30 m, 0.25 mm i.d., 1.0 μm film thickness, Phenomenex, USA) by rapid heating of the cold trap to 250°C for 5 min. The temperature gradient of the GC was as follows: 60°C hold for 3 min, 10°C min^{-1} gradient to 200°C, then 40°C min^{-1} gradient to 280°C, 2 min hold, constant column flow of 1 ml min^{-1}). Mass spectra were acquired by electron impact ionization (70 eV) with a scanning from 45–200 m/z with a scan rate of 7.3 scans s^{-1}. Benzyl cyanide was identified by comparing the mass spectrum and retention time with an authentic reference standard. A linear calibration curve made from 0.1, 1, 10, 100, and 1000 ng synthetic BC was used to determine the amount of BC released by mated female butterflies.

Wasp Response to Mated Female Butterfly Odors In a static two-chamber olfactometer, we tested the response of *T. brassicae* to odors released by differently treated singly-mated female butterflies (1dI=1 day after mating, housed individually; 5dI=5 days after mating, housed individually; 5dG=5 days after mating, housed in a group) as previously described (Fatouros et al., 2005b; Huigens et al., 2009, 2010). The olfactometer differed only in height (7 cm) from the one that was used before (18 cm). One *P. brassicae* female per chamber was introduced as odor source. The time spent (residence time) by the wasps in one of the two odor fields was observed for 300 sec.

Results and Discussion

The gas chromatography-mass spectrometry (GC-MS) analysis shows that the storage of BC in mated female *P. brassicae* butterflies is depleted over time by frequent display of the mate-refusal posture. Co-habitating female butterflies released significantly less BC on day 5 than on day 1 (Fig. 1a; *Wilcoxon signed-rank test*, $P=0.003$). This is consistent with the fact that when housed in a group, females frequently adopted the male-refusal posture (Andersson et al., 2004). This posturing does not occur as frequently when a female is housed individually (Andersson et al., 2004). Therefore, BC levels emitted from individually housed females were lower than day 1 levels, although they were not statistically different (Fig. 1a; *Wilcoxon signed-rank test*, $P=0.480$). On day 5 after mating, female butterflies that were housed alone also released significantly more BC than those that were housed in a group (Fig. 1a; *Mann–Whitney U test*, $P=0.002$). Moreover, mated female butterflies that were maintained together with a virgin female during volatile trapping, and consequently exhibited the mate-refusal posture, released significantly more BC than those that were maintained alone (Fig. 1a; *Mann–Whitney U test*, $P=0.001$). The anti-aphrodisiac thus, is released mostly during the mate-refusal posture in *P. brassicae*, just as in *P. napi* (Andersson et al., 2004), thereby suggesting this phenomenon to be more widespread among Pierid butterflies.

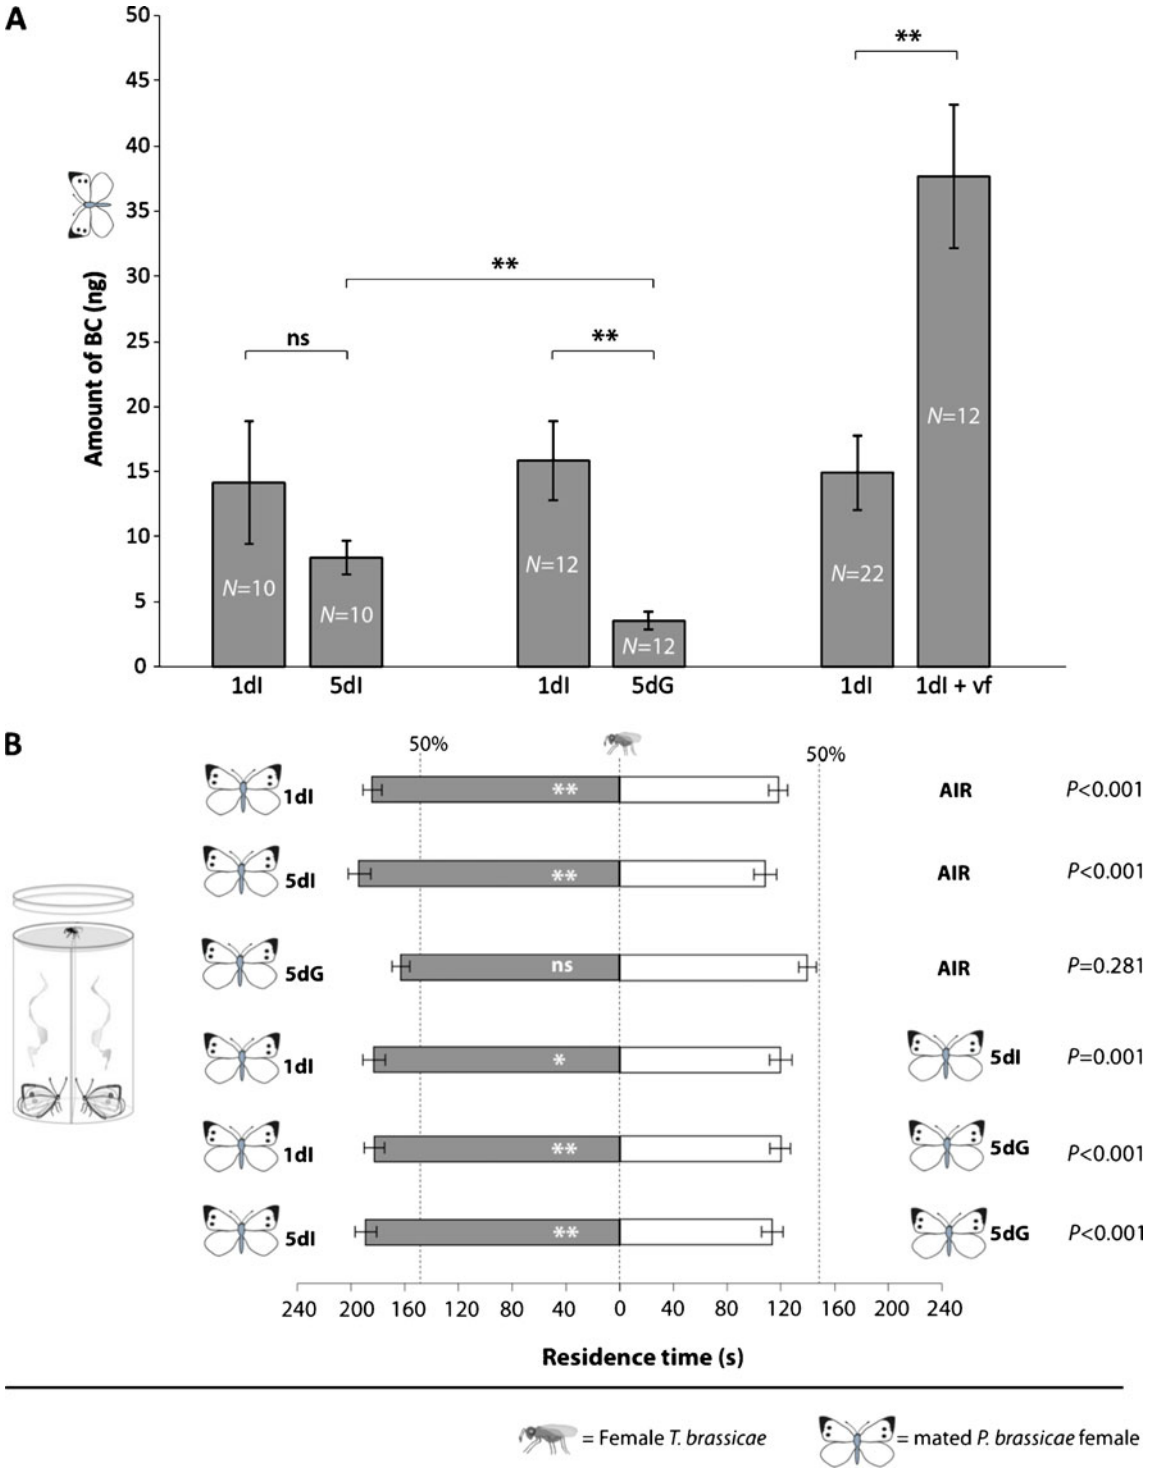

Fig. 1 **a** Amount of BC (ng) released by differently treated singly-mated females of the large cabbage white butterfly *Pieris brassicae* on day 1 and days 5 after mating during 1.5 hr of volatile trapping. **b** Response of *Trichogramma brassicae* wasps to the odors of differently treated singly-mated female butterflies on day 1 and days 5 after mating; mean residence time (± s.e.m.) in two odor fields in a static olfactometer; N=40 wasps tested per experiment. 1dI=1 day after mating, housed individually; 5dI=5 days after mating, housed individually; 5dG=5 days after mating, housed in group; 1dI + vf=1 day after mating, housed individually, accompanied by a virgin (BC free) *P. brassicae* female during volatile trapping. In **a**, a *Wilcoxon signed-rank test* was used for comparisons of 1dI with 5dI (same female butterflies) and 1dI with 5dG (same female butterflies), and a *Mann–Whitney U test* for comparisons of 5dI with 5dG (different female butterflies) and 1dI with 1dI + vf (different female butterflies). In **b**, we used a *Wilcoxon signed-rank test* for comparisons within a choice test. *Asterisks* indicate significant differences, $^{**}P<0.01$, ns: not significant

Our results indicate that a depletion of BC in female *P. brassicae* butterflies over time since mating has important ecological consequences. In two-choice olfactory bioassays, *T. brassicae* wasps showed clear odor preferences for mated *P. brassicae* females that released the largest amount of BC. When offered against clean air, odors of female butterflies that were housed alone significantly arrested the wasps on day 1 and day 5 after mating (Fig. 1b; *Wilcoxon signed-rank test*, $P<0.001$ and $P<0.001$, respectively). However, wasps did not discriminate between odors of female butterflies that were housed in a group until day 5 after mating and clean air (Fig. 1b; *Wilcoxon signed-rank test*, $P=0.281$). Wasps also were more strongly arrested by female butterfly odors 1 day after mating when tested against odors of female butterflies that were either housed alone, or in a group, until day 5 after mating (Fig. 1b; *Wilcoxon signed-rank test*, $P<0.001$ and $P<0.001$, respectively). Although the amount of BC released by 5-d-individually housed mated females is not significantly lower than that released by 1-d-individually housed mated females, it might be sufficiently lower to result in a reduced arrestment of *T. brassicae* wasps.

In nature, recently mated female *P. brassicae* butterflies are likely to run a higher risk of attracting the hitch-hiking egg parasitoid *T. brassicae* than do older mated females that have frequently adopted the mate-refusal posture, and consequently emit less BC. The mutual benefit of using an anti-aphrodisiac for both the mated female and the male (Forsberg and Wiklund, 1989; Andersson et al., 2004) could turn into a conflict over time after mating, because the female may benefit later from mating a second time, i.e., from a reduction in anti-aphrodisiac release, whereas the male does not (Andersson et al., 2004). Our results, however, suggest that a decrease in anti-aphrodisiac emission by the female due to a frequent display of the mate-refusal posture after mating also is beneficial for the male because it reduces the risk of indirectly attracting natural enemies to his offspring via the mated female.

Abstract Plants attacked by herbivorous insects emit volatile organic compounds that are used by natural enemies to locate their host or prey. The composition of the blend is often complex and specific. It may vary qualitatively and quantitatively according to plant and herbivore species, thus providing specific information for carnivorous arthropods. Most studies have focused on simple interactions that involve one species per trophic level, and typically have investigated the aboveground parts of plants. These investigations need to be extended to more complex networks that involve multiple herbivory above- and belowground. A previous study examined whether the presence of the leaf herbivore *Pieris brassicae* on turnip plants (*Brassica rapa* subsp. *rapa*) influences the response of *Trybliographa rapae*, a specialist parasitoid of the root feeder *Delia radicum*. It showed that the parasitoid was not attracted by volatiles emitted by plants under simultaneous attack. Here, we analyzed differences in the herbivore induced plant volatile (HIPV) mixtures that emanate from such infested plants by using Orthogonal Partial Least Squares-Discriminant Analysis (OPLS-DA). This multivariate model focuses on the differences between odor blends, and highlights the relative importance of each compound in an HIPV blend. Dual infestation resulted in several HIPVs that were present in both isolated infestation types. However, HIPVs collected from simultaneously infested plants were not the simple combination of volatiles from isolated forms of above- and belowground herbivory. Only a few specific compounds characterized the odor blend of each type of damaged plant. Indeed, some compounds were specifically induced by root herbivory (4-methyltridecane and salicylaldehyde) or shoot herbivory (methylsalicylate), whereas hexylacetate, a green leaf volatile, was specifically induced after dual herbivory. It remains to be determined whether or not these minor quantitative variations, within the background of more commonly induced odors, are involved in the reduced attraction of the root feeder's parasitoid. The mechanisms involved in the specific modification of the odor blends emitted by dual infested turnip plants are discussed in the light of interferences between biosynthetic pathways linked to plant responses to shoot or root herbivory.

Introduction

Herbivory induces the emission of volatile organic compounds, which are called herbivore induced plant volatiles

(HIPVs). Such chemicals are involved in plant indirect defense when they are used by the herbivores' natural enemies to locate their host or prey (e.g., Dicke and Sabelis, 1987; Geervliet et al., 1994; Turlings et al., 1995; Dicke and van Loon, 2000; Heil, 2008). The HIPV blends resulting from herbivore damage are not identical to those elicited by mechanical damage or released by intact plants (reviewed by Turlings et al., 1995; Takabayashi and Dicke, 1996). Indeed, mechanical wounding and chemical elicitors from insect oral secretions synergistically activate plant HIPV emissions (reviewed by Arimura et al., 2009). HIPVs are complex mixtures commonly consisting of 20 to over 200 compounds, ranging from simple alkanes to more elaborate structures such as sesquiterpenes (Dudareva et al., 2004). Such complexity may provide specific information to carnivorous arthropods and result in reliable cues for detection of suitable host or prey. The composition of the blend may vary according to plant and herbivore species, conditions, and developmental stage (Takabayashi et al., 1995; De Moraes et al., 1998; Gouinguené et al., 2003). Most published papers have described the role of HIPVs in simple tritrophic interactions that involve one species on each trophic level in the aboveground compartment of a plant system. However, roots can also emit HIPVs that attract enemies of belowground feeding herbivores (Aratchige et al., 2004; Rasmann et al., 2005; Ali et al., 2010). Therefore, more complex networks involving multiple herbivores should be studied (see Bezemer and van Dam, 2005; Dicke et al., 2009 for reviews). Feeding damage caused by root and shoot herbivores may lead to quantitative and qualitative changes of primary and secondary metabolites in both compartments of the plant (Bezemer and van Dam, 2005; van Dam et al., 2009). Such changes not only affect the development of herbivores in the two spatially separated compartments, but also the organisms on the third trophic level associated with these plants (Gols and Harvey, 2009). For instance, simultaneous feeding by aboveground herbivores (*Spodoptera littoralis*) and below-ground herbivores (*Diabrotica virgifera virgifera*) in maize plants affects the production of a single HIPV, (*E*)-β-caryophyllene, which in turn impacts on the behavior of respective natural enemies. This altered emission of volatiles reduced the attraction of the parasitic nematode that attacks the belowground herbivore (Rasmann and Turlings, 2007). Such changes in individual HIPV compounds may function synergistically with other less specific components as reliable cues for carnivores. For example, the homoterpene dimethyl-tridecatetraene (DMTT), is emitted by prey-infested lima bean plants (*Phaseolus lunatus*) but is not attractive to the predatory mite *Phytoseilus persimilis* as a pure compound. However, when it is added to a blend of compounds emitted from a plant infested by non-prey herbivores, predatory mites are attracted (Dicke et al., 1990). Thus, the specificity of each induced odor blend may be a function of the mixture, quantity or the relative amounts of the volatile compounds (De Boer et al., 2004; Mumm and Hilker, 2005). Plant volatile emissions should always be considered in the context of all the other volatiles of the blend (van Dam and Poppy, 2008; van Dam et al., 2010; Ranganathan and Borges, 2010). HIPV emissions thus require multivariate analysis to allow understanding in terms of insect behavior. Furthermore, herbivores not only increase the emission of certain compounds but also can reduce the release of some wound-elicited constituents (Gaquerel et al., 2009). Although there are few examples in the literature, blends of HIPVs also may differ qualitatively and then provide specificity of chemical cues in host location by parasitoids (Takabayashi et al., 2006). Both quantity and quality of the volatiles perceived by natural enemies may determine the reliability of the informative odor (Vet et al., 1991).

Delia radicum, the cabbage root fly, is a major pest of brassicaceous crops. Females aggregatively lay their eggs near plant stems, and the larvae crawl down to feed on the roots and develop until they pupate in the soil. These larvae frequently are parasitized by *Trybliographa rapae*, a specific larval endoparasitoid of *Delia* species. This parasitoid forages aboveground for hosts that are feeding on plant roots belowground; therefore, systemically emitted volatiles play a key role in its host location. Females are attracted by volatiles emitted by undamaged leaves of *D. radicum* infested plants but not by volatiles emitted by leaves of artificially damaged plants (Neveu et al., 2002). Furthermore, volatiles emitted by leaves of plants artificially damaged at the roots to which crushed larvae are applied are attractive; this suggests that the attractive blend of HIPVs produced is specific to *D. radicum* feeding activity (Neveu et al., 2002). The specific composition of the HIPV blend elicited by *D. radicum* feeding on turnips and involved in *T. rapae* attraction has not been determined. A recent study showed that when *Pieris brassicae* (a specialist leaf feeder of brassicaceous plants) and *D. radicum* simultaneously attack a turnip plant (*Brassica rapa* subsp. *rapa*), *T. rapae* is no longer attracted (Pierre et al., 2011). Reduced attraction of root and shoot infested plants in olfactometer experiments was correlated with lower levels of parasitism in a separate field study (Pierre et al., 2011).

In this study, we analyzed the blends of HIPVs emitted by turnip plants after (1) infestation by *D. radicum*, (2) infestation by *P. brassicae*, (3) simultaneous infestation by *D. radicum* and *P. brassicae*, or (4) no infestation. The combination of experiments revealed specific modifications of HIPV blends following single and dual infestations. This is a first step towards understanding the altered foraging behavior of *T. rapae* in the presence of leaf herbivory. The analysis of HIPVs needs a multivariate approach in which

the relative amounts of volatiles are as important as the amounts themselves. Therefore, Orthogonal Partial Least Squares-Discriminant Analysis (OPLS-DA) was used to observe the effect of different forms of herbivore infestation on HIPV emission blends. The resulting model gives the relative importance of each volatile in a system-wide model describing the entire blend. It optimally describes the effect of each infestation as a classification between control and treated plants. However, OPLS-DA does not assess differences in the patterns of HIPV emissions between single herbivore infestations and dual herbivory. So it does not explicitly reveal the synergistic or antagonistic effects of additional herbivory. To address this question, univariate analysis was used to evaluate *a posteriori* the interaction between leaf and root herbivory effects on the levels of important HIPVs.

Method and Materials

Plants Cultivated turnip plants, *Brassica rapa* subsp. *rapa* (var. Nancy) were used. Seeds were sown in compost-soil, and after 10 days, seedlings were transplanted into 9×9× 9 cm plastic pots, filled with sandy soil. Plants were grown in a greenhouse, at 60% r.h., 21°C/16°C, 16/8 h L:D photoperiod. Natural day-light was supplemented when needed with metal halide lamps (200 μmol/s/m^2 PAR = photosynthetically active radiation; 1 lamp per m^2). Plants were watered every day and supplemented with nutrients (4 N: 6P: 8 K and micronutrients) twice a week until they were 7- to 8–wk-old.

Insects Delia radicum larvae used for plant infestation originated from our rearing. The populations were originally established in the laboratory from flies collected in the field at St Méloir des Ondes (Brittany, France) during the summer of 1994. The brood was reared as described in Neveu et al. (1996) and supplemented yearly with new field-captured individuals coming from the same region. *Pieris brassicae* caterpillars originated from an insect culture maintained at the Laboratory of Entomology of Wageningen University, the Netherlands, and were reared on *Brassica oleracea* subsp. *gemmifera* (Brussel sprout) plants.

Induction Procedure Plants were infested when they had five to eight fully expanded leaves (7-8-wk old). Twelve to thirteen plants of similar size and stature were selected for each of the different treatment groups. Infestation with *P. brassicae* (P) consisted of placing ten first instars with a small brush on the two youngest leaves (5 per leaf) of each plant. Plants were infested by *D. radicum* (D) by placing 5 s instars with a brush onto the soil surface, immediately adjacent to the stem of each plant. Plants were checked 1 h later to control whether all larvae had disappeared into the sand. With dual infestation (DP), larvae of *P. brassicae* (see above) were applied first to each plant followed 1 h later by *D. radicum* larvae. A nutrient solution (4 N: 6P: 8 K and micronutrients) then was applied to both infested and uninfested plants.

Collection of Volatiles and GC-MS Analysis Volatiles were collected 3 days after induction by infestation. Based on our previous studies with turnip plants, 3 days of infestation sufficed for effective induction of *T. rapae* attracting volatiles (Neveu et al., 2002; Pierre et al., 2011). The entire plants (including pots and sand) were transferred to four separate 17 l glass bell-shaped collection chambers placed in a controlled climate cabinet (21°C, 70% r.h.). The chambers were supplied constantly at the top with pressurized air (Hoek Loos, NL) cleaned over a Zero Air generator to remove hydrocarbons (Parker Hannifin Corp, Tewksbury, MA, USA). Plant-generated HIPVs were collected over a steel trap filled with 150 mg Tenax TA and 150 mg Carbopack B by using a vacuum pump. Collection flow rates were set to 100 ml/min. The HIPVs were collected from an outlet on the side of the flask, which was at the same height as the plant leaves. The supply rate of clean air at the top of the flask was set to 200 ml/min. After 1 h, the traps were removed from the pump and capped until analysis. In this way, within 1 days we measured six full series of four plants representing the four different treatments tested and two background HIPV profiles from an empty glass chamber. We sampled the following numbers of individual plants: 13D, 13P, 12DP, and 13C. Volatiles were desorbed from the traps, then analyzed by GC-MS using the same methods and reference compounds as described by van Dam et al. (2010). All integrated signals were generated from the MS-chromatograms by the AMDIS software, except those of alpha-pinene, isobutyl isothiocyanate, and 2-isothiacyanato-butane, which were extracted as ion traces from the same peak from which they co-eluted by Xcalibur software. Note that these three compounds co-eluted so close that they could not be separated even by deconvolution. However, strong unique ions were found in the mass spectrum of the mixture (alpha-pinene, 93; isobutyl isothiocyanate, 115, 2-isothiacyanato-butane, 86) and relative trends generated from these single qualifier ions are in theory proportional to trends in the total ion traces.

Peak areas obtained in each sample were divided by the total volume in ml that was sampled in the trap, to correct for minor differences in sampling time and flow rates over individual traps.

Data Analysis of Volatile Profiles Peaks relating to mixtures and impurities were removed from the dataset.

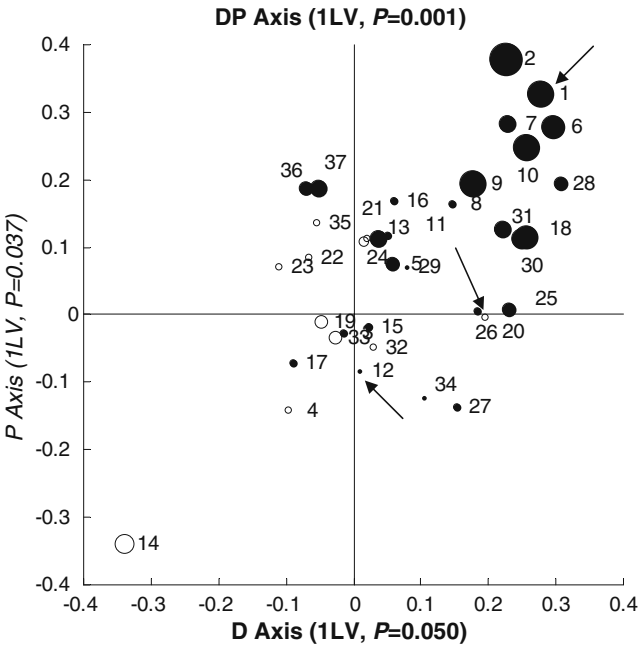
Furthermore, to avoid rare compounds that disproportionably could affect the outcome, only those compounds that were found at least six times in at least one treatment group were retained for the multivariate analyses. This resulted in a dataset of 37 HIPVs for detailed analysis. We constructed three separate models, each of which compared the HIPV profiles of one form of herbivore infestation to the control plants, thereby isolating the effect of one herbivory form on the HIPV composition. For these models, the Orthogonal Partial Least Squares-Discriminant Analysis (OPLS-DA) method was chosen. It takes existing biochemical relations among the volatile compounds into account, and the interpretation of results from the model compare well in terms of the differences among the plant groups (Bylesjö et al., 2006). In brief, OPLS-DA is a supervised component analysis method that uses *a priori* knowledge about the form of herbivory that every plant received. The models consist of a small number of 'Latent Variables'—comparable to the components of Principal Component Analysis—which together describe the difference between control and treated plants. The models in this study consisted of a description of the treatment each plant most likely received (the class membership description, γ_{hat}) and the metabolic profile with relative importance of each volatile in the total blend (the OPLS-DA weight vector). Although OPLS-DA models may contain multiple latent variables, there is always only one class prediction and one weight vector *per* plant when two groups are compared.

The OPLS-DA model thereby specifically focuses on differences among plant groups, and like all supervised models it is thereby prone to 'over fit' these differences, i.e., describing the variation among the individual plants used in the experiment, rather than generic phenomena caused by the experimental manipulations (Jansen et al., 2010). Therefore, the observations from the resulting models were evaluated thoroughly by cross-validation, in which the data of randomly chosen individual plants are left out of the data set and the model is re-made, after which the treatment of the left-out plants is estimated. This procedure was repeated 2,000 times, which then leads to a misclassification rate; a measure of model error. The number of latent variables for which the misclassification rate is lowest results in a model that includes all systematic information useful for predicting treatment groups, but does not contain superfluous 'random' information that relates to over fit. As a second validation, the determined misclassification rate then was compared to that of a large number of models in which treatments were artificially shuffled by permutation: this naturally should lead to considerably higher misclassification, because true biological difference between the permuted treatments is lacking. The permutation is repeated 1,000 times, each time consisting of 2,000 cross-validated models providing a misclassification rate. The difference in misclassification rate between the model with real and permuted treatments can be expressed as a *P*-value that describes the likelihood that the observed effect is real.

The chemistry in the 'weight' vector of treatments with a significant effect on HIPV emissions was analyzed further. This vector—showing the importance of each volatile in describing the differences between two groups— was compared to those obtained from the models on permutated treatments described before. These permutated models collectively form a 'null distribution' of the OPLS-DA weights for every volatile, from which the weight of the model fitted on real treatments should differ. This last permutation analyses results in a *P*-value for every volatile for each form of herbivory.

In our case, there were three separate OPLS-DA models that we compared for communalities and differences caused by different forms of herbivory. This comparison was done by plotting the weight vectors of each volatile on the first latent variable (LV) for each treatment. However, three-dimensional figures that compare the different forms of herbivory are difficult to interpret. By condensing the relevant information to a two-dimensional figure, it becomes more insightful. This figure, called a bubble plot (Markus and Gu, 2010), compares the chemistry underlying two forms of herbivory as positions of each volatile on two axes (i.e., a scatter plot). In addition, the amount of volatile from the third form of herbivory is represented as the area of a circle: this graphical tool is useful for comparing both forms of individual herbivory and the third, combined infestation.

Afterwards, compounds of which the weight vector values were significant for at least one form of herbivory were selected for univariate analysis. Indeed, for each important compound, we tested the effect of root herbivory (D), leaf herbivory (P), and the interaction (D*P) by using two-way analysis of variance on peak areas transformed as log (x + 1) (van Dam et al., 2010). The significance of such an interaction is of interest, as it could reveal a positive or negative influence of dual herbivore treatment (DP) compared to a single herbivore one (P or D). A similar procedure was used previously by Soler et al. (2007a) to support the results of their multivariate analysis. In the present study, homogeneity of variance was checked by Levene's test using the "robvar" function in Stata 9 software (StataCorp LP, College Station, TX, USA).



Results

The fitted OPLS-DA models showed that the effect of all three herbivore treatments on the HIPV emissions can be described

by simple low-dimensional multivariate models. The cross-validation yielded a single latent variable for all three to significantly distinguish the volatile blends emitted by turnip plants (Table in Fig. 1). The comparison of these three separate OPLS-DA models for communalities and differences caused by different forms and levels of herbivory was done by plotting the discriminate functions of root herbivory by *D. radicum* (D) and leaf herbivory by *P. brassicae* (P) against each other (Fig. 1). Increased levels of a compound in D or P are indicated by a positive weight vector value on the respective axis, while reduced levels are shown by a negative value. The size of each bubble corresponds to the weight vector value of a volatile for the dual herbivory treatment (DP). The maximal bubble size corresponds to (*3E*)-4,8-dimethyl-1,3,7-nonatriene DMNT (2), which then is related to the highest vector value for DP (0.394) and to the most significant difference from the vector value for the control (P=0.004). The absolute minimal bubble size is associated with heptadecene (29), which has the lowest absolute vector value for DP (0.002) and the least significant difference from the vector value for the control (P=0.595). The bubble size of hexylacetate (9) represents a threshold of significance (weight vector value=0.300; P=0.044) of weight vector values associated with DP.

For instance, the level of (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene TMTT (1) increased after any form of herbivory, as indicated by its high and positive weight vector value on the D axis (0.276), the P axis (0.329) and the large black bubble indicating a high and positive weight vector value for (DP) (0.305). By contrast, the level of 2-undecanone (20) was mildly increased by (D), which is represented by a relatively high and positive value in the D axis (0.196), but this did not respond for (P) and (DP) as indicated by a low weight vector in P axis (−0.004) and a small size of the bubble meaning a low weight vector value for (DP) (−0.055). An example of a compound whose level mildly decreased in (P) is 1-hexadecanol (12) which has a negative value on the P axis (−0.083); this compound did not respond to (D) or (DP), as revealed by the low value in the D axis (0.008) and the small size of the bubble (0.005) (Fig. 1).

Hence, the bubble plot representation allows visual identification of interesting compounds that are important for differentiating between D, P, and DP volatile profiles. In particular, the right upper quarter of the bubble plot shows the compounds, TMTT (1), DMNT (2), (*E,E*)-alpha-farnesene (6), hexylacetate (9), and (*E*)-3-hexen-ol-acetate (10) the levels of which were relatively high in all three herbivore treatments as indicated by the large filled dots (Fig. 1). Interestingly, in the same quarter of the figure, smaller black dots indicate compounds that increased in P or D but not in DP, i.e., methysalicylate (7) and 4-methyltridecane (28) (Fig. 1). Consequently, the latter

treatment	number of LVs	*P*-values
(D)	1	0.050
(P)	1	0.037
(DP)	1	0.001

Fig. 1 Two dimensional bubble plot representation of volatiles emitted after different forms of herbivore infestations in *Brassica rapa* subsp. *rapa* plants: discriminate functions of root herbivory by *Delia radicum larvae* (D) and leaf herbivory by *Pieris brassicae* caterpillars (P) plotted against each other. Numbers correspond to compounds listed in Table 1. The size of each bubble representing a volatile corresponds to the weight vector value of that volatile for the dual herbivory treatment, i.e., herbivory by *Delia radicum* larvae and *Pieris brassicae* caterpillars (DP). The *color* shows if the volatile increases (*filled*) or decreases (*open*) in the DP treatment. The *three arrows* indicate examples of compounds given in the text. The table below presents the number of latent variables (LVs) prescribed by cross-validation and the *P*-values for the significance ($P \leq 0.050$) of the system-wide effect brought about by each form of herbivory

compounds are compounds that would differentiate between single herbivory and dual herbivory effects on the plant volatile profile.

Volatile Profiles of Plants Exposed to Root Herbivory (D)

Permutation tests of weight vector values showed that the level of 4-methyltridecane (28) was higher in plants exposed to herbivory by D alone compared to control plants (Table 1). This compound appeared to be specific for the volatile blend emitted by (D), as its level was significantly modified in D plants but neither in P nor DP plants. The levels of the homoterpene TMTT (1) and the sesquiterpene (*E,E*)-alpha-farnesene (6) also were higher,

whereas that of the alcohol 2-octen-1-ol (14) was lower in plants exposed to (D) (Table 1). In addition to these significant differences, a marginal increase (arbitrary threshold for marginal variations: $P \leq 0.065$) was observed for salicylaldehyde (18) and the green leaf volatile (*E*)-3-hexen-1-ol-acetate (10) (Table 1). All those compounds appeared to be important in characterizing the volatile blend emitted by root infested plants, since their corresponding weight vectors had either high or low values compared to control plants (Fig. 1).

Volatile Profile of Plants Exposed to Leaf Herbivory (P) The level of methylsalycilate (7) significantly increased after (P) compared to control plants (Table 1). This phenomenon is specific for the odor blend emitted by leaf infested plants, as it does not appear in the other forms of herbivore treatment. Similar to (D), the volatile emissions of TMTT (1) and (*E,E*)-alpha-farnesene (6) significantly increased, whereas they decreased for 2-octen-1-ol (14) in plants exposed to (P) (Table 1). In addition, the levels of DMNT (2), and of the green leaf volatile (*E*)-3-hexen-1-ol acetate (ten marginally, i.e., $P \leq 0.065$) increased after (P) compared to control plants (Table 1).

Volatile Profile of Plants Exposed to Both Forms of Herbivory (DP) The level of hexylacetate (9) was significantly higher in (DP) compared to control plants (Table 1). This is specific for the volatile blend from dual infested plants. Indeed, no significant increase in hexylacetate was observed in (P) or (D), (Table 1). Furthermore, some compound levels in the headspace of DP followed patterns similar to single infested plants, either with D or P. This was true for increased levels of TMTT (1), (*E*)-3-hexen-1-ol-acetate (10) and, marginally so (i.e., $P \leq 0.065$) for (*E,E*)-alpha-farnesene (6) (Table 1). DMNT (2) also increased in DP plants, which followed the same tendency as P (Table 1). By contrast, lower levels of 2-octen-1-ol (14) were observed both in (D) and (P), but not in (DP), despite a similar tendency in the single infestations (Table 1).

In summary, both the bubble plot and permutation tests show that the plant response to dual herbivory (DP) is different from the combined effects of *D. radicum* and *P. brassicae* feeding alone (Fig. 1), despite a few communal patterns.

Effect of Interactions Between Root (D) and Leaf Herbivory (P) Only compounds of which the weight vector values were found to be significant for at least one form of herbivory were selected for univariate analysis to assess the interaction between (D) and (P) effect (Table 2). ANOVA analysis (Table 2) showed a significant interaction between (D) and (P) effects on 4-methyltridecane (28). This implies that the positive effect of (D) on the emission of this compound was reduced in the presence of (P) (Table 1, Table 2). Together with the bubble plot (mentioned above), such interaction indicates that the effect of root herbivory on this compound was different from the effect of dual herbivory. This confirms the high specificity of this compound for turnip plants infested by the root herbivore alone. In addition, an antagonistic effect between D and P was observed for 2-octen-1-ol (14; Table 1, Table 2). Indeed, the concentration of this compound was reduced in plants infested by D or P alone (as already mentioned) but not in dual infested plants.

The positive effect of P on the levels of methylsalycilate (7; Table 1) was significantly reduced by the additional presence of D. In other words, the effect of P was different from the effect of DP, as shown by the bubble plot (Fig. 1 mentioned above) and the significant interaction between D and P (Table 2). This confirms the specificity of methylsalycilate (7) induction as a cue for the leaf herbivores on plants without root damage. In addition, a significant interaction between D and P was observed for (*E,E*)-alpha-farnesene (6) (Tables 1, 2). The interaction was suggested by a marginal (i.e., $P \leq 0.065$) although not significantly higher level of (*E,E*)-alpha-farnesene in dual infested plants compared to control plants. Permutation tests revealed higher levels of hexylacetate (9) in DP compared to control plants (Table 1), which is specific for such herbivore treatment since no significant increases were observed in D and P plants. However, ANOVA did not show any significant effects of interaction between D and P on that compound.

Discussion

Our results show that higher levels of the branched alkane, 4-methyltridecane were highly specific for the volatile blend of plants infested by the root herbivore alone. Different alkanes, including branched alkanes, already have been detected in leaf and floral headspace of brassicaceous plants (Jakobsen et al., 1994; Gruber et al., 2009). However, we are unaware of any publications on the specific involvement of alkanes in the attraction of natural enemies of herbivores. In addition, salicylaldehyde emissions were marginally ($P=0.058$) modified by root herbivore feeding. Salicylaldehyde already has been reported to play an important role in some tritrophic systems that involve leaf beetle larvae (*Chrysomela* spp.) and their natural enemies (reviewed by Gross and Schmidtberg, 2009). The two specific HIPVs, 4-methyltridecane and salicylaldedhyde, thus, could serve as cues for the parasitoid *T. rapae* when searching for *D. radicum* infested plants without leaf herbivores present as well. Further investigations based for example on gas chromatography coupled to electro-antennography (GC-EAG) could reveal which compounds

Table 1 Peak areas transformed as log (X+1) of volatile compounds from *Brassica rapa* subsp. *rapa* plants exposed to root herbivory by *Delia radicum* (D) or leaf herbivory by *Pieris brassicae* (P), dual herbivory by *Delia radicum* and *Pieris brassicae* (DP), or no herbivory (control)

[a] The table contains those volatile organic compounds (VOCs) that were retained for multivariate analysis. Compounds indicated with a * were identified by comparison of pure standards, the other compounds were tentatively identified according to the same references as cited by van Dam et al. (2010). The numbers in the first column refer to the numbers in the two dimensional bubble plot in Fig. 1

[b] RI = retention index on the GC-MS; column RTX5-MS. Peak areas of compounds are means±SE

[c] The *P*-values were determined from a permutation test of the weight vector value which reflects the importance of each compound in the difference between herbivory by one form of herbivory and the control: root herbivory by *Delia radicum* larvae = *P* (D); leaf herbivory by *Pieris brassicae* caterpillars = *P* (P); dual herbivory by *Delia radicum* larvae and *Pieris brassicae* caterpillars = *P* (DP). Bold face type indicate compounds for which the weight vector value is significant for a specific treatment ($P \leq 0.050$)

Table 2 *P*-values (*P*(D*P)) from two way analysis of variance on peak areas transformed as log (X+1), testing the effect of the interaction between root herbivory by *Delia radicum* larvae (D) and leaf herbivory by *Pieris brassicae* caterpillars (P) treatments of *Brassica rapa* subsp. *rapa* plants for each selected volatile organic compound

No.	Compound name	*P* (D*P)
1	(*E,E*)-4,8,12-Trimethyl-1,3,7,11-tridecatetraene	0.084
2	(3*E*)-4,8-Dimethyl-1,3,7-nonatriene	0.083
6	(*E,E*)-alpha-Farnesene	**0.032**
7	Methylsalicylate	**0.041**
9	Hexylacetate	0.490
10	(*Z*)-3-Hexen-1-ol-acetate	0.223
14	2-Octen-1-ol	**0.005**
28	4-Methyltridecane	**0.037**

The numbers in the first column refer to the numbers in the two dimensional bubble plot in Fig. 1. The table contains those compounds of which the weight vector values refered in Table 1 were significant for at least one form of herbivory. Bold face types indicated significant *P*-values ($P \leq 0.050$)

within the blend of HIPVs elicit a response in the chemoreceptors of the parasitoid (Dicke and Baldwin, 2010).

The volatile blend of plants after leaf herbivory by *P. brassicae* was characterized by higher levels of methylsalicylate. The herbivore-induced emissions of this compound were annulled in the presence of the root herbivore. This volatile is known to be active at very low levels (Gouinguené et al., 2005), attractive for carnivorous arthropods under laboratory conditions (Dicke et al., 1990; Ozawa et al., 2000; De Boer and Dicke, 2004), and for hymenopteran parasitoids in the field (James and Price, 2004; Poelman et al., 2009). On the other hand, methylsalicylate diminished the attraction of the parasitoid *Diadegma semiclausum*, a specialist of another *Brassica* specialist herbivore (*Plutella xylostella*) in a mutant of *Arabidopsis* (Snoeren et al., 2010). Therefore, the lack of attraction of *T. rapae* towards *P. brassicae* infested plants compared to root infested plants (Pierre et al., 2011) could be attributed at least partly to a higher level of methylsalicylate and/or to lower levels of 4-methyltridecane and salicylaldehyde.

Dual infested plants exhibited a specific increase of one compound, the green leaf volatile hexylacetate. Specific compounds that were induced by leaf or root herbivory (i.e., 4-methyltridecane and methylsalycilate) did not show changes in emission levels after dual herbivory. Therefore, it appears that simultaneous herbivory significantly reduces or even suppresses the induction of specific compounds that characterize the volatile profile of single infested plants. Only one compound, 2-octen-1-ol, decreased after both single herbivory treatments, but not after dual herbivory.

In addition to specific variations, we also observed communal trends in the volatile profiles among the three forms of herbivory. In particular, the levels of the terpenoids TMTT and (*E,E*)-alpha-farnesene (marginally induced in dual infested plants) increased after any form of herbivory. Furthermore, the levels of the terpenoid DMNT increased after infestation by the leaf herbivore only, or after dual infestation. These terpenoid compounds are attractive for herbivorous and carnivorous (especially parasitoid) insects associated with brassicaceous plants (e.g., Soler et al., 2007a; van Dam et al., 2010). The present study shows that the specificity of each volatile blend may be due to a mixture of a few specific compounds that increase within the more common odor context of terpenoids and green leaf volatiles. The potential role of such background odors in the use of volatiles by foraging parasitoids has already been reviewed (Hilker and McNeil, 2007). In brassicaceous plants, terpenoids and green leaf volatiles often are abundant within HIPV mixtures, irrespective of the herbivore species that damages the plant. Thus, they themselves may not provide specific cues that allow specialist parasitoids to identify their hosts, which suggests that the specificity of the odor cue then may lie in ratios of the emitted volatiles within the blend (Gols and Harvey, 2009). In this way, the minor quantitative changes in dual infested plants may have contributed to the lack of attractiveness towards *T. rapae* and to the lower levels of parasitism of *D. radicum* in the field (Pierre et al., 2011). The reduced attractiveness of *T. rapae* towards dual infested plants may be adaptive, as both survival and size of *T. rapae* developing in *D. radicum* on plants infested by *P. brassicae* are reduced (Soler et al., 2007b). The combination of the host *D. radicum* and the non-host *P. brassicae* on the same plant often occurs in the field (Pierre et al., 2011), and it is likely that the parasitoid has learned to detect the characteristic volatile blend of this combination. Similar trends also were found for reverse interactions: root herbivory by *D. radicum* altered the foraging and egg laying behavior of *C. glomerata*, a parasitoid of *P. brassicae* (Soler et al., 2007a). In this case, the volatile blend of dual infested plants also differed only by a few compounds; the emissions of two sulfur compounds were higher, whereas two terpenoids were less prominent in dual infested plants (Soler et al., 2007a). These minor modifications of the complex plant odor blend were hypothesized to be sufficient for the aboveground parasitoids to avoid plants with root herbivores.

The mechanisms involved in the non-additive modification of the odor blends emitted by *D. radicum* and *P. brassicae* infested turnips remain to be elucidated. Crosstalk between signaling hormones, such as jasmonic acid and salicylic acid, involved in responses to different herbivore species may have contributed (van Poecke and Dicke, 2002; Erb et al., 2008; Koornneef and Pieterse, 2008; Zhang et al., 2009). Alternatively, interference

between HIPV biosynthetic pathway activation by root and shoot herbivory may be involved. A recent study suggested that root induced responses are regulated fundamentally differently from responses triggered by shoot herbivory (van Dam et al., 2010). It was found that the biosynthesis of sesqui- and homoteperne volatiles was induced only by shoot jasmonic acid treatment of *B. oleraceae* plants, whereas monoterpenes were equally elicited by root and shoot jasmonic acid treatment. In the present study, we observed an interaction between root herbivory and leaf herbivory at the level of sesquiterpene (*E,E*)-alpha-farnesene. Therefore, these results support the hypothesis that root and shoot plant responses interfere, leading to variations in the dual infested plant odor mixture. A molecular approach that analyzes the expression of genes coding for markers of signaling or biosynthetic pathways could help to reveal which one is activated or suppressed in response to dual herbivory. Our chemical analysis supports previous behavioral studies in the multitrophic system, turnip-*D. radicum-P. brassicae-T. rapae.* Attraction of the parasitoid towards host infested plants was cancelled when these plants were also infested by the leaf feeder *P. brassicae* (Pierre et al., 2011). Analysis of volatile profiles revealed minor quantitative differences between plants infested by a single herbivore species and dual infested plants. However, these subtle changes were found to be highly specific, and thus may be sufficient for *T. rapae* to discriminate between the different HIPV mixtures. Our data interpretation using OPLS-DA, a novel multivariate analysis approach, has enabled us to identify the minimal, but relevant, changes within a complex HIPV background. This approach provides insight into the information processing of insects that base their behavioral responses upon quantitative differences in HIPV profiles as well as on qualitative contrasts within the context of an odor blend (Hilker and Mcneil, 2007; van Dam and Poppy, 2008). However, additional bioassays coupled with chemical analysis are required to conclude with certainty which compounds or combination of compounds within the plant volatile blend are behaviorally active towards the parasitoid *T. rapae*.

Acknowledgements The authors thank two anonymous reviewers and Dr. D. Webb for constructive comments on an earlier version of this manuscript. We thank C.E. Raaijmakers, R. Wagenaar, and G. Disveld for assistance in plant maintenance and volatile collection set up, R. Soler and J. Harvey at NIOO-KNAW (Netherlands) for constructive comments during the experiment, L. Koopman at the laboratory of Entomology, Wageningen University for supplying *P. brassicae* cultures, V. Chaminade, C. Josso, and S. Dourlot at Rennes University (France) for supplying *D. radicum* cultures, M. Hervé at Rennes University (France) for precious advice in statistics. P.S. Pierre thanks the European Science Foundation (ESF) for funding her work with a VOCBAS exchange grant, no 2076. This work also was supported by a PhD grant to P.S. Pierre from the Region Bretagne.

Specificity of Induced Resistance in Tomato Against Specialist Lepidopteran and Coleopteran Species

Seung Ho Chung · Gary W. Felton

Abstract When challenged by herbivorous insects, plants produce a suite of antinutritive proteins that disrupt digestion and absorption of essential nutrients by the insects. We hypothesized that plants would induce distinct defense responses corresponding to the distinct midgut conditions of different herbivores. We investigated whether or not tomato responds specifically to two specialist herbivores: Colorado potato beetle (CPB; *Leptinotarsa decemlineata; C*oleoptera: Chrysomelidae) and tobacco hornworm (THW; *Manduca sexta*; Lepidoptera: Sphingidae), and we evaluated whether the induced defenses triggered by either species affect CPB growth. Tomato did not induce different defense genes in response to CPB or THW but accumulated more transcripts for some defense genes after damage by THW feeding compared to damage by CPB feeding. In addition, trypsin protease inhibitor activity and polyphenol oxidase activity were higher in plants damaged by THW than in plants damaged by CPB. Application of oral secretions from THW to wounded tomato plants increased transcripts compared to controls, but oral secretions from CPB decreased defense transcripts. CPB growth was compromised on plants damaged by either species, suggesting a low specificity of effect. Together, these data suggest distinct quantitative responses of tomato to two different specialist herbivores. Herbivore oral secretions might be responsible for these species-specific responses.

Key Words Oral secretions · Plant defense · Tomato · Colorado potato beetle · Tobacco hornworm · Protease inhibitors · Induced resistance · Specificity

Introduction

Plants have evolved a wide array of defense mechanisms against insect herbivores. Some of these include physical defenses (e.g., thorns) or chemical toxins (e.g., alkaloids) that are expressed constitutively, but others are induced in response to herbivore attack. Induced defenses can be categorized into two groups: (1) direct defenses, including induced toxins, trichomes, and antinutritive proteins, and (2) indirect defenses, including emission of volatiles that attract natural enemies (Howe and Jander, 2008). The specificity of induced responses may be an important trait to cope with a variety of stimuli.

Specificity of induced responses to herbivores comprises two parts: the specificity of elicitation and the specificity of effect (Karban and Baldwin, 1997; Stout et al., 1998). Specificity of elicitation is defined as distinct defense responses against different herbivores. For example, chewing and phloem-feeding insects cause different damage on plants and induce different suites of plant responses (Walling, 2000). In tomato, defense proteins induced by tomato fruitworm (*Helicoverpa zea*) feeding are different from those induced by potato aphid (*Macrosiphum euphorbiae*) feeding (Stout et al., 1998). Feeding by insects in the same feeding guild also may show different responses. The tobacco hornworm (THW; *Manduca sexta*) elicited different phytohormones and transcriptional responses compared to the beet armyworm (*Spodoptera exigua)* (Voelckel and Baldwin, 2004; Diezel et al., 2009). Specificity of effect occurs when induced defenses have different effects on the

growth of an herbivore. For example, the growth of *S. exigua* was reduced by consumption of plants damaged by conspecific species compared to consumption of the control or aphid-treated plants (Rodriguez-Saona et al., 2005).

Insect feeding damages tissue and introduces herbivore-derived compounds that may elicit defensive responses. The specificity of plant responses to herbivores may be determined by insect elicitors or herbivore-associated molecular patterns and by the feeding pattern of herbivores (Felton and Tumlinson, 2008; Mithöfer and Boland, 2008). Elicitors trigger biosynthesis of wound hormones including jasmonic acid and ethylene, induction of defense genes, and release of volatile emissions. In addition to insect elicitors, feeding patterns of herbivores play a key role in the specificity of induced responses. In lima beans, continuous mechanical wounding alone is sufficient to mimic volatile emissions produced by caterpillar damage (Mithöfer et al., 2005).

The specificity of response and effect may be revealed through the expression of induced proteins. Antinutritive proteins such as proteinase inhibitors (PIs), arginase (ARG), threonine deaminase (TD), or polyphenol oxidase (PPO) can be induced by mechanical wounding, insect feeding, or jasmonic acid (Ryan, 2000; Felton, 2005; Chen et al., 2005, 2007; Zhu-Salzman et al., 2008). PIs inhibit insect digestive proteases and disrupt absorption of essential nutrients (Ryan, 1990). PIs are categorized into several groups such as serine protease inhibitor (SerPI), cysteine protease inhibitor (CysPI), and aspartic protease inhibitor (AspPI) according to the protease they inhibit. Induction of PIs could be herbivore-specific to produce defensive proteins that are effective against specific proteases or in specific gut environments characteristic of the herbivore. ARG and TD degrade essential amino acids and retard growth of herbivores with alkaline midguts (Chen et al., 2005, 2007). PPOs catalyze the oxidation of phenolics to quinones and diminish the nutritional value of ingested proteins especially in herbivores with alkaline midguts (Felton et al., 1992).

Coleopteran species often have an acidic midgut and use cysteine and aspartic proteases as the major proteases for protein digestion (Wolfson and Murdock, 1987; Felton et al., 1992). In contrast, lepidopteran larvae normally have an alkaline midgut and rely on serine proteases (Felton and Duffey, 1991). Therefore, CysPI and AspPI would be predicted to have little effect on lepidopteran species, and SerPI should be less effective on coleopteran species (Zhu-Salzman et al., 2008). We hypothesized that plants may produce distinct suites of antinutritive proteins in response to specific attacking herbivores, and that production of SerPI, ARG, TD, and PPOs would increase in plants damaged by a lepidopteran species compared to plants damaged by a coleopteran species.

In this investigation, we tested whether the induced responses of tomato *Solanum lycopersicum* are specific to two different herbivore species: THW (*M. sexta*) and the Colorado potato beetle (CPB; *Leptinotarsa decemlineata*). Both species are specialist herbivores on Solanaceous plants such as tomato. To test specificity of elicitation, we evaluated whether tomato plants damaged by CPB accumulate different transcripts and have different protein activities compared to plants damaged by THW feeding. To test specificity of effect, we evaluated whether larval CPB growth is compromised more on plants damaged by CPB than on plants damaged by THW.

Methods and Materials

Plants, Insects and Oral Secretions Tomato (*Solanum lycopersicum* cv Better Boy) plants grown in Pro-mix potting soil (Premier Horticulture, Quakertown, PA, USA) were watered every day and fertilized with 3 g of Osmocote plus (15-9-12, Scotts, Marysville, OH, USA) until they reached the four-leaf stage. All leaf samples were frozen immediately in liquid nitrogen and stored at −80°C until analysis. Eggs of THW were purchased from Carolina Biological Supply (Burlington, NC, USA) and hatched in a growth chamber at 27°C with 16:8 hL: D, and larvae were reared on artificial diet. Adult CPB were collected from potato fields in Hamburg, PA, USA (Dr. Jim Steffel, Lehigh Agricultural & Biological Services, Inc., Hamburg, PA, USA) and were maintained on tomato plants in a greenhouse with 16:8 hL: D. Eggs of CPB were hatched in a growth chamber, and larvae were supplied with detached tomato foliage until pupation. Oral secretions were collected from fourth-instar larvae of THW and CPB with a Pipetteman micropipette (Gilson, Middleton, WI, USA) by gently disturbing the larval mouth. Crude oral secretion was centrifuged at 10,000 x *g* for 10 min to remove particulates and stored at −80°C until used.

Herbivore Treatments To compare gene expression of plants damaged by CPB and THW, one first-instar of CPB or THW was confined to a clip cage (diam: 2 cm) and allowed to feed for 24 hr, followed by removal of the insect. The damaged leaflets were scanned to measure the area consumed using SigmaScan Pro 5 (SPSS) and approximately 100 mg of leaf tissue were then harvested from damaged leaves. Control plants included undamaged plants, and negative control plants had empty cages.

To investigate the effects of CPB and TWH feeding on trypsin protease inhibitor activity, one first instar of CPB or THW was confined in a clip cage on the third leaf for 24 hr, resulting in consumption of 25 to 50% of available leaf area, based on visual estimates. The insect was removed,

and 48 hr later leaves were collected (72 hr after placing insects on plants). Empty cages were used for the negative controls, and no cages were used on the control plants.

To determine the effects of larval oral secretions on gene expression, plants were wounded using pipette tips to punch two holes next to the midveins of leaves, removing 0.26 cm^2 of tissue from each leaf. Oral secretions were diluted with 4 volumes of water before applying 20 µl to wounded areas on the experimental plants, or water on the wounded control plants. After 12 hr, leaf samples were harvested.

RNA Extraction and Quantitative Real Time Polymerase Chain Reaction (qRT-PCR) RNA was extracted and purified with an RNeasy Plus Mini-kit (Qiagen, Valencia, CA, USA), and cDNA was synthesized using 1 µg RNA as the template (High Capacity cDNA Reverse Transcription kit, Applied Biosystems, Foster City, CA). The Power SYBR Green PCR Master Mix and 7500 Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, USA) were used to carry out qRT-PCR under following conditions: 95°C for 10 min, then 40 cycles of 15 sec at 95°C, 60 sec at 60°C. Gene-specific primers for *SerPI, CysPI, AspPI, ARG2, TD2,* and *UBQ* were used (Table 1) with dissociation curve analysis to confirm specificity of each primer. The expression levels of each genes were normalized relative to the housekeeping gene, ubiquitin, and were calculated using $2^{-\Delta\Delta C(T)}$ method (Livak and Schmittgen, 2001). Efficiencies of the amplification reaction for genes tested and validation data for reference gene are described in Supplemental Tables 1, 2 and Supplemental Fig. 1.

Trypsin Protease Inhibitor (PI) Activity The activity of trypsin PI was measured in leaves using an assay for trypsin activity (Worthington, 1988). A 50 mg sample of leaf tissue treated as described above was ground in liquid nitrogen and extracted with 1.25 ml buffer (0.046 M Tris buffer, pH 8.1, 0.0115 M $CaCl_2$) containing 5% (w/v) insoluble polyvinyl-polypyrrolidone. Samples were centrifuged at 11,000 x *g* for 10 min at 4°C, and 20 µl of the supernatant were mixed with 10 µl of 1 mM HCl containing 0.4 µg bovine trypsin (Sigma, St Louis, MO, USA; T1426) and 70 µl of extraction buffer. The mixture was incubated for 10 min at room temperature, mixed with 100 µl of 2 mM p-toluene-sulfonyl-L-arginine methyl ester (Sigma, T4626), and monitored for 5 min at 247 nm. Trypsin PI activity was calculated as PI (%)=[1-A/C] x 100, where A represents trypsin activity of the sample and C represents the maximum value of tryspin activity in control plants without clip cages.

Feeding Assay To investigate whether defenses induced by prior feeding negatively affect insect performance, CPB larval growth was determined. Two first-instars of THW or five first-instars of CPB were confined in clip cages on the terminal leaflet of the 3 rd leaf and allowed to feed for 24 hr, resulting in consumption of 50 to 100% of the leaf area in each cage. Empty cages were clipped on control plants. Four days after initiating insect feeding the damaged leaflets were excised, and one first-instar CPB was placed on each damaged leaflet in 1 oz diet cup containing 1% agar. The fresh mass of each larva was measured 6 d later. PPO activity was measured on a 50 mg subsample of tissue from each treatment collected 4 d after the initial treatment.

Polyphenol Oxidase (PPO) Activity The tissue was ground in liquid nitrogen, extracted with 1.25 ml buffer (0.1 M potassium phosphate buffer, pH 7.0) containing 5% insoluble polyvinylpolypyrrolidone, and centrifuged at 11,000 x g for 10 min at 4°C. Five microliters of supernatant were mixed with 200 µl of 3 mM caffeic acid

Table 1 Primer lists for qRT-PCR

Gene name	Description	Genebank Accession No.	Forward/reverse sequence	Reference

[a] Solanaceous Gene Network (SGN) identifier

(Sigma, Cat. No. C0625), and absorbance at 450 nm was monitored for 5 min. PPO activity was expressed as change in absorbance/min/mg tissue (Felton et al., 1989).

Statistical Analyses Transcript levels of defense genes and trypsin PI activities were analyzed by the non-paramatric Kruskal-Wallis and Tukey multiple comparison. Larval weight and PPO activities were analyzed by one-way ANOVA followed by Tukey multiple comparison. Weight data and PPO activities were log-transformed to meet assumptions of normality and homogeneity of ANOVA. All analyses were conducted with SAS 9.2.

Results

Gene Expression and Trypsin PI Activity CPB and THW feeding for 24 hr in a clip cage increased expression levels of defense genes compared to the control treatment (Fig. 1;

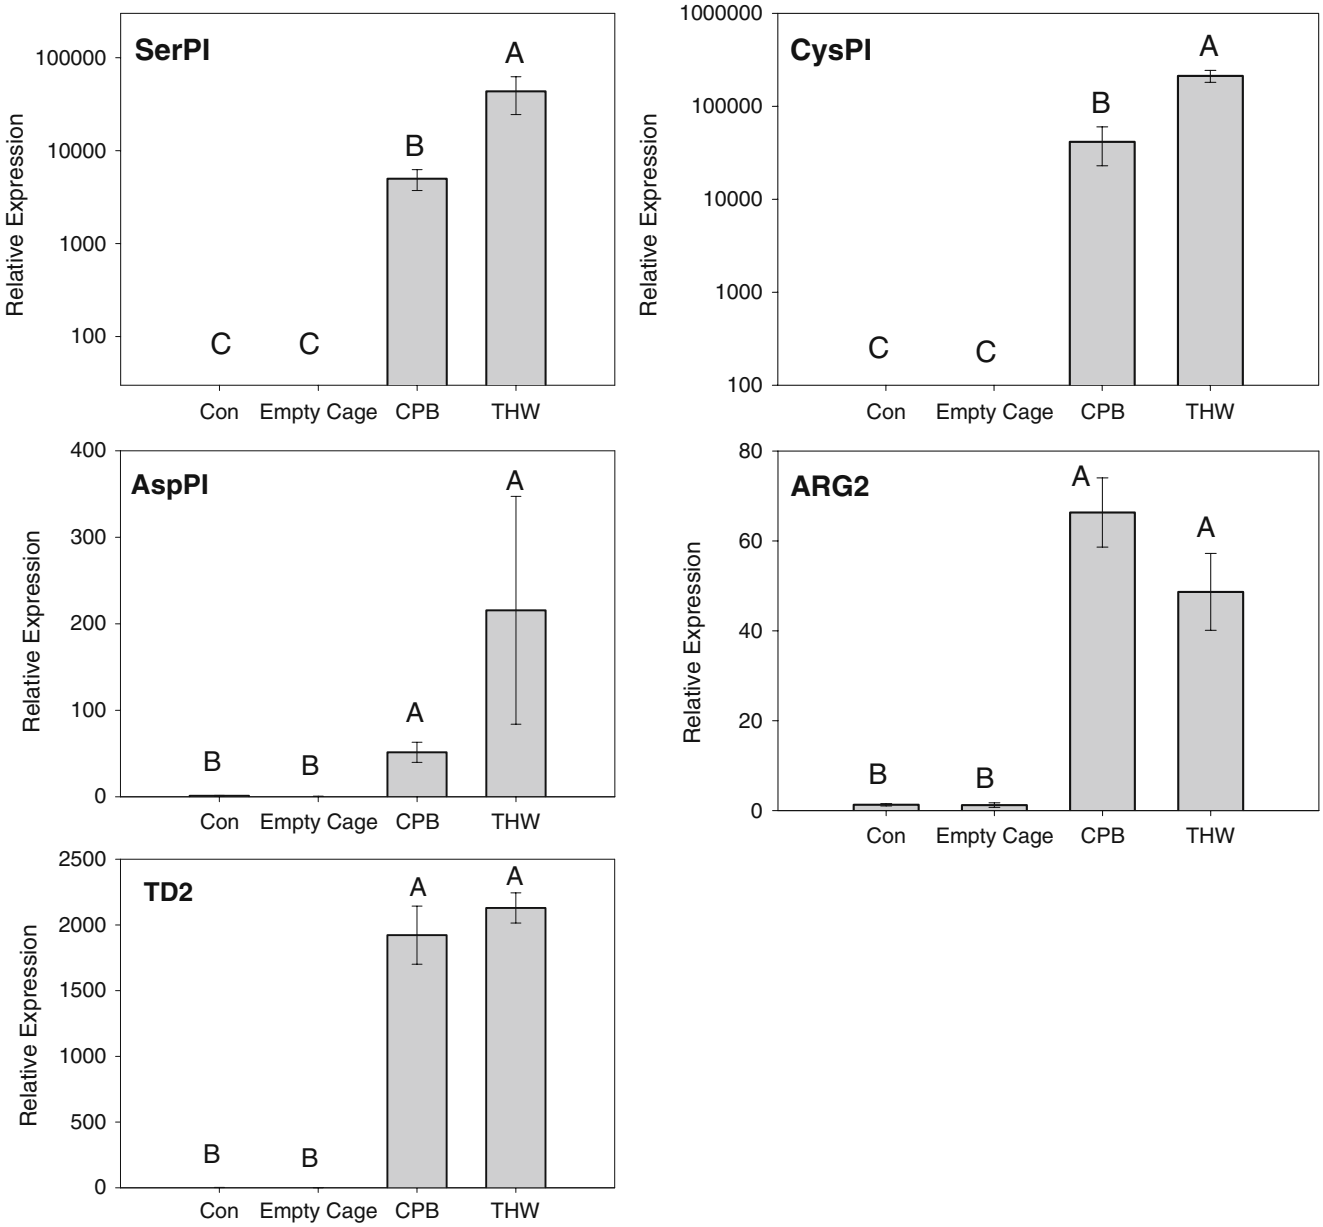

Fig. 1 Quantitative effects of insect feeding on expression of defense genes. Expression relative to ubiquitin was measured after 24 hr of Colorado potato beetle (CPB) or tobacco hornworm (THW) feeding (N=5). Con, unwounded control plants; Empty cages, unwounded plants with empty cages. *SerPI*, Serine protease inhibitor; *CysPI*, Cysteine protease inhibitor; *AspPI*, Aspartic protease inhibitor; *ARG2*, Arginase 2; *TD2*, Threonine deaminase 2. Values are mean ± SE. Different letters represent significant differences (Kruskal-Wallis; P<0.05)

P< 0.05). The amount of damage by the two herbivores was not significantly different (CPB consumption: 0.44±0.13 cm^2 and THW consumption: 0.81±0.15 cm^2; $P>0.05$). There were no significant correlations between the amount of damage by either CPB or THW and transcript accumulations (for CPB, *SerPI*: $r=0.346$, $P>0.05$, $N=5$; *CysPI*: $r=0.557$, $P>0.05$, $N=5$, for TWH, *SerPI*: $r=0.702$, $P>0.05$, $N=5$; *CysPI*: $r=0.476$, $P>0.05$, $N=5$). *SerPI* transcript accumulation was 9 fold higher in plants damaged by THW than in plants damaged by CPB (Fig. 1; $P<0.05$). *CysPI* transcript accumulation was 5 fold higher in plants damaged by THW than in plants damaged by CPB (Fig. 1; $P<0.05$). However, expression levels of *AspPI*, *ARG2*, and *TD2* were not significantly different in plants damaged by THW than in plants damaged by CPB (Fig. 1; $P>0.05$).

To investigate the effects of CPB and TWH feeding on trypsin PI activity, one larva of either CPB or THW was allowed to feed for 24 hr, followed by tissue extraction and assessment of trypsin PI activity 48 hr later. CPB and THW feeding induced higher trypsin PI activities than the control treatment (Fig. 2; $P<0.05$). Trypsin PI activities were 3-fold higher in plants damaged by THW than in plants damaged by CPB (Fig. 2; $P<0.05$).

Oral Secretions from CPB and THW Expression levels of defense genes were measured 12 hr after application of oral secretions to wounded leaves. Levels of defense gene transcripts were higher in wounded plants than in control plants (Fig. 3; $P<0.05$). Compared to mechanical wounding without oral secretions, CPB secretion suppressed expression levels of some defense genes, while THW secretion induced expression of defense genes (Fig. 3). Transcript accumulations of *CysPI*, *ARG2*, and *TD2* were 50% lower on wounded plants treated with CPB secretion than on control wounded plants (Fig. 3; *P< 0.05*). Expression levels of *SerPI*, *CysPI,* and *TD2* were 2- to 3-fold higher on wounded plants treated with THW secretion than on plants that were only wounded (Fig. 3; *P< 0.05*).

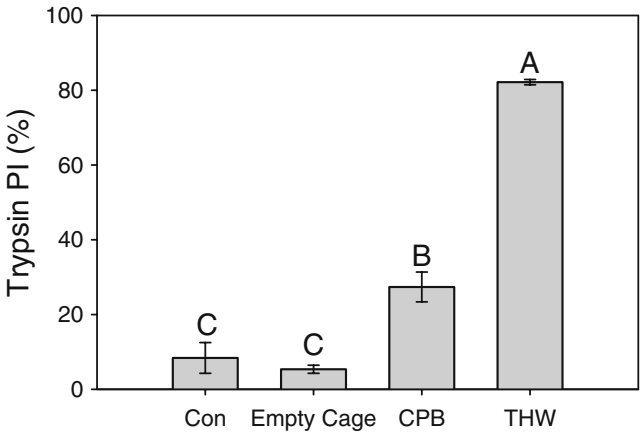

Fig. 2 Effects of insect feeding on trypsin proteinase inhibitor (PI) activity. Colorado potato beetle (CPB) or tobacco hornworm (THW) ($N=4$–6) were allowed to feed for 24 hr, followed by a 48 hr lag before activity was measured. Con, unwounded control plants; Empty cages, unwounded plants with empty cages. Values are mean ± SE. Different letters represent significant differences (Kruskal-Wallis; $P<0.05$)

CPB Growth Rate and PPO Activity CPB larvae grew more slowly when consuming leaf tissue that had previously been attacked by CPB or THW compared with consumption of control tissue (Fig. 4A; $P<0.05$). CPB growth on plants previously damaged by CPB was not significantly different from that on plants previously damaged by THW (Fig. 4A; $P>0.05$). PPO activity was measured 4 days after initiating insect feeding. CPB and THW feeding increased PPO activities compared with control treatment and PPO activities were higher on plants damaged by THW than on plants damaged by CPB (Fig. 4B; $P<0.05$).

Discussion

Coleopteran and Lepidopteran species frequently have different midgut pH levels and may use different proteases to digest plant proteins (Wolfson and Murdock, 1987; Felton and Duffey, 1991; Felton et al., 1992). The functions of induced antinutritive plant proteins such as PIs, ARG, TD, and PPO might vary depending on herbivore midgut pH and digestive enzymes. We hypothesized that tomato plants would respond specifically to different herbivores by increasing transcript accumulation of defense genes that are specifically effective against each herbivore. However, tomato did not express defense transcripts that encoded specific detrimental proteins against THW or CPB. Wounding by insect feeding or by mechanical damage increased transcript level for antinutritive proteins such as PIs, ARG, and TD, and increased activity for trypsin PI and PPO (Figs. 1, 2, 3). This is consistent with some other studies; for example, CPB feeding induced SerPI and PPO in tomato (Green and Ryan, 1972; Felton et al., 1992). Mechanical wounding, jasmonic acid, and herbivory all elicit the production of defense gene transcripts and proteins in tomato and potato leaves (Green and Ryan, 1972; Felton et al., 1992; Bolter, 1993; Korth and Dixon, 1997; Ryan, 2000; Wu and Haard, 2002).

Although *qualitative* differences in the induction of antinutritive proteins were not found, the induced responses of tomato were *quantitatively* different for different stimuli, suggesting specificity of elicitation in tomato. The level of transcripts for *SerPI* and *CysPI* was higher in plants damaged by THW than in plants damaged by CPB

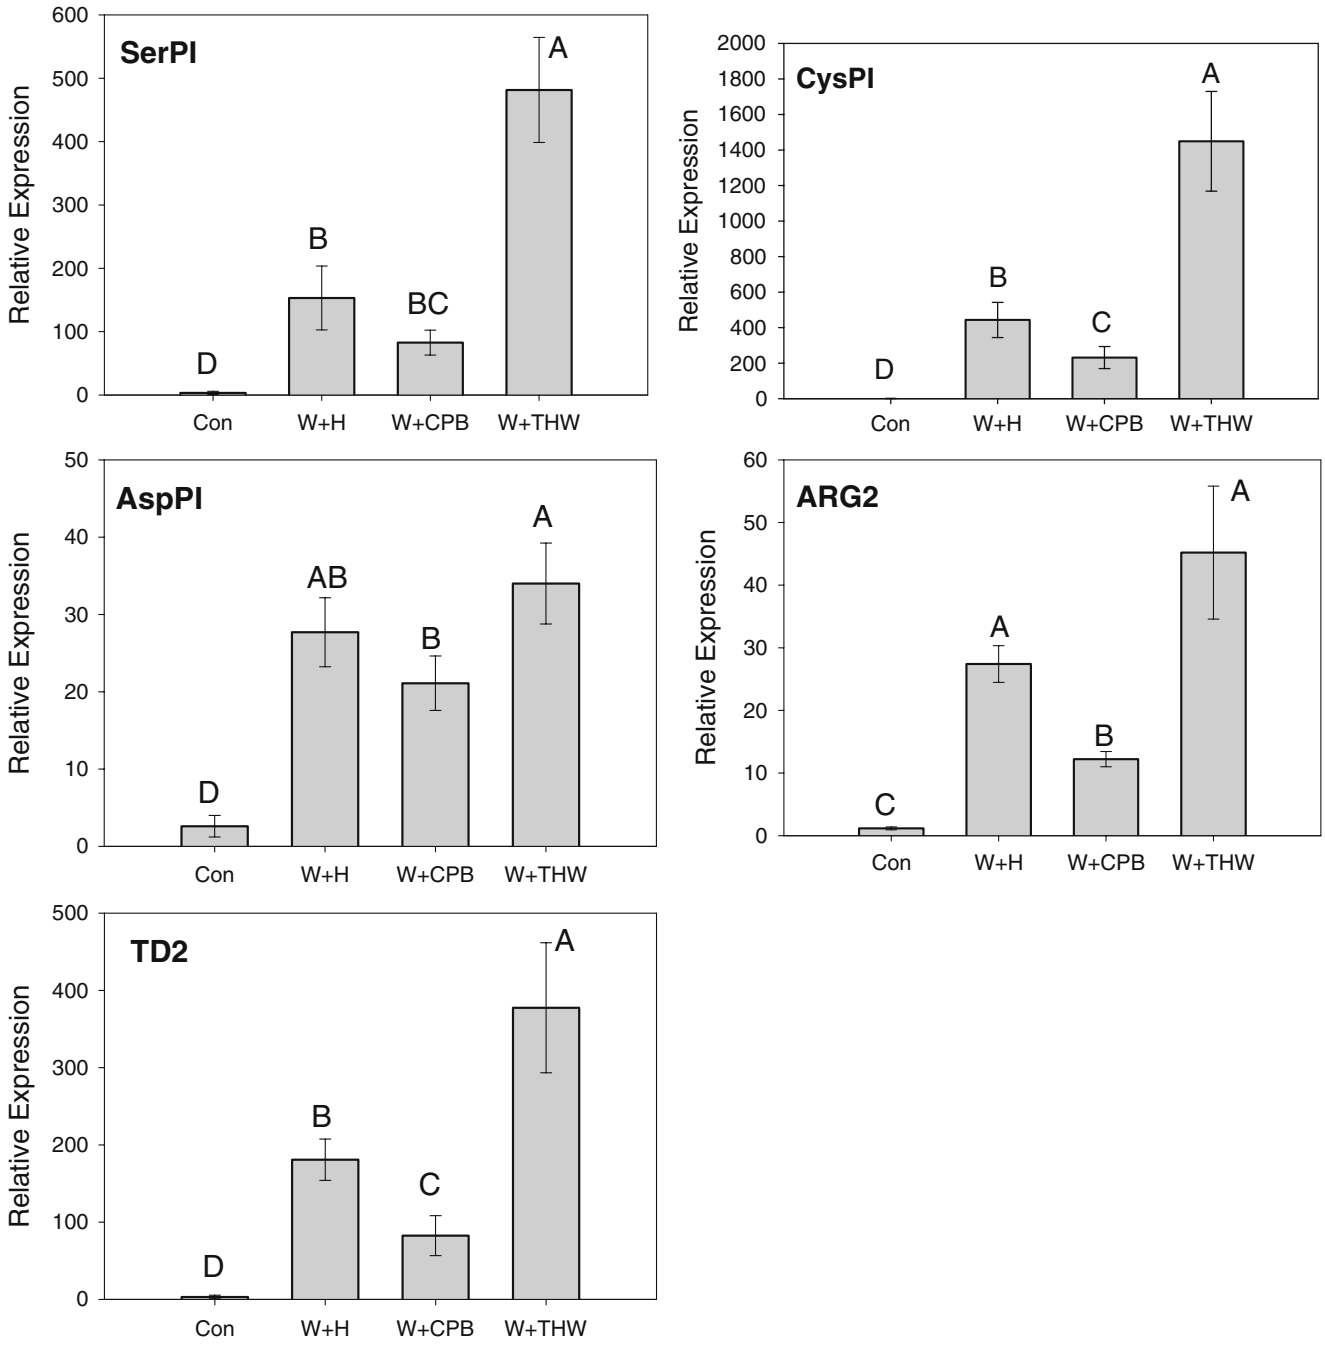

Fig. 3 Effects of oral secretions on expression of defense genes. Expression relative to ubiquitin was measured after 12 hr of treatment (N=5). Con, unwounded control plants; W+H, mechanical wounding plus H_2O; W+Colorado potato beetle (CPB), mechanical wounding plus CPB oral secretions; W+tobacco hornworm (THW), mechanical wounding plus THW oral secretions. *SerPI*, Serine protease inhibitor; *CysPI*, Cysteine protease inhibitor; *AspPI*, Aspartic protease inhibitor; *ARG2*, Arginase 2; *TD2*, Threonine deaminase 2. Values are mean ± SE. Different letters represent significant differences (Kruskal-Wallis; $P<0.05$)

(Fig. 1). Trypsin PI activity followed the same pattern as defense gene expression (Fig. 2). Traw and Dawson (2002) demonstrated specificity of elicitation in *Brassica nigra* in response to herbivores in the same feeding guild, but in different insect orders. Trichome densities and sinigrin concentration increased in plants damaged by a lepidopteran species, *Pieris rapae*, but did not change in plants damaged by the coleopteran species, *Phllotreata cruciferae*.

Few studies have investigated induced responses to herbivory by insects in different orders. However, species-specific induced responses elicited by different herbivores in the same feeding guild and insect orders have been noted

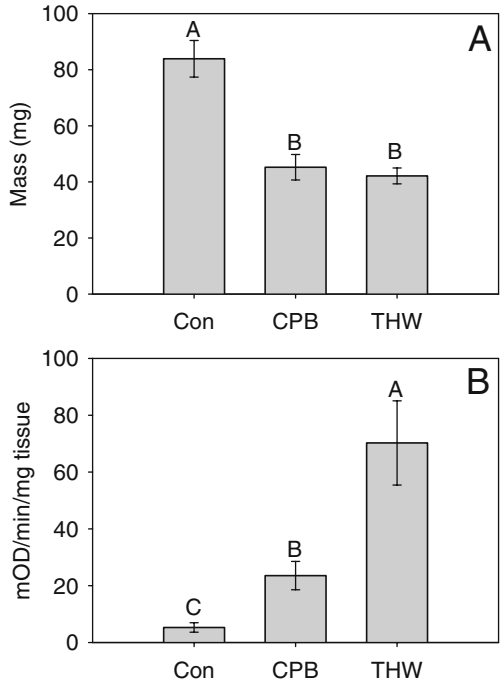

Fig. 4 Colorado potato beetle (CPB) growth and polyphenol oxidase (PPO) activity in tissue previously attacked by CPB or tobacco hornworm (THW) larvae. Plants were challenged with 5 CPB or 2 THW larvae for 24 hr. The damaged leaflets were excised 72 hr after removing the larvae, and one CPB larva was then allowed to feed for 6 days on the excised damaged leaves. (A) Mass of CPB larvae (N= 10–15). (B) PPO activity was measured from subsample of each treatment 4 days after initiating insect feeding (N=4). Con, unwounded control plants. Values are mean ± SE. Different letters represent significant differences (ANOVA; P<0.05)

in other studies. For example, in *Nicotiana attenuata*, transcriptional responses to a specialist *M. sexta* were different from those to the generalists *S. exigua* and *Heliothis virescens* (Voelckel and Baldwin, 2004). In *Boechera divaricarpa*, the specialist *Plutella xylostella* elicited transcription patterns different from the generalist *Trichoplusia ni* (Vogel et al., 2007). On the other hand, Reymond et al. (2004) reported that in *A. thaliana*, transcriptional responses to feeding by the specialist *P. rapae* or the generalist *S. littoralis* were similar. Thus, it appears that differential and specific induction may be found among some but not all systems of plants and herbivorous insects.

This study suggests that distinct responses to the herbivores may be due to insect-specific elicitors or effectors found in oral secretions, not due to differences in the amount of damage caused by different insects. The areas consumed by CPB and THW were not different, and there were no correlations between the amount of damage and transcript accumulation. We found that oral secretions from THW applied to mechanically wounded areas on tomato leaves induced transcription of defense genes, but oral secretions from CPB suppressed gene expression, except *SerPI* and *AspPI* (Fig. 3). In contrast, Lawrence et al. (2007) found that application of 100 µl of oral secretions from CPB to wounded tomato plants suppressed *SerPI* transcript accumulation 4 hr after the treatment, compared to wounded tomato plants. This discrepancy may be due to differences in the amount of oral secretion applied or to harvest time.

Oral secretions have been associated with herbivore-specific responses in several other systems. For example, oral secretion from THW increased production of jasmonic acid, transcription of defense-related genes, and release of volatiles in *N. attenuata* compared with the wounded control (Halitschke et al., 2001). Diezel et al. (2009) demonstrated that *M. sexta* and *S. exigua* feeding elicited different profiles of phytohormone production, perhaps due to differences in glucose oxidase activity and in fatty acid-amino acid conjugate profiles in the oral secretions of the two herbivore species. Bede et al. (2006) showed that glucose oxidase activity in saliva of *S. exigua* suppressed defense transcripts in *Medicago truncatula*. Lawrence et al. (2007) demonstrated that a protein fraction from CPB oral secretion may be responsible for suppression of PI transcript accumulation. In *N. attenuata*, oral secretion from THW suppressed nicotine accumulation (Winz and Baldwin, 2001). In *N. tabacum*, glucose oxidase (GOX) from *Heliocoverpa zea* saliva inhibited nicotine production (Musser et al., 2002). However, Schmelz et al. (2009) showed that tomato does not respond to elicitors such as volicitin (N-17-hydroxylinolenoyl-L -glutamine), N-linolenoyl-glutamine, inceptin, or califerin. In the current study, oral secretion from THW increased transcript accumulations of defense genes compared to wounded plants (Fig. 3). In *N. attenuata*, synthetic blends of N-linolenoyl-L-glutamine and N-linolenoyl-L-glutamate mimicked induced responses to oral secretion from THW. It is suggested that these two fatty acid-amino acid conjugates are necessary for herbivore-specific responses (Halitschke et al., 2003; Roda et al., 2004). Thus, it is likely that components other than fatty acid-amino acid conjugates in the oral secretion of THW might be responsible for the induced responses that we observed in tomato.

In tomato, application of oral secretions of CPB or THW to a wounded area on a leaf appears to mimic the induced responses to insect feeding. Peiffer and Felton (2009) showed that lepidopteran larvae release less than 10 nl of oral secretion, and may regurgitate during feeing on some host plant species. In that study, THW larvae did not regurgitate when they fed on tomato leaves, perhaps thus avoiding the induction of plant host defense responses. In contrast, CPB larvae consistently release oral secretion on tomato leaves (Chung and Felton, unpublished data), consistent with the suppression of plant defense responses by CPB oral secretion. We argue that CPB larvae secrete oral secretions that suppress host defense responses, but

THW larvae normally avoid secretion, thus minimizing the induction of defense responses.

The growth of CPB larvae was reduced to the same extent when the larvae consumed plants that had been previously damaged by either CPB or THW (Fig. 4), suggesting that there is low specificity of effect. The data also indicate that feeding by either species elicits the same kinds of antinutritive proteins. Although CPB feeding increased smaller amounts of defense proteins such as trypsin PI and PPO than THW feeding did, the levels might be sufficient to reduce subsequent CPB growth. In addition, it is possible that other defensive chemicals induced by CPB feeding deter CPB growth. Low specificity of effect has been found in other studies. Traw and Dawson (2002) showed that growth of *P. rapae* and *P. cruciferae* was reduced when the insects fed on plants damaged by either species. However, Agrawal (2000) showed a complex pattern for specificity of effect. In *Raphanus sativus*, three of four herbivore species showed reduced growth on plants damaged by conspecifics compared with undamaged control.

Overall, tomato shows distinct induced responses to different herbivores: induction by THW and minimal induction by CPB. Oral secretions of the two herbivores may play a key role in these species-specific responses. However, tomato does not increase transcripts that encode specifically deleterious proteins against THW or CPB when damaged by THW or CPB. There is low specificity of effect in tomato by CPB or THW feeding on subsequent CPB growth.

Acknowledgments We thank the USDA AFRI programs (2010-65105-20639 and proposal 2010–03720 awarded to GWF and DSL) for support of the project.

Abstract Studies were conducted to develop an attractant for the cranberry weevil, *Anthonomus musculus*, a pest of blueberry and cranberry flower buds and flowers in the northeastern United States. In previous studies, we showed that cinnamyl alcohol, the most abundant blueberry floral volatile, and the green leaf volatiles (*Z*)-3-hexenyl acetate and hexyl acetate, emitted from both flowers and flower buds, elicit strong antennal responses from *A. musculus*. Here, we found that cinnamyl alcohol did not increase capture of *A. musculus* adults on yellow sticky traps compared with unbaited controls; however, weevils were highly attracted to traps baited with the *Anthonomus eugenii* Cano aggregation pheromone, indicating that these congeners share common pheromone components. To identify the *A. musculus* aggregation pheromone, headspace volatiles were collected from adults feeding on blueberry or cranberry flower buds and analyzed by gas chromatography-mass spectrometry. Three male-specific compounds were identified: (*Z*)-2-(3,3-dimethyl-cyclohexylidene) ethanol (*Z* grandlure II); (*Z*)-(3,3-dimethylcyclohexylidene) acetaldehyde (grandlure III); and (*E*)-(3,3- dimethylcyclohexylidene) acetaldehyde (grandlure IV). A fourth component, (*E*)-3,7-dimethyl-2,6-octadien-1-ol (geraniol), was emitted in similar quantities by males and females. The emission rates of these volatiles were about 2.8, 1.8, 1.3, and 0.9 ng/adult/d, respectively. Field experiments in highbush blueberry (New Jersey) and cranberry (Massachusetts) examined the attraction of *A. musculus* to traps baited with the male-produced compounds and geraniol presented alone and combined with (*Z*)-3-hexenyl acetate and hexyl acetate, and to traps baited with the pheromones of *A. eugenii* and *A. grandis*. In both states and crops, traps baited with the *A. musculus* male-produced compounds attracted the highest number of adults. Addition of the green leaf volatiles did not affect *A. musculus* attraction to its pheromone but skewed the sex ratio of the captured adults towards females. Although the role of plant volatiles in host-plant location by *A. musculus* is still unclear, our studies provide the first identification of the primary *A. musculus* aggregation pheromone components that can be used to monitor this pest in blueberry and cranberry pest management programs.

Introduction

The genus *Anthonomus* contains more than 100 North American species (Borror et al., 1989), many of which are considered among the most destructive pests of cultivated plants. One such example is the cranberry weevil, *Anthonomus musculus* Say (Coleoptera: Curculionidae), a pest that causes major economic losses annually to highbush blueberries, *Vaccinium corymbosum* L., and cranberries, *Vaccinium macrocarpon* Aiton (Ericales: Ericaceae), in the northeastern United States (Marucci, 1966; Averill and Sylvia, 1998; Long and Averill, 2003). Native to North America, *A. musculus* is distributed from Ontario (Canada) and New England (United States) to the Rocky Mountains and Florida (United States) (Lacroix, 1926; Averill and Sylvia, 1998). Although it utilizes many host plants within the family Ericaceae (Mechaber, 1992), *A. musculus* is considered a major pest only on cultivated *Vaccinium* spp. In New Jersey, this insect is commonly recognized as one of the top pests of highbush blueberries, whereas in Massachusetts it is considered a pest of cranberries (Doehlert and Tomlinson, 1947; Averill and Sylvia, 1998). *Anthonomus musculus* rarely occurs on cranberries in New Jersey (Mechaber, 1992).

Anthonomus musculus feeding and oviposition activity causes damage to blueberry and cranberry flower buds and flowers. Females lay their eggs inside unopened flowers, and the larvae complete their development within the flower buds. Most *A. musculus* adults overwinter outside commercial blueberry and cranberry fields, under debris and fallen leaves in surrounding wooded areas. Mechaber (1992) suggested that *A. musculus* can complete two generations a year, but a single generation is thought to be typical (Lacroix, 1926; Doehlert and Tomlinson, 1947). In New Jersey, adults become active in late April and move from overwintering sites to cultivated blueberries before the buds start to swell (Doehlert and Tomlinson, 1947). The adults emerge in late May–June (summer generation), and feed on tender leaves and young fruit. The majority of these adults eventually move out of the blueberry fields to alternative hosts in the surrounding woods, where they have been observed to mate (Mechaber, 1992; Z. Szendrei, personal observation). In Massachusetts, overwintering adults move from wild hosts (e.g., wild *Vaccinium* spp.) to cranberries in late May–June, mate, and lay eggs on the developing flower buds (Mechaber, 1992; Averill and Sylvia, 1998). Summer generation adults appear from late June to early July, and these adults will overwinter (Lacroix, 1926).

Current monitoring methods for *A. musculus* are labor-intensive and inaccurate. Because adults overwinter in wooded areas surrounding blueberry and cranberry fields, pest pressure is typically highest close to field edges; thus, monitoring efforts focus along these areas. Monitoring for adults is initiated when buds begin to swell. In highbush blueberries, overwintered *A. musculus* adults are monitored by using beating trays or by visually inspecting buds and flowers for injury; whereas in cranberries, adults are monitored by using sweep nets (Averill and Sylvia, 1998). In addition, adults are active almost exclusively on warm days. They drop to the ground when disturbed, and their populations are patchily distributed, causing inconsistent scouting results. Thus, a cost-effective and consistent sampling method for detecting *A. musculus* adults is critical to better estimate population occurrences and densities.

Previous studies have identified semiochemical-based attractants, i.e., aggregation pheromones, host-plant volatiles, and their combinations, which in some cases have been used successfully to monitor *Anthonomus* species (e.g., Tumlinson et al., 1969; Dickens, 1989; Eller et al., 1994; Innocenzi et al., 2001; Tinzaara et al., 2007). For example, Dickens (1989) showed that the green leaf alcohols (*E*)-2-hexen-1-ol, (*Z*)-3-hexen-1-ol, and 1-hexanol in combination with the boll weevil, *Anthonomus grandis* Boheman, aggregation pheromone enhances trap captures of boll weevils compared to the pheromone alone. Hence, our objective was to develop similar attractants to monitor more precisely *A. musculus* populations in blueberries and cranberries. In a recent study, we showed that female *A. musculus* are attracted to blueberry flowers, whereas males are attracted to undamaged flower buds and are repelled by damaged flower buds (Szendrei et al., 2009). In that study, volatile compounds from blueberry flower buds and flowers were identified; of these, cinnamyl alcohol and the green leaf volatiles (GLVs) (*Z*)-3-hexenyl acetate and hexyl acetate elicited strong antennal responses from both male and female *A. musculus*. Here, we conducted studies to: a) investigate the response of *A. musculus* to these blueberry volatiles and to the pepper weevil, *Anthonomus eugenii* Cano, and boll weevil, *A. grandis*, aggregation pheromones; b) isolate and identify the major components of the *A. musculus* aggregation pheromone; and c) evaluate the response of *A. musculus* to its aggregation pheromone alone and in combination with the antennally-active green leaf acetates.

Methods and Materials

Insects Field-collected *A. musculus* adults were used for headspace volatile collections. Adult *A. musculus* were collected in March–April 2008 and 2009 from highbush blueberries in Hammonton (Atlantic Co.) and Chatsworth (Burlington Co.), New Jersey, USA and transported to the laboratory. In the laboratory, adults were held in environmental chambers (16:8 hL:D, 15°C), in screen cages (30×30×30 cm), and were fed fresh highbush blueberry (cv. Bluecrop)

buds and foliage collected from an unsprayed field located at the P.E. Marucci Blueberry & Cranberry Center (Chatsworth, NJ, USA). Adult weevils were separated by sex under a stereomicroscope based on characters of the pygidium (Szendrei et al., 2009). The pygidium is fused with the last tergite in females, but these two segments are separate in males.

Volatile Collections Headspace volatiles were collected from *A. musculus* males and females in the laboratory (16:8 hL:D, 25°C), in 6 ml clear scintillation glass vials (Thermo Fisher Scientific Inc., Pittsburgh, PA, USA). The cap of each vial held an adsorbent trap, filled with 30 mg Super Q (80/100 mesh; Alltech, Deerfield, IL, USA), and a Pasteur pipette (Thermo Fisher Scientific Inc.), containing 1.25 g of activated charcoal (Alltech) to clean the incoming air. Volatiles from inside the vials were drawn through the trap by pulling air at a flow rate of ca. 1 l/min for 72 h. During volatile collections, weevils were provided daily with 0.3 g field collected blueberry or cranberry flower buds. Males and females were separated prior to volatile collections, and 20 adults of each sex were placed in a vial. In addition, volatile emissions were compared between males feeding on either blueberry or cranberry flower buds (N=4 replicates of 20 adults each per crop). After collections, traps were washed with 150 µl methylene chloride, an internal standard [400 ng of nonyl acetate (Sigma-Aldrich; St. Louis, MO, USA)] was added to each extract, and samples were stored in a freezer until used in gas chromatography-mass spectrometry (GC-MS) analysis.

Chemical Analyses Samples and synthetic standards were analyzed by GC-MS (Instruments 7890 and 5975 C; Agilent, Palo Alto, CA, USA) in both EI and CI (isobutane) modes by using a 30 m×0.25 mm i.d. × 0.25 µm film thickness medium polar DB35 (35%-Phenyl-methylpolysiloxane) and non-polar DB-1 (100% Dimethylpolysiloxane) capillary column (Agilent). Samples were introduced with cold on-column injection into a 1 m deactivated fused silica retention gap between injector and analytical column. For both columns, the oven temperature was kept at 30°C for 2.5 min after injection and then temperature programmed 20°C/min to 90°C and then 2°C/min to 125°C followed by 20°C /min to 240°C. The He carrier gas flow rate was 30 cm/sec (constant flow), and the MS transfer line temperature was 250°C. The ion source temperature was 220°C in EI mode and 250°C in CI mode. The presence of known pheromone components was confirmed by analyzing synthetic standards (compounds **1**–**7**; Fig. 1), as well as selected natural samples in EI- and CI-mode with both GC columns. For quantitative analyses on the DB-1 column, the synthetic standards and the internal standard nonyl acetate were analyzed in CI mode to establish diagnostic ions: for compounds **1**, **2**, **3**, and **6** they were *m/z* 155 (M + 1) and *m/z* 137 (M + 1-18); for compounds **4** and **5** it was *m/z* 153 (M + 1); for compound **7** it was *m/z* 169 (M + 1); and finally, for nonyl acetate it was *m/z* 187 (M + 1). The MS was set to collect data for all five ions during the whole analysis. In that way, known compounds could be selectively detected in the complex natural samples while at the same time making it possible to detect the presence of related compounds. Response factors for all compounds were calculated by injecting known amounts of the standards (for the synthetic geranic acid the areas for both isomers were added prior to conducting calculations).

Synthetic Chemicals (*Z*)-2-isopropenyl-1-methylcyclobutaneethanol (grandlure I; compound **1**, Fig. 1), (*Z*)-2-(3,3-dimethyl-cyclohexylidene)ethanol (*Z* grandlure II; compound **2**, Fig. 1), (*E*)-2-(3,3-dimethyl-cyclohexylidene) ethanol (*E* grandlure II; compound **3**, Fig. 1), a mixture of (*Z*)-(3,3-dimethylcyclohexylidene) acetaldehyde (grandlure III; compound **4**, Fig. 1) and (*E*)-(3,3- dimethylcyclohexylidene) acetaldehyde (grandlure IV; compound **5**, Fig. 1), (*E*)-3,7-dimethyl-2,6-octadien-1-ol) (geraniol; compound **6**, Fig. 1), and (*E*)-3,7-dimethyl-2,6-octadienoic acid [geranic acid (including neric acid); compound **7**, Fig. 1] were purchased from Bedoukian Research Inc. (Danbury, CT, USA) (all >95% purity). Cinnamyl alcohol, (*Z*)-3-hexenyl acetate, and hexyl acetate were purchased from Sigma-Aldrich (all≥97% purity).

2008 Field Experiments Field studies were conducted to test the response of *A. musculus* to yellow sticky traps (23 by 28 cm Unbaited Pherocon AM; Trécé Inc., Adair, OK,

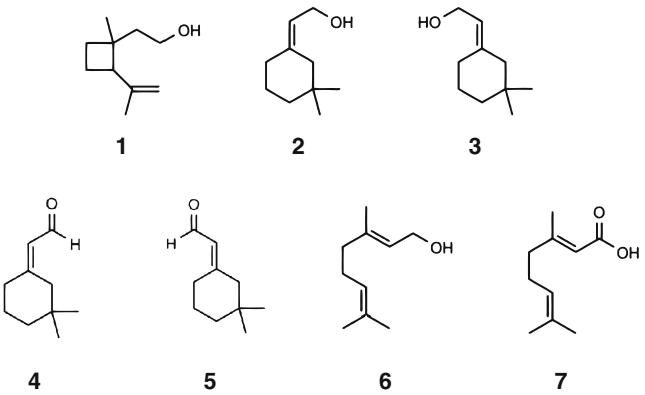

Fig. 1 Structures of seven common aggregation pheromone components in *Anthonomus* spp. weevils (Coleoptera: Curculionidae). **1**: (*Z*)-2-isopropenyl-1-methylcyclobutaneethanol (grandlure I); **2**: (*Z*)-2-(3,3-dimethyl-cyclohexylidene) ethanol (*Z* grandlure II); **3**: (*E*)-2-(3,3-dimethyl-cyclohexylidene) ethanol (*E* grandlure II); **4**: (*Z*)-(3,3-dimethylcyclohexylidene) acetaldehyde (grandlure III); **5**: (*E*)-(3,3-dimethylcyclohexylidene) acetaldehyde (grandlure IV); **6**: (*E*)-3,7-dimethyl-2,6-octadien-1-ol) (geraniol); and **7**: (*E*)-3,7-dimethyl-2,6-octadienoic acid (geranic acid)

USA) baited with cinnamyl alcohol and commercial *A. eugenii* pheromone (Trécé Inc.). Preliminary studies determined that *A. musculus* were caught successfully in yellow sticky traps placed at canopy level in highbush blueberry fields, whereas no weevils were caught in black cone traps placed on the ground for capturing walking insects (Z. Szendrei, unpublished data); thus, we used yellow sticky traps placed at canopy level in our studies. Cinnamyl alcohol is the main blueberry flower volatile (Szendrei et al., 2009), and was tested in three different types of release devices: plastic bubble (average release rate: 2.2 mg/d; ChemTica Internacional S.A., San José, Costa Rica), plastic 2-ml centrifuge vials (average release rate: 2 μg/day for 100 mg of cinnamyl alcohol in 1 ml mineral oil; ISCA Technologies, Riverside, CA, USA), and SPLAT® (Specialized Pheromone and Lure Application Technology, ISCA Technologies) at three different doses: 0, 30, 100 mg of cinnamyl alcohol per lure (mean release rate: 0.1 μg/d/mg lure). The responses to 10 treatments were compared to the response to the unbaited yellow sticky traps. All lures were attached to the sticky traps by using 22-gauge green florist wire. Traps were placed at four commercial highbush blueberry farms in New Jersey. One of the farms was located in New Lisbon (Burlington Co., NJ, USA), one in Chatsworth (Burlington Co., NJ, USA), and two in Hammonton (Atlantic Co., NJ, USA). Traps were positioned along the field edges near wooded borders, 10 m apart from each other, and were hung from a metal pole within the blueberry canopy ca. 1.6 m above ground. Treatments were set up in a randomized complete block design with four replications per farm. The position of the treatments within blocks was rotated weekly and the number of *A. musculus* on the traps was recorded weekly from April through June (11 wk). Lures were replaced with new ones every 3 wk.

2009 Field Experiments Field studies were conducted to test the attraction of adult *A. musculus* to a mixture of prospective components of the *A. musculus* aggregation pheromone at four commercial highbush blueberry farms in New Jersey (same locations as described above) and four cranberry farms in Massachusetts (three in East Wareham and one in West Wareham, Plymouth Co., MA, USA by using the same type of yellow sticky traps as in 2008. The *A. musculus* aggregation pheromone lures contained compounds **2**, **4**, **5**, and **6** loaded at a ratio of 4: 1: 1: 0.1, at a dose of 30 mg per lure, and a release rate of ca. 1 mg/day (ChemTica Internacional S.A., San José, Costa Rica). Because green leaf volatiles often synergize with insect pheromones (Reddy and Guerrero, 2004), we also tested the attraction of *A. musculus* to the GLVs (*Z*)-3-hexenyl acetate and hexyl acetate alone or in combination with the aggregation pheromone components. Both (*Z*)-3-hexenyl acetate and hexyl acetate are emitted from blueberry flower buds and flowers and elicit strong antennal responses from *A. musculus* (Szendrei et al., 2009). All custom-made lures were formulated into plastic bubble release devices (ChemTica Internacional S.A.) that were stapled to the yellow sticky traps. In addition to these lures, we also tested the commercially available *A. eugenii* and *A. grandis* pheromones (Trécé Inc.). Thus, we tested the following treatments: 1) geraniol (compound **6**); 2) (*Z*)-3-hexenyl acetate; 3) geraniol and (*Z*)-3-hexenyl acetate; 4) a blend of *Z* grandlure II (compound **2**), grandlure III (compound **4**), and grandlure IV (compound **5**); 5) a blend of *Z* grandlure II, grandlure III, grandlure IV, and geraniol (the *A. musculus* aggregation pheromone; see results); 6) a blend of *Z* grandlure II, grandlure III, grandlure IV, (*Z*)-3-hexenyl acetate and hexyl acetate; 7) a blend of *Z* grandlure II, grandlure III, grandlure IV, geraniol, and (*Z*)-3-hexenyl acetate; 8) the commercial *A. eugenii* pheromone lure; 9) the commercial *A. grandis* pheromone lure; and 10) an unbaited control. The GLV lures were loaded with 30 mg of (*Z*)-3-hexenyl acetate or hexyl acetate. Treatments were set up in a randomized complete block design with four replications at each of the eight farms. Treatments were rotated weekly among the positions in each block. In blueberries, traps were placed at canopy level as described above; and in cranberries traps were placed 1 m above canopy level. Traps were checked weekly between April and June (9 weeks) in blueberries and in May (3 weeks) in cranberries. Lures were replaced with new ones every 3 wk. All weevils captured on 27 April (overwintered adult generation) and 26 May (summer adults) in blueberry fields were removed from sticky traps and the sexes were separated.

2010 Field Experiments To further evaluate the *A. musculus* pheromone, an experiment was conducted to test the attraction of adult *A. musculus* to its aggregation pheromone in eight fields at four commercial highbush blueberry farms in New Jersey (same locations as described above). Yellow sticky traps were either baited with the ChemTica pheromone lures (containing compounds **2**, **4**, **5**, and **6** loaded at the ratio, dose, and release rate described above) or unbaited (controls). Trap position was the same as that described above, and the numbers of weevils on traps were recorded weekly from 1 April to 22 June.

Statistical Analyses For the 2008 and 2009 field data, the number of *A. musculus* captured in yellow sticky traps was analyzed by using a generalized linear mixed model (SAS Institute, Version 9.1, Cary, NC), with lure treatment as fixed factor, farm and block as random factors, and week as the repeated variable in the model. This analysis was used to determine the effects of lure types on attractiveness of traps to *A. musculus*. Differences among treatment means

were assessed by using the lsmeans statement with the pdiff option, and differences were considered significant at an α level of 0.05. Numbers of *A. musculus* were $\log_{10}$-transformed prior to analyses. Data were analyzed separately by years and states. For the 2010 data, a paired *t*-test was conducted to compare the number of *A. musculus* captured in pheromone-baited versus unbaited traps. We used a *Chi-square* test to determine whether there was a significant difference between the quantities of compounds emitted by male *A. musculus* feeding on cranberries versus blueberries and to test whether the sex ratio among captured weevils was different from 1:1 (α=0.05).

Results and Discussion

This study reports the first identification and field activity of components of the *A. musculus* aggregation pheromone. Our 2008 field experiment showed that there was a significant treatment effect on the number of *A. musculus* caught on yellow sticky traps among cinnamyl alcohol, *A. eugenii* aggregation pheromone, and unbaited control traps (F=3.80, df=9, 339, P<0.01) (Fig. 2). The *A. eugenii* pheromone-baited traps caught more *A. musculus* adults than all other treatments (t>3.12; df=9; P<0.01) (Fig. 2). These results are likely due to the fact that these two *Anthonomus* species share common pheromone components (Table 1). Subsequent headspace analysis of adult *A. musculus* showed that males emit (*Z*)-2-(3,3-dimethylcyclohexylidene) ethanol (*Z* grandlure II; compound **2**, Fig. 1), (*Z*)-(3,3-dimethylcyclohexylidene) acetaldehyde

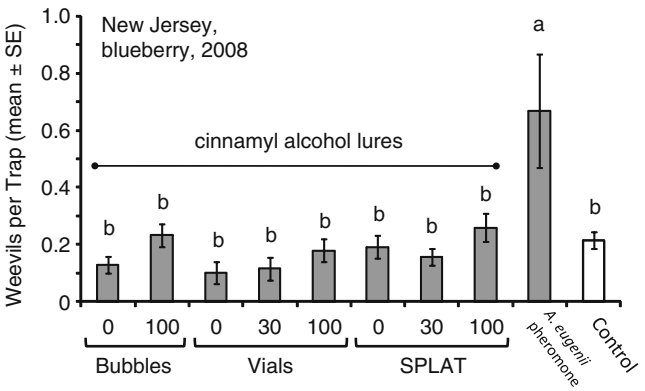

Fig. 2 Average number of *Anthonomus musculus* adults on yellow sticky traps baited with different lures at four commercial highbush blueberry farms in New Jersey in 2008. Cinnamyl alcohol was formulated in three different types of release devices at three different concentrations (numbers on x-axis represent cinnamyl alcohol concentrations in mg). The *Anthonomus eugenii* pheromone lure was purchased from a commercial source. Control yellow sticky traps were unbaited. Treatments with different letters above columns are significantly different (P≤0.05)

(grandlure III; compound **4**, Fig. 1), and (*E*)-(3,3-dimethylcyclohexylidene) acetaldehyde (grandlure IV; compound **5**, Fig. 1) (Fig. 3a). Female *A. musculus* did not emit any of these grandlure components (Fig. 3b); however, geraniol [(*E*)-3,7-dimethyl-2,6-octadien-1-ol; compound **6**, Fig. 1] was detected in similar quantities in male and female *A. musculus* samples when feeding on cranberry flower buds (Fig. 3b). This suggests that cranberry flower buds release geraniol in response to damage. When insects were fed blueberry buds, we did not detect geraniol in female samples (data not shown), but small quantities were found in male collections (Fig. 4), suggesting that this compound may be a part of the aggregation pheromone. Similarly, *A. eugenii* males emit compounds **2**, **4**, **5**, and **6**, but they also emit compounds **3** and **7** (Table 1; Eller et al., 1994). In the 1999 study, however, geraniol was emitted only by males; thus, all six compounds were designated as "male-specific" (Eller et al., 1994). So far, geraniol has been reported only from *A. eugenii* and *A. musculus* (Table 1), but it has been suggested as a possible host precursor for the different grandlures in *Anthonomus* spp. (Tumlinson et al., 1970). Compound **2** (the most abundant component of both *A. musculus* and *A. eugenii* pheromones; Table 1) as well as compounds **4** and **5** are also found in *A. grandis*; the strawberry blossom weevil, *Anthonomus rubi* Herbst. (Innocenzi et al., 2001); and the pecan weevil, *Curculio caryae* (Horn) (Hedin et al., 1997) (Table 1); however, compounds **4** and **5** were found in trace amounts in *A. rubi* and had no effect on their behavior (Innocenzi et al., 2001).

The emissions of the four *A. musculus* pheromone components: **2**, **4**, **5**, and **6** were 2.8±0.4 (mean±SE), 1.8±0.2, 1.3±0.2, and 0.9±0.1 ng/male/d, respectively. The total amount of all grandlures (i.e., sum of **2**, **4**, and **5**) emitted by male *A. musculus* was 5.6±0.7 (mean±SE) ng/male/d. This amount is >50-fold lower than those reported for *A. grandis* (4.2 μg/male/d; Chang et al., 1989), *A. eugenii* (15 μg/male/d; Eller et al., 1994), *A. rubi* (8.1 μg/male/d; Innocenzi et al., 2001), and *C. caryae* (0.3 μg/male/d; Hedin et al., 1997). Our quantitative assessment of the pheromone components may have been influenced by the field-collected weevils of unknown age and sexual maturity that we used in our assays. Once methods of maintaining these insects in laboratory culture have been worked out, we intend to control the developmental and reproductive variables to achieve a more precise determination of the quantity of pheromone components emitted.

There were minimal differences in volatile collections from *A. musculus* feeding on different host plants (blueberries versus cranberries). Qualitatively, the headspace of male *A. musculus* that were feeding on blueberry flower buds did not differ from those feeding on cranberry flower buds (Fig. 4). Quantitatively, grandlure components in the headspace of male *A. musculus* sampled on blueberry

versus cranberry hosts were similar, but geraniol (compound **6**; Fig. 1) was significantly (χ^2=19.25, *df*=3, *P*< 0.01) more abundant in the headspace from males feeding on cranberries (Fig. 4). Although the reason for this difference remains unknown, it is possible that host plant might affect the production of geraniol in male *A. musculus* or its emission after herbivore feeding damage. Geraniol is a monoterpenoid alcohol commonly emitted from plants, particularly flowers (Schiestl, 2010), that is induced by herbivore feeding (Han and Chen, 2002), and with known activity on insects, including mosquitoes (e.g., Qualls and Xue 2009) and bees (e.g., Williams et al., 1981). Besides *Anthonomus* spp., it is a component of the honey bee pheromone (Boch, 1962; Pickett et al., 1980). Geraniol is a

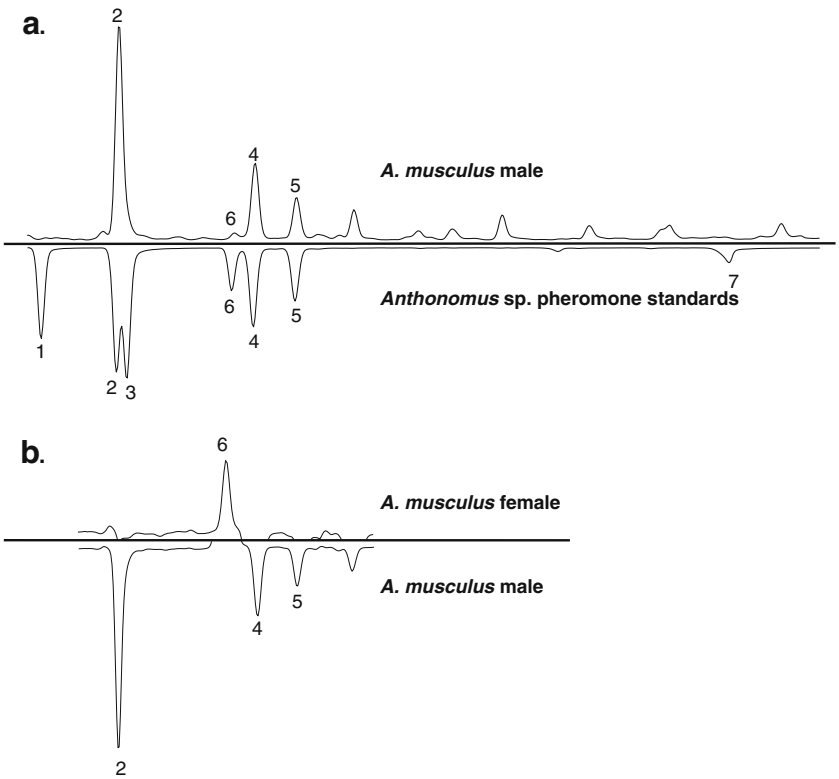

Fig. 3 Comparison between a representative chromatogram trace of male *Anthonomus musculus* (top) and a blend of standard pheromone components from *Anthonomus* spp. (bottom) **a**; and between male and female *A. musculus*, showing a selective ion trace of female samples when male compounds were subtracted from the trace (top) and for male samples when female peaks were subtracted (bottom) **b**. Names of compounds 1–7 are provided in Fig. 1

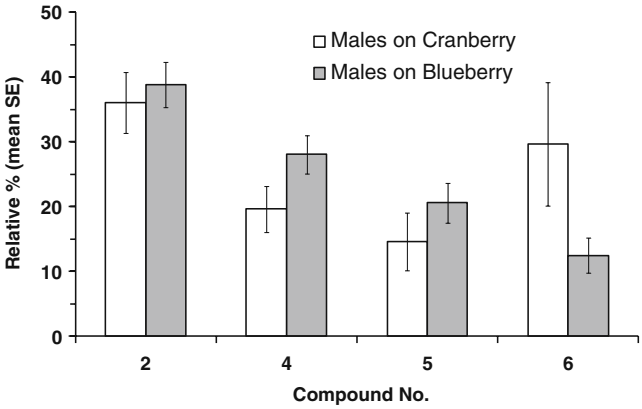

Fig. 4 Emissions of the four identified *Anthonomus musculus* aggregation pheromone components from males fed on blueberry and cranberry flower buds. Amounts of compound **6** (geraniol) were significantly greater in males fed on cranberry flower buds compared with those fed on blueberry flower buds ($P<0.05$); host plant did not affect any of the grandlure compounds **2**, **4**, and **5** ($P>0.05$). Names of compounds **2**, **4**, **5**, and **6** are provided in Fig. 1. $N=4$ replicates (of 20 males each) per crop

possible precursor of the *A. grandis* pheromone (Tumlinson et al., 1970; Thompson and Mitlin, 1979), and can be either derived from the host plant or produced *de novo* by male *Anthonomus* spp. Blueberry flower buds and flowers, however, did not emit detectable amounts of geraniol even after damage by *A. musculus* adults (Szendrei et al., 2009); thus, it is likely that *A. musculus* produces this compound. We will conduct more studies to elucidate the importance of host plant parts and phenology on pheromone production in *A. musculus*.

To support our behavioral data from field flight trapping (see below), we also attempted to evaluate headspace volatiles from *A. musculus* by gas chromatography-electroantennal detection (GC-EAD). However, this was a major technical challenge because of the small size of the insects and the relatively small amount of pheromone components in the extracts (see above). Similar problems have been encountered with the plum curculio, *Conotrachelus nenuphar* (Herbst) (Curculionidae) (T. Leskey and Aijun Zhang, USDA-ARS, Beltsville, MD, USA, personal correspondence). We plan to continue to pursue electrophysiological assays of this system in collaboration with Drs. Leskey and Zhang.

In 2009, the attractiveness of the identified main four-component pheromone blend to *A. musculus* was evaluated in commercial blueberry and cranberry farms. In New Jersey blueberry fields, the numbers of adult *A. musculus* caught on yellow sticky traps with different lure treatments were significantly different ($F=15.02$; df=9, 315; $P<0.01$) (Fig. 5a). Yellow sticky traps baited with compounds **2**, **4**, **5**, and **6** (*A. musculus* aggregation pheromone components) caught more adult *A. musculus* ($t>2.21$; $df=9$; $P<0.03$) than any of the other lure treatments. Relative to the unbaited control, this treatment attracted ~2.9 times more weevils over the course of the field season. All treatments that contained the *A. musculus* species-specific lure increased attraction of weevils to traps relative to the unbaited control, lures

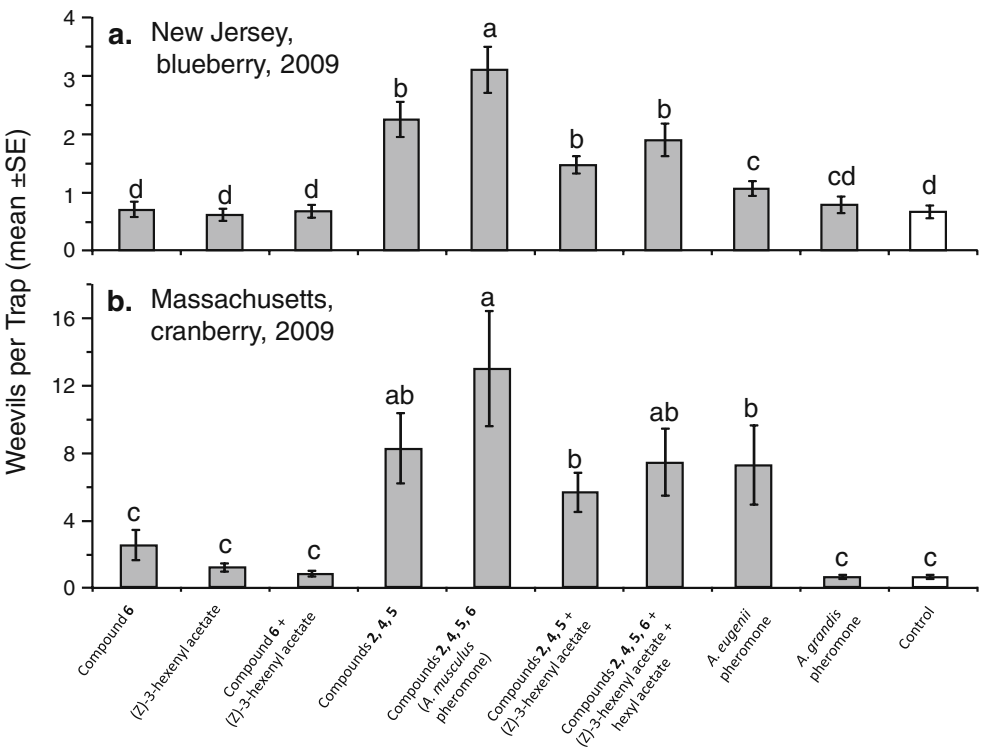

Fig. 5 Mean (± SEM) trap catch of *Anthonomus musculus* on yellow sticky traps baited with different compounds in the 2009 field experiment in New Jersey **a** and Massachusetts **b**. Names of compounds **2**, **4**, **5**, and **6** are provided in Fig. 1. Treatments with different letters above bars are statistically different ($P\leq0.05$)

containing only plant volatiles, and related *Anthonomus* species pheromones (t>3.39; df=9; P<0.05). Although the number of weevils in blueberry fields was lower in 2010 than in 2009, our results from 2009 were confirmed in 2010: i.e., ~ 2 times more adult *A. musculus* were captured in pheromone-baited compared with unbaited traps (mean number of weevils (± SE) in: unbaited traps=4.9 ±1.3; pheromone-baited traps=9.3±1.7; t=2.57, P=0.037). Lures baited with the *A. musculus* pheromone (compounds **2**, **4**, **5**, and **6**) caught similar numbers of males and females in blueberry fields (Table 2). However, females from the summer generation but not from the overwintered generation were significantly more attracted to lures baited with compounds **2**, **4**, and **5** (Table 2), indicative that newly emerged, virgin females might be more responsive to the male-produced grandlures. Similar variation in male:female ratio in response to pheromone-baited traps was observed for *A. rubi* during the trapping season (Innocenzi et al., 2001).

In Massachusetts cranberries, the numbers of *A. musculus* caught on yellow sticky traps were also different among lure treatments (F=9.02; df=9, 90; P<0.01), (Fig. 5b). The most attractive trap for *A. musculus* weevils in this state and crop was the same as in New Jersey, i.e., traps baited with the lure containing compounds **2**, **4**, **5**, and **6**. The response of *A. musculus* weevils to the other *Anthonomus* pheromones was similar in the two states and crops (Fig. 5). Compared to the unbaited control, the *A. eugenii* pheromone but not the *A. grandis* pheromone attracted more *A. musculus* weevils. Four of six pheromone components are shared by *A. musculus* and *A. eugenii*; whereas, three of four components are shared between *A. musculus* and *A. grandis* (Table 1). Key differences are the presence of compound **1** in the *A grandis* pheromone blend and compounds **3** and **7** in the *A. eugenii* blend; these compounds are absent in the *A. musculus* blend and can account at least in part for the specificity in *A. musculus* attraction to its aggregation pheromone. Overall, the abundance of weevils in yellow sticky traps was approximately 4 times higher in Massachusetts than in New Jersey.

In our 2009 and 2010 field studies, 30 mg of compounds **2**, **4**, **5**, and **6** were loaded at a 4:1:1:0.1 ratio. This ratio was estimated based on preliminary data collected from a few males. Subsequent analysis (Table 1; Fig. 4) with more replications revealed that the ratio of these compounds is closer to 2:1:1:0.7. Further studies are needed to determine whether this latter ratio is more attractive to *A. musculus*. Despite using a potentially suboptimal ratio, our field study clearly shows that a lure containing compounds **2**, **4**, **5**, and **6** attracts adult *A. musculus*. Whether all components in the *A. musculus* pheromone blend are needed for this attraction requires further investigation; however, a blend of compounds **2**, **4**, and **5** was less attractive than the full blend, and compound **6** alone did not attract *A. musculus* (Fig. 5). Most recent analysis of the headspace emissions from adult *A. musculus* indicate the presence of two previously undetected minor compounds (an acid similar to nerolic/geranic acid and an alcohol similar to nerol/geraniol; data not shown) released by males only, which might have behavioral significance. Future studies will identify these compounds and determine their biological activity.

Table 2 Trap catch and sex ratio of male and female *Anthonomus musculus* captured in response to synthetic lures in New Jersey blueberry fields

Lure[a]	27 April 2009 (Overwintered Adults)			26 May 2009 (Summer Generation Adults)			Totals (Both Generations)

In addition to the aggregation pheromone, volatiles from host plants may inform foraging *A. musculus* about suitable feeding and oviposition sites. Several species related to *A. musculus*, e.g., *Anthonomis pomorum*, *A. grandis*, and *A. rubi*, have shown electrophysiological antennal (EAG) responses to host plant volatiles (Dickens, 1990; Kalinova et al., 2000; Bichao et al., 2005) and several species of weevils, such as the pine weevil, banana weevil, vine weevil, and pepper weevil (Budenberg et al., 1993; Wibe et al., 1997; van Tol and Visser, 2002; Addesso and McAuslane, 2009), responded to host-plant volatiles in behavioral bioassays. In Y-tube olfactometer assays, Mechaber (1992) found that adult *A. musculus* were more attracted to conspecific-damaged cranberry vines compared with undamaged vines, as well as to undamaged and damaged flower buds compared to clean air (Mechaber, 1992). Recently, we found that female *A. musculus* are attracted to blueberry flowers, whereas males are attracted to undamaged flower buds and are repelled by damaged flower buds (Szendrei et al., 2009). These studies indicate that *A. musculus* adults might use host-plant volatiles during host or mate location, but did not identify the specific volatile cues responsible for this attraction. In this study, we tested two potential host-plant attractants for *A. musculus*. In 2008, we tested the main blueberry floral component, cinnamyl alcohol, at different doses and formulations. However, regardless of the dose and formulation, cinnamyl alcohol baited traps caught similar numbers of *A. musculus* when compared to the control trap (Fig. 2). In 2009, we tested the GLV (*Z*)-3-hexenyl acetate. GLV compounds are highly ubiquitous in plants and play important roles in insect-plant interactions (Visser, 1986; Szendrei and Rodriguez-Saona, 2010). For example, a mixture of plant volatiles that includes (*Z*)-3-hexenyl acetate attracts the Colorado potato beetle, *Leptinotarsa decemlineata* Say (Visser, 1986), and the scarab beetle *Anomala octiescostata* Burmeister (Leal et al., 1994). Although (*Z*)-3-hexenyl acetate was found in headspace collections from both blueberry flower buds and flowers and elicited significant EAG responses in *A. musculus* (Szendrei et al., 2009), it did not increase adult weevil attraction compared with unbaited control traps (Fig. 5). Host-plant volatiles, particularly GLVs, can enhance the response of insects to their pheromone (Dickens et al., 1990; Reddy and Guerrero, 2004). For example, (*Z*)-3-hexenyl acetate enhanced the response of the diamondback moth, *Plutella xyllostella* (L.), to its sex pheromone (Reddy and Guerrero, 2000). A synergistic effect has also been reported between GLVs and the *A. grandis* aggregation pheromone (e.g., Dickens, 1989). Here, we tested the response of *A. musculus* to its aggregation pheromone in combination with (*Z*)-3-hexenyl acetate and hexyl acetate. Our results suggest an interruptive effect of these GLVs: addition of (*Z*)-3-hexenyl acetate to a blend of compounds **2**, **4**, and **5** reduced numerically (but not significantly) *A. musculus* trap captures (Fig. 5). Similarly, addition of (*Z*)-3-hexenyl acetate and hexyl acetate to a blend of compounds **2**, **4**, **5**, and **6** reduced (significantly in New Jersey and numerically in Massachusetts) *A. musculus* trap captures (Fig. 5). A reduction in the number of insects caught in traps was observed when the GLVs (*E*)-2-hexen-1-ol, (*Z*)-2-hexen-1-ol, and (*Z*)-3-hexen-1-ol were added to lineatin, the aggregation pheromone of the striped ambrosia beetle, *Trypodendron lineatum* Olivier (Borden et al., 1997), as well as when the GLVs 1-hexanol, (*Z*)-3-hexen-1-ol, and (*E*)-3-hexen-1-ol were added to the pheromone of the spruce bark beetle, *Ips typographus* (L.) (Zhang et al. 1999). Furthermore, addition of the GLV acetates to the *A. musculus* aggregation pheromone skewed the sex ratio of the captured weevils towards females in the summer (Table 2).

Similarly to our results, Cha et al. (2008) failed to find a significant change in the number of male grape berry moths captured between host-plant volatile-baited and control traps. Plant volatile attractants for codling moth failed under certain cases in the field (Knight and Light, 2005). The failure of plant volatiles to attract insects to traps in our field experiments could be because the tested volatiles were already present in the environment at the time when lures were placed in the field, and the background cues may have masked odors from the lures (Schröder and Hilker, 2008). In the case of cinnamyl alcohol, habituation or lack of sensitivity may also explain the low response rate, since this volatile stands out prominently from the background during bloom in blueberry fields. It is also possible that male *A. musculus* were repelled by the GLV plus pheromone baits as a result of odor camouflaging, where an odor is less detectable when presented in a combination with other odors. In our case, the quality or quantity of GLVs may have disrupted the perception of pheromone compounds by the insect and thus lead to lower or non-significant response.

Although the role of plant volatiles in host-plant location by *A. musculus* remains unclear, the *A. musculus* aggregation pheromone identified here can be an easy-to-use and cost-effective tool for monitoring this pest in blueberry and cranberry pest management programs. In highbush blueberries, an attractant for this weevil will be most useful for early detection of overwintered adults. The *A. musculus* pheromone was more attractive to the newly-emerged summer generation adults than to the overwintered adults (Table 2). Considering that the overwintered adults are the most damaging to the crop, the pheromone needs to be optimized by testing different pheromone doses, formulations, and ratios. Then, traps must be optimized by testing, trap colors, designs, and placements. A refined pheromone

blend that may contain plant volatiles and other minor components is required to optimally monitor *A. musculus* populations. Once optimized, this pheromone can also be used to develop an attract-and-kill formulation to manage *A. musculus*, similarly to the ones tested for *A. grandis* (e.g., McKibben et al., 1990).

Acknowledgments Thanks to Vera Roth-Kyryczenko, Elizabeth Bender, Marty Sylvia, and Judson Parker for field assistance and to Robert Holdcraft for help with illustrations and tables. Many thanks go to the MA cranberry and NJ blueberry growers who provided field sites. This project was funded by a USDA Northeast IPM Competitive grant (No. 2007-34103-18055 to C. R-S. and A.A.).

Identification and Field Evaluation of the Sex Pheromone of *Synanthedon bicingulata* (Staudinger)

Chang Yeol Yang · Sung Jong Kim · Sang Guei Lee

Received: 2 August 2010 / Revised: 8 November 2010 / Accepted: 24 February 2011 / Published online: 12 March 2011
© Springer Science+Business Media, LLC 2011

Abstract The sex pheromone of *Synanthedon bicingulata* (Staudinger), a major pest of *Prunus* species in many regions of northeast Asia, was identified. Two major components from the pheromone gland extracts of female moths are (*E*,*Z*)-3,13-octadecadienyl acetate (*E*3,*Z*13-18:OAc) and (*Z*,*Z*)-3,13-octadecadienyl acetate (*Z*3,*Z*13-18:OAc), and the average ratio of these components is about 4:6, respectively. In addition to the major components, four minor components, (*Z*)-13-octadecenyl acetate (*Z*13-18:OAc), (*E*,*Z*)-2,13-octadecadienyl acetate (*E*2,*Z*13-18:OAc), (*E*,*Z*)-3,13-octadecadien-1-ol (*E*3,*Z*13-18:OH), and (*Z*,*Z*)-3,13-octadecadien-1-ol (*Z*3,*Z*13-18:OH) also were identified from pheromone gland extracts. Field tests showed that *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc are essential for attraction of male *S. bicingulata* moths, and males are optimally attracted to the blend ratio found in pheromone gland extracts of conspecific females. Addition of the minor glandular components (*Z*13-18:OAc, *E*2,*Z*13-18:OAc, *E*3,*Z*13-18:OH, and *Z*3,*Z*13-18:OH) did not affect captures of males to the primary binary blend. Thus, the blend of *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc at the natural ratio can be used for monitoring populations of this species.

Key Words *Synanthedon bicingulata* · (*E*,*Z*)-3,13-octadecadienyl acetate · (*Z*,*Z*)-3,13-octadecadienyl acetate · Lepidoptera · Sesiidae

Introduction

Synanthedon bicingulata (Staudinger) (Lepidoptera: Sesiidae) is an economically important pest of *Prunus* species (Rosaceae), such as *P. persica*, *P. mume*, *P. salicina*, and *P. serrulatavar* in Korea, China, and the Russian Far East (Arita et al., 2004). Larvae feed on the cambial tissue within tree trunks of host plants, resulting in significant production losses. This insect can be difficult to control with conventional insecticides due to the sheltered larval development. Species-specific sex pheromone baited traps for *S. bicingulata* may be useful for monitoring populations and timing application of control measures. In addition, the pheromone is potentially useful for population control using mating disruption or mass trapping (e.g., Leskey et al., 2009). The sex pheromone of *S. bicingulata* has not been previously reported.

Although sex attractants for more than 110 sesiid moth species have been determined in field screening experiments, to date, sex pheromones of only 19 species have been identified (El-Sayed, 2010). Typically, sesiid moths use 3,13- and 2,13-octadecadien-1-ols and their corresponding acetates and aldehydes as sex pheromone components. In moths, species specificity of sex pheromone blends is responsible for pre-mating reproductive isolation between sympatric species (Löfstedt et al., 1991; Yang et al., 2009a). Therefore, it is important to examine the pheromone components produced by different species to understand the evolutionary diversification of pheromone signals in Lepidoptera (Roelofs and Brown, 1982). We report here the

chemical identification and field testing of the female-produced sex pheromone blend of *S. bicingulata*.

Methods and Materials

Insects Pupae of *S. bicingulata* were collected by excavating them from infested trunks of peach trees in May 2009 at Jeonju (35.4°N,127.0°E), Korea. They were placed individually into capped plastic cups (30 ml), and maintained at 25°C under a 14L:10D photoperiod. After emergence, the sexes were separated based on distinctive hair tufts. Moths were provided with a cotton pad soaked with a 10% sucrose solution as food.

Chemicals Synthetic pheromone standards used in this study were purchased from Pherobank (Wageningen, The Netherlands). Isomeric purity of these compounds exceeded 99%. Straight-chain hydrocarbons, dimethyldisulfide, iodine, and sodium thiosulfate were obtained from Sigma-Aldrich (St. Louis, MO, USA).

Pheromone Extraction Virgin females of *S. bicingulata* exhibited the characteristic calling posture by extruding the abdominal tip during photophase. Therefore, pheromone gland extracts were taken from 1- to 2-d-old females at 7 h into the photophase. Excised pheromone glands were placed in 10 μl hexane in a 0.3-ml conical glass vial (Wheaton, Millville, NJ, USA) for 10 min at room temperature. The supernatant was transferred to a clean vial and stored at −20°C until analysis.

Dimethyldisulfide Derivatizations Dimethyldisulfide (DMDS) derivatives of pheromone gland extracts and synthetic standards were prepared according to procedures by Buser et al. (1983). Approximately 50 μl DMDS and 5 μl iodine solution (60 mg of I_2 in 1 ml of diethyl ether) were added to an extract (10 μl) of 18 female equivalents of *S. bicingulata* pheromone, and held at 60°C for 48 h. After addition of 50 μl of sodium thiosulfate (5%), the organic layer was transferred to a clean vial and concentrated to ca. 10 μl for GC-MS analysis. The same procedures described above were followed for hexane solutions (10 ng in 10 μl n-hexane) of synthetic *Z*3-18:OAc, *E*3,*Z*13-18:OAc, *Z*3,*Z*13-18:OAc, *E*2,*Z*13-18:OAc, *E*3,*Z*13-18:OH, and *Z*3,*Z*13-18:OH.

Chemical Analysis Pheromone gland extracts and synthetic standards were analyzed on an Agilent 6890N GC interfaced to an Agilent 5975C mass-selective detector. Samples were run on DB-Wax and DB-23 columns (30 m×0.25 mm ID, 0.25 μm film thickness, J&W Scientific, Folsom, CA, USA). The oven temperature was maintained at 80°C for 1 min, increased to 180°C at 10°C/min, then to 220°C at 5°C/min, and held at the final temperature for 10 min. Helium was the carrier gas (1 ml/min), and injections were splitless. Injector temperature was 250°C with the purge valve opening 0.75 min after a manual injection. The ionization voltage was 70 eV, and the ion source temperature was 230°C. Compounds from pheromone gland extracts were identified tentatively by comparison of their mass spectra with the mass spectra library (Wiley-NIST, Hoboken, NJ, USA); and identifications were subsequently confirmed by comparison of retention indices (RI; relative to alkane standards, Van den Dool and Kratz, 1963), and mass spectra with those of authentic standards on two different columns. DMDS derivatives were analyzed with a DB-1 column (30 m× 0.25 mm ID, 0.25 μm film thickness), using a temperature program of 100°C to 300°C at 10°C/min. The GC conditions were the same as those described above.

Field Experiments Experiments were conducted in June 2009 at Jeonju, Korea. Sticky delta traps (Green Agro Tech, Korea) baited with rubber septa (Aldrich Chemical Co., Milwaukee, WI, USA) impregnated with candidate pheromone components in hexane were hung in peach orchards at a height of 1.5 m. Field tests employed a complete randomized block design with four replicate blocks of each treatment. The distance between traps within a block was about 10 m. Captured moths were counted at intervals of 3–4 d.

Experiment 1 compared attraction of male *S. bicingulata* to *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc alone or in various combinations. Experiment 2 tested whether attractiveness of standard baits of two major components could be enhanced by addition of four minor components identified in female gland extracts; *Z*13-18:OAc, *E*2,*Z*13-18:OAc, *E*3,*Z*13-18:OH, and *Z*3,*Z*13-18:OH. Trap catch data (x) were transformed to log (x+1) and submitted to one-way analysis of variance (ANOVA). Treatments that failed to capture males were not included in the analyses to avoid violating assumptions of ANOVA. Means were compared by Tukey's test at α=0.05 (SAS Institute Inc. 2008).

Results

Chemical Analysis Analysis of pheromone gland extracts of female *S. bicingulata* by GC-MS revealed the presence of two major components and four minor components, as well as normal alkanes including pentacosane and heptacosane (Fig. 1). The mass spectrum of compound 1 showed a molecular ion *m/z* 310, and diagnostic fragment ions *m/z* 250 (M-60), 222, and 61 (indicative of an acetate functionality), which suggested an octadecenyl acetate. The DMDS adduct of compound 1 showed a molecular ion *m/z* 404 and diagnostic ions *m/z* 287, 227, and 117,

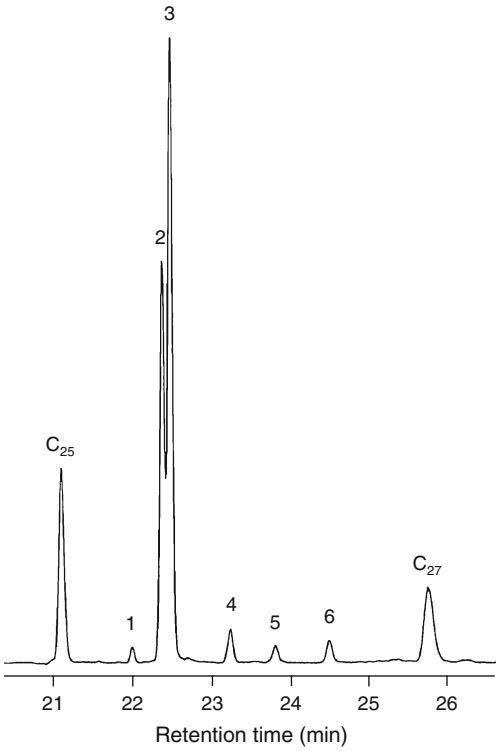

Fig. 1 Total ion chromatogram of GC-MS analysis of pheromone gland extract from female *Synanthedon bicingulata* on DB-Wax column. 1 (*Z*)-13-octadecenyl acetate, 2 (*E*,*Z*)-3,13-octadecadienyl acetate, 3 (*Z*,*Z*)-3,13-octadecadienyl acetate, 4 (*E*,*Z*)-2,13-octadecadienyl acetate, 5 (*E*,*Z*)-3,13-octadecadien-1-ol, 6 (*Z*,*Z*)-3,13-octadecadien-1-ol, C_{25} pentacosane, C_{27} heptacosane

indicating the original double bond at position 13 of the monounsaturated acetate (Buser et al., 1983). The calculated retention indices (RIs) of compound 1 coincided with *Z*13-18:OAc standard on two columns (KIs of 2548 on the DB-Wax column, and 2625 on the DB-23 column). The mass spectra of compounds 2 and 3 were similar and had diagnostic ions at *m/z* 308 (M^+), 248 (M-60), 219, 205, 191, and 61 suggestive of octadecadienyl acetates. The mass spectrum of the DMDS adduct of compounds in the pheromone extract showed a molecular ion *m/z* 496 (308+ 2MeSSMe) and diagnostic ions *m/z* 301, 255, 147, and 117, indicating the original double bonds at the 3- and 13-positions of octadecadienyl acetate (Vincenti et al. 1987). However, the geometry of the dienes was not confirmed by retention time comparisons because DMDS adducts of the isomers were poorly resolved on the DB-1 column. Comparison of RIs of the natural compounds with the 3,13 isomers of octadecadienyl acetates on the DB-Wax and DB-23 columns confirmed that compounds 2 and 3 were *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc, respectively (Table 1).

The mass spectrum of compound 4 showed diagnostic fragment ions of octadecadienyl acetate at *m/z* 248 (M-60), 219, and 61. Compounds 5 and 6 had a molecular ion *m/z* 266, and diagnostic fragment ions *m/z* 248 (M-18), 219, 205, and 191 suggestive of an octadecadien-1-ol. Whereas it was not possible to verify the structure of compounds 4, 5, and 6 using DMDS derivatization because of coelution with the large amount of unidentified products and/or the small amount of material in the derivatized gland extract, we were able to tentatively identify compounds 4, 5, and 6 as *E*2,*Z*13-18:OAc, *E*3,*Z*13-18:OH, and *Z*3,*Z*13-18:OH, respectively, by comparison of their RIs with those of synthetic standards on two columns. The relative ratio of compounds 1–6 in gland extracts was 2:58:100:6:3:4 (N=10).

Field Experiments In field experiment 1, a total of 181 male *S. bicingulata* were caught, with no catch in controls or traps baited with single components. The maximum number of males was attracted to a 4:6 mixture of *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc, although it was not significantly better than the 3:7 and 2:8 blends (Fig. 2). A total of 267 males were captured in field experiment 2. Trap catches of males to the binary blend of *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc were unaffected by the addition of the minor glandular components, *Z*13-18:OAc, *E*2,*Z*13-18:

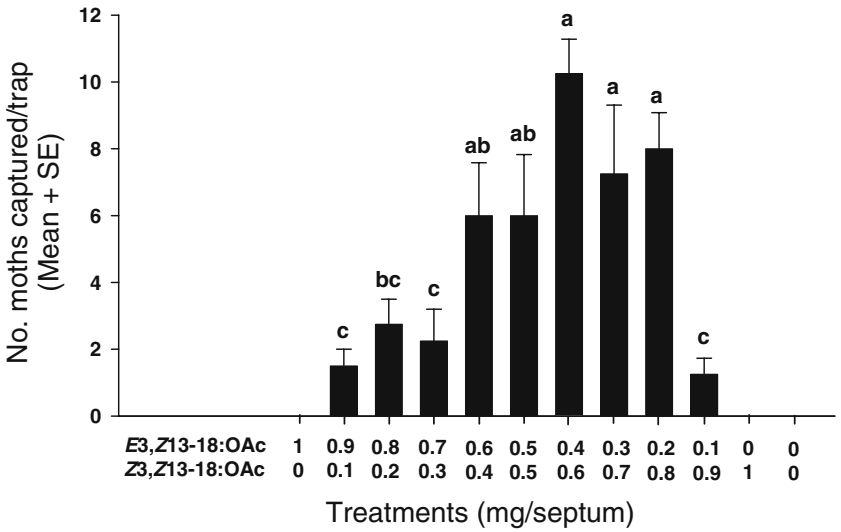

Fig. 2 Number of *Synanthedon bicingulata* males captured in traps baited with lures containing different ratios of *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc at peach orchards in Jeonju, Korea, 10–18 June 2009 (*N*=4). Bars with the same letter are not significantly different (Tukey's test: $P>0.05$)

OAc, *E*3,*Z*13-18:OH, and *Z*3,*Z*13-18:OH (Fig. 3). Moreover, the full six-component blend mimicking the blend found in a female gland extract did not increase trap catches compared with traps baited with the primary binary blend.

Discussion

Chemical analyses and field trials indicate that the sex pheromone of *S. bicingulata* consists of two major synergistic components, *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc, at a ratio of 4:6, respectively. In our previous study on the pheromone of the congeneric *S. haitangvora*, GC-MS analyses of the DMDS-derivatized extract conducted on a polar DB-Wax column did not show the presence of DMDS adducts (*m/z* 496) of octadecadienyl acetate derivatives (Yang et al., 2009b). The failure of the previous attempt probably was because the tetrasubstituted linear high-boiling derivatives are not eluted on the polar column (Vincenti et al., 1987). In this study, we found that DMDS adducts of octadecadienyl acetates eluted on the nonpolar DB-1 column. Thus, DMDS adducts can be useful in pheromone identification of sesiid species.

*E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc have been identified as constituents of a sex pheromone in several other sesiid species (El-Sayed, 2010). However, *Synanthedon hector* is the only previously reported sesiid species that uses a mixture of these two dienes as its sex pheromone. *Synanthedon hector* is distributed only in Japan, and is an important economic pest of cultivated *Prunus* spp. This species can be distinguished easily from *S. bicingulata* based upon the color patterns of the adult abdominal

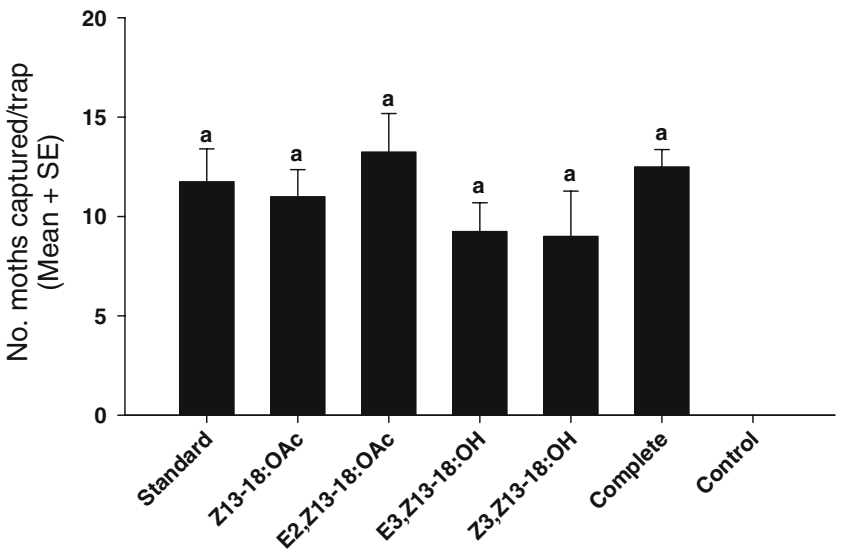

Fig. 3 The effect of adding 3% of different minor components to standard baits with 1 mg/septum of a 4:6 blend of *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc on captures of male *Synanthedon bicingulata* at peach orchards in Jeonju, Korea, 19–28 June 2009 (*N*=4). The complete blend consisted of all six components in a ratio found in the pheromone gland extract. Bars with the same letter are not significantly different (Tukey's test: $P>0.05$)

sternites (Arita et al., 2004). The pheromone glands of female *S. hector* contain *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc at 38:62 ratio (Naka et al., 2008), and conspecific males are optimally attracted to 5:5 blend (Yaginuma et al., 1976; Naka et al., 2008). These data show that allopatric *S. bicingulata* and *S. hector* utilize the same sex pheromone and host plants.

*Z*13-18:OAc, *E*2,*Z*13-18:OAc, *E*3,*Z*13-18:OH, and *Z*3,*Z*13-18:OH were identified as minor components of female *S. bicingulata* gland extracts, but addition of these components to the two major components had no significant effect on attraction of conspecific males. These minor components may serve an antagonistic function to suppress attraction of sympatric species. However, it is not known whether they are actually released from the female glands during calling. Previous studies with other sesiid species have shown that geometrical isomers or biosynthetic precursors of the major components are present in female pheromone glands, but the biological significance of these components remain unclear (Klun et al., 1990; Francke et al., 2004; Mozûraitis et al., 2006; Yang et al., 2009b). Hence, *Z*13-18:OAc and *E*2,*Z*13-18:OAc may just be by-products of the pheromone biosynthetic pathway, and *E*3,*Z*13-18:OH and *Z*3,*Z*13-18:OH are presumed to be biosynthetic precursors of the two major components, *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc, respectively.

During the course of this study, we found that no other sesiid species were attracted to a 4:6 mixture of *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc. In Korea, the genus *Synanthedon* is composed of 12 species (Arita et al. 2004), but sex pheromones or attractants have been reported for only three species, *S. haitangvora, S. tenuis* and *S. quercus* (Tamaki et al. 1977; Yang et al. 2009b). As shown in Fig. 2, *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc were essential for attraction of male *S. bicingulata*. This result suggests that *S. bicingulata* males may not be attracted to *S. haitangvora* females that emit *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc as its pheromone (Yang et al., 2009b). In field screening trials for *S. tenuis*, Tamaki et al. (1977) found an antagonistic effect of *E*3,*Z*13-18:OAc on male attraction when it was mixed with the major component, *Z*3,*Z*13-18:OAc, in a very low ratio. Therefore, *E*3,*Z*13-18:OAc may prevent cross-attraction between *S. bicingulata* and *S. tenuis* where they occur sympatrically. They also confirmed that *E*3,*Z*13-18:OAc and *Z*3,*Z*13-18:OAc attracted few *S. quercus* males when tested separately or in binary mixture. We, therefore, suggest that specific chemical signals contribute strongly to the maintenance of premating reproductive isolation between sympatric populations of *Synanthedon* species.

Variable Responses by Southern Pine Beetle, *Dendroctonus frontalis* Zimmermann, to the Pheromone Component *endo*-Brevicomin: Influence of Enantiomeric Composition, Release Rate, and Proximity to Infestations

Brian T. Sullivan · Mark J. Dalusky · Kenji Mori · Cavell Brownie

Abstract The male-produced bicyclic acetal *endo*-brevicomin is a component of the pheromone blend that mediates colonization of host pines by the bark beetle *Dendroctonus frontalis* Zimmermann. Efforts to identify its behavioral function have been complicated by contrasting reports that it either enhances or reduces attraction of flying beetles. Our studies failed to support the hypothesis that this published variability is due to differences in release rate and/or the enantiomeric composition [i.e., the beetle-produced (+)-enantiomer vs. the racemate] of the *endo*-brevicomin used in the experiments. In trapping trials within active *D. frontalis* infestations, racemic and (+)-*endo*-brevicomin did not differ from each other in behavioral effects when tested at seven different release rates ranging from 0.005 to 3 mg/d. At the highest release rates, racemic and (+)-*endo*-brevicomin similarly reduced catches in traps baited with an attractant (frontalin and turpentine), but neither enhanced catches at any release rate. Furthermore, the activity of racemic *endo*-brevicomin baits depended on trap proximity to *D. frontalis* infestations. Addition of these baits to attractant-baited traps located inside active infestations reduced catches, but they enhanced catches at traps located either 100 or 200 m outside these infestations. The contrasting responses may reflect differences in host-seeking strategies by either aggregated or dispersing *D. frontalis,* and may be elicited by differing abundance of natural sources of semiochemicals or differing responsiveness of beetles inside vs. outside of infestations. We suspect that much of the published variability in *D. frontalis* responses to *endo*-brevicomin is attributable to differing proximity of experimental field sites to infestations.

Introduction

Aggressive species of bark beetles (Coleoptera: Scolytidae) overcome host defenses by attacking trees in large numbers, and thus are able to colonize trees that would not be susceptible to infestation by smaller numbers of insects (Paine et al., 1997). These aggressive species stimulate and synchronize such "mass attacks," which inevitably result in death of the host tree, by releasing pheromones whose activity is often modified by compounds from the tree itself (Wood, 1982; Byers, 1989). Pheromones of aggressive bark beetles likely fulfill at least two functions in the mass-colonization process: as aggregation pheromones that attract beetles from the general area and concentrate landings and attacks on one or a few trees, and as

antiaggregation pheromones that terminate aggregation on a fully-colonized host and prevent overcrowding (Borden, 1982). Due to the essential role that these semiochemicals play in the beetles' ability to kill trees, substantial effort has been invested in developing semiochemical-based management techniques (Borden, 1995).

The southern pine beetle, *Dendroctonus frontalis* Zimmermann, is an aggressive bark beetle pest of pines in the southeastern United States, Mexico, and much of Central America (Payne, 1980). Population outbreaks are conspicuous as spatially discrete infestations or "spots," which are zones of contiguous, currently-infested or dead, abandoned trees surrounded by healthy forest (Franklin, 1970; Thatcher and Barry, 1982; Clarke and Nowak, 2010). During summer, brief (i.e., ~40 d), broadly-overlapping generations of brood beetles emerge from previously-infested trees within these infestations and are attracted to semiochemicals released from newly-infested trees at the leading edge of the growing infestation (Gara et al., 1965; Gara and Coster, 1968; Billings and Pase, 1979). These beetles either attack non-colonized areas of the main stem on these newly-infested trees or initiate colonization of adjacent, uninfested trees. Infestations accumulate new trees typically along just one side, and thus normally have a single, well-defined "head" and trajectory of infestation growth (i.e., the direction of newly-infested trees relative to those previously infested) at any given time (Coster et al., 1978; Schowalter et al., 1981).

The bicyclic acetal *endo*-brevicomin appears to be a key component of the semiochemical blend that mediates *D. frontalis* aggregation and infestation growth. Male beetles pairing with attack-initiating females in the host bark release apparently enantiomerically pure (+)-*endo*-brevicomin (Sullivan et al., 2007). Baits of synthetic (+)-*endo*-brevicomin can greatly enhance responses by both sexes to traps baited with pine volatiles and the female-produced attractant frontalin (Vité et al., 1985; Sullivan et al., 2007), implying that (+)-*endo*-brevicomin is a component of the aggregation pheromone. Furthermore, *endo*-brevicomin baits can have an even greater catch-enhancing effect when displaced 4–16 m away from such traps (Sullivan and Mori, 2009). Thus, in addition to enhancing attraction to the tree of origin, male-produced *endo*-brevicomin may mediate switching of the focus of mass attack from fully colonized trees (i.e., ones with many established pairs) to adjacent trees receiving initial attacks by females (Sullivan and Mori, 2009).

This interpretation of the biological function of *endo*-brevicomin is based upon results of behavioral studies performed with the beetle-produced (+)-enantiomer (Vité et al., 1985; Sullivan et al., 2007; Sullivan and Mori, 2009). However, the potent attractant synergism observed for (+)-*endo*-brevicomin in published studies contrasts sharply with several reports that racemic *endo*-brevicomin baits can inhibit *D. frontalis* responses to traps baited with frontalin and host odors (Vité and Renwick, 1971; Payne et al., 1978a; Salom et al., 1992). The inhibitory activity of racemic *endo*-brevicomin was reported earlier than the synergistic capacity of (+)-*endo*-brevicomin, and this led to the original classification of *endo*-brevicomin as a component of an antiaggregation pheromone for *D. frontalis* (Borden, 1982, 1985; Skillen et al., 1997). Vité et al. (1985) hypothesized that the reported inhibitory activity of *endo*-brevicomin was due to earlier studies' use of high release rates of the racemate and the presence of the (−)-enantiomer, which they demonstrated could inhibit *D. frontalis* responses to its attractant. However, no single, controlled study has evaluated this hypothesis by directly comparing *D. frontalis* responses to racemic and (+)-*endo*-brevicomin across a range of doses.

Furthermore, there are other possible reasons for the disparity among published results of field studies on *D. frontalis* responses to *endo*-brevicomin. Those trapping studies that demonstrated potent attractant synergism for *endo*-brevicomin generally were performed in uninfested tracts of forest (i.e., Sullivan et al., 2007; Sullivan and Mori, 2009; half of replicates in Vité et al., 1985); whereas those that demonstrated inhibition were performed mostly inside of growing infestations (i.e., Payne et al., 1978a; Salom et al., 1992; not detailed in Vité and Renwick, 1971). Host seeking behavior of *D. frontalis* ostensibly differs inside and outside of active infestations (Gara, 1967; Payne and Coulson, 1985); hence flying *D. frontalis* may respond differently to sources of *endo*-brevicomin located within or close to infestations rather than some distance away.

In this study, we tested the hypothesis that variation in the reported behavioral activity of *endo*-brevicomin can be attributed simply to variation in the enantiomeric composition and/or dose of the baits by comparing the flight response of *D. frontalis* to a range of release rates of racemic and (+)-*endo*-brevicomin in the field. Secondly, we tested the hypothesis that proximity of an active infestation affects the flight response of *D. frontalis* to *endo*-brevicomin by simultaneously operating attractant-baited traps inside and outside of infestations and altering the presence of an *endo*-brevicomin bait.

Methods and Materials

All experiments utilized multiple-funnel traps (12-unit; ChemTica Internacional, S.A., San Jose, Costa Rica) that were suspended from vertical standards consisting of 1.7 cm diam pieces of electrical conduit staked into the ground. Each trap cup was positioned 1–1.5 m above the ground and contained several centimeters of propylene glycol and water (1:3) to retain and preserve captured insects.

Experiment 1: Variable Dose and Enantiomeric Composition of endo-Brevicomin Baits Deployed Inside of Infestations Sixteen different trap bait treatments were compared: an unbaited trap, a standard attractant consisting of frontalin and pine turpentine, or the standard attractant plus one of seven logarithmically increasing release rates of either (+)- or racemic *endo*-brevicomin (Table 1). *endo*-Brevicomin was released either from glass capillaries with one heat-sealed end, or from open, 100 μl-capacity glass autosampler vial inserts (Table 1). Capillaries and inserts were secured open-end-up inside of an uncapped, inverted 4 ml-capacity screw-cap glass vial (Sullivan and Mori, 2009). One device was deployed per trap for the (+)-*endo*-brevicomin treatments; two devices were deployed for the racemic treatments. Hence, the release of (+) was equal for both enantiomeric treatments at each level of release rate. (+)-*endo*-Brevicomin was synthesized (Sullivan et al., 2007) and was >99% pure (enantiomerically and chemically) by NMR spectroscopy and GC. There were no detected contaminants with known behavioral activity. Racemic *endo*-brevicomin [Phero Tech International (now Contech Enterprises Inc.), Delta, BC, Canada] was 95% chemically pure by GC (<1% *exo*-brevicomin contamination). Racemic frontalin was released from a pair of capped 400 μl-capacity LDPE microcentrifuge tubes each containing 200–300 μl frontalin [>95% chemical purity (contaminants with no known behavioral activity), ChemTica]. Turpentine (steam distilled from loblolly pine, *Pinus taeda* L.; Hercules Inc., Brunswick, GA, USA; composition determined by GC-FID as 72% α-pinene, 1% *trans*-verbenol, 1% *trans*-pinocarveol, <1% myrtenal, myrtenol, and verbenone, with the remainder consisting of 5% β-pinene, 6% camphene, and other monoterpenes of no known behavioral activity) was released from a pair of LDPE transfer pipettes filled to capacity (4 ml) and heat-sealed at the tip. Bait release rates were measured in a fume hood at 24±2°C (23±2°C for frontalin), either gravimetrically for turpentine (0.12 g/d) and frontalin (5 mg/d) or by volume loss for *endo*-brevicomin (Table 1). Baits were attached at the fourth funnel from the bottom of the trap.

Sixteen traps were placed inside each of two actively-growing *D. frontalis* infestations (located >1 km apart) in stands of *P. taeda*, in the Homochitto National Forest, Mississippi. Traps were clustered (i.e., with no particular geometric arrangement) within portions of the infestations occupied by trees with predominantly larval-stage *D. frontalis* brood (Payne et al., 1978b), and were <10 m away from a brood tree and <50 m away from trees undergoing mass attack and presumably releasing aggregation semiochemicals. Traps were spaced >1 m from the nearest pine and 5–10 m apart; this close trap spacing was required in order to test all 16 treatments simultaneously within each infestation. The 16 bait treatments were assigned randomly and without duplication to the traps of each infestation. Trap catch was collected after 1–4 d, and then the treatment assignments were re-randomized without replacement to any previous position. Randomization and catch collection were repeated 9 times at one of the infestations (5–19 July 2005) and 7 at the other (5–13 July 2005; we were required to abandon this latter infestation so it could be controlled).

Mean daily catch for both males and females was calculated for every collection. All trap catch data for both experiments 1 and 2 were cube root transformed to meet the distributional assumptions of the tests; conformity to assumptions was confirmed by examination of residuals plots. Catches by the unbaited traps were omitted from the statistical analyses (Reeve and Strom, 2004). A mixed model ANOVA was carried out by using PROC MIXED (SAS 9.0, SAS Institute Inc., Cary, NC, USA) with effects for treatment, sex, and sex by treatment assumed fixed. Infestation and date within infestation were considered random sources of replication, and so treatment by infestation and treatment by date within infestation were also random. Sex was viewed as a repeated measures factor within each trap and date combination, hence sex by treatment by infestation, and sex by date within infestation, were also included as random effects. Treatment was partitioned to test for a significant effect of release rate, enantiomeric composition of *endo*-brevicomin, and interactions between these factors. Treatment by sex was partitioned analogously. An ESTIMATE statement was used to test for an interaction between sex and presence/absence of *endo*-brevicomin (averaged for both enantiomeric compositions). Degrees of freedom were obtained by using the default containment option. Since no significant interactions between treatment and sex were found, total catches of *D. frontalis* (i.e., with males and females pooled) were cube root transformed and subjected to the same mixed model ANOVA with omission of all effects involving sex. ESTIMATE statements were used to compare mean catches (averaged over enantiomeric compositions) at each release rate to catches by the standard attractant alone, with a Bonferroni correction applied to the resulting *P*-values (α=0.05).

Experiment 2: endo-Brevicomin Activity Inside vs. Outside of Infestations Tests were performed in 16 *D. frontalis* infestations; 8 in the Oconee National Forest, Georgia (25 June–26 July 2007) and 8 in the Homochitto National Forest, Mississippi (9 August–21 September 2007). Selected infestations had at least 5 recently-infested trees (i.e., with green crowns) and at least one tree visibly undergoing mass attack at the infestation head when trapping was initiated. All but one of the infestations continued to accumulate new, infested trees during the trapping period, but in all cases, the infestation heads advanced less than 20 m. Three traps were placed at each infestation: (1) inside the infestation head (surrounded by trees containing egg-stage brood and 4–20 m

Table 1 Construction and elution rate of *endo*-brevicomin release devices for experiment 1

Dose level	Glass insert/capillary characteristics				Elution rate[a] (mg/d ± s.d.)
	Diameter (i.d. mm)	Length (mm)	Height filled (mm)	Number per device	
1)	0.200	32	10	1	0.0049±0.0001
2)	0.346	32	10	1	0.015±0.001
3)	0.631	32	10	1	0.049±0.001
4)	1.17	32	10	1	0.16±0.01
5)	1.17	32	10	3	0.47±0.02
6)	3.66	30	10	1	1.2±0.1
7)	3.66	30	8	3	3.0±0.2

Each device consisted of 1–3 glass autosampler vial inserts or glass capillaries secured open-end-up inside of an inverted, uncapped 4 ml capacity screw-cap vial

[a] Measured with the racemate by volume loss in a fume hood over 26 d at 24±2°C (N=3). One device was deployed per trap for the (+)-*endo*-brevicomin treatments; two devices were deployed per trap for the racemic *endo*-brevicomin treatments. Hence, this rate represents the release of each enantiomer of *endo*-brevicomin

from trees being mass attacked); 2) 100 m; and 3) 200 m beyond the limit of infested trees and within forests with a pine component within the general trajectory of infestation growth. In some instances, trap locations diverged from the trajectory of infestation growth as much as 90° if land within the infestation trajectory did not contain susceptible pines or was not publicly owned. Due to the inherently limited size of forest management units ("stands"), it was often necessary to locate the 2nd or 3rd (i.e., the 100 or 200 m) traps within adjacent forest stands that may not have been identical in tree composition, age, density, and other characteristics to the stand containing the beetle infestation itself. In some cases, the stand containing the infestation and those containing the 2nd or 3 rd traps were separated by treeless zones such as roads and utility right-of-ways. No multiple-tree infestations were closer to the 2nd and 3rd traps than the selected infestation, and no solitary colonized trees were closer than 50 m. Traps typically were placed no closer than 4 m from healthy pines to reduce chances of artificially inducing new infestations in these trees, but distances as small as 2 m were unavoidable in high-density pine stands.

All three traps at an infestation were consistently baited with frontalin and turpentine. A device releasing racemic *endo*-brevicomin was either attached simultaneously to all 3 traps assigned to an infestation or not attached to any, with the initial treatment (*endo*-brevicomin present/absent) chosen by a coin toss. Catch was collected at intervals of 1–5 d, and the treatment assignment was reversed for all 3 traps at an infestation on each date that catch was collected (3–10 collections over a 5–26 d trapping period). The frontalin bait was the same as experiment 1 except a single tube was used (i.e., 2.5 mg/d at 23°C). The turpentine bait (4–7 g/d at 24°C) was a single 250 ml-capacity brown glass bottle with a 1 cm diam piece of cotton dental wick immersed in the liquid (200–250 ml, same source and chemical composition as in experiment 1) and extending 1–2 cm through a hole in the cap. The *endo*-brevicomin bait (0.5–0.8 mg/d at 24°C) was an LDPE "bubble"-type device (ChemTica) containing 49 mg racemic *endo*-brevicomin (>95% purity with 2–3% *exo*-brevicomin). Frontalin and *endo*-brevicomin baits were attached near the center of each trap, whereas the turpentine bottle was placed within the funnel immediately below the trap top to protect the wick from rain.

At each trap collection, pines adjacent to the 100 and 200 m traps were checked for the presence of pitch tubes and other evidence of *D. frontalis* attack. Small numbers of attacks (1–5) were sometimes observed on one or more nearby pines. However, if a mass attack were observed on one or more adjacent trees (as occurred at one infestation in Mississippi), catch data from this trap collection were discarded, and the trap was relocated >50 m away from the infested trees while maintaining the assigned treatment distance from the infestation.

For each trap, catches were pooled across collections to obtain a single mean value for daily catch with *endo*-brevicomin either absent or present. We performed a mixed-model ANOVA on these cube root transformed means by using PROC MIXED (SAS 9.0) with main and interaction effects for four fixed factors (*endo*-brevicomin treatment, trap position, state, and beetle sex) plus the following four random effects: infestation within state, trap position by infestation within state, *endo*-brevicomin treatment by infestation within state, and trap position by *endo*-brevicomin treatment by infestation within state. Thus, infestation within state was the random source of replication, whereas trap position and *endo*-brevicomin

treatment were considered stripped (i.e., applied uniformly) across each other within infestations. Sex was considered a repeated measures factor within each combination of trap position and *endo*-brevicomin treatment. To examine significant interactions, means for levels of one factor were compared at each fixed level of another factor by using the SLICE option with the LSMEANS statement. A Bonferroni correction was applied to the resulting *P*-values separately for each significant interaction (α=0.05).

Results

Experiment 1: Variable Dose and Enantiomeric Composition of endo-Brevicomin Baits Deployed Inside of Infestations No significant interactions were revealed between sex of the responding beetles and bait treatment overall (F=1.34; df=14,15; P=0.29), or between sex and the various treatment components, specifically, between sex and the presence/absence of *endo*-brevicomin (t=0.42; df=15; P=0.68); between sex and *endo*-brevicomin dose (F=1.87; df=7,15; P=0.15); between sex and the enantiomeric composition of the *endo*-brevicomin bait (F=0.00; df=1,15; P=0.97); or among sex, dose, and enantiomeric composition of *endo*-brevicomin (F=0.94; df=6,15; P=0.50). With both sexes of *D. frontalis* pooled and averaging over dose, the enantiomeric composition of the *endo*-brevicomin bait had no significant effect on trap catches (F=0.00; df=1,14; P=0.98), and catches were not influenced by an interaction between dose of *endo*-brevicomin and its enantiomeric composition (F=1.04; df=6,14; P=0.44). However, averaging over enantiomeric composition, the release rate of *endo*-brevicomin had a highly significant effect on trap catches (F=17.5; df=6,14; P<0.001). Traps with the two highest release rates of *endo*-brevicomin caught significantly fewer beetles than traps baited with the standard attractant alone (F≥14.8; df=1,14; Bonferroni adjusted P≤0.013; Fig. 1). Traps with lower release rates of *endo*-brevicomin did not catch beetles in numbers that differed significantly from the attractant-only traps (P>0.45).

Experiment 2: endo-Brevicomin Activity Inside vs. Outside of Infestations A highly significant two-way interaction was revealed between trap location relative to the infestation head and presence/absence of the *endo*-brevicomin bait (F=40.3; df=2,28; P<0.001). Averaging over states, *endo*-brevicomin significantly reduced *D. frontalis* catches at frontalin/turpentine baited traps located inside the head of the infestation, but significantly increased catches in such traps located 100 and 200 meters beyond the head of the infestation (Table 2). However, a marginally-significant three-way interaction was detected between presence/absence of *endo*-brevicomin, trap location relative to the infestation head, and the state where the infestations were located (F=2.97; df=2,28; P=0.068). With the two states considered separately, *endo*-brevicomin significantly reduced catches at traps within the infestation in both states, but it significantly enhanced catches at traps outside the infestation only at the 100 m distance in Georgia and the 200 m distance in Mississippi (Table 2). However, this interaction with state was a quantitative (i.e., non-crossover) interaction, and the mean trend in both states was catch enhancement by *endo*-brevicomin for both trap locations outside the infestations. There was no significant interaction between sex and the effect of *endo*-brevicomin: there was not a significant three-way interaction among sex, *endo*-brevicomin presence, and trap location relative to the infestation head (F=0.91; df=2,84; P=0.406) nor a significant four-way interaction among sex, *endo*-brevicomin presence, state, and trap location relative to the infestation head (F=1.92; df=2,84; P=0.153). However, there was a highly significant two-way interaction between trap location relative to the infestation head and sex (F=35.2; df=2,84; P<0.001), apparently due to more strongly male-skewed sex ratios trapped within the infestation than outside. Furthermore, there was as a highly significant interaction between state and sex (F=83.0; df=1,84; P<0.001), apparently from more strongly male-skewed sex ratios trapped in Georgia than in Mississippi.

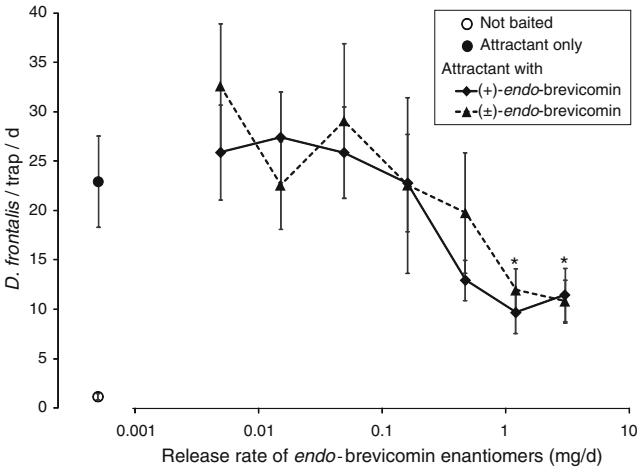

Fig. 1 Catches of *Dendroctonus frontalis* in multiple-funnel traps baited with an attractant (racemic frontalin and turpentine) alone or with varying release rates of either racemic or (+)-*endo*-brevicomin, Homochitto National Forest, Mississippi, July 2005. Catches at release rates of *endo*-brevicomin denoted with an asterisk were significantly different from catches by the attractant-only control trap (Proc Mixed ANOVA on transformed data; CONTRASTS with Bonferroni correction; α=0.05). The release rate indicated by the X-axis is for each individual enantiomer, thus the total release of *endo*-brevicomin [that is, the (+)- and (−)-enantiomers summed] by the racemic bait was twice that for the (+)-*endo*-brevicomin bait

Discussion

Experiment 2 demonstrated that an *endo*-brevicomin bait with a fixed release rate can produce apparently opposite behavioral effects depending on whether it is deployed inside or outside the head of an active *D. frontalis* infestation. The *endo*-brevicomin bait of experiment 2 consistently inhibited attraction and/or landing at point sources of attractant within infestations, but generally enhanced these responses outside. Furthermore, inside infestations we failed to observe attraction enhancement by either racemic or (+)-*endo*-brevicomin at any tested dose (experiment 1), including doses within a range that significantly enhanced catches in previous studies that we conducted outside of infestations [approximately 0.2–3 mg/d for (+); 0.5 mg/d for racemic; Sullivan et al., 2007; Sullivan and Mori, 2009].[1]

This variability may in part explain the alternatively synergistic or inhibitory activity reported by the six published trapping studies with *D. frontalis* that investigated the attractant-modifying capacity of *endo*-brevicomin alone. Although there was variation in the enantiomeric composition and release rate of the deployed baits, two of these studies performed away from infestations reported attraction enhancement or no effect by *endo*-brevicomin (Sullivan et al., 2007; Sullivan and Mori, 2009), whereas two performed inside infestations reported either attractant inhibition or no effect (Payne et al., 1978a; Salom et al., 1992). Vité and Renwick (1971) observed attractant inhibition, but did not report proximity of their traps to infestations. However, our results appear inconsistent with those of Vité et al. (1985), who observed significant attraction enhancement by both racemic and (+)-*endo*-brevicomin with half of their replicates conducted "within (a *D. frontalis*) infestation" and half in "uninfested stands." Although they pooled data from these two locations for their statistical analyses, their means reported for each site suggest similar responses to *endo*-brevicomin.

Furthermore, modest inconsistencies in our data from experiment 2 suggest that caution be used in inferring that *endo*-brevicomin invariably has opposite activities inside vs. outside of *D. frontalis* infestations. Significant catch enhancement by *endo*-brevicomin at both distances outside of infestations (100 m and 200 m) was detected only when data from both Mississippi and Georgia were pooled, and between the two states there appeared to be no consistent relationship between distance from the infestation and the degree of the enhancement effect of *endo*-brevicomin. The

[1] It should be noted that experiment 1 and the tests cited in Sullivan et al. (2007) and Sullivan and Mori (2009) differed substantially in the rate of turpentine released from the standard bait (i.e., 0.12 vs. 7 g/d, respectively).

Table 2 Effect of *endo*-brevicomin baits on *Dendroctonus frontalis* flight responses to attractant-baited traps positioned either inside or outside of active infestations

Attractant consisted of racemic frontalin and steam distilled *Pinus taeda* turpentine (see Methods and Materials for details)

[a] Each replicate was a single infestation of *D. frontalis*

[b] P-value for test of hypothesis that catch was the same with *endo*-brevicomin either present or absent at the trap (SLICE option of the LSMEANS statement, SAS PROC MIXED on cube root transformed data, with Bonferroni correction, α=0.05)

marginally-significant interaction detected between treatment effect and state may be related to large differences in the abundance of infestations in the forests utilized in either state: during the Summer of 2007 approximately 1.6 infestations/km^2 were detected on the Oconee National Forest, Georgia, but only 0.12/km^2 in the Homochitto National Forest, Mississippi (Valli Peacher, USFS-FHP, personal communication).

The contrasting activities of *endo*-brevicomin possibly reflect the very different demands on host/mate-seeking *D. frontalis* either inside or outside of infestations. Beetles dispersing outside infestations may be hundreds of meters from the nearest suitable host (Coulson et al., 1985), and natural selection should presumably favor strategies that reduce energy and time consumed during host location. For these insects, the combination of pheromone components of both sexes (i.e., frontalin and *endo*-brevicomin) with host odors may serve as a more reliable indicator of an established infestation—where high densities of attacking conspecifics assures continuous host and mate availability—than frontalin and host odors alone (Sullivan and Mori, 2009). For beetles flying within infestations, by contrast, host trees are immediately available through the continuous cycle of new mass attacks on adjacent, healthy trees at the infestation head (Thatcher, 1960; Gara et al., 1965). In this circumstance, individual reproductive success may be maximized through discrimination of phloem resource availability and quality within individual hosts undergoing mass attack. *endo*-Brevicomin may aid beetles in avoiding trees that have reached their colonization capacity (i.e., ones having many established pairs and presumably releasing elevated quantities of *endo*-brevicomin) in favor of incompletely colonized trees (i.e., ones with at least some solitary females releasing frontalin and fewer or no *endo*-brevicomin producing males). Thus, *endo*-brevicomin may have distinct functions for dispersed and aggregated *D. frontalis*, aiding the former in locating active infestations and the latter in assessing resource availability within individual hosts.

A range of variables relating to the environment, the physiological state of responding insects, and the chemical signal itself can ultimately determine how bark beetles respond to semiochemicals (Borden et al., 1986; Raffa, 2001; Miller et al., 2005; Pureswaran et al., 2008). Pheromone components that alternately exhibit either attractive or inhibitory activity within a single population have been identified in several bark beetle species (Rudinsky, 1973; Borden et al., 1987; Schlyter et al., 1987; Seybold et al., 1992). In these reports, the precise activity of such "multifunctional" pheromone components is governed by a quality intrinsic to the pheromone source, namely the release rate of the compound, with low release rates being attractive but high ones inhibitory (Borden, 1996). In our experiment 2, however, the experimentally deployed *endo*-brevicomin baits were identical both inside and outside of the *D. frontalis* infestations, hence the reversal of activity we observed in either situation ostensibly had causes extrinsic to the baits themselves. These might include:

(a) *Differing background semiochemicals associated with the traps.* A prevailing background of *D. frontalis* semiochemicals presumably exists within the microenvironment of infestations but not in the surrounding forest. Trees within the advancing head of an infestation may contain many thousands of pheromone-producing beetles (Pureswaran et al., 2008), and evidence indicates that the associated semiochemical plume can profoundly influence behavior of *D. frontalis* orienting within and near these infestations (Gara et al., 1965; Gara, 1967; Cronin et al., 1999). These background semiochemicals conceivably could alter beetle responses to point sources of semiochemicals established within the infestation, such as our baits. This possibility is suggested by the observation that a device releasing approximately a single infested tree equivalent of *endo*-brevicomin can alter *D. frontalis* catches in traps within a radius of at least 30 m (Sullivan and Mori, 2009), a distance that is greater than what separated the infestation-imbedded traps of our experiments and the nearest mass-attacked trees. It should be noted that in experiment 1 the presence of *endo*-brevicomin and the other bait components on adjacent treatments also may have influenced trap catches, since intertrap spacing was merely 5–10 m. However, we presume that the 100 m spacing among traps in experiment 2 was sufficient to preclude any significant cross-interference by experimental baits.

(b) *Relative abundance of competing sources of beetle attraction.* Nearby, alternative sources of attractive cues and landing sites (namely, mass-attacked trees) are readily available to beetles inside infestations but not outside. Thus, whether or not an orienting beetle lands in a trap within an infestation is likely influenced by the bait's attractiveness relative to these competing, attractive sources. One effect of *endo*-brevicomin is apparently to render collocated sources of attractant relatively less attractive than adjacent sources of attractant: when one of a group of adjacent frontalin/turpentine-baited traps is baited additionally with *endo*-brevicomin, this trap becomes relatively less attractive to *D. frontalis* than the adjacent traps lacking *endo*-brevicomin, even though catch is enhanced in all traps (Sullivan and Mori, 2009). Thus, in our experiments, the absence/presence of an *endo*-brevicomin bait on traps inside the infestations could have rendered the traps more/less attractive than nearby infested trees, altering the

number of beetles trapped. By contrast, there were no adjacent mass-attacked trees to serve as alternative, attractive targets to the baited traps located outside infestations in experiment 2.

(c) *Differing responsiveness of dispersed* vs. *aggregated individuals*. Evidence suggests that flying beetles within *D. frontalis* infestations are predominantly newly-emerged brood or re-emerged parent adults from trees within the infestation (Gara, 1967; Cronin et al., 1999). Thus, beetles responding to traps located within infestations likely had flown a shorter average distance and spent less time outside of a host than beetles responding to traps located outside the infestations. Flight exercise alters *D. frontalis* responses to aggregation semiochemicals (Andryszak et al., 1982), and both flight exercise and changes in fat reserves have been shown to alter semiochemical responses in other bark beetle species (Borden et al., 1986). Furthermore, one study found that *D. frontalis* trapped outside of infestations express genes in different frequencies than those trapped inside (Florence et al., 1982), suggesting that dispersing and aggregated beetles differ in their inherent physiological and, perhaps, behavioral capacities. However, this finding is cast into some doubt by the study's failure to examine the sexes separately and by our evidence from experiment 2 that sex ratios trapped inside and outside infestations differ substantially.

Vité et al. (1985) reported that pure (+)-*endo*-brevicomin baits enhanced, whereas pure (−)-*endo*-brevicomin baits reduced, *D. frontalis* responses to traps baited with frontalin and host odors. However, in infested stands (experiment 1), we failed to observe a significant difference in beetle response to either racemic or (+)-*endo*-brevicomin at any of seven release rates spanning nearly four orders of magnitude. Likewise, in a previous study performed in uninfested stands, racemic and (+)-*endo*-brevicomin released at approximately 0.23 mg/d did not differ in their capacity to enhance attraction of *D. frontalis* (Sullivan and Mori, 2009). Thus, despite evidence that (−)-*endo*-brevicomin can inhibit attraction by *D. frontalis* (Vité et al., 1985), we did not find that it modified the activity of the (+)-enantiomer in racemic baits. For this reason, we chose to use the more readily-available and less expensive racemic *endo*-brevicomin rather than (+)-*endo*-brevicomin in experiment 2.

We believe this is the first report of a bark beetle semiochemical bait reversing its apparent behavioral effect (i.e., between attraction enhancement and inhibition) due to its proximity to sites of beetle aggregation. This particular expression of multifunctionality in bark beetle semiochemicals could obviously complicate efforts to use them in beetle management, since failure to deploy such compounds in the appropriate context (i.e., either within infestations or within uninfested stands) could result in the opposite of the intended effect. Efforts to develop *endo*-brevicomin as a management semiochemical for *D. frontalis* have been frustrated by unintended effects, but ones apparently unrelated to *endo*-brevicomin's multifunctionality. Blends of *exo*- and *endo*-brevicomin can greatly reduce *D. frontalis* attacks on trees within infestations (Payne et al., 1977), suggesting these compounds might have value as tree protectants. However, trees within infestations treated with these two isomers of brevicomin experience reciprocal increases in attacks by secondary *Ips* spp. DeGeer bark beetles and therefore no reduction in mortality (Payne and Richerson, 1979; Richerson and Payne, 1979; Watterson et al., 1982). Although, tree protection with *endo*-brevicomin has not been attempted outside of infestations, our results lead us to expect that such treatment would also fail because it would likely enhance, rather than reduce, risk of *D. frontalis* attack.

Acknowledgments We thank Joanne Barrett, James MacDonald, Brad Hoosier, Zach Oliver, Erich Vallery, Tessa Bauman, and Chris Young for technical assistance; Drs. T. Tashiro, K. Fuhshuku and Y. Masuda of RIKEN, Japan, for help with the synthesis of (+)-*endo*-brevicomin; Lee Dunnam, Homochitto National Forest, MS, for assistance and cooperation in field studies; Rhonda Tam and Jessica Norris for administrative assistance; and Drs. Dan Miller and Kamal Gandhi for their comments on earlier versions of this manuscript. The work was funded in part by US Forest Service cooperative agreements 03-CA-11330129-172 and 05-IC-11330129-186 with the University of Georgia, Athens, GA, U.S.A. and RIKEN, Tokyo, Japan, respectively.

Abstract The pine caterpillar moth, *Dendrolimus kikuchii* Matsumura (Lepidoptera: Lasiocampidae), is a pest of economic importance on pine in southwest China. Three active compounds were detected during analyses of solvent extracts and effluvia sampled by solid phase microextraction (SPME) from virgin female *D. kikuchii* using gas chromatography (GC) coupled with electroantennographic (EAG) recording with antennae from a male moth. The compounds were identified as (5*Z,*7*E*)-5,7-dodecadien-1-yl acetate (*Z*5,*E*7-12:OAc), (5*Z,*7*E*)-5,7-dodecadien-1-ol (*Z*5,*E*7-12:OH), and (5*Z*)-5-dodecenyl acetate (*Z*5-12:OAc) by comparison of their GC retention indices, mass spectra, and EAG activities with those of synthetic standards. Microchemical reactions of gland extracts provided further information confirming the identifications of the three components. Solvent extractions and SPME samples of pheromone effluvia from virgin calling females provided 100:18:0.6 and 100:7:1 ratios of *Z*5,*E*7-12:OAc:*Z*5,*E*7-12:OH:*Z*5-12:OAc, respectively. Field behavioral assays showed that *Z*5,*E*7-12:OAc and *Z*5,*E*7-12:OH were essential for attraction of male *D. kikuchii* moths. However, the most attractive blend contained these three components in a 100:20:25 ratio in a gray rubber septa. Our results demonstrated that the blend of *Z*5,*E*7-12:OAc, *Z*5,*E*7-12:OH, and *Z*5-12:OAc comprise the sex pheromone of *D. kikuchii*. The optimized three-component lure blend is recommended for monitoring *D. kikuchii* infestations.

Key Words *Dendrolimus kikuchii* · (5*Z,*7*E*)-5,7-dodecadien-1-yl acetate · (5*Z,*7*E*)-5,7-dodecadien-1-ol · (5*Z*)-5-dodecenyl acetate · Field behavioral assay · Lasiocampidae · Lepidoptera · Sex pheromone · Solid phase microextraction

Introduction

Pine caterpillars (Lepidoptera: Lasiocampidae) are a serious pest of pine in China. Until now, about eighty species from seven genera have been identified (Hou, 1987). Species in the genus *Dendrolimus* Germar, including the six principal species *Dendrolimus punctatus* (Walker), *D. tabulaeformis* Tsai et Liu, *D. spectabilis* (Butler), *D. superans* Butler, *D. houi* Lajonquière, and *D. kikuchii* Matsumura, are considered to be most harmful, with populations that frequently reach outbreak status and cause significant damage to forests throughout China (Hou, 1987). The Simao pine caterpillar moth, *D. kikuchii*, is broadly distributed across southern China and causes severe damage to *Pinus yunnanensis* Franch., *P. kesiya* var. *langbianensis* (A. Chev.), *P. massoniana* Lamb., *P. armandii* Franch., *P. thunbergii* Parl., *P. taiwanensis* Hayata, *Keteleeria evelyniana* Mast., and other trees in Anhui, Jiangxi, Hunan, Hubei, Fujian,

Zhejiang, Jiangsu, Yunnan, and portions of several other Chinese provinces (Xiao, 1991). The number of generations per year of *D. kikuchii* varies geographically. In Simao prefecture in southern Yunnan province, *D. kikuchii* has two generations per year, but in the northern part of Yunnan province only one generation occurs (Xiao, 1991). In Simao prefecture, larvae (especially the 4th through 7th instars) cause significant damage annually to large areas of pine trees during two disjunct periods (March to May, and then August to September) reducing stand volume and resin productivity. Flights of adult *D. kikuchii* usually occur in June/July and again in September/October, which overlap with the seasonal flight periods of the broadly sympatric species, *D. houi*, in Simao prefecture.

In heavily infested areas, *D. kikuchii* is controlled mainly by insecticide applications, the use of which could be enhanced and the environmental impact minimized by the timing of insecticide sprays by monitoring with pheromone traps (Zhang et al., 2003). So far, sex pheromones have been reported for the masson pine caterpillar moth, *D. punctatus* (Zhao et al., 1993), the pine moth, *D. spectabilis* (Ando et al., 1982; Kong et al., 2003), the larch caterpillar moth, *D. superans* (Klun et al., 2000; Kong et al., 2007a), the Yunnan pine caterpillar moth, *D. houi* (Kong et al., 2007b), and the European pine moth *D. pini* (Priesner et al., 1984; Kovalev et al., 1993). Sex pheromones components that have been identified from *Dendrolimus* species are all (5*Z*,7*E*)-5,7-dodecadienes with different terminal functional groups (alcohol, acetate, propionate, and aldehyde), except for the sex pheromone of *D. houi*, which was reported as a mixture of (5*E,*7*Z*)-5,7-dodecadien-1-yl acetate (*E*5,*Z*7-12:OAc), (5*E,*7*Z*)-5,7-dodecadien-1-ol (*E*5,*Z*7-12:OH), and (5*E*,7*Z*)-5,7-dodecadienal (*E*5,*Z*7-12:Ald) (Kong et al., 2007b). In preliminary GC analyses, appreciable amounts of *Z*5,*E*7-12:OAc were observed in extracts of pheromone glands of female *D. kikuchii*, along with smaller amounts of *Z*5,*E*7-12:OH (Kong et al., 2001). However, the identities of these compounds as pheromone components remained to be confirmed. In this study, we present additional analytical data on the pheromone gland components from female *D. kikuchii*, and report on their electrophysiological and behavioral activities in the laboratory and the field.

Methods and Materials

Collection and Handling of Insects Cocoons of *D. kikuchii* were collected from the host tree, *Pinus kesiya* var. *langbianensis,* near Pu'er city, Yunnan province and maintained in a rearing room at 25±1°C, 60-80% relative humidity with a 16L:8D photoperiod until adult emergence. Newly emerged males and females were housed separately under the same conditions. Virgin females were used for preparation of pheromone extracts, whereas males were used for electroantennographic studies.

Preparation of Samples Pheromone extracts were prepared as described previously (Kong et al., 2007a, b). Briefly, individual female sex pheromone glands were excised during the peak period of calling (0–2 d-old, 4–7 h into the scotophase) and extracted about 30 min in redistilled hexane (10 µl per gland). Glands were removed before sealing the extracts in glass tubes, which were stored at −20°C until bioassay and chemical analyses. Individual pheromone gland extracts were prepared (N=25) and 5 ng of (*Z*)-12-tetradecenyl acetate (*Z*12-14:OAc) were added to each as an internal standard to quantify the pheromone components.

Volatile pheromone collection was performed by solid phase microextraction (SPME) from virgin female moths (N=3) held in groups of 3-5 in 0.02 m^3 screen cages under ambient laboratory lighting and temperature conditions. After females were at rest on the walls of the cage for at least 30 min (to ensure quiescence during sample collection), we initiated collection of volatiles on a 70 µm SPME fiber (Supelco Inc., Bellefonte, PA, USA) coated with CarboWax/divinylbenzene (CW/DVB). The fiber was positioned close to the sex pheromone gland of a virgin female (2 mm) for the entire duration of the scotophase period. For analysis by GC-MS and GC-EAD, a 1 µl aliquot of a series of straight-chain aliphatic hydrocarbons (36 ng/µl of each in dichloromethane, see below for commercial source) was added directly to the sample-loaded fiber with syringe. The purpose of these standards was to assign Kováts retention indices (KI) to the components of the crude extract.

Chemical Standards Chemicals used in our analysis, e.g., all geometrical isomers of 5,7-dodecadien-1-yl acetate (*Z*5,*Z*7-, *E*5,*E*7-, *E*5,*Z*7-, and *Z*5,*E*7-12:OAc) and the corresponding alcohols (*Z*5,*Z*7-, *E*5,*E*7-, *E*5,*Z*7-, and *Z*5,*E*7-12:OH) and aldehydes (*Z*5,*Z*7-, *E*5,*E*7-, *E*5,*Z*7-, and *Z*5,*E*7-12:Ald), together with *Z*5-, and *E*5-12:OAc were purchased from Chemtech B. V. (Amsterdam, The Netherlands). *Z*12-14:OAc originated from our laboratory collection. All chemicals were purified by preparative GC using a 2 m×3.2 mm column (packed with 8% PEG 20 M on 80–100 mesh Chromosorb G-HP) in a Model 990 gas chromatograph (Perkin-Elmer Corp., Norwalk, CT, USA) as described by Kong et al. (2001, 2007b). Chemicals used as stimuli for electrophysiological and field trials were ≥99% chemically and ≥95% isomerically pure. C_{14}-C_{22} straight-chain hydrocarbons for assigning Kováts retention indices were purchased from TCI Co. (Tokyo, Japan). 4-Methyl-1,2,4-triazoline-3,5-dione (MTAD, 95%) was purchased from Aldrich Chemical (Milwaukee, WI, USA), and dimethyl disulfide (DMDS, 99%) and acetyl chloride (>99%) were purchased from Acros Organics (Geel, Belgium).

Derivatization Acetylation and methanolysis were performed to verify the conversion of alcohols (acetates) to the corresponding acetates (alcohols) (Bjostad et al., 1984). Positions of double bonds in conjugated dienes were determined by MTAD derivatization (Young et al., 1990; McElfresh and Millar, 1999), and in mono-unsaturated alkenes by the iodine-catalysed addition of dimethyl disulfide across the double bond (Buser et al., 1983). Derivatizations were performed in glass capillaries with one end sealed or in 1 ml conical vials with Teflon-lined screw caps. For acetylation and methanolysis, 14 female equivalents were evaporated to apparent dryness with a gentle nitrogen stream, then 20 µl acetyl chloride were added and allowed to react with extracted substances at room temperature for about 20 min. The product was again evaporated to dryness and re-dissolved in 6 µl of hexane. A 2 µl aliquot of the resulting solution was analyzed by GC with a flame ionization detector (FID). The remaining product of acetylation (4 µl) was evaporated again and 15 µl of KOH solution in methanol (0.5 M) were added. After 0.5 h at room temperature, 15 µl of a solution of HCl (1 M) and 30 µl hexane were added and the mixture was shaken for 2–3 min. Then 30 µl of redistilled water were added, the layers were separated and the recovered hexane portion was dried over anhydrous sodium sulfate for 24 h. After concentration with a stream of nitrogen, the solution was analyzed by GC-FID. For determination of double bond positions of conjugated dienes, MTAD derivatives of synthetic standards and compounds extracted from pheromone glands were prepared by adding 3 µl of 2 µg/µl MTAD in CH_2Cl_2 to gland extracts (7 female equivalents in 20 µl CH_2Cl_2) or to 10 ng of respective synthetic standard dissolved in 20 µl CH_2Cl_2. Mixtures were allowed to react at room temperature for 1 h. The products were concentrated and analyzed by GC-MS. For determination of double bond positions in mono-unsaturated acetates, synthetic standards and 14 female equivalent extracts in 20 µl hexane were derivatized following Buser's methods (Buser et al., 1983).

Electrophysiology The GC-EAD system consisted of a Hewlett-Packard 6890 GC equipped with flame ionization (FID) and electroantennogram (EAD) detectors. The EAD preparation consisted of a detached antenna from a 1-to 3-d-old male with the terminal segment removed, mounted directly between two EAG probes with electrically conductive gel (Spectra 360 electrode gel, Parker Laboratories Inc. Orange, NJ, USA). The signal from the EAD detector was amplified using a 10 × pre-amplifier and an AC/DC UN-6 amplifier (Syntech, The Netherlands) and fed to a personal computer equipped with an analog to digital conversion board (IDAC, Syntech). Acquisition and analysis of the EAD signals were performed by GC-EAD software (16-bit version, Syntech, The Netherlands). The GC was equipped with a split/splitless injector, a DB-WAX column (J&W Scientific, Folsom, CA, USA, 30 m× 0.25 mm i.d. × 0.25 µm) with the column effluent split by a splitter (SGE, part # OSS-2) between the FID and EAD detectors. The splitter (with a 12 ml/min N_2 make up gas to compensate for flow reduction) split the column effluent equally between the FID and EAD detectors, which were connected with the splitter by deactivated fused silica capillary columns (0.22 mm i.d.). The EAD arm was led out of the GC oven through a heated (250°C) EAD interface (Syntech) and the effluent exited into a purified and humidified airstream (~500 ml/min) directed over the antennal preparation. Synthetic compounds, solvent extracts, and SPME fibers with loaded samples were injected splitless using a temperature program starting at 80°C for 1 min, then programmed at 10°C /min to 200°C (20 min hold), N_2 was used as carrier gas, and the injector and detector temperature was set at 220°C and 250°C, respectively.

Gas Chromatography (GC) Products of acetylation and methanolysis were analyzed on an HP 5890 series II GC using a BP-20 capillary column (SGE analytical science, Brisbane, Australia, 25 m×0.22 mm i.d. × 0.25 µm) in splitless mode, temperature program: 80°C (1 min)-10°C/min-200°C (30 min). Quantitative analyses of 25 glands extracted individually were conducted on an HP6890 GC with a FID detector using a DB-WAX column (J&W Scientific, Folsom, CA, USA, 30 m×0.25 mm i.d.×0.25 µm) in splitless-mode, temperature program: 80°C (1 min)-6°C/min-200°C (10 min).

Coupled Gas Chromatography-Mass Spectrometry (GC-MS) Pheromone gland extracts and SPME samples (and all analyses for calculation of Kováts retention indices) were analyzed with a Finnigan Trace DSQ GC-MS (EI mode, 70 eV, mass range 41–460 amu) on DB-WAX and DB-5MS capillary columns (30 m×0.25 mm i.d. × 0.25 µm) with helium carrier gas (1.0 ml/min). SPME CW/DVB fibers were desorbed in the injection port for 2 min in splitless mode, program: 60°C (1 min)-6°C/min to 240°C (10 min hold), injector, ion source, and transfer line temperatures were set at 220°C, 250°C and 250°C, respectively. Full scan (TIC) and selected ion monitoring (SIM) spectra were recorded simultaneously. In SIM mode, diagnostic ions for the respective compounds were monitored. Thus, *m/z* 224 (M^+), 164 (M^+-CH_3COOH), and 136 ($C_{10}H_{16}^+$) were selected to characterize dodecadienyl acetates, *m/z* 182 (M^+), 164 (M^+-H_2O), and 121 (M^+-C_3H_9O) for dodecadienols, and *m/z* 166 (M^+-CH_3COOH) and 138 ($C_{10}H_{18}^+$) for dodecenyl acetates.

MTAD adducts were analyzed with a Finnigan Trace 2000 GC interfaced with a Voyager mass spectrometer fitted with a nonpolar HP-1 capillary column (50 m× 0.20 mm i.d.×0.33 µm; Agilent, J&W Scientific) in

splitless mode, program 80°C-15°C/min-280°C (20 min) with helium (0.6 ml/min) carrier gas in EI mode (70 eV), mass range from 41–401 amu, ion source, injector and transfer line temperatures 200°C, 280°C and 250°C, respectively. DMDS adducts were analyzed with a Finnigan Trace DSQ GC-MS (EI mode, 70 eV, mass range 41–560 amu) on a DB-5MS capillary column (30 m×0.25 mm i.d.×0.5 μm) in splitless mode. The column temperature was programmed as follows: 60°C (1 min)-6°C/min to 240°C (15 min hold). Injector, ion source, and transfer line temperatures were set at 250°C, 220°C, and 250°C, respectively. In GC-MS analysis, compounds were identified by comparison of retention indices and mass spectra with those of synthetic standards or their derivatives.

Field Behavioral Assays Lures consisted of gray rubber septa (The West Company, Phoenixville, PA, USA) loaded with hexane solutions (20 μl) of test compounds, plus 20 μl of butylated hydroxytoluene (BHT, 10 μg/μl) in dichloromethane as an antioxidant. Control septa were loaded only with 200 μg BHT in 20 μl dichloromethane. Once the treatment solutions had soaked into the septa, the lures were sealed in glass vials for transport. The lures were prepared 2 d before use and were mounted in the trap below the lid and about 2–3 cm above the sticky bottom. Experiments were set up in randomized, complete blocks with traps positioned approximately 20–30 m apart in a line and blocks separated by at least 150 m. Sticky traps, similar in shape to Pherocon 1C traps from Trécé Inc. (Salinas, CA, USA), were constructed from two pieces of cardboard (42×28 cm) with a wire in the center of the lid to suspend the septum. In traps baited with virgin females, a single virgin female moth that had emerged in the laboratory from field collected pupae was housed in a metal mesh container (8×6 cm) in place of the pheromone dispenser. Female moths were renewed every 4 d. Traps were fixed on pine tree branches ca. 1.5 m above ground, with the lures left unchanged for the entire flight period. Experiments in 2001 (eight treatments, four replicates) were designed to test male moth responses to *Z*5,*E*7-12:OAc and *Z*5,*E*7-12:OH alone, and in binary combinations in different ratios. Experiments in 2007, 2009, and 2010 were designed to evaluate the effects of the trace compounds, *Z*5-12:OAc and *Z*5,*E*7-12:Ald, added to a base blend of *Z*5,*E*7-12:OAc/*Z*5,*E*7-12:OH in a 5:1 ratio. Male moths were removed and counted at 1-to 2-d intervals, depending on weather conditions during each study.

Data Handling and Statistical Analyses Kováts retention indices were calculated by using the formula described by Marques et al. (2000). For statistical analysis of field trials, the day counts for each treatment in a given block were pooled and this sum was transformed to log(x+1) to facilitate variance homogeneity prior to conducting one-way ANOVA. If significant treatment effects were detected ($P<0.05$), then the responses to the treatments were ranked by LSD *post hoc* tests ($\alpha=0.05$, SPSS13.0).

Results

GC-EAD Analyses In analyses of solvent extracts and SPME entrained volatiles from virgin female *D. kikuchii* moths by GC-EAD, up to three compounds that elicited responses from antennae of male moths were detected. The most active compound eluted at 19.33 min (Fig. 1, peak 2, Mean ± SD, 3.0±2.6 mV), and all male *D. kikuchii* antennae tested responded to this compound ($N=8$). The other two compounds that elicited antennal responses eluted earlier at 17.28 min (Fig. 1, peak 1, 0.3±0.6 mV, detected by 4 out of 8 antennae) and later at 21.09 min (Fig. 1, peak 3, 0.3±0.4 mV, detected by 3 out of 8 antennae). The GC retention times and EAD responses of the three compounds from glands agreed well with those of synthetic *Z*5-12:OAc (Mean ± SD, 2.3±1.7 mV, detected rate 100%, $N=6$), *Z*5,*E*7-12:OAc (4.0±2.9 mV, detected rate 100%, $N=6$), and *Z*5,*E*7-12:OH (0.1±0.1 mV, detected rate 33%, $N=6$), respectively, injected in 5 ng doses (2.5 ng at the antenna) during GC-EAD analyses. In addition, the antennae of male *D. kikuchii* also responded to synthetic *Z*5,*E*7-12:Ald and *E*5,*Z*7-12:Ald.

Quantitative analysis showed that single-gland extracts contained on average 1.2±0.9 ng (mean ng/female ± SD, $N=25$) of *Z*5,*E*7-12:OAc, 0.2±0.2 ng (mean ng/female ± SD, $N=25$) of *Z*5,*E*7-12:OH, and 0.01±0.05 ng (mean ng/female ± SD, $N=25$) of *Z*5-12:OAc corresponding to a ratio of 6:1:0.05.

GC-MS Analyses of Pheromone Extracts and MTAD and DMDS Adducts The first EAD-active compound EAD1 was characterized by retention indices on DB-WAX ($KI_{WAX}=1{,}909$) and DB-5 columns ($KI_{DB\text{-}5}=1{,}588$), respectively, with diagnostic ions of 166 (M^+-CH_3COOH, 14%), 138 ($C_{10}H_{18}^+$, 17%), 123 ($C_9H_{15}^+$, 11%), 110 ($C_8H_{14}^+$, 33%), and 67 ($C_5H_7^+$, 100%) (Tables 1, 2). The most abundant compound EAD2 had $KI_{WAX}=2{,}052$, and $KI_{DB\text{-}5}=1{,}636$, and was characterized by ions of *m*/*z* 224 (M^+, 4%), 164 (M^+-CH_3COOH, 23%), 136 ($C_{10}H_{16}^+$, 17%), 121 ($C_9H_{13}^+$, 28%), and 79 ($C_6H_7^+$, 100%). The third EAD-active compound EAD3 had $KI_{WAX}=2{,}149$, and $KI_{DB\text{-}5}=1{,}511$, respectively, and displayed ions at *m*/*z* 182 (M^+, 4%), 164 (M^+-H_2O, 17%), 135 (M^+-C_2H_7O, 6%), 121 (M^+-C_3H_9O, 19%), and 79 ($C_6H_7^+$, 100%). Mass spectra and retention times of the three EAD-active compounds

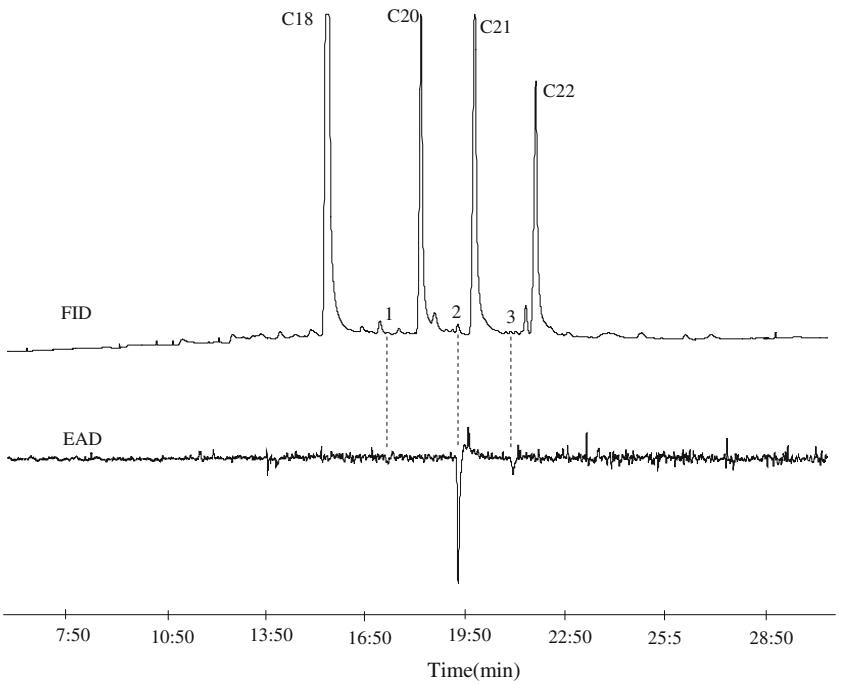

Fig. 1 Simultaneously recorded FID and EAD responses using antennae of male *Dendrolimus kikuchii* in response to sample collected by the CW/DVB fiber from one virgin female *D. kikuchii* moths. Peaks indicated by 1, 2, and 3 represent *Z*5-12:OAc, *Z*5,*E*7-12:OAc, and *Z*5,*E*7-12:OH, respectively. A 1 μl solution of hydrocarbon standards (36 ng/μl each) was added onto the fiber before injection

were identical to those of *Z*5-12:OAc (EAD1), *Z*5,*E*7-12:OAc (EAD2), and *Z*5,*E*7-12:OH (EAD3), respectively (Tables 1, 2), confirming the presence of the three compounds in the pheromone glands of *D. kikuchii*. Identities of the EAD2 and EAD3 compounds were further confirmed by microchemical analyses. Mass spectra and retention times of MTAD derivatized compounds in the gland extracts were identical to those obtained by MTAD treatment of synthetic *Z*5,*E*7-12:OAc and *Z*5,*E*7-12:OH (Table 1). Conjugated double bond positions of the EAD2 and EAD3 compounds were 5,7 based on examination of diagnostic fragments from cleavage on either side of the adducts formed between the gland components and the dienophile MTAD (Table 1). In addition, acetylation and

base methanolysis of gland extracts resulted in disappearance and re-appearance of the alcohol peak, confirming unambiguously the OH moiety in the EAD3 compound. The mass spectral data of compounds in the DMDS derivatized gland extracts of *D. kikuchii* (Table 1) indicated the presence of the double bonds in the Δ^5 position (*m*/*z* 175 and 145) for the minor EAD1 components. The retention times matched those of the corresponding derivative from *Z*5-12:OAc, thus confirming the previous identifications. The other 5,7-isomers were excluded from consideration because their retention times were different from those of the *Z*5,*E*7-compounds. These data, along with the MTAD data, would completely prove the double bond positions and stereochemistries.

Field Behavioral Assays Preliminary field trials in 2001 had indicated that neither *Z*5,*E*7-12:OAc nor *Z*5,*E*7-12:OH was attractive alone and must be presented together (Table 3). Lures with higher doses of *Z*5,*E*7-12:OAc than *Z*5,*E*7-12:OH (9:1, 3:1 ratios) showed better attractiveness than the blends with opposite ratio (Table 3). Field experiments performed in 2007 showed that there was no significant difference in male moth captures to *Z*5,*E*7-12:OAc and *Z*5,*E*7-12:OH at different ratios tested (Table 3).

Increasing the amount of *Z*5-12:OAc from 1% to 25% of the major component, *Z*5,*E*7-12:OAc, suggested an optimum level of 25% in trap captures relative to the acetate/alcohol blend (5:1 ratio) (Table 4). The same field trials conducted in 2009 and 2010 confirmed the results; the most attractive blend contained these three components in a 100:20:25 ratio released from a gray rubber septum (Table 4). The optimum synthetic pheromone blend caught more than twice as many male *D. kikuchii* moths as traps baited with a single virgin female moth (Table 4). Addition of 20 μg *Z*5,*E*7-12:Ald to either the binary blend (*Z*5,*E*7-12:OAc and *Z*5,*E*7-12:OH) or ternary blend (*Z*5,*E*7-12:OAc, *Z*5,*E*7-12:OH, and *Z*5-12:OAc) resulted in significant reductions in trap catches relative to the acetate/alcohol blend or the optimum 3-component blend (Table 4).

Discussion

Two suspected pheromone components, *Z*5,*E*7-12:OAc and *Z*5,*E*7-12:OH, have been known from *D. kikuchii* moths for quite some time but their functions were unclear (Kong et al., 2001). The present study describes efforts to clarify the female-produced sex pheromone of *D. kikuchii*, which apparently consists of at least three compounds, i.e., the primary component *Z*5,*E*7-12:OAc and the less abundant *Z*5,*E*7-12:OH and *Z*5-12:OAc. These three compounds were detected in both pheromone gland extracts and SPME entrained volatiles of calling females by GC-MS and GC-EAD methods. The antennae of male *D. kikuchii* were most sensitive to *Z*5,*E*7-12:OAc followed by *Z*5-12:OAc and *Z*5,*E*7-12:OH in GC-EAD analyses, although *Z*5-12:OAc is 20-fold less abundant than *Z*5,*E*7-12:OH in gland extracts. Following the common pattern of pheromone chemistry in the *Dendrolimus* genus, female moths of *D. kikuchii* employ the *Z*5,*E*7-configuration of the acetate and alcohol pheromone components and both components are essential for attraction. In this study, field trapping data also have provided some evidence for the behavioral role of the minor EAD-active component, *Z*5-12:OAc, confirming its status as a pheromone component of *D. kikuchii*. In addition, *Z*5-12:OAc also has been found in *D. punctatus*, although it is not part of the attractive pheromone blend of that species (Zhao et al., 1993).

SPME samples obtained by CW/DVB coated fiber (70 μm) and conventional samples obtained by solvent extraction were similar, and provided enough material for GC-MS analyses of the most abundant *Z*5,*E*7-12:OAc. Clear mass spectra were not obtained from solvent extracts of *Z*5,*E*7-12:OH and *Z*5-12:OAc because the compounds were present in much smaller quantities than in the SPME samples. SPME sampling was more effective and provided enough material for unambiguous full scan GC-MS identification. The assignments of the stereoisomers of the EAD-active peaks were completed by comparison of their retention indices with those of the synthetic acetate and alcohol on DB-WAX and DB-5MS columns. The retention times on two columns of different polarity provide strong evidence of the identity of the three compounds. In addition, the GC-MS data of MTAD and DMDS derivatization with gland extracts further confirmed the presence of *Z*5,*E*7-12:OAc, *Z*5,*E*7-12:OH, and *Z*5-12:OAc in the pheromone glands. The fact that the retention times of the other 5,7 isomers were different also confirms the stereochemistry as *Z*5,*E*7.

Female-emitted sex pheromones typically have two or more components, and component ratio often is important in evoking optimal responses from males (Linn and Roelofs, 1989). Although the response of *D. kikuchii* males broadly overlaps the component ratios found in the gland extracts of virgin females with different methods, in the species studied here, the pheromone component ratios are important as in the closely related *D. punctatus* and *D. spectabilis*, which are sympatric in northern China. *Dendrolimus kikuchii* and *D. spectabilis* are entirely allopatric and so can use *Z*5,*E*7-12:OAc and *Z*5,*E*7-12:OH as major pheromone components, *D. kikuchii* in a 100:7 (SPME) ratio and *D. spectabilis* in about the inverse ratio (Kong et al., 2003). Over much of southern China, *D. kikuchii* is broadly sympatric with *D. punctatus*, which employs a 100:75 blend of *Z*5,*E*7-12:OH and *Z*5,*E*7-12:OAc as major pheromone components (Zhao et al., 1993).

The difference in ratios between major pheromone components could serve as a premating reproductive isolation mechanism between the sympatric *D. kikuchii* and *D. punctatus*. Furthermore, the minor components, *Z*5-12:OAc and (5*Z*,7*E*)-5,7-dodecadien-1-yl propionate, function to enhance the specificity of the signals, respectively. In addition, *Z*5,*E*7-12:OAc is known to serve as a strong inhibitor of European pine caterpillar moth *D. pini* whose major pheromone component is *Z*5,*E*7-12:Ald (Priesner et al., 1984). In the current research, *Z*5,*E*7-12:Ald at relatively high dose showed strong antagonistic effects on attraction of male *D. kikuchii*, although trace quantities of it have been found in the gland extracts. From the point of electrophysiological evidence, *Z*5,*E*7-12:Ald and *E*5,*Z*7-12:Ald might be involved in the inhibition of sympatric species *D. kikuchii* and *D. houi*.

Acknowledgments We are grateful to Dr. Blanka Kalinová, Institute of Organic Chemistry and Biochemistry, Academy of Sciences of the Czech Republic and Dr. Steven J. Seybold, USDA Forest Service, Davis, CA, for critical comments on an earlier version of this manuscript; to Dr. Jocelyn G. Millar, University of California Riverside, CA, for corrections on the revised version. We gratefully acknowledge three anonymous reviewers for their perceptive and constructive comments on this manuscript. We also thank Simao Department of Pests and Quarantine Control Station for assistance with field trials. This work was supported by grants 30771737 and 30300275 from the National Natural Science Foundation of China. Partial financial support from Basic Research Special Funds of Central Public Welfare Research Institutes (CAFRIFEEP201002) and Forest Conservation and Community Development Project is also gratefully acknowledged.

Abstract Insect cuticular hydrocarbons (CHCs) are not only essential for desiccation resistance, they also play an important role as chemical signals and cues in social as well as solitary insects. The identification of CHCs is, therefore, crucial to an understanding of the chemical communication within and between insect species. We describe a method for rapid, simple, and unambiguous identification of CHCs using gas chromatography—ion-trap mass spectrometry. External ionization configuration in combination with a low ion-trap temperature resulted in dramatically increased intensities of molecular ions for alkanes, alkenes and alkadienes, and in high-mass fragmentation patterns with intense ions characteristic for methyl-branched hydrocarbons comparable to those obtained with quadrupole instruments. Additionally, we present an external chemical ionization—tandem mass-spectrometric method that allows for the determination of double-bond positions in alkenes and alkadienes without the need for derivatization prior to analysis.

Introduction

Cuticular hydrocarbons (CHCs) play a key role for the ecology and chemical communication in solitary and social insects and have, therefore, been subject to extensive study (e.g., Ferveur, 2005; Howard and Blomquist, 2005; Le Conte and Hefetz, 2008; Martin and Drijfhout, 2009). In addition to their importance for desiccation resistance, CHCs can serve as pheromones (i.e., sex, trail, queen, recruitment, dominance pheromones) that confer information in a diverse range of contexts to con- or heterospecific individuals. Insect CHCs comprise simple to very complex mixtures of saturated, unsaturated, and methyl-branched hydrocarbons.

Although many CHCs can be analyzed by using matrix-assisted laser desorption/ionization (MALDI) or laser desorption/ionization time-of-flight (LDI-TOF) mass spectrometry (Cvacka et al., 2006; Yew et al., 2009), most studies use gas chromatography—mass spectrometry (GC-MS) for routine identification of these substances. Single-quadrupole analyzers have been used most frequently for these studies due to ease of use, availability, and simple interpretation of mass spectra (e.g., molecular ions of alkanes and alkenes can readily be identified, characteristic fragmentation patterns of methyl-branched hydrocarbons; e.g. Nelson et al., 1972; Pomonis et al., 1978). Determination of double-bond positions in alkenes usually is accomplished by dimethyldisulfide (DMDS) derivatization followed by GC-MS analysis (Dunkelblum et al., 1985). However, due to retention time shift and the high boiling point of derivatized long-chained alkenes, determination of double-bond positions is limited to hydrocarbons of medium molecular weight, and assignment of derivatized compounds to the corresponding alkene may be difficult.

Compared to single-quadrupole analyzers, ion-trap mass spectrometers rarely have been used for the identification of

CHCs, despite the fact that they offer many advanced features such as tandem mass spectrometry (MS-MS) and various chemical ionization (CI) techniques that make them the instrument of choice for many other applications. The rare use of ion-trap instruments is due mainly to differential fragmentation patterns of methyl-branched hydrocarbons (Doolittle et al., 1995) and low abundance of molecular and characteristic fragment ions in internal ionization configuration, which can be partially overcome by a low ion-source temperature and increased ionization time in high-mass segments (Doolittle et al., 1995). However, these measures may have certain disadvantages, e.g., increased detector tailing and elevated background ions. Recent advances in ion-trap instrumentation, especially the use of external ionization, combine the advantages of both quadrupole and ion-trap technologies. Briefly, in internal ionization configuration, both the GC transfer line and the CI gas transfer line terminate directly in the ion-trap, and ionization occurs in the trap itself. In external ionization configuration, however, the GC transfer line and the CI gas transfer line end in an external ion source, where the sample is ionized and then directed towards the ion-trap assembly by ion lenses using electrostatic focusing.

Here, we report on the optimization of the ion-trap temperature of a GC ion-trap mass spectrometer in external ionization mode for the identification of alkanes, methyl-branched alkanes, alkenes, and alkadienes in combination with a CI MS-MS *in situ* double bond derivatization method. This procedure allows for the unambiguous, simple, and rapid identification of insect CHCs, including the determination of the double-bond position(s), without the need of pre-analysis chemical derivatization.

Methods and Materials

GC-MS GC-MS analyses were performed using a Varian 240MS ion-trap mass detector coupled to a Varian 450GC. All analyses were performed in the external ionization configuration. A VF-5 ms column (30 m×0.25 mm ID; 0.25 μm df; Varian Inc. Palo Alto, CA, USA) was used to separate the hydrocarbons. The temperature of the split/splitless GC injector was set to 250°C, and the injector was operated in the split [electron ionization (EI)] or splitless mode [chemical ionization (CI)], respectively. The GC oven temperature was programmed as follows: 150°C for 1 min, 5°C/min to 300°C, hold 5 min. Helium was used as a carrier gas at a constant flow rate of 1 ml/min. EI spectra were recorded with a mass range of *m/z* 45–500 at maximum scan rate. CI spectra were recorded using acetonitrile (ACN) as a reagent gas with a mass range of *m/z* 60–500. In ACN-CI, the diagnostically useful $[C_3H_4N]^+$ ion is formed from an ion/molecule reaction between $[C_2H_2N]^+$ (*m/z* 40) and neutral acetonitrile, followed by a loss of HCN (Oldham, 1999). CI MS-MS experiments of alkene $[M+54]^+$ adducts (Moneti et al., 1997; Oldham and Svatos, 1999) were conducted with the resonant waveform type for precursor ion excitation, an isolation window of *m/z*=5, and 20 ms excitation time. The automatic "q" calculator was used for the determination of precursor ion excitation energy and product ion mass range. CI MS-MS experiments of alkadienes were conducted in the same fashion as for the alkenes with the $[M+54]^+$ adduct serving as the precursor ion. All CI measurements were conducted with an ion-trap temperature of 90°C, a manifold temperature of 40°C, and an ion-source temperature of 160°C. Data were analyzed using the MS Workstation software (version 6.9.3, Varian Inc., Palo Alto, CA, USA).

Influence of Ion-trap Temperature on Characteristic Ion Abundance in EI Mode The influence of ion-trap temperature on the abundance of alkane, alkene, and alkadiene molecular ions as well as "classical" fragment ions of methyl-branched alkanes in the external ionization EI mode was assessed by varying the ion-trap temperature from 80°C to 160°C in 10°C-steps. The ion-source temperature was always kept at 160°C. The ion-trap temperature was not lowered below 80°C to avoid excess temperature differences between the ion source and the ion-trap. The manifold temperature was kept at 40°C (for ion-trap temperatures between 80°C and 120°C) or at 50°C (for ion-trap temperatures between 130°C and 160°C), respectively. After each temperature change, the ion-trap radio frequency ramp was adjusted and the instrument was tuned in EI mode using the auto-tune function. At each ion-trap temperature step, an alkane standard solution containing all alkanes from C_8 to C_{40} with a concentration of 40 ng/μl for each compound (composed from alkane solutions C_8-C_{20} (Fluka) and C_{21}-C_{40} (Fluka)), a CHC extract of a *Cerceris arenaria* female, and a CHC extract of *Drosophila melanogaster* females (see below) were injected into the GC-MS in EI mode.

Insects and Sampling Females of the solitary digger wasp *Cerceris arenaria* (Hymenoptera, Crabronidae) were caught in a sand pit near Alzenau, Germany. The wasps were anesthetized with CO_2, frozen at −20°C, and individually extracted in 1 ml of hexane for 10 min. CHCs of this species have been identified previously using a GC quadrupole MS, and the position of alkene double-bonds has been determined using DMDS derivatization followed by GC-MS analysis (Strohm et al., 2008). *Drosophila melanogaster* (Diptera, Drosophilidae) was used as a second model organism to study the suitability of the CI

MS/MS method for the determination of the double-bond positions in alkadienes. CHCs of this species have been studied extensively (e.g., Everaerts et al., 2010), and double-bond positions of alkadienes have been described. For CHC extraction, 490 6-d-old virgin *D. melanogaster* females (wt, Berlin) were deposited in a Pasteur glass pipette, stopped on the narrower end with pre-extracted glass wool, and gradually washed with hexane (2.45 ml; Aldrich) to yield one female equivalent per 5 µl of solution.

Data Analysis The abundance of molecular ions of alkanes was calculated for the C_{21} to C_{31} alkanes from the alkane standard solution. This represents the range of alkanes that are most commonly found in insects. The abundance of molecular ions of alkenes was calculated from five naturally occurring alkenes (from *C. arenaria* and *D. melanogaster)*: (*Z*)-7-tricosene, (*Z*)-7-pentacosene, (*Z*)-7-heptacosene, 7-nonacosene, 7-hentriacontene (Strohm et al., 2008). The abundance of alkadiene molecular ions was calculated from (*Z*,*Z*)-7,11-tricosadiene, (*Z*,*Z*)-7,11-pentacosadiene, (*Z*,*Z*)-7,11-heptacosadiene, and (*Z*,*Z*)-7,11-nonacosadiene of the *D. melanogaster* extract (Everaerts et al., 2010). The abundance of "classical" diagnostic fragment ions of methyl-branched alkanes (α-cleavage) was calculated from six selected cuticular compounds of *C. arenaria* (7-methylpentacosene = 7me-C25 (*m/z* 281), 5me-C25 (*m/z* 309), 3me-C25 (*m/z* 337), 7me-C27 (*m/z* 309), 5me-C27 (*m/z* 337), and 7me-C29 (*m/z* 337)). Although internally branched monomethyl-alkanes and dimethyl-alkanes also yield good mass spectra, we used terminally branched hydrocarbons for the calculation of ion abundances for two reasons. First, internally branched hydrocarbons are chromatographically difficult to separate (Carlson et al., 1998) and, therefore, calculation of ion abundances is hampered by the coelution of several different compounds resulting in a mixed mass spectrum. Second, if the methyl-group is located in the middle of a molecule, both characteristic ions resulting from the cleavages at the methyl-group occur in similar (intermediate) abundances, and are less prominent than the more abundant ion in terminally branched alkanes. The only exceptions are symmetric molecules (e.g., 13me-C25). This behavior, however, also is observed in quadrupole instruments. Therefore, the effect of the ion-trap temperature on the abundance of characteristic ions of methyl-branched alkanes was assessed from terminally branched alkanes.

All abundances are expressed as the percentage of the base peak (*m/z* 57 for alkanes and methyl-alkanes, *m/z* 55 for alkenes, and *m/z* 67 for alkadienes). We compared abundances of the diagnostic ions of all compound classes among different ion-trap temperatures using a Friedman test. The statistical analyses were conducted using SPSS 17.0.0 software.

Molecular ions ($[M]^{+\bullet}$, *m/z* 294), acetonitrile adduct ions (*m/z* 335 and *m/z* 348, representing $[M+41]^+$ and $[M+54]^+$, respectively), and characteristic fragment ions after MS/MS (*m/z* 250 and *m/z* 208, representing fragment ions $[A]^+$ and $[B]^+$, respectively) are indicated by *arrows*

Results

In EI mode, we observed a strong influence of the ion-trap temperature on the abundance of molecular ions for alkanes (Friedman test: $N=11$, $P<0.001$) and alkenes (Friedman test: $N=5$, $P<0.001$). The influence on abundances of molecular ions of alkadienes was smaller, but still significant (Friedman test: $N=4$, $P<0.01$). Lower ion-trap temperature resulted in a significant increase of molecular ion intensity with a maximum at 80°C (Fig. 1). Alkenes and alkadienes generally had more abundant molecular ions than alkanes.

In contrast to previous reports that used ion-trap instruments in the internal ionization mode (Doolittle et al., 1995), our use of external ionization yielded σ-cleavages and hydrogen transfer reactions characteristic for fragmentation of methyl-branched hydrocarbons comparable to those observed in quadrupole or sector-field instruments (Fig. 2). As for the molecular ions of linear alkanes, the abundance of diagnostic fragment ions was strongly dependent on the ion-trap temperature, with a lower temperature resulting in a higher abundance of diagnostic ions (Friedman test: $N=6$, $P<0.001$; Fig. 1). The strongest diagnostic ions were observed at the lowest ion-trap temperature tested (80°C). As in quadrupole MS, terminally branched CHCs yielded much stronger diagnostic ions than internally branched CHCs at low ion-trap temperatures (Fig. 2).

For the determination of the double-bond positions in alkenes and alkadienes, we applied a CI MS/MS approach using acetonitrile as a reagent gas. For alkenes, CI gave strong $[M+41]^+$ and $[M+54]^+$ adduct ions (Fig. 3b). The molecular ions also were easily visible. We did not find, however, the diagnostic *j*- and *l*-ions (cleavage at the position of the former double bond), described by Moneti et al. (1997) under internal ionization conditions. MS/MS experiments using the $[M+54]^+$ adducts as fixed precursor ions resulted in fragmentation at the (former) allylic positions (Fig. 3c and d). This finding is congruent with the pattern described by Oldham and Svatoš (1999) for CI

with ACN under internal ionization, and a reaction level of 50 (only reagent gas ions > *m/z* 50 react with the analyte). With increasing chain length of alkenes, the intensity of the respective small diagnostic ion decreased markedly. The larger ion became more prominent, and allowed for the unambiguous determination of the double-bond position. This dominance of the larger fragment ion is in congruence with Stevenson's rule, which dictates that the more stable carbocation (in this case, the larger fragment) is able to keep the charge more effectively. Formation of the larger ion is favored, and this ion will be more abundant in the mass spectrum. In addition to the characteristic ions, a whole series of ions spaced by 14 u (CH_2-moieties) are detectable, which is due to the stochastic nature of the fragmentation process that also allows less probable ions to be formed, albeit in lower quantities.

For alkadienes, CI using ACN as the reagent gas resulted in strong $[M+54]^+$ adduct ions. However, the $[M+41]^+$ adduct ion peak was much less pronounced (Fig. 4b). CI MS/MS experiments using the $[M+54]^+$ adduct ions as precursor ions gave two characteristic fragments with cleavages at the outward α-position of the two respective double bonds (Fig. 4c and d). This observation agrees with results of a previous ACN CI MS/MS study performed on diunsaturated fatty acids methyl esters, which also proposed a mechanism for the formation of the characteristic ions by cycloaddition of the ACN $[M+54]^+$ ion across the double bond, followed by Cope rearrangement and a retro-ene reaction after collision-induced dissociation (Van Pelt et al., 1999).

Discussion

Our experiments show that GC ion-trap mass spectrometry offers an excellent possibility for rapid and uncomplicated analysis of insect CHCs. External ionization in combination with low ion-trap temperature yields a sufficient abundance of diagnostic ions of alkanes,

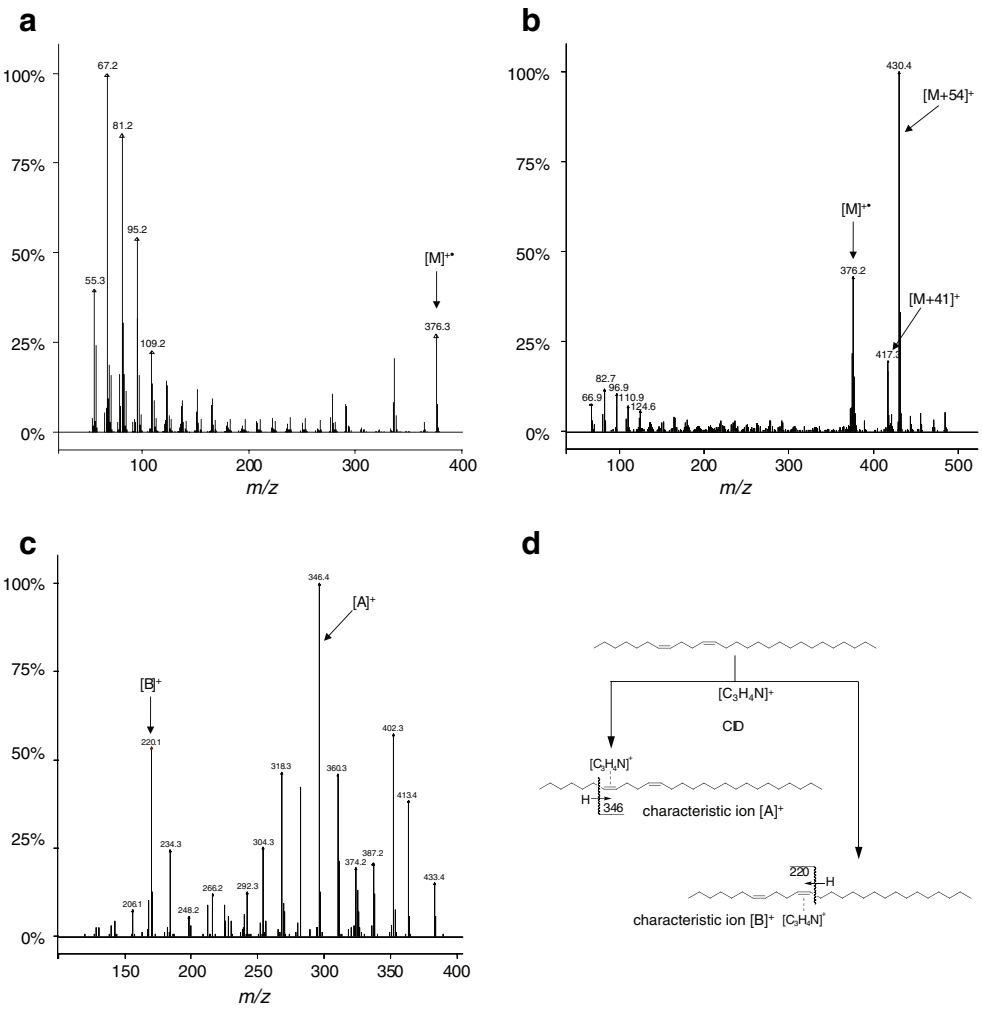

Fig. 4 Mass spectra of (*Z*,*Z*)-7,11-heptacosadiene from a cuticular extract of *Drosophila melanogaster* after **a** electron ionization (EI); **b** chemical ionization (CI) with acetonitrile; **c** acetonitrile-CI MS/MS of the $[M+54]^+$ adduct ion; and **d** observed fragmentation pattern upon collision-induced dissociation (CID) in the ion-trap MS/MS experiment. Molecular ions ($[M]^{+\bullet}$, *m/z* 376), acetonitrile adduct ions (*m/z* 417 and *m/z* 430, representing $[M+41]^+$ and $[M+54]^+$, respectively), and characteristic fragment ions after MS/MS (*m/z* 346 and *m/z* 220, representing fragment ions $[A]^+$ and $[B]^+$, respectively) are indicated by *arrows*

alkenes, and methyl-branched alkanes comparable to quadrupole and sector-field instruments. The dramatic effect observed for alkenes and linear and methyl-branched alkanes indicates that keeping the trap at high temperatures reduces lifetime of the molecular and high-mass diagnostic ions, thus resulting in the widespread prejudice against using ion-traps for CHC analysis. Molecular ions of polyunsaturated CHCs, however, are more stabilized and, therefore, readily detectable, even at high ion-trap temperatures. Thus, it is not surprising that the gain in sensitivity achieved by lowering the ion-trap temperature is smaller for alkadienes as compared to alkenes and saturated CHCs.

A decrease of the ion-trap temperature seems to be preferable over a decrease of the ion-source temperature as described by Doolittle et al. (1995), since the latter results in significant loss of sensitivity and a pronounced detector tailing, which hampers the identification of CHCs despite a greater intensity of diagnostic ions (data not shown). An increase of the ionization time of higher-mass scanning segments, as suggested by Doolittle et al. (1995) for internal ionization, gave no satisfactory results in our experiments with external ionization setup (data not shown). Although the abundance of higher mass ions increased considerably, the diagnostic value of these ions was low, as background ions from the sample or column-bleeding also were dramatically enhanced.

CI MS/MS of alkene adduct ions using ACN as a reagent gas allowed for the routine determination of the double bond position without the need for derivatization prior to analysis. This procedure previously has proven useful for the localization of double-bond positions in unsaturated hydrocarbons as well as fatty acid methyl esters (Moneti et al., 1997; Oldham and Svatos, 1999; Van Pelt and Brenna, 1999; Van Pelt et al., 1999; Michaud et al., 2002, 2003; Lawrence and Brenna, 2006). In comparison to DMDS derivatization followed by GC-MS, the ACN CI MS/MS method has the advantage of no shift in retention time of *in-situ* derivatized alkenes, which facilitates the assignment of the double-bond position. Additionally, high molecular weight alkenes and especially alkadienes, whose DMDS derivates have a high boiling-point and cannot be analyzed due to the temperature limit of many GC columns, can still be analyzed conveniently. Moreover, the CI MS/MS method can be conducted with comparatively low amounts of sample. It should be noted, however, that CI using ACN may significantly reduce the lifespan of the MS filament.

Our method allows for rapid, easy, and unambiguous identification of insect CHCs in one EI and one or two CI MS/MS runs, and it combines the advantages of quadrupole and ion-trap instruments. In summary, GC ion-trap mass spectrometry is a valuable tool for the identification of insect CHCs and offers alternative and complementary capabilities to quadrupole instruments.

COMMENTARY

New Synthesis – Plant Defense Signaling: New Opportunities for Studying Chemical Diversity

Georg Jander · Nicole Clay

Published online: 5 May 2011

Higher plants have evolved multilayered defense signaling systems that are based on the generation and perception of small molecules. These signaling pathways provide warning of incoming danger, triggering not only local resistance responses but also long-distance signals that lead to the protection of the whole plant against subsequent attack. This induced resistance against pathogens and herbivores often involves the production of alkaloids, terpenes, phenolics, and other small molecules with toxic and deterrent properties. However, although there are thousands of known plant metabolites with direct defensive functions, relatively few signaling molecules have been identified. Among these, salicylate, jasmonate, and related metabolites are the most extensively studied, and likely have universal functions as components of pathways leading to the induction of both local and systemic plant defense responses.

Salicylate and jasmonate-dependent signaling pathways in plants are presumed to have their evolutionary origins in the production of metabolites with a direct defensive function. Salicin, a metabolic precursor of salicylate, has a protective function in plants such as willows, and lipid intermediates in jasmonate biosynthesis also have been implicated in plant defense. For plants under attack, the induction of a local defense response is a reliable indicator of pests or pathogens that have the potential to spread more widely. Small molecules that are phloem mobile or even volatile, e.g., methyl salicylate and methyl jasmonate, provide an efficient means for propagating a systemic signal. Thus, by eliciting additional defenses and turning on signaling pathways, secondary metabolites (SMs) can contribute to a signal amplification loop that prepares otherwise naïve plant tissue for imminent attack.

Plant defense signaling does not occur through linear pathways, but rather is a complex network with numerous examples of crosstalk and an ever increasing number of known signaling molecules. In particular, the accumulation of certain SMs not only provides direct protection against disease and herbivory, but also serves as a trigger for further plant defense responses. For instance, our own work shows that 4-methoxyindol-3-ylmethylglucosinolate in *Arabidopsis thaliana* not only protects against pathogens and herbivores, but also elicits callose production as a secondary defense response. Azelaic acid is a phloem-mobile metabolite that can prime salicylate-dependent plant responses (Jung et al., 2009) and, as suggested by its use as a human acne treatment, also has antimicrobial properties. Production of reactive oxygen species has long been implicated in plant resistance to disease and herbivory. More recently, hydrogen peroxide was reported as a key reactive oxygen signal in plant immune responses, acting downstream or independently of salicylate and jasmonate signaling pathways (Miller et al., 2009).

Just as the great diversity of plant SMs is required for defense against multiple threats, there is likely also natural selection for a diversity of defense signaling pathways. Species-specific pathways should be less susceptible to interference by herbivores and pathogens, either through the targeted degradation of plant-derived signals or by the insertion of interfering molecules, e.g., the jasmonate-isoleucine mimic coronatine, which promotes virulence of plant-pathogenic *Pseudomonas syringae* bacteria (Uppalapati et al., 2007). In this respect, defensive SMs may be particularly suitable as plant signaling molecules. These compounds exhibit great chemical diversity, generally are resistant to catabolism by non-specialist pathogens and herbivores, show increased local accumulation in response to infection or herbivory, and can spread through the plant vasculature to provide a systemic signal.

Given that the vast majority of plant SMs have been investigated primarily for their function as direct defenses, there are numerous opportunities for discovering as yet unidentified or incipient signaling pathways. New research tools, including metabolite profiling by mass spectrometry and analysis of gene expression by high-throughput sequencing, make it cost-effective to study global responses in non-model species. One approach would be an examination of plant responses to well-studied SMs, specifically to determine whether phloem and xylem-mobile toxins, e.g., nicotine, elicit additional systemic responses. New signaling molecules also may be discovered through systematic analysis of the countless unidentified plant metabolites that accumulate in response to pathogens and herbivores. Conducting such research with well-studied model species such as *A. thaliana*, rice, or tomato will make it possible to move beyond the identification of new signaling molecules to finding the genes and enzymes involved in their biosynthesis and response pathways.

Production of Herbivore-Induced Plant Volatiles is Constrained Seasonally in The Field but Predation on Herbivores is not

J. Daniel Hare · Jia J. Sun

Abstract Natural enemies of herbivorous insects utilize numerous cues to locate and identify their prey. One class of such cues is volatile organic compounds (VOCs) often produced by plants after attack by herbivores (hereafter herbivore-induced plant volatiles or HIPVs). Under simplified laboratory conditions, natural enemies often make clear choices between different HIPV blends, but such clear choices may be more difficult in more complex field environments. We studied the impact of VOC production by the undomesticated species, *Datura wrightii* on predation of eggs and larvae of *Lema daturaphila* by the omnivore, *Geocoris pallens* in the field. HIPV production in *D. wrightii* is developmentally and seasonally constrained to the early stages of plant growth even though *L. daturaphila* and *G. pallens* inhabit plants throughout the plant's growing season. We, therefore, asked if predation of *L. daturaphila* by *G. pallens* might be similarly constrained seasonally. Higher levels of VOC production were associated with higher levels of predation throughout the growing season, and the greater quantities of VOC production in May caused greater increases in predation than did VOC production later in the season (June–September). However, predation in the absence of VOC production ranged from 60–70% in June–September compared to only 14% in May, probably because plants were already colonized by predators later in the season. High levels of VOCs in response to herbivore damage by *D. wrightii* therefore may aid in the discovery of herbivore-damaged plants early in the season but the seasonal decline in VOC production does not limit predation of *L. daturaphila* by *G. pallens* later in the season.

Key Words Induced defense · Ontogenetic variation · Indirect defense · VOCs · HIPVs · Tritrophic interactions · Predation · *Datura wrightii* · *Lema daturaphila* · *Geocoris pallens*

Introduction

Predators and parasitoids of plant-feeding insects utilize a range of visual and chemical cues to guide them through the stepwise process of first locating a damaged plant, then locating a potential host on that plant, and ultimately assessing the quality of a host individual for utilization (Vinson, 1976). Among the chemical cues are the inducible plant odors that facilitate the discovery by natural enemies of the habitats of potential prey species (Vinson, 1976, 1981; Nordlund et al., 1988). Many of the plant odors are inducible and only released by plants after they have been damaged by herbivores (Elzen et al., 1983; Dicke and Sabelis, 1988; Turlings et al., 1991; Tumlinson et al., 1992; Vet and Dicke, 1992). These compounds are termed herbivore-induced plant volatiles (HIPVs) and are a subset of the more general class of volatile organic compounds (VOCs) emitted by plants either constitutively or in response to other plant stresses. Inducible VOCs may serve as relatively long distance cues to signify that a plant may be infested with potential hosts, although "long distance" rarely is defined (Puente et al., 2008).

Most studies on the role of HIPVs on the behavior of natural enemies have been performed under controlled laboratory conditions (Hunter, 2002; Turlings and Wäckers, 2004; Allison and Hare, 2009). The laboratory environment, however, greatly simplifies the choices that natural enemies need to make, and it eliminates the effect of biotic and abiotic factors that may complicate the behavioral choices that natural enemies would make under more natural field conditions. Such factors would include, among other things, variation in light intensity, variation in the time since damage occurred, damage by non-host herbivores, and the potentially interfering volatiles from other species of plants (Takabayashi et al., 1994; Gouinguene and Turlings, 2002; Gols et al., 2005; Bukovinszky et al., 2007). These differences between the field and laboratory environments therefore raise questions as to whether the behavioral responses observed under laboratory conditions commonly occur under the more complex field environments. Additionally, most field research is performed on domesticated plant species far removed from their natural habitats and grown under simplified conditions. Such conditions may not represent the more complex environments in which any interactions among plants, their herbivores, and the natural enemies of those herbivores might have evolved. Finally, the available studies performed in the field often assess the attraction of natural enemies to plants only at selected times during plant development (De Moraes et al., 1998; Thaler, 1999; Kessler and Baldwin, 2001; Halitschke et al., 2008), although ontogenetic variation in the ability of some plant species to emit HIPVs has been demonstrated (Köllner et al., 2004; Rostas and Eggert, 2008; Hare, 2010). All of these factors may add complications to the use of HIPVs by natural enemies under natural conditions. The rarity of studies on tritrophic interactions on undomesticated plant species in their natural environments is a major limitation to confirm, if not challenge, the results from the laboratory to develop a thorough and accurate understanding of plant-mediated interactions between herbivores and their natural enemies (Turlings and Benrey, 1998; Dicke and van Loon, 2000; van der Meijden and Klinkhamer, 2000; Hare, 2002; Janssen et al., 2002; Turlings and Wäckers, 2004).

One system in which the ecological significance of VOC production can be investigated under natural conditions involves the undomesticated plant species *Datura wrightii* (Solanaceae) and its native herbivores and natural enemies in its native environment. Previous research showed that, in the laboratory, young *D. wrightii* plants could be induced to produce blends of VOCs either when fed upon by the specialist chrysomelid beetle, *Lema daturaphila*, or when treated with the plant hormone methyl jasmonate (MeJA) (Hare, 2007). Different genetic lines of *D. wrightii* differed in both the quantities of inducible VOCs as well as the composition of the VOC blends, and the quantitative differences were heritable (Hare, 2007).

Unlike most of the rapidly-growing annual species in which HIPV production has been studied, *D. wrightii* has a long growing season in the sage scrub habitats of inland southern California. Seeds germinate in March or April after winter rains, but flowering usually is not initiated until June, after which plants continue to grow while also producing flowers and seed capsules through November. HIPV production in *D. wrightii* is confined largely to the early part of the plant's growing season when plants are growing vegetatively, and it declines as plants begin to flower and produce fruit (Hare, 2010). Similar levels of herbivory by *L. daturaphila* resulted in the production of nearly 25-times more HIPVs when inflicted on plants in April than when inflicted in August or September. Ontogenetic constraints on HIPV production were further demonstrated by showing that HIPV production could be partially restored simply by cutting plants back to ground level in mid-summer and allowing them to re-sprout and re-grow (Hare, 2010). Interestingly, despite the clear seasonal variation in HIPV production, the most important herbivores of *D. wrightii, L. daturaphila* and the mirid bug, *Tupiocoris notatus*, and their shared natural enemy, the omnivorous Western big-eyed bug, *Geocoris pallens*, (Heteroptera: Lygaeidae) inhabited plants throughout the plant's growing season (Hare, 2010).

Geocoris pallens and/or its more tractable congener, *G. punctipes,* respond positively to several individual VOC components, including linalool, α-bergamotene, 2-hexenal, indole, and methyl salicylate (MeSA) under field conditions depending upon the precise details of the experimental design (Kessler and Baldwin, 2001; James, 2003, 2005; Halitschke et al., 2008). In the wild tobacco species, *Nicotiana attenuata, G. pallens* was attracted to plants damaged either by *T. notatus* or *Manduca* spp. such that *G. pallens* inflicted 4.6-fold higher mortality of *Manduca* eggs experimentally placed on *T. notatus*—damaged plants in the field (Kessler and Baldwin, 2004). In addition to possibly using plant chemical cues to locate potential prey, *Geocoris* spp. also utilize their acute sense of vision (Eubanks and Denno, 2000).

Here, we investigated the impact of seasonal and genetic variation of VOC production in *D. wrightii* on predation of eggs and larvae of *L. daturaphila* by *G. pallens* in the greenhouse and field. Two trichome phenotypes occur in natural populations of *D. wrightii* in southern California, with some individuals producing leaves with short, non-glandular trichomes, and others producing leaves with longer glandular trichomes (van Dam et al., 1999). Prior laboratory studies showed *G. pallens* to be a more effective predator on plants with nonglandular trichomes (Gassmann

and Hare, 2005). We, therefore, investigated the role of variation in trichome morphology on predation by *G. pallens*. Our specific goals were to determine 1) if predation by *G. pallens* was greater on induced than on uninduced plants, 2) if the seasonal decline in HIPV production caused any seasonal decline in predation rates, 3) if genetic lines of plants that produced greater quantities of HIPVs and/or different HIPV blends benefitted from greater predation of *L. daturaphila*, and 4) if predation rates were lower on plants producing glandular trichomes than on plants producing nonglandular trichomes, as previous laboratory studies would predict. Our experimental designs also included the opportunity to test for all two- and three-way interactions between trichome morphology, genetic line, and plant developmental stage on HIPV production and predation by *G. pallens*.

Methods and Materials

The Study System Aspects of the ecology and genetics of the trichome dimorphism have been described elsewhere (van Dam and Hare, 1998b; van Dam et al., 1999). Leaves of the 'velvety' phenotype are densely covered by short, non-glandular trichomes and feel velvety to the touch, whereas leaves of the 'sticky' phenotype are less densely covered by glandular trichomes that secrete esters of glucose and aliphatic acids, and these leaves feel sticky to the touch. The trichome phenotype is governed by a single locus and is inherited in a Mendelian fashion; the allele for the sticky phenotype is dominant over that of the velvety phenotype (van Dam et al., 1999). Under natural conditions, *D. wrightii* is embedded in a community of plants, each with their own communities of herbivores and natural enemies. Plants occur in patches that persist for several years (Hare and Elle, 2004). Individual plants within patches quickly become colonized by overwintering adults of *L. daturaphila*, *T. notatus*, and other herbivores in the early spring, then suffer chronic herbivory throughout the growing season. The herbivore community attacking *D. wrightii* is relatively simple, being comprised of some five to ten species, depending upon season and location (Elle and Hare, 2000; Hare and Elle, 2002). The most abundant herbivore species overall is *L. daturaphila*, a folivore whose adult and larval stages impose chronic, season-long herbivory on both trichome phenotypes. A number of generalist natural enemies are associated with the herbivores of *D. wrightii*, but the most abundant is the omnivore, *G. pallens* (Gassmann and Hare, 2005). We have confirmed that *G. pallens* behaves poorly in several different laboratory olfactometers (see also Halitschke et al., 2008) but it does behave more naturally in larger-scale greenhouse experiments to be described below.

The plant lines used in these experiments were fifth-generation backcross progeny of heterozygous sticky progeny backcrossed to their original velvety pollen parent. The expected ratio of adult heterozygous sticky to homozygous recessive velvety sibs within each of the lines derived from each of eight original pollen donors is 1:1, and sibs within families are expected to be at least 98.4% similar after five generations of backcrossing. Seeds were germinated in the winter of 2009–2010 in a greenhouse equipped with high-pressure sodium lamps providing supplemental illumination for 16 h/day so that mid-day light intensities averaged 1,250±39 μmol m^{-2} s^{-1} PAR illumination (N=5 readings) at plant height. Greenhouse temperatures ranged between 15° and 35°C. Plants were maintained under these conditions for about 3 mo until trichome differentiation was complete (van Dam et al., 1999).

Greenhouse Experiments For the greenhouse experiments, fifth-generation backcross progeny from the highly inducible MVV6 and MVV8 lines were used (Hare, 2007). Survival of newly-hatched first-instar *L. daturaphila* was monitored on induced and uninduced sticky or velvety plants in the presence or absence of *G. pallens* in two separate experiments. In the first experiment, plants were induced by feeding by adult *L. daturaphila* on two young but fully expanded leaves of test plants for 48 h prior to the beginning of the experiment. In the second experiment, plants were induced by spraying the plant with 8 mM MeJA in 0.1% Tween 20® in water just to runoff. These treatments routinely induce similarly high levels of HIPV production in young *D. wrightii* (Hare, 2007). Induction treatments were initiated 48 h prior to the beginning of the predation experiment because maximum HIPV production usually occurs within 2–3 d after induction (Hare, 2007). Five newly-hatched first-instars of *L. daturaphila* were placed on the lower surface of each of the two leaves damaged by *L. daturaphila*, or leaves of similar age for uninduced plants and plants induced by MeJA. The plants were placed near the corners of a cage 1 m^3 in size. A three-piece hardboard floor with overlapping slots for the plant stems was placed on top of the pots and around the plants so that the stems emerged from a uniform surface. A quantity of shredded paper toweling was placed in the center of the cage to provide cover. Groups of 20 *G. pallens* were collected from the field, starved for 48 h, then released into the shredded paper toweling in the cages. Each group of treatments was repeated in 3–5 cages per wk, and the whole experiment was replicated over several weeks. One 'control' cage, containing plants only with *L. daturaphila* larvae and no predators, also was established within each weekly trial. After releasing the group of 20 adult *G. pallens,* survival of *L. daturaphila* larvae was assessed 72 h

later. By this time, surviving larvae had reached the 2nd or early 3rd instars but were still susceptible to predation by *G. pallens* (*pers. obs.*). In sum, there were 4 control and 8 predation replicates in the experiments utilizing MeJA as the inducer and 3 control and 11 predation replicates in the experiments utilizing damage by *L. daturaphila* adults as the inducer.

Field Plot Layout Plants used in this experiment included fifth-generation backcrosses of the UCV9, UCV8, OFV8, and OFV6 lines described previously (Hare, 2007). In the greenhouse, the UCV9 line produced relatively low levels of VOCs after induction, whereas the OFV6 line produced relatively high levels, and the other two lines produced intermediate levels (Hare, 2007, Fig. 3). Seeds were planted in a greenhouse and allowed to germinate and differentiate according to adult trichome type, then transplanted at the 8- to 10-leaf stage to the field on 21 April, 2010. Plants were transplanted adjacent to a 3-yr-old plot of *D. wrightii* (ca. 46×40 m) that was maintained in a 'naturalized' condition with no weed control and no irrigation after normal winter rains. Both herbivorous insects and natural enemy populations had become established in this field in previous years.

Experimental plants were planted in rows 2.7 m apart with plants spaced 2.7 m apart within rows and 0.8 m between rows. Plants were staggered between rows to maximize separation between plants in adjacent rows. Each row contained 16 plants with a pair of sticky and velvety plants from each of the four lines, and sticky and velvety plants were planted alternately. The closest row to the naturalized field was 1.8 m away. The new plot was treated with a pre-emergence herbicide (Trifluralin at the rate of 668 ml/ha) for weed control prior to transplanting. The plot was furrow-irrigated prior to transplanting for 24 h, then for 8 h, 3 d after transplanting, and weekly for 8 h for 3 wk thereafter. The plants were not irrigated after 17 May, 2010, and no rainfall occurred during the experiment. The absence of any rainfall during the spring and summer is characteristic of the sage scrub habitats in which *D. wrightii* commonly occurs.

VOC Production and Predation in the Field Experiments were carried out five times during the growing season during the weeks of 10 May, 10 June, 15 July, 5 August, and 2 September using five sets of adjacent pairs of rows providing a maximum of 32 plants per experiment. Plants were protected from natural attack by *L. daturaphila* prior to utilization in experiments with carefully-timed applications of acephate (Orthene 97, Valent Chemical Co., Walnut Creek, CA, USA 1.2 g/l) in water, and applications were stopped at least 1 wk prior to the initiation of each experiment. Prior to each experiment, plants were tested against *L. daturaphila* to determine that they were no longer toxic. This was verified by caging adult *L. daturaphila* on a similarly-treated set of plants and noting insect survival 2 d later.

To start each experiment, two branches of similar age and leaf production on each of 16 plants were infested with a pair each of field-collected adult *L. daturaphila* contained in a small cage enclosing a terminal of leaves. Adults were allowed to feed for 48 h to induce VOC production. The remaining 16 plants remained uninfested. After the 48 h induction period, the VOC production from damaged and undamaged plants was determined using procedures described previously (Hare, 2010). Briefly, aeration chambers were made from polyester cooking bags (unprinted 45× 55 cm bags, Terinex, Bedford, U.K.) and placed over the terminal leaves of a branch. Each chamber enclosed 4–6 full-sized leaves and a similar number of developing leaves. For the damaged plants, adult insects were removed before aerating branches with damaged leaves. VOCs were adsorbed on traps made of 4.6-mm O.D. glass tubing and filled with 25 mg of Super-Q (Alltech, State College, PA, USA). Air was introduced into the bag through PTFE tubing (4.6-mm O.D.) and was withdrawn from the bags through the traps through PVC tubing (4.6-mm I.D.) downstream of the traps in a "push-pull" scheme using two 12-V portable air pumps (Model # MOA- P125-JH, Gast Manufacturing, Benton Harbor, MI, USA). A 12-V deep-cycle marine battery powered both pumps. A manifold with 16 pairs of flow meters (Aalborg Instruments, Orangeburg, NY, USA) was constructed so that inlet and exhaust flow to and from the sampling bags could be precisely and independently regulated at 1.0 l/min for each plant. Inlet air was drawn through a filter of activated charcoal placed between the pump and the manifold. Preliminary studies showed that the charcoal filter was sufficient to remove all ambient VOCs. Plants were aerated in groups of up to 16 for 90 min and two groups of plants were aerated on each sampling day between the hours of 08.30 h and 10.00 h for the first group and between 11:00 h and 12.30 h for the second group. Data on air temperature, relative humidity, and light intensity, recorded hourly on each sampling day from 09.00 h until 13.00 h were obtained from records from the California Irrigation Management Information System (CIMIS) weather station located no more than 90 m from the experimental plot (Table 1). At the termination of the aeration, traps were wrapped in aluminum foil, labeled, returned to the laboratory, and stored at −20 ° C for extraction later that day. The twist-tie used to seal the bags was reattached to the branch at its original location to identify the branch and aerated leaves.

Volatiles were eluted from the traps with 150 µl of CH_2Cl_2 containing 4 ng/µl of 1-bromoheptane as an internal standard into autosampler vials with 250 µl glass

Table 1 Mean (± standard error) temperature, relative humidity, and light intensity during the aeration periods on each sampling date in 2010. Means and standard errors were calculated over the 5-h aeration period (09.00–13.00 h) on each date

Date	Temperature (°C)	Relative humidity (%)	Light intensity ($w \cdot m^{-2}$)
10 May	16.5±0.7	48±3	648±53
10 June	18.6±1.2	68±6	540±148
15 July	34.4±1.1	27±2	701±54
5 August	23.6±1.9	55±8	719±60
2 September	32.1±1.9	26±5	700±59

inserts and sealed with crimp caps and PTFE-lined rubber septa. Samples were analyzed by gas-liquid chromatography largely as described in Hare (2010). To confirm identifications, selected samples were analyzed with a Hewlett- Packard 6890 gas chromatograph coupled to a Hewlett- Packard 5973 mass selective detector, and the mass spectra and retention times of compounds were matched with those of authentic standards as described in Hare (2007). Peak quantification, in units of $ng \cdot g^{-1}$ leaf (dry wt.)$\cdot h^{-1}$, was made using Agilent ChemStation® software based on comparison of their peak height with that of the internal standard and leaf dry weights at the end of the experiment.

Prior to aeration, clusters of ten *L. daturaphila* eggs were prepared by dividing natural egg clusters collected from field-grown *D. wrightii* outside of the experiment into groups of ten and placing them on a disc 1 cm diam punched from a *D. wrightii* leaf collected from plants not in the experimental plot. The natural adhesive on these eggs was sufficient to affix the eggs to the leaf disk. After plants were aerated, two to four leaf disks, depending upon plant size, were glued to the lower surface of the aerated leaves with a synthetic resin adhesive (UHU Adhesives, Saunders Mfg. Co., Readfield, ME, USA). Half of the disks were enclosed in 'closed' clip cages constructed from spring hair clips and 2.5-cm diam plastic vials glued to rubber washers (1.8-cm I.D., 2.5-cm O.D.) The caps of the vials were bored out and covered with brass screen to provide ventilation. The other half of the egg masses were enclosed in 'open' cages constructed from hair clips and rubber washers only. The 'open' cages provided free access to predators and controlled for the possibility of subsequent induction of VOCs from mechanical wounding of the leaves caused by the cages themselves. In many cases, especially in the later trials, we noted that experimental plants already were colonized by *G. pallens* even before placing experimental eggs on plants.

After 4 d in the field, branches with cages were removed and returned to the laboratory. The number of hatched eggs was determined, and disks with unhatched eggs were removed from their leaves and assessed for damage under a microscope. Aerated leaves were then dried to a constant weight (80°C, 48 h) then weighed.

Eggs attacked by predators were easily recognized by their shriveled appearance. Any unhatched eggs were monitored for an additional 5 d. Because first-instars feed in groups after hatching and do not disperse, it was relatively simple to reconcile the number of larvae with the number of hatched, unhatched and shriveled eggs in both closed and open cages. Although mortality in the closed cages was quite low (see Results), it did differ among dates, lines, and the date by line interaction. Thus, the mortality due to predation must take into account these sources of mortality in the absence of predation. Accordingly, the mean mortality in the closed cages was calculated on a per-plant basis and was subtracted from the observed mortality in each of the open cages for each plant to estimate mortality due to predation. Values for predation could take on non-integer values if mortality in the two closed cages per plant were not equal, and on two occasions, calculated predation was −1 when all ten eggs in the open cages completely escaped predation and only nine eggs hatched in the closed cages. Although the initial design encompassed 160 plants, data were collected from 110 due to accidental loss of samples (leaky fittings, punctured bags), and limitations on the number of experimental adults and larvae for the experiments. Most plants used after the May aerations were large enough for two pairs of cages so the final sample size for the predation experiments was 208.

Statistical Analysis For the greenhouse experiments, larval survival was converted to a percentage then analyzed by two-factor restricted maximum likelihood (REML) ANOVA using PROC MIXED of SAS (SAS Institute 2008) separately for larvae exposed to and protected from predators. Fixed effects included trichome phenotype, induction status, and their interaction. The arcsine square root transformation was applied to ensure normality of errors.

For the field experiments, the data on predation were analyzed by a REML ANOVA using PROC MIXED. The full ANOVA model on predation included 1) the fixed effects of damage status (damaged or undamaged), genetic line, and trichome type, 2) all two- and three-way interactions of the fixed effects, and 3) replicate plants

within date by line by trichome type combinations and the 'row within date', a surrogate for the distance of plants from the source of the predator population, as random effects.

Because the effect of induction on VOC production was expected to vary over time (Hare, 2010), we also examined VOC production directly on predation over the full season by analysis of covariance (ANCOVA) by replacing the categorical variable of damage status with the continuous variable of observed VOC production. All interactions, including the potential interaction between VOC production and all fixed effects, were included in the full model. A significant interaction between VOC production and date, for example, would indicate that the linear relationships between predation and VOC production varied over time. Where appropriate, two-way interactions were decomposed using the SLICE option of PROC MIXED. For all VOC analyses, the $\log_{10}$ (x+1) transformation was applied prior to analysis to ensure normality of errors; the x+1 transformation was required because some VOC components were not detectable, especially late in the season. Predation was converted to a percentage and required no transformation.

To explore the potential importance of variation in the composition of VOC blends on predation, we also performed an exploratory Principal Components Analysis (PCA) based upon the covariance matrix of samples from all 110 plants to calculate a smaller number of uncorrelated components that were linear combinations of the original variables and to identify particular components contributing most to the patterns of variation in VOC production. The factor loadings show how much each of the original variables contributes to each new component, and factor scores for the new components were calculated for each original observation. An ANCOVA on these factor scores (PCA-ANCOVA) was used to determine the influence of the principal components on predation after accounting for the other sources of variation of sampling date, genetic line, trichome phenotype, and their interactions.

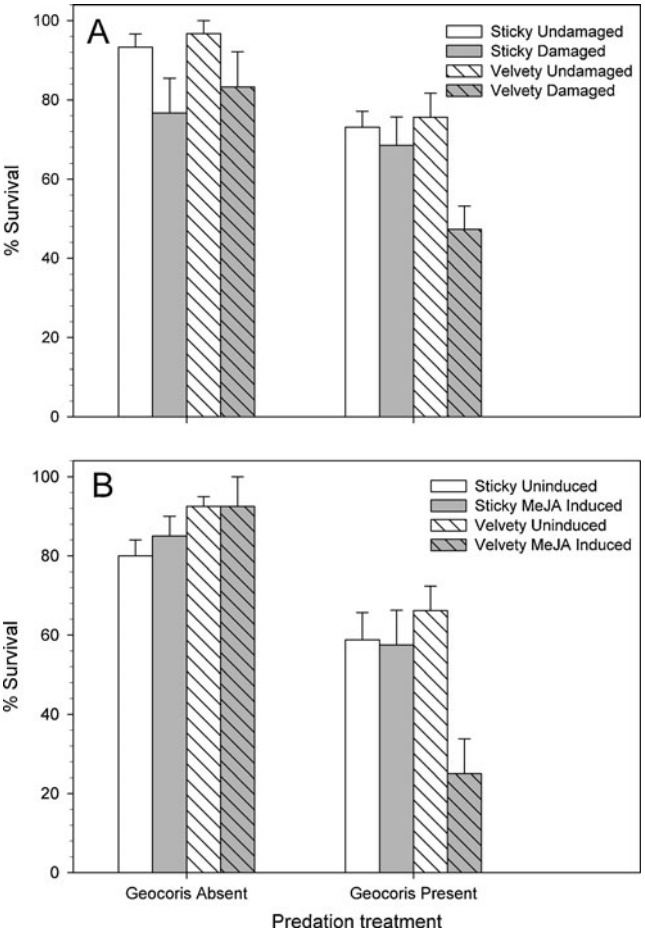

Fig. 1 Mean (+ standard error) percent survival of *Lema daturaphila* larvae 72 h after being placed on induced or uninduced plants in cages in the presence or absence of *Geocoris pallens.* Plot A: Plants induced by damage from feeding by adult *L. daturaphila* for 48 h prior to the beginning of the experiment. Plot B: Plants induced with 8 mM MeJA in 0.1% Tween 48 h prior to the beginning of the experiment. White bars: undamaged plants; shaded bars, insect-damaged plants; open bars, sticky trichome phenotype; hatched bars, velvety trichome phenotype

Results

Greenhouse Experiments For the plants induced by feeding damage by adult *L. daturaphila,* survival of larvae of *L. daturaphila* in the absence of *G. pallens* averaged 87.5% and did not differ significantly due to trichome phenotype ($F_{1,\ 8}$=0.95, P=0.36), induction status ($F_{1,\ 8}$=4.06 P=0.08), nor due to their interaction ($F_{1,\ 8}$=0.02, P=0.89, Fig. 1A). In the presence of *G. pallens,* overall survival was reduced to 66% but differed due to induction status ($F_{1,\ 44}$=6.61, P=0.01) and also due the interaction between induction status and trichome type ($F_{1,\ 44}$=4.06, P=0.05); predation was greatest on the induced velvety phenotype (Fig. 1A). The main effect of trichome type was not statistically significant, however ($F_{1,\ 44}$=1.53, P=0.22). The initial analyses included the replicate week as a random effect but this was deleted from the final model because it was never statistically significant.

For the experiment with MeJA as the inducer, survival in the absence of predators also averaged 87.5% but was lower on sticky than on velvety plants ($F_{1,\ 12}$=6.07, P=0.03, Fig. 1B). Survival did not differ due to induction status or the trichome phenotype by induction interaction (both $P \geq 0.38$). In the presence of predators, however, survival dropped to an average of 51.8% but differed due to trichome phenotype ($F_{1,\ 28}$=6.25, P=0.019) and due to the trichome by induction status interaction ($F_{1,\ 28}$=4.82, P=

0.037). In both experiments, the significant trichome type by induction status demonstrates that predation by *G. pallens* was greatest on induced velvety plants.

Total VOC Production in the Field When including damage status (i.e., damaged or undamaged) as a fixed effect, total VOC production varied only over time ($F_{4,\ 66}$=52.96, P< 0.001). The effect of damage was not statistically significant overall ($F_{1,\ 66}$=3.19, P=0.07), but VOC production was higher in insect-damaged plants than in undamaged plants in May ($F_{1,\ 14}$=5.12, P=0.04) and in June ($F_{1,\ 14}$= 4.58, P=0.05, Fig. 2). Overall VOC production was substantially lower in July–September (Fig. 2), and not different between damaged and undamaged plants (all $P\geq$ 0.15, Fig. 2). No other main effect (genetic line, trichome phenotype) or any of the two-, three-, or four-way interactions were statistically significant.

Predation: Preliminary Analyses Monthly mean percent (± s.e.) egg hatch in closed cages ranged from a low of 80± 2% in September to a high of 92±2% in June when pooled over lines and trichome types (data not shown). These high values of survival show that mortality due to handling or residual insecticide activity on the plants was minimal. The observed larval mortality differed among dates ($F_{4,\ 158}$= 18.47, P=0.004), lines ($F_{3,\ 158}$=2.93, P=0.035), and the date by line interaction ($F_{12,\ 158}$=2.05, P=0.023). Natural mortality in the closed cages, therefore, was used to calculate additional mortality due to predation in the open cages on a per-plant basis (Fig. 3).

When analyzed by ANOVA that included damage status as a fixed effect (damaged vs. undamaged), predation varied significantly over time ($F_{4,\ 171}$=19.56, P<0.001) and due to the damage status by date interaction ($F_{4,\ 171}$=3.07, P=0.018), the date by genetic line interaction ($F_{12,\ 171}$=2.55, P=0.004), and the genetic line by trichome type interaction ($F_{3,\ 171}$=3.29, P=0.02). Nonsignificant interactions were deleted from the final model. The random factors of row within date, and plant within date by line by trichome type combinations were also dropped from the final model because they did not account for a significant portion of the total variation (P=1.00 for rows within dates and P=0.75 for replicate plants within treatment combinations). The significant two way interaction between damage status and date resulted from predation being higher on damaged than on undamaged plants in May, July, and August, but not in June or September. The interaction between genetic line and trichome was because predation was higher on velvety than sticky plants overall for all lines except OFV8, and the date by genetic line interaction was because predation on the different lines varied in a complex way over time. The seasonally variable effect of damage status may not be surprising, given the substantial seasonal variation in VOC production of damaged and undamaged plants (Fig. 2). More meaningful results were obtained by replacing the fixed effect of damage status by the continuous variable of VOC production for each damaged or undamaged plant.

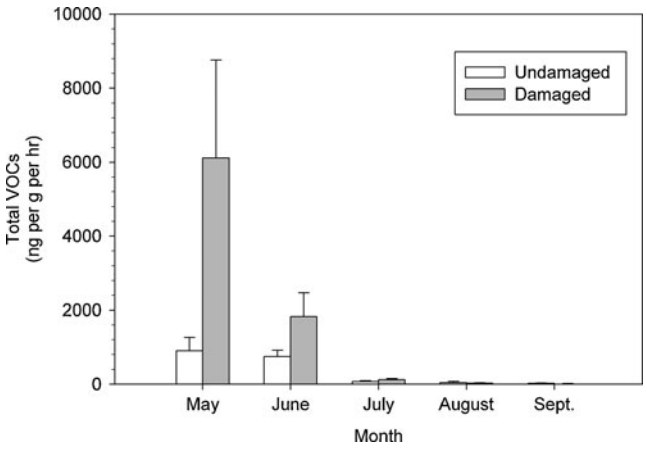

Fig. 2 Mean (+ standard error) total VOC production (ng·g^{-1} leaf (dry wt.)·h^{-1}) of undamaged plants or plants damaged by 48 h feeding by adult *Lema daturaphila* in the field for each monthly experiment. White bars: undamaged plants; shaded bars, insect-damaged plants

Predation and Relationship to Total VOC Production In the final model for the analysis of predation in the field, predation increased with increasing VOC production (slope=9.91±2.14, $F_{1,\ 179}$=21.48, P<0.001). The adjusted treatment means for percent predation (i.e., the expected predation in the absence of VOC production) also varied among sampling dates ($F_{4,\ 179}$=25.80, P<0.001, Fig. 3). The lowest value was 14.5±5.3 % in May, and the values for the other 4 months ranged from a low of 60.0±4.1% in June to a high of 70.4±2.6% in July. Nonsignificant interactions and the two nonsignificant random factors, replicate plants within date by line by trichome type combinations and row within date were dropped from the final model. There were no significant interactions between VOC production and any of the fixed effects or their interactions (all $P\geq$0.33), indicating nonsignificant differences in the slopes of the regression lines relating predation to VOC production across all treatment combinations; this justifies using VOC production as a simple covariate. After adjusting for the variation in VOC production, then neither genetic line nor trichome phenotype were statistically significant as main effects ($P\geq$0.55), but the date by trichome phenotype interaction and the line by trichome phenotype interactions both were statistically significant ($F_{4,\ 179}$=3.46, P=0.009 and $F_{3,\ 179}$=4.41, P=0.005, respectively). The date by trichome phenotype interaction was caused by predation differing between trichome phenotypes only in the month of August ($F_{1,\ 179}$= 12.72, P<0.001) and was higher on velvety plants. The line

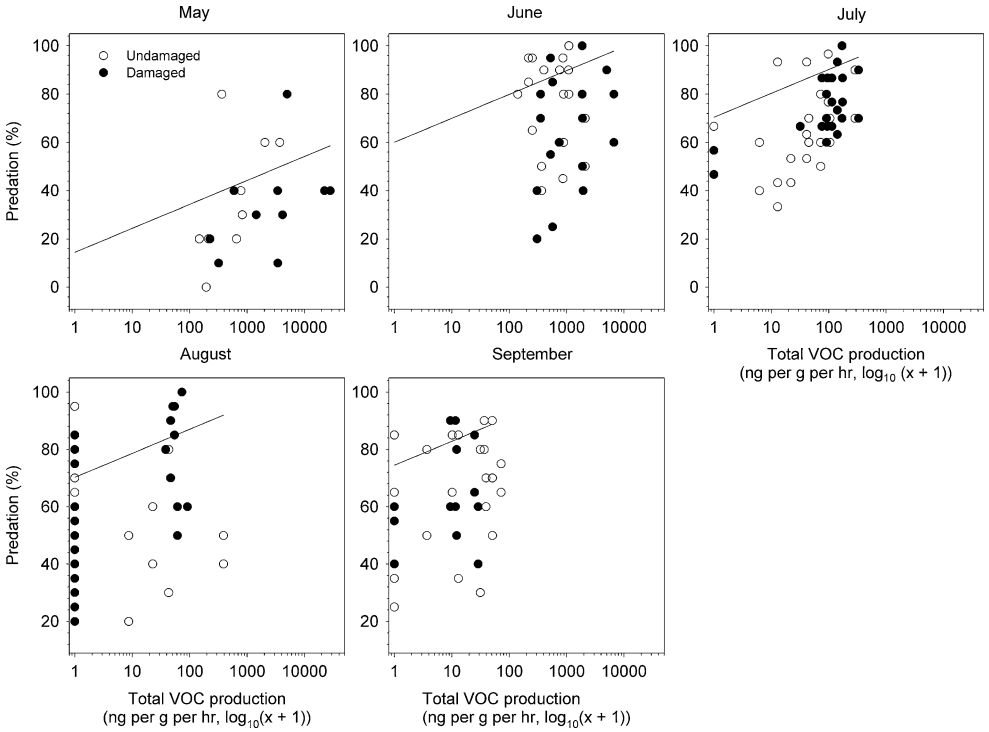

Fig. 3 Predation (%) and VOC production (ng·g^{-1} leaf (dry wt.)·h^{-1} $\log_{10}$ (x+1) transformation) for insect-damaged plants (filled circles) and undamaged plants (open circles) for each monthly experiment. Response lines were drawn using the common slope relating VOC production to predation from ANCOVA over the range from the *y*-intercept, i.e., the expected predation in the absence of VOC production, to the maximum VOC production observed for each monthly experiment. Data were pooled over trichome phenotype and genetic lines because these factors were not statistically significant in ANCOVA

by trichome phenotype interaction was caused by predation differing between trichome phenotypes only for the UCV9 line ($F_{1,\ 179}$=5.59, P=0.019), and was higher on sticky plants.

In summary, although predation increased with increasing VOC production over all sampling dates, the baseline predation of *L. daturaphila* by *G. pallens* in the absence of VOCs was ca. 4–5 times higher in June through September than it was in May (Fig. 3). The data for the month of May had two plants with extremely high VOC production after damage, and it was possible that these results might have been unduly dependent upon the data from these two plants. Accordingly, the data were reanalyzed after deleting these two extreme plants, and the pattern of statistically significant differences was unchanged. The absence of an overall effect of trichome phenotype and the inconsistent effects of interactions including trichome phenotype may suggest that the greenhouse experiments overestimated the effect of the trichome dimorphism on predation by *G. pallens* in the field.

Predation and Relationship to the Composition of VOC Blends Seven principal components were extracted. PC 1 accounted for more than 60% of the total variation, and the remaining six accounted for additional, independent proportions of the total variance ranging from 9.5 to 2.4% (Table 2). All individual VOC components except one loaded positively on PC 1, indicating that this component is a "general production" component. The individual compounds had positive or negative loadings in the other PCs, indicating relative differences in the composition of the blend. PC 2, for example, had positive loadings for most compounds but high negative loadings for (*E*)-β-caryophyllene and (*Z*)-3 hexenyl acetate. This component contrasts plants that produced high levels of these two compounds with plants that produced relatively high levels of all others. PC 3 independently separates blends relatively rich in (*E*)-β-ocimene from those relatively rich in (*E*)-β-caryophyllene, but the interpretation of the other PCs are less obvious (Table 2). Although there was statistically significant variation in both the overall quantity of the blend (PC 1) and different aspects of the composition of the blends (PCs 2–7, Table 3) only the variation in PC 1 was significantly related to predation; predation increased linearly with PC 1 ("general production") but was not statistically associated with the variation in the composition of the blends (Table 4). The variation in the composition of the blends among genetic lines of plants or over time, therefore, will not be presented in detail.

Discussion

The greenhouse experiments showed significantly increased predation of *L. daturaphila* larvae by *G. pallens* on herbivore- or MeJA-induced plants, especially on the velvety trichome phenotype. The results from the field experiments were more complex. VOC production was positively related to predation overall, but the overall

increase in predation due to VOC production was less during the summer months than in the spring due to the overall seasonal decline in VOC production in response to damage. The differences in predation between damaged and undamaged plants varied over the season, and the apparent benefits of VOC production declined over the season. Simultaneously, overall levels of predation increased over the season even in the absence of VOC production, and we speculate that the omnivorous *G. pallens* congregated on *D. wrightii* and other perennials during the summer as the spring-growing annual plant species senesced and died. The utility of VOCs to facilitate predation of eggs and young larvae *of L. daturaphila* by *G. pallens* in the field, therefore, varied seasonally but correlated reasonably well with the time period when plants produced maximum levels of VOCs.

VOC production was not an explicit indicator of damage by herbivores. Although VOC production was significantly higher in damaged than undamaged plants in May and June, mean VOC production by undamaged plants during these months exceeded that for damaged plants later in the season (Fig. 2). Depending upon the particular plant species and experimental conditions, the production of plant volatile compounds can be elicited by factors other than herbivory, including simple mechanical wounding (Mithofer et al., 2005), exposure to UV light, (Johnson et al., 1999), and ozone (Vuorinen et al., 2004). Although the role of these potential abiotic factors in inducing volatile production in young *Datura* has not been investigated, their potential to contribute to the background production of volatile organic compounds under field conditions cannot be ignored.

Although we utilized genetic lines of plants that differed in inducible VOC production in the greenhouse, there were no season-long differences in predation among genetic lines. Predation, PC 1 (general production) and PC 3 (largely contrasting (*E*)-β-caryophyllene with (*E*)-β-ocimene), however, all varied due to the date by genetic line interaction, as might be expected due to the seasonal variation in VOC production overall. Only a few studies to date compare either the ability of plant genotypes to attract natural enemies or VOC production in both the laboratory and field. Results from laboratory and field studies concur in some cases but not in others. Preference studies on *Cotesia* sp. attracted to volatiles produced by different cultivars of *Brassica oleraceae* in the laboratory reliably predicted differences in parasitization of herbivores on those cultivars in the field (Poelman et al., 2009). In *Trifolium repens,* however, fewer individual components were detected in field-grown than in laboratory-grown plants, and the emission of some compounds declined in response to increasing herbivory in the field but increased in response to herbivory in the laboratory (Kigathi et al., 2009). These authors argued that the release of volatiles from plants in the field was influenced by additional unmeasured biotic and abiotic factors that were absent in the laboratory and recommended caution in extrapolating profiles from VOC production to plants growing in the field. The results with *D. wrightii* additionally suggest caution in extrapolating results from plant genotypes assayed at a single developmental stage to potential differences over their full growing season.

The greenhouse experiments showed a greater effect of glandular trichomes on predation by *G. pallens* than did the field experiments. The major products of the glandular trichomes are esters of glucose and straight-chain organic acids (van Dam and Hare, 1998a). In *D. wrightii,* these acylsugars largely act as deterrents against the herbivores of *D. wrightii* as well as the natural enemies of those herbivores, but not as toxins to either group (Gassmann and Hare, 2005; Hare, 2005). There can be substantial environmental variation in acylsugar production under field conditions, however (Forkner and Hare, 2000; Hare, 2005). Although no direct comparisons of acylsugar production were made in this study, previous research has shown that acylsugar production has been higher in the greenhouse (ca. 0.8 μmol·cm^{-2}, Hare and Walling, 2006) than in the field (ca. 0.1–0.5 μmol·cm^{-2}, Hare, 2005). If generally true, then it is possible that the use of greenhouse-grown plants may overestimate the impact of glandular trichomes on predation by *G. pallens* because of the greater acylsugar production in the greenhouse environment.

One area of controversy in the study of HIPVs concerns the specificity and complexity of HIPV blends. The cases in which successful biological control has been achieved by the importation and release of specialist natural enemies against introduced crop pests in conventional agroecosystems argues in favor of herbivore suppression by specialized natural enemies, and, by inference, the emission of specific HIPV blends by plants to attract those specialists. Such systems, however, may be inappropriate models in which to understand how herbivore populations are regulated in natural systems (Hawkins, 1992; Hunter and Price, 1992). Instead, for native herbivore populations in their native environments, generalist predators more frequently impose top-down suppression of herbivores than do specialist parasitoids (Hawkins et al., 1999). As linear systems of crops, a single introduced herbivore species, and a single species of specialized natural enemy may be inappropriate models to understand how herbivore populations are regulated in natural systems, then such linear systems also may be inappropriate models to infer how HIPV-mediated indirect defenses of plants may have evolved (Hare, 2011). For generalist predators like *G.*

pallens, which preys on several species within *D. wrightii*'s herbivore community (Gassmann and Hare, 2005), it may not be necessary for the predator to identify the species of herbivore, and complex and herbivore-specific VOC blends may not be necessary to attract *G. pallens* to plants damaged by any suitable prey species. Similarly, the fact that *G. pallens* is known to respond to individual compounds when presented in isolation (Kessler and Baldwin, 2001; James, 2003, 2005; Halitschke et al., 2008) may constrain or eliminate the possibility of *G. pallens* being differentially attracted to herbivore-damaged plant genotypes that produce different HIPV blends and, ultimately, imposing natural selection on plant genotypes for the production of any particular blend.

In view of the rapid colonization of plants by both herbivores and natural enemies (Elle and Hare, 2000; Hare and Elle, 2002), it may not be necessary for *D. wrightii* to produce any strong "long-range" cues except perhaps in the early spring, when some plants are colonized by herbivores but most are not. It would be tempting, therefore, to conclude that the seasonal pattern of VOC production by *D. wrightii* has been optimized by natural selection so that plants produce these cues in large amounts only when the cues greatly increase predation. Such a conclusion depends upon a number of untested assumptions, however. The first is that high levels of VOC production in response to herbivory through the remainder of the season are detrimental and selected against. One possibility is that these compounds have such high allocation costs that reproduction would be reduced due to the allocation of photosynthate away from reproduction to HIPV production when HIPVs were no longer needed. Unfortunately, we know of no study showing that HIPV production imposes a fitness costs on plants (see also Kessler and Heil, 2011).

Another possibility is that there may be ecological costs later in the season associated with high levels of HIPV production that counterbalance their potential benefits. Possibly HIPVs induced in *D. wrightii* may attract other herbivorous insects, as is known to be the case for HIPVs of the host plants of the Colorado potato beetle (Landolt et al., 1999), Japanese beetles (Loughrin et al., 1995), and flea beetles (Halitschke et al., 2008). Although no similar studies have been carried out to determine if additional herbivores also are attracted to *D. wrightii* damaged by *L. daturaphila*, aspects of the life history of both *D. wrightii* and *L. daturaphila* may call into question whether continued high levels of HIPV production by *D. wrightii* throughout the season imposes a significant ecological cost mediated by attraction of additional individuals of *L. daturaphila* or other herbivore species to insect-damaged plants. Individual *D. wrightii* plants within patches quickly become colonized by overwintering herbivores in the early spring, then suffer chronic herbivory throughout the growing season (Elle and Hare, 2000; Hare, 2010). Because of the rapid colonization of plants and chronic, season-long herbivory, the ecological significance of additional herbivores being preferentially attracted to damaged plants would seem to be short-lived.

Another type of ecological cost that may account for the seasonal decline in HIPV production is based upon the observation that volatiles induced by herbivores repel potential pollinators. In the allogamous species, *Solanum peruvianum*, pollinators visited fewer flowers and spent less time at flowers of herbivore-damaged plants than undamaged plants (Kessler and Halitschke, 2009). If this is a general phenomenon, then it is at least plausible that there could be evolutionary or physiological conflicts between the competing processes of attracting the natural enemies of herbivores vs. attracting pollinators. The magnitude of such conflicts may vary among plant species with different mating and pollination systems. Such conflicts may be less important for autogamous species like *D. wrightii*, in which ca. half of the seeds produced by flowers may be due to self-pollination in absence of pollinators (Elle and Hare, 2002; Bronstein et al., 2009) than for species that absolutely require insect pollinators for reproduction.

Alternative explanations exist for the production of inducible VOCs by plants. One such explanation is that the production of such compounds alleviates certain abiotic stresses. High temperatures generally increase VOC production within broad limits (Holopainen and Gershenzon, 2010), and limited research shows that the emission of HIPVs also are temperature-dependent. In maize, total HIPVs increased with temperature from 17–27°C but were reduced at 37°C; the quantities of emissions at 37°C were not significantly different from those at 17°C or 22°C (Gouinguene and Turlings, 2002). At still higher temperatures (ca. 40–45°C) then, terpene emissions may be inhibited in other plant species (Loreto and Schnitzler, 2010), but the ambient temperatures during the volatiles collection period in this study were never that high (Table 1). A hypothesis of temperature inhibition certainly could not account for the low levels of VOC production in August, when temperatures during the collection period were relatively cool. Previous research also has shown that local summer temperatures are no barrier to VOC production for plants that are sufficiently young (Hare, 2010).

Finally, such seasonal patterns may reflect general processes of plant development and internal source-sink relationships as the plants transition from vegetative growth to reproduction (Herms and Mattson, 1992) independently of seasonal variation in herbivory and herbivore-natural-enemy interactions. Such patterns also may reflect general patterns of plant development and not patterns specific to *D. wrightii*. Given the high similarity of the induced defenses of different solanaceous species, it is likely that those defenses are homologous traits inherited from a

common ancestor and not novel, species-specific adaptations. These homologous traits no doubt have gone through ecological and evolutionary diversification among extant sister clades even as the life histories of species within those clades also have diverged. Thus, the role of phylogenetic legacy in governing for the seasonal patterns of VOC production in *D. wrightii* and potentially other species also must be considered along with the adaptive explanations above.

In summary, the greenhouse experiments showed that predation of *L. daturaphila* on young *D. wrightii* plants by *G. pallens* depended upon the interaction between trichome phenotype and induction status in a predictable way: in the greenhouse, induction or damage increased predation of larvae on velvety plants more than on sticky plants. The field experiments, however, revealed a more dynamic series of results that were strongly influenced by season and ecological context. High levels of VOCs in response to plant damage facilitated predation especially in the spring, but high levels of predation also occurred on plants that emitted lower levels of VOCs later in the summer. VOC production may facilitate the colonization of herbivore-infested plants and the discovery of prey by predators in the spring, but western big-eyed bugs apparently can discover and attack prey using other senses such as vision (Eubanks and Denno, 2000) when VOC production declines. It is unclear why or how VOC production in *D. wrightii* declines with plant development, but, because of the nonspecific association between *G. pallens* and either *D. wrightii* or *L. daturaphila*, the seasonal decline in VOC production more likely is incidental to the interaction between *L. daturaphila* and *G. pallens* rather than because of that interaction. Future research to better understand the ecological significance of inducible VOC production and other inducible defenses in the Solanaceae may benefit through comparative studies of several different species that exhibit a range of life history traits in their natural environments.

Acknowledgments We thank A. Phan, T. J. Burhans, and T. Spencer for field and laboratory assistance and R. Stouthamer and L. Walling for comments on previous drafts of this manuscript. This research was supported in part by the National Science Foundation under Grant No. NSF DEB 0414181.
