

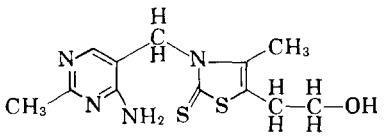
The oxythiamine which was formed did not give the thiochrome reaction.

Chromatography of a solution of thiamine hydrolyzed under Rydon's conditions, indicated that the oxythiamine produced had the same R_f value as thiamine (B) but gave a negative test with ferricyanide reagent. The fact that both thiamine and oxythiamine have the same R_f values in this system may explain why no additional spot was found on chromatographs of solutions degraded at low pH. Only faint traces of the products of the methylene bridge cleavage were found in highly acidic solutions, indicating that the formation of oxythiamine was the main product of the reaction in this range.



As the pH of the system was increased above 7, the pyrimidine (D) and the thiazole (F) fractions again decreased in intensity. Their decrease was accompanied by the appearance of two new spots, (A) and (E). This progressive change in the nature of the degradation products suggested that the open ring thiol form degraded in a different manner than the closed ring form.

Study of its ultraviolet absorption and paper chromatographic characteristics and reaction to Tollen's reagent and to bromphenol blue-silver nitrate solution suggests that compound (A) is 2-methyl-4-amino-5-aminomethyl pyrimidine, a previously detected degradation product (1, 19).

2-Methyl-4-amino-5-aminomethyl pyrimidine

The nature of the compound giving rise to spot (E) was not clearly established. Other investigators (20, 21) had indicated that at high pH and 100°, thiamine thiothiazolone was formed along with the pyrimidine diamine (A).

Thiamine thiothiazolone

Their conclusions were based on the nature of the ultraviolet absorption spectrum of the degraded solution when adjusted to pH 2.7. It was noted that under these conditions, an absorbance peak was found at 320 mμ which initially increased with time and then decreased, indicating secondary degradation. This absorbance was ascribed to thiamine thiothiazolone as this compound exhibits a marked absorption peak at this wavelength in solutions varying in pH from 2.7 to 9.0. No other thiamine derivative has shown an absorbance peak in this range.

In an effort to identify the compound represented by spot (E), the area was cut out of the paper and the compound eluted with distilled water and the ultraviolet absorption spectrum was determined in solutions at pH 2.8 and 8.5. In the acidic solution a peak was found at 325 and at 243 mμ, the 243 mμ peak being characteristic of the pyrimidine structure. In basic solution, a hypsochromic shift of the spectrum was observed with a new maximum at 305 mμ. Similar results were obtained when samples of the degraded solution were passed through ion exchange columns containing Amberlite IRA-400[1] resin, in the base form, to remove the undegraded thiamine. The eluate adjusted to pH 2.8 and 8.5 exhibited the same spectral characteristics as the samples eluted from the paper. The absorbance at 325 mμ was followed in a kinetic manner, and the results indicated that the compound which was responsible for the observed absorbance appeared to be formed directly from thiamine, based on no observable lag in the time between the initiation of degradation and increase of absorbance. These results were also borne out by following the kinetic procedure by paper chromatographic separations.

The shift of the spectrum of the isolated com-

[1] Rohm and Haas Co.

pound as compared to the stability of known thiamine thiothiazolone possibly casts some doubt on the assumption that the thiothiazolone compound is one of the major degradation products of the reaction under the conditions of this study.

Effect of Ionic Strength on the Reaction Rate.—As might be expected from the various possibilities of thiamine to exist in a charged state, it was found that the rate of the reaction was influenced by ionic strength. The salt effects varied as a function of the thiamine species present and of the mechanism of degradation. It is of pharmaceutical interest, that where the salt effect was operative, an increase of ionic strength resulted in a lower rate of degradation. As pointed out earlier, this effect might also have been a contributing factor to the apparent changes in the order of the reaction found by others (1–3).

Solutions were prepared at pH 2.0, 3.90, 6.40, 6.95, and 10.0 and all degraded at 96.4° except the pH 10.0 samples which were run at 75.0° due to the rapidity of the reaction. The results shown in Fig. 4 only depict the changes found at pH 3.90, 6.40, and 6.95, because at pH 2.0 and 10.0 the reaction was found to be independent of ionic strength. In all cases where changes in rates were observed, it was noted that a plateau existed over which the rates were invariant in respect to ionic strength. For the purpose of accuracy, all subsequent work was conducted at ionic strength 0.5 as this value corresponded to the middle of the plateau at each pH.

To conduct these studies, solutions were prepared at constant thiamine concentration, constant buffer concentration, constant pH, but at varying ionic strength. The ionic strength was controlled by the addition of sodium chloride.

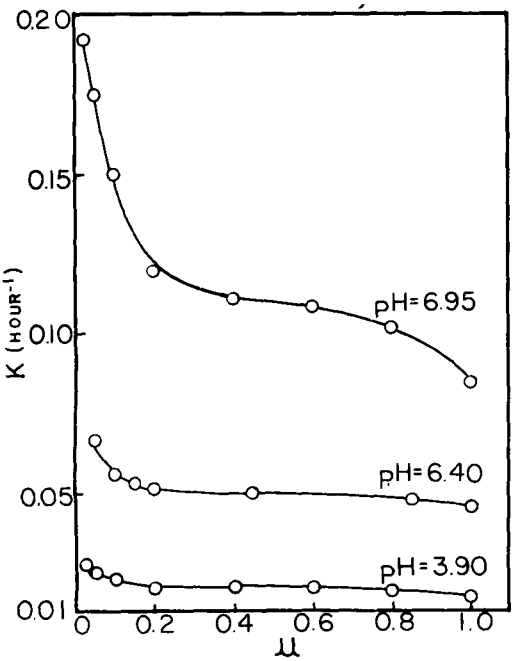


Fig. 4.—Effect of ionic strength on the observed overall rate of hydrolysis at 96.4° at several pH values.

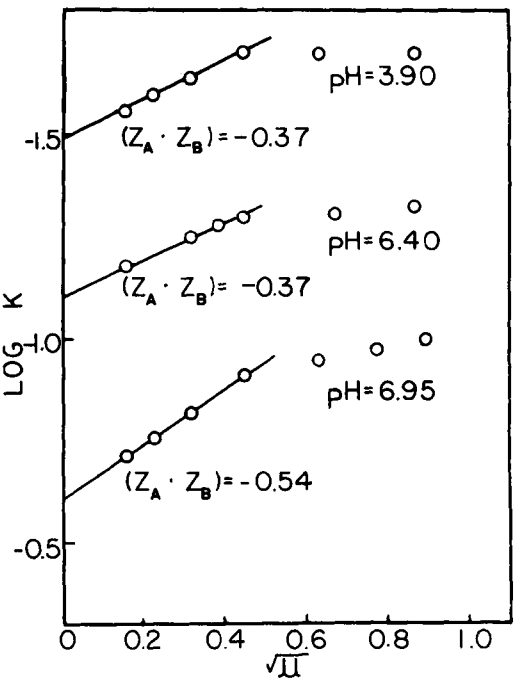

Fig. 5.—Bronsted-Bjerrum-type plot of the logarithm of the observed rate constants against $\sqrt{\mu}$ to estimate the charges on the interacting species at 96.4°.

The data were analyzed by utilization of the Bronsted-Bjerrum equation (22), which relates the primary salt effect on the observed rate to the ionic strength. Figure 5 shows the results of the treatment of the data in this manner. As might be expected, the experimental values deviate rapidly from linearity as this relationship was derived on the assumption of low ionic strength, but the values obtained from the initial slopes were of interest. The finding of nonintegral values for $(z_a \cdot z_b)$ might be due to high ionic strength, the occurrence of more than one reaction at the point of determination, or to a significant contribution by the secondary salt effect. A more complete correlation of these effects will be taken up under the discussions leading to a possible rate equation describing the pH profile of the reaction.

Effect of Buffers as General Acid or General Base Catalysts.—Although earlier studies utilizing phosphate, acetate, and citrate buffers have shown that hydrolysis of thiamine was apparently hastened in their presence, no serious analysis of this effect was made. The findings of the present study indicated that the vitamin was subject to general base catalysis but not to general acid catalysis, the effect being functions of both the buffer species and the forms of thiamine present in the solution. Figures 6–9, representing the results of these studies, are shown as plots of the reciprocal of the half-lives of the reactions *vs.* buffer concentrations under conditions of constant pH. In these studies, solutions were prepared at constant ionic strength, constant pH, and constant thiamine concentration, with only the buffer concentration varying at a given pH.

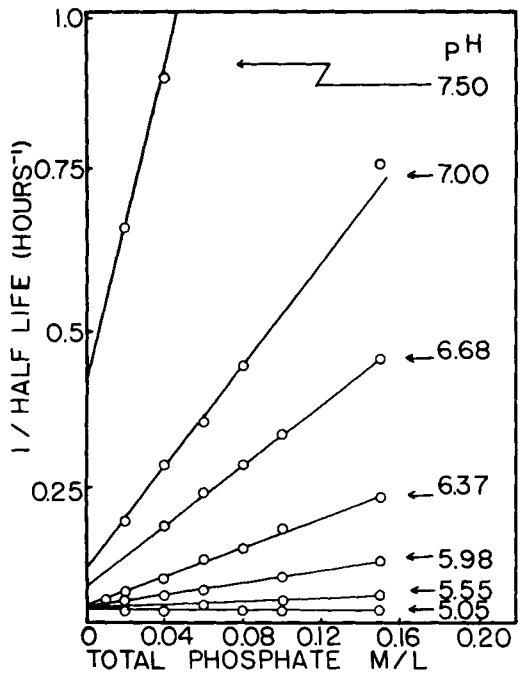

Fig. 6.—Reciprocal of the half-life of thiamine hydrolysis in a phosphate system at 96.4°. Effect on the reaction rate of changing buffer concentration at constant pH and constant ionic strength.

This was repeated at a number of pH values within the effective range of the buffers employed.

It was not possible as a part of this investigation to separate clearly the observed total buffer catalysis into the specific contributions of the several general acids and bases present acting on any or several of the thiamine species in solution. If the catalytic activities of these systems are largely limited to their base forms, as apparently indicated by the increasing slopes of the lines in the plots at higher pH, it can be readily shown that

$$[H^+] = Ka \cdot a(1/m) - Ka$$

where Ka is the apparent dissociation constant of the buffer at the temperature of the study; a is a proportionality constant between the slope of the line and the concentration of the conjugate base; m is the slope of the line resulting from the plot of the reciprocal of the half-life against buffer concentration at constant pH. The equation is, as indicated, based on the assumption that only the conjugate base of the buffer is catalytic and that the concentration of the effective substrate is constant. It predicts that a plot of $[H^+]$ against the reciprocal of the slope should yield a straight line with a slope of $Ka \cdot a$ and having an intercept of $-Ka$.

Figure 10 shows the data obtained from the acetate system plotted in accordance with the above equation. The linearity of the experimental points in the higher pH range where essentially only nonprotonated thiamine exists is in conformance with the derived equation. At lower pH, a deviation is noted which indicates that protonated thiamine is perhaps slightly more prone to acetate catalysis. Extrapolation to the intercept yields the dissociation constant of the buffer 1×10^{-5}, which is in good agreement with the experimentally determined value at 96.4°.

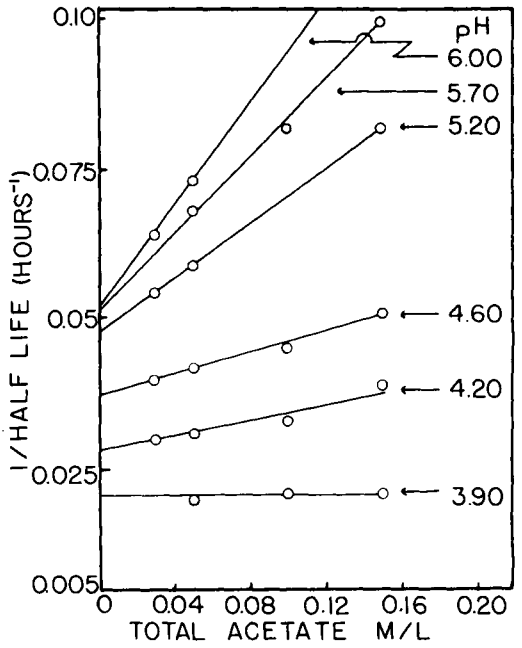

Fig. 7.—Reciprocal of the half-life of thiamine hydrolysis in an acetate system at 96.4°. Effect on the reaction rate of changing buffer concentration at constant pH and constant ionic strength.

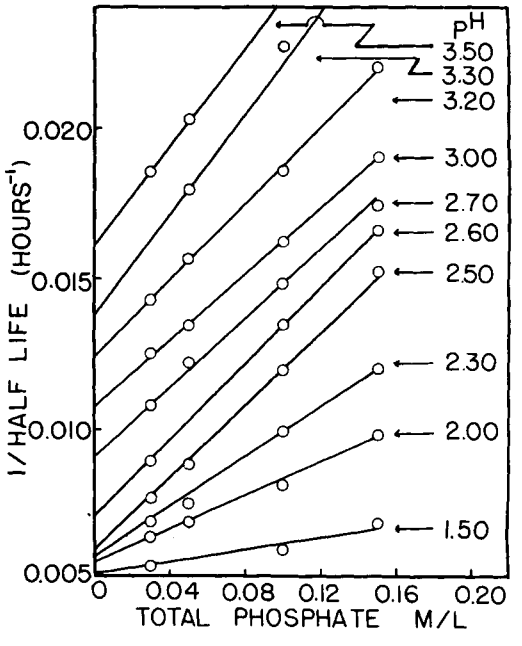

Fig. 8.—Reciprocal of the half-life of thiamins hydrolysis in a phosphate system at 96.4°. Effect on the reaction rate of changing buffer concentration at constant pH and constant ionic strength.

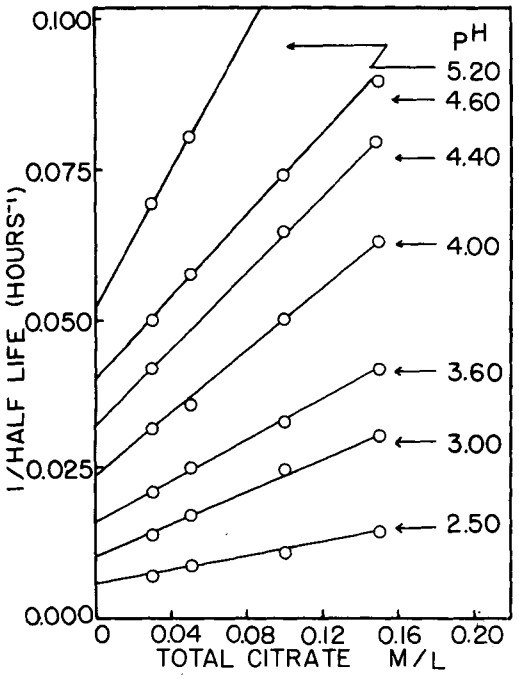

Fig. 9.—Reciprocal of the half-life of thiamine hydrolysis in a citrate system at 96.4°. Effect on the reaction rate of changing buffer concentration at constant pH and constant ionic strength.

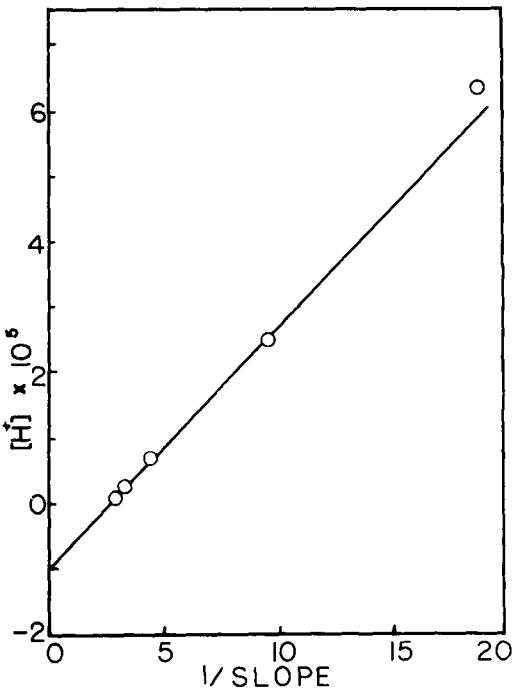

Fig. 10.—Plot of $[H^+]$ *vs.* the reciprocal of the slope of the lines from the acetate system of Fig. 7 in accord with the equation: $[H^+] = Ka\,(a)\,(1/m) - Ka$.

Analysis of the data presented in Fig. 7, depicting the results of degradation in a phosphate buffer system in the pH range 5–7.5, indicates that this reaction may be a function not only of the dibasic phosphate ion, but of the tribasic phosphate ion as well. In this pH range, the nonprotonated thiamine is in equilibrium with the thiol form, whose concentration will increase as the pH is increased. From studies at pH 10, it has been found that the thiol thiamine is not subject to general base catalysis. The essentially zero slope of the line at pH 5.05 indicates that the monobasic phosphate salt is noncatalytic with respect to the nonprotonated thiamine. From these observations it can be suggested that the results found are due to the following reactions

$$B_1 \text{ (nonprotonated)} + HPO_4^{=} \rightarrow \text{products}$$

$$B_1 \text{ (nonprotonated)} + PO_4^{\equiv} \rightarrow \text{products}$$

Mathematical treatment of the data based on the above reactions yields results which are in good agreement with the experimental findings up to pH 7. Above this value there is a negative deviation of the calculated values from the experimental. This deviation may be indicative that the reaction is more complex than anticipated in this region.

Further investigation of the phosphate catalysis was carried out in the pH range 1.5–3.5. The experimental data as shown in Fig. 8 indicate that protonated thiamine is catalyzed by monobasic phosphate ion and not attacked by the undissociated acid. Calculations based on this assumption, together with the previous supposition that the nonprotonated thiamine was not catalyzed by monobasic phosphate, were in good accord in the experimental findings.

The catalytic effects of a citrate system are shown in Fig. 9. From this plot it can be suggested that again the undissociated acid form of the buffer has no catalytic action, but that the buffer anions act as general base catalysts. The interactions are not postulated on a species basis, as this system is too complex to lend itself to this treatment.

Effect of Various Compounds on the Rate of Hydrolysis.—It has previously been reported authoritatively in the literature (2) that a number of compounds such as amino acids, amides, and amines had a marked and surprising effect on the rate of this mode of degradation. A concentration of 0.05 moles per L. of glycine added to a thiamine solution at pH 6.0 apparently produced a threefold decrease in the rate of hydrolysis at 100°. The addition of the same concentration of γ-aminobutyric acid under the same conditions, on the other hand, appeared to increase the rate of the degradation fourfold. Similar effects were found with other compounds and it was noted that in the case of the amino acids, α and β acids tended to stabilize thiamine, whereas those with the amino group further removed from the carboxyl group enhanced degradation. In the cases of the other compounds tested, the effects could not be so clearly related to structural changes.

The magnitude of the effects apparently observed at the low concentrations employed was surprisingly large, in fact so great as to be rationalized on the basis of complex formation between the thiamine and the added agent which might enhance or retard hydrolysis. This type of behavior has been re-

ported by other investigators (23, 24), compounds such as procaine and benzocaine having been stabilized by complexation with a number of xanthine derivatives. Because of the great theoretical significance of this effect, if real, a number of compounds studied earlier were reinvestigated. Table II summarizes the results of present investigations designed to retest this effect.

TABLE II.—EFFECTS OF A SERIES OF COMPOUNDS IN 0.05 *M* CONCENTRATION ON THE OBSERVED HALF-LIFE OF THIAMINE HYDROLYSIS AT pH 6.0 AND 96.4°

Compound Added	$t_{1/2}$, hr.
Control	9.5
Glycine	7.4
Alanine	7.5
Nicotinamide	7.1
Nicotinic acid	7.3
Isonicotinic acid	7.5
Picolinic acid	9.7
Salicylic acid	8.6

In obtaining these results, 0.05 mole per L. of the compound being tested was added to separate thiamine solutions maintained at pH 6.0 by a 0.1 molar phosphate buffer. The ionic strength of the system was maintained at 0.5 by the addition of sodium chloride. Data shown represent means of duplicate runs, reproducibility of the result being of the order of 0.1 hr.

Contrary to the previously published findings, glycine and alanine were found not to exhibit any stabilizing effects on the reaction, but instead showed slight catalytic activity. The other compounds listed, with the exception of picolinic and salicylic acids, exhibited approximately the same slight degree of catalysis. This limited study suggests that the previously reported remarkable changes brought about by the use of some of these compounds may well have been due to other kinetic variables such as ionic strength effects, pH changes, or general base catalysis.

pH-Rate Profile of Thiamine Hydrolysis.—Although the marked influence of hydrogen ion concentration on the rate of the hydrolytic degradation of thiamine was recognized by many early workers (4–8), no previous serious attempts clearly separating the influence of pH from the effects of buffer catalysis seem to have been made. Buffer-free rates at various pH values can, however, be readily picked from Figs. 6–9 since the intercepts of these plots represent the hydrolytic rates at zero buffer concentration. These rates expressed as first-order rate constants are shown in Fig. 11 as a function of pH.

The data shown for pH values above 7.5 were actually run at 75.0° since the hydrolytic rates were too fast at 96.4°, the temperature used for the more acid systems. Actual values obtained at the lower temperature are shown plotted in Fig. 12. These were corrected to the higher temperature by determining the thermal coefficient as shown in Fig. 13, and are represented on the profile by solid circles.

The profile suggested that the overall degradative rate represented a summation of a relatively large number of separate reactions. This is apparent in the analysis of the plot in terms of its observed slope over limited ranges as shown in Table III.

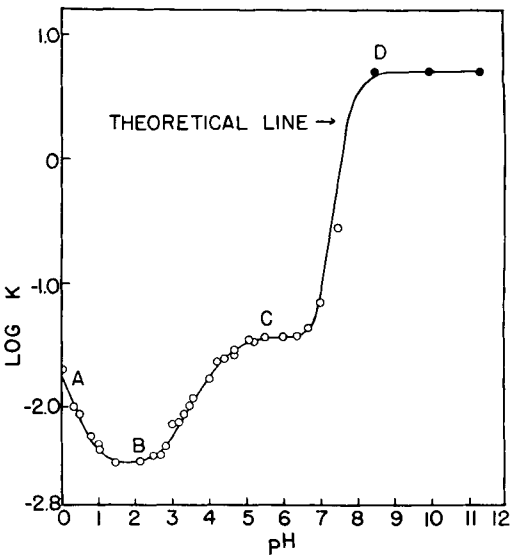

Fig. 11.—pH-rate profile of thiamine hydrolysis at 96.4°. The circles represent the experimental results and the line corresponds to that expected theoretically from the four proposed reactions. The solid circles were calculated from lower temperature studies.

As with all kinetic relationships, a number of different chemical reactions can lead to the same observed experimental dependencies. For the present system a series of four reactions such as

1. protonated thiamine (B^{++}) + [H^+] $\xrightarrow{k_{H^+}}$
2. protonated thiamine (B^{++}) + H_2O $\xrightarrow{k_{H_2O}}$
3. protonated thiamine (B^{++}) + OH^- $\xrightarrow{k_{OH^-}}$
4. thiol thiamine (B^-) + H_2O $\xrightarrow{k'_{H_2O}}$

would be sufficient to fit the experimental points. It is apparent that we can write

$$-dB_T/dt = k_{H^+}[B^{++}][H^+] + k_{H_2O}[B^{++}] + k_{OH^-}[B^{++}][OH^-] + k'_{H_2O}[B^-]$$

where k_{H^+} k_{H_2O} k_{OH^-} and k'_{H_2O} are the specific catalytic constants and B_T represents the total thiamine. By substituting for the thiamine species in terms of their equilibrium concentrations in the manner previously utilized by Higuchi, *et al.* (25), in their studies of procaine hydrolysis, the equation can be rewritten to yield the following

$$k_{obs} = k_{H^+}\left[1 - \frac{Ka_1[H^+]^2 + Ka_1(Ka_2)^2}{[H^+]^3 + Ka_1(Ka_2)^2 + Ka_1[H^+]^2}\right][H^+] + k_{H_2O}\left[1 - \frac{Ka_1[H^+]^2 + Ka_1(Ka_2)^2}{[H^+]^3 + Ka_1(Ka_2)^2 + Ka_1[H^+]^2}\right] + k_{OH^-}\left[1 - \frac{Ka_1[H^+]^2 + Ka_1(Ka_2)^2}{[H^+]^3 + Ka_1(Ka_2)^2 + Ka_1[H^+]^2}\right] \times \frac{k_w}{[H^+]} + k'_{H_2O}\left[\frac{Ka_1(Ka_2)^2}{[H^+]^3 + Ka_1(Ka_2)^2 + Ka_1[H^+]^2}\right]$$

Ka_1 is the equilibrium constant for the conversion

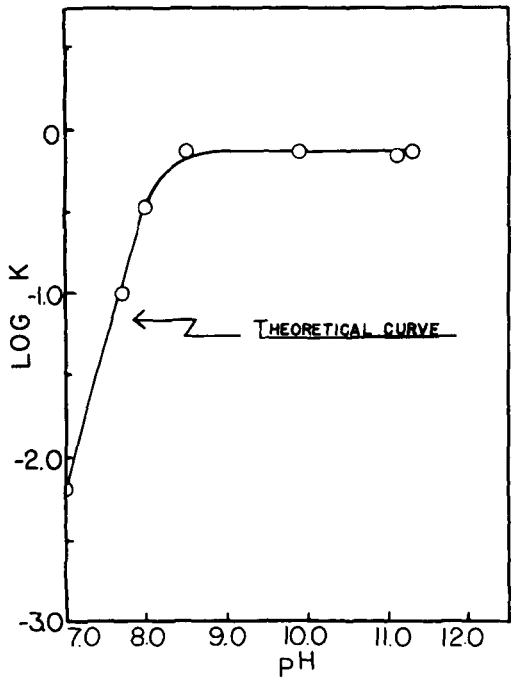

Fig. 12.—Logarithms of experimentally determined overall rate constants for the hydrolysis shown as functions of pH at 75.0°. The solid line corresponds to the theoretical function calculated from the observed rate at pH 9.9 and previously determined pKa values.

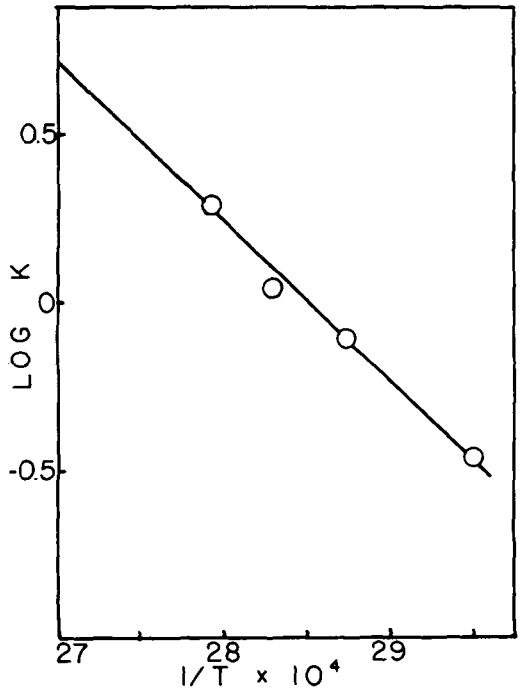

Fig. 13.—Arrhenius-type plot of the logarithm of the observed rate constants against the reciprocal of absolute temperature for the hydrolysis at pH 9.9 under conditions of constant pH. The line is extrapolated to 96.4°.

TABLE III.—APPARENT HYDROXYL ION DEPENDENCY OF THE HYDROLYTIC REACTION

pH Range	Apparent Slope
0–1	−1
1.5–2.5	0
3–4	0.4
5–6	0
7–7.5	2
9–11	0

of protonated thiamine to the nonprotonated form; Ka_2 is the average equilibrium constant for the conversion of the nonprotonated form to thiol thiamine.

It is evident that k'_{H_2O} and k_{H^+} can be readily evaluated from the two extremities of the profile. The remaining two rate constants can be easily calculated from any two points in the central part of the profile and from the two Ka values previously determined. When the constants thus obtained were substituted into the expanded equation, the functions shown as solid lines on Figs. 11 and 12 resulted.

The good agreement of the experimental data and the calculated theoretical profile does not unambiguously establish the nature of the interactions along all segments of the curve. The major reaction along the D portion of the curve on Fig. 11 could be formulated on the basis of nonprotonated thiamine being attacked by two hydroxyl ions or by the spontaneous cleavage of thiol thiamine by water. The choice of the latter interaction, reaction 4 above, as largely representing the D section of the curve is based on the absence of a primary salt effect and general base catalysis in this region; whereas in the alternative case, both of these effects would be expected.

Similar equivalences could be set forth for the dominant reaction along the C segment. Here, the observed effects could be due to protonated thiamine reacting with hydroxyl ion or due to water cleavage of the nonprotonated thiamine; these are kinetically indistinguishable. Again the choice as the most probable mechanism must be made on the basis of other supportive evidence. The negative dependency on ionic strength, as indicated in Fig. 5, points to the reaction of negatively and positively charged groups. The value of −0.37 for the product of the charges of the interacting species does not agree with the −2 predicted by the Bronsted-Bjerrum theory, but this discrepancy might be attributed to the high ionic strength of the experimental solutions as compared with the limitations of the equation. Further, the postulation of a cleavage of the nonprotonated thiamine by water alone would also indicate that B^+ reacted faster with water than B^{++}. This would not be in accord with the results found with buffered systems, where it was found that although the monobasic phosphate ion did not appear to catalyze the degradation of B^+, it was active in respect to B^{++}. In general, it appears that the protonated thiamine is more susceptible to nucleophilic attack than the nonprotonated species. Hence it would appear probable that the main reaction in the C segment can be attributed to B^{++} reacting with OH^-, reaction 3 above.

The failure to find any salt effect at pH 2.0 tends to support the suggestion that the most important

reaction in the B region is reaction 2, cleavage of B^{++} by water. The salt effects observed at pH 3.90 are in agreement with the proposed reactions, as in this region the observed effects are a composite of reactions 2 and 3.

In the strongly acid region designated by the letter A, the reaction is first order in respect to hydrogen ion. From the work of Rydon (13) and our own studies, it appears that the mode of degradation changes from the methylene bridge cleavage associated with reactions 2 and 3, to the hydrolysis of the 4-amino group on the pyrimidine ring. They night be postulated to involve ring protonation with subsequent attack by water.

Although it would appear from the above discussion that the series of four reactions adequately fit the data at hand, the possibility and perhaps the probability that the true situation may involve one or more substitute reactions is acknowledged. Kinetic analyses can readily eliminate many proposed reaction mechanisms, but they cannot establish the correct ones with absolute certainty.

Determination of the Apparent Activation Energies of the Hydrolytic Reactions.—The apparent activation energies of the reactions were determined by measurements of the observed rate constants at varying temperatures under conditions of constant pH. These determinations were made on solutions at pH 0.05, 1.70, 6.37, and 9.90. These points were picked because at each, only one term of the proposed rate equation for the pH dependency of the reaction was significant, therefore it was possible to estimate the temperature dependence of the individual reactions responsible for the profile. At pH 6.37, where buffers were employed, the rates were those obtained by extrapolation to zero buffer concentration.

The results shown in Fig. 13 were obtained from studies at pH 9.90 and changes at the other pH values followed similar linear relationships when log k was plotted against the reciprocal of the absolute temperature. The linearity of the points over the temperature range indicated the adherence of the observed reactions to the Arrhenius equation and allowed calculation of the apparent activation energies from the slopes of the lines. The results are summarized in Table IV.

These energy values appear to be within the expected magnitude based on the stability of the vitamin as found in our studies and by others. These high activation energies are of practical significance in the preparation of sterile thiamine solutions. Near 100°, the rate of the degradation increases by a factor of approximately 2.5 for every 10° rise in temperature. This change in the rate may be important when determining the most suitable conditions for sterilization.

TABLE IV.—APPARENT ACTIVATION ENERGIES FOR HYDROLYSIS DETERMINED UNDER SEVERAL CONSTANT pH CONDITIONS

Corresponding Reaction	pH of Experiment	E_a, Kcal./mole
1	0.05	24
2	1.70	29
3	6.37	25
4	9.90	21

EXPERIMENTAL

Reagents.—All chemicals used in the preparation of the buffers and for the preparation of the kinetic solutions were of analytical reagent grade except for the special compounds listed below: Thiamine chloride hydrochloride was obtained by double recrystallization of U. S. P. grade material from 95% ethanol and dried under vacuum at room temperature, m.p. 247–248°. 2-Methyl-4-amino-5-aminomethyl pyrimidine dihydrochloride was prepared by the acid degradation of thiamine disulfide according to the method of Zima and Williams (19), m.p. 264°. 2-Methyl-4-amino-5-hydroxymethyl pyrimidine hydrochloride was isolated from the hydrolysis of thiamine according to the method of Watanabe (1), m.p. 219°. 4-Methyl-5-hydroxyethyl thiazole hydrochloride was also isolated from thiamine hydrolysis in the manner described by Watanabe (1), m.p. 96°. Oxythiamine hydrochloride was prepared according to the method of Rydon (13), m.p. 193–194°.

Analytical Procedure.—Residual thiamine concentrations were determined by the thiochrome method of U. S. P. XVI (26). All compounds used in the kinetic studies were tested for interference with the analytical method.

Kinetic Procedure.—All solutions for kinetic studies were prepared with glass-distilled water to minimize metal catalyzed oxidation. Prior to the addition of the thiamine to the buffers, the solutions were heated to expel oxygen and cooled under an atmosphere of nitrogen. After the addition of the thiamine, the solutions were filled into ampuls and again flushed with nitrogen before sealing. The samples were then placed in a constant temperature bath which was maintained at the desired temperature, ±0.05°. After allowing 15 minutes for temperature equilibration, the zero-hour samples were removed and further samples were withdrawn at time intervals suitable to the nature of the system. The reaction was quenched by immersion of the samples in ice water.

Control of pH.—In all cases except where citrate buffers were used, the solutions were prepared by precalculation of the buffer concentrations utilizing experimentally determined apparent pKa values of the buffers. The pKa values were determined from pH measurements on solutions containing equal concentrations of the buffer acid and salt at the ionic strength desired. These determinations were made at various temperatures and the results extrapolated to 96.4°. In all cases, the ionic strength was adjusted by the addition of sodium chloride.

In the case of the citrate system, due to its complexity, it was not feasible to precalculate the solutions, therefore the literature pKa values were used to calculate ionic strength and the pH of the solutions were adjusted by the addition of base.

Determination of Thiamine Dissociation Constants.—The acid dissociation constants of thiamine were determined spectrophotometrically using the method of Flexer, *et al.* (17), which was modified by use of circulating apparatus for photometric titrations as described by Rehm, *et al.* (27). This modification allowed titration of the sample to a desired pH, and after recording the spectrum, titrating further without the necessity of preparing separate solutions. The method is based on the determina-

tion of the absorbance of a compound at a pH where it is completely unionized and then measuring the absorbance of the same concentration at a pH where it is completely ionized and at some intermediate point. The apparent pKa_1 was calculated from the following equation

$$pKa = pH - \log A_{B^{++}} - A/(A - A_{B^{+}})$$

where $A_{B^{++}}$ is the absorbance of the protonated thiamine, $A_{B^{+}}$ is the absorbance of the nonprotonated thiamine, and A the absorbance of a solution containing a mixture of the two species. The absorbance was measured at 255 mμ using a Cary recording spectrophotometer. This wavelength was used as it most readily reflected the changes of the species in the solution.

Although the above procedure was suitable for the determination of pKa_1, which is a simple one-step dissociation, modifications in the equation were required for the estimation of the second constant. As described in the earlier sections, the second dissociation constant is essentially an average value for a two-step mechanism, therefore a new model was used in the calculation. The model used was that of a dibasic acid in which the first and second dissociation constants were equal, only allowing measurement of the initial and final forms. Application of this relationship to the thiamine system, the equation derived was as follows

$$pKa_2\ (av.) = pH - {}^1/_2 \log A_{B^{+}} - A/(A - A_{B^{-}})$$

where $A_{B^{-}}$ is the absorbance of the solution when all of the thiamine is in the thiol form. The other symbols are as used above.

The thiamine concentration was maintained at 4 mg./100 ml. throughout the titrations and the ionic strength maintained at 0.5. The change of ionic strength during the titration was negligible due to the swamping effect of the added electrolyte. Solutions were allowed to equilibrate at least 15 minutes after each change of pH before recording the spectrum.

Chromatographic Separation of Degradation Products.—Solutions of thiamine in 1% concentration were prepared at various pH's employing the same methods as used with the kinetic samples, and degraded at 96.4° for a time equivalent to two half-lives of the reaction. Since the observed R_f value of a compound is dependent on the form in which it exists in a system, all solutions were readjusted to pH 3.5 prior to spotting on the paper to maintain constancy of species. The samples were chromatographed using the method described by Lhoest, *et al.* (18), with several modifications. Whatman No. 4 chromatography paper used by the previous workers and sample size was reduced from 0.1 ml. to 0.01 ml. to yield better definition of the spots. Development of the spots was carried out in the same manner as that of earlier workers, except that known degradation products were run along with the degraded solutions. The inclusion of the known compounds allowed identification of most of the spots found from the degraded solutions.

Analysis of Thymol and Eugenol Employing Ion Exchange Resins

By FLOYD A. WAGNER and MURIEL C. VINCENT

A quantitative analysis for thymol, eugenol, and clove oil has been developed by means of a spectrophotometric-anion exchange procedure. Suitable reagents which will produce colored compounds with small amounts of the phenolic substances have been selected. A comparison with the official assay for clove oil has been made. The ion exchange method indicated a full recovery of the phenols present in the oil and could be conducted in a much shorter period of time than the official method.

THE QUANTITATIVE determinations for volatile oils and their constituents are numerous, and in the case of the oils the assays frequently depend on a particular group of chemical substances rather than a specific compound. In this respect, then, it would be quite desirable to have a procedure capable of rapidly, accurately, and conveniently assaying an aqueous or nonaqueous mixture of such products for the major constituent only.

The presently accepted assay procedure for thyme oil (1) and clove oil (2) for their respective principal constituents, thymol and eugenol, have several disadvantages. These are primarily the nonspecificity of the alkali hydroxide to eugenol and thymol because of its reaction to phenolic compounds in general, inexact measurements of volumes, and inaccurate readings of the meniscus (3).

It was the purpose of this study to develop a method which would rapidly and accurately remove eugenol or thymol from a solution by means of an ion exchange resin.

The application of chromatographic techniques in the analysis of volatile oils has been somewhat limited. However, gas chromatographic analysis has been employed by Naves (4) for thyme oils and by Naves and Odermatt (5) and Stahl and Trennheuser (6) for eugenol. Bielenberg and Fischer (7) have reported the adsorption of thymol and other monohydroxy benzenes on alumina columns. Frydman (8) and coworkers used silicic acid-starch paste-covered glass plates to achieve the separation of thymol and other compounds of volatile oils.

EXPERIMENTAL

Experiments were first undertaken to find reagents which would produce soluble colored compounds with various known concentrations of thymol and eugenol. These solutions were observed at different wavelengths of light using a spectrophotometer to obtain the characteristic curves, and standard curves were then established. Subsequently, samples of thymol, eugenol, and clove oil were passed through a weakly basic ion exchange resin, and the eluates were treated with the reagent and observed at the required wavelength.

Reference to the standard curve showed that quantitative recoveries were obtained.

Color Reagents and Standard Curves.—Alcoholic thymol solutions of 0.1 *M*, 0.01 *M*, and 0.001 *M* concentrations were treated in the following manner with Hammarsten-Rolbert reagent (9). One milliliter of solution to be tested was placed in a cell and 5 ml. each of glacial acetic acid and concentrated sulfuric acid were added to produce the characteristic red-violet color. The solutions were allowed to stand 5 minutes to permit maximum color development before viewing in the Colemen spectrophotometer between wavelengths of 400 and 650 mμ (Fig. 1). The standard curve was prepared from the data, using transmittance at 520 mμ (Fig. 2).

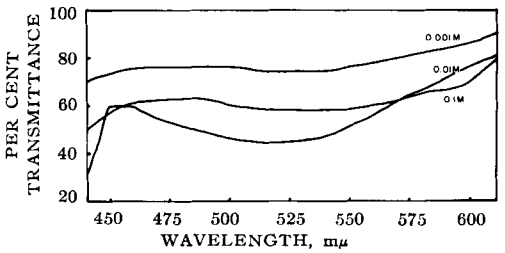

Fig. 1.—Concentration-transmittance curves for thymol.

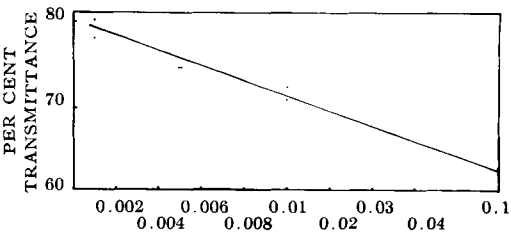

Fig. 2.—Standard curve for thymol, 520 mμ.

Received April 28, 1961, from North Dakota State University, College of Pharmacy, Fargo.
Accepted for publication July 21, 1961.
Abstracted in part from a thesis presented by Floyd A. Wagner in partial fulfillment of the requirements for the degree of Master of Science.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

TABLE I.—ANALYSIS OF PHENOLS AND PHENOL-CONTAINING OILS

Phenol or Volatile Oil	*T*, %	Concentration, *M*	Phenols,[a] %	Phenols Recovered,[b] %
Thymol	73.8	0.0067	.....	100.0 ± 2.99 (11)[c]
Eugenol	23.1	0.0251	.....	100.0 ± 0.80 (3)
Clove oil	21.8	0.0289	87.9 ± 2.0 (3)	98.8 ± 2.10 (3)

[a] Calculated by official assay. [b] Analyzed by ion exchange-spectrophotometric method. [c] Number of determinations.

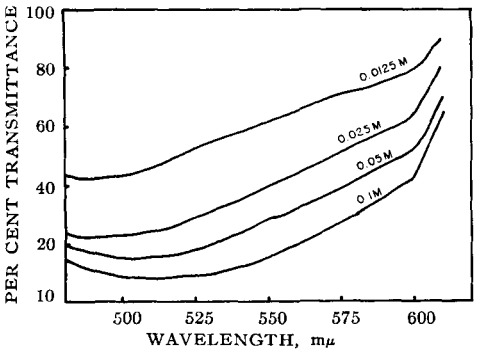

Fig. 3.—Concentration-transmittance curves for eugenol.

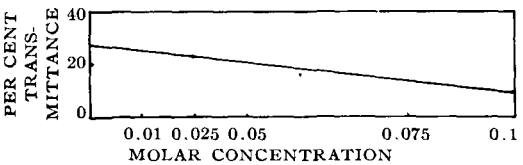

Fig. 4.—Standard curve for eugenol, 500 mμ.

Solutions of eugenol in dimethylformamide were prepared in concentrations of 0.1 *M*, 0.05 *M*, 0.025 *M*, and 0.0125 *M* and treated with Ehrlich's diazo reagent (10). In performing the test, 3 ml. of sulfanilic acid solution was added to 3 ml. of sodium nitrite solution previously placed in a cell; to this solution was added 0.1 ml. of eugenol sample and finally 3 ml. of sodium bicarbonate solution. The resulting yellow-brown solution was observed in the spectrophotometer after 15 minutes and the transmittance of light recorded between 400 and 650 mμ (Fig. 3). The standard curve was based on the transmittance of light at 500 mμ (Fig. 4).

Ion Exchange Procedure.—The weakly basic anion exchange resin, Amberlite IR-45, was employed. Ten-gram samples of the air dried resin were moistened with water, transferred to columns (22 × 3 cm.), and regenerated with 50 ml. of 4% sodium carbonate solution. After regeneration and rinsing of the columns, the distilled water was removed from the columns by washing with 30 ml. of alcohol or dimethylformamide for thymol and eugenol, respectively.

The sample to be analyzed was then added to the columns by means of a graduated 1-ml. pipet to provide 50 to 100 mg. of thymol or eugenol. All columns were washed with alcohol or dimethylformamide at a rate of 1 ml. per minute until 100 ml. of eluate was collected in a volumetric flask. After thorough mixing of the eluate, the color developing agent was added as previously described. Blank determinations were made with all samples.

Table I shows the data obtained when the phenols and clove oil were analyzed in this manner. Comparative official assays were performed on clove oil.

SUMMARY

A quantitative analysis for thymol, eugenol, and clove oil has been developed by means of an anion exchange-spectrophotometric procedure.

Suitable reagents which will produce colored compounds with small amounts of the phenolic substances have been selected. Ehrlich's reagent, which produces an azo dye with eugenol, is very sensitive and will give the characteristic yellow-brown color with eugenol in quantities as minute as 0.2 mcg. The Hammarsten-Rolbert reagent will give the characteristic red-violet color of thymosulfonic acid with amounts as low as 10 mcg. of thymol.

A comparison with the official assay for clove oil has been made. The method indicated a full recovery of the phenols present in the oil and could be conducted in approximately 3.5 hours, which is considerably less than the 18 hours required for the official assay.

Attempts to perform a similar assay on thyme oil gave consistently high results, which indicated that the reagent evidently reacted with other components of the oil. Thus, more specific color reagents for thymol will have to be developed or more selective ion exchange resins employed. Such improvements are presently being investigated.

Pharmacognosy of Indian Substitutes of Male Fern II

Dryopteris barbigera and *Dryopteris cochleata*

By P. N. MEHRA and T. C. MITTAL

A macroscopic and microscopic description of the rhizome and leaf bases of *Dryopteris barbigera* (Moore) O. Ktze. and *D. cochleata* (Don) C. Chr. is presented. Both the species compare very favorably in oleoresinous content and 'crude filicin' with the official male fern. The two species, described in this paper are differentiated from each other on the basis of the shape and size of the rhizome, structure of the ramenta present on the rhizomes, the presence and absence of dark sclerotic nests in the ground tissue, the number of cauline vascular bundles, and the shape and size of the stalk of internal secretory unicellular glandular hairs.

EXTRACTUM FILICIS has been extensively used as a teniacide for the last two centuries or so (1). Since the drug has been included in various pharmacopeias and also the International Pharmacopoeia, its importance cannot be overemphasized. Considerable quantities of the expensive male fern extract are imported into India for medicinal purposes, since both the official species, *Dryopteris filix-mas* (L.) Schott and *D. marginalis* (L.) Asa Gray are not met with in India. Search for an Indian substitute for this important drug has shown that there are some excellent substitutes that grow wild in the Himalayas, some abundantly enough to be commercially exploited (2, 3). The detailed pharmacognosy of two of them has already been published (4), while that of *D. barbigera* (Moore) O. Ktze. and *D. cochleata* (Don) C. Chr. is described in this communication. The oleoresin content of both the species varies from 7 to 9% and the "crude filicin" in *D. barbigera* is approximately 2.2% and in *D. cochleata* up to 1.8% (2).

The purpose of the study is to report the macroscopic and microscopic characteristics of these two species in order to establish satisfactorily their identity in commerce. The description of the plant has been provided to facilitate its collection, as no such appropriate description is available in previous literature on Indian ferns (5–11).

MATERIAL AND METHODS

The material for *Dryopteris barbigera* was gathered from alpine meadows above Khillanmarg (Kashmir) and en route to Rohtang pass (Kulu Hills), between altitudes of 10,000–13,000 feet, where it grows in fair abundance. The sample of *D. cochleata* was collected from Raiwala forests, Dehradun (Western Himalayas), and Majitar bridge (Eastern Himalayas), between altitudes of 1,500–3,000 feet where it occurs gregariously. The technique employed was the same as described in an earlier communication (4).

Received June 30, 1960, from the Department of Pharmacognosy, Panjab University, Chandigarh (India).
Accepted for publication May 23, 1961.

INVESTIGATIONS

***Dryopteris barbigera* (Moore) O. Ktze.**

Plant.—The rhizome is thick, ascending, sometimes branched, copiously covered with chaffy, chestnut brown, large ramenta. The stipes are tufted, 15–30 cm. long, rachis as well as the stipes are densely covered with large, bright, rufo-brown, imbricate ramenta, and soft silky hairs; lamina 60–90 cm. long, ovate-lanceolate (Fig. 1, part 1). Pinnae are close, up to 20 pairs or more, 8–15 cm. long, 2.5–4 cm. broad, gradually reduced below, linear-lanceolate. Pinnules are usually distinct, ovate-oblong, double serrate, or deeply lobatoincised and each lobe again provided with copious aristate teeth, the edge often incurved; texture herbaceous, both the surfaces copiously fibrillose-scaly, more so the lower surface; midrib fibrillose-scaly; sori in two rows close to the midrib of the pinnules; indusium small, entire, pale colored, of thick texture with small and shallow sinus.

Macroscopy of the Rhizome.—Rhizome may be branched or unbranched, of variable shapes, ovoid, oblong, or elongated (Fig. 1, part 2), measuring up to 20 cm. long and up to 6 cm. or more thick at the crown. Externally reddish-brown, entirely covered by thick, stout, persistent, curved, or flattened, or angular frond bases which are up to 15 mm. thick and somewhat wrinkled. Long shreds of hypodermal sclerenchyma are observed attached to the frond base. The entire rhizome and stipe bases are densely clothed in rufus-castaneous, broadly lanceolate, hair-pointed scales which are 2–4 cm. in length. The rhizome breaks with hard and uneven fracture. Transversely cut surface, which in fresh drug is markedly pale green and in dried drug is brown, reveals 6–9 whitish patches of cauline meristeles arranged in a diffused circle and 4–5 leaf-traces, each composed of 10–13 smaller vascular strands, arranged in the form of closed 'C' at angular regions. Odor slight, taste at first sweetish, later becoming acrid and nauseous.

The ramenta are ovate to lanceolate with acuminate apex, each measuring 2–4 cm. or more in length,

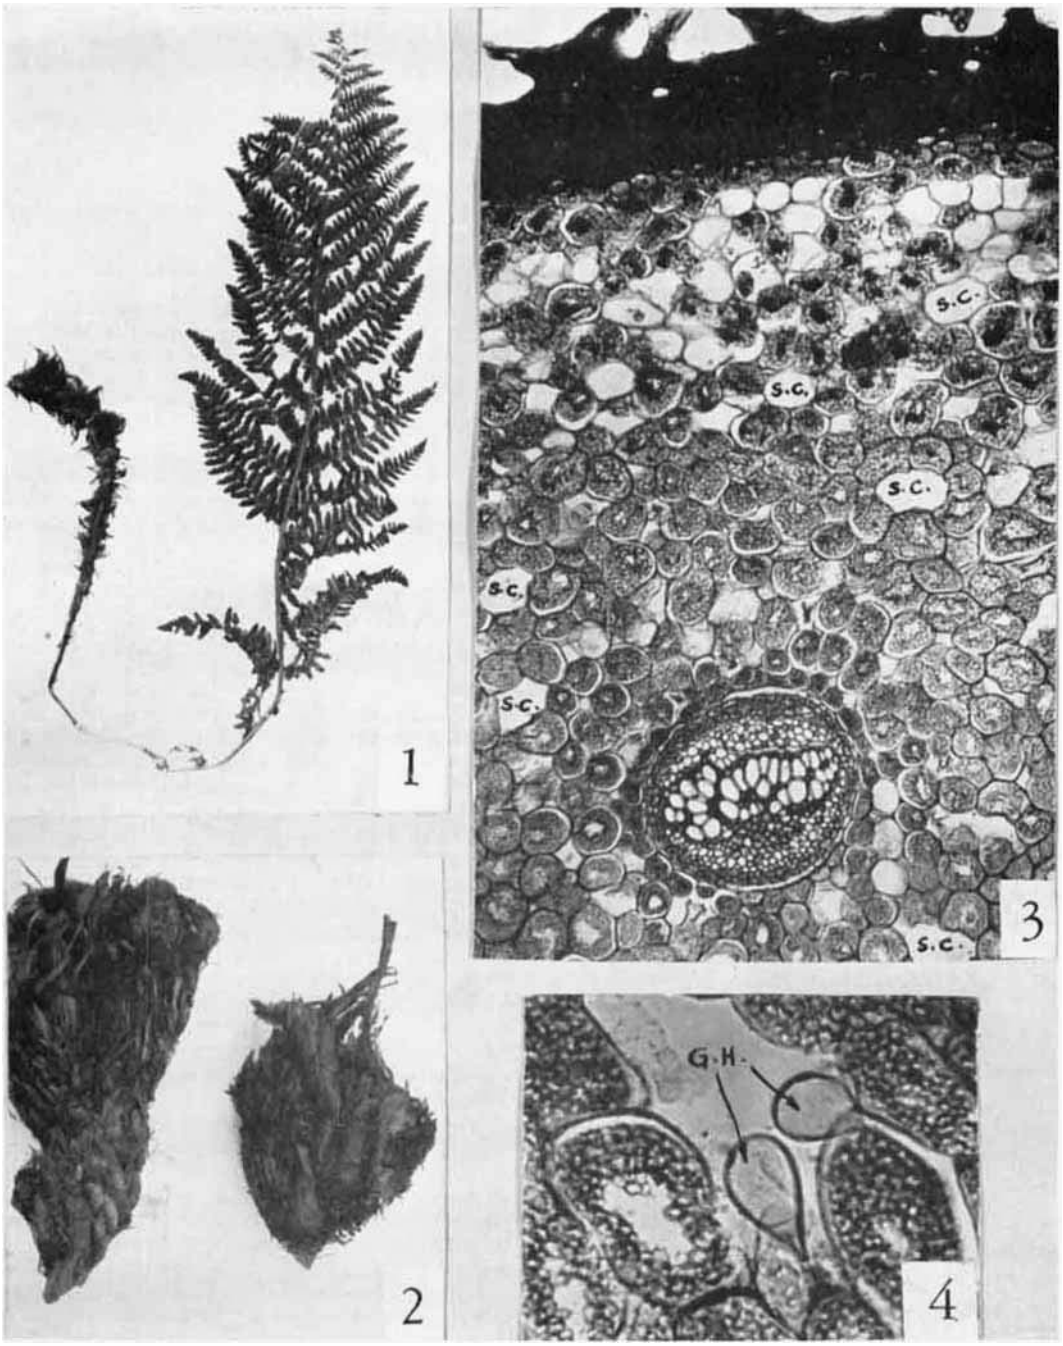

Fig. 1.—*Dryopteris barbigera* frond, × 1/5. 2, Rhizome, × 1/3. 3, Sector of T.S. of the rhizome magnified × 200; S.C., schizogenous cavity. 4, L.S. of the rhizome showing schizogenous cavity containing unicellular secretory glandular hairs, × 250; G.H., glandular hairs.

and 3–8 mm. in breadth. Each ramentum is composed of thin-walled, elongated cells, each measuring 500–1200 × 20–30 μ. At places the marginal cells form peg-like projections, each consisting of two parallel and contiguous cells. No glandular hairs are observed on the margin or the surface of the ramenta.

Histology of the Rhizome.—A transverse section of the rhizome from the periphery to the center is shown in Fig. 1, part 3. The epidermis is composed of a single layer of cells which vary in shape from oblong to rectangular. These cells are brownish in color and contain occasional tannin-resin masses. Some of the cells bear unicellular pyriform glandular hairs, and a few others the ramenta cut variously. Since the rhizome is profusely scaly a large number of cut ramenta are observed in a cross section.

The hypodermis is differentiated into two zones,

an outer one of 2–3 layers of cellulosic fibers, and an inner band of 5–8 layers of thick-walled lignified fibers. The cells of the latter appear yellowish to orange in unstained preparations due to the deposition of tannin-like material on the walls. In T.S. the cells of the inner zone appear polygonal and are more or less isodiametric, but in maceration they are 10–20 times as long as broad and possess flat or somewhat tapering ends (Fig. 2*a*). This region is compact and lacks intercellular spaces.

The cortex is composed of several layers of rather thick-walled parenchymatous cells, often filled with simple starch grains. Besides starch, the cells, particularly next to the hypodermis and around the meristeles, contain spherical masses or granule aggregates of tannins. The walls of such cells are cellulosic in nature while the remaining cells possess suberized walls. Some of the cells possess simple pits on their walls and such cells are devoid of inclusions. The cortical cells in maceration appear either isodiametric or slightly elongated (Fig. 2*c*), each measuring 70–90 × 40–90 μ. In T.S. they number about 400/mm.^{2}.

The cortex shows numerous small intercellular air spaces and large schizogenous cavities. Within the latter project characteristic unicellular glandular hairs (Fig. 1, part 4), each surrounded by greenish-yellow oily secretion. The glands are 60–100 μ long of which 20–25 μ is the stalk. The head is oval or pyriform in shape and measures 35–56 μ in diameter. The schizogenous cavities in the region of their maximum distribution number about 45/mm.^{2}, as observed in T.S. In longitudinal section, the cavities measure 160–350 × 60–160 μ and each contains 2–3 glands.

Sclerotic nests are absent both in the cortex and the pith. Pith cells are identical with the cortical cells.

Within the ground tissue is present a diffused ring of 6–9 large cauline meristeles. Numerous smaller strands arranged in the form of closed 'C' constituting leaf traces are present at angular regions of the rhizome. Occasionally root traces are also observed, passing out of the cortex.

Meristele.—The cauline meristeles and the leaf trace bundles are oblong to elliptical in outline and amphicribral in nature. The leaf trace bundles are relatively much smaller and in longitudinal sections are observed to arise from the margin of the leaf gaps.

Each meristele shows a single-layered endodermis of rectangular cells, the walls of which are suberized and the radial ones possess feebly developed Casparian thickenings. This is followed by 1–3 layers of thin-walled, nonlignified parenchymatous pericyclic cells, filled with starch grains and amorphous tannin deposits. In cross section the cells appear polygonal to oblong in shape. Phloem is many layered and encircles the central xylem on all sides except at two lateral ends where the pericycle directly abuts on the xylem. It consists of sieve tubes and phloem parenchyma. The cells of the phloem parenchyma are filled with tannin deposits. Xylem is central in position and consists of tracheids and xylem parenchyma. The tracheids in cross section have typical polygonal outline. In maceration they appear elongated and the metaxylem elements show scalariform thickenings. The bundle, according to its size, may have 2–3 small protoxylem groups consisting of small annular or spiral tracheids; frequently one is found at each end of the xylem mass.

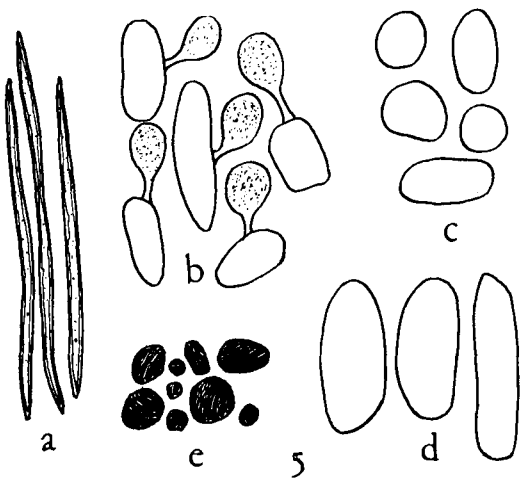

Fig. 2.—*Dryopteris barbigera*, tissue macerations. *a*, Hypodermal fibers, × 160; *b*, gland bearing cortical cells, × 160; *c*, ordinary cortical cells of the rhizome, × 160; *d*, ordinary cortical cells of the stipe base, × 160; *e*, starch grains, × 700.

Histology of the Stipe.—In T.S. it is somewhat oval in outline. The hypodermis is well developed and formed of lignified fibers. Unlike the rhizome it is not differentiated into two zones. The cells of the cortex are 2–3 times larger than those of the rhizome (Fig. 2*d*), and are predominantly oblong or rectangular. The few layers that lie next to the hypodermis contain tannoid aggregates, but such contents are missing from other cells. The cortical cells number about 250/mm.^{2} in contrast to nearly 400 in the rhizome. The number of schizogenous cavities per unit area is almost the same as in the rhizome. The number of vascular strands varies from 10–14. They are arranged in the form of closed 'C', and the two adaxial ones are larger with the xylem notched internally.

Dryopteris cochleata (Don) C. Chr.

Plant.—Rhizome is ascending, and clothed in golden yellow, ovate-lanceolate, or linear-subulate ramenta. Fronds are strongly dimorphic (Fig. 3, part 6); the stipe is up to 40 cm. long, comparatively much longer and thicker in fertile fronds, tufted; main rachis glabrous; lamina up to 40 cm. long, deltoid or ovate-oblong with slightly cordate or rounded base. Pinnae are up to 10 pairs, basal pinnae not any longer than the ones next above, not much basiscopically produced, ovate-lanceolate, acuminate, the sterile basal ones are subsessile or sessile, up to 13 cm. long and 4 cm. broad, fertile ones distinctly though shortly petiolate, up to 8 cm. long and 2 cm. broad, the lower ones ascending, others patent; the rachis deeply canaliculated above, the underside of the rachis and rachises of fertile fronds fibrillose but of sterile fronds is setose hairy; sterile pinnules more or less adnate to a winged costule, oblong-obtuse, base truncate, serrate; fertile pinnules subsessile with serrate margin; texture subcoriaceous, green or pale green, veins inconspicuous; sori large, well below the middle of upper veinlet

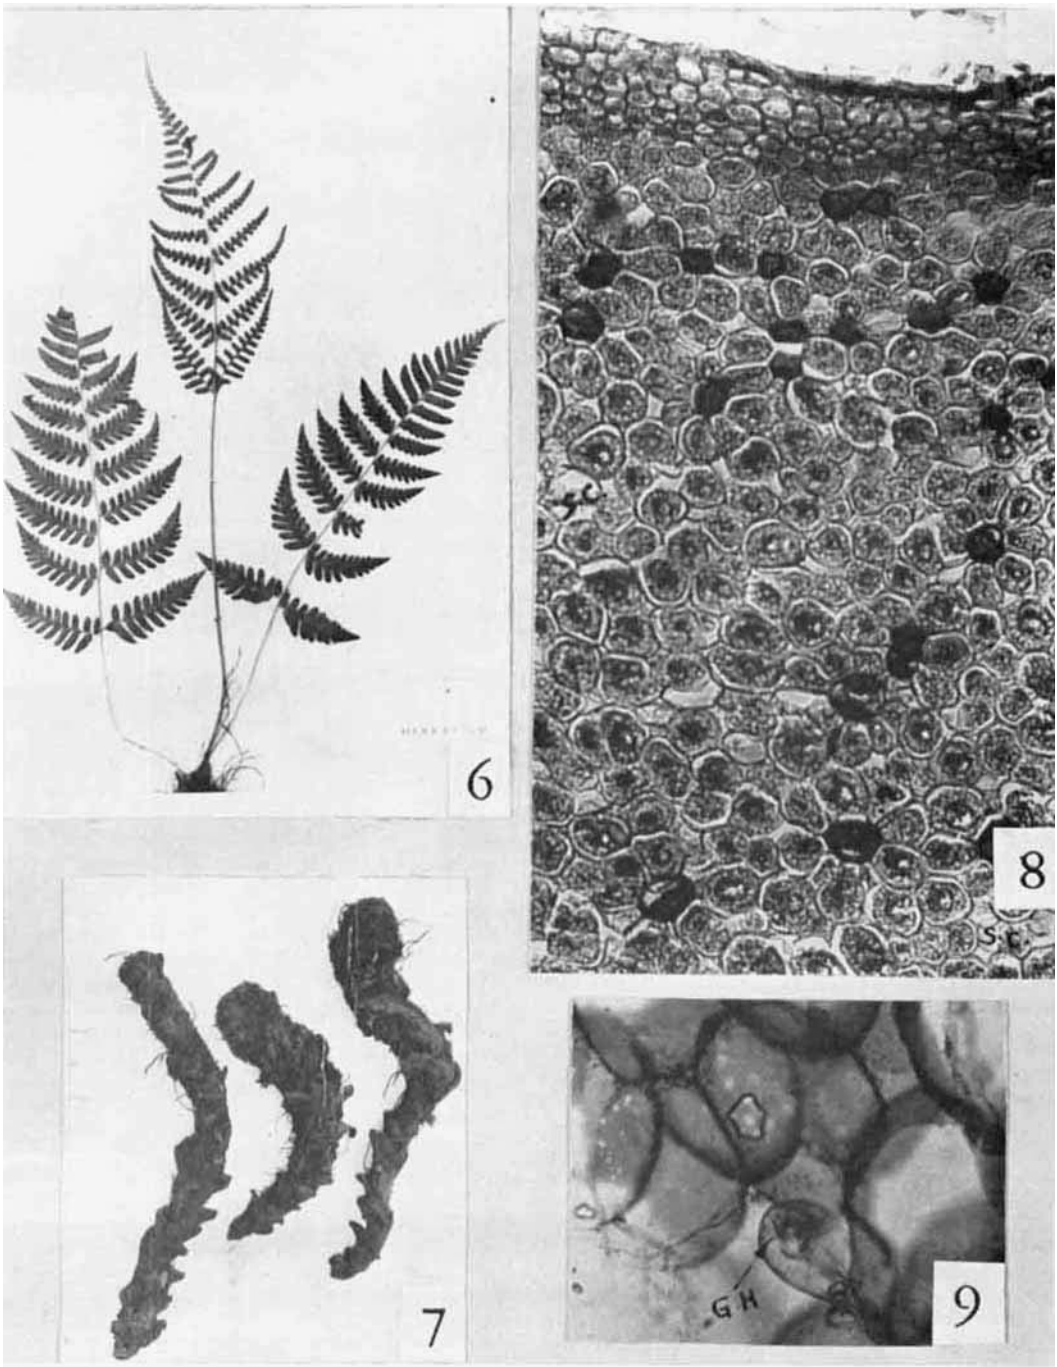

Fig. 3.—*D. cochleata*, plant with two sterile fronds and central fertile one, × 1/5. 7, Rhizome, × 1/2. 8, Sector of T.S. of the rhizome magnified, × 100; S.C., schizogenous cavity. 9, L.S. of rhizome showing a gland in a schizogenous cavity, × 250; G.H., glandular hair.

forming a row on each side of the pinnule near the midvein; indusium is reniform, and persistent.

Macroscopy of the Rhizome.—Rhizomes are flattened-cylindrical, tapering at the base (Fig. 3, part 7), 8–20 cm. long, 1.5–2.5 cm. thick, actual thickness without leaf bases varies from 1–1.5 cm. Externally rufo-castaneous or dull brown, covered by distantly situated frond bases which are 6–11 mm. thick and wrinkled. The entire rhizome and the frond bases are profusely scaly. Fracture is short. Freshly cut surface is pale green, marked by 3–5 cauline meristeles and numerous smaller vascular strands constituting leaf traces. Dark spots of sclerotic nests are abundant in the rhizome and leaf bases. Odor is slight. Taste at first sweetish, later becoming acrid and nauseous.

The ramenta vary in shape from linear-lanceolate to ovate-lanceolate with acuminated apex, each measuring 1–2 cm. × 1–6 mm. Unicellular glands are found all over the surface and the margin. In older scales the marginal cells are somewhat drawn out in groups to form multicellular, long fibrils. In addition, two-celled projections, characteristic of the genus *Dryopteris*, are also present on the margin. The unicellular glands measure 40–50 μ in length, and about 20 μ in diameter at the globular head.

Histology of the Rhizome.—A sector of the transverse section of the rhizome is represented in Fig. 3, part 8. The general histological pattern is the same as described in the earlier species except that numerous dark scattered sclerotic cells or groups of such cells forming sclerotic nests are observed in the ground tissue. In T.S. the number of cortical cells is about 275/mm.². These cells in maceration measure 56–210 × 42–100 μ. Schizogenous cavities are fewer than in the previous species, being only about 25/mm.² as seen in T.S. In longitudinal section, the cavities measure 64–180 × 35–60 μ. Into each cavity project one or two characteristic unicellular glandular hairs (Fig. 3, part 9). The latter are 38–80 μ long including the stalk which is 6–14 μ long with a somewhat swollen base. The diameter of the head measures 24–42 μ. Embedded in the ground tissue are numerous sclerotic cells or selerotic nests, scattered all over but more frequent in the outer cortical region (Fig. 3, part 8), particularly where the frond bases are attached. The sclerotic nests in the outer zone consist of two macrosclereids but those in the pith region are broader and formed of a number of sclereids. The sclereids, which in T.S. appear isodiametric to polygonal in outline with narrow lumen, are elongated cells with pointed or blunt ends and highly pitted walls (Fig. 4*d*). The walls are impregnated with a coloring matter which is responsible for the dark appearance of the nests. Each sclereid measures 250–1275 × 45–120 μ. The number of cauline meristeles varies from 3–5 and each leaf trace is comprised of 10–14 smaller vascular strands.

Histology of the Stipe.—The cortical cells are only slightly broader than those of the rhizome and they number about 200/mm.².

The sclerotic cell/nests are numerous and scattered all over the ground tissue. Each sclerotic nest consists of up to four sclereids. The vascular strands are 10–14, arranged in the form of a closed 'C'. As in the previous species, the two inner bundles are larger than the rest and their xylem possesses anterior hooks.

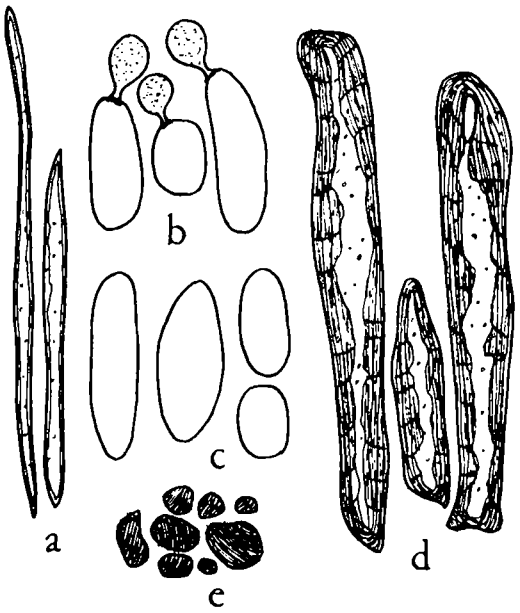

Fig. 4.—*D. cochleata*, tissue macerations. *a*, Hypodermal fibers, × 160; *b*, gland bearing cortical cells, × 160; *c*, cortical cells, × 160; *d*, sclereids × 160; *e*, starch grains, × 700.

SUMMARY

The present investigation provides macroscopic and microscopic descriptions of the rhizome and stipe bases of *Dryopteris barbigera* (Moore) O. Ktze. and *D. cochleata* (Don) C. Chr.

D. cochleata is strongly dimorphic, but *D. barbigera* is monomorphic. The rhizome of the former is flattened-cylindrical with the frond bases distantly situated. That of *D. barbigera* is ovoid, oblong, or elongated in shape with numerous closely arranged frond bases. Rhizomes of both the species are covered all over with ramenta. Size and structure of the ramenta is characteristic in each species.

The histological pattern in both the species is similar except for the presence of scattered dark spots of sclerotic cells and nests in the ground tissue of the rhizome and stipe bases of *D. cochleata* which are absent in *D. barbigera*. Both the species possess schizogenous cavities distributed in the ground tissue, into which project characteristic unicellular secretory glandular hairs. The secretory glands possess longer stalks are *D. barbigera* than in *D. cochleata*. The base of the stalk is slightly swollen only in *D. cochleata*. The number of cauline meristeles and the leaf traces are less in *D. cochleata* than in *D. barbigera*.

Sensitization of the Pigeon to Epinephrine-Induced Ventricular Fibrillation by a Substituted Propiophenone

By VIIU V. KLEIN, STANLEY E. SRENSEK, and LEHMAN M. LUSKY

The cardiac effects of a substituted propiophenone (U-0882) have been studied in the pigeon. The results obtained and the techniques used indicate that a simple test may be employed to evaluate the cardiac-sensitizing propensities of a compound. The test is based on the biological determination of the quantity of epinephrine required to induce ventricular fibrillation in pigeons which have been pretreated with a usually tolerated parenteral dose of the compound being tested.

PAST INTEREST in cardiac sensitization has been primarily limited to volatile halogenated hydrocarbons in medical anesthesia and industrial toxicology. However, an increasing number of parenterally administered chemical substances have been shown capable of sensitizing the heart to fatal epinephrine-induced ventricular fibrillation (1–4). Moore and Swain (4) recently suggested that compounds under pharmacologic investigation be examined for possible cardiac-sensitizing action in order to prevent the inadvertent induction of ventricular fibrillation. Conventional *in vivo* procedures demonstrating the capability of a substance to sensitize the heart to ventricular fibrillation are unfortunately impractical for routine examination of compounds under investigation because they are expensive, cumbrous, and time-consuming.

Previous studies in this laboratory by Braun and Lusky (5) demonstrated that the action of certain cardiac agents in the pigeon was similar to that in mammals. The pigeon is currently used in the official assay of digitalis (6).

The present communication describes the cardiac effects of alpha-phenoxy-alpha-dimethylaminomethylpropiophenone hydrochloride (hereafter designated as U-0882)[1] in the unanesthetized pigeon. The sensitizing action of this compound on the heart of the dog has previously been reported by Moore and Swain (3).

Although the present paper describes certain toxic manifestations and properties of U-0882, the main purpose of these studies was to devise a feasible method for measuring the cardiac-sensitizing propensities of a compound.

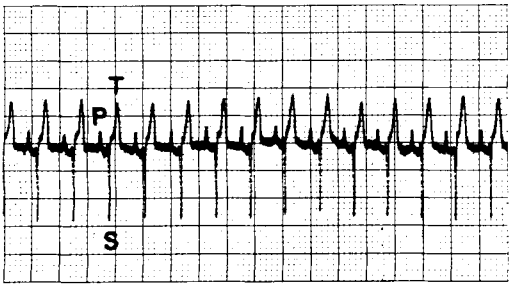

Fig. 1.—Lead II of normal electrocardiogram of pigeon.

EXPERIMENTAL PROCEDURES AND RESULTS

Unanesthetized, common barn pigeons, predominantly of the male sex, ranging in weight from 290 to 400 Gm. were employed in this study. All pigeons were immobilized and the vagi were intact. Artificial respiration was not employed and tracheal cannulation was not performed. Platinum electrodes were inserted into the right wing base, the left wing base, and the left leg of the pigeon. Standard lead II electrocardiograms were taken using a Sanborn Viso-Cardiette, model 51.

Varying doses of U-0882 and epinephrine were administered through an indwelling polyethylene catheter into an alar vein. Each dose was followed immediately by a 0.2-ml. wash of isotonic saline. All doses of epinephrine hydrochloride were so diluted in physiological saline that each of the test dosage levels was administered in a 1 ml./Kg. volume. The U-0882 was administered as a 1.0% solution in physiological saline.

Normal Electrocardiogram, Lead II, of the Pigeon.—The electrocardiogram of a normal, unanesthetized, adult male pigeon taken on lead II is illustrated in Fig. 1. The P, S, and T waves are well defined, but the electrocardiogram differs from that of man in that the pigeon exhibits no Q wave. There is controversy among investigators as to the existence of an R wave in the bird (7, 8).

Induction of Ventricular Fibrillation by U-0882 Alone.—When U-0882 was administered intravenously to groups of 12 pigeons each at dose levels of 20, 30, and 40 mg./Kg., ventricular fibrillation was induced in a few of the unanesthetized birds without the use of epinephrine or other triggering agent. The results show that ventricular fibrillation was induced in 1 of 12 pigeons receiving 20 mg./Kg., in 2 of 12 receiving 30 mg./Kg., and in 4 of 12 pigeons receiving 40 mg./Kg. The 40-mg./Kg. dose caused violent clonic convulsions in 8 of 12 pigeons. The convulsions were fatal to 2

[1] The compound U-0882 used in this study was kindly provided by the Upjohn Co., Kalamazoo, Mich.

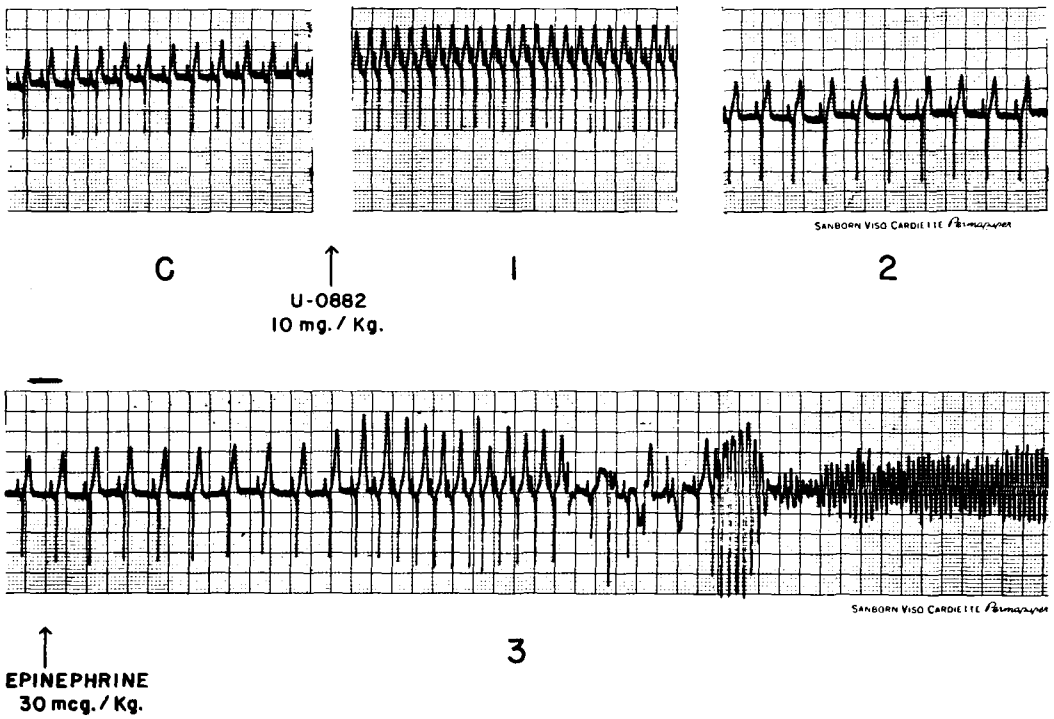

Fig. 2.—Lead II, electrocardiogram of pigeon. C, control; 1, tachycardia following U-0882; 2, bradycardia 2 minutes after U-0882; 3, progression into fibrillation after dose of epinephrine.

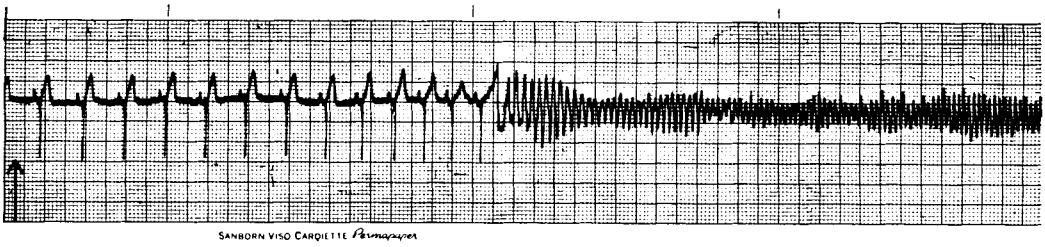
of these 8 pigeons; ventricular fibrillation was the cause of death of 2 others, and 4 pigeons recovered from the convulsions. Of the 4 pigeons which did not have convulsions, 2 succumbed from ventricular fibrillation and 2 pigeons did not exhibit any serious toxic effects.

Influence of U-0882 on the Heart Rate of the Pigeon.—The heart rate varied from pigeon to pigeon following the administration of 10 mg. of U-0882/Kg. intravenously. Tachycardia occurred in all of the birds within 1 minute after the injection, but by the end of the second minute, the rate either approximated normal or bradycardia ensued (Fig. 2). The electrocardiograms of 59 pigeons were examined to determine whether the reduction of heart rate following the administration of U-0882 bears a relationship to the incidence of ventricular fibrillation induced by a subsequent injection of epinephrine. The dose of 10 mg. of U-0882/Kg. caused cardiac slowing of varying degree in 43 pigeons and no significant change in rate in 16 pigeons. Following the administration of epinephrine, ventricular fibrillation was induced in 25 of 43 pigeons of the first group and also in 8 of the 16 pigeons of the second group. The apparent higher incidence of fibrillation in the group with the bradycardia was not statistically significant ($p = 0.07$).



Epinephrine Dose as Index to Cardiac Sensitizing Activity.—Six groups of 12 pigeons each were pretreated with 10 mg. of U-0882/Kg. intravenously. Two minutes later these groups received 3, 5, 10, 20, 30, and 40 mcg./Kg. of epinephrine, respectively. Electrocardiograms were taken to observe any effects on the heart. The electrocardiograms in Fig. 3 illustrate the two observed typical progressions into ventricular fibrillation. In the upper panel the onset of fibrillation is sharp and devoid of ectopic beats. The lower panel, in contrast, shows numerous ectopic beats preceding the onset of ventricular fibrillation in the pigeon. Two of the 72 pigeons on experiment were discarded because fibrillation was induced before the injection of epinephrine by U-0882 alone. Ventricular fibrillation was fatal to all pigeons. No deaths were due to other causes.

Figure 4 shows the dose-response curve obtained in these experiments. The dose of epinephrine (HCl) found to produce ventricular fibrillation in 50% of the pigeons, was calculated by the method of least squares to be 8.3 mcg./Kg. with a range of 6.2–12.8 mcg./Kg. The calculated slope was 1.3 probits per log dose.

In general, the onset of ventricular fibrillation occurred 5 to 10 seconds after the injection of epinephrine. For 15 to 20 seconds after the onset of fibrillation the pigeons lay quietly, respiration appeared normal, and there was no overt indication of the toxic manifestation. This was followed by an arching of the head and neck, brief clonic convulsions, and a final gasp. A similar sequence of events is observed in pigeons after toxic doses of digitalis.

DISCUSSION

The sensitization of the heart to fatal epinephrine-induced ventricular fibrillation by a chemical compound has not been previously described in the pigeon or any other member of the avian genus. The results of the present investigation indicate that the cardiac-sensitizing activity may be evalu-

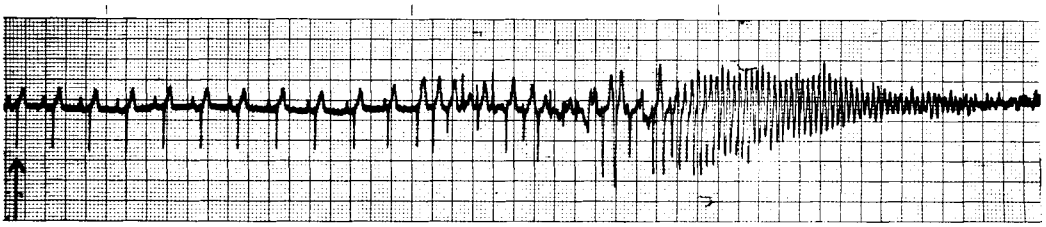


Fig. 3.—Two modes of electrical progression into U-0882–epinephrine ventricular fibrillation.

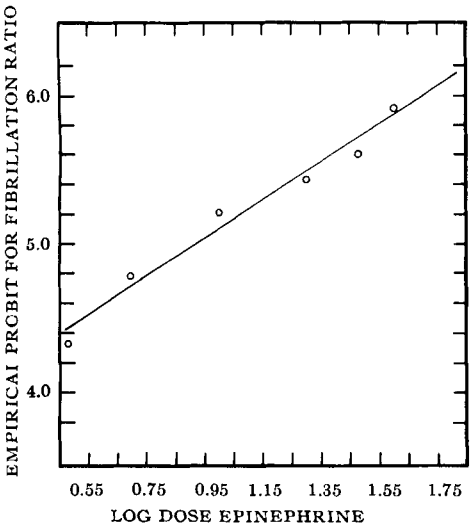

Fig. 4.—Relationship of dosage of epinephrine to incidence of ventricular fibrillation in pigeons sensitized with U-0882.

ated by the dose of epinephrine which will induce fibrillation in 50% of the pigeons previously receiving a usually tolerated dose of the compound under examination.

The observed slope of the dose-response curve obtained from the data of these experiments was 1.3 probits per log dose. This is a relatively flat dose-response curve in comparison with the dose-response curves of various other drugs and their actions. The present data are obviously insufficient to conclude whether this flatness is characteristic of pigeons, epinephrine, U-0882, the combination, or of drug-induced ventricular fibrillation. In any event the low cost of pigeons makes it economically feasible to use relatively large numbers of test animals to attain any desired degree of precision in evaluating the potential of a drug for inducing ventricular fibrillation. The use of the pigeon in cardiac-sensitization studies has other advantages over the use of other species. Artificial respiration often required in other species may not be necessary. The time-saving factor should encourage the use of pigeons. Only 5 to 10 minutes were required for the completion of each individual pigeon test.

SUMMARY

The sensitizing action of a substituted propiophenone, U-0882, on the heart of the pigeon to epinephrine-induced ventricular fibrillation has been demonstrated.

The results of these experiments suggest a simple, rapid, and inexpensive approach to the detection and evaluation of cardiac-sensitizing properties of compounds as a routine toxicity procedure.

Carbon Dioxide Uptake Studies in Algae Grown in Water and Deuterium Oxide

By MARTIN I. BLAKE†, ARLENE S. KAGANOVE‡, and JOSEPH J. KATZ‡

A procedure is described for studying carbon dioxide uptake in algae using C^{14}-labeled sodium bicarbonate as the source of carbon dioxide. Actively dividing, water grown and deuterium oxide adapted, *Scenedesmus obliquus* and *Chlorella vulgaris* were employed in these studies. Uptake comparisons were made over pH range 6 to 9 using appropriate buffer systems. Uptake was fairly constant in the range pH 6 to 8 for both the aqueous and deuterated algae. Above pH 8 uptake dropped markedly. In general, the deuterated algae showed between 10 and 30% lower uptake than ordinary algae. Greater chlorophyll content is associated with higher carbon dioxide uptake.

RECENT REPORTS (1, 2) indicate that it is possible to culture certain algae in a medium containing better than 99% deuterium oxide. Algae grown under these conditions are a practical source of fully deuterated compounds. A number of monosaccharides and amino acids have been isolated from a hydrolysate of deuterated algae (3). The isolation and characterization of deuterated chlorophylls a and b from chloroplasts of algae and some preliminary experiments on photosynthesis in deuterated algae have also been described (4). The present report deals with further studies on photosynthesis in ordinary and deuterated green algae. Carbon dioxide uptake comparisons are made here between ordinary water and deuterium oxide-grown algae.

The influence of the kinetic isotope effect on photosynthesis is probably among the most significant differences in the culturing of algae in water and deuterium oxide. It is hoped that such comparative studies as are reported here will aid in a better understanding of the complexities involved in the conversion of carbon dioxide to organic compounds by the photosynthetic process.

EXPERIMENTAL

Algae Cultures.—*Scenedesmus obliquus* and *Chlorella vulgaris* were grown autotrophically as stock cultures in 250-ml. culture flasks; there were two such cultures for each organism in both aqueous and deuterated media. The composition of the media has previously been given (2). The volume of the cultures was maintained at 125 ml. The flasks were kept on a mechanical shaker and the algae were continuously illuminated by overhead fluorescent lighting at an intensity of about 700-ft. candles measured at the level of the algae culture. Carbon dioxide was fed as a 5% mixture in nitrogen. The cultures were maintained at room temperature (25–27°).

An algae suspension for an experiment was prepared by centrifuging the harvested cells for 5 minutes at full speed in an International clinical centrifuge. The supernatant liquid was discarded, and the cells were washed once with water or deuterium oxide. The cells were resuspended in fresh solvent, and the packed cell volume was determined by centrifuging for 20 minutes. In all experiments a 1% suspension of algae in buffer solution was prepared by suspending 0.5 ml. of packed cells in 50 ml. of buffer. Only algae from rapidly growing cultures were used in these studies since older cultures were far less active in photosynthesis.

Photosynthesis Flask.—A specially constructed flask was used for the carbon dioxide uptake studies. A ground-glass standard-taper 125-ml. Erlenmeyer flask (male joint) was fitted with a cap (female joint) having a tapered opening extending about 2 cm., over which was fitted a rubber injection-type stopper. Aliquots of the solution within the flask were conveniently removed by hypodermic syringe without loss of carbon dioxide from the system. Experimentation showed that no measurable diffusion of carbon dioxide through the rubber stopper occurred over an 8-hour period. The cap was held tightly to the flask by springs fixed to glass prongs. A circular glass shelf, about 1 cm. in diameter and having a lip 4 mm. high, was fitted to the inner wall of the flask just above the 50-ml. mark. The flask was fitted with a jacket, covering the base and side of the flask above the 50-ml. mark. The algae suspension was maintained at 26° by passing water from a constant temperature water bath through the jacket. The temperature of the algae suspension was determined by inserting a thermometer into the well provided on the side of the flask. Figure 1 shows a diagram of the flask.

$NaHC^{14}O_3$ Stock Solution.—A stock solution of C^{14}-labeled sodium bicarbonate was prepared by dissolving 2 mc. of isotope in 4 ml. of pH 9 phosphate buffer solution. The solution was assayed by diluting a 25-λ aliquot to the mark of a 50-ml. volumetric flask. A 100-λ aliquot of this solution was added to 15 ml. of liquid scintillator in a 5-dr. vial and the system was counted in a Tri-Carb

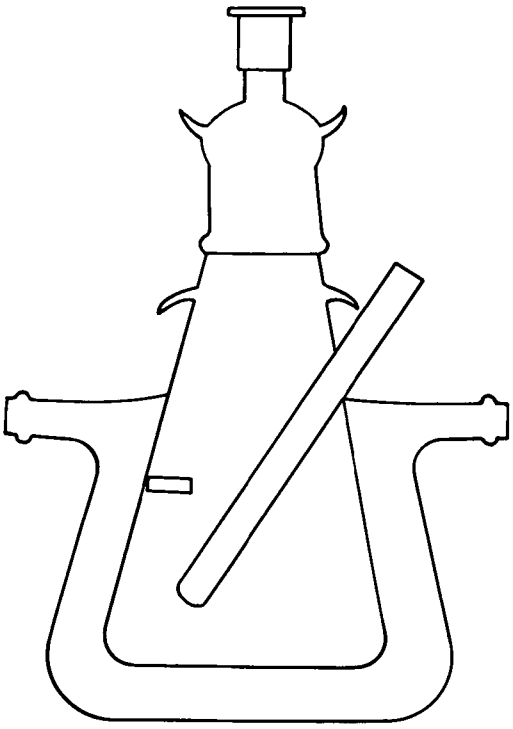

Fig. 1.—Schematic diagram of photosynthesis flask.

liquid scintillation spectrometer (model 314). A count rate of about 30,000 counts/min./100 λ was observed. This was compared to a standard.

General Procedure.—In all photosynthetic experiments 50 mg. of sodium bicarbonate and 25 λ of $NaHC^{14}O_3$ solution (12.5 μc.) were placed on the shelf of the photosynthesis flask. The algae suspension, prepared as described above, was added to the flask, below the shelf, with the aid of a long stem funnel. The flask was capped and, at zero time, was shaken vigorously to distribute the sodium bicarbonate and isotope throughout the algae suspension. The flask was placed on the shaker where the algae were permitted to photosynthesize. At 90-minute intervals for a total of 6 hours a small aliquot was removed from the flask by hypodermic syringe, centrifuged for 3 minutes, and 100 λ of the supernatant solution was counted.

Calibration Curves.—*Aqueous System.*—At pH 7.0 and below, a substantial portion of the sodium bicarbonate is present as carbon dioxide, part of which is in solution and part in the gas phase. The equilibria involved may be illustrated as follows

$[CO_2]$ gas phase

$\Downarrow\Uparrow$

$[CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-]$ aqueous phase

$\Downarrow\Uparrow$

[CO_2 taken up by algae[1]]

A calibration curve was necessary in order to determine the amount of carbon dioxide in the gas phase and the carbon dioxide plus other species in the liquid phase from a measurement of the C^{14} content of an aliquot of the liquid phase. Theoretically, this information could be obtained by calculation, but some of the necessary constants are not available for the deuterium oxide system. An empirical calibration curve supplied a more certain answer.

To the shelf of each of a series of 5 flasks was added respectively: 50 mg., 40 mg., 30 mg., 20 mg., and 10 mg. of sodium bicarbonate. This was followed by the addition of 25 λ of $NaHC^{14}O_3$ solution to the shelf of each flask. Fifty milliliters of buffer solution was added to the flasks below the shelf. The flasks were capped and shaken mechanically for 90 minutes. An aliquot of 100 λ was counted. Since the specific activity (counts/min./mg.) of the sodium bicarbonate was known, the amount of sodium bicarbonate in the aqueous phase was readily determined. The amount of carbon dioxide, as sodium bicarbonate equivalent, in the gas phase was then known. As an illustration, when 50 mg. of sodium bicarbonate and 25 λ of $NaHC^{14}O_3$ solution were used in pH 6.0 buffer, the specific activity was 300,000 counts/min./mg. of sodium bicarbonate. After equilibration, the activity in the liquid phase was observed to be 8,500 counts/min./100 λ or 4,250,000 counts/min./50 ml. This represented 14.2 mg. of sodium bicarbonate in the aqueous phase and 35.8 mg. of sodium bicarbonate equivalent in the gas phase as carbon dioxide. Corresponding values were obtained for the other weights of sodium bicarbonate which were employed. A calibration curve was constructed by plotting mg. of sodium bicarbonate equivalent in the gas phase *vs.* mg. of sodium bicarbonate in the aqueous phase. A straight line was obtained which passed through the origin.

For pH 6.0 a phosphate buffer system (KH_2PO_4 + NaOH) was used. For pH 7.0 a tris(hydroxymethyl)aminomethane-hydrochloric acid buffer system was used. The calibration curve for pH 7.0 with this buffer was not linear. More carbon dioxide was bound in the liquid phase than expected, due probably to the formation of carbamate. Since the calibration curves apply only to the vessels and conditions used in this study, the curves are not given here.

The "tris" buffer system was used for those studies at pH 8.0, 8.5, and 9.0. Since the carbon dioxide in the gas phase at pH values of 8.0 and above is negligible, a calibration curve was not necessary here. The observed activity in the aqueous phase of blank runs did not deviate from the theoretical value, and the direct count of the liquid phase was all that was required at these pH values.

Deuterium Oxide System.—The equilibria involved in the carbon dioxide uptake studies with deuterium oxide-grown algae are essentially the same as those involved in the aqueous system except that deuterium replaces hydrogen. Calibration curves were prepared as described for the aqueous system. The buffer solution corresponding to pH 6.0 was prepared from NaOD and KD_2PO_4. The apparent pH as observed with a Beckman pH-meter (model G) was 5.9. The buffer solutions in deuterium oxide (D_2O) corresponding to pH values of 7.0, 8.0, 8.5, and 9.0 were prepared from tris(hydroxymethyl)-aminomethane (in which all of the exchangeable hydrogen was replaced by deuterium) and DCl. All buffers in D_2O were prepared using the same stoichiometry as for the H_2O buffers. The apparent pH was measured with the pH-meter and an ap-

[1] Species other than carbon dioxide may be involved.

propriate correction (5) to the reading was made. The pD values of the buffer solutions in D_2O corresponding to the aqueous buffer values were 6.3, 7.3, 8.3, 8.8, and 9.3.

Effect of pH on Carbon Dioxide Uptake.—Carbon dioxide (or bicarbonate) uptake was studied over a 6-hour period. The algae were agitated continuously at 26° at a light intensity of 700-ft. candles. Comparison was made between algae grown in water and deuterium oxide over a pH range of 6.0 to 9.0. At pH values (and corresponding pD values) of 8.0, 8.5, and 9.0% uptake was determined directly from the counts/min./100-λ aliquot of the aqueous phase at zero time and the counts/min./100-λ aliquot after an interval of photosynthesis. It was assumed that at these pH values there was a negligible amount of carbon dioxide in the gas phase. For pH (and pD) values of 6.0 and 7.0 the carbon dioxide in the gas phase must be taken into account. The total count rate in the liquid phase was determined from the count rate in a 100-λ aliquot of the solution. The amount of bicarbonate in the liquid phase was readily determined, and the amount of sodium bicarbonate equivalent in the gas phase was ascertained from the calibration curve. The sum in the aqueous phase and the gaseous phase was then subtracted from the original amount. This represented the amount taken up by the algae. Per cent uptake was then calculated. The data for these experiments are shown in Figs. 2–5.

Radioactive Excretion Products.—Tolbert and Zill (6) have reported that at pH values greater than 4.5 glycolic acid is an excretion product of *Chlorella*. Experiments were therefore conducted to determine whether significant amounts of glycolic acid or other radioactive organic compounds were excreted into the medium in these studies. Samples of algae suspensions were centrifuged and the supernatant liquid transferred to a second tube. Concentrated hydrochloric acid was added (50 λ) and the solution was flushed with nitrogen. A 250-λ aliquot was then counted. In no instance was the count rate sufficiently above background to indicate the presence of significant amounts of radioactive metabolic products. This was further confirmed by applying the color reaction with 2,7-dihydroxy naphthalene as described by Calkin (7) and used by Tolbert and Zill in their work.

Chlorophyll Content.—The chlorophyll content of the algae used in this study was determined. Exactly 0.5 ml. of wet packed cells (representing 0.1 Gm. of dried cells) was transferred to a 15-ml. centrifuge tube. About 10 mg. of sodium bicarbonate was added, followed by the addition of 10 ml. of actively boiling water. The tube was then placed into boiling water for 1 minute, cooled under tap water, and centrifuged. The supernatant liquid was discarded. Ten milliliters of a mixture of ethyl ether (2 volumes) and methanol (1 volume) was added, and the tube was shaken vigorously until its contents were

thoroughly mixed. The tube was centrifuged and the supernatant liquid was transferred to a separator. This extraction procedure was repeated twice. An additional 30 ml. of ether-methanol solvent mixture was added to the separator and the solution was extracted several times with saturated salt solution, followed by extraction with distilled water. The chlorophyll layer was transferred to a 100-ml. volumetric flask and was diluted to the mark with ether. Absorption was determined with a Cary model 14 recording spectrophotometer at 660.0 and 642.5 mμ, and both total chlorophyll and chlorophyll a were calculated by the method of Comar (8). The data are recorded in Table I.

TABLE I.—DETERMINATION OF TOTAL CHLOROPHYLL AND CHLOROPHYLL a IN DEUTERIUM OXIDE AND WATER-GROWN ALGAE

Algae	Total Chlorophyll,[a] %	Chlorophyll a,[a] %	Total Chlorophyll D_2O/H_2O	Chlorophyll a, D_2O/H_2O

H_2O	2.45	1.84	0.955	0.880
D_2O	2.34	1.62	...	...

[a] Grams per 100 Gm. of dried algae.

DISCUSSION

The availability of fully deuterated algae has made possible a comparative study of photosynthesis in both deuterium oxide-adapted and water-grown algae. The replacement of hydrogen by deuterium probably affects the relative rates of reactions involved in photosynthesis, and does not interfere with the pathways by which carbon dioxide is converted to organic compounds. This is substantiated by the fact that the same metabolites, but which contain deuterium where hydrogen is normally found, have been isolated (3). Identical, but deuterated, chloroplast pigments have also been extracted (4). In other studies (9) essentially similar radioautograms have been obtained using the techniques described by Bassham and Calvin (10). Although similar compounds were identified, it is quite possible that the relative abundances may differ. The course of photosynthesis, at least in its earlier phases, appears to be substantially the same in both varieties of algae.

Figures 2–5 show carbon dioxide uptake by deuterated and water-grown algae as a function of time and pH (or pD). It is apparent that the water-grown algae take up carbon dioxide to a greater extent than the deuterated algae over a 6-hour study period. Greater differences are to be noted between the *Chlorella* cultures than between the *Scenedesmus* organisms. Although there is a greater disparity in uptake between the aqueous and deuterated *Chlorella*, it is interesting to note that in an earlier report (2) it was shown that adaptation in deuterium oxide occurs more readily with *Chlorella* than with *Scenedesmus*.

In general, under the conditions of the experiments described here, deuterated algae showed between 10 and 30% lower uptake than ordinary algae. The influence of variation in pH on bicarbonate uptake by ordinary and deuterated algae was studied. Since the electrochemistry of D_2O and H_2O is different, it is essential to distinguish between kinetic isotope effects and changes in uptake rate due to pH sensitivity. Solutions in H_2O and D_2O made up stoichiometrically identical will have different ion concentrations and activities. Suitable corrections were made for the observed values in the deuterium oxide systems. Uptake was fairly constant in the range pH 6 to 8 for both ordinary and deuterated algae. The uptake is thus insensitive to pH changes in this range. Therefore, differences in uptake are attributable to metabolic effects involving deuterium rather than pH sensitivity. Above pH 8, uptake dropped markedly and at pH 9, the algae showed signs of damage in a short period of time.

The question of whether carbon dioxide, bicarbonate ion, or both are utilized by algae as a source of carbon has been considered by numerous workers. Evidence in the literature is very conflicting. This matter is discussed by Krauss (11). Emerson and Green (12) claim that sufficient carbon dioxide is released in carbonate-bicarbonate buffer systems for photosynthesis even at high pH values. The equilibrium curve shows that at pH values above 8, only traces of carbon dioxide are present and, therefore, it appears improbable that sufficient carbon dioxide is released to satisfy the requirements of algae cultures. Osterlind (13) has found that *Scenedesmus quadricauda* assimilates bicarbonate ion while *Chlorella pyrenoidosa* does not. On the basis of the present report it seems probable that bicarbonate is acceptable to the algae in the alkaline pH region. For example, at pH 8.0, where free carbon dioxide is practically negligible, satisfactory photosynthesis was observed. At pH 8.5 and above, the alkalinity of the solution was found to have a detrimental effect on photosynthesis and growth. One can also speculate that since a "tris" buffer was employed in much of this work, carbamate may also be capable of being absorbed by the algae. Finally, the possibility exists that algae may possess two independent mechanisms for assimilating carbon: (*a*) one for carbon dioxide and (*b*) another independent path for bicarbonate ion. In an occasional run it was noted that while the algae consumed carbon dioxide normally at pH values around 7, they were refractory to bicarbonate uptake at pH 8.

Preliminary experimentation indicated that the absolute amount of sodium bicarbonate consumed by the algae over a time period was independent of the initial concentration. This was studied over the range of starting concentrations from 25 to 200 mg.

Experiments were conducted to determine whether significant amounts of glycolic acid, as reported by Tolbert and Zill (6), or other C^{14}-labeled compounds were excreted into the medium under the conditions of these studies. Tolbert and Zill used essentially weightless amounts of sodium bicarbonate while in the present study macroscopic quantities of bicarbonate, mainly nonlabeled, were employed. This precluded carbon dioxide starvation which may be responsible for glycolic acid excretion. Radioactive excretion products were not detected in our studies.

The relationship of chlorophyll content and carbon dioxide uptake was examined. Total chlorophyll and chlorophyll a were determined for both the aqueous and deuterated algae. As shown in Table I, the ratio of chlorophyll content for the deuterated to that of the aqueous algae approximates the carbon dioxide uptake relationships shown by the uptake curves. Greater differences are to be noted between the *Chlorella* cultures than between the *Scenedesmus* organisms, which is consistent with the results from the uptake studies.

The procedure described in this report for studying carbon dioxide uptake is a simple one and reproducible results within 5% were obtained when duplicate runs were conducted. Further work is currently in progress in this laboratory to extend these studies to include the effect of variation in light intensity and temperature on the photosynthesis of deuterated algae.

Determination of Barbiturates in Urine Containing Salicylate

By DONALD M. STOKES, WALTER J. R. CAMP, and ERNST R. KIRCH

A procedure is described in which urine pigments, salicylate, and other chromogenic materials which preclude spectrophotometric evaluation of barbiturate by virtue of their strong absorption in the ultraviolet region are removed from a chloroform solution by selective adsorption.

THE EXTRACTION from urine specimens of salicylate and other substances together with barbiturates has been a problem frequently encountered during toxicologic analysis. At the present time, the quantitative determination of barbiturates in biological material is best accomplished by means of ultraviolet spectrophotometry (1, 2). Analytical procedures commonly employed involve preliminary extraction of the malonylurea derivative from the specimen. by an immiscible solvent such as ether or chloroform. The spectral characteristics of the malonylurea molecule are most definitive in alkaline solution, which may be obtained by re-extraction of the barbiturate from an immiscible solvent into aqueous alkali. Normal physiological constituents which absorb strongly in the ultraviolet region and other drugs including salicylates are often extracted along with the barbiturate. The presence of these nonbarbiturate chromogens in the final alkaline extract precludes definitive spectrophotometric evaluation of the malonylurea compound unless steps are taken to remove the interference.

The attempts by various investigators to eliminate interfering substances by use of lengthy, complicated extraction procedures which resulted in loss of sensitivity, low recoveries, and failure to eliminate nonbarbiturate chromogens have been criticized (3). Differential spectrophotometric techniques (3–5) in which determination of barbiturate is based on the differences in the ultraviolet absorption spectra of strongly alkaline and pH 10–10.5 buffered solutions represent a significant improvement over older methods employing conventional spectrophotometry. It has been reported (3) that ultraviolet-absorbing substances including the drugs

Determination of Barbiturates in Urine Containing Salicylate

By DONALD M. STOKES, WALTER J. R. CAMP, and ERNST R. KIRCH

A procedure is described in which urine pigments, salicylate, and other chromogenic materials which preclude spectrophotometric evaluation of barbiturate by virtue of their strong absorption in the ultraviolet region are removed from a chloroform solution by selective adsorption.

THE EXTRACTION from urine specimens of salicylate and other substances together with barbiturates has been a problem frequently encountered during toxicologic analysis. At the present time, the quantitative determination of barbiturates in biological material is best accomplished by means of ultraviolet spectrophotometry (1, 2). Analytical procedures commonly employed involve preliminary extraction of the malonylurea derivative from the specimen. by an immiscible solvent such as ether or chloroform. The spectral characteristics of the malonylurea molecule are most definitive in alkaline solution, which may be obtained by re-extraction of the barbiturate from an immiscible solvent into aqueous alkali. Normal physiological constituents which absorb strongly in the ultraviolet region and other drugs including salicylates are often extracted along with the barbiturate. The presence of these nonbarbiturate chromogens in the final alkaline extract precludes definitive spectrophotometric evaluation of the malonylurea compound unless steps are taken to remove the interference.

The attempts by various investigators to eliminate interfering substances by use of lengthy, complicated extraction procedures which resulted in loss of sensitivity, low recoveries, and failure to eliminate nonbarbiturate chromogens have been criticized (3). Differential spectrophotometric techniques (3–5) in which determination of barbiturate is based on the differences in the ultraviolet absorption spectra of strongly alkaline and pH 10–10.5 buffered solutions represent a significant improvement over older methods employing conventional spectrophotometry. It has been reported (3) that ultraviolet-absorbing substances including the drugs

Presented to the Scientific Section, A. PH. A., Chicago meeting, April 1961.

dicoumarol, diphenylhydantoin, and sulfadiazine, which appear in the final alkaline extract, do not interfere with barbiturate determination by differential spectrophotometry because they have the same absorption in strong alkali and in pH 10.5 solution. But salicylate, like barbiturate, exhibits spectral differences (6) dependent on pH and must be removed from a sample before quantitative analysis of the malonylurea derivative can be made.

Although it has been claimed (3, 4, 6) that separation of barbiturate from salicylate can be accomplished by extraction from phosphate-buffered aqueous solution at pH 7.4, the present authors have been unable to secure complete separation of the two compounds by this method. Furthermore, extraction with ether or chloroform of many urine specimens at various pH levels ranging from less than 1 to 7.4 has been found to result in subsequent alkaline extracts which were often highly colored and contained such large amounts of nonspecific chromogenic material that differential spectrophotometric evaluation was not possible.

In this investigation, a reasonably short, simple procedure was employed in which salicylate as well as urinary pigments and chromogens were removed from a chloroform solution by means of a selective adsorption column and barbiturates were eluted quantitatively from the column in sufficient purity to permit determination by automatic differential ultraviolet spectrophotometry.

Spectrophotometric Determination of Barbiturates.—The ultraviolet absorption spectrum of 5,5-disubstituted malonylurea derivatives in strong alkali such as 0.45 *N* sodium hydroxide exhibits a maximum at 252–255 mμ and a minimum at 234–237 mμ. In a buffer solution at pH 10–10.5 there occurs a higher maximum at 238–240 mμ with no minimum (3, 4). The difference between the absorbance in strong alkali and that in the buffered solution is greatest at 260 mμ, decreasing through zero at 247–250 mμ to a maximum negative at 235–240 mμ, and increasing through zero at 227–230 mμ to a positive difference at lower wavelengths. The absorbance difference at 260 mμ has been employed to measure the concentration of barbiturate solutions by differential spectrophotometry (3, 4).

Recently, the differential spectrophotometric technique has been adapted to utilize the automatic ratio-recording features of the Beckman model DK-2 spectrophotometer by Williams and coworkers, who have published procedures for determination of both barbiturates (5) and salicylates (6). The method is based on the fact that in alkaline solution salicylate, like barbiturate, can exist in two different ionic states which give rise to two different ultraviolet spectra, depending on the pH of the solution. The instrument automatically substracts one spectrum from the other and draws a composite curve.

The composite curves shown in Fig. 1 are representative of the differential absorption spectra of 5,5-disubstituted malonylurea derivatives and were obtained using various standard concentrations of secobarbital. In each case the 0.45 *N* sodium hydroxide solution was scanned against the pH 10–10.5 solution as reference, using the differential absorbance range (−0.3 to +0.7) of the Beckman model DK-2 spectrophotometer as described by Williams and Zak (5). The maximum and minimum absorption peaks, occurring at 260 and 238 mμ, respectively, represent the corresponding absorbance differences between strongly alkaline and pH 10–10.5 spectra.

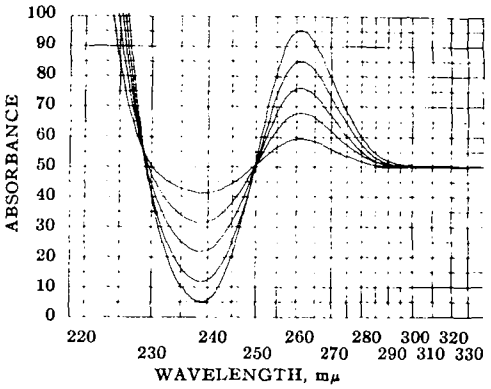

Fig. 1.—Differential absorption spectra of standard solutions of secobarbital in concentrations of 4.994, 9.988, 14.98, 19.98, and 24.97 mcg. per ml.

Salicylate in 0.45 *N* sodium hydroxide, when read against 0.45 *N* sodium hydroxide as a reference blank, exhibits a maximum at 300 and a minimum at 267 mμ. In a buffered solution at pH 10–10.5 there occurs a maximum at 295 and a minimum at 257 mμ. This spectral shift with change in pH gives rise to the differential spectrum. The composite spectrum of salicylate exhibits maxima at 318 and 246 mμ and minima at 283 and 233 mμ (6).

When both barbiturate and salicylate are present in the solutions scanned in the spectrophotometer the differential spectrum exhibits the 318 mμ peak characteristic of salicylate, but the shorter wavelength peaks for barbiturate and salicylate are replaced by a single absorption maximum occurring at about 253 mμ (6). The effect of the presence of salicylate on the differential absorption spectrum of barbiturate is demonstrated in Fig. 2. The composite curve illustrated here was obtained using a solution of salicylate and pentobarbital, each being present in a concentration of 20 mcg. per ml. The composite barbiturate-salicylate spectrum is inadequate for definitive determination of the malonylurea derivative, although quite accurate estimation of the salicylate concentration is possible using the 318 mμ peak (6). Thus it is imperative that salicylate be removed before definitive determination of the barbiturate content of a sample can be made.

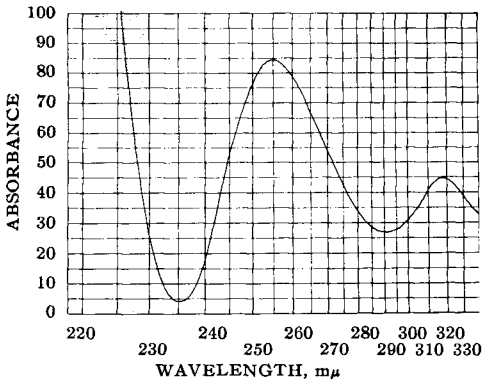

Fig. 2.—Differential absorption spectrum obtained from a solution containing both salicylate and pentobarbital in concentrations of 20 mcg. per ml.

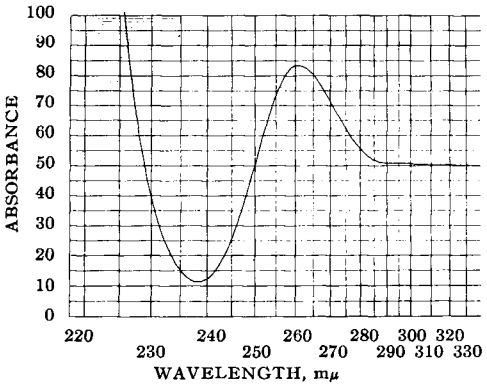

Fig. 3.—Differential absorption spectrum of secobarbital recovered from a Florisil column. A mixture of 10.0 ml. of standard secobarbital solution, 19.98 mcg. per ml., and 10 ml. of urine containing 20 mg. of salicylate was extracted.

A typical differential spectrum obtained on barbiturate recovered from a Florisil[1] adsorption column by the procedure described in this investigation is illustrated in Fig. 3. An extract of a mixture of 10.0 ml. of standard secobarbital solution, 19.98 mcg. per ml., and 10 ml. of urine containing 20 mg. of salicylic acid was purified by passage through the column followed by elution of the barbiturate. The quantitative recovery of secobarbital as well as the effectiveness of the method in removing salicylate and urinary chromogenic material is indicated by comparison of Fig. 3 with the curve obtained on the corresponding standard secobarbital solution shown in Fig. 1.

EXPERIMENTAL

Reagents.—Florisil, 60/100 mesh; diethyl ether, anhydrous reagent; chloroform, reagent grade, redistilled; methanol, anhydrous reagent; hydrochloric acid (A.R.) solution, approximately 6 *N*; sodium hydroxide (A.R.) solution, 0.45 *N*; ammonium chloride (A.R.) solution, 16%.

[1] Florisil is a granular magnesia-silica gel adsorbent supplied by the Floridin Co., Tallahassee, Fla.

Standardization of Barbiturate Solutions.—Standard solutions of the representative 5,5-disubstituted malonylurea derivatives amobarbital, pentobarbital, phenobarbital were prepared as follows: a pure sample of each barbiturate was dried for at least 1 week under vacuum over phosphorus pentoxide. A portion close to 0.25 Gm. was weighed accurately and dissolved in 0.45 *N* sodium hydroxide to make 500.0 ml. of stock solution. Standard solutions ranging in barbiturate concentration from 5 to 30 mcg. per ml. in 0.45 *N* sodium hydroxide were immediately prepared from the stock solution and subjected to differential spectrophotometry. To 3.0 ml. of the standard solution, 0.5 ml. of 0.45 *N* sodium hydroxide was added. A second 3.0-ml. portion of the standard was mixed with 0.5 ml. of 16% ammonium chloride to obtain a buffered solution of pH 10–10.5. The strongly alkaline solution was scanned as sample against the buffered solution as reference, using the differential absorbance range of the Beckman model DK-2 spectrophotometer as described by Williams and Zak (5).

The differential absorbance spectra of various standard concentrations of secobarbital are shown in Fig. 1. Similar curves were obtained on standard solutions of amobarbital and pentobarbital. Although the value of the differential absorbance maximum at 260 mμ was found to be nearly proportional to the concentration, much better linearity resulted when the differences in absorbance between the maximum at 260 mμ and the minimum at about 238 mμ were plotted as a function of the concentration. Calibration curves (Fig. 4) in which the absorbance differences ($A_{max} - A_{min}$) are graphed against concentration demonstrate adherence to the Beer-Lambert law found for each of the barbiturates tested.

Preparation of Adsorption Column.—A small piece of glass wool was fitted into the bottom of a glass tube having the approximate dimensions 65 cm. in height and 1 cm. in inside diameter. Five grams of Florisil was packed fairly loosely to a height of about 10 cm. in the tube by gentle tapping. Another small piece of glass wool was placed on top

of the adsorbent and lightly pressed into place with a glass rod. The column so prepared was ready for use.

Isolation of Barbiturate from Urine.—A 10.0-ml. sample of urine was acidified to pH 1 or below by addition of 3–4 ml. of 6 *N* hydrochloric acid and extracted with ether in three successive portions of about 40 ml. each. The ether phases were carefully separated, combined, and evaporated to dryness on a 70° water bath with the aid of a gentle stream of air. Approximately 10 ml. of redistilled chloroform was added to the dry residue thus obtained and the mixture was warmed on the water bath to facilitate solution of the barbiturate. The Florisil column was treated with 20 ml. of chloroform to initiate solvent flow and wash out any loose particles of adsorbent. The chloroform extract was then placed on the column and followed by two additional 10-ml. portions of chloroform similarly employed to insure complete transfer of barbiturate to the adsorption column. At no time was the liquid level in the column allowed to fall below the upper surface of the adsorbent.

As the developing solvent flowed through the column, a yellow color band was formed within the uppermost part of the adsorbent and a clear, colorless effluent was obtained. The rate of flow varied between 0.5 and 3 ml. per minute, depending on the height of the liquid in the column. When the level of the chloroform was 1 or 2 cm. above the surface of the Florisil, 25 ml. of 10% (by volume) methanol in chloroform was carefully added to the column to elute the barbiturate. The resulting colorless eluate was collected in the receiver containing the chloroform effluent. Little if any diffusion of the urine pigment in the colored band was discernible during elution and salicylate, if present, was retained on the adsorption column.

After the eluant had ceased to flow, the methanol-chloroform solution was evaporated to dryness on a 70° water bath with the aid of a gentle stream of air. The resulting dry residue was subsequently taken up in 10.0 ml. of 0.45 *N* sodium hydroxide and stirred to dissolve the barbiturate completely. The clear, colorless, or nearly colorless solution so obtained was suitable for spectrophotometric determination of quantities of barbiturate less than 0.25 mg. Further dilution to an accurately measured volume was necessary when a larger amount was present in the eluate residue in order to secure a final concentration of 0.025 mg. per ml. or less.

Spectrophotometric determination of the barbiturate concentration of the 0.45 *N* sodium hydroxide solution obtained from the eluate was carried out in exactly the same manner as described for the standardization, using the differential technique described by Williams and Zak (5). The quantity of barbiturate present was then calculated by comparison of the spectrum so obtained with that of a standard solution of the barbiturate.

In order to evaluate the recovery of barbiturate from a Florisil column, the procedure was carried out using 10.0-ml. aliquots of the standard solutions. When the eluate residue was subsequently dissolved in 0.45 *N* sodium hydroxide to make 10.0 ml. of solution, the percentage of barbiturate recovered could then be calculated from the relationship

$$\frac{(A_{max} - A_{min})\ \text{eluate}}{(A_{max} - A_{min})\ \text{standard}} \times 100 = \text{per cent recovery}$$

The recovery of pentobarbital from pure aqueous solution (Table I) and from urine (Table II) is representative of the results obtained for all of the barbiturates studies. The actual absorbances as read from the differential curves, together with the percentage recovered using 10.0 ml. of the indicated concentrations of standard solutions are shown in Table I. A 10.0-ml. portion of each of the standard solutions was added to 10 ml. of drug-free urine to obtain the results listed in Table II. Duplicate determinations were made as an indication of the reliability of the method.

The separation of barbiturate from salicylate using the Florisil column technique was demonstrated by addition of an aliquot of a solution containing 10 mg. of salicylic acid to 10.0 ml. of standard barbiturate solution before extraction and passage of the chloroform extract through the adsorption column. The results of duplicate analyses carried out on phenobarbital are shown in Table III.

Table IV lists the average recoveries obtained by duplicate determinations on each of the four barbiturates investigated. In each case 10.0 ml. of a standard barbiturate solution and 20 mg. of salicylic acid were added to 10 ml. of drug-free urine prior to extraction and separation on a Florisil column.

As a further test of the Florisil separation technique, the column procedure was applied to actual toxicological specimens. In a limited number of such cases in which sufficient urine containing barbiturate was available for experimental purposes, a 10.0-ml. sample of the urine was extracted and subjected to the Florisil column procedure in order to determine the concentration of barbiturate present. To a second 10.0-ml. portion of the specimen an aliquot of a standard barbiturate solution was added and the procedure was again carried out. The results of these analyses are shown in Table V. The barbiturate concentration before and after addition of a known quantity of a specific malonylurea derivative was then calculated from the standard spectrophotometric calibration curve for that particular compound. Thus, when phenobarbital was added, the amount of barbiturate originally present in the specimen was calculated as phenobarbital. In this way the amount of phenobarbital recovered could be determined by subtracting the number of milligrams originally present from the total number of milligrams recovered after addition of a known quantity of phenobarbital.

A ferric chloride test was performed to indicate the presence or absence of salicylate in each specimen. Urine samples B and C were large enough to permit separate determination of salicylate by the method of Williams and co-workers (6). In these samples the salicylate concentration was so high that the absorbance peak at 318 mμ could be used to estimate the salicylate even though barbiturate was also present.

DISCUSSION

A procedure for determination of barbiturates in urine specimens containing salicylate is described which involves the separation of barbiturate from salicylate by selective adsorption on Florisil. A chloroform extract obtained from urine is passed through a Florisil column. Upon subsequent elution with a 10% solution of anhydrous methanol in chloroform, salicylate as well as other chromogenic material normally present in urine extracts remains adsorbed, while barbiturate is recovered quantitatively in the eluate. Spectrophotometric determination of the barbiturate can then be carried out without interference from salicylate and urinary constituents which exhibit absorption in the ultraviolet region.

Selection of Adsorbent.—Of the several adsorbents investigated, only Florisil was found to give consistent and reproducible results. This magnesia-silica gel preparation has been successfully used for the chromatography of a wide variety of compounds which have otherwise proven difficult to separate. The 60/100 mesh grade may be easily and uniformly packed in a column which permits the solvent to flow at a fairly rapid rate. The material activated at 1200° F. or 500° F. was found to give equally satisfactory results. The complete retention of at least 20 mg. of salicylic acid on the adsorption column (Table IV), together with the purity of the barbiturate eluate obtained attest to the efficiency of Florisil as used in the procedure described in this study.

Selection of Solvents.—In order to facilitate extraction of barbiturate from urine samples acidified with hydrochloric acid, ether rather than chloroform was used. Troublesome emulsions usually encountered with chloroform were thus avoided, and the ether as well as the small amounts of dissolved water and hydrochloric acid present in the extract could be readily evaporated on a 70° water bath. Application of an ether extract containing dissolved water and hydrochloric acid to a Florisil column resulted in incomplete retention of salicylate and urinary chromogenic material but barbiturate was apparently not adsorbed and could be at least partially removed from the column by washing with ether. The removal of some water-soluble material from the Florisil which produced a yellow color in 0.45 *N* sodium hydroxide was also found to be due to the presence of water and hydrochloric acid. When an ether extract was evaporated to dryness to remove all traces of water and hydrochloric acid and a dry ether solution of the residue was applied to a Florisil column, barbiturate, salicylate, urinary pigments, and chromogens were completely adsorbed.

A number of different solvents were investigated in order to determine optimum conditions for retention of salicylate and urinary chromogens during elution of barbiturate from a Florisil column. A close parallel was found between the action of these solvents and their polarity. Although barbiturate was completely adsorbed from ether solution, the somewhat more polar solvents, chloroform and ethyl acetate, permitted small amounts of barbiturate to pass through the column when 50 ml. of either solvent were applied, while pigments and salicylate were retained. On application of acetone, urinary chromogenic material was removed. Increasing the polarity still further by use of ethanol or methanol resulted in partial elution of salicylate, which was accompanied by removal of most of the urinary pigments as well. It therefore became necessary to select a suitable solvent for elution of barbiturate which would not elute salicylate or urinary chromogenic material under practical analytical conditions. A 10% solution of anhydrous methanol in redistilled chloroform proved effective for this purpose. The addition of methanol to chloroform in this proportion produced a solvent of

[b] In each case the amount of barbiturate was calculated in terms of the particular compound added as a recovery standard.

sufficient polarity to elute as much as 5 mg. of barbiturate (corresponding to a urinary concentration of 50 mg. % based on a 10-ml. sample) using only 25 ml. of eluant (Table IV).

The capacity of the adsorption column for retention of salicylate under the condition used for elution of barbiturate was determined by extracting aliquots of standard salicylic acid solutions and subjecting the extracts to the Florisil column procedure. Although the quantity of salicylate added to urine samples was limited to 20 mg. for recovery experiments on barbiturates (Table IV), it was found that as much as 25.0 mg. of salicylic acid could be retained successfully on the column provided that no more than 25.0 ml. of 10% methanol in chloroform was added in the elution step.

While urinary pigments as well as salicylate were not removed from a Florisil column by washing with chloroform, it was found that barbiturate was not completely retained on the column from chloroform solution, a small amount appearing in the effluent. For this reason the eluate obtained by treatment of the column with 10% methanol in chloroform was combined with the chloroform effluent. By use of these particular solvents, salicylate and interfering substances present in urine extracts were completely eliminated from the barbiturate eluates. The degree of purity of the eluates thus obtained made possible the quantitative recovery of as little as 0.05 mg. of barbiturate (Table IV), corresponding to a level of 0.5 mg. % in urine using a 10-ml. sample.

The technique herein described has been applied successfully in the isolation of barbiturates from a number of specimens of urine for toxicological purposes. That recovery of barbiturate by this method is quantitative from such specimens is evident from the data in Table V. It is to be noted that accurate determination of the relatively low barbiturate content of these urine samples was made possible by first removing the salicylate from the extract on a Florisil column. Chloroform extracts from blood and gastric contents have also been subjected to the Florisil purification process, resulting in solutions free of nonbarbiturate chromogenic substances and thus making possible the accurate determination of barbiturates by automatic differential ultraviolet spectrophotometry.

SUMMARY

A procedure for separation of barbiturates from urine specimens containing salicylate is described which is based on selective adsorption. Isolation of the barbiturate present in a chloroform extract is accomplished by means of an adsorption column from which the malonylurea derivative may be eluted conveniently while interfering substances are retained.

Salicylate, urine pigments, and other chromogenic materials which preclude spectrophotometric determination of barbiturate by virtue of their strong absorption in the ultraviolet region are removed from chloroform solution by Florisil. Elution of the barbiturate with a small volume of 10% methanol in chloroform results in quantitative recovery of the drug in sufficient purity to permit spectrophotometric analysis.

Radiochemical Purity of Tritium Exchange Labeled Barbital

By C. R. BOSHART†, G. K. W. YIM, and T. S. MIYA

Barbital (diethylmalonylurea) was isotopically labeled with tritium by the Wilzbach gas exposure procedure. The specific activity of the tritiated barbital was 266 mc./Gm. after removal of labile tritium. The following criteria of homogeneity were employed: recrystallization to constant specific activity using 2 solvent systems; column liquid-liquid partition and paper chromatography; and evidence for stability in a biological system. Final specific activity was 253 mc./Gm.

THE ADVANTAGES associated with the use of tritium as a tracer isotope prompted our studies with barbital (diethylmalonylurea) tritiated according to the Wilzbach gas exposure procedure (1). Our purpose was to determine radiochemical purity as well as biological stability of this exchange labeled tritiated compound. Criteria of homogeneity included recrystallization to constant specific activity using two solvent systems; column liquid-liquid partition and paper chromatography; and evidence for stability in a biological system.

EXPERIMENTAL

Analytical.—Radioactivity measurements were carried out using the Tri Carb Beta liquid scintillation spectrometer.[1] Five-dram vials made from glass of low potassium content were used to hold radioactive samples.[2] Aqueous solutions containing tritium radioactivity were incorporated into a xylene:dioxane:ethanol (5:5:3) system containing in each liter, 80 Gm. naphthalene, 5 Gm. 2,5-diphenyloxazole (PPO), and 0.1 Gm. 1,4-di[2-(5-phenyloxazolyl)] benzene (POPOP) (2). Toluene containing 0.3% PPO and 0.01% POPOP was used for counting radioactive samples miscible with it. Barbital was determined spectrophotometrically in 0.5 *N* sodium hydroxide at 255 mμ (3).

Tritiation, Exchange, and Recrystallization.—Barbital sodium was tritiated according to the Wilzbach (1) procedure by the New England Nuclear Co., Boston, Mass. The compound was exposed to 10 c. of carrier-free tritium gas for 2 weeks at room temperature and 0.39 Atm. pressure. The tritiated product was repeatedly equilibrated with water by the New England Nuclear Co. and in our laboratory to remove labile tritium. Specific activity of the free acid following the equilibration steps was 266 mc./Gm. The tritiated barbital was successively crystallized from ethanol-water, three times from toluene, and finally from water, yielding a product which retained approximately 96% of the radioactivity present after removal of labile tritium. Unlabeled barbital was added before final recrystallization from water, however, so that the actual specific activity was reduced to 166 mc./Gm.

Paper Chromatography.—Unlabeled barbital and barbital-t were chromatographed on Whatman No. 1 paper using *n*-butanol:5% ammonium hydroxide (1:1) (4). Radioactive areas were visualized autoradiographically. The papers were sprayed with 0.1 *N* aqueous silver nitrate:10% ammonium hydroxide (1:1) for detection of the barbital (5). A substance with very low specific activity and which was more polar than barbital was detected in the first recrystallization product. For all other cases, the darkening of the film was coincident with the barbital-t area and parallel to unlabeled barbital chromatographed concurrently.

Column Liquid-Liquid Partition Chromatography.—Barbital-t was chromatographed on a diatomaceous earth[3] column (6) using borate buffer 0.1 *M*, pH 9.2 as the internal phase and chloroform:butanol (93:7) as the external phase. Following the third recrystallization from toluene, barbital-t exhibited a homogeneous peak followed by a minor peak containing less than 5% of the radioactivity. The homogeneity of the major component was confirmed by analyzing the specific activities of fractions throughout the peak by the method of Baggett and Engel (7). The slope of specific activities for successive tubes through the peak was not significantly different from zero. After recrystallization from water, the barbital-t exhibited a single peak as illustrated in Fig. 1. The specific activity of six combined peak fractions was the same before and after column partition and the minor peak was no longer evident.

Biological Stability.—A suitable dilution of the final product was injected intravenously into a rabbit. Two hours later barbital was recovered from the serum by the method of Askevold and Løken (8). Table I shows the amount of barbital and radioactivity injected and recovered from the serum. Specific activities shown in the last column agree within 5%. This is within the range of experimental error associated with the analytical procedure.

DISCUSSION

Three types of evidence have been presented to demonstrate the degree of purity of exchange-labeled tritiated barbital. First, there was negligible loss of tritium radioactivity upon successive

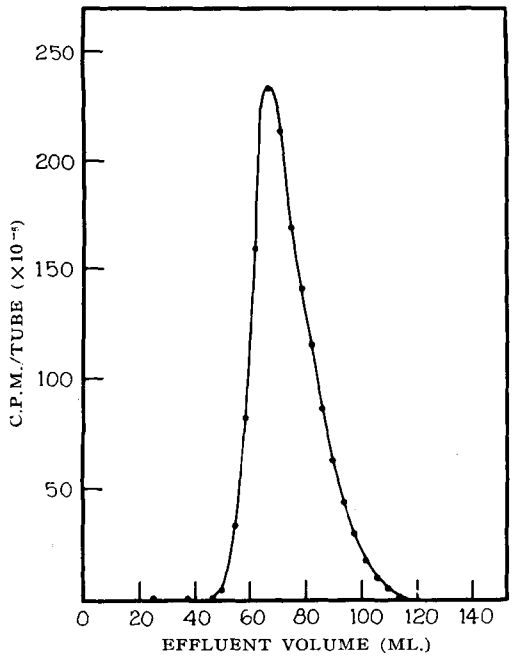

Fig. 1.—Celite column partition chromatogram of barbital-t.

recrystallization from toluene and water. Second, chromatographic methods indicated that a single substance, identical with barbital, constituted most of the detectable radioactivity. On paper chromatography of the first crystalline product, and in one column chromatogram of the third toluene recrystallization product, a minor radioactive component was present. The minor component of the column chromatogram constituted less than 5% of the radioactivity. After subsequent recrystallization from water, this secondary peak did not appear. Third, barbital-t lost little, if any, of its tritium after injection into an experimental animal and recovery after 2 hours. This latter observation nearly eliminates the possibility of the presence of high specific activity contaminants in barbital-t inasmuch as we would not expect, if contaminants were present, that their distribution, metabolic degradation, sojourn in the body, or chloroform extractability from serum would be identical with that of barbital. We have concluded from these results that a product with a high degree of radiochemical purity and stability suitable for pharmacologic studies was obtained. After removal of labile tritium by exchange with water, the barbital-t retained approximately 96% of the remaining isotope through recrystallization and chromatography. This is the highest yield yet reported for the Wilzbach exchange-labeling method. If the barbital-t had been subjected to the procedures outlined without dilution with unlabeled barbital, its specific activity would have been 253 mc./Gm. This represents the presence of approximately 1 tritium atom per 610 molecules of barbital. The results with this compound are unusual since there was little evidence for the presence in the labeled material initially of a high specific activity contaminant.

TABLE I.—BARBITAL AND RADIOACTIVITY INJECTED AND RECOVERED FROM RABBIT SERUM

Acid and Enzymic Hydrolysis of N-Butylformamide and Its Oral Inefficacy

By EDWARD R. GARRETT† and DENNIS J. WEBER

The kinetics of acid and enzymic hydrolysis of the parenterally pharmacologically active N-butylformamide have been studied by titrimetric and color assay procedures. It is expected that the half-life of the amide under the conditions of the human stomach would exceed 30 hours. The stability of the drug greatly exceeds any stomach retention time.

INITIAL recognition of the pharmacological efficacy of a drug often results from a screening program where the potential agent is parenterally administered. However, this mode of administration severely limits a drug's utility and marketability so that the product potential has to be evaluated with regard to oral efficacy. If a drug is parenterally effective but orally ineffective, a physical-chemical evaluation may possibly demonstrate the reason so that the drug may be properly chemically or pharmaceutically modified (1).

The compound, N-butylformamide, $HCNCH_2-CH_2CH_2CH_3$ (O double-bonded to C; H on N), was shown to have a selective effect on the avoidance behavior of rats similar to that of chlorpromazine when administered parenterally but not when administered orally (2). The purpose of this study was to predict the possible gastric stability of the material for a possible explanation of its oral inefficacy.

EXPERIMENTAL

Kinetics of Acid Hydrolysis.—Weighed amounts of the liquid N-butylformamide, synthesized by R. B. Moffett of these laboratories, were placed in thermally equilibrated 50-ml. volumetric flasks and brought up to volume with thermally equilibrated standard hydrochloric acid, immediately mixed, and maintained in the constant temperature bath. The detailed concentrations and temperatures are given in Table I. Five-milliliter aliquots of the hydrolyzing amide solutions were taken at planned intervals and quenched with sufficient 1 *M* sodium hydroxide so that the excess hydrochloric acid was almost neutralized. To the 6 ml. of the resultant solution was added 25 ml. dimethylsulfoxide, and the resultant mixed solution was cooled to room temperature. This solution was subsequently titrated with standard 0.1 *N* sodium hydroxide on the Precision-Dow recording titrator equipped with glass-saturated calomel electrodes. This solvent mixture gave two sharp inflections, the first one indicative of complete neutralization of the excess hydrochloric acid and the second one indicative of the complete neutralization of the formic acid produced by the acid hydrolysis.

Kinetics of Enzymic Hydrolysis.—Accurately weighed samples of N-butylformamide were diluted to 50 ml. with thermally equilibrated degrading solutions. There were three different degrading solutions used. One contained 0.4 *N* hydrochloric acid and 0.1% w/v pepsin at 40°; another contained 0.01 *N* hydrochloric acid and 0.1% w/v pepsin at 40°; and the third contained a Clark and Lubbs buffer (3) of pH 7.9 at 40° and contained 0.1% w/v trypsin. The pepsin and trypsin were obtained from the Worthington Biochemical Corp.

One-milliliter aliquots were taken at recorded time intervals and their N-butylamine content determined by the method evaluated by Forist and Judy (4) of these laboratories. The spectrophotometric procedure for the determination of amines based on reaction with bromcresol purple in chloroform (5) was applicable to the determination of N-butylamine in chloroform (4). Under the conditions of extraction (0.1 *N* sodium hydroxide) production of butylamine from intact butylformamide was less than 2% over a period of 15 minutes and indicated adequate stability of the amide. Beer's law was followed for butylamine over the range 10^{-4} to 10^{-3} *M*, the concentration range of the samples. Determination of standard butylamine samples gave a mean recovery ± standard deviation of 99.1 ± 3.5% (4). The presence of enzyme was shown not to interfere with the assay.

CALCULATIONS AND RESULTS

The basic expression for the hydrolysis kinetics is

$$d(A - X)/dt = -k[A - X] = -k_{H^+}[H^+][A - X] \quad \text{(Eq. 1)}$$

where A is the initial concentration of the N-butylformamide, X is the concentration of formed formic acid at time t, and k is the pseudo first-order rate constant obtained from the slope of the first-order plot of the integrated expression

$$\log [A - X] = -kt/2.303 + \log [A] \quad \text{(Eq. 2)}$$

Typical plots are given in Fig. 1. The conditions, pseudo first-order and actual second-order rate constants, are given in Table I.

The Arrhenius plot of the logarithm of the rate constant, k_{H^+} in L/M/sec., against the reciprocal of the absolute temperature as per

$$\log k = -(\Delta H_a/2.303R)(1/T) + \log P \quad \text{(Eq. 3)}$$

is given in Fig. 2. The heat of activation is 19.8 Kcal./mole and the log P value is 9.16.

Apparent rate constants for the hydrolysis of N-

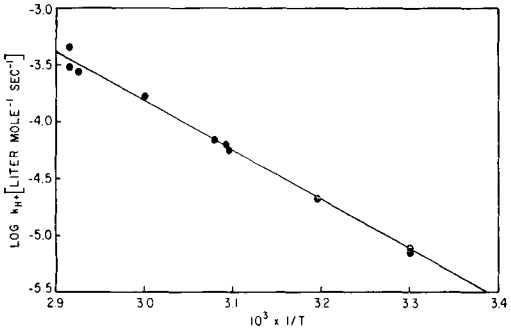

Fig. 2.—Arrhenius plot of the bimolecular rate constant for the acid hydrolysis of N-butylformamide.

butylformamide in the presence of the enzymes trypsin and pepsin are given in Table II. A specific example of a pseudo first-order rate plot is given in Fig. 3. The line is drawn on the basis of the acid hydrolysis equations evaluated in Eq. 2 and shows no enhancement of rate by the presence of the enzyme pepsin. The pH 2 solution of pepsin, a better approximation of stomach conditions, also demonstrated a hydrolysis rate not inconsistent with simple acid hydrolysis. The experiment using trypsin at its optimum pH value also showed no significant enzymic effect.

DISCUSSION

Kinetic analysis of the enzymatic degradation of N-butylformamide showed that the oral inefficacy of the drug cannot be attributed to gastrointestinal degradation by the enzymes, pepsin or trypsin, at their optimum pH values, 2 and 7.8, respectively. Since the half-life of N-butylformamide at 39° in 0.4 *N* hydrochloric acid is 22.8 hours, the inefficacy of oral administration where parenteral administration is effective cannot be attributed to acid degradation of the compound in the gastrointestinal tract. This large half-life proves that the rates of acid degradation are grossly less than any stomach retention time.

This work indicates that the lack of oral activity is not due to enzymatic or solution degradation in the gastrointestinal tract. An alternative explanation is that the drug is orally inactive due to its inability to pass through the lipid-like gastrointestinal mucosa. This is consistent with its high insolubility in fat solvents (6).

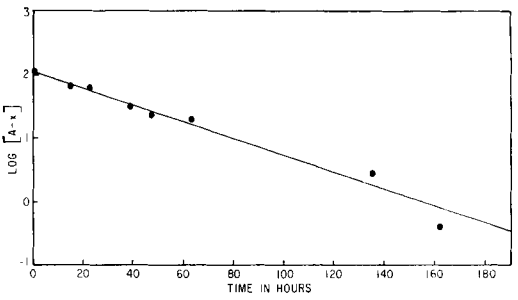

Fig. 3.—Pseudo first-order plot of the hydrolysis of N-butylformamide in the presence of 0.1% w/v pepsin at 40° and 0.411 *M* hydrochloric acid. The drawn line is expected from acid hydrolysis alone.

The heats of activation for the acid hydrolysis of various unsubstituted acylamides listed in the literature (7) are all in the range 19–21 Kcal./mole. These amides include formamide, acetamide, benzamide, propionamide, and butyramide. However, all of these compounds hydrolyzed at much faster rates; for example, formamide has a half-life at 42° in 0.1 *N* hydrochloric acid of 2.2 hours, at 25° of 7.0 hours (7). Apparently substitution on the nitrogen of the amide markedly slows the rate of hydrolysis.

Preparation of Microcrystalline Progesterone Using Ultrasound

By JOSEPH R. PRINCIPE† and DONALD M. SKAUEN

Microscopic crystals of progesterone were prepared by insonating saturated solutions of the hormone. Suspensions were made of the crystalline precipitates in 1% tyloxapol solution. Individual crystals were measured by projecting photographs on a calibrated screen.

THE DESIRABILITY of obtaining a chemical compound of uniform microscopic size is considered to be of importance to the pharmaceutical industry, particularly in the preparation of suspensions.

The usual methods of preparing suspensions for injection involve size reduction by milling or crystallization from various solvents to produce crystals of microscopic size and uniformity.

This investigation was undertaken to ascertain the suitability of employing ultrasonic energy in the production of microcrystalline progesterone.

EXPERIMENTAL

Saturated solutions of progesterone in solvent mixtures of varying proportions of ethyl alcohol and ethylene glycol at different temperatures were prepared. This solvent was selected because of good solvent action and because viscosity could be varied without the use of a secondary agent.

One-milliliter samples of the supernatant liquid from the saturated solutions were transferred to small hard-glass test tubes, stoppered, and immediately insonated.[1] The contents of the sound chamber was kept at approximately 20° by means of a cold water coil. The effect of length of time of insonation and the effect of power were explored.

Immediately after insonation, the test tubes containing the resulting precipitates were centrifuged, the supernatant discarded, and the crystals allowed to dry before resuspension in a 1% aqueous tyloxapol solution.

Photomicrographs of the uniformly distributed suspended material were made and examined for particle size by a projection technique.

Table I shows typical data obtained by insonating saturated solutions prepared at 55°.

[a] Solvent, ethyl alcohol U.S.P., 25 parts, ethylene glycol, 75 parts; insonation time, 5 seconds; saturated solution prepared at 55°.

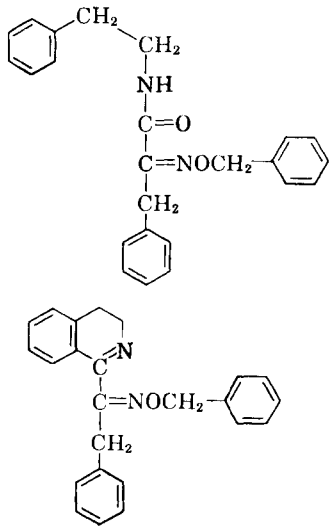
Figure 1 shows crystals obtained under the conditions specified in Table I, at a plate power of 50 ma. and 5 seconds exposure time. Figure 2 shows crystals exposed for 5 seconds at a plate power of 100 ma.

SUMMARY

1. Microscopic crystals of progesterone were prepared by insonating saturated solutions of the hormone.

2. The results indicated that: (*a*) in general, an increase in plate power from 50 to 100 ma. results in smaller crystals; (*b*) the solvent system 25% ethyl alcohol–75% ethylene glycol appears to favor smaller and more uniform crystal size; (c) the temperature at which the saturated solution is prepared seems to affect crystal size; (*d*) length of time of insonation appears to have minimal influence on crystal size.

3. Crystals prepared under insonation conditions were smaller and more uniform than controls prepared without insonation.



Amides of α-Alkyloximino Acids

By WALTER H. HARTUNG† and DOMINICK A. COVIELLO‡

N-β-Phenethyl amides of α-benzyloximino acids were prepared as intermediates for an attempted cyclization to the corresponding 3,4-dihydroisoquinoline derivatives.

THE ISOQUINOLINE nucleus is found in a large number of medicinally active compounds, both natural and synthetic. With this and the fact that little is known about the biological activity of the alkyloximino group in mind, it was thought that if a substituent containing the alkyloximino group could be introduced into the isoquinoline nucleus a compound of biological interest might result. At the same time, there was also the opportunity to explore further the chemical stability and limitations of the group under various conditions of reaction.

The plan was to prepare N-β-phenethyl amides of α-benzyloximinopropionic acids with the hope that they could be cyclized under the conditions of the Bischler-Napieralski reaction (1) to obtain new 3,4-dihydroisoquinoline derivatives containing the alkyloximino group. These presumably could be dehydrogenated to yield isoquinolines. For example, N-β-phenethyl-β-phenyl-α-benzyloximinopropionamide would yield 1-(1-benzyloximino-2-phenylethyl) 3,4-dihydroisoquinoline.

The amides prepared in this investigation are listed in Table I.

Cyclization was attempted by refluxing the amides

These presumably could be dehydrogenated to yield isoquinolines. For example, N-β-phenethyl-β-phenyl-α-benzyloximinopropionamide would yield 1-(1-benzyloximino-2-phenylethyl) 3,4-dihydroisoquinoline.

The amides prepared in this investigation are listed in Table I.

Cyclization was attempted by refluxing the amides

TABLE I.—AMIDES PREPARED

Amide	M.P., °C.	Yield Based on Amine, %	Kjeldahl Nitrogen Calcd., %	Kjeldahl Nitrogen Found, %
N-β-Phenethyl-β-phenyl-α-benzyloximinopropionamide	54–56	55.3	7.53	7.52[a] 7.54
N-β-(3,4-Dimethoxyphenethyl)-β-phenyl-α-benzyloximinopropionamide	46–48	40.3	6.48	6.47 6.35
N-β-(3,4-Methylenedioxyphenylethyl)-β-phenyl-α-benzyloximinopropionamide	53–54	33.7	6.71	6.67 6.52
N-β-Phenethyl-α-benzyloximinopropionamide	41–43	[b]	9.49	9.38 9.22

[a] *Anal.*—Calcd. for $C_{24}H_{24}N_2O_2$: C, 77.4; H, 6.45; N, 7.53. Found: C, 77.3, 77.4; H, 6.24, 6.33; N, 7.3. Analyses done by Drs. Weiler and Strauss, Oxford, England. [b] No yield was calculated on this compound because an attempt was made to distil a portion since it showed no inclination to crystallize by the usual methods. The remaining portion, standing at room temperature for several weeks, crystallized. The portion which distilled at 184–195°/0.2 mm. did not crystallize even after standing for several months.

in toluene in the presence of phosphorus oxychloride and phosphorus pentoxide. The experiment was repeated with *p*-xylene solvent and without solvent. In another experiment, the amide was allowed to stand at room temperature for one week in phosphorus oxychloride. Another experiment at room temperature employed phosphorus pentoxide with the phosphorus oxychloride. In no case was a product isolated which had amine properties.

In light of this, an attempt was made to effect cyclization with polyphosphoric acid according to the procedure of Snyder and Werber (2). By this method the amine moiety was recovered and characterized as the picrate. From this it was assumed that the unchanged amide was hydrolyzed during decomposition of the hot reagent with ice. This was borne out by the fact that if the reaction mixture was allowed to cool before decomposition of the reagent, nothing could be isolated that had amine properties.

Experiments using polyphosphoric acid were run varying reaction time from 30 seconds to one and one-half hours at temperatures ranging from 50 to 145°, and at room temperature for one week without success.

EXPERIMENTAL

Amides were best prepared by the procedure of Vaughan and Osato (3). The products appeared at first to be intractable oils, but a pure product was ultimately obtained by taking up the oil in methanol and adding hexane until precipitation was imminent. After 2 days to a week in the freezing compartment of the refrigerator, a solid formed which was crystallized from methanol.

Use of an Approximate Dielectric Constant in Solubility Studies

By WILLIS E. MOORE

THE DATA published by Autian and Udani (1) on the solubility of secobarbital have been further evaluated in terms of solubility in relation to the approximate dielectric constant (A.D.C.) of the solvent(s) by the techniques proposed by Moore (2).

This additional analysis is noted here to further illustrate the utility of using an A.D.C. in solubility studies.

The binary systems in Autian and Udani's work (their Fig. 2) were examined. Only glycerin showed a linear relationship between A.D.C. and solubility [log A.D.C. was plotted *vs.* (concentration)$^{1/2}$ of solute]. Alcohol, propylene glycol, and PEG 400 showed varying degrees of positive deviation.

The ternary systems (their Fig. 3) show linear portions in all three systems when plotted as above. The slopes differed, since solubility was different, but the intercepts were identical at a log A.D.C. value equal to an A.D.C. of 88 (see Fig. 1). This predicts a zero solubility of secobarbital in a mixed solvent with an A.D.C. of 88. This value could, of course, be meaningless. Further investigation of this relationship is required for better understanding.

Figure 1 further shows that an inconsistency appears. For example, at an A.D.C. value of 59.5 (log A.D.C. = 1.775) the solubilities of secobarbital are predicted as in Table I.

Why the solubility should vary at a constant A.D.C. but with different solvent systems cannot be explained precisely by this empirically established relationship. It is recognized that the dielectric

constant of a solvent(s) system is only one factor, among many, that account for solubility.

The relationship of the apparent pKa values (their Fig. 7) for secobarbital and the A.D.C. of the solvent blend was also examined (apparent pKa was plotted *vs.* log A.D.C.). Figure 2 shows that the glycerin solvent blends were the only blends to exhibit a linear relationship. Alcohol and propylene glycol show linear portions but with positive deviations at low levels of the respective semipolar solvent. The distinctly different behavior of the PEG 400 blends is evident.

The mechanism of dissolution in aqueous blends of alcohol, propylene glycol, and glycerin may be the same (possibly solute-solvent interaction)

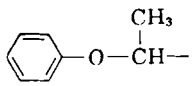
TABLE I.—PREDICTED SOLUBILITIES OF SECOBARBITAL

% Alcohol	% Glycerin	% Water[a]	$\sqrt{C}$	Concentration of Secobarbital, %
10	40.0	50.0	0.94	0.88
20	25.5[a]	54.5	1.10	1.21
30	10.0	60.0	1.30	1.70

[a] Estimated.

differing only in degree. The adverse effect (i.e., lowering solubility) of water on the solvent power of the "good" solvents could be due to water competing with the solute for intermolecular H-bonding with the "good" solvent rather than a polarizing (i.e., dielectric) effect.



Additional experimental work such as examining the binary systems of glycerin with the other glycols and alcohol and conductance measurements of the entire series would provide further information, particularly since PEG 400 has, relatively, such a depressant effect on the ionization of secobarbital at concentrations above 40%.

Gas Chromatography of Sympathomimetic Amines

Sir:

Methods for the separation and identification of microquantities of sympathomimetic amines are of great importance for work in pharmacy, pharmacology, and toxicology. Although the literature in this field is extensive, there is still a need for a simple and rapid method that permits positive identification and lends itself to quantitative analysis.

This communication reports the separation and identification of 11 sympathomimetic amines by gas-liquid chromatography at temperatures ranging from 104° for the nonphenolic to 135° for the phenolic amines. A Barber Colman model 15 gas chromatograph equipped with an argon ionization detector has been used for this work. A suitable column is prepared from Gas-Chrom P, 100 to 140-mesh, coated with about 1% of silicone rubber SE-30. A typical sample is 1.0 μl. of a solution containing 0.5 to 1.0% of each amine. A mixture of six commonly used nonphenolic amines dissolved in chloroform gives five distinct peaks, ephedrine and pseudoephedrine being eluted together (Fig. 1). However, the two latter amines can be separated by using acetone as the solvent. Pseudoephedrine reacts relatively rapidly with acetone to produce an addition product, whereas the reaction between ephedrine and acetone is very slow.

Several sympathomimetic amines react with ketones. The reaction products produce sharp, symmetrical peaks, suitable for quantitative estimation. The compounds are readily identified on the basis of the relative retention values for the free amines and their ketone derivatives.

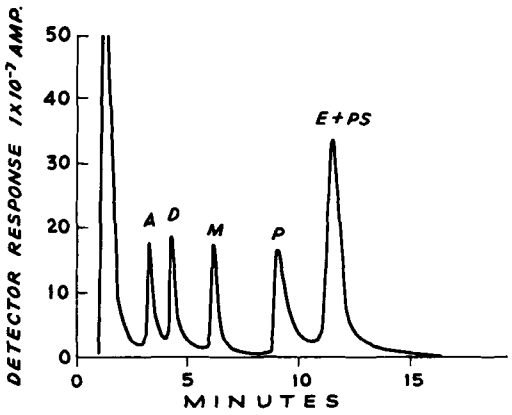

Fig. 1.—Gas chromatogram of six sympathomimetic amines on silicone rubber SE-30, 1.15%. Temp., 104°; column, 8 feet long, 3 mm. i.d.; pressure, 20 p.s.i.; flow rate, 22.5 ml./min. A, amphetamine; D, methamphetamine; M, mephentermine; P, phenylpropanolamine; E, ephedrine; PS, pseudoephedrine.

A complete report will be published shortly.

Occurrence of Psilocin in *Psilocybe baeocystis*

Sir:

Psilocybe baeocystis Singer and Smith is a comparatively small, nondescript agaric belonging to the stirps cyanescens of the section Caerulescentes of the genus *Psilocybe* (1). As such, it might be expected to produce cerebral mycetism following ingestion; indeed, three recent cases of poisoning have been reliably attributed to this species (2). The nature of the active principle(s) in this mushroom has not previously been determined, probably due to its restricted habitat which appears to be limited to western Oregon.

Recently, several dried carpophores of *P. baeocystis*, collected on October 30, 1960 from a lawn in Portland by C. Goetz, were made available to us through the courtesy of Mrs. H. J. Oswald. The identity of the specimens was verified by Prof. D. E. Stuntz, Department of Botany, University of Washington.

Samples of the dried carpophores were extracted with cold 70% methanol and the extract

examined chromatographically, essentially as described by Tyler (3). Solvent systems employed included water-saturated *n*-butanol, *n*-butanol:acetic acid:water (4:1:5), and *n*-propanol:1 *N* ammonia (5:1). In all three of these systems, a compound was detected by spraying with 2% *p*-dimethylaminobenzaldehyde in 1 *N* hydrochloric acid (blue-violet color) and with Pauly's reagent (orange-red color). It had an R_f value identical with reference psilocin and did not separate from that compound when spotted in admixture. Tryptophan was also identified on the chromatograms by its characteristic R_f value and the color formed with the *p*-dimethylaminobenzaldehyde reagent, but psilocybin could not be detected.

Failure to detect psilocybin is remarkable in that it is more stable than psilocin and has been found in every hallucinogenic *Psilocybe* species which has been investigated for its presence, although it is not always accompanied by detectable amounts of psilocin (4). Since psilocin is known to possess psychotropic activity following ingestion, *Psilocybe baeocystis* must be added to the ever increasing list of hallucinogenic mushrooms (5). It is the second such species whose reported distribution is restricted to the northwestern United States (3).

Book Notices

Précis de Microbiologie. Vol. 1, Technique Microbiologique Microbiologie Générale. By S. Lambin and A. German. Masson & Cie., 120, boulevard Saint-Germain, Paris VIe, 1961. viii + 458 pp. 16 × 21 cm. Price 39 NF.

Volume one of this series (in French) is divided into two parts: microbiological technique and general microbiology. It is intended for use as a textbook for pharmacy students. A general index is appended.

Microtechniques of Clinical Chemistry. 2nd ed. By Samuel Matelson. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. xv + 578 pp. 15 × 23 cm. Price $14.75.

New sections in this edition cover emission spectroscopy, automation, gas chromatography, and the theory and technique of the urea and creatinine clearance tests. The revised and expanded text is intended to make the book more suitable for use in teaching analytical clinical chemistry. Author and subject indexes are included.

Medicinal Chemistry. Vol. 5. Edited by Walter H. Hartung. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. vi + 432 pp. 14.5 × 23 cm. Price $18.

Volume five of this monograph series covers Anticonvulsant drugs and Bis(4-aminophenyl) sulfone and related compounds in tuberculosis and leprosy. The style and format of the earlier volumes are continued, and the objective to include in each chapter or monograph references to all the compounds that have been tested for a particular type of pharmacological activity still maintains. The extent of the work with anticonvulsants is indicated by the 1,113 references to publications and 16 pages of patents grouped according to chemical types. A general index is appended.

Structural Forms of Anesthetic Compounds. By Hugh S. Mathewson. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. xvi + 223 pp. 15 × 22.5 cm. Price $6.75

Intended as an introductory text, this book is based upon seminars on anesthetic drugs. The relation of structure-activity principles to the pharmacologic properties of drugs in clinical use by anesthesiologists is the frame upon which the subject is developed. An index is appended.

Progesterone and the Defence Mechanism of Pregnancy. Edited by G. E. W. Wolstenholme and Margaret P. Cameron. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. viii + 108 pp. 12 × 18.5 cm.

A compilation of the reports by the Ciba Foundation Study Group No. 9 in February 1961. A general index is included.

Biological Activity of the Leucocyte. Edited by G. E. W. Wolstenholme and Maeve O'Connor. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. viii × 120 pp. 12 × 18.5 cm.

A compilation of the reports by the Ciba Foundation Study Group No. 10 in March 1961. A general index is included.

The style and format of the earlier volumes are continued, and the objective to include in each chapter or monograph references to all the compounds that have been tested for a particular type of pharmacological activity still maintains. The extent of the work with anticonvulsants is indicated by the 1,113 references to publications and 16 pages of patents grouped according to chemical types. A general index is appended.

Structural Forms of Anesthetic Compounds. By Hugh S. Mathewson. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. xvi + 223 pp. 15 × 22.5 cm. Price $6.75

Intended as an introductory text, this book is based upon seminars on anesthetic drugs. The relation of structure-activity principles to the pharmacologic properties of drugs in clinical use by anesthesiologists is the frame upon which the subject is developed. An index is appended.

Progesterone and the Defence Mechanism of Pregnancy. Edited by G. E. W. Wolstenholme and Margaret P. Cameron. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. viii + 108 pp. 12 × 18.5 cm.

A compilation of the reports by the Ciba Foundation Study Group No. 9 in February 1961. A general index is included.

Biological Activity of the Leucocyte. Edited by G. E. W. Wolstenholme and Maeve O'Connor. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. viii × 120 pp. 12 × 18.5 cm.

A compilation of the reports by the Ciba Foundation Study Group No. 10 in March 1961. A general index is included.

examined chromatographically, essentially as described by Tyler (3). Solvent systems employed included water-saturated *n*-butanol, *n*-butanol:acetic acid:water (4:1:5), and *n*-propanol:1 *N* ammonia (5:1). In all three of these systems, a compound was detected by spraying with 2% *p*-dimethylaminobenzaldehyde in 1 *N* hydrochloric acid (blue-violet color) and with Pauly's reagent (orange-red color). It had an R_f value identical with reference psilocin and did not separate from that compound when spotted in admixture. Tryptophan was also identified on the chromatograms by its characteristic R_f value and the color formed with the *p*-dimethylaminobenzaldehyde reagent, but psilocybin could not be detected.

Failure to detect psilocybin is remarkable in that it is more stable than psilocin and has been found in every hallucinogenic *Psilocybe* species which has been investigated for its presence, although it is not always accompanied by detectable amounts of psilocin (4). Since psilocin is known to possess psychotropic activity following ingestion, *Psilocybe baeocystis* must be added to the ever increasing list of hallucinogenic mushrooms (5). It is the second such species whose reported distribution is restricted to the northwestern United States (3).

Book Notices

Précis de Microbiologie. Vol. 1, Technique Microbiologique Microbiologie Générale. By S. Lambin and A. German. Masson & Cie., 120, boulevard Saint-Germain, Paris VIe, 1961. viii + 458 pp. 16 × 21 cm. Price 39 NF.

Volume one of this series (in French) is divided into two parts: microbiological technique and general microbiology. It is intended for use as a textbook for pharmacy students. A general index is appended.

Microtechniques of Clinical Chemistry. 2nd ed. By Samuel Matelson. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. xv + 578 pp. 15 × 23 cm. Price $14.75.

New sections in this edition cover emission spectroscopy, automation, gas chromatography, and the theory and technique of the urea and creatinine clearance tests. The revised and expanded text is intended to make the book more suitable for use in teaching analytical clinical chemistry. Author and subject indexes are included.

Medicinal Chemistry. Vol. 5. Edited by Walter H. Hartung. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. vi + 432 pp. 14.5 × 23 cm. Price $18.

Volume five of this monograph series covers Anticonvulsant drugs and Bis(4-aminophenyl) sulfone and related compounds in tuberculosis and leprosy. The style and format of the earlier volumes are continued, and the objective to include in each chapter or monograph references to all the compounds that have been tested for a particular type of pharmacological activity still maintains. The extent of the work with anticonvulsants is indicated by the 1,113 references to publications and 16 pages of patents grouped according to chemical types. A general index is appended.

Review Article

Percutaneous Absorption

By MARTIN BARR

THE STUDY of the passage of medicinal substances through the skin offers a great challenge to research workers in the fields of pharmacy and dermatology. Although dermatological vehicles themselves may not penetrate the skin to any extent nor actually carry the medicament through the epidermal barrier, it is known that the clinical effectiveness of a drug may vary when it is incorporated in different vehicles (1). The choice of an optimum vehicle for a particular medicament depends on the physical and chemical properties of the drug alone and in the vehicle as well as the nature of the skin condition being treated. Much information has been gained on this subject in the last few years but much more is needed in order to treat the various skin disorders encountered with maximum effectiveness.

Intelligent formulation of dermatological preparations depends on a thorough understanding of percutaneous absorption. Although recent studies have led to a better understanding of this phenomenon, there are many uncovered facets concerning its mechanism. This paper serves as a review of studies made in the field of percutaneous absorption. Space limitations make it impossible to summarize every work in the field but an attempt has been made to review those which appear to be most significant to its understanding.

Before going further, it is appropriate to define the term "percutaneous absorption." Rothman (2) defines percutaneous absorption as the penetration of substances from the outside into the skin and through the skin into the blood stream. As the literature in this field is studied, it is found that many terms have been employed: namely, absorption, sorption, persorption, permeation, and penetration. As Blank (3) has stated, it is actually not necessary to define the term "percutaneous absorption" with great accuracy but it is of greater importance to know how molecules move into the skin from a unit area of cutaneous surface in a unit of time, and where these molecules go after leaving the skin surface.

MECHANISM OF PERCUTANEOUS ABSORPTION

The modern concepts of percutaneous absorption are relatively new, especially when compared to the long history of preparations used for application to the skin. The earliest records of the use of fats and oils as vehicles for cosmetics and medicaments date back to the early records of Babylonian and Egyptian medicine (4). Broadly sketching the historical views and experimentations, one finds that the subject may be divided into three periods: (*a*) the period antedating 1877 and covering 100 years, during which much of the evidence was accepted as indicating that a large number of substances, chiefly gases and volatile substances, penetrated the skin freely; (*b*) the period extending from 1877 until 1900, during which Fleischer's school of thought held forth, in which Fleischer and his collaborators concluded from their experiments, and a critical appraisal of the older observations, that the skin of man and higher animals was absolutely impermeable to all substances (5); and (*c*) the period from 1900 to the present, the first few years of which saw the decline of the absolute impermeability theory, chiefly under the impetus of Schwenkenbecher's work (6).

Received from the Department of Pharmaceutics, College of Pharmacy, Wayne State University, Detroit, Mich.

Despite the voluminous literature in the field, there is as yet very little agreement on the basic mechanism which is largely responsible for percutaneous absorption through intact skin. One group of investigators is of the opinion that the major role of entry for medicaments is directly through the intact epidermis (transepidermal route). Another group believes that most absorption takes place through the appendages, either through the pilosebaceous apparatus or the spiral sweat glands. There is evidence that indicates it is likely that all these avenues take part in the transfer of substances through the skin (7). No attempt will be made in this review to resolve this controversy. It is very likely that a specific substance may prefer one avenue to the other, depending on the many factors which will be discussed later in this paper.

Before reviewing the work that has been done on the mechanism of percutaneous absorption, it is appropriate to consider briefly the anatomical zones a penetrating substance meets in transit from the skin surface to the blood vessels (Fig. 1). In order, it encounters a surface film of emulsified lipids, the stratum corneum (horny layer), the barrier, the stratum germinativum (living epidermis), and finally the dermis (true skin) and blood vessels. Other avenues of penetration through the skin are shown diagrammatically in Fig. 2.

Transepidermal Absorption.—Mali (8) states that the pathway through the epidermis is much more likely the main avenue of penetration for substances than are the sebaceous glands or sweat glands, simply because the epidermis presents a surface area 100 or 1,000 times greater than the other two.

Various anatomical zones of the skin behave differently with regard to transepidermal absorption (9). The film on the surface of the skin is composed of sebum, sweat, and desquamating horny layer, and has a complex chemical composition. The character and extent of its interaction with the penetrating agent are unpredictable. This surface film is discontinuous and offers relatively little resistance to a penetrating molecule (9).

The horny layer, which is 20 to 40 μ in thickness, is composed largely of keratin, a sulfhydryl containing protein which adsorbs a large amount of water and other polar compounds. It also contains surface lipids which may spread along the channel walls between cells and adsorb lipid-soluble material. In other words, the horny layer may act as a sponge, becoming a reservoir for the penetrating agent and maintaining a maximum concentration gradient just above the barrier, thus possibly hindering penetration. This is especially true for ions and dyes of low molecular weight. Blank and Gould (10), using an autoradiographic technique, have shown that ionic surfactants tagged with S^{35} are bound by the horny layer and often do not penetrate beyond the orifice of the hair follicle (9).

The barrier zone was originally demonstrated by Rein (11) who reported that it was located between the horny layer and granular layer underlying it and that it was an electronegatively charged barrier which repelled anions and attracted and held cations for further penetration. Rothman (12) reported that the barrier layer checked the transfer of water across the skin. Blank (13) showed graphically that the barrier to water transfer in skin is a layer a few microns thick at the base of the stratum corneum. He used the plastic tape stripping method of Wolf (14) and Pinkus (15) to remove the horny layer gradually. He found that the diffusion of water through skin remained low until the base of the horny layer had been stripped away; thereafter the permeability to water rose sharply. In 1951 Szakall (16) reported that after the horny layer had been stripped off with tape, the entire barrier could be removed on Tesa tape in a single stripping. Subsequently he recovered the barrier layer by dissolving the tape in petroleum ether. Mali (8) isolated the barrier utilizing another method in 1955.

The barrier layer is 10 μ thick and prevents the penetration of molecules having molecular weights greater than 200 or 300 (17); yet the diameter of the pores in the material in the intercellular spaces in the barrier is much larger than the largest penetrating molecule. Thus, the restraining force must be the molecular interaction between penetrant and pore contents. If the substance has a high electrostatic charge, e.g., ions, the attraction is so great that no penetration occurs. If the substance has a water-lipid partition coefficient of about 1.0, it has the highest permeability; the barrier must then have both polar and nonpolar groups in the pore contents (9).

The few molecules which do penetrate the barrier layer are either bound by the living epidermis or the dermis, or carried away by the tissue fluids to the lymphatic and blood vessels. The electron-dense zone which is present at the junction between the epidermis and the dermis offers little resistance to the penetrating molecules (9).

Blank, Griesemer, and Gould (18) have pub-

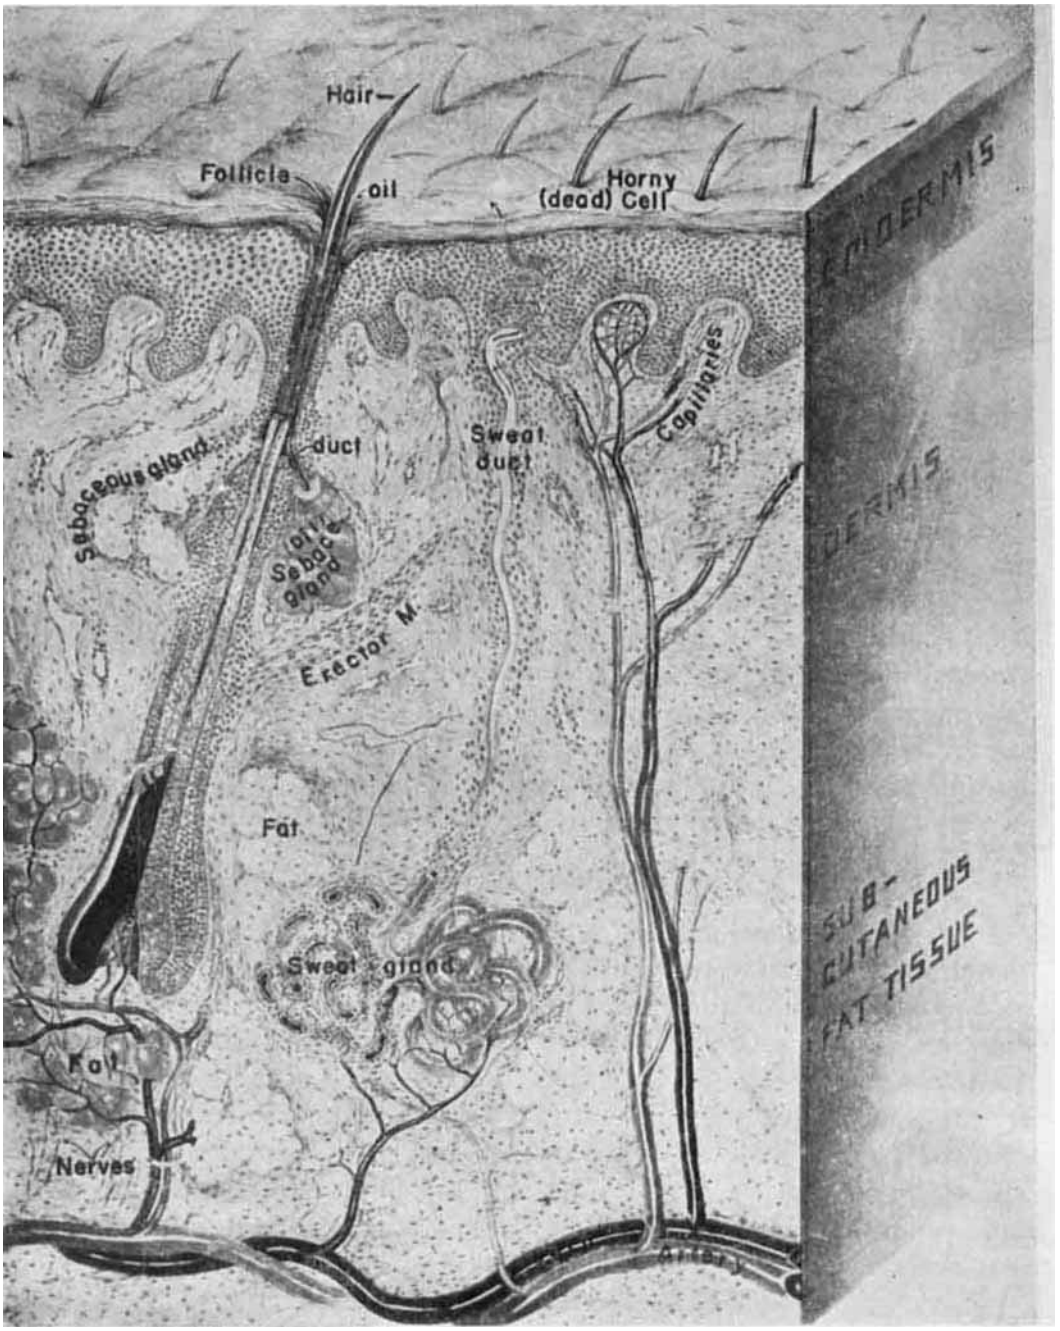

Fig. 1.—Anatomical zones encountered by a penetrating substance in transit from the skin surface to the blood vessels [from Griesemer, R. D., *J. Soc. Cosmetic Chemists*, **11**, 80(1960)].

lished autoradiograms of rabbit skin which had been exposed to the anticholinesterase agent, sarin, tagged with P^{32}. These indicate that penetration occurred through the transepidermal route. A similar route of penetration was described for hydrocortisone by Scott and Kalz (19).

It appears to be true that the ratio of the solubilities in water and in lipids, as originally advocated by Meyer and Overton, is actually important for the absorption of substances through the skin. Rothman (12) has shown that lipid-soluble substances penetrate the skin more readily than polar substances, and that substances soluble in both lipids and water penetrate most rapidly of all. Treherne (17) obtained quantitative data on the permeability of excised human skin to a series of radiotagged substances. He showed

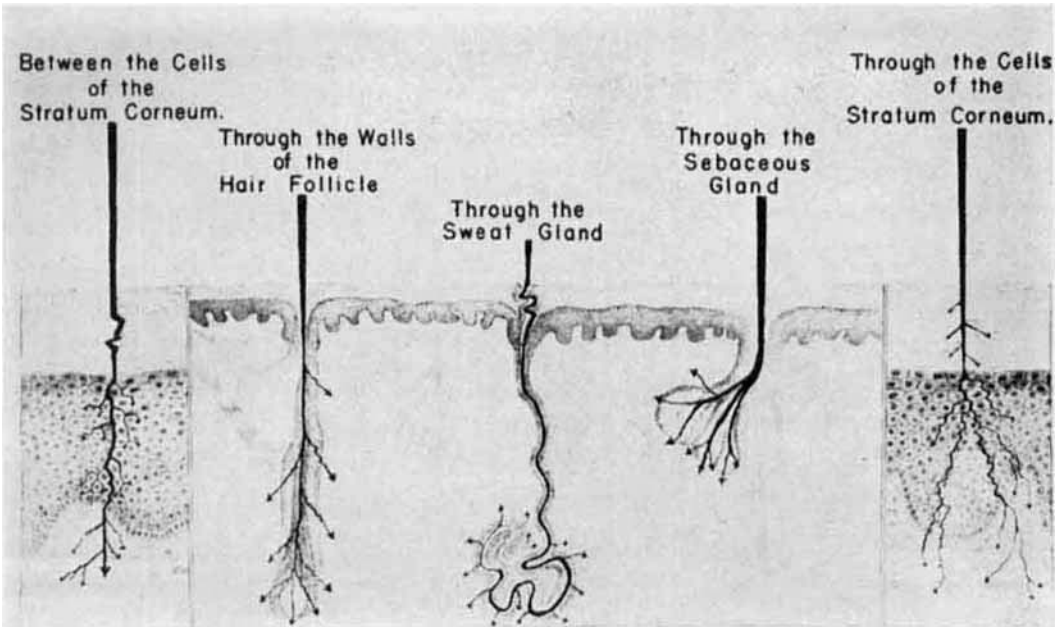

Fig. 2.—Possible avenues of penetration into and through the unbroken skin [from Griesemer, R. D., *J. Soc. Cosmetic Chemists*, 11, 81(1960)].

conclusively that the permeability of skin is directly proportional to the ether/water partition coefficients of these substances.

Absorption Through Appendages.—Hair follicles and sweat gland ducts open on the surface of the skin in the form of visible pores and these are believed to be avenues for the passage of medicaments through the skin. As has been previously stated, a majority of investigators believe that the hair follicles are the major avenue for percutaneous absorption.

Pilosebaceous Apparatus.—There are many studies which have shown the prominent role of the pilosebaceous apparatus in percutaneous absorption. This concept takes into consideration the solubility of the drug in sebum.

In the upper portion of the follicular canal, the hair shaft does not adhere to the follicular wall, and therefore a space is formed which is filled with horny scale and air. This interspace is continuous with the duct of the sebaceous gland. The sebum from this duct eventually empties into the interspace (20). Therefore, any medicament possessing a solubility in sebum may penetrate this space and reach inside of the sebaceous gland whose membrane is more permeable than the epidermal barrier. Similarly, the wall of the follicular sheath is less resistant to penetration than the surface epidermis. From the sebaceous glands and hair follicles, medicaments may penetrate downward into the corium and from there into the blood, thus bypassing the barrier. Medicaments may also move upward from the sebaceous glands into the epidermis but without penetrating the barrier layer. This pathway of absorption was demonstrated by MacKee, *et al.* (21), and by other workers (22, 23) who detected the presence of various tracers in the deeper parts of the hair follicles and in the sebaceous glands.

Sweat Ducts.—There is much controversy as to whether the sweat ducts serve as an avenue for percutaneous absorption. Rein (24) reported that he observed the staining of the pores of sweat ducts, like those of follicles, when he introduced dyes into the human skin by electrophoresis. Ichihashi (25) postulated that this "pore pattern" indicated absorption of the dye through the sweat ducts. Abramson, *et al.* (26–28), agreed with Ichihashi's conclusion and found the development of the sweat pore patterns dependent on the electric charge of the skin. On the other hand, Flesch (29) could not demonstrate penetration of dye into sweat ducts. Other studies (30–32) militate against any substantial penetration or percutaneous absorption through the palms and soles, which possess a predominance of eccrine sweat glands.

FACTORS INFLUENCING PERCUTANEOUS ABSORPTION

There are many factors which are thought to influence the rate and extent of percutaneous absorption. These will be discussed in this section.

Condition of the Skin.—The routes which a medicament may take in its passage through the intact skin have been discussed previously. If the skin is in an abnormal state, the limitations placed on the penetration of a medicament do not apply. If the barrier is destroyed by trauma, as in cuts, chapping, ruptured blisters, or in eczema, all substances pass freely into the dermis (9). Blank, *et al.* (18), have demonstrated by autoradiography that there is a striking increase in the penetration of sarin tagged with P^{32} following a superficial scratch extending just barely through the barrier. Similar data were obtained from trauma by adhesive tape stripping and puncture wounds.

Shelmire (33) pointed out that the vehicle of a topical preparation assumes more importance when the stratum corneum is intact and that differences in drug penetration attributable to the vehicle are more pronounced. On abraded or diseased skin there may be a large increase in both rate and extent of absorption of a drug in a vehicle (33).

It may be shown experimentally that the percutaneous absorption of materials coming in contact with the skin is significantly reduced in old age (34). This may be due in part to the atrophic changes of the pilosebaceous apparatus through which such substances are absorbed. It is a clinical fact that sensitization reactions to contactants are less commonly encountered in the older patient. In addition to lowered absorption, there may be a decreased capacity to form antibiotic conjugates in the skin or to form circulating antibodies.

Thermodynamic Properties of the Medicament.—The importance of the thermodynamic properties of a medicament as it relates to its percutaneous absorption has been discussed by Higuchi (35). These include the thermodynamic activity of the drug in the vehicle and in the skin barrier phase, and the diffusion coefficient of the drug in the vehicle and skin barrier phase.

Assuming that the vehicle containing the penetrating substance does not appreciably affect the skin, the following approximate relationship was set by Higuchi for an idealized system

$$\frac{dq}{dt} = (P.C.)\frac{(\text{concn. of drug})\,DA}{L} \qquad \text{(Eq. 1)}$$

where $(P.C.)$ is the effective distribution coefficient of the penetrating medicament between the vehicle and the barrier of the skin; (concn. of drug), the concentration of the medicament in the vehicle; D, the effective average diffusivity of the medicament in the barrier phase; A, the effective cross section area; and L, the effective thickness of the barrier phase. The main characteristics of the penetrating agent which determine its rate of entry through the skin, according to this equation, are its effective distribution coefficient and diffusivity in the barrier phase. The product of these two is referred to as the "permeability constant."

Actually, the important variable in the permeability constant of Higuchi is the effective distribution coefficient factor since the diffusivity of a substance of similar molecular weight and shape usually differs only slightly. The distribution coefficient, on the other hand, is an extremely sensitive function of molecular structure and size (35). Rothman (36) also emphasized the importance of the distribution coefficient of a penetrating substance between its vehicle and a membrane and between a membrane and its receptor solution on permeability. It depends chiefly on the force of molecular interaction between membrane and penetrating molecule. A substance can easily enter a membrane when the partition coefficient (membrane/vehicle) is high; it cannot easily leave the membrane when the partition coefficient (receptor solution/membrane) is low. In complex structures such as the skin, where the membrane may be nonpolar and the receptor-tissue fluids polar, a substance whose partition coefficient between polar and nonpolar solvents is nearly 1.0 will have the highest penetration rate. Thus, permeability is more rapid if there is some, but not too much, affinity between a penetrating molecule and a membrane. Under these conditions, the membrane will attract the penetrating molecule, but not so strongly that it fails to release it on the other side.

Higuchi (35) expressed Eq. 1 in another form in terms of the thermodynamic activity of the penetrating agent in its vehicle

$$\frac{dq}{dt} = \frac{A}{\gamma}\frac{DA}{L} \qquad \text{(Eq. 2)}$$

where a is the thermodynamic activity of the drug in its vehicle and γ is the effective activity coefficient of the agent in the skin barrier phase. Equation (2) shows the role of the activity of the drug in its vehicle while the properties of the base itself seem to play no part. For such systems the rate of percutaneous absorption measured for different ointment bases would be approximately constant provided the thermodynamic activity of the drug in the vehicles was maintained constant. Thus, all ointments containing finely ground suspensions of the drug

(thermodynamic activity equal to that of the solid drug) will produce the same rate of penetration. This again presupposes that the rate-determining step is essentially in the passage of the barrier phase. Since activities are more important than any absolute concentration, it is obvious that, for a given concentration of a penetrating substance, vehicles which have lower affinity (poorer solvent power) will normally produce faster penetration (35). For additional discussions on the absorption of medicaments from suspension and solution, readers are referred to works by Higuchi (35) and Wagner (37).

Effect of Moisture.—There are two opposite views on the influence of moisture on percutaneous absorption (38). Based on the concept that the skin is relatively impermeable to water, one school assumes that moisture on the outside has little to do with promoting percutaneous absorption. On the other hand, since it has been a long-standing clinical experience that watertight covering of the skin surface does influence percutaneous absorption, another school believes that moisture is a most important factor in promoting the passage of medicaments through the skin.

Renshaw (39) and Cullumbine (40) reported that much more severe lesions develop on human skin if mustard gas and nitrogen mustard gases are applied to wetted skin than to dry skin. Their work was interpreted by some to indicate that moisture plays an important role in promoting skin penetration. However, it is known that, in contact with water, mustards transform to various highly soluble, reactive, and toxic intermediary products before the inactive end products of the water-mustard reactions are formed (41, 42), and these may be responsible for the production of the severe lesions.

Laug, *et al.* (43), demonstrated that increased moisture promotes transfollicular absorption. They found that the absorption of mercury is increased fourfold by covering the site of inunction. It was assumed that the cover acts by interfering with the normal loss of moisture. Shelley and Melton (44) found that the application of histamine solution to the skin produced a prolonged effect when the site was covered, a result also probably due to the inhibition of water evaporation. Leslie-Roberts (45) concluded that moisture causes maceration of the horny layer and, therefore, provides a condition promoting the retention of substances in contact with the skin.

Recent work has more definitely established the importance of moisture in promoting percutaneous absorption. Higuchi (35) has stated that the transfer properties of several layers of the skin are probably strongly influenced by the presence of water since it is well sorbed by protein and protein degradation products contained in the outer skin. He demonstrated this type of behavior using artificial membranes. He has shown experimentally that, at very low humidity, the permeability of glyceryl monostearate is relatively insensitive to relative humidity, whereas near 100%, the rate of penetration is actually dependent on water activity. This is attributed to imbibition of water by the barrier phase exposed to saturated water vapor and consequent changes both in the diffusion coefficient and activity coefficient. Wurster and Kramer (46), investigating the absorption of three salicylate esters, demonstrated that a large increase in its absorption rate was produced by increased moisture conditioning. They assumed that percutaneous absorption involves a diffusional process, i.e., the spontaneous movement of a substance from an area of high concentration to an area of low concentration in the tissue fluids. They concluded that the magnitude of the effect of moisture on percutaneous diffusional rates has been shown to be proportional to the oil/water distribution coefficient and the water solubility of the test substance. The greatest increase of the penetration rate by moisture was found in the penetrant with the smallest oil/water distribution coefficient.

Shelmire (33) stated that hydration of the stratum corneum is one of the most important factors in the penetration of skin by a medicament. The hydration of the stratum corneum appears to increase the rate of passage of all substances which penetrate the skin. He (33) suggested that the mechanism was to increase the size of the pores. There will not only be a physical alteration of the tissue due to hydration but also at high water activities there will be changes in both the diffusion coefficient and activity coefficients of the penetrating agent (35). Shelmire (33) believes that the nature of the vehicle upon application and, when the water in it has evaporated, may markedly alter the activity of water in the stratum corneum.

Greases and oils are the most occlusive vehicles and induce the greatest hydration through sweat accumulation at the skin-vehicle interface (33). Emulsions of the water-in-oil type are somewhat less occlusive than greases (33). Oil-in-water emulsions tend to invert as the outer aqueous phase evaporates, and the final state may be considered to be a continuous oil film, containing other dissolved or suspended substances (33).

Humectants in such emulsions tend to decrease the extent of hydration of the stratum corneum by interference with the formation of a continuous oil film on the skin surface (33). Water-soluble vehicles produce the least change in hydration of the stratum corneum (33). Hydrophilic powders will decrease the extent of hydration by increasing surface area and, hence, increasing the rate of evaporation of water (33). Hydrophobic powders probably cannot retain moisture because they form a discontinuous film (33). All powders probably tend to interfere with the continuity of oil films and, in this manner, probably decrease the occlusive effect of any vehicle in which they are used (33). It should also be remembered that if an ointment is covered with a bandage there will be a tendency to hold perspiration and increased hydration; if left open to the air the perspiration can evaporate and hydration may occur (33). The thickness of the applied film of topical preparation will also directly affect hydration of the stratum corneum (33).

Effect of Vehicles.—There have been many studies on the role that a topical vehicle plays in the percutaneous absorption of drugs but until recently this subject has been somewhat in a state of confusion. This has been due in part to deficiencies in many of the methods used for measuring the extent of percutaneous absorption and to a lack of consideration of the thermodynamics involved in the interpretation of results. The thoughtful discussions by Higuchi (35), Shelmire (33), and Wagner (37) have clarified many aspects of this subject. They have thrown new light on the results obtained by workers in the field and indeed on the entire subject of percutaneous absorption.

It has been thought by a majority of workers in the field that the function of the vehicle in percutaneous absorption is to facilitate contact between the medicament and the absorbing cells. Absorption is best from vehicles which spread easily over the skin surface, readily mix with the sebum, and so bring the medicament into contact with the absorption cells. It was believed at one time that the primary factor influencing penetration through the skin was the vehicle itself. Thus the subdivision of ointment bases into epidermic, endodermic, and diadermic types became popular (47). It gradually became apparent that the thermodynamic activity and the diffusion coefficient of the medicament in the vehicle and skin barrier phase (35), the thermodynamic activity of moisture in the vehicle and skin barrier phase (35), and the degree of hydration of the skin (33) were of greater significance in influencing percutaneous absorption. It is believed that the vehicle itself is not capable of promoting the absorption of nonabsorbable drugs dispersed in it, but rather may modify the absorption properties of absorbable drugs (48).

In this section, some of the studies on the effect of vehicles on the percutaneous absorption of medicaments will be reviewed.

It has long been known that absorption of medicaments is better from animal and vegetable oils than from mineral oils because they readily penetrate the skin (49–51). Organic solvents like ether, chloroform, benzene, and acetone penetrate the skin with ease (52) and enhance the percutaneous absorption of a drug (53) to such an extent that toxic effects can occur. On the other hand, it has been demonstrated that defatting the skin with ether decreased the absorption rate of methyl salicylate (46). Higuchi (35) stated that the application of many solvents other than water appears to cause marked alteration in the resistance of the skin barrier toward penetration and that this phenomenon is possibly caused by marked changes produced by such solvents in the activity coefficient and diffusion constant of the penetrating agent in the skin barrier.

Strakosch (54) concluded from his histological studies that emulsion type bases do not have any effect on the degree of percutaneous absorption of salicylic acid. In contrast, results obtained from patch tests (1, 55), and analyses of urine (56, 57), and blood samples (58) obtained after topical application of ointment vehicles containing salicylic acid indicated differences in absorption from various emulsion-type bases. Similar contradictory results may be noted in percutaneous absorption studies of ointment vehicles containing sulfonamides (59–63).

Nogami, *et al.* (64), stated that the influence of the ointment base on the percutaneous absorption of salicylic acid was not great but that its absorption from hydrophilic ointment was less than from soft paraffin, simple ointment, and absorption ointment.

Bourget (65) and Kimura (66) made a quantitative study of the effect of different fatty bases on the percutaneous absorption of salicylic acid as judged by excretion of the drug. It was found that salicylic acid was rapidly absorbed and the amount depended on the vehicle; the ones giving the greatest absorption being lard and lanolin; the least effective, petrolatum.

Many workers have reported that the type of vehicle is of importance in the absorption of

mercury (22, 43, 67–69). However, Sollmann, *et al.* (70), have contradicted these reports.

Using radioactive iodine (71), radioactive sodium iodide (72), and potassium iodide (73), several investigators concluded that these substances appear to be more efficiently absorbed from wool fat than from lard. A difference in the type of emulsion vehicle had practically no effect on the absorption of the iodide.

Oil-in-water emulsions as well as water-soluble vehicles deserve special mention because of the claims that they would promote percutaneous absorption of drugs due to either the presence of surfactants or their water-miscible properties (43, 74). Eisner (75) demonstrated that a continuous oil phase would tend to reduce percutaneous absorption, a fact contradicted quite recently by the work of Gemmell and Morrison (60). There is no doubt, however, that a continuous water phase would be miscible with the secretions of the denuded and oozing surfaces of the abraded skin, and thereby promote the release of the medication. This was demonstrated by Zeutlin and Fox (76) who concluded that the release from water-soluble and oil-in-water type vehicles was far superior to the release from oleaginous and water-in-oil type vehicles. Strakosch and Clark (61) and Laug, *et al.* (43), supported with their experiments the theory of superiority of emulsion-type vehicles to oleaginous vehicles; they could not, however, show a significant difference in absorption for oil-in-water or water-in-oil emulsion vehicles while working with mercury (43) and sulfonamides (61). In contrast to this, a superiority of a water-in-oil vehicle to an oil-in-water vehicle was demonstrated by Gemmell and Morrison (60) who studied the absorption of sulfonamides.

It should be remembered that a great majority of percutaneous absorption studies have been carried out on animals. There may be a considerable difference in the rate and extent of absorption of a given drug in various species of animals and in man. The use of many types of test subjects is a further reason why results obtained from percutaneous absorption studies are somewhat confusing.

Effect of Surfactants.—Surfactants offer possibilities of improving topical vehicles and promoting a more thorough diffusion of the medicament from the vehicle, thus influencing therapeutic performance (77–78). Sweet (79) suggested that the mode of action for surfactants was that they are capable of emulsifying the sebum and, therefore, increase percutaneous absorption in this manner.

Duemling (74) reported that deeper and more rapid penetration of ammoniated mercury is obtained by the addition of a wetting agent to a paraffin ointment base. Meyers, *et al.* (80), investigated the absorption of potassium iodide and of phenolphthalein from various ointment bases through the intact skin of albino rats. They found no promoting action to be produced by the wetting agent, sodium tetradecyl sulfate.[1] MacKee (30) demonstrated penetration through intact skin of ferric chloride, bismuth (sobisminol), and sulfonamide from a series of topical vehicles called "penetrasols." These bases are composed of propylene glycol, antipyrine, xylene, and sulfonated wetting agents of the fatty acid esters of sulfosuccinic acid type. Shelley and Melton (32) confirmed the fact that these vehicles promote the percutaneous absorption of water-soluble drugs. In addition, they demonstrated that absorption occurred only from areas containing hair follicles. By analyzing the liver and kidneys of rats for mercury, Laug, *et al.* (43), compared the absorption of mercury from various ointment bases, some of which contained a surfactant, and found a significant increase in percutaneous absorption from the vehicles containing these agents. Duemling (74) demonstrated rapid and complete penetration of mercury from vehicles containing sodium lauryl sulfate. The incorporation of cholesterol in liquid petrolatum seemed to increase the penetrating powers of the vehicles (81), but the application of cholesterol to the skin appeared to reinforce the resistance of the fatty substances normally present in the skin and, therefore, reduced the percutaneous absorption of water-soluble drugs (82).

Stolar, Rossi, and Barr (83) detected a marked reduction in the percutaneous absorption of salicylic acid in hydrophilic ointments as the concentration of surfactants having polyoxyethylene groups was increased. They concluded that this is due to the complexing of the salicylic acid by the polyoxyethylene groups, i.e., salicylic acid has a low thermodynamic activity in these vehicles.

Stark, *et al.* (84), studied the influence of the nature of the surfactant in ointment bases on the release of various substances using an *in vitro* technique utilizing a membrane. Radioactive mercuric (Hg^{203}) and iodide (I^{131}) ions were incorporated into hydrophilic ointments emulsified with various concentrations of anionic, cationic, and nonionic surfactants. It was found

[1] Marketed as Tergitol 4 by Union Carbide Chemicals Co., 270 Park Ave., New York 17, N. Y.

that the ionic or nonionic nature of the surfactants substantially influenced the release. The nonionic-type surfactants promoted the release of both the iodide and mercuric ions to a greater extent than did the anionic or cationic types. Vinson and Choman (85) investigated the relative effects of surfactants on the cutaneous penetration of nickel sulfate through the skin of guinea pigs. They found that whereas the nickel sulfate did not penetrate when applied alone, sodium lauryl sulfate and sodium dodecyl benzyl sulfate did provoke its penetration.

Effect of Concentration of Medicament.—Strakosch and Clark (61) reported that increasing the concentration of sulfonamide from 1 to 10% in the vehicle caused no increase in their absorption when applied to the skin. It was similarly demonstrated by Laug, *et al.* (43), that the concentration of mercury in different ointment vehicles has very little effect on the degree of percutaneous absorption.

Higuchi (35) emphasized the role of concentration of a drug on its rate of absorption from a suspension-type ointment. He presented the following equation

$$\frac{dQ}{dt} = \sqrt{\frac{ADC_s}{2t}}$$

where A is the concentration of the drug expressed in units/cm.^{3}; C_s, the solubility of the drug as units/cm.^{3} in the external phase of the ointment; D, the diffusion constant of the drug molecule in the external phase; and dQ/dt, the rate of absorption. He concluded that the rate of release of drugs from such preparations can be regulated by controlling A, D, and C_s.

Effect of pH.—The rates of absorption of acidic and basic drugs are strongly influenced by the effective pH of the vehicle (35). The activity coefficient of the molecular form of such drugs is a rapidly changing function of pH for pH values greater than pKa for acidic compounds and less than pKw-pKb for alkaloidal drugs. Thus, as Higuchi states (35), the rate of absorption of histamine would be 10 times greater from a base buffered at pH 7.5 than from a base at 5.5, assuming that only the nonionized molecule is involved in the absorption process.

Bhatia and Barber (86) evaluated the effect of pH on the local anesthetic activity of benzocaine by measuring the pain threshold. They concluded that the maximum local anesthetic activity appeared to occur between the pH of 6 and 7, and decreased when the pH was varied. This was substantiated by Roques, *et al.* (87). Other workers (66, 88) concluded that systemic alkalosis increased the percutaneous absorption and excretion rates of various drugs while systemic acidosis decreased the rate of percutaneous absorption and excretion.

Miscellaneous Factors.—Other factors which influence the rate and extent of percutaneous absorption of medicaments include: the route of absorption (33, 35); the area to which the drug is applied (33, 35); the effective thickness of the skin barrier phase (35); and the individual contact time and frequency of reapplication (33).

It is well known that the elevation of skin temperature enhances percutaneous absorption. This may be due to a lowering of the viscosity of the sebum which would facilitate its mixing with the inuncted preparation. Furthermore, a rise in skin temperature also increases the cutaneous circulation through vasomotor dilation of the skin vessels. Blank, *et al.* (89), reported that the rate of penetration of sarin increases approximately twofold for a 10° rise in temperature. And finally, Higuchi (35) pointed out that the diffusion coefficient of a medicament, D, is inversely proportional to the viscosity of the vehicle.

METHODS OF MEASURING PERCUTANEOUS ABSORPTION

The results obtained by the various investigators who have studied the percutaneous absorption of drugs have been, for the most part, quite contradictory, probably due to inadequate and in many cases uncontrolled measuring procedures. There have been several excellent papers published in recent years in which the methods of measuring percutaneous absorption have been reviewed (3, 90–92).

Some authors classify the methods employed in measuring percutaneous absorption into *in vitro* and *in vivo* procedures. *In vitro* methods are of limited value but they are a means of assessing the ability of a vehicle to liberate the medicament under the conditions of the test. However, these methods can be, for the most part, dismissed as being quite useless in providing reliable information on percutaneous absorption. On the other hand, *in vivo* methods give a more accurate picture of percutaneous absorption, although the results obtained from such methods are often confusing.

Blank (3) has proposed a new classification of the various methods which have been used in studying percutaneous absorption. His classification will be used in this review.

Penetration into Models.—All measuring methods using models are of the *in vitro* type. They are of limited value but they are a means of assessing the ability of a vehicle or base to liberate medicament under the conditions of the test. Those reported are of a comparative nature and most are empirical, which prevents results from being compared with those from other techniques. Lockie and Sprowls (93) hold that the study of ointment bases by *in vitro* methods is essentially a study of diffusion rates.

The most common model which has been used to simulate skin is agar gel. It has been commonly used in studying the release of antibacterial agents from ointment bases. It has been too often assumed that those ointment bases which best release antibacterial agents to an agar gel will similarly release these substances to the skin when the ointments are placed on the skin. This is not so since the continuous phase in agar gel is water, and the skin is a much more complex chemical and physical structure.

Membranes composed of cellulose film (94) and sheep's bladder (95) have also been employed as skin models in *in vitro* procedures. While the assumption is made that the process of penetration in the skin is similar to the quantitative diffusion through a membrane, this does not make any allowance for differences in physicochemical properties of "dead membranes" and living tissue, the latter presenting a much more complex system, both physically and chemically.

Histological Studies.—A variety of procedures under this heading has been adopted to evaluate drug release from vehicles. Strakosch (96) has studied the penetration of salicylic acid, sulfur, resorcinol, and other substances by examining histological sections for evidence of keratolysis. No effort was made to measure such penetration quantitatively. Duemling (74) also utilized histological studies to measure the absorption of medicaments. Goldzieher, *et al.* (97), used histologic sections in their study of the penetration of estrogen. Histological studies made by Sobel, *et al.* (98), indicated that vitamin A is absorbed and utilized by the skin.

Use of Tracers.—Dyes and fluorescent materials have been utilized for a long time in percutaneous absorption studies. In recent years use has been made of radioactive substances as tracers in such studies.

Dyes.—One of the early methods used for studying penetration of substances into skin employed an oil-soluble dye to color the material being studied (99–102). Histological sections of the skin were then examined for the presence of dye. This method is subject to much criticism as one cannot be certain that the dye remains with the substance whose penetration is being studied.

Fluorescent Compounds.—The use of fluorescent compounds (100, 103) in penetration studies is open to the same criticism as those in which a dye is used as a tracer. One cannot be sure that the fluorescent material remains with the substance whose penetration is being studied. This objection is not valid if the penetrating substance itself is fluorescent.

Radioactive Tracers.—The use of radioisotopes has become increasingly popular for studying percutaneous absorption (104). In such procedures an attempt is often made to synthesize the substance being studied so that it includes a radioisotope. Sometimes the molecular structure of the penetrating substance is modified somewhat by incorporation of the radioactive element, as for instance in the iodination of an unsaturated fat with I^{131} (100). Most of the percutaneous absorption studies involving the use of radioactive tracers are carried out by one of the following techniques: (*a*) direct counting at the surface; (*b*) autoradiographic technique; and (*c*) measurement of the radioisotope within the body.

The direct counting technique is performed by counting the amount of radioactivity on a given area of the surface of the skin by using an end window Geiger tube if the substance under study is an alpha- or beta-emitter of sufficient intensity. One such investigation (105) involved the application of 0.005 ml. of an alcoholic solution of thorium X, with an activity of approximately 2,000 disintegrations per minute, to four areas on the forearm. The activity on each of these areas was counted with an end window tube immediately following the application of the solution and 24 hours after application. The loss in activity represented the amount of thorium X which was absorbed. Ainsworth (92) described a method for studying percutaneous absorption of a radioactive compound by following its disappearance from the skin surface.

Autoradiographic technique, first developed by Axelrod and Hamilton (106), is a very useful procedure for demonstrating the penetration and localization of radioactive materials providing they emit alpha and beta rays. In order to prepare an autoradiogram, a biopsy must be made and tissue sections cut for transfer to nuclear track emulsions. The particular tech-

nique which is used will be determined by the type of radiation, the half-life, and the solubility of the radioactive isotope being studied. The penetration of thorium X (7, 107) and sarin (18) have been studied by this method and it was found that the penetration of the first is by way of the appendages and the penetration of the second is primarily transepidermal. Choman (108) has reported on an improved autoradiographic technique in which he measured the percutaneous absorption of sodium lauryl sulfate (S^{35}) and nickel chloride (Ni^{63}). An investigation of the pathways of absorption of hydrocortisone (C^{14}) free alcohol was carried out by the technique of autoradiography by Scott and Kalz (19).

In working with autoradiography one should be familiar with the following pitfalls. When a radioactive element that emits high energy radiation is being used, there will be a considerable scatter on the autoradiogram. Secondly, reducing substances in the tissues may react chemically with the emulsion and produce a shadow even when no radioactivity is present. Third, a shadow may be produced in the autoradiogram even when no radioisotope is present if the tissue and photosensitive emulsion are on separate slides which, during exposure, are clamped tightly together.

Percutaneous absorption has been studied by measuring the concentration of a radioactive substance which has been absorbed in the blood, urine, expired air, thyroid gland, and hair.

Hadgraft, *et al.* (109), have studied percutaneous absorption in rats by measuring the concentration of diiodofluorescein (I^{131}) in the blood. Hupf, Chase, and Barr (110) studied the effect of various ointment bases on the percutaneous absorption of salicylic (carboxyl C^{14}) acid through intact rabbit skin by measuring blood concentrations of the radioactive substance.

Goldzieher and Baker (111) investigated the absorption of estradiol 17-β (H^3) and progesterone (C^{14}) through the skin of guinea pigs by measuring the concentrations of the radioactive substances in urine. Hellman, *et al.* (112), Malkinson and Ferguson (113), Livingood (114), and Malkinson, *et al.* (115), studied the percutaneous absorption of topical corticosteroids (C^{14}) through human skin by measuring the concentrations of the radioactive substances in the urine.

Lange and Evans (116) applied an ointment containing radon to patients and the amount of radon in the expired air was taken as a measure of the amount passing into the bloodstream.

Cyr, *et al.* (117), and Skauen, *et al.* (72), studied the effect of ointment bases on the absorption of sodium iodide (I^{131}) through the skin of rats by measuring the concentrations of the radioactive substance in thyroid glands which were removed from the animals.

Edwards (118) has studied the absorption of topically applied amino acids in guinea pigs using methionine (S^{35}) by measuring the concentration of radioactive material in newly grown hair.

Measurement of Physiological Reactions.—The percutaneous absorption of certain drugs in ointment form has been studied making use of their pharmacological effects or end points. Those which have been used include a rise in blood pressure (119), measurement of vasodilation (120), red tear response (121), production of anesthesia (122), reduction in pain threshold (123–125), production of convulsions (126), production of urticaria (127, 128), vasodilation (129), and death (122, 129).

The effect of passage of hormones through the skin has been the subject of wide research; a few of the many references will be quoted. Different criteria have been used for the measurement of percutaneous absorption of hormones. These consisted of the growth of testes (130), development of a scrotal hernia (131), mammary growth (132, 133), the increase in weight of the seminal vesicles and the prostate gland (134, 135), increase in growth rates of feathers and comb of a capon (135), and the ejaculation reflex as well as the weight of the ejaculate (133, 136).

Among the methods used for studying the percutaneous absorption of vitamins may be mentioned those based on the dark adaption test for vitamin A (137), the thickening of skin in rats by vitamin A (138, 139), weight gain and increase in growth caused by vitamin A in vitamin A-deficient rats (98, 140, 141), and curative effects in man for vitamin C (142), vitamin D (143), and panthenol.

Analysis of Tissues: Skin, Blood, Urine, etc.—Probably the most common method of studying percutaneous absorption *in vivo* is by analysis of the circulating blood (58, 60, 110, 144), urine (145–150), and feces (151) at different intervals following application of the material to the cutaneous surface. One of the difficulties encountered in attempting to estimate quantitatively the amount of material which has penetrated the skin by analyzing the blood, urine, or feces is the fact that the rate at which material leaves the blood stream and is excreted or stored in the tissues is seldom known.

In those cases where drugs appear to have a greater affinity for a particular organ, the organ may be excised and analyzed for drug content. This principle has been used by some workers for the determination of the percutaneous absorption of mercury (43, 152–154), iodides, and iodine (117, 155, 156).

Loss of Penetrating Substance from the Surface.—If a known amount of a nonvolatile substance which has been allowed to remain on the cutaneous surface for a definite period of time is quantitatively removed from the surface and analyzed, the difference between the amount applied and the amount removed may be thought to have penetrated the skin (157). Blank (3) discusses several pitfalls in this method. Quantitative removal is difficult. Some materials combine chemically with the constitutents of the cornified epithelium and then cannot be easily separated from it although they have not penetrated into skin any further than the stratum corneum. The amount of most substances which penetrates is often so small that errors in analysis may be of the same order of magnitude as the amount absorbed and, therefore, one can never be sure that the difference between "before" and "after" determinations truly represents the amount of material which has penetrated. Now that radioactive substances can be prepared it is possible to determine loss from the surface simply by determining the decrease in radioactivity. This subject has been discussed previously.

PERCUTANEOUS ABSORPTION OF MEDICAMENTS

The consensus of the majority of investigators who have studied the percutaneous absorption of medicaments appears to be that the greater the solubility of the drug in oil than in water, the greater its percutaneous absorption. However, it should be emphasized that some degree of solubility of a medicament in both oil and water is thought to be essential for it to be absorbed percutaneously. This phenomenon is not specific to percutaneous absorption, but holds true to absorption and action of drugs in general (158).

The following drugs, all more oil-soluble than water-soluble, have been reported to be absorbed percutaneously: benzocaine (86), iodine (117, 145, 155, 156), phenolsulfonphthalein (159), sulfathiazole (160), sulfanilamide (60, 61), sulfadiazine (161), ammoniated mercury (67), mercuric oxide (43), salicylic acid (45, 54, 58, 83, 153, 162–164), methyl salicylate (163), glycol salicylate (163), diiodofluorescein (109), pyribenzamine (165), morphine (166), strychnine (126, 166), pilocarpine (166), aconitine (126, 166), acetylcholine oleate (167), eserine (121), nicotine (129, 166), stearic acid (100), mustard gas (40, 101), phenol (168–172), and sarin (18, 89).

Although it is thought by many that predominantly water-soluble drugs are not absorbed percutaneously, there are many references in the literature which report that such absorption does take place. Among the water-soluble drugs which have been proved to be absorbed percutaneously are: tritium oxide (173, 174), deuterium oxide (175), sodium chloride (146, 176), thiamine hydrochloride (12), vitamin C (12), mercury bichloride (177), morphine sulfate (166), strychnine sulfate (12), pilocarpine nitrate (32), acetylcholine chloride (32), epinephrine hydrochloride (32), histamine phosphate (32), sodium iodide (71, 72), potassium iodide (71, 178, 179), pyribenzamine hydrochloride (180), penicillin G potassium (181), chlorcyclizine hydrochloride (182), and sodium salicylate (6, 183–186).

Much work has been carried out in recent years on the percutaneous absorption of vitamins, corticosteroids, and sex hormones, and these will be reviewed.

Vitamins.—The percutaneous absorption of vitamins has been reviewed recently by Rubin (187). In brief, vitamin A has been shown to be absorbed percutaneously in animals (53, 140, 141, 189–191) and in man (137, 191). Vitamin D has been shown to be absorbed percutaneously in animals and humans (192, 193); vitamin K in infants (194); and vitamin E in the rat (195). All four of these vitamins are oil-soluble and this property undoubtedly is largely responsible for its absorption.

Of the water-soluble vitamins, panthenol has the largest literature concerning percutaneous absorption. Absorption has been demonstrated in animals (196, 198) and in man (198, 199). The percutaneous absorption of vitamin B_6 (200, 201), thiamine hydrochloride (200, 202), riboflavin (200), calcium pantothenate (200), and vitamin C (203) has also been reported.

Sex Hormones.—The effectiveness of estrogens and progesterones in dermatology and in cosmetics is based on their percutaneous absorption. The rate of absorption of these substances is primarily determined by the vehicle (204).

The most widely used hormones in cosmetics are the estrogens. These substances have produced demonstrable results in the treatment of acne in both sexes. Topical estrogens were also

observed to have a restorative effect on distorted elastic fibers common in aging skin. Among others, Masters (205) and Goldzieher and Baker (206) have demonstrated the percutaneous absorption of estrogens.

Progesterone has been reported to penetrate the intact skin rapidly and with great ease (206, 207). The absorption of progesterone appears to be more rapid than with estradiol (206). Both testosterone and its propionate ester are absorbed through the skin, the free alcohol being more effectively absorbed than the ester (208).

Corticosteroids.—Much interest has been shown in recent years on the percutaneous absorption of the corticosteroids. This subject will be reviewed here.

Earliest studies to demonstrate the percutaneous absorption of hydrocortisone were based either on the physiological effects it produces or an increase in its metabolites in plasma or urine. Smith (209) found no significant change in the circulating eosinophile count following the application of 150 mg. of hydrocortisone acetate to normal or clinically inflamed skin of patients. In another investigation (210), this author failed to note any changes in the urinary excretion of 17-ketosteroids and 17-hydroxycorticosteroids in similar-type subjects. Witten, *et al.* (211), studied the blood and urinary levels of 17,21-dihydroxy-20-ketosteroids in humans for 3 days in response to external application of hydrocortisone acetate-containing ointments without finding significant changes. In another study, Fitzpatrick, *et al.* (212), could not demonstrate the absorption of hydrocortisone acetate in a lotion vehicle following its application to the skin of patients. As a result of these studies, it became apparent that for humans there was little danger from the absorption and consequent systemic effects of topical hydrocortisone in concentrations of 1 to 2.5%.

The first direct demonstration of the percutaneous absorption of hydrocortisone was carried out by Malkinson and Ferguson (113) who demonstrated the radioactive 17-ketosteroid fraction in the urine following the topical application of hydrocortisone (4-C^{14}) to normal human skin in the form of an ointment. Livingood, *et al.* (114), confirmed the absorption of hydrocortisone (4-C^{14}) in humans. Liddle (213) and Paulsen and Rerup (214) also demonstrated the percutaneous absorption of hydrocortisone in humans.

Although it had been shown that hydrocortisone penetrates the superficial barrier (19), Malkinson (215) found that removal of the barrier layer tremendously enhances the penetration of this hormone.

Investigations of the type previously described for hydrocortisone have been carried out with cortisone. Danto and Maddin (216) did not observe any change in the number of circulating eosinophiles in humans after the topical application of cortisone acetate. Malkinson and Ferguson (113) detected the radioactive 17-ketosteroid fraction in the urine following the topical application of cortisone (4-C^{14}) to normal human skin in ointment form. No increase in the penetration of cortisone (4-C^{14}) acetate occurred upon application to stripped sites (215).

Fitzpatrick, *et al.* (212), reported five cases of increased weight and ankle edema in patients treated with 0.2% fluorohydrocortisone acetate lotion. Livingood, *et al.* (217), found edema, weight gain, and/or diminished urinary excretion of sodium in a group of 11 patients receiving topical fluorohydrocortisone. Although it is apparent that fluorohydrocortisone is absorbed percutaneously, as yet there is no decisive evidence of its penetration through normal skin.

There has been very little carried out on percutaneous absorption studies of other corticosteroids.

SYSTEMIC TOXICITY RESULTING FROM PERCUTANEOUS ABSORPTION

Investigations for potential systemic toxicity resulting from percutaneous absorption must be considered as simply one aspect of the overall evaluation of safety which is carried out to determine whether products are safe for patient use (218). The systemic toxicity resulting from the absorption of medicaments applied to the skin is influenced by two independent properties: (*a*) the ability of the medicament to penetrate the skin and (*b*) the inherent toxicity of the medicament toward the patient. Systemic toxicity can occur only when the medicament in question is both absorbed and toxic. However, dangerous toxic symptoms may result on application of potent medicaments to large areas of broken skin. Also of importance are the concentration of medicament and the area of broken skin to which it is applied.

Systemic toxic reactions are important from the standpoint of both acute and chronic effects. Acute toxicity is easier to measure and the results are easier to interpret. On the other hand, in studying the chronic effect of a medicament, it is important to relate the induced changes to the dosage and the frequency of application to the subject. On this basis, the possibility of a similar human exposure may be drawn.

Facile Acid Hydrolysis of *p*-Chlorobenzaldoxime and Its Oral Inefficacy

By EDWARD R. GARRETT†

The kinetics of acid hydrolysis of *p*-chlorobenzaldoxime have been studied. A polarographic assay for reactant and product has been devised. The oxime readily hydrolyzes in acid solution to form an equilibrium mixture with the products. It is expected that the half-life of this oxime would be less than 20 minutes in the human stomach and that the oral inefficacy may be ascribed to this mode of degradation.

OXIMES have been shown to have interesting pharmacological properties (1). In recent animal work at our laboratories, a typical oxime, *p*-chlorobenzaldoxime (PCBO), was inactive as a muscle relaxant (2, 3) when administered orally but active when administered parenterally. The facile hydrolysis of the oximes to *p*-chlorobenzaldehyde (PCB) and hydroxylamine at the pH of the stomach may be a possible explanation.

This paper considers the appropriate assay for such kinetics of hydrolysis and the validity of this possible explanation of oral inefficacy.

EXPERIMENTAL

Choice of Assay Method.—The change of the ultraviolet absorption spectra of *p*-chlorobenzaldoxime in hydrochloric acid solution was extremely small and surprisingly fast. The asymptotic value of the spectra with time was too close to the initial spectra. This made it necessary to investigate a more sensitive method of following the possible transformation of the *p*-chlorobenzaldoxime in hydrochloric acid solution to the *p*-chlorobenzaldehyde and the hydroxylamine hydrochloride.

The method chosen was polarography with the Leeds and Northrup dropping mercury electrode Electrochemograph.

Typical polarographic waves for the reactant and the possible products are given for 10^{-3} *M* solutions in 10% ethanol, 0.100 *M* hydrochloric acid at 25° in Fig. 1. Curve A is the diffusion current in microamperes, i_D, *vs.* volts for *p*-chlorobenzaldoxime, $E_{1/2} = -0.64$; i_D/M at -0.75 v. is $(10.98 - 0.90) \div 10^{-3} = 10.08 \times 10^3$ μa./mole/L. where the blank has 0.90 μa. at -0.75 v. Curve B for *p*-chlorobenzaldehyde shows an $E_{1/2} = -0.855$ v., i_D/M at -1.00 v. is $(3.50 - 1.08) \div 10^{-3} = 2.42 \times 10^3$ μa./mole/L. where the blank has 1.08 μa. at -1.00 v. Curve C for the hydroxylamine at 10^{-3} *M* indicates that this product of the hydrolysis will not significantly interfere with the polarographic assay of the *p*-chlorobenzaldoxime and the *p*-chlorobenzaldehyde. Table I gives the $E_{1/2}$ values after accounting for the i_D of the blank solutions for these two compounds in various hydrochloric acid solutions.

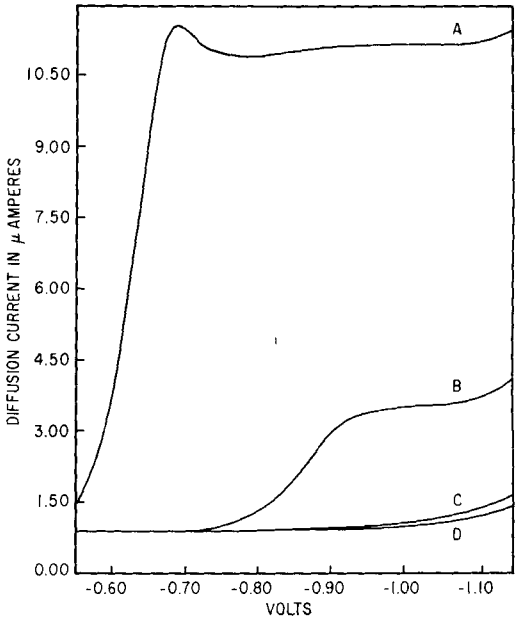

Fig. 1.—Polarographic waves at $10^{-3}M$ in 0.100 *M* hydrochloric acid and 10% ethanol-water at 25°. Curve A, *p*-chlorobenzaldoxime; curve B, *p*-chlorobenzaldehyde; curve C, hydroxylamine hydrochloride; and curve D, blank solution.

Figure 2 is the calibration curve for the i_D at -0.75 v. for *p*-chlorobenzaldoxime in 0.100 *M* hydrochloric acid, 10% ethanol, 25°, as a function of the oxime concentration. The i_D values are corrected for the i_D of the blank under these conditions. The slope or the specific i_D is 0.0633 μa./mcg./ml.

Figure 3 is a typical series of polarograms with time of the reacting solution, 10^{-3} *M* in *p*-chloro-

Received September 7, 1961, from the Research Laboratories of The Upjohn Co., Kalamazoo, Mich.

TABLE I.—HALF-WAVE POTENTIALS, $E_{1/2}$, OF *p*-CHLOROBENZALDOXIME AS A FUNCTION OF HYDROCHLORIC ACID MOLARITY AT 25° IN 10% ETHANOL

$E_{1/2}$	*M* HCl
−0.658	0.05
−0.648	0.075
−0.638	0.10
−0.627	0.15
−0.621	0.20

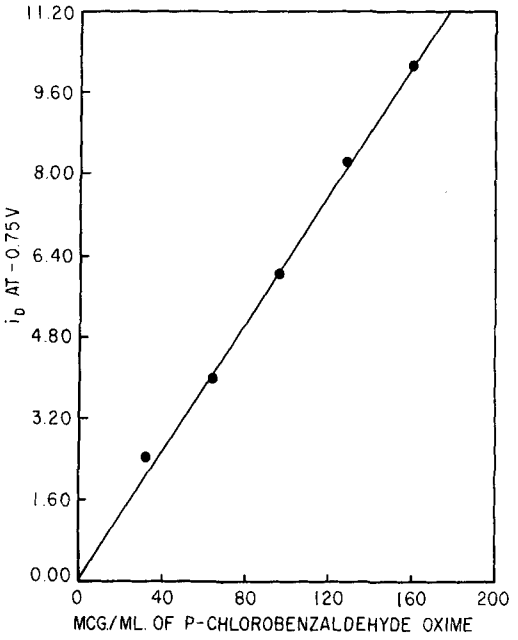

Fig. 2.—Calibration curve for *p*-chlorobenzaldoxime in 0.100 *M* hydrochloric acid, 10% ethanol-water at 25°; diffusion current, i_D in μa., *vs.* concentration in mcg./ml.

benzaldoxime, 0.20 *M* hydrochloric acid, 25°, 10% ethanol. A maximum appeared at −0.68 v. which necessitated the addition of gelatin. The decrease of the wave height characterized by an $E_{1/2}$ of −0.64 is associated with the hydrolysis of the *p*-chlorobenzaldoxime whereas the increase of the wave characterized by an $E_{1/2}$ of −0.84 is associated with the appearance of the hydrolysis product, *p*-chlorobenzaldehyde.

Procedure.—*p*-Chlorobenzaldoxime (PCBO), molecular weight = 155.58, synthesized and recrystallized by G. H. Smith and A. J. Lemin of these laboratories, was titrated and had pKa's of 10.35 in 20% ethanol, 10.70 in 50% ethanol. An 80-mg. quantity of PCBO was weighed into a tared 50-ml. volumetric flask and diluted to volume with nitrogen-purged ethanol. Ten milliliters of the resultant solution was pipetted into a 100-ml. volumetric flask which contained hydrochloric acid plus 2 ml. 0.1% gelatin solution. Subsequently, the solution was diluted up to volume with sufficient hydrochloric acid so that the resultant molarities were 10^{-3} in PCBO, and 0.050, 0.075, 0.150, or 0.200 *M* in hydrochloric acid and 10% in ethanol. The solutions were assayed on the polarograph immediately and at timed intervals thereafter. The solution was maintained in a 25° constant temperature bath between polarographic assays and was degassed with nitrogen for approximately 3 minutes before each run.

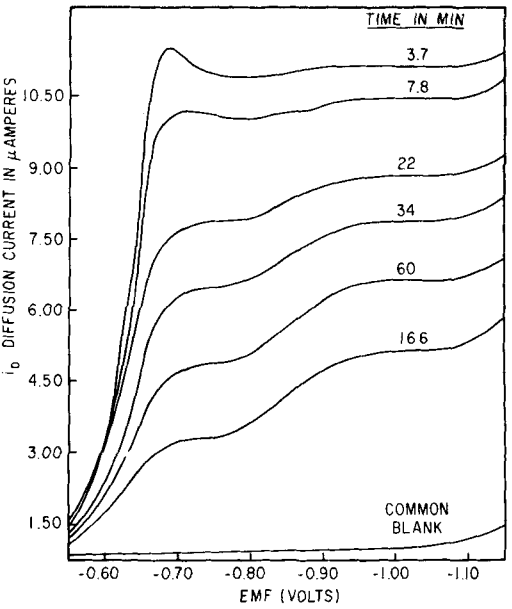

Fig. 3.—Polarographic waves of *p*-chlorobenzaldoxime in 0.200 *M* hydrochloric acid, 10% ethanol-water at 25° at various times.

CALCULATIONS AND RESULTS

The i_D diffusion current at −0.75 and −1.00 v. for the PCBO solutions decreased with time, the latter less than the former since the plateau of the wave representing the *p*-chlorobenzaldehyde concentration appeared prior to −1.00 volts. This wave does not interfere with the −0.75 v. reading. Typical plots of these i_D values as functions of time are given at the top of Fig. 4. The net i_D, i.e., i_D (−1.0 v.) $-i_D$ (−0.75 v.), representing the appearance of the benzaldehyde is given in the bottom of Fig. 4.

The fact that the i_D at −0.75 v. did not approach the i_D of the blank at infinite time indicated that this is an equilibrium reaction.

The plots of Fig. 5 are typical examples on the assumption of an apparent first-order transformation of PCBO to, and in equilibrium with, PCB at constant hydrochloric acid. Curve A represents the first-order disappearance of PCBO by the expression

$$\log [i_D - (i_D)_\infty] = \frac{-(k_1 + k_2)}{2.303} t + \log [(i_D)_0 - (i_D)_\infty] \quad \text{(Eq. 1)}$$

where the i_D values are read at −0.75 v., $(i_D)_0$ is the initial reading, and $(i_D)_\infty$ the reading in μa. at infinite time. Curve B represents the first-order appearance of PCB by the expression

$$\log \{[(i_D)_\infty(-1.0 \text{ v.}) - (i_D)_\infty(-0.75 \text{ v.})] - [i_D(-1.0 \text{ v.}) - i_D(-0.75 \text{ v.})]\} = -\frac{(k_1 + k_2)}{2.303} t + \text{constant} \quad \text{(Eq. 2)}$$

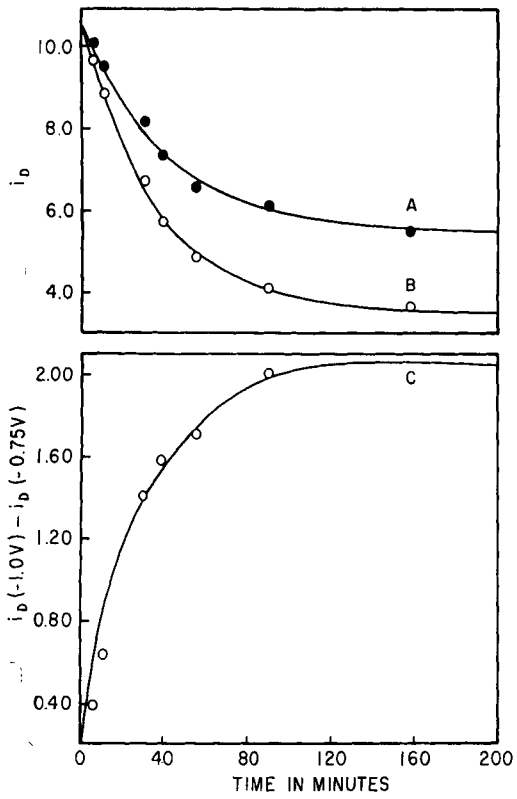

Fig. 4.—Polarographic diffusion current, i_D, of 10^{-3} M p-chlorobenzaldoxime in 0.150 M hydrochloric acid 10% ethanol-water at 25° against time of reading: ○, −0.75 v., ●, −1.00 v.

When it is realized that the data for curve B is obtained from the subtraction of small differences of relatively large values, the empirical use of the assumed model is not unwarranted.

From the slopes of plots similar to curve A, Fig. 5, the sum of the forward and backward rate constants, $k_1 + k_2$, can be calculated as per the postulated equilibrium

$$p\text{-chlorobenzaldoxime} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} p\text{-chlorobenzaldehyde} \qquad \text{(Eq. 3)}$$

where

$$\frac{k_1}{k_2} = \frac{[\text{Benzaldehyde}]}{[\text{Benzaldoxime}]} = K \qquad \text{(Eq. 4)}$$

where K is defined as the equilibrium constant. This K may be estimated from

$$K = \frac{(i_D)_0 - (i_D)_\infty}{(i_D)_\infty} \qquad \text{(Eq. 5)}$$

for all i_D at −0.75 v. From Eqs. 1, 4, and 5; k_1' k_2, and K can be calculated and are given in Table II.

The k_1, k_2, and K values of Table II are plotted in Fig. 6 and dependence on hydrochloric acid concentration may be estimated as

$$k_1\,(\text{min.}^{-1}) = 0.045\,[\text{HCl}] + 0.0134 \qquad \text{(Eq. 6)}$$

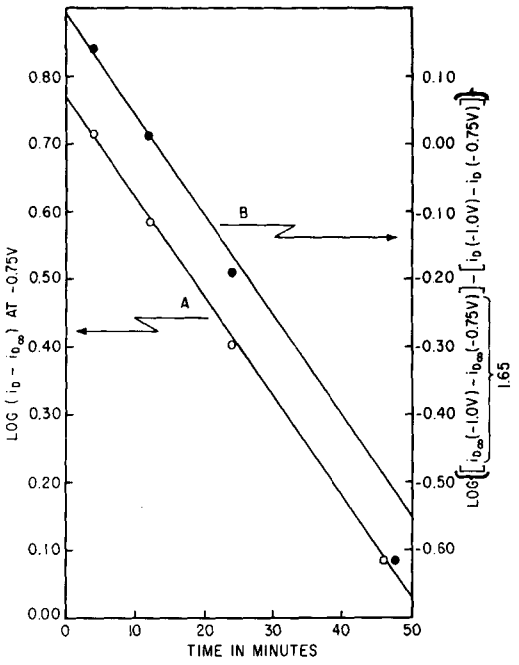

Fig. 5.—Apparent first-order rate plots for the hydrolysis of $10^{-3}M$ p-chlorobenzaldoxime (PCBO) in 0.075 M hydrochloric acid, 10% ethanol-water at 25°. Curve A is for the disappearance of PCBO; curve B is for appearance of p-chlorobenzaldehyde.

TABLE II.—RATES k_1 AND k_2 IN MIN.$^{-1}$ AND EQUILIBRIUM (K) CONSTANTS FOR THE ASSUMED FIRST-ORDER (FORWARD AND REVERSE) TRANSFORMATION OF p-CHLOROBENZALDOXIME $\underset{k_2}{\overset{k_1}{\rightleftharpoons}}$ p-CHLOROBENZALDEHYDE IN 10% ETHANOL, 25°, $10^{-3}M$ IN PCBO. K' IS WHEN THE BACK REACTION IS ASSUMED SECOND ORDER WITH RESPECT TO PCB AND HYDROXYLAMINE

[HCl]	$k_1 + k_2$	k_1	k_2	K	$10^4K'$
0.050	0.0326	0.0152	0.0174	0.870	4.35
0.075	0.0340	0.0185	0.0155	1.194	6.99
0.150	0.0312	0.0211	0.0102	2.071	15.0
0.200	0.0273	0.0216	0.0057	3.778	32.1

A possible alternate dependency is given by the dashed line. The other estimated constants are

$$k_2\,(\text{min.}^{-1}) = -0.00751\,[\text{HCl}] + 0.021 \qquad \text{(Eq. 7)}$$

$$K = 17.5\,[\text{HCl}] \qquad \text{(Eq. 8)}$$

Actually, a more elegant postulation of the equilibrium would be

$$\text{PCBO} \underset{k_2'}{\overset{k_1}{\rightleftharpoons}} \text{PCB} + \text{Hydroxylamine} \qquad \text{(Eq. 9)}$$

and

$$K' = \frac{[\text{PCB}]\,[\text{Hydroxylamine}]}{[\text{PCBO}]} \qquad \text{(Eq. 10)}$$

where

$$[\text{PCB}] = [\text{Hydroxylamine}] \qquad \text{(Eq. 11)}$$

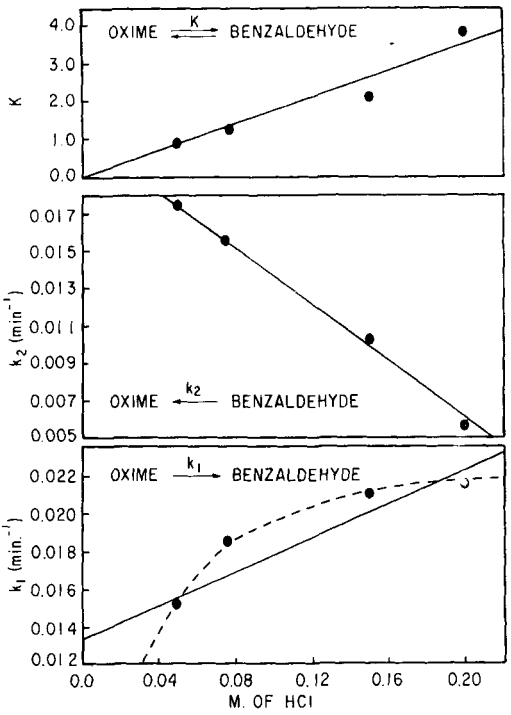

Fig. 6.—Plots of apparent equilibrium constant, K and rate constants, k_1 and k_2, for the simplified equilibrium

$$\text{PCBO} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{PCB}$$

as a function of hydrochloric acid molarity.

so that an equation comparable to Eq. 5 would be

$$K' = \frac{\{(i_D)_0 - (i_D)_\infty \div 10^{-4}\}^2}{(i_D)_\infty \div 10^{-4}} = \frac{\{(i_D)_0 - (i_D)_\infty\}^2 \times 10^4}{(i_D)_\infty} \quad \text{(Eq. 12)}$$

where

$$i_D/C = 10^4\ \mu\text{a.}/M/L. \quad \text{(Eq. 13)}$$

Values for K' are also given in Table II. The plots to determine rate constants could be based on the more elegant and complete expression (4)

$$2.303 \log \frac{[\text{PCBO}]_0 [\text{PCB}]_{eq} + [\text{PCB}]\{[\text{PCBO}]_0 - [\text{PCB}]_{eq}\}}{[\text{PCBO}]_0\{[\text{PCB}]_{eq} - [\text{PCB}]\}} = \frac{kt\{2[\text{PCBO}]_0 - [\text{PCB}]_{eq}\}}{[\text{PCB}]_{eq}} \quad \text{(Eq. 14)}$$

However, since the Eq. 1 satisfactorily fits the data, the simplified assumption of opposing first-order reactions is adequate for the purposes of this study.

DISCUSSION

For our purposes k_1 is given at 25° in 10% ethanol by Eq. 6.

The hydrolysis of PCBO is an equilibrium reaction under the conditions studied. On ingestion into the stomach, however, it is reasonable to postulate the removal of end products PCB and hydroxylamine, so that the hydrolysis tends to be complete.

If the acid concentration of the stomach is assumed to be 0.05 M, the apparent first-order rate constant may be estimated as 0.015 min.$^{-1}$ from Eq. 6 or the half-life for the hydrolysis of the PCB oxime would be

$$t_{1/2} = \frac{2.303 \log 0.5}{k} = \frac{(0.69)}{0.015} = 46 \text{ min.} \quad \text{(Eq. 15)}$$

This is at 25° and in 10% ethanol. It is to be expected that at 37° or body temperature the rate would be at least doubled so that $t_{1/2}$ = 23 min. at 37°. Also, in truly aqueous system the rate should be further increased. Thus, it may be estimated that the half-life of PCBO under the physiological conditions of the human stomach would be less than 20 minutes, and the oral inefficacy of such oximes may be attributed to acid hydrolysis in the stomach.

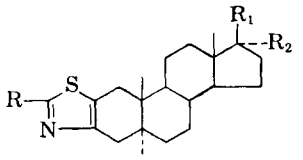
Steroids IX

Synthesis of Some Thiazolosteroids

By NORMAN J. DOORENBOS and CONRAD P. DORN, Jr.†



The synthesis of thiazolo[d-3,2]-5α-cholest-2-ene, and thiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol, and eight of their 2′-derivatives is reported. These derivatives include the 2′-methyl, 2′-amino, 2′-allylamino, and 2′-phenylamino substituted thiazolosteroids. Preliminary data indicate that 2′-methylthiazolo[d-3,2]-17α methyl-5α-androst-2-en-17β-ol is a good anabolic agent.

In recent years the search for an effective anabolic agent possessing only low androgenic activity has been markedly intensified. Many modifications of the basic androstane nucleus have been made with moderate success. Recently, however, the Sterling-Winthrop Research Institute announced that a pyrazole derivative, namely, pyrazolo[c-3,2]-17α-methyl-5α-androstan-17β-ol has 35 times the anabolic potency and only one-fourth the androgenic potency of methyltestosterone (1).

The structural features by which this molecule differs from methyltestosterone include: hydrogenation of the Δ^4 double bond with transfusion of rings A and B, a nitrogen atom attached to carbon 3 in place of oxygen, and a heterocyclic ring system fused to ring A between positions 2 and 3. It appears that the above modifications of the steroid nucleus increase the anabolic/androgenic ratio of the compound.

With the above facts in mind, we sought to prepare a series of thiazolosteroids in the cholestane and androstane series. These compounds have the following structure

R_1 = C_8H_{17}; R_2 = H
R_1 = OH; R_2 = CH_3
R = H, CH_3, NH_2, C_6H_5—NH—, CH_2=CH—CH_2—NH—

The cholestane derivatives were prepared as a means of perfecting our synthetic methods before we began working with the more expensive androstane compounds. We were also hopeful that the thiazolocholestanes would have some interesting biological activity, perhaps that of inhibiting cholesterol biosynthesis.

A preliminary report (2) of the thiazoloandrostanes was made following a communication (3) from Syntex describing the independent synthesis of two of these compounds, XI and XII.

The synthesis of thiazole compounds may be accomplished by the method of Hantzsch (4). This method involves the reaction of an α-halo carbonyl compound with a thioamide. By using the proper combination of reactants, compounds may be prepared with alkyl, aryl, or other groups attached to the three carbons of the thiazole nucleus.

We prepared the α-halo carbonyl compound, 2α-bromo-5α-cholestan-3-one (II) according to the method of Fieser and Dominguez (5). This procedure entails the bromination of 5α-cholestan-3-one (I) in glacial acetic acid in the presence of hydrobromic acid to give 2α-bromo-5α-cholestan-3-one (II) in a 44% yield. The carbonyl group of the brominated ketone absorbs at 5.77 μ compared to 5.86 μ in the nonbrominated ketone. This hypsochromic shift indicates that the bromine atom is equatorial and in the 2α-position (6).

The first step in the preparation of the thiazoloandrostanes was the reduction of 17α-methyl-

testosterone (VIII). This reaction was carried out in liquid ammonia in the presence of lithium metal according to the procedure which Weisenborn and Applegate (7) used for the reduction of testosterone. This procedure, when used for the reduction of 17α-methyltestosterone (VIII), gave 17α-methyl-5α-androstan-17β-ol-3-one (IX) in a 90% yield. The melting point was in agreement with that previously reported for the 5α-isomer (8).

The bromination of 17α-methyl-5α-androstan-17β-ol-3-one (IX) was accomplished by the use of pyridine hydrobromide perbromide as the brominating agent (9). Tetrahydrofuran was used as the solvent for this reaction to absorb the hydrogen bromide evolved and thus prevent dehydration at position 17. This procedure gave 2α-bromo-17α-methyl-5α-androstan-17β-ol-3-one (X) in a 41% yield. Once again the shift in the carbonyl absorption from 5.85 μ to 5.76 μ indicates that the bromine is equatorial or in the 2α-position.

The substituted thiazole compounds were prepared by refluxing the steroid bromoketones with the appropriate thioamide in ethanol or a mixture of ethanol and chloroform for 3 to 6 hours. Isolation of the free thiazolosteroid was accomplished by treating the hydrobromide salt with base. No difficulty was encountered when the thioamide was thioacetamide, thiourea, N-phenylthiourea, or N-allylthiourea. 2α-Bromo-5α-cholestan-3-one (II) reacted with thioacetamide to yield 22% of 2′-methylthiazolo[d-3,2]-5α-cholest-2-ene (IV); with thiourea to yield 79% of 2′-aminothiazolo[d-3,2]-5α-cholest-2-ene (V); with N-phenylthiourea to yield 45% of 2′-phenylaminothiazolo[d-3,2]-5α-cholest-2-ene (VI); and with N-allylthiourea to yield 50% of 2′-allylaminothiazolo[d-3,2]-5α-cholest-2-ene (VII). Likewise, 2α-bromo-17α-methyl-5α-androstan-17β-ol-3-one (X) reacted with thioacetamide to yield 49% of 2′-methylthiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XII); with thiourea to yield 57% of 2′-aminothiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XIII); with N-phenylthiourea to yield 35% of 2′-phenylaminothiazolo-[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XIV); and with N-allylthiourea to yield 71% of 2′-allylaminothiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XV).

The preparation of the unsubstituted thiazole derivatives, however, presented a problem. Thioformamide is unstable and must be prepared just prior to use, usually by reacting formamide with phosphorus pentasulfide. We attempted the synthesis of the unsubstituted thiazole in the cholestane series by two methods. The first was a modification of the procedure suggested by Schwartz (10) for the synthesis of 2,4-dimethylthiazole from chloroacetone, acetamide, and phosphorus pentasulfide. We first treated formamide with phosphorus pentasulfide in dry benzene for 1 hour and then added the steroid bromoketone. This procedure gave a product which was extremely difficult to purify. In addition the yield of thiazolo[d-3,2]-5α-cholest-2-ene (III) was only 3.5%.

The method recommended by Cerecedo and Tolpin (11) for the synthesis of thioformamide was then tried. The crude thioformamide was prepared by the addition of phosphorus pentasulfide to formamide which have been covered with anhydrous ether. This mixture was allowed to stand overnight in an ice bath and was then shaken for 15 hours. The ether layer was separated and evaporated at reduced temperature and pressure to yield the crude thioformamide. The thioformamide was added in generous excess to a solution of 2α-bromo-5α-cholestan-3-one (II) in a mixture of chloroform and ethanol. The reaction mixture was stored in the refrigerator for 4 days and allowed to stand at room temperature for 2 weeks. The yield of thiazolo[d-3,2]-5α-cholest-2-ene (III) was 48%. Similarly, 2α-bromo-17α-methyl-5α-androstan-17β-ol-3-one (X) when allowed to react with crude thioformamide for 5 days in the cold and 6 weeks at room temperature yielded 33% of thiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XI).

Proof of the thiazole structures was based on elemental analyses and infrared spectral data. Randall, *et al.* (12), report that thiazoles show characteristic absorption at 6.12–6.37 μ (thiazole I) and 6.50–6.70 μ (thiazole II). All of our compounds with the exception of the methyl thiazoles absorbed in these regions. The methyl compounds had the thiazole II peak at approximately 6.40 μ. In addition, the characteristic absorptions of hydroxyl, amino, phenyl, and allyl groups were observed in the appropriate spectra.

EXPERIMENTAL[1]

Thiazolo[d-3,2]-5α-cholest-2-ene (III).—(*Method A*).—Formamide, 1.8 Gm., and 1.8 Gm. of phosphorus pentasulfide were heated for 1 hour in dry benzene on a steam bath. To this mixture was added a solution of 9.3 Gm. of 2α-bromo-5α-cholestan-3-one (II) dissolved in 100 ml. of dry benzene. The reaction mixture was refluxed 5 hours and filtered

[1] All melting points are uncorrected and were determined with either a Fisher Johns or a Thomas Hoover melting point apparatus. The infrared spectra were prepared on a Perkin Elmer Infracord recording spectrophotometer. The specific rotations were determined by the analytical section of Smith Kline & French Laboratories.

while hot to remove the insoluble impurities. The benzene solution was evaporated to dryness and yielded a yellow-white mass. This material was dissolved in 500 ml. of ethanol and, upon the addition of 2 Gm. of potassium hydroxide, turned orange-red. The solution was heated 30 minutes and the solvent evaporated. Ether was added to the solid material and the ether solution washed well with water. The ether solution was evaporated and the noncrystallizable mass was treated with anhydrous ether saturated with hydrogen bromide in an attempt to isolate the hydrobromide salt. The colloidal precipitate could not be filtered and the ether suspension was evaporated to dryness. The resulting brown mass was washed with dry acetone and yielded a white precipitate. This precipitate was dissolved in ethanol and 2 Gm. of potassium hydroxide was added. The solution was refluxed 30 minutes, cooled, and water added to precipitate the product. This dirty white powder was treated with charcoal in ethanol, filtered while hot, and cooled. The steroid was precipitated by the addition of water. This crude material (m.p. 163–170°) was recrystallized from methanol-water and finally from dimethylformamide to yield 300 mg. (3.5%) of thiazolo[d-3,2]-5α-cholest-2-ene (III) as yellow-white crystals; m.p. 163.5–165°.

Anal.—Calcd. for $C_{28}H_{45}NS$: C, 78.63; H, 10.60; N, 3.27. Found: C, 78.67; H, 10.60; N, 3.09.

(*Method B*).—To 5.0 Gm. of 2α-bromo-5α-cholestan-3-one (II), dissolved in 50 ml. of chloroform-ethanol (1:1), was added 5.0 Gm. of crude thioformamide (11) dissolved in 50 ml. of chloroform-ethanol (1:1). The solution was placed in the refrigerator for 4 days and then allowed to stand at room temperature for 2 weeks. The reaction mixture was made alkaline by the addition of methanolic potassium hydroxide and washed well with water. The organic solution was dried over sodium sulfate and evaporated to dryness. The yellow solid obtained was recrystallized from dimethylformamide-acetone (1:1) to yield 2.2 Gm. (48%) of thiazolo[d-3,2]-5α-cholest-2-ene (III) as fine yellow-white needles; m.p. 166–168°; $[\alpha]_D^{25}$ +55.3° (c, 0.7 chloroform); $\lambda_{max.}^{KBr}$ 6.12 and 6.42 μ.

Anal.—Calcd. for $C_{28}H_{45}NS$: C, 78.63; H, 10.60; N, 3.27. Found: C, 78.72; H, 10.64; N, 3.21.

2′-Methylthiazolo[d-3,2]-5α-cholest-2-ene (IV).—2α-Bromo-5α-cholestan-3-one (II), 2.0 Gm., and 0.5 Gm. of thioacetamide were refluxed 5 hours in 200 ml. of chloroform-ethanol (1:1). The solvent was evaporated and the hydrobromide salt washed with a small amount of ether. The solid material was dissolved in 25 ml. of boiling ethanol. The solution was made alkaline by the addition of potassium hydroxide and refluxed for 30 minutes. The solution was cooled and the precipitated thiazole collected by filtration. The precipitate was washed with 50 ml. of cold acetone and yielded 800 mg. (22%) of 2′-methylthiazolo[d-3,2]-5α-cholest-2-ene (IV) as a white powder; m.p. 168.5–169.5°; $[\alpha]_D^{25}$ +52.9° (c, 0.81 chloroform); $\lambda_{max.}^{KBr}$ 6.12 and 6.41 μ.

Anal.—Calcd. for $C_{29}H_{47}NS$: C, 78.84; H, 10.73; N, 3.17. Found: C, 78.58; H, 11.02; N, 3.21.

2′-Aminothiazolo[d-3,2]-5α-cholest-2-ene (V).—2α-Bromo-5α-cholestan-3-one (II), 2.0 Gm., and 5.0 Gm. of thiourea were refluxed for 5 hours in 75 ml. of chloroform-ethanol (1:1). A white precipitate formed after about 1 hour. The reaction mixture was evaporated to dryness. The solid residue was redissolved in 250 ml. of ethanol and made alkaline with potassium hydroxide. The solution was cooled and the precipitate collected by filtration. The crude thiazolosteroid was recrystallized from ethanol to yield 1.5 Gm. (79%) of 2′-aminothiazolo-[d-3,2]-5α-cholest-2-ene (V) as fluffy white crystals; m.p. 271–271.5°; $[\alpha]_D^{25}$ +58.3° (c, 0.78 chloroform); $\lambda_{max.}^{KBr}$ 2.82–3.02, 3.13–3.25, 6.10, and 6.53 μ [reported m.p. 266°; $[\alpha]_D^{25}$ +64.4° (c, 0.49 chloroform)] (13).

Anal.—Calcd. for $C_{28}H_{46}N_2S$: C, 75.97; H, 10.47; N, 6.32. Found: C, 75.88; H, 10.47; N, 6.32.

2′-Phenylaminothiazolo[d-3,2]-5α-cholest-2-ene (VI).—2α-Bromo-5α-cholestan-3-one (II), 4.0 Gm., and 1.5 Gm. of N-phenylthiourea were refluxed for 6 hours in 400 ml. of ethanol The reaction mixture was made alkaline with methanolic potassium hydroxide and concentrated until crystals began to appear. The solution was cooled and the precipitate collected. The crude product was recrystallized from ethanol to yield 2.0 Gm. (45%) of 2′-phenylaminothiazolo[d-3,2]-5α-cholest-2-ene (VI) as white needles; m.p. 194.5–195.5°; $[\alpha]_D^{25}$ +62.9° (c, 0.99 chloroform); $\lambda_{max.}^{CHCl_3}$ 2.93, 6.21, 6.50, and 6.67 μ.

Anal.—Calcd. for $C_{34}H_{50}N_2S$: C, 78.70; H, 9.71; N, 5.40. Found: C, 78.68; H, 9.47; N, 5.34.

2′-Allylaminothiazolo[d-3,2]-5α-cholest-2-ene (VII).—2α-Bromo-5α-cholestan-3-one (II), 5.0 Gm., and 2.0 Gm. of N-allylthiourea were refluxed 3 hours in ethanol. The solution was made alkaline with methanolic potassium hydroxide, concentrated, and the precipitate collected by filtration. The crude product was recrystallized from chloroform-methanol to give 2.6 Gm. (50%) of 2′-allylaminothiazolo-[d-3,2]-5α-cholest-2-ene (VII) as white granules; m.p. 189.5–192°; $[\alpha]_D^{25}$ +57.4° (c, 1.03 chloroform); $\lambda_{max.}^{CHCl_3}$ 2.92, 6.07, 6.30, and 6.49 μ.

Anal.—Calcd. for $C_{31}H_{50}N_2S$: C, 77.13; H, 10.44; N, 5.80. Found: C, 76.63; H, 10.30; N, 5.91.

17α-Methyl-5α-androstan-17β-ol-3-one (IX).—17α-Methyltestosterone (VIII), 5.0 Gm., was dissolved in 120 ml. of 50:50 dry dioxane-ether. This solution was added, dropwise, with stirring to a solution of 1.0 Gm. of lithium metal in approximately 500 ml. of liquid ammonia. Thirty minutes after the addition was completed the blue color of the ammonia solution was discharged by the cautious addition of ammonium chloride. The ammonia was evaporated and the solid material taken up in chloroform and washed well with water. The chloroform solution was dried over sodium sulfate and evaporated to dryness. The residue was crystallized from methanol to yield 4.5 Gm. (90%) of 17α-methyl-5α-androstan-17β-ol-3-one (IX) as white granular crystals; m.p. 192–194°; $\lambda_{max.}^{CHCl_3}$ 2.76, and 5.85 μ (reported m.p. 193°) (8).

2α-Bromo-17α-methyl-5α-androstan-17β-ol-3-one (X).—17α-Methyl-5α-androstan-17β-ol-3-one (IX), 6.0 Gm., was dissolved in 500 ml. of tetrahydrofuran. To this solution was added, portionwise, 6.4 Gm. of pyridine hydrobromide perbromide. The mixture was allowed to stand overnight at room temperature and then poured into 200 ml. of water. This mixture was extracted well with ether and the ether solution dried over sodium sulfate and evaporated to dryness. The residue was crystallized from ethyl acetate-petroleum ether to yield 3.1 Gm. (41%)

of 2α-bromo-17α-methyl-5α-androstan-17β-ol-3-one (X) as tan crystals; m.p. 185–187°; $\lambda_{max.}^{CHCl_3}$ 2.76 and 5.76 μ (reported m.p. 196–198°) (3).

Anal.—Calcd. for $C_{20}H_{31}BrO_2$: C, 62.66; H, 8.15; Br, 20.84. Found: C, 62.54; H, 8.14; Br, 21.30.

Thiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XI).—2α-Bromo-17α-methyl-5α-androstan-17β-ol-3-one (X), 5.0 Gm., was dissolved in 100 ml. of chloroform. To this solution was added 10 Gm. of crude thioformamide (11) dissolved in 50 ml. of chloroform-ethanol (1:1). The reaction mixture was stored in the refrigerator for 5 days and then allowed to stand at room temperature for 6 weeks. The reaction mixture was then made alkaline and washed well with water. The chloroform solution was dried over sodium sulfate and evaporated to yield a dark oil. The oil was dissolved in a minimum of dimethylformamide and allowed to stand at room temperature. After a week, oily crystals appeared and were collected by filtration. The crude material was recrystallized from anhydrous ether-petroleum ether to yield 1.5 Gm. (33%) of thiazolo-[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XI) as salmon colored granules; m.p. 177–179°; $[\alpha]_D$ +48.8°; $\lambda_{max.}^{EtOH}$ 251 mμ, log ε 3.64; $\lambda_{max.}^{CHCl_3}$ 2.75, 3.00–3.05, and 6.40 μ (reported m.p. 192–193°; $[\alpha]_D$ +33°; $\lambda_{max.}^{EtOH}$ 252 mμ, log ε 3.61) (3).

Anal.—Calcd. for $C_{21}H_{31}NOS$: C, 73.02; H, 9.04; S, 9.53. Found: C, 72.66; H, 9.01; S, 9.53.

2′-Methylthiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XII).—2α-Bromo-17α-methyl-5α-androstan-17β-ol-3-one (X), 1.5 Gm., and 1.5 Gm. of thioacetamide were refluxed 5 hours in ethanol. The reaction mixture was made alkaline with methanolic potassium hydroxide. Ether (150 ml.) was added and the resulting solution washed well with water. The organic layer was dried over sodium sulfate and evaporated to dryness. The crude material was recrystallized twice from acetone to yield 700 mg. (49%) of 2′-methylthiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XII) as yellow-white needles; m.p. 198–199.5°; $[\alpha]_D$ +35.6°; $\lambda_{max.}^{EtOH}$ 253 mμ, log ε 3.72; $\lambda_{max.}^{CHCl_3}$ 2.76, and 6.40 μ (reported m.p. 212–215°; $[\alpha]_D$ +47°; $\lambda_{max.}^{EtOH}$ 254 mμ, log ε 3.76) (3).

Anal.—Calcd. for $C_{22}H_{33}NOS$: C, 73.48; H, 9.25; N, 3.90; S, 8.92. Found: C, 73.42; H, 9.23; N, 4.12; S, 9.04.

2′-Aminothiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XIII).—2α-Bromo-17α-methyl-5α-androstan-17β-ol-3-one (X), 5.0 Gm., and 3.0 Gm. of thiourea were refluxed 5 hours in ethanol. The reaction mixture was then made alkaline with methanolic poatassium hydroxide and concentrated until the crude product precipitated. This precipitate was filtered and recrystallized from methanol-water to yield 2.7 Gm. (57%) of 2′-aminothiazolo-[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XIII) as white plates; m.p. 270–272°; $[\alpha]_D$ +45.0°; $\lambda_{max.}^{CHCl_3}$ 2.76, 2.86, 2.94, 6.25, and 6.57 μ.

Anal.—Calcd. for $C_{21}H_{32}N_2OS$: C, 69.95; H, 8.95; N, 7.77. Found: C, 69.80; H, 9.26; N, 7.47.

2′-Phenylaminothiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XIV).—2α-Bromo-17α-methyl-5α-androstan-17β-ol-3-one (X), 3.0 Gm., and 3.0 Gm. of N-phenylthiourea were refluxed 3 hours in ethanol. The reaction mixture was made alkaline with methanolic potassium hydroxide and concentrated until the crude product precipitated. This material was filtered and recrystallized from ethanol to yield 1.2 Gm. (35%) of 2′-phenylaminothiazolo-[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XIV) as white plates; m.p. 250–252°; $[\alpha]_D$ +46.0°; $\lambda_{max.}^{EtOH}$ 298 mμ, log ε 4.21; $\lambda_{max.}^{KBr}$ 2.76, 2.90, 2.06, 6.19, 6.48, and 6.64 μ.

Anal.—Calcd. for $C_{27}H_{36}N_2OS$: C, 74.27; H, 8.31; N, 6.42. Found: C, 74.61; H, 8.41; N, 6.14.

2′-Allylaminothiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XV).—2α-Bromo-17α-methyl-5α-androstan-17β-ol-3-one (X), 5.0 Gm. and 2.0 Gm. of N-allylthiourea were refluxed 3 hours in ethanol. The reaction mixture was made alkaline by the addition of methanolic potassium hydroxide and concentrated until the crude product precipitated. This material was filtered and recrystallized from ethanol-water to yield 3.7 Gm. (71%) of 2′-allylaminothiazolo[d-3,2]-17α-methyl-5α-androst-2-en-17β-ol (XV) as white needles; m.p. 232–234°; $[\alpha]_D$ +50.5°; $\lambda_{max.}^{EtOH}$ 266 mμ, log ε 3.93; $\lambda_{max.}^{CHCl_3}$ 2.76, 2.90, 6.07, 6.27, and 6.49 μ.

Steroids X

Preparation of Azasteroids from Cholestenone and Progesterone

By NORMAN J. DOORENBOS and HARKISHAN SINGH†

Cholestenone (I) was converted into 3-aza-A-homo-4a-cholesten-4-one (II) by means of the Schmidt reaction in polyphosphoric acid. The structure was assigned on the basis of its ultraviolet spectrum, resistance to hydrolysis, and hydrogenation to a mixture of 3-aza-A-homo-5α-cholestan-4-one (IV) and 3-aza-A-homo-5β-cholestan-4-one (V). By similar procedures, progesterone (VI) yielded either 17β-acetylamino-4-androsten-3-one (VII) or 17β-acetylamino-3-aza-A-homo-4a-androsten-4-one (VIII), depending upon the quantity of sodium azide used. The structure of VII was confirmed by preparing it from 17β-acetylamino-5-androsten-3β-ol (IX) by Oppenauer oxidation.

THE ANDROGENIC, progestational, and corticosteroid hormones each contain an α,β-unsaturated ketone system in ring A. As an extension of our investigation of azasteroids, we sought to synthesize A-homosteroid homologs of some of these steroids with a nitrogen in position 3 by means of the Schmidt reaction. An example of such a steroid is illustrated by structure II.

The initial studies were carried out with cholestenone (4-cholesten-3-one) (I). No crystalline products were isolated when the Schmidt reaction was carried out by the usual procedures with sulfuric acid as the catalyst (1). However, when polyphosphoric acid was used as the solvent and catalyst (2, 3), 3-aza-A-homo-4a-cholesten-4-one (II) was obtained as a white crystalline product. Chromatographic studies on II established that it was a single compound and not a mixture. Structure II was assigned to this product (*a*) because of its resistance to hydrolysis, (*b*) since its spectrum resembles that of a known steroidal α,β-unsaturated lactam, and differs from known steroidal enamine lactams, and (*c*) because it is hydrogenated to a mixture of 3-aza-A-homo-5α-cholestan-4-one (IV) and 3-aza-A-homo-5β-cholestan-4-one (V).

Enamine lactams of the type represented by structure III are relatively easy to hydrolyze as illustrated by the ease of hydrolysis of 3β-acetoxy-17-acetylamino-5,16-androstadiene (4) and 4-aza-5-cholesten-3-one (5). The product obtained by the Schmidt reaction on cholestenone was not hydrolyzed by refluxing in 5 per cent ethanolic potassium hydroxide or by refluxing in dioxane-concentrated hydrochloric acid mixture. This resistance to hydrolysis indicates that it is the α,β-unsaturated lactam represented by structure II.

Table I lists the major absorption peak in the ultraviolet spectrum for several enamine and α,β-unsaturated steroid lactams. The first four compounds listed are enamine lactams. The fifth is an α,β-unsaturated lactam. The spectrum of lactam II, the sixth compound in this list, is similar to that of the α,β-unsaturated lactam.

This unsaturated lactam (II) was reduced with platinum and hydrogen in glacial acetic acid at 70° and 60 lb. pressure. A reduced lactam was separated from some unreacted starting material by chromatography. This reduced lactam, m.p. 202–245°, was a mixture of the 5α-[m.p. 268–271° (6)] and 5β-[m.p. 166–174° (6)] isomers. Repeated crystallization from absolute ethanol yielded a sample, m.p. 263–269°, which was shown, by mixed melting points and a comparison of infrared spectra, to be 3-aza-A-homo-5α-cholestan-4-one (IV).

It should be noted that the α,β-unsaturated steroid lactam described in Table I was also

TABLE I.—MAJOR ABSORPTION PEAKS OF SOME UNSATURATED STEROID LACTAMS

Compound	Solvent	$\lambda_{max.}$	Log ϵ
2β-Acetoxy-17-acetylamino-5,16-androstadiene (4)	EtOH	240 mμ	3.82
4-Aza-5-cholesten-3-one (7)	EtOH	233 mμ	4.14
6-Aza-4-cholesten-7-one (8)	EtOH	234 mμ	4.11
4-Aza-4-methyl-5-cholesten-3-one (9)	EtOH	234 mμ	4.13
3β-Acetoxy-12a-aza-C-homo-5α,22α-spirost-9-(11)-en-12-one (10, 11)	MeOH	220 mμ	4.20
3-Aza-A-homo-4a-cholesten-4-one (II)	EtOH	220 mμ	4.05
17β-Acetylamino-3-aza-A-homo-4a-androsten-4-one (VIII)	EtOH	220 mμ	4.14

prepared from an α,β-unsaturated ketone. Mazur (10) prepared this compound from 3β-acetoxy-5α,22α-spirost-9(11)-en-12-one by means of the Beckmann rearrangement of its oxime. The structure which Mazur tentatively assigned to the product was confirmed by Bladon and McMeekin (11).

The Schmidt reaction was carried out with progesterone (VII) under conditions similar to those used for cholestenone (I). 17β-Acetylamino-4-androsten-3-one (VII) was obtained with 1 mole of sodium azide and 17β-acetylamino-3-aza-A-homo-4a-androsten-4-one (VIII) with an excess of sodium azide. The structural assignments were made on the basis of analysis and spectra.

Compound VII (12, 13) was prepared by Oppenauer oxidation of 17β-acetylamino-5-androsten-3β-ol (IX) (14) and shown by means of mixed melting points and a comparison of spectra to be identical with the sample prepared by the Schmidt reaction of progesterone.

EXPERIMENTAL[1]

3-Aza-A-homo-4a-cholesten-4-one (II).—A mixture of 5.0 Gm. of 4-cholesten-3-one (I), 160 Gm. of polyphosphoric acid, and 1.0 Gm. of sodium azide was heated at 50–60° for 10 hours with frequent stirring, following a previously described procedure for the Schmidt reaction of steroids in polyphosphoric acid (3). The mixture was poured onto crushed ice, made alkaline with cold 50% potassium hydroxide, extracted with chloroform, and washed with water. Removal of the solvent, after drying over sodium sulfate, yielded 5.1 Gm. of a brown solid residue. The residue was chromatographed with 60 Gm. of neutral Woelm alumina, activity grade I, which had been prepared with benzene. Elution with benzene (3 × 150 ml.) yielded a sticky material which melted completely by 63°. A series of elutions extending from chloroform-benzene (1:19) through chloroform yielded 3.1 Gm. (60%), m.p. 220–240°. An analytical sample was prepared by crystallization from benzene-acetone; m.p. 255–260°; $[\alpha]_D^{27}$ +20.0° (c, 1.0 $CHCl_3$); $\lambda_{max.}^{EtOH}$ 220 mμ, log ε 4.05; $\lambda_{max.}^{CHCl_3}$ 291 mμ (free NH); 6.05 μ (lactam C=O); 6.22 μ (C=C).

Anal.—Calcd. for $C_{27}H_{45}NO$: C, 81.14; H, 11.35; N, 3.51. Found: C, 80.89; H, 11.40; N, 3.70.

During the course of subsequent preparations it was established that the product of this reaction could be purified by repeated digestion with petroleum ether.

The initial attempts to prepare this product by the Schmidt reaction using chloroform as the solvent and sulfuric acid as the catalyst yielded an oily product which could not be separated by chromatography.

Attempted Hydrolysis of 3-Aza-A-homo-4a-cholesten-4-one (II).—A 1-Gm. sample of II was added to 100 ml. of 5% potassium hydroxide in 95% ethanol and the mixture was refluxed 1½ hours. The lactam was recovered unchanged.

A mixture of 1 Gm. of II, 150 ml. of dioxane, and 50 ml. of concentrated hydrochloric acid was refluxed 3 hours. The lactam was recovered unchanged.

Hydrogenation of 3-Aza-A-homo-4a-cholesten-4-one (II).—3-Aza-A-homo-4a-cholesten-4-one, 4.0 Gm., was dissolved in 200 ml. of glacial acetic acid. Platinum oxide, 700 mg , was added and the mixture was shaken in a Parr hydrogenator at 72° with a hydrogen pressure of 60 lb. for 9 hours. The mixture was cooled, filtered, diluted, and saturated with sodium chloride. The mixture was extracted with methylene chloride. The extracts were washed with sodium carbonate solution and water and then dried over sodium sulfate. The residue, 3.8 Gm., obtained by evaporating the solvent was chromatographed on a column prepared with 125 Gm. of neutral Woelm alumina, activity grade I. The column was prepared with benzene. No product was obtained by elution with benzene or methylene chloride. Elution with absolute ethanol-methylene chloride, 1:99, (6 × 500 ml.) yielded 2.6 Gm. (frac-

[1] Melting points are uncorrected. Analyses were obtained from Drs. Weiler and Strauss, Oxford, England. Spectra were obtained on Perkin-Elmer Infracord and Spectracord spectrophotometers. The authors wish to express their thanks to the Cancer Chemotherapy National Service Center for the steroid intermediates used in this investigation.

tion A), m.p. 202–245°. There was no absorption which could be attributed to an olefinic double bond. A series of fractions were combined as fraction A since they had similar melting points and identical infrared spectra.

Repeated crystallizations from absolute ethanol raised the melting point to 263–269° without changing the infrared spectrum. A mixed melting point with an authentic sample of 3-aza-A-homo-5α-cholestan-4-one, m.p. 270–272°, gave a m.p. of 264–269°, establishing that these samples are identical.

Further elution of the column with ethanol yielded 800 mg. of starting material, II.

17β-Acetylamino-4-androsten-3-one (VII).—*Method A, from Progesterone.*—Progesterone (VI), 2.0 Gm., was allowed to react with 0.4 Gm. of sodium azide in polyphosphoric acid in a procedure similar to that used for cholestenone. After repeated crystallizations from acetone the crude product yielded 220 mg. of an analytical sample of 17β-acetylamino-4-androsten-3-one (VII), m.p. 275–278°; $[\alpha]_D^{27}$ + 58.0° (c, 1.0 $CHCl_3$); $\lambda_{max.}^{EtOH}$ 239 mμ, log ε 4.11; $\lambda_{max.}^{CHCl_3}$ 2.92 μ (free NH), 3.00 μ (associated NH), 6.01 μ (C=O), and 6.20 μ (C=C). A second crop (500 mg.) was obtained giving a total yield of 720 mg. (35%).

Anal.—Calcd. for $C_{21}H_{31}NO_2$: C, 76.55; H, 9.48; N, 4.25. Found: C, 76.42; H, 9.39; N, 4.69.

Method B, from 17β-Acetylamino-5-androsten-3β-ol (IX).—To a refluxing suspension of 681 mg. of 17β-acetylamino-5-androsten-3β-ol (IX) (14) in a mixture of 100 ml. of dry benzene and 40 ml. of acetone, was added a solution of 4.1 Gm. of aluminum isopropoxide in 20 ml. of benzene. The mixture was refluxed 44 hours. After cooling, 10 ml. of water was added and the mixture was shaken vigorously. Then 40 ml. of dilute sulfuric acid was added and the mixture was again shaken. The benzene layer was separated, washed with water, and dried over sodium sulfate. The residue obtained by evaporating the solvent was crystallized from acetone to yield 345 mg. of 17β-acetylamino-4-androsten-3-one, m.p. 272–277° [reported 270° (12) and 284–286° (13)]. This product was shown to be identical to that prepared by method A by a comparison of infrared spectra and a mixed melting point.

17β-Acetylamino-3-aza-A-homo-4a-androsten-4-one (VIII).—The Schmidt reaction was carried out by the procedure described for cholestenone using 1.6 Gm. of progesterone, 60 Gm. of polyphosphoric acid, and 800 mg. of sodium azide. The residue obtained by the usual workup was triturated with cold acetone and filtered to yield 500 mg. (29%) of a white powder, m.p. 270–280°. A mixed m.p. with VII showed a marked depression, m.p. 230–250°. An analytical sample was prepared by crystallization from methanol-acetone; m.p. 289–291°; $[\alpha]_D^{27}$ − 2.0; $\lambda_{max.}^{EtOH}$ 220 mμ, log ε 4.14; $\lambda_{max.}^{CHCl_3}$ 3.07 μ, 3.20 μ, 5.98 μ, 6.05 μ, 6.30 μ.

Anal.—Calcd. for $C_{21}H_{32}N_2O_2$: N, 8.13. Found: N, 7.43.

Studies on Sciatic Stimulated Rat Brain Sulfhydryl Levels

By JOHN H. MENNEAR, TOM S. MIYA, and GEORGE K. W. YIM

Rat brain nonprotein sulfhydryl levels were increased by electrical stimulation of the sciatic nerve. Pretreatment with morphine sulfate, meperidine hydrochloride, chlorpromazine hydrochloride, or meprobamate blocked the rise in cerebral levels of nonprotein sulfhydryl. The compounds had no effect on nonstimulated cerebral nonprotein sulfhydryl.

UNGAR AND ROMANO (1) demonstrated that electrical stimulation of the sciatic nerve of unanesthetized rats induces increased brain levels of free and bound sulfhydryl groups. Earlier work in our laboratories (2) showed that stimulation of the sciatic nerve of pentobarbitalized rats increased brain levels of nonprotein sulfhydryl (NPSH). Only the NPSH levels of the cerebrum were increased by sciatic stimulation.

Glutathione, a sulfhydryl-containing tripeptide, has been implicated as playing some role in conditions of mental aberration. The levels of NPSH detected by the amperometric titration

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

procedure employed in this investigation consists mainly of reduced glutathione (3). Lowered blood glutathione levels in schizophrenic patients have been reported (4–6) and another report indicated that glutathione was useful in the treatment of schizophrenic states (7). Other workers have been unable to confirm these results. This investigation was undertaken to study further the effects of sciatic nerve stimulation on brain NPSH and to study the effects of chlorpromazine,[1] and meprobamate,[2] morphine, and meperidine on increased cerebral NPSH levels produced by sciatic nerve stimulation.

EXPERIMENTAL

Holtzman albino rats of both sexes weighing 150–250 Gm. were curarized, rather than pentobarbitalized, with 0.02 mg. of dimethyl tubocurarine iodide per rat and artificially respired during the course of the stimulation. The sciatic nerve was stimulated for 20 minutes with a Grass model S4E stimulator with square wave pulses of 40 volts intensity, 3 milliseconds duration at a frequency of 100 cycles per second. After the nerve was stimulated the rat was sacrificed by decapitation. The brain was removed, washed immediately with cold 2% sulfosalicylic acid, the cerebrum removed and frozen with dry ice. The tissue was weighed and homogenized in cold 2% sulfosalicylic acid, centrifuged, and filtered through shark skin filter paper. The filtrate was diluted to a volume in which 2 ml. represented the extract of 100 mg. of tissue. Two-milliliter aliquots were assayed for NPSH by a modification of the amperometric titration procedure of Benesch and Benesch (8). Duplicate titrations of each sample were made, the results averaged and expressed as micromoles per cent of NPSH.

Control rats were curarized and artificially respired for 20 minutes with the electrode placed on the sciatic nerve, but without stimulation.

With the exception of the meprobamate suspension, all drug solutions were prepared daily. Meprobamate was prepared as an 8% suspension with 4% acacia and 0.1% sodium benzoate. All compounds were administered intraperitoneally. Chlorpromazine hydrochloride was administered 4 hours and meprobamate 2 hours prior to stimulation in doses of 10 mg./Kg. and 275 mg./Kg., respectively. Morphine sulfate and meperidine hydrochloride were administered in doses of 15 mg./Kg. and 30 mg./Kg., respectively. Sciatic stimulation was begun 15 minutes later.

The instability of tissue NPSH, even when frozen, necessitated rapid analysis of tissue samples. All frozen samples were assayed for NPSH within 8 hours after removal. Since the experimental procedures were time consuming, a design was employed in which each experimental group was completed as a separate study. An equal number of control animals was used for each experimental group. Nine rats were used for each treatment in the morphine experiment, while 6 rats were used for each treatment in the three remaining experimental groups.

TABLE I.—EFFECTS OF DRUGS ON SCIATIC STIMULATED CEREBRAL NPSH LEVELS

Treatment	Cerebral NPSH μm. % ± S.E.
Control	158.0 ± 1.5
Sciatic stimulation	205.0 ± 5.5
Stimulation plus chlorpromazine 10 mg./Kg. (4 hr. pretreatment)	161.0 ± 4.0
Chlorpromazine control 10 mg./Kg. (4 hr. pretreatment)	160.8 ± 2.3
Control	156.6 ± 1.0
Sciatic stimulation	182.0 ± 4.0
Stimulation plus meprobamate 275 mg./Kg. (2 hr. pretreatment)	152.5 ± 1.5
Meprobamate control 275 mg./Kg. (2 hr. pretreatment)	157.3 ± 2.0
Control	131.0 ± 5.0
Sciatic stimulation	171.5 ± 7.0
Stimulation plus morphine 15 mg./Kg. (15 min. pretreatment)	132.0 ± 7.0
Morphine control 15 mg./Kg. (15 min. pretreatment)	135.0 ± 9.0
Control	162.5 ± 5.5
Sciatic stimulation	210.5 ± 4.0
Stimulation plus meperidine 30 mg./Kg. (15 min. pretreatment)	168.0 ± 5.0
Meperidine control 30 mg./Kg. (15 min. pretreatment)	167.5 ± 2.5

RESULTS

The results of this investigation are summarized in Table I.

Cerebral NPSH levels of sciatic stimulated rats were significantly greater than those of control rats in each of the four experimental groups. The overall mean increase in cerebral NPSH after sciatic stimulation was 22%. When the applied voltage was reduced from 40 to 4 or less volts, cerebral levels of NPSH were still increased. In an experiment in which 4 rats were subjected to sciatic stimulation with 5 volts, an increase of 12.7% over control rats was noted.

In preliminary experiments, pretreatment with 10 mg./Kg. of chlorpromazine 10 minutes prior to sciatic stimulation was not effective in preventing the rise of cerebral NPSH. These rats were deeply sedated and had lost their righting reflexes. A longer pretreatment period of 4 hours was used before sciatic stimulation. The rats were beginning to regain their righting reflexes before stimulation was begun. As illustrated in Table I, this latter treatment with chlorpromazine completely blocked the rise in cerebral NPSH after sciatic stimulation. Chlorpromazine alone had no effect on cerebral NPSH levels in nonstimulated rats.

Bradley, *et al.* (9) had reported that pretreatment with 400 mg./Kg. of meprobamate intraperitoneally 20 minutes before stimulation was ineffective in preventing the rise of cerebral NPSH. In this study, a 275 mg./Kg. dose of meprobamate given 2 hours prior to stimulation blocked the NPSH rise, as did chlorpromazine. Meprobamate itself had no effect on the NPSH levels of the nonstimulated brain.

[1] Generously supplied by Smith Kline and French Laboratories, Philadelphia, Pa.

[2] Generously supplied by Wallace Laboratories, New Brunswick, N. J.

Morphine and meperidine-treated rats exhibited analgesia at the time stimulation was begun, and retained their righting reflexes. The results obtained were almost identical as those obtained with the meprobamate and chlorpromazine-treated rats. Both drugs prevented the NPSH rise in stimulated rats and neither affected NPSH levels of nonstimulated rats.

DISCUSSION

Ungar and Romano (1) found an increase of 55% in brain protein-bound sulfhydryl and a nonsignificant rise of 29% in dialyzable sulfhydryl in sciatic stimulated rats. In our studies, the 22% increase in NPSH observed was highly significant ($t_{10} = 6.3$; $P < 0.01$). The coefficients of variation in our studies were only about 4%, whereas in their data they were 12 and 16%. The fact that the dialyzable sulfhydryl was estimated by difference may account for the greater variability. It is possible that dialyzable sulfhydryl is not equivalent to the NPSH remaining after protein precipitation with sulfosalicylic acid. Another factor to be considered is that only cerebral NPSH levels were measured in our studies since NPSH of the cerebellum, medulla, and midbrain did not rise after sciatic stimulation.

Ungar and Romano postulated that the increased levels of protein-bound sulfhydryl after stimulation resulted from structural rearrangement of proteins participating in the mechanism of excitation. If NPSH changes parallel protein-bound sulfhydryl changes, then one possible explanation of the blockade of the NPSH rise by morphine, meperidine, chlorpromazine, and meprobamate is that these drugs may have prevented the excitation of the cerebrum, perhaps by a blockade of the neuronal paths from the sciatic nerve. One would have to assume, then, that pentobarbital, which did not block the NPSH rise, is relatively ineffective in preventing excitation of the cerebrum. Whether blockade of neuronal paths occurs can be confirmed by the use of electrophysiological approaches.

The biological roles of glutathione have not been established with certainty. Krimsky and Racker (10) have found glutathione to be a firmly bound prosthetic group of the glycolytic enzyme phosphoglyceraldehyde dehydrogenase. Glutathione reductase has been identified (11) and found to catalyze the oxidation of reduced triphosphopyridine nucleotide in the presence of oxidized glutathione with the resulting formation of reduced glutathione.

Szent-Gyorgyi (12) has suggested that glutathione and ascorbic acid, with their respective enzymes, might form a respiratory chain. The reduced and oxidized forms of these substances form reversible redox systems, and are found in highest concentrations in tissues with the highest metabolic activity. Mapson and Moustafa (13) constructed a model respiratory system in which oxygen consumption fell when levels of reduced glutathione decreased and oxidized glutathione increased. They proposed that oxidized glutathione is reduced by reduced triphosphopyridine nucleotide in the presence of glutathione reductase. The reduced glutathione is then oxidized by dehydroascorbic acid in the presence of dehydroascorbic acid reductase. This involvement of glutathione in carbohydrate metabolism suggests that the rise in cerebral glutathione may possibly be a consequence of accelerated cerebral metabolism which occurs when the sciatic nerve is stimulated.

The psychotropic agents employed in this investigation had no effect on nonstimulated cerebral NPSH levels and, as has been previously shown in this laboratory (9), behavioral changes induced by psychomimetic agents are not reflected by changes in cerebral NPSH. The tranquilizers as well as the analgetics employed in this study blocked the NPSH rise produced by sciatic stimulation. It is interesting to note that the analgetics used block the conditioned avoidance response. It is apparent that induced rises in cerebral NPSH levels are blocked by only certain types of central nervous system depressants since pentobarbitalized animals respond to the sciatic stimulation. Also, loss of consciousness is not essential to the blocking effect. Further work is contemplated to elucidate the mechanism of this blocking action.

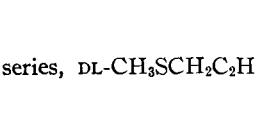
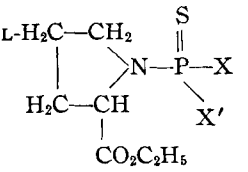
Thiophosphoric Acid Derivatives of Ethylamine, DL-Methionine, and L-Proline Ethyl Esters I

Synthesis



By FLORENCE C. KLEE† and ERNST R. KIRCH

Thiophosphoric acid derivatives having structures similar to known anticholinesterases, were synthesized for the investigation of their possible enzyme inhibition *in vivo*. Based on theoretical considerations concerning structures of known chemotherapeutic agents, these compounds may possess antitumor activity. The phenyl ester was found to be white needle-like crystals rather than the liquid reported by Michaelis. Procedures for obtaining good yields of the ethyl esters of L-proline and DL-methionine are given. A modified method of King's colorimetric determination of phosphorus is presented.



THE PURPOSE of this investigation was to prepare some thiophosphoric acid derivatives which have structures similar to known anticholinesterases, and to investigate their biological action *in vivo*. The three series of compounds synthesized are the following: ethylamine series,

C_2H_5N—P—X (X = X′ = Cl; X = X′ = OR where R is an ethyl, *n*-propyl, isopropyl, *n*-, *sec*-, *tert*- or iso-butyl, or a phenyl group; X = OC_2H_5, X′ = Cl); DL-methionine ethyl ester

series, DL-$CH_3SCH_2C_2H_5O_2C$—P—X, and L-proline ethyl ester series,

where

X = X′ = OC_2H_5

X = X′ = Cl

X = OC_2H_5, X′ = Cl.

These derivatives were selected with the intention of synthesizing anticholinesterases with potential antitumor activity. The rationale for the synthesis of these derivatives is as follows: (*a*) The phosphate radical is very important in biological systems and these organothiophosphorus derivatives may interfere with metabolic pathways providing the energy for cell metabolism of cancer cells. There is a possibility that the P=S group is converted to P=O *in vivo*, but this conversion would not be undesirable, since the anticholinesterase activity of these compounds would be enhanced (1).

(*b*) The amino acids, methionine and proline, were bound to the thiophosphorus radical in an attempt to produce potential amino acid antagonists since the amino acid antagonists DL-ethionine (2) and the bis-chloroethyl derivative of carbamoylserine (3) have been reported as tumor inhibitors. S-Carbamylcysteine has been observed to exhibit antitumor action (4). Methionine has been reported to reduce the growth of a rat sarcoma (5). Certain derivatives of proline have insecticidal activity (6).

(*c*) Certain phosphoric acid ester amides (7) and certain ethylenephosphoramides (8) have carcinostatic activity. A thiophosphoramide (thio-TEPA) (9, 10) is said to be curative and widely used.

(*d*) In the literature, anticholinesterase activity by alkyl phosphate compounds (11 – 13) and antitumor activity by certain chemotherapeutic agents (9) have been explained by proposed mechanisms involving an alkylation. The former activity is due to a dialkylphosphorylation of the enzyme.

The monosubstituted amides of dialkoxy(or diphenoxy)thiophosphoric acids were prepared according to a method similar to that reported by Michaelis (14) for the synthesis of dimethylamidodiethoxyphosphate.

The use of triethylamine in N-phosphoryl amino ester synthesis has been reported by Li (15). This tertiary amine was used in the synthesis of the thiophosphoric acid derivatives of DL-methionine and L-proline esters and in the preparation of ethylamidoethoxythionophosphoryl chloride.

Received April 26, 1961, from the College of Pharmacy, University of Illinois, Chicago.

Accepted for publication August 21, 1961.

This paper is abstracted in part from a dissertation submitted to the Graduate College at the Chicago Professional Colleges of the University of Illinois by Florence C. Klee in partial fulfillment of the requirements for the degree of Doctor of Philosophy in pharmaceutical chemistry.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

The authors wish to thank Monsanto Chemical Company for the supply of O,O-diethyl phosphorochloridothioate (Ethyl PCT) used in this investigation.

† Present address: University of Illinois, Navy Pier, Chicago.

EXPERIMENTAL

Thiophosphoryl chloride was prepared by the Knotz method (16) from 24 Gm. (0.75 mole) of powdered sulfur, 100 Gm. (0.73 mole) of phosphorus trichloride, and 2 Gm. (0.015 mole) of aluminum chloride as the catalyst. Reported b.p. 125–126°; yield, 120 Gm. (97.6%). Observed b.p. 124° (uncorr.); yield, 88.5 Gm. (71.8%).

Ethylamidothiophosphoryl chloride, $C_2H_5NHP(S)Cl_2$, was prepared from 32.6 Gm. (0.4 mole) of ethylamine hydrochloride and 136 Gm. (0.8 mole) of thiophosphoryl chloride according to the procedure of Michaelis (14). Reported b.p. 105°/9 mm.; yield is very good. Observed b.p. (uncorr.) 98–102°/8 mm.; yield, 58.0 Gm. (81.5%); n_D^{20} 1.5432.

Anal.—Calcd. for $C_2H_5Cl_2NPS$: N, 7.87; P, 17.40; S, 18.02. Found: N, 7.69; P, 17.49; S, 17.91. Qualitative chemical test for halogen.

Dialkoxyethylamidothiophosphates, $C_2H_5NHP(S)(O\text{-}Alkyl)_2$.—A solution of ethylamidothiophosphoryl chloride (8.90 Gm., 0.05 mole)[1] in anhydrous ether was slowly introduced into a warm sodium alkoxide solution prepared from 2.3 Gm. (0.1 mole) of sodium[2] dissolved in an excess of absolute alcohol. The ester formed upon heating for one-half hour and sodium chloride separated out on cooling. Distilled water was added dropwise to the mixture until the sodium chloride was completely dissolved, and the two layers were transferred to a separator and additional ether was introduced. The ethereal layer was removed, the aqueous layer was extracted again with ether, and the combined ether extracts were dried over anhydrous potassium carbonate. The ether was distilled and the remaining oil was subjected to vacuum distillation. The physical constants, yields, and analyses of the synthesized compounds are shown in Table I.

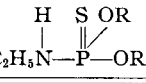
Diphenoxyethylamidothiophosphate, $C_2H_5N(H)-P(=S)(OC_6H_5)OC_6H_5$.—In 1903, Michaelis (14) reported that the phenyl ester analog of $C_2H_5N(H)-P(=S)(OC_2H_5)OC_2H_5$ is a liquid, but failed to report its method of preparation, analysis, or physical constants. The phenyl ester used in this investigation was prepared in the following manner: sodium phenoxide was prepared from 2.3 Gm. (0.1 mole) sodium in 10 ml. (10.7 Gm., 0.11 mole) of phenol. A small volume of phenol was added to cover the sodium phenoxide. A large excess of phenol was avoided in order to facilitate the isolation of the ester. Ethylamidothiophosphoryl chloride (8.9 Gm., 0.05 mole) in anhydrous ether was added to the cooled sodium phenoxide mixture and warmed on a steam bath for 10 minutes. The cooled mixture was treated with distilled water, extracted, and dried as given in the procedure for the dialkyl esters. After removal of the ether and excess phenol by distillation, the residue decomposed in part when subjected to vacuum distillation, as evidenced by the dark colored residue and evolution of gaseous products. The residue was dissolved in ether and, upon evaporation of the solvent, a crystalline tarry mass resulted. The mass was dissolved in warm 95% ethanol and filtered. Distilled water was added dropwise into the filtrate at 0° until precipitation began to take place. After repeated recrystallization, slow evaporation of the alcoholic solution produced white needle-like crystals rather than the liquid reported by Michaelis. Caution was used in the recrystallization of the product because an oil would form if the proper amount of water was not used. The melting point of the product was 64–64.5° (uncorr.) and the yield was 1.49 Gm. (10.2%).

Anal.—Calcd. for $C_{14}H_{16}NO_2PS$: N, 4.78; P, 10.56; S, 10.93. Found: N, 4.92; P, 10.56; S, 10.68. Quantitative chemical analysis and infrared data are consistent with the desired phenyl ester.

Ethylamidoethoxythionophosphoryl Chloride, $C_2H_5N(H)-P(=S)(OC_2H_5)Cl$.—Ethylthiophosphoryl dichloride ($C_2H_5OP(S)Cl_2$) was prepared according to the method of Bakanova, *et al.* (17), from 17 Gm. (0.1 mole) of thiophosphoryl chloride, 3 Gm. (0.065 mole) of absolute ethanol, and 0.5 Gm. (0.0185 mole) of fine aluminum wire. Reported b.p. 68°/20 mm., yield, 40%. Observed b.p. (uncorr.) 67°/20 mm.; yield, 3.50 Gm. (30%).

A solution of 4.48 Gm. (0.025 mole) of $C_2H_5OP(S)Cl_2$ and 5.06 Gm. (0.05 mole) of triethylamine in 30 ml. of dry chloroform was added dropwise (20 minutes) to a constantly stirred suspension of 2.04 Gm. (0.025 mole) of ethylamine hydrochloride in 25 ml. of dry chloroform at 0°. Stirring was continued at 25° for 40 minutes. A minute quantity of precipitate formed which did not increase in amount even after a 5-day period at 25° followed by heating at 45–50° for 2½ hours. After filtration, the chloroform solution was washed with two 25-ml. portions of distilled water, 1 *N* hydrochloric acid, 10% sodium bicarbonate solution, three 25-ml. portions of distilled water, and then dried over anhydrous sodium sulfate. Removal of the solvent by means of flash evaporation left a residue which distilled as a clear, colorless oil. Observed b.p. (uncorr.) 65–67°/0.25 mm.; n_D^{20} 1.4999; yield, 2.84 Gm. (60.6%).

Anal.—Calcd. for $C_4H_{11}ClNOPS$: N, 7.47; P, 16.51; S, 17.10. Found: N, 7.34; P, 16.59; S, 16.89. Qualitative chemical test for halogen.



Preparation of Thiophosphoric Acid Derivatives of DL-Methionine Ethyl Ester.

Synthesis of the Ethyl Ester of DL-Methionine.—It was found that the highest yield of ester was obtained when a suspension of 14.92 Gm. (0.1 mole) DL-methionine in 150 ml. of absolute ethanol was saturated at 0° with hydrogen chloride and refluxed for 1 hour. After a 48-hour period, most of the solvent was removed by use of a flash evaporator. The remaining viscous yellow liquid was dissolved in 40 ml. of absolute ethanol, 50 ml. of anhy-

[1] The ethyl ester was prepared from 0.2 mole (35.6 Gm.) and the isobutyl ester from 0.08 mole (14.2 Gm.) of ethylamidothiophosphoryl chloride.

[2] Potassium was used to make the alkoxide of tertiary butyl alcohol since the reaction was too sluggish with sodium and the yield was less than that obtained with the more active metal.

[a] Uncorrected b.p. at 0.25 mm. [b] Calculated for $C_6H_{16}NO_2PS$ (ethyl ester); $C_8H_{20}NO_2PS$ (propyl esters); $C_{10}H_{24}NO_2PS$ (butyl esters). [c] Reported in literature (14), b.p. 94°/12 mm.; yield, none reported.

drous ether was added, and anhydrous ammonia gas was bubbled through the two phase system at 0° for 1 hour. After 66 hours, the ammonium chloride and any unreacted amino acid were removed by filtration. The solvent was removed by flash evaporation and the residue subjected to vacuum distillation, giving 12.5 Gm. (70.3%) of the ethyl ester as a clear, colorless, oil. Observed b.p. (uncorr.) 84–86°/0.25 mm. Reported (18) b.p. 112°/2.5 mm.; yield, 88%.

Synthesis of N-(Diethoxyphosphinothioyl)-DL-methionine Ethyl Ester.—A dry chloroform solution (25 ml.) of O,O-diethyl phosphorochloridothioate (Ethyl PCT-Monsanto) (2.36 Gm., 0.0125 mole) was added dropwise within 60 minutes to a constantly stirred dry chloroform solution (25 ml.) of DL-methionine ethyl ester (2.19 Gm., 0.0124 mole) and triethylamine (1.25 Gm., 0.0125 mole) at 0–5°. Stirring was continued for 30 minutes at room temperature and after 18 hours the chloroform solution was washed and dried in the same manner as ethylamidoethoxythionophosphoryl chloride. A flash evaporator was used to remove chloroform and any remaining halogen-containing reactant. The ester distilled as a clear, colorless oil. Observed b.p. (uncorr.) 145–147°/0.25 mm.; n_D^{20} 1.4950; yield, 2.31 Gm. (56.8%).

Anal.—Calcd. for $C_{11}H_{24}NO_4PS_2$: N, 4.25; P, 9.40; S, 19.47. Found: N, 4.23; P, 9.47; S, 19.57.

Synthesis of N-(Ethoxychlorophosphinothioyl)-DL-methionine Ethyl Ester.—This ester was prepared according to the directions given for N-(diethoxyphosphinothioyl)-DL-methionine ethyl ester. The ethylthiophosphoryl dichloride (4.48 Gm., 0.025 mole) was added within 70 minutes to 4.43 Gm. (0.025 mole) of DL-methionine ethyl ester and 2.53 Gm. (0.025 mole) of triethylamine. This ester, a clear yellow oil, underwent complete decomposition when high vacuum distillation was attempted. n_D^{20} 1.4962; yield, 6.18 Gm. (77.3%).

Anal.—Calcd. for $C_9H_{19}ClNO_3PS_2$: N, 4.38; P, 9.69; S, 20.06. Found: N, 4.22; P, 9.65; S, 19.83. Qualitative chemical test for halogen.

Synthesis of N-(Dichlorophosphinothioyl)-DL-methionine Ethyl Ester.—This derivative was prepared in the same manner as the N-(diethoxyphosphinothioyl)-DL-methionine ethyl ester. Thiophosphoryl chloride (2.99 Gm., 0.0176 mole) was added within 180 minutes to 3.13 Gm. (0.0176 mole) of DL-methionine ethyl ester and 1.79 Gm. (0.0176 mole) of triethylamine. The product was washed with four 25-ml. portions of each solution instead of the indicated number. This derivative, a clear yellow oil, underwent complete decomposition when high vacuum distillation was attempted. Yield, 3.76 Gm. (68.6%). It was observed that the dichloro derivative was unstable at room temperature, since approximately 10 days after its synthesis, the yellow oil started to decompose.

Preparation of the Thiophosphoric Acid Derivatives of L-Proline Ethyl Ester

Synthesis of the Ethyl Ester of L-Proline.—It was found that the following procedure gives a 65% yield of the ester from 0.109 mole of L-proline. Dry hydrogen chloride gas was introduced very slowly (4 hours) into a constantly stirred suspension of L-proline (12.58 Gm., 0.109 mole) in absolute ethanol (150 ml.) at 0°. After 2 days at 25°, the solvent was removed by flash evaporation and the residue dissolved in absolute ethanol (40 ml.). After the addition of anhydrous ether (50 ml.), dry ammonia gas was introduced slowly at 0° until saturation occurred (1 hour). After an 18-hour period the ammonium chloride was removed by filtration and washed with anhydrous ether. The ether of the combined ethereal solutions was removed by flash evaporation and the residue was subjected to vacuum distillation. Reported (19) b.p. 78°/12–14 mm.; yield, 40.5 Gm. (66%). Observed b.p. (uncorr.) 77–78°/12 mm.; yield, 10.1 Gm. (64.5%).

Synthesis of N-(Diethoxyphosphinothioyl)-L-proline Ethyl Ester.—A dry chloroform solution (25 ml.) of O,O-diethyl phosphorochloridothioate (4.72 Gm., 0.025 mole) (Ethyl PCT-Monsanto) was introduced within 30 minutes into a constantly stirred dry chloroform solution (25 ml.) of proline ethyl ester (3.58 Gm., 0.025 mole) and triethylamine (2.53 Gm., 0.025 mole) at 0°. Stirring was continued for 30 minutes and the solution was allowed to stand at 25° for 18 hours.[3] The chloroform solution was washed, dried, and distilled in the same manner as the ethylamidoethoxythionophosphoryl chloride. This ester is a clear, colorless, distillable oil. Observed b.p. (uncorr.) 118–120°/0.25 mm.; n_D^{20} 1.4810; yield, 4.65 Gm. (63.0%).

[3] This derivative was heated for 1 hour at 55–60° on 2 successive days to insure completeness of reaction. It was found that the quantity of white precipitate that had originally formed did not increase in amount upon further heating.

Anal.—Calcd. for $C_{11}H_{22}NO_4PS$: N, 4.74; P, 10.49; S, 10.86. Found: N, 4.68; P, 10.47; S, 10.86.

Synthesis of N-(Ethoxychlorophosphinothioyl)-L-proline Ethyl Ester.—This ester was prepared in a similar manner as the N-(diethoxyphosphinothioyl)-L-proline ethyl ester. Ethylthiophosphoryl dichloride (3.97 Gm., 0.022 mole) was introduced within 120 minutes into the proline ethyl ester (3.18 Gm., 0.022 mole) and triethylamine (2.24 Gm., 0.022 mole). No additional heating was applied after the solution was allowed to stand at 25° for 18 hours. The ester is a clear, yellow, undistillable oil. n_D^{25} 1.5088; yield, 4.81 Gm. (75.9%).

Anal.—Calcd. for $C_9H_{17}ClNO_3PS$: N, 4.90; P, 10.84; S, 11.23. Found: N, 4.83; P, 10.86; S, 10.99. Qualitative chemical test for halogen.

Synthesis of N-(Dichlorophosphinothioyl)-L-proline Ethyl Ester.—This derivative was prepared according to the procedure given for the N-(diethoxyphosphinothioyl)-L-proline ethyl ester. Thiophosphoryl chloride (4.24 Gm., 0.025 mole) was introduced within 120 minutes into the proline ethyl ester (3.58 Gm., 0.025 mole) and triethylamine (2.53 Gm., 0.025 mole). No additional heating was applied after the solution was allowed to stand at 25° for 18 hours. The ester is a clear, yellow, undistillable oil. Yield, 5.67 Gm. (82.2%). As was found in the methionine series, this dichloro derivative is not stable at room temperature.

Colorimetric Determination of Phosphorus.—The thiophosphoric acid derivatives of ethylamine, methionine, and proline were analyzed for phosphorus by the method of King (20). The following modifications were introduced: A standard curve was made up from aliquots (containing 0.01 to 0.15 mg. of phosphorus) of a standard phosphate solution. Readings were obtained in a Coleman spectrophotometer at 650 mμ. King compares the color of a standard phosphate solution with that of the unknown solution in a Duboscq colorimeter.

Double quantities of 72% perchloric acid, 5% ammonium molybdate, and sulfonic acid were used and diluted to 100 ml. instead of 15 ml.

The sample (approximately 40 mg.) was digested with 1 ml. of perchloric acid,[4] diluted to 100 ml. with distilled water and an aliquot (usually 1 ml.), containing between 0.05 and 0.1 mg. phosphorus, was used for the colorimetric determination. Results were very satisfactory.

DISCUSSION

Since the yield of DL-methionine ethyl ester when prepared by the method of Booth, *et al.* (18), did not furnish enough starting material for further syntheses, the method of preparation was investigated to improve the yield. The highest yield of ester was obtained by the procedure given in the experimental section.

Kapfhammer and Matthes (19) reported the synthesis of the ethyl ester of L-proline from 50 Gm. of L-proline with no mention of the amount of ethanol, rate of hydrogen chloride introduction, time, and temperature at which the reaction took place. It was found in this investigation that a 65% yield of the ester could be obtained from 12.58 Gm. of L-proline according to the directions given in the experimental part. Freshly prepared ester was used in the syntheses of the thiophosphoramides, since this ester loses ethanol spontaneously at room temperature, to form the solid anhydride or diketopiperazine derivative.

The thiophosphoric acid derivatives of both amino acid ethyl esters were prepared from the amino acid ester and an appropriate thiophosphoryl chloride (1:1 molar ratio) in the presence of triethylamine. The tertiary amine reacted with the liberated hydrogen chloride gas and allowed most of the amino acid ester to form the desired product instead of the amino acid ester hydrochloride.

Analytical Methods.—Nitrogen analyses were by a semimicro Kjeldahl method and phosphorus analyses were determined by a modified King method. With the exception of the methionine series compounds, sulfur was determined gravimetrically after a perchloric-nitric acid oxidation method of Webster and Powers (21). Callan and Toennies (22) have reported the incomplete oxidation of sulfur in methionine when wet-oxidative methods were used. In this investigation it was found that the methionine derivatives were incompletely oxidized by perchloric-nitric acid, but completely oxidized when they were burned in the Parr bomb. The sulfur was then determined gravimetrically as barium sulfate. Halogen was detected by a qualitative chemical test after a sodium fusion of the halogen-containing compounds in the three series.

SUMMARY

The thiophosphoric acid derivatives of ethylamine, DL-methionine, and L-proline ethyl esters of the general formula, $-\overset{|}{N}-\overset{\overset{S}{\|}}{P}(X)_2$ where $(X)_2$ is $(O\text{-alkyl})_2$, $(O\text{-phenyl})_2$, $(C_2H_5O)Cl$, or $(Cl)_2$, were synthesized for the investigation of their possible enzyme inhibition *in vivo*.

It was found that the phenyl ester is crystalline rather than liquid as reported by Michaelis who failed to report its method of preparation, analysis, and physical constants. The procedures for obtaining good yields of the ethyl esters of these two amino acids from 0.1 mole of the amino acid are given.

All of the compounds, with the exception of the methionine derivatives, were oxidized by the wet-oxidative perchloric-nitric acid method of Webster and Powers. The methionine derivatives were completely oxidized in the Parr bomb.

It was found that a modified King method gave very satisfactory results for the colorimetric determination of phosphorus.

Thiophosphoric Acid Derivatives of Ethylamine, DL-Methionine, and L-Proline Ethyl Esters II

Biological Activities in Guppies

By FLORENCE C. KLEE† and ERNST R. KIRCH

Observed biological responses of guppies in 0.01% w/v aqueous solutions of the thiophosphoric acid derivatives indicate that the compounds are acetylcholinesterase inhibitors. The 0.001% solutions furnished additional information concerning the biological activity of these compounds. Structure-toxicity relationship is discussed.

THE SYNTHESIS of thiophosphoric acid derivatives of ethylamine, DL-methionine, and L-proline ethyl esters has recently been published (1).

The thiophosphoric acid derivatives used in this investigation have the general formula

—N—P(X)$_2$, where (X)$_2$ = (O-alkyl)$_2$, (O-C$_6$H$_5$)$_2$, (C$_2$H$_5$O)Cl, or (Cl)$_2$, and N represents the amine or amino acid ester moiety. These structures are similar to those of known anticholinesterases, thus the thiophosphoric acid derivatives may be acetylcholinesterase inhibitors. If so, then the following types of biological responses may be visualized in guppies (*Lebistes Reticulatus*): difficulty in breathing, dizziness, evacuation of rectum and bladder, convulsions, and total paralysis (death).

The purpose of this investigation was to observe the biological responses of baby guppies which have been immersed for 24 hours in 0.01 and 0.001% w/v aqueous solutions of each compound.

EXPERIMENTAL

Table I lists the compounds used in this study. Stock aqueous solutions or aqueous suspensions (0.1% w/v) were prepared from which 0.01 and 0.001% w/v solutions were obtained after making a tenfold dilution of the stock and 0.01% w/v solution.

An alcoholic stock solution and alcoholic dilutions were made of diphenoxyethylamidothiophosphate, since it was not possible to obtain a uniform 0.1% w/v aqueous suspension. Aliquots of the alcoholic solutions were allowed to evaporate to dryness and a volume of distilled water equal to the volume of alcohol was introduced before testing the biological activity of the compound.

Ten milliliters of 0.01 and 0.001% w/v aqueous solutions of each compound were placed in separate vials (2.4 cm. diameter and 5.5 cm. in height) and 10 young guppies were placed in each vial. For control purposes, distilled water was used instead of an aqueous solution of a compound under test and it was observed that all of the guppies survived after 24 hours. The O,O-diethyl phosphorochloridothioate (Ethyl PCT-Monsanto), C$_2$H$_5$O—P(S)—Cl,

Thiophosphoric Acid Derivatives of Ethylamine, DL-Methionine, and L-Proline Ethyl Esters II

Biological Activities in Guppies

By FLORENCE C. KLEE† and ERNST R. KIRCH

Observed biological responses of guppies in 0.01% w/v aqueous solutions of the thiophosphoric acid derivatives indicate that the compounds are acetylcholinesterase inhibitors. The 0.001% solutions furnished additional information concerning the biological activity of these compounds. Structure-toxicity relationship is discussed.

THE SYNTHESIS of thiophosphoric acid derivatives of ethylamine, DL-methionine, and L-proline ethyl esters has recently been published (1).

The thiophosphoric acid derivatives used in this investigation have the general formula

—N—P(X)$_2$, where (X)$_2$ = (O-alkyl)$_2$, (O-C$_6$H$_5$)$_2$, (C$_2$H$_5$O)Cl, or (Cl)$_2$, and N represents the amine or amino acid ester moiety. These structures are similar to those of known anticholinesterases, thus the thiophosphoric acid derivatives may be acetylcholinesterase inhibitors. If so, then the following types of biological responses may be visualized in guppies (*Lebistes Reticulatus*): difficulty in breathing, dizziness, evacuation of rectum and bladder, convulsions, and total paralysis (death).

The purpose of this investigation was to observe the biological responses of baby guppies which have been immersed for 24 hours in 0.01 and 0.001% w/v aqueous solutions of each compound.

EXPERIMENTAL

Table I lists the compounds used in this study. Stock aqueous solutions or aqueous suspensions (0.1% w/v) were prepared from which 0.01 and 0.001% w/v solutions were obtained after making a tenfold dilution of the stock and 0.01% w/v solution.

An alcoholic stock solution and alcoholic dilutions were made of diphenoxyethylamidothiophosphate, since it was not possible to obtain a uniform 0.1% w/v aqueous suspension. Aliquots of the alcoholic solutions were allowed to evaporate to dryness and a volume of distilled water equal to the volume of alcohol was introduced before testing the biological activity of the compound.

Ten milliliters of 0.01 and 0.001% w/v aqueous solutions of each compound were placed in separate vials (2.4 cm. diameter and 5.5 cm. in height) and 10 young guppies were placed in each vial. For control purposes, distilled water was used instead of an aqueous solution of a compound under test and it was observed that all of the guppies survived after 24 hours. The O,O-diethyl phosphorochloridothioate (Ethyl PCT-Monsanto), C$_2$H$_5$O—P(S)—Cl,

an anticholinesterase (2), was chosen as the reference standard for making biological response comparisons.

The behavior of the fish was closely observed for 2 hours, and at the end of 24 hours the number of fish which survived was recorded. There were no survivors in the 0.01% w/v aqueous solutions of the compounds with the exception of N-ethoxychlorophosphinothioyl-L-proline ethyl ester (Table I). The three fish (survivors) matured in 1 month and the male and a female expired shortly thereafter.

The 0.01% w/v (3.04 to 5.62 × 10^{-4} *M*) aqueous solutions of the compounds produced biological responses similar to those of known acetylcholinesterase inhibitors. Before total paralysis occurred, the guppies exhibited difficulty in breathing and intermittent convulsions (head and tail flutter) followed by coma. Many of the fish lost their sense of balance and were seen in abnormal positions.

An unusual spinal effect was seen when the fish were subjected to the diphenoxyethylamidothiophosphate (0.01% w/v). This compound caused the bending of the tail of several fish to such an extent that the tip of the caudal fin was adjacent to the head of the fish.

The fish which survived after 24-hour chemical treatment with aqueous 0.001% w/v solutions were transferred to fresh water and observed periodically for several months to determine the sex, the months required for the fish to mature, and any abnormal development.

Behavior Toward Food.—An interesting observation concerning the behavior of the fish in fresh water toward food was made immediately after the 24-hour chemical treatment with 0.001% solutions of the compounds (Table II). Most of the fish consumed the food, but the fish which had been in solutions of the dihalo and four carbon chain derivatives, ignored the food. Fish previously in contact with the *sec*-butyl ester, actually leaped out of the water in an attempt to get away from the food which had touched them.

Sex Differentiation(?)—Unfortunately, the female/male ratio cannot be established at the start of the experiment since it is impossible to determine the sex of a baby guppy. However, after the guppies matured, it was found that the female/male survival ratio was greater than two to one, since there were more female survivors than males when both sexes survived (Table II). The larger number of female survivors may be due to the possibility that the compounds are more toxic to the male guppies or else most of the baby guppies (sex unknown) are females. The first reason seems more probable, since experimentation involving mature fruit flies shows that in general, the compounds are more toxic to the males than to females.

It is interesting to note that with the exception of the ethoxychloro derivative in the proline series, there were no male survivors in the ethyl and ethoxychloro derivatives in the three series of compounds, the reference standard, the normal, and isobutyl esters.

It is noteworthy that only the male fish survived in the aqueous solution of the normal propyl ester.

Effect on Growth.—Normal guppies mature in about 3 months after birth as evidenced by full

TABLE II.—SOME BIOLOGICAL RESPONSES OF GUPPIES

[a] The compounds in each series are arranged according to decreasing toxicity as determined by the per cent expired after 24 hours in the 0.001% w/v aqueous solutions. $(C_2H_5O)_2P(S)Cl$ is the reference standard; X = $C_2H_5NHP(S)$; Y = DL-$CH_3SCH_2CH_2CH(CO_2C_2H_5)NHP(S)$; Z = L-$CH_2CH_2CH_2CH(CO_2C_2H_5)N{-}P(S)$. [b] A, Consumed food; B, ignored food; C, darted away from food. [c] M, Male; F, female. [d] n, Normal, fish matured in 3 months; R, rapid, fish matured in two months; I_1 inhibited or retarded, fish were immature after 3 months; I_2, inhibited or retarded, fish were immature after 6 months. [e] The remaining fish expired 3 hours after transfer to fresh water. [f] Gave birth to young.

development of the body. Caudal fin pigmentation and modification of the pelvic fins in the male as claspers are secondary sexual characteristics which can be easily observed.

Growth Stimulation.—It was noted that both male and female fish matured in 2 months when they had been in aqueous solutions of the dihalo derivatives in the methionine and proline series, and the ethoxychloro derivative in the latter series (Table II). Female guppies, the only survivors, matured in 2 months after being in contact with aqueous solutions of the ethoxychloro derivatives in the ethylamine and methionine series, reference standard, and the ethyl derivative in the proline series.

The greatest stimulation of growth was produced by the aqueous solution of N-(dichlorophosphinothioyl)-L-proline ethyl ester. Gigantism, or abnormal overgrowth, of the female and male fish, which are slightly more than twice the size of normal fish of the same age, was observed.

Growth Inhibition or Retardation.—After 3 months there is no apparent change in size of some of the fish which survived in aqueous solutions of the ethoxychloro derivative in the methionine series and reference standard. The fish which had been exposed to the methionine derivative are the same size and immature even at 6 months of age (Table II). It is possible that these fish are males, since the only fish which did mature are females.

Abnormal Body Development.—The female fish which survived in the aqueous solution of the ethoxychloro ester (methionine series) do not have well-proportioned bodies. Their short bodies and unusually long caudal fins give the fish a "stretched out" appearance. The ventral side is not curved like that of normal fish, but appears to be rather straight. This peculiar shape was noted in other female fish but, unfortunately, the previous chemical treatment is unknown since all the female survivors were placed into the same vessel with all the male survivors for the purpose of observing whether reproduction can occur. The female fish which had matured rapidly and were not well-proportioned expired at the age of $4^1/_2$ months.

In contrast, the giant female fish resulting from the 24-hour contact with the dichloro derivative in the proline series are beautifully proportioned and appear to be in perfect health at 6 months of age.

Reproduction.—The guppies which had undergone 24-hour contact with the same compound were placed into 2 L. of fresh water and observed periodically until they matured. Only the fish which had been in the aqueous solution of the tertiary butyl ester produced progeny (Table II).

The male and female survivors were introduced into the same container and after 6 months, it is interesting to note, only one of the many females had given birth to young. There is a possibility that the synthetic thiophosphoric acid derivatives cause sterility in guppies in view of the fact that alkylating agents are known to produce transient sterility in male rats (3).

Tail Pigment.—Normal female guppies do not have highly pigmented tails. The tip of the caudal fin is a very pale yellow and practically unnoticeable. The giant female fish which resulted after 24-hour contact with an aqueous solution of the N-(dichlorophosphinothioyl)-L-proline ethyl ester have large tails and the bright yellow pigment near the end of the fin can be easily seen in daylight. The ends of the caudal fins of the females which had been exposed to other compounds are green and black.

The bodies and tail of normal male guppies are orange, green, blue, and black. The pigment of the male survivors is essentially the same as that of fish which have not been in 24-hour contact with thiophosphoric acid derivatives, however, there appears to be a predominance of brilliant red color and almost complete absence of orange pigment.

DISCUSSION

The structures of the synthesized compounds are similar to those of compounds known to be acetylcholinesterase inhibitors. Since very frequently the anticholinesterase activity *in vitro* of a given organophosphorus compound is not related to its toxicity *in vivo*, guppies were chosen to investigate the biological activity of the thiophosphoric acid derivatives of ethylamine, DL-methionine, and L-proline ethyl esters. Fish possess acetylcholinesterase in addition to other enzymes, and their biological responses can be readily observed when enzyme inhibition occurs.

If these derivatives are acetylcholinesterase inhibitors then certain biological responses such as difficulty in breathing, dizziness, and convulsions should have been observed. These responses were observed but other responses such as growth stimulation and retardation were also noted. It appears to the authors that the compounds probably have anticholinesterase activity.

The compounds of the three series are arranged in Table III according to decreasing toxicity as determined by the expiration time of the fish which represents time, in minutes, when the last fish of each group of 10 ceased to breath. For making biological response comparisons, $(C_2H_5O)_2P(S)Cl$, an anticholinesterase, was chosen as the reference standard.

Structure-Toxicity Relationship.—The compounds as 0.01% solutions are toxic to guppies. Based on the maximum time for expiration (Table III), in general, the ethylamine derivatives are faster acting than the methionine derivatives, and the latter are faster acting than the proline derivatives. As the expiration time decreases, most probably the toxicity increases, and with this assumption, the following observations concerning toxicity of the compounds are made.

Varying X[1] Groups of the Amine[2]—P—Nucleus:

Ethylamine Series, $C_2H_5N—P(X)_2$.—Observations of the results obtained with the 0.01% solutions indicate that halogen derivatives are the most toxic to fish (Table III). Branching of the three carbon chain produces an ester which is one-third as toxic as the straight chain ester because the expiration time is almost tripled. The four carbon esters are about one-half as toxic as the normal propyl ester. The two carbon ester is the least toxic since the biological responses of the guppies were observed for almost 2 hours.

Comparison of the results observed with the 0.001% solutions indicate that the dichloro and phenyl esters are the most toxic to guppies because there were no survivors (Table II). Both sexes survived in the isopropyl, secondary, and tertiary butyl esters; however, it is interesting to note that there were more female survivors than males. The fish which had been exposed to the tertiary butyl ester produced offspring. Only females survived in the normal butyl, isobutyl, ethyl, and ethoxychloro esters. The latter ester stimulated growth since the females matured in 2 months. There were exclusively male survivors in the normal propyl ester which suggests that females are more susceptible than males to this compound.

Varying X[3] Groups of the Amine[2]—P—Nucleus: DL-

Methionine Series, DL-$CH_3SCH_2CH_2CH$—NH—P

$(X)_2$; **L-Proline Series,** L-$CH_2CH_2CH_2CHN$—$P(X)_2$

—In the two amino acid series, the 0.01% solutions of the diethyl esters are the most toxic to guppies. The diethoxy and dichloro derivatives are more toxic (quicker acting) than the ethoxychloro ester (Table III). However, the proline derivatives are less toxic (slower acting) than the corresponding methionine derivatives. The ethoxychloro ester in the proline series is the least toxic of the amino acid derivatives because there are survivors.

The 0.001% solutions furnished additional information in regards to the biological activity of these compounds in guppies.

When the X groups attached to the methionine nucleus[4] are ethoxy and chlorine, the ester has the unusual ability to retard or inhibit the growth of some of the guppies (possibly males) and stimulated the growth of the females, since the only fish which matured are females (Table II). Replacement of the ethoxy group by chlorine produced the dihalo derivative which caused rapid growth of both females and males. The latter matured in only 2 months. When X groups are OC_2H_5, only females survived which matured in about 3 months.

As 0.001% solutions, the proline derivatives obtained when diethoxy, ethoxychloro, and dichloro groups are attached to the proline nucleus[5] produced rapid growth in female guppies. The latter two compounds also caused rapid growth in the males that survived. The dichloro derivative stimulated growth to such an extent that both male and female fish are more than twice the size of normal fish of the same age.

Varying the Amine[2] of the —P—OC_2H_5 **Nucleus.**

—It was found that the methionine derivative is more toxic than the ethylamine and proline derivatives (Table III). Female guppies are the only survivors in the 0.001% solutions of these compounds (Table II). The proline derivative stimulated growth as evidenced by the females maturing in a relatively short time.

Varying the Amine[2] of the —P—OC_2H_5 **Nucleus.**

—The ethylamine derivative is much more toxic than the methionine derivative which, in turn, is more potent than the proline derivative (Table III). All of these esters (0.001%) promoted rapid growth of the females and the proline ester, in addi-

[a] Reference standard, $(C_2H_5O)_2P(S)Cl$, expiration time, 11 minutes; for control purposes, distilled water was used instead of the 0.01% solution of the compound under test, and it was observed that all of the guppies were alive after 24 hours. [b] X = $C_2H_5NHP(S)$. [c] Y = DL-$CH_3SCH_2CH_2CH(CO_2C_2H_5)NHP(S)$. [d] Z = L-$CH_2CH_2CH_2CH(CO_2C_2H_5)N—P(S)$. [e] Survival of 30% after 24 hours.

tion, had the same effect on males (Table II). The methionine ester is outstanding in that it retarded or inhibited the growth of some of the guppies (possibly the males).

Varying the Amine[2] of the —P(S)Cl Nucleus.—

The order of decreasing toxicity is ethylamine, methionine, followed by proline (Table III). There were no survivors in the 0.001% solution of the ethylamine derivative (Table II). The amino acid derivatives actually stimulated the growth of both sexes. The proline derivative excelled in this ability in that it caused gigantism.

SUMMARY AND CONCLUSIONS

The observed biological responses of baby guppies which had been immersed in 0.01% w/v aqueous solutions of the thiophosphoric acid derivatives of ethylamine, DL-methionine, and L-proline ethyl esters, indicate that these derivatives probably have anticholinesterase activity. It was noted that the phenyl ester caused extreme bending of the caudal fin of some of the fish.

Other biological responses were observed with the 0.001% solutions. There were very few male survivors, and only one of the many female survivors produced progeny. Behavior toward food, growth stimulation, growth retardation or inhibition, abnormal body development, and enhancement of pigmentation were observed.

Almost all of the amino acid derivatives, the ethoxychloro derivative (ethylamine series), and the reference standard caused rapid growth of both sexes or of the female survivors. Maximum growth stimulation was observed with the dichloro proline derivative. The female fish which had matured rapidly and were not well-proportioned expired at the age of $4\frac{1}{2}$ months.

The ethoxychloro methionine derivative and the reference standard caused growth inhibition of some of the guppies (possibly the males) and stimulated the growth of the females.

There were exclusively male survivors in the normal propyl ester.

The fish which had been in the dichloro and butyl derivatives (ethylamine series) ignored food. The guppies previously in contact with the *sec*-butyl ester actually leaped away from the food which had touched them.

Pigmentation was enhanced in both sexes.

Based on the maximum time for expiration, in general, the ethylamine derivatives are the fastest and the proline derivatives are the slowest acting. Structure-toxicity relationship is discussed. Observations of the results obtained with the 0.01% solutions indicate that halogen derivatives (ethylamine series) and diethoxy derivatives (both amino acid series) are the most toxic to guppies.

Loss of Sensitivity in Distinguishing Real Differences in Dissolution Rates Due to Increasing Intensity of Agitation

By W. E. HAMLIN, E. NELSON†, B. E. BALLARD†, and J. G. WAGNER

Two polymorphic forms of methylprednisolone, designated I and II, were compressed into constant surface pellets and their dissolution rates determined *in vitro* by four different methods and *in vivo* following implantation in rats. There was a highly significant difference between the rates of dissolution of forms I and II *in vivo*. There were also highly significant differences between the rates of dissolution of forms I and II in the two *in vitro* tests where the intensity of agitation was of a relatively low order of magnitude. There were no significant differences in the rates of dissolution of forms I and II in the two *in vitro* tests which produce the greatest velocity of dissolution medium across the surface of the pellet. One of the *in vitro* methods which gave no significant difference in rates for forms I and II employed the machine of Souder and Ellenbogen, rotating at 40 r.p.m. This machine is now being used in interlaboratory tests of timed release and prolonged action oral products in an attempt to "develop a test procedure which may be generally useful as a routine control procedure." The implications of our results in relation to such testing procedures are discussed.

IN PERFORMING dissolution rate experiments several investigators (1–6) have used relatively high intensities of agitation, and Nelson (7) has described a method in which free convection, diffusion coefficient, and concentration were stated to be the rate determining factors. Several authors (4, 5, 8) have reviewed the literature concerning the effect of agitation speed on the velocity of heterogeneous reactions and the kinetics of dissolution; some of these results are discussed in the Appendix. We have studied the *in vitro* dissolution of many substances by several methods and have attempted in some cases to correlate the results with *in vivo* measurements of absorption rate, either after implantation of the substances or following their oral administration. With respect to relative intensity of agitation (rate of stirring or velocity of the dissolution medium across the surface of the dissolving substance), we have been interested in determining: (*a*) what *in vitro* method correlates best with *in vivo* results; (*b*) whether differences between substances or lots of the same substance or product can be differentiated with respect to dissolution rate at different intensities of agitation; and (*c*) whether the error in the measured dissolution rate is independent of or dependent upon the relative intensity of agitation. Results of such investigations are important, not only from a theoretical viewpoint but also from a very practical viewpoint. Recently the Pharmaceutical Contact Section of the Pharmaceutical Manufacturer's Association (9) has been carrying out interlaboratory tests on timed release and prolonged action oral products. These investigations are intended to "develop a test procedure which may be generally useful as a routine control method." One of us (J. G. Wagner) wrote a memorandum (10) to the Tablet Subcommittee of the Contact Section outlining some of the pitfalls in the current tests under consideration. One of the pitfalls mentioned was that the intensity of agitation resulting from use of the machine described by Souder and Ellenbogen (11), and used in these interlaboratory tests, may be too great. On the basis of theory it was hypothesized that there may be examples where products would give a significant difference in results *in vivo*, yet by such a method the difference would not be measurable *in vitro*. We now have some experimental data obtained *in vivo* and by several *in vitro* methods to support this viewpoint.

EXPERIMENTAL

In order to test the above hypothesis we chose to use constant surface pellets of two polymorphic forms of methylprednisolone, hereafter termed forms I and II. Form II has a greater water solubility than form I, hence one could deduce that form II would have a greater initial dissolution rate in water than form I on the basis of dissolution rate theory (8). We chose to use pellets compressed at high pressures since with methylprednisolone I and II we observed these remained intact during dissolution and the surface areas during the experiments were accurately known. By operating in the region where the concentration of methylpredni-

The authors greatly appreciate the samples of the polymorphic forms of methylprednisolone supplied by Dr. John W. Shell, The Upjohn Co.

solone in the dissolution medium was very small compared with the concentration of a saturated solution, the mathematics was greatly simplified. In the *in vitro* tests such low concentrations were readily determined by means of ultraviolet spectrophotometry using the Cary recording spectrophotometer. See Fig. 1. In the implantation experiments in rats, rate of loss of weight was used as a criterion of dissolution and absorption rate. However, for constant surface pellets we have correlated rate of loss of weight with rate of appearance in the dissolution medium. Most of the details of the *in vivo* and *in vitro* experiments are given below. An adequate description of the pellet holder and the Wruble machine (12) will be made at a later date.

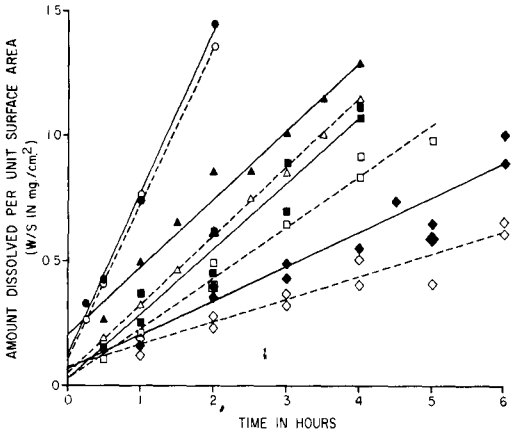

Fig. 1.—Pseudo zero-order plots for dissolution of methylprednisolone polymorphs I and II from constant surface pellets in water at 37°. ●—Polymorph II and ○—polymorph I, pellet holder method, 40 r.p.m. in the Souder and Ellenbogen machine. ▲—Polymorph II and △—polymorph I, pellet holder method, 12 r.p.m. in the Wruble machine. ■—Polymorph II and □—polymorph I, pellet holder method, 6 r.p.m. in the Wruble machine. ◆—Polymorph II and ◇—polymorph I, hanging pellet method.

Pellet Implants in Rats.—Pellets of pure methylprednisolone I and methylprednisolone II, 0.25 inch in diameter, were compressed at high pressure. Two disks of one polymorph were implanted in each rat. After different intervals of time the pellets were removed and weighed. Knowing the loss in weight, the surface area, and the time of exposure, the rate of weight loss, equivalent to the rate of absorption with opposite sign, was calculated. Thirty separate determinations involving three series of 10 different rats were used with methylprednisolone I, and 15 separate determinations involving three series of five different rats were used with methylprednisolone II. The overall average rates obtained are shown in Table I. The complete data have been published by Ballard and Nelson (13).

Hanging Pellet Method.—Pellets of pure methylprednisolone I and methylprednisolone II, 0.50 inch in diameter, were compressed at high pressure. The rates of dissolution in deionized water at 37° were determined by the method of Nelson (7), with the exception that instead of determining weight loss, the fluid surrounding the pellet was assayed for the steroid by ultraviolet spectrophotometry.

Pellet Holder in Wruble Machine.—Pellets of pure methylprednisolone I and methylprednisolone II, 0.375 inch in diameter, were compressed at high pressure. The rates of dissolution in deionized water at 37° were determined as follows. The pellets were held in a polyethylene holder at the center of oval 4-fl. oz. bottles containing 120 ml. of deionized water. The bottles were attached to the wheel of the machine described by Wruble (12). After rotation for different intervals of time, the fluid surrounding the pellet was assayed for steroid by ultraviolet spectrophotometry. The dimensions of the pellet initially and after exposure were determined and the average surface area during exposure to the water calculated. The weight of methylprednisolone in solution, which had been released by the pellet, was divided by the average surface area during exposure. The latter values were plotted against time of exposure to the water. The points were fitted by the method of "least squares." The intercepts and slopes (rates) of the lines are shown in Table I. Experiments were made with the wheel rotating at 6 r.p.m. and at 12 r.p.m.

Pellet Holder Method in the Machine of Souder and Ellenbogen (11).—The experiments were performed similarly as described above for the Wruble machine, except the machine described by Souder and Ellenbogen (11) was used in place of the Wruble machine. The bottles were rotated at 40 r.p.m. during exposure in a constant temperature bath held at 37°.

Estimation of Film Thickness.—Under the conditions of our *in vitro* experiments we can substitute D/h for k in Eq. 3 shown in the Appendix, where D is the diffusion coefficient of methylprednisolone in water and h is the diffusion layer or film thickness. Higuchi, Rowe, and Hiestand (14) have estimated D for methylprednisolone in water at 25° to be 4.7×10^{-6} cm.^{2} sec.$^{-1}$ which is equivalent to 1.8×10^{-2} cm.^{2} hr.$^{-1}$ at 37°. Estimations of D/h and h in our experiments, using the latter value, are shown in Table II.

DISCUSSION OF RESULTS

Effect of Intensity of Agitation.—The data in Table I and Fig. 2 indicate that when the intensity of agitation, or velocity of dissolution medium across the dissolving solid, was of a low order of magnitude, then a significant difference in dissolution rates was observed for methylprednisolone forms I and II. When the speed of rotation of the wheel in the Wruble machine was increased from 6 to 12 r.p.m., the rates of dissolution of the two polymorphs became equal within the errors of measurement. Rotation at 40 r.p.m. in the machine described by Souder and Ellenbogen (11) also led to no observable significant difference in rates of dissolution. When implanted in rats the pellets of the two polymorphs lost weight at significantly different rates. These data then indicate that *in vitro* tests in which there is a relatively low intensity of agitation, or only natural convection, correlate best with the *in vivo* implantation data.

TABLE I.—RESULTS OF DISSOLUTION RATE EXPERIMENTS PERFORMED WITH CONSTANT SURFACE PELLETS OF METHYLPREDNISOLONE POLYMORPHS I AND II BY AN *In Vivo* AND SEVERAL *In Vitro* METHODS

Test[a]	Methyl-prednisolone Polymorph	95% Confidence Interval of the Intercept, mg./cm.²	95% Confidence Interval of the Rate, mg./cm.²/hr.	Percentage Difference in Rates[b]	Significance of Difference Between Rates by *t*-test

[a] Obtained by dividing the rate of dissolution by the solubility of methylprednisolone I or II. The latter values are 0.1174 and 0.141 mg. ml.$^{-1}$ at 37°, respectively. [b] Obtained by dividing D, namely 1.8×10^{-2} cm.² hr.$^{-1}$, by the suitable value of D/h.

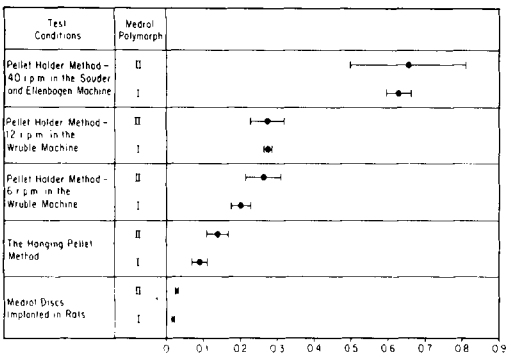

Fig. 2.—Dissolution rates and their 95% confidence intervals for methylprednisolone polymorphs I and II determined under various conditions.

The implications of these results with respect to *in vitro* tests for timed release or prolonged action oral products are important. Before an *in vitro* test is accepted as a routine procedure to be applied to a wide variety of products, one should be sure that the test can differentiate differences between lots of a given product and between different products which do show a difference *in vivo* by their intended route of administration. Otherwise the control test is just a routine operation without any meaning.

Film Thicknesses.—Parrott, Wurster, and Higuchi (2) calculated a diffusion layer or film thickness of 3.28×10^{-3} cm. for benzoic acid dissolving in pure water under their experimental conditions. This is very comparable to the values of 3.4×10^{-3} and 3.9×10^{-3} cm. which we estimated for methylprednisolone I and II, respectively, when the $^3/_8$ inch pellets in our tests were held in the center of a 4-fl. oz. bottle containing 120 ml. of water rotated in the machine described by Souder and Ellenbogen (11). Under the usual conditions in which this machine is used to test timed release or prolonged action products, the effective film thickness would be much less and the intensity of agitation much greater since the tablets or granules are allowed to fall freely through the fluid during the test and are not held rigidly in the center of the bottle as in our tests. Hence, one might expect much greater difficulty in distinguishing between lots of a product by the test used by the Pharmaceutical Contact Section (9) than we experienced in our tests.

In the hanging pellet test we estimated a diffusion layer or film thickness of 0.11 and 0.087 cm. for methylprednisolone I and II, respectively. These film thicknesses are 33 and 22 times, respectively, those estimated when the machine of Souder and Ellenbogen was used. When the Wruble machine, rotating at 6 r.p.m., was used in our tests, the film thicknesses estimated were 1.0×10^{-2} and 9.6×10^{-3} cm. for methylprednisolone I and II, respectively. These are about one-tenth the film thicknesses estimated for the hanging pellet tests.

Hence, diminishing the film thickness by increasing intensity of agitation beyond this point led to failure to distinguish between the polymorphs with respect to dissolution rate.

APPENDIX

Some Literature Concerning Kinetics of Dissolution and Effect of Intensity of Agitation.—Hixson and Crowell (8) derived the relationship shown as Eq. 1.

$$dW/dt = kS(C_s - C) \qquad \text{(Eq. 1)}$$

where $-(dW/dt)$ is the rate of change of weight of the dissolving substance or velocity of solution of a dissolving substance and dW/dt is the rate of appearance of the dissolving substance in the dissolution medium, k is a constant with dimensions distance/time, S is the surface area of the dissolving substance, C_s is the concentration of a saturated solution of the dissolving substance in the dissolution medium, and C is the concentration of the dissolving substance in the dissolution medium at time t. The value of the constant k has been shown (8) to be dependent upon the temperature, the structure of the surface of the dissolving substance, the arrangement of the apparatus, and the rate of stirring or agitation (or the velocity of the dissolution medium across the surface of the dissolving substance).

When C is always negligible in comparison to C_s, Nelson (15) showed that Eq. 1 reduces to

$$dW/dt = kSC_s \qquad \text{(Eq. 2)}$$

Integrating Eq. 2, with S considered a constant, yields

$$W = kSC_st \qquad \text{(Eq. 3)}$$

Polli (4) reviewed the literature concerning the effect of agitation speed on the velocity of heterogeneous reactions. Investigators have usually reported the following relationship

$$K = aV^b \qquad \text{(Eq. 4)}$$

where K is a constant similar to k in Eq. 1, V is the velocity of agitation, and a and b are constants. In accordance with the Nernst-Brunner theory, the value of the exponent b has been found to be 1, or approximately 1, when the reaction taking place was diffusion controlled. On the other hand, for reactions controlled by the rate of the interfacial reaction, values for b were found to approach zero. After studying the dissolution of inorganic salts, Davion (5) reported he obtained a value of 0.5 for the constant b. Hence, in terms of the symbols used above Davion found

$$k = a\sqrt{V} \qquad \text{(Eq. 5)}$$

Van Krevelen and Krekels (16) found a similar relationship for the rate of dissolution of solid substances when they are contacted with a liquid current in the form of a granular bed. Hence a plot of k *vs.* V would pass through the origin and be parabolic with the slope of the line approaching zero, but always positive as V increases.

Linton and Sherwood (6) and Davion (5) applied the methods of investigation applicable to heat transfer to the kinetics of dissolution. The former authors measured the rate of solution of slightly soluble fused salts from the inner walls of cast tubes through which water was forced both in streamline and turbulent flow at velocities from 0.5 to 500 cm./sec. Data were also obtained on the rate of solution of cast plates, cylinders, and spheres of the same materials with water velocities of 5 to 90 cm./sec. For streamline flow in tubes their data checked reasonably well with the Leveque equation, which is

$$\frac{C - C_0}{C_s - C_0} = 5.5\left(\frac{R}{D_L\rho L}\right)^{-2/3} \qquad \text{(Eq. 6)}$$

where C is concentration of exit stream in Gm./ml., C_0 is the concentration of inlet stream, C_s is concentration at saturation, R is the flow rate of the fluid in Gm./sec., D_L is molecular diffusivity in cm.^{2}/sec., ρ is the density in Gm./ml., and L is the length of the tube in cm. Their results supported the assumption of parabolic flow, molecular diffusion, and saturation at the solid-liquid interface.

Prediction of Stability in Pharmaceutical Preparations IX

Solution Degradation and Chemical Assay of the Antibiotic Actinospectacin

By EDWARD R. GARRETT† and GERALD R. UMBREIT

The kinetics of degradation of the antibiotic actinospectacin[1] in solution have demonstrated that the material is unstable in the alkaline region and that its degradation is catalyzed by buffer anions such as borate, phosphate, and carbonate. Equations have been obtained to characterize degradation as a function of hydroxyl ion concentration and temperature. A chemical assay has been devised based on the formation of the copper complex of a derived dithiocarbamic acid which is extractable and spectrophotometrically measurable in organic solvent. Optimum conditions are described to measure the unique secondary amine functions of the active antibiotic and the change in solubility characteristics of the copper complex of the derived dithiocarbamic acids. Bioassay has been correlated with this chemical assay and optimum conditions defined for its use.

ACTINOSPECTACIN sulfate (1) is a new, therapeutically effective antibiotic, active *in vitro* and *in vivo* against a variety of Gram-positive and Gram-negative organisms (2). It is a material of apparent molecular formula $C_{14}H_{26}N_2O_7$ which is isolated as the hydrated sulfate, and in that form has an apparent molecular weight of 506 (3). It has two secondary amine groups and the two pKa values assigned to these groups are 6.95 and 8.70 (3). Its high water solubility and low organic solubility indicate a hydroxylated compound.

This paper reports on studies designed to establish a chemical assay based on the presence of secondary amine groups, to determine the stability of actinospectacin as a function of pH and temperature, to compare chemical and biological assay procedures, and to predict the possible nature of the solution degradation and the conditions for maximum stability.

EXPERIMENTAL

General Procedure.—The isolation and characterization of the actinospectacin sulfate used has been reported (1–3). Kinetic studies were conducted principally at 30 and 60° in 0.1 *M* hydrochloric acid, acetate buffers (pH 4.65); phosphate, bicarbonate, and borate buffers (pH 7–11); and in varying concentrations of sodium hydroxide. No significant degradation of actinospectacin was observed by chemical or biological assay in 0.1 *M* hydrochloric acid and at pH 4.65 for over 43 days at 30°. Alkaline degradation, however, was significant and studied in considerable detail.

Aliquots were taken at recorded intervals from the actinospectacin solutions maintained in constant temperature baths at ±0.05°.

The aliquots were immediately neutralized and then diluted 1:4 with 0.1 *M* pH 7.85 phosphate buffer for microbiological assay, or diluted 1:4 with 0.2 *M* sodium hydroxide – 0.4 *M* acetic acid buffer for chemical assay, except for the phosphate and acetate buffered solutions which were assayed without dilution. The resultant solution submitted for microbiological assay was 0.08 *M* in pH 7.85 phosphate buffer and contained 450 mcg./ml. as based on undegraded actinospectacin. The resultant solution assayed chemically contained 400 mcg./ml. as based on undegraded actinospectacin.

Estimates of heats of activation of alkaline degradation were obtained by kinetic studies in 0.1 *M* sodium hydroxide at several temperatures.

The complete conditions are given in Table I for the kinetic runs and the estimated apparent first-order rate constants.

Chemical Assay Procedure.—The basis of the chemical assay was the reaction of the secondary amine function of undegraded actinospectacin with carbon disulfide to form dithiocarbamic acid. Addition of a cupric salt gave a complex extractable into organic solvents which could be measured spectrophotometrically (4–6).

The actinospectacin aliquot (1 ml. of an aqueous solution containing 50 to 500 mcg.) was pipetted into a 15-ml. glass-stoppered test tube and 4 ml. of a solution of carbon disulfide, pyridine, and isopropyl alcohol in the ratio 35:25:65 was added. Then, 2 ml. of an 0.0025 *M* cupric chloride solution in water-pyridine, 1:1, was added. The tube was swirled to mix the reactants and allowed to stand at room temperature for 30 ± 5 minutes. Some of the carbon disulfide settled to the bottom.

Subsequently, 3 ml. of water and 3 ml. of benzene were added and the mixture was shaken and inverted to extract the actinospectacin-dithiocarbamate-copper complex. The liquid phases were allowed to separate and 5 ml. of the organic layer was with-

Received June 12, 1961, from the Research Division, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication July 24, 1961.
The authors are greatly indebted to Mrs. Lillian G. Snyder and Mr. Max E. Royer for excellent technical assistance and to Dr. L. J. Hanka and Mr. M. R. Burch and associates for the microbiological assays.
† Present address: College of Pharmacy, University of Florida, Gainesville.
[1] The trade name of The Upjohn Co. for the antibiotic actinospectacin is Trobicin.

TABLE I.—CONDITIONS AND RATE CONSTANTS (k in sec.$^{-1}$) FOR THE APPARENT FIRST-ORDER DEGRADATION OF ACTINOSPECTACIN SULFATE AS DETERMINED BY CHEMICAL ASSAY

Kinetic Run No.	°C.	Buffer Composition after Correction for Neutralization of Actinospectacin Salt		Molarity of Actinospectacin in Degrading Solution[a]	Average Observed pH for Run[b]	10^4k sec.$^{-1}$

[a] Calculated from assumed molecular weight, 505.87. [b] Maximum range of 0.1 pH unit for duration of study. pH was read at the temperature of the run. [c] Was prepared to be 7.7 pH. [d] Because of the few points available for this run, this represents only the magnitude of the rate.

drawn, dried over 0.3 Gm. of anhydrous sodium sulfate, and transferred to a cell. Spectrophotometric measurement at 470 mμ with a Beckman model B spectrophotometer was made against a reagent blank prepared in the same manner but without antibiotic. A typical absorption band for the copper-dithiocarbamate complex of actinospectacin is given in Fig. 1. A standard curve of absorbance of organic phase extracted antibiotic *vs.* actinospectacin sulfate concentration was prepared in the same manner and followed Beer's law (see Fig. 2).

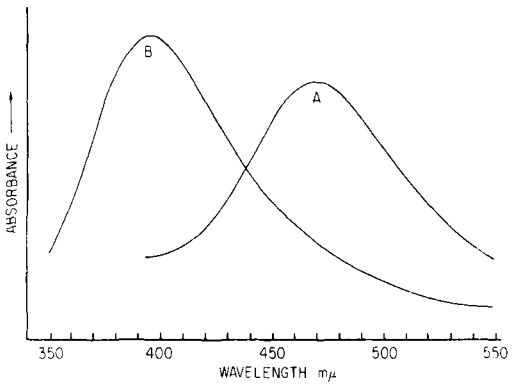

Fig. 1.—Typical visible absorption bands for the copper-dithiocarbamate complex of actinospectacin extracted in the upper organic phase (A) and for the copper dithiocarbamate complex of degraded actinospectacin unextracted from the lower aqueous phase (B).

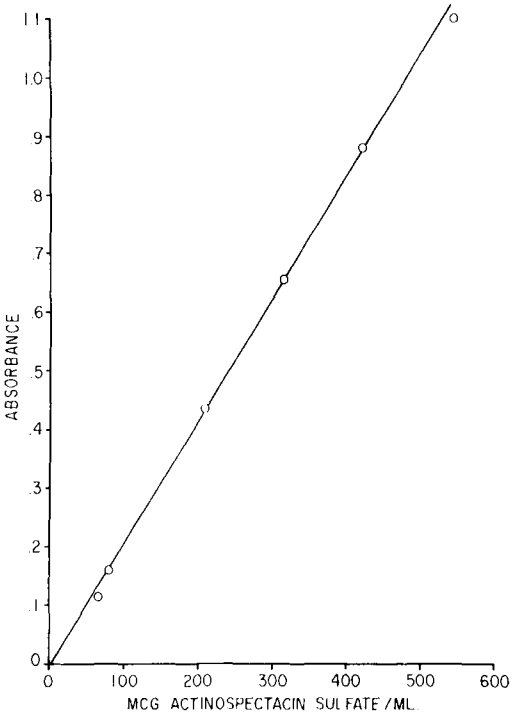

Fig. 2.—Standard curve for the 470 mμ absorbance of the complex, actinospectacin-dithiocarbamate-Cu^{++}, extracted into the upper organic phase against the initial concentration of actinospectacin-sulfate in aqueous solution.

As the alkaline degradation proceeded, color attributable to complex increased in the aqueous phase. At the beginning of a reaction, colored complex was totally soluble in the organic layer; at the end of a reaction, colored complex was totally soluble in the aqueous layer. The reaction could also be followed by the increasing appearance by spectrophotometry of colored reaction complex remaining in the aqueous phase after extraction (see Fig. 1).

Effect of Conditions on Absorbance of Colored Complexes.—A phenomenon occurred with several of the kinetic runs that warranted further investigation. The absorbance of the actinospectacin-dithiocarbamate-copper complex extracted in the organic phase at zero time for several of the kinetic runs did not agree with the values expected from the standard curve (see Fig. 2). In several instances the apparent absorbances were significantly less.

Of course, this did not affect the estimation of the apparent first-order rate constants for the decomposition of actinospectacin but it did raise the question as to the validity of the assay. The assay's reliability was checked by its excellent replication under the same conditions.

To investigate this phenomenon, aliquots of aqueous actinospectacin solutions of the same antibiotic concentration with various amounts of other materials were chemically assayed. The resultant apparent absorbances of the complex extracted into the organic phases were plotted as a function of the concentrations of these other materials present. These addends were similar to the components of the buffers used in the kinetic runs, i. e., acetic acid, sodium acetate, hydrochloric acid, and potassium chloride (see Fig. 3).

Chloride and acetate ions had no effect when the source of these ions was a neutral salt, but the corresponding acids gave a definite decrease in the color intensity of the actinospectacin-dithiocarbamate-copper complex extracted in the organic phase. In contrast, no decrease in the intensity of color from the complex with di-*n*-butylamine was noted when excess acetic or hydrochloric acid was added.

Characterization of Actinospectacin-Dithiocarbamate-Copper Complex.—An 0.7701-Gm. sample of actinospectacin sulfate was dissolved in 50 ml. pyridine, 25 ml. water, and 50 ml. isopropyl alcohol. This was titrated by the method of Critchfield and Johnson (4) with 31.15 ml. 0.100 *M* sodium hydroxide to phenolphthalein end point. Then 5 ml. of carbon disulfide was added and 30.40 ml. 0.100 *M* sodium hydroxide was necessary to reach the phenolphthalein end point again. A simultaneously prepared blank took 0.2 ml. titer to neutralize and another 0.2 ml. subsequent to the addition of carbon disulfide. Thus, 3.09 meq. of sulfuric acid and 3.02 meq. of dithiocarbamic acid (R_1R_2N—CS—SH) were found which calculates to 1.023 sulfuric acid per molecule and is consistent with the characterization of the original actinospectacin sulfate used, $C_{14}H_{26}N_2O_7 \cdot 1.12H_2SO_4 \cdot 3.43H_2O$. mol. wt. 505 (3). The pKa's were 7.0 and 8.8. It also demonstrates the formation of two dithiocarbamic acid groups per molecule.

The actinospectacin-dithiocarbamate-copper complex in the organic phase was isolated from the separated organic layer by evaporation of the solvent at room temperature. The infrared spectrum of this material was nearly identical with that of the original actinospectacin sulfate and thus indicated that no apparent degradation had occurred in this isolation procedure.

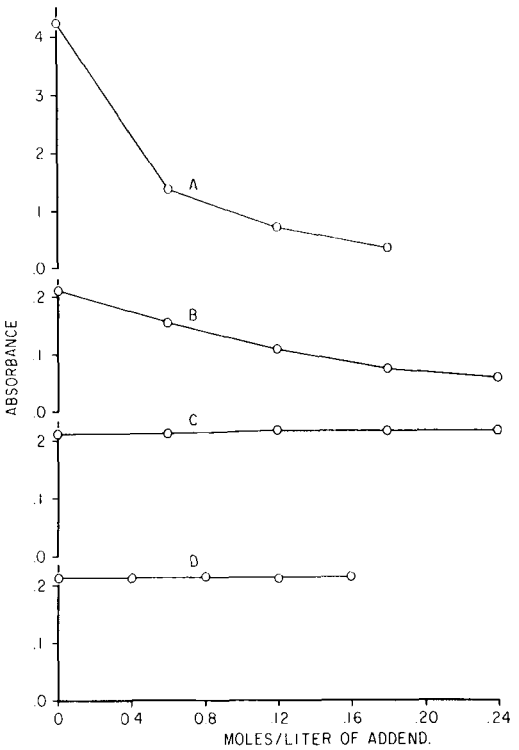

Fig. 3.—Effect of addends in original aqueous solution on 470 mμ absorbance of actinospectacin-dithiocarbamate-Cu^{++} complex extracted into upper organic phase

Curve	Initial Amount of Actinospectacin (mcg.)	Addend
A	208	HCl
B	104	$HC_2H_3O_2$
C	104	$NaC_2H_3O_2$
D	104	KCl

This material had 11.68% ash. If it is assumed that the nonhydrated form of the actinospectacin-dithiocarbamate-copper complex, $C_{14}H_{24}N_2O_7(CS_2)_2$-Cu, mol. wt. 547, is extracted in the organic phase, then the theoretical per cent copper for a copper to complex ratio to be 1:1 would be 11.5% as copper. If the ash were copper oxide, the theoretical for a 1:1 ratio would be 14.4% on the assumption of a nonsolvated sample. The experimentally obtained value is inconsistent with a 2:1 ratio where a 25.9% ash would be expected and thus confirms a 1:1 ratio of copper to partially solvated complex.

Samples of 0.304 mg. actinospectacin sulfate were treated in the manner described by the chemical assay procedure with slight modifications. The concentration of cupric chloride was varied. The absorbances of the colored actinospectacin-dithiocarbamate-copper complex in the organic layer attained the following values for a stated copper: actinospectacin sulfate molar ratio: 0.214, 1:1;

0.409, 2:1; 0.427, 3:1; 0.427, 5:1; 0.410, 7:1; 0.385, 10:1; 0.061, 20:1; and 0.055, 50:1.

The colored complex extracted into the organic phase achieved a maximum at *ca.* 4:1 ratio of reactants, copper to actinospectacin. With additional copper concentrations, the amount of 1:1 colored complex drastically decreased, proving the formation of a noncolored actinospectacin-dithiocarbamate-copper reaction product of a copper:actinospectacin ratio of 2:1 or more.

Characterizations of Degraded Actinospectacin and Its Dithiocarbamate Complex.—A 25-mg. sample of actinospectacin sulfate was degraded in 25 ml. 0.1 *M* sodium hydroxide at 25° for 24 hours, which is greatly in excess of the time necessary for complete loss of biological activity and identification as actinospectacin by the chemical assay. The resultant solution was neutralized so that the original material was at a 1:1 dilution with water. A series of aliquots of x ml., varying from 0.000 to 1.000 ml. by 0.050-ml. increments, were transferred to test tubes. A solution of cupric chloride of a molarity equivalent to the neutralized, diluted reaction solution was prepared. Then, $(1 - x)$ ml. of this cupric chloride solution was added to each test tube containing x ml. of the degraded actinospectacin solution according to the method of continuous variations (7). The chemical assay reagents and solvents were added as in the manner previously described. The absorbances were read in the Cary recording spectrophotometer, model 11, from 350–500 mμ using the tungsten lamp. The observed maximum was 462.5 mμ in the aqueous phase. The organic layer was colorless. A plot of the absorbance at this wavelength maximum against the mole fraction of degraded actinospectacin in degraded actinospectacin + copper gave a clear maximum at 0.5 mole fraction. This demonstrates that the 462.5 mμ maximum is defined by a 1:1 ratio of copper to the dithiocarbamate of degraded actinospectacin (7). When the ratio of copper to degraded actinospectacin was 4:1 or greater, a 390 mμ maximum started to appear. When additional copper was added so that the ratio was 10:1 in favor of the copper, the wavelength of the maximum absorbance in the aqueous layer shifted to 391 mμ (Fig. 1) and the 463 mμ maximum disappeared. This clearly indicates that a 2:1 complex of copper to the dithiocarbamate of degraded actinospectacin is formed at higher copper concentrations.

Infrared spectroscopy could not differentiate between actinospectacin and its degradation product. Nuclear magnetic resonance indicated that a doublet assigned to $-\underset{|}{CH}-CH_3$ in actinospectacin has been transformed to two sets of doublets in degraded actinospectacin; a new $-\underset{|}{CH}-CH_3$ has appeared. The area of the resultant two $-\underset{|}{CH}-CH_3$ groups is equivalent to the area attributable to one in the original actinospectacin. The same functional groups exist in actinospectacin and degraded actinospectacin except that all peak values are shifted about 10 cycles higher in the latter case. However, the peaks are superimposable when shifted, thus indicating slight changes in geometry.

The sulfate salt of the isolated degraded actinospectacin, dried in the same manner as actinospectacin sulfate at high vacuum and room temperature, had an equivalent weight of 252, so that its molecular weight of 504 is the same as actinospectacin sulfate. Its pKa's were 7.1 and 8.9.

Optical Activity and Degradation.—A solution of actinospectacin was prepared so that it was 0.05 *M* in actinospectacin free base and 0.10 *M* in sodium hydroxide. The optical rotation was read in a 1-dcm. tube at intervals of time at 400 mμ. The initial reading of +0.020 changed with time and asymptotically approached −1.700. The logarithm of the difference of the optical rotation at any time, t, and the asymptotic value was plotted against the time, t, and was a straight line. The resultant rate constant for the degradation as followed by this stereochemical transformation at 25° in 0.10 *M* sodium hydroxide was 9.73×10^{-4} sec.$^{-1}$, a half life of 11.8 minutes. The extrapolated initial rotation was +0.0188.

It will later be shown (from Eq. 13) that the degradation at 25° in 0.092 *M* sodium hydroxide by chemical assay is 9.55×10^{-4} sec.$^{-1}$.

Biological Assay Procedure.—The biological assay was a plate-disk assay against *Klebsiella pneumoniae* (8) and was run simultaneously with the chemical assay on aliquots of degrading actinospectacin. When anomalies resulted in bioassay dependent on whether or not the aliquot was diluted with phosphate buffer, a special study on the effect of pH 7.85 phosphate buffer concentration on apparent antibiotic potency was undertaken.

Actinospectacin (125.4 mg.) was weighed into a 50-ml. volumetric flask, diluted to volume with 0.15 *M* sodium hydroxide from the 30° bath, maintained at 30° and assayed at recorded times by the following procedures: *Bioassay Samples.*—Five-milliliter aliquots were pipetted into 10-ml. volumetric flasks containing 0.4 ml. 1.904 *M* hydrochloric acid to "stop" the reaction. One milliliter of neutralized solution was then pipetted into each of five 5-ml. volumetric flasks and diluted to volume with the appropriate concentration of pH 7.85 phosphate buffer to make the resultant solutions 0.16, 0.10, 0.05, 0.025, and 0.01 *M* in phosphate buffer. One milliliter of each of the five resultant solutions was transferred to an assay bottle and submitted for microbiological assay without further dilution. The concentration of the final solution prior to alkali degradation was 465 mcg./ml.

Chemical Assay Samples.—Aliquots (0.8 ml.) were pipetted into a 5-ml. volumetric flask containing *ca.* 4 ml. of an equal mixture of 0.2 *M* sodium hydroxide and 0.4 *M* acetic acid, and diluted up to 5 ml. with the same buffer mixture. One milliliter of the resultant solution was assayed by the chemical assay procedure. The concentration of the final solution prior to alkali degradation was 402 mcg./ml.

The results showed that the molarity of 7.85 pH phosphate buffer significantly affected the estimate of the apparent antibiotic concentration from microbiological assay as compared with the concentration from chemical assay (see Fig. 4). It was clearly shown that if the 7.85 pH buffer concentration was maintained above 0.05 *M* in the solution to be microbiologically assayed, a 1:1 correspondence with the chemical assay resulted for material degraded in 0.15 *M* sodium hydroxide at

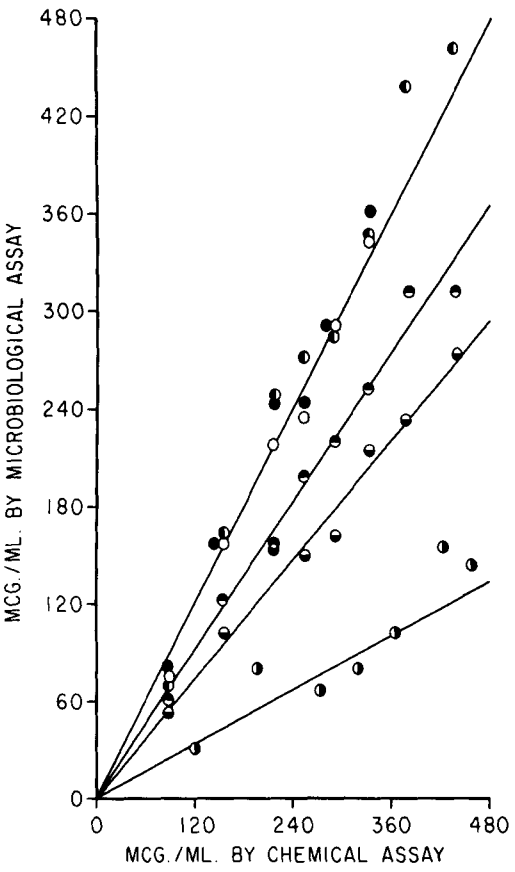

Fig. 4.—Effect of pH 7.85 phosphate buffer concentration on the microbiological assay of actinospectacin. The aliquots assayed were sampled at various times from an actinospectacin solution degrading in 0.15 *M* sodium hydroxide at 30°. ○, 0.160; ●, 0.100; ◐, 0.050; ◓, 0.025; ◒, 0.010; ◑, 0.000 *M* of phosphate buffer.

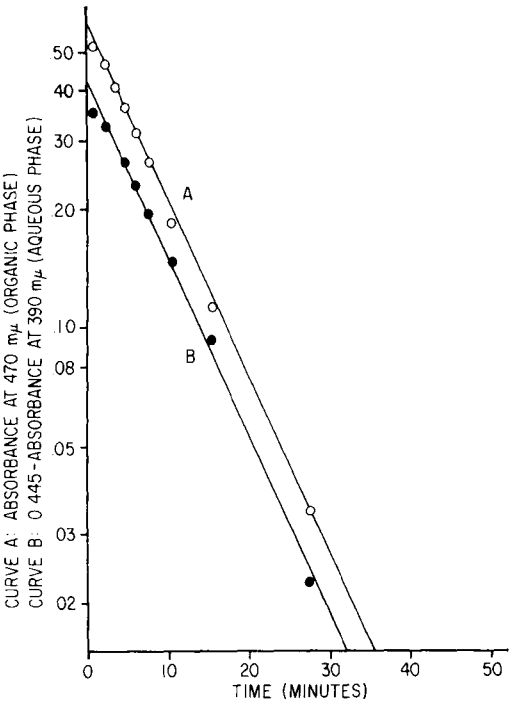

Fig. 5.—Apparent first-order rate plots for the degradation of actinospectacin in 0.15 *M* sodium hydroxide aqueous solution at 30°. Curve A is derived from the absorbance at 470 mμ of the actinospectacin-dithiocarbamate-Cu^{++} complex extracted in the upper organic phase and is a measure of the disappearance of the antibiotic. Curve B is derived from the absorbance at 390 mμ of the dithiocarbamate-Cu^{++} complex of degraded actinospectacin and is a measure of the appearance of the product of degradation.

30°. Thus, in all attempted correlations of bioassay with color assay, this minimum phosphate buffer concentration was maintained. The attempted correlations were conducted on the series of alkali-degrading actinospectacin solutions where the statistics of regression are given in Table II.

RESULTS AND DISCUSSION

Apparent First-Order Rates of Alkaline Degradation.—The alkaline degradation of actinospectacin in solution is the major route of antibiotic decomposition. At a given pH or hydroxyl ion concentration, it is apparently first order

$$\log A = \frac{-kt}{2.303} + \log A_0 \qquad \text{(Eq. 1)}$$

where A is the absorbance at 470 mμ of the organic phase complex (with Cu^{++} and CS_2) at any time, t, and A_0 is the absorbance at initial time, t_0. Figure 5 demonstrates the linearity of such semilogarithmic plots. The extraordinary phenomenon of the Cu^{++} CS_2 complex of the degraded actinospectacin being completely water soluble is demonstrated by curve B in Fig. 5, a line parallel to curve A for the decrease of actinospectacin complex absorbance in the organic phase. The rate of degraded actinospectacin complex appearance in the aqueous phase completely parallels the rate of actinospectacin complex disappearance from the organic phase. This former plot is based on the expression

$$\log (A'_\infty - A') = \frac{-kt}{2.303} + \log A'_\infty \qquad \text{(Eq. 2)}$$

where A' is the aqueous phase absorbance at 390 mμ (the $\lambda_{max.}$ of the degraded complex absorbance in the water phase) at any time, t, and A'_∞ is the final or asymptotic value of this absorbance, 0.445.

Formation of Dithiocarbamates and the Possible Nature of the Complexes.—The presumed reactions (4, 5) in the formation of dithiocarbamates and their copper complexes are

$$R_1R_2NH + CS_2 \rightleftharpoons R_1R_2N{-}CS{-}SH \qquad \text{(Eq. 3)}$$

$$R_1R_2N{-}CS{-}SH + Cu^{++} \rightleftharpoons R_1R_2N{-}CS{-}SCu^{+} + H^{+} \qquad \text{(Eq. 4)}$$

$$R_1R_2N{-}CS{-}SCu^{+} + R_1R_2N{-}CS{-}SH \rightleftharpoons (R_1R_2N{-}CS{-}S)_2Cu + H^{+} \qquad \text{(Eq. 5)}$$

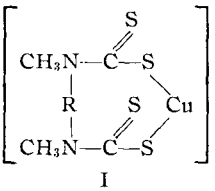

TABLE II.—STATISTICS OF REGRESSIONS OF BIOASSAYS (y) ON CHEMICAL ASSAYS (x) FOR ACTINOSPECTACIN DEGRADING IN ALKALINE SOLUTION AT 30.2°

Molarity of NaOH	No. of Points Used	Line Forced through Origin; $y=mx$				Line of Best Fit; $y=mx+b$

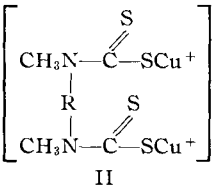
$$(R_1R_2N{-}CS{-}S)_2Cu + Cu^{++} \rightleftharpoons 2R_1R_2N{-}CS{-}SCu^{+} \quad \text{(Eq. 6)}$$

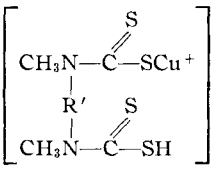
The introduction of two CS_2 per molecule was demonstrated experimentally by the titration method of Critchfield and Johnson (4).



When these series of reactions and the previously described procedures were used to follow the rates of degradation of actinospectacin there was, initially, no colored complex in the aqueous phase. Finally, after degradation, there was no colored complex in the organic phase. It thus follows that this degradation of actinospectacin modified the amine groups in a manner that changes an organic phase-soluble complex to a water-soluble one. A possible explanation is an alkaline induced variation of a stereospecific relation of the two nitrogens in actinospectacin. In the case of the organic phase-soluble actinospectacin complex, both dithiocarbamic acid groups in the molecule may be complexed by one cupric ion as per Eqs. 3–5, giving I.

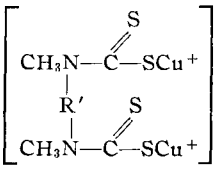
I

Actinospectacin-2CS_2-Cu Complex
Organic Phase Soluble; $\lambda_{max.}$ = 470 mμ



The 1:1 = Cu:actinospectacin nature of this complex, I, was shown experimentally by the agreement of the per cent ash as CuO with the theoretical for 1:1. Addition of excess cupric ion, 20:1 = Cu:actinospectacin, dramatically decreased the absorbance extracted into the organic phase, proving the formation of a new complex consistent with Eq. 6 so that we have II

II



Actinospectacin-$(CS_2Cu^{+})_2$ Complex

For degraded actinospectacin a chelated copper ion may not be sterically possible as in I so that a charged water-soluble 1:1 complex would be III, a 2:1 complex would be IV.

III

Degraded Actinospectacin-2CS_2-Cu^{+} Complex
Aqueous Phase Soluble; $\lambda_{max.}$ = 462.5 mμ

IV

Degraded Actinospectacin-$(CS_2Cu^{+})_2$ Complex
Aqueous Phase Soluble; $\lambda_{max.}$ = 390 mμ

By the method of continuous variations (7), III was shown to be a 1:1 = Cu:degraded actinospectacin complex. The new 390 mμ maximum characteristic of IV appeared when excess cupric ion was added in a 10:1 ratio to the degraded actinospectacin.

Infrared and nuclear magnetic resonance spectroscopy could only indicate steric transformation in the alkaline degradation of actinospectacin; they could not identify changes in functional groups.

Comparison of the equivalent weights and pKa's of actinospectacin sulfate and isolated degraded actinospectacin sulfate also could not demonstrate any change in the molecule on degradation.

In addition, the change in optical activity in 0.1 *M* sodium hydroxide confirmed the models proposed. Alkaline degradation of actinospectacin involved a stereochemical transformation and the rates so calculated were identical to the rates by chemical assay.[2]

The variation in the absorbance of the actinospectacin-dithiocarbamate-copper complex extracted into the organic phase when acids were added needs explanation.

The pyridine which is used as part of the solvent mixture for the analytical reaction may be implicated. It partially neutralizes the salt of the secondary amine and helps solubilize the carbon

[2] These experimental facts may not be considered conclusive evidence to negate functional group changes. It is possible that degraded actinospectacin may have enhanced aqueous solubility and that its dithiocarbamate-copper complex may have low organic solvent solubility.

disulfide in the mixed aqueous system. Pyridine has an aqueous pKa = 5.36 (9) so that the resultant apparent pH of the pyridine–isopropyl alcohol–water–carbon disulfide–cupric chloride solution prior to extraction is significantly decreased by the addition of acids (see Fig. 6). The shape of the pH *vs.* molarity of acid curve (Fig. 6) is very similar to the shape of the curve, absorbance *vs.* molarity of acid (Fig. 3).

This implies that the equilibria of Eqs. 4 and 5 are forced to the left by increased hydrogen ion concentration and that the dithiocarbamate-Cu^+ complex is water soluble and does not contribute to the color in the organic layer.

Rate of Degradation as a Function of Alkalinity.—Figure 7 plots the apparent first-order rate constant, k in $sec.^{-1}$, as a function of the [NaOH] solution prepared for degradation. Actually, since the actinospectacin has an apparent molecular weight of 506 and has two amine groups in the salt form, twice the molar concentration of the actinospectacin should be subtracted from the abscissa values to give the true $[OH^-]$ concentration. Generally, actinospectacin = 0.0040 and thus, the given $[NaOH]_{apparent} = [NaOH]_{true} + 0.0080$ in Fig. 7.

The two lines in Fig. 7 represent linear estimates of the variation of apparent first-order rate constants, k in $sec.^{-1}$ at 30.2°, with hydroxyl ion concentration and may be given as

$$k = k_{OH}[OH^-] = 0.0533\ [OH^-] \quad \text{(Eq. 6)}$$

$$[OH^-] < 0.020$$

$$k = k'_{OH}[OH^-] + K = 5.33 \times 10^{-3}\ [OH^-] + 11.6 \times 10^{-4} \quad \text{(Eq. 7)}$$

$$0.020 < [OH^-]$$

The fact that this apparent hydroxyl ion catalysis constant varies as a function of the magnitude of the $[OH^-]$ is a strong indication of a change in the nature of the actinospectacin with hydroxyl ion. The most natural explanation is that the sugar-like antibiotic has one or more ionizable protons of high pKa, *ca.* 12–13, and the anionic form resists hydroxyl ion attack more readily than the neutral molecule.

An alternative method of correlating the apparent first-order rate constant, k in $sec.^{-1}$, for alkaline attack and hydroxyl ion concentration is by a log k *vs.* pOH plot. See Fig. 8 where pOH is calculated from

$$pOH = \log f[NaOH]_{true} \quad \text{(Eq. 8)}$$

where the activity coefficient, f, at 30° is obtained from Harned and Owen (10).

An empirical relation valid over the pOH range 0.6 to 2.2, from Fig. 8, is

$$\log k = -0.376\ pOH - 2.324;\ pOH < 2.2 \quad \text{(Eq. 9)}$$

This is most probably an estimate of

$$k\ [\text{actinospectacin}] = k_{OH}[OH^-][\text{uncharged actinospectacin}] + k'_{OH}[OH^-]\ [\text{anionic actinospectacin}] \quad \text{(Eq. 10)}$$

where from the dashed line of Fig. 8

$$\log k = -pOH + \log k_{OH}^-;\ pOH > 2.2 \quad \text{(Eq. 11)}$$

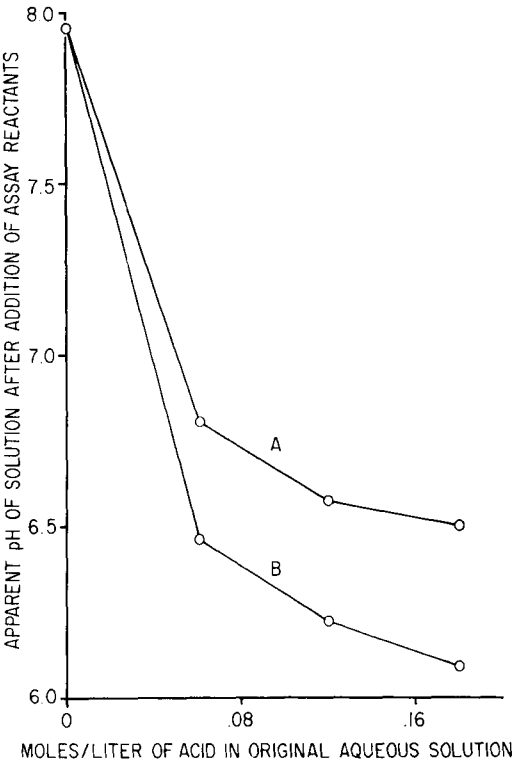


Fig. 6.—Effect of acid added to the original aqueous solution to be assayed for actinospectacin on the apparent pH of the pyridine-isopropyl alcohol-water-carbon disulfide-cupric chloride solution, the composition of the solution just prior to extraction with benzene. Curve A is for acetic acid and Curve B is for hydrochloric acid.

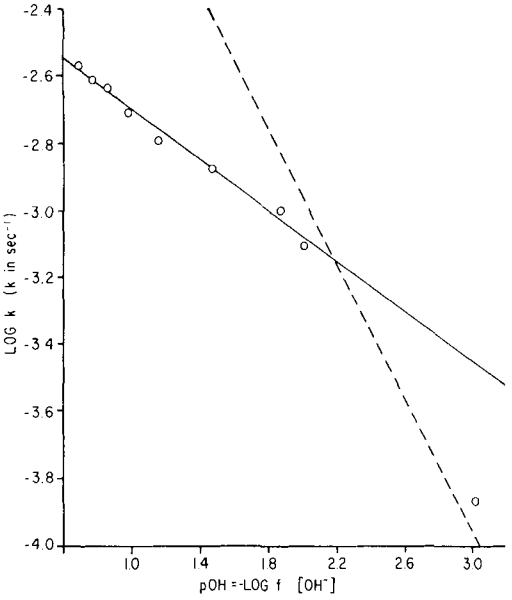

Fig. 8.—Plot of the logarithm of the apparent first-order rate constant for the alkaline degradation of actinospectacin at 30.2° against pOH = log f [OH$^-$] where f is the activity coefficient (9) and [OH$^-$] = [NaOH]$_{True}$. The dashed line has a slope of unity.

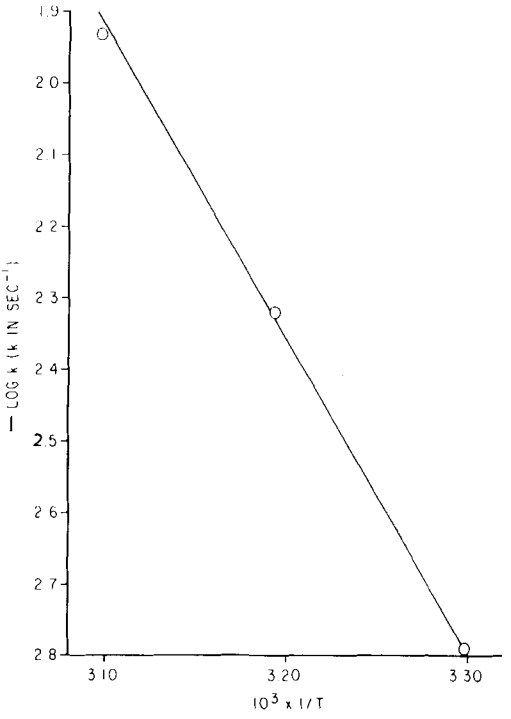

Fig. 9.—Arrhenius plot for the degradation of actinospectacin in 0.092 M sodium hydroxide.

so that log k_{OH^-} = 0.95 or that k_{OH^-} = 0.11 L./M/sec.[3] An estimated pKa of uncharged actinospectacin would be 12.6.[4]

Rate of Degradation as a Function of Buffer Kind.—Since stability in the less alkaline regions had more practical significance and it was indicated that significant degradation did occur at 30° in pH 8 phosphate buffer (half life *ca.* 50 days), an attempt to study degradation in phosphate, borate, and carbonate buffers at 60° was made (see Table I). The rate was not completely dependent on pH but was also a function of the buffer used with carbonate buffers 10 times more catalytic than borate at pH 9 and phosphate *ca.* four times more than borate at pH *ca.* 7.5.

Rate of Alkaline Degradation as a Function of Temperature.—Figure 9 gives the Arrhenius plot for the degradation of actinospectacin at 0.092 M sodium hydroxide. The representative equation is

$$\log k = -4{,}350\,(1/T) + 11.57 \quad \text{(Eq. 12)}$$

where T is absolute temperature and the heat of activation is 20.0 Kcal./mol.

Correlation of Chemical Assay and Microbiological Assay.—During the course of several alkaline degradations, aliquots removed at varying intervals of time were subjected to both microbiological and chemical assays. The statistics of the regression of bioassay *vs.* chemical assay are given in Table II for lines of best fit independent of intercept and for lines of best fit forced through the origin. Of the seven regressions only two, the first and the last listed in Table II, can be stated as having statistically significant nonzero intercepts. Two of the regressions are given in Fig. 10 where the solid lines represent the curve fitted by least squares and the dashed lines are based on adjusted intercepts, $b \pm \sigma_b$, and forced through the mean values, $\bar{y}$ and $\bar{x}$, of the microbiological and chemical assays, respectively. The bracketing of the origin by the intercepts of these dashed curves is apparent. The slope of unit, in general, is demonstrated within the estimated error of the slopes and it can be concluded that a good correspondence exists between the microbiological and the chemical assays.

Prediction of Stability.—Significant solution degradation of actinospectacin occurs in alkaline solution and appears to be a function of hydroxyl ion concentration and the type of buffer anion, *viz.*, carbonate, borate, and phosphate. At 30°, the half life is 50 days in pH 8 phosphate buffer.

On the basis of studies in varying sodium hydroxide concentrations, the half life at 30° in unbuffered aqueous solutions is 1000 days at pH 7.0, 100 days at pH 8.0, and 10 days at pH 9.0.

Experimental studies have shown no significant degradation over two months at pH 4.5 and in 0.1 M hydrochloric acid at 30°.

[3] The reader should not be disturbed at the difference between this value and the one for k_{OH^-} given in Eq. 6. They are defined for different equations. The latter value and [NaOH] are used with Eq. 6 to derive k. The former value and pOH derived from Eq. 8 from consideration of OH$^-$ activity are used with Eq. 11 to derive k. Both methods are valid within experimental error to define k under the conditions specified.

[4] Subsequent titration by D. J. Weber of actinospectacin salt in pyridine with 0.1 N tetra n-butylammonium hydroxide against standard glass-calomel electrodes (methanol saturated with lithium chloride) demonstrated a weakly acidic group that was consistent with this deduced function.

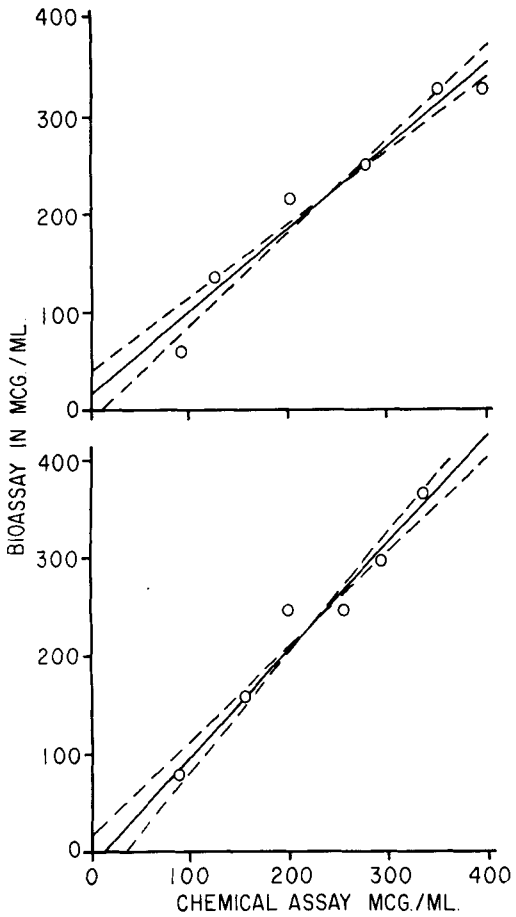

Fig. 10.—Correlation of microbiological plate-disk assay (*Klebsiella pneumoniae*) with chemical assay. The solid line represents the best fit by least squares whereas the dashed lines pass through the mean values and the intercept ± standard deviation of the intercept. The upper curve is based on degradation in 0.044 *M* sodium hydroxide; the lower is based on degradation in 0.115 *M* sodium hydroxide at 30.2°.

SUMMARY

1. Actinospectacin is degraded by specific hydroxyl ion catalysis and the anionic constituents of various buffers: carbonate, phosphate, and borate with decreasing effectiveness in that order. At 30°, the half life is 50 days in pH 8 phosphate buffer, whereas in unbuffered aqueous solution the predicted half life is 1000 days at pH 7.0 and 100 days at pH 8.0 at 30°. Below pH 5, actinospectacin should be stable for all practical purposes.

2. A chemical assay procedure has been devised and applied to the determination of actinospectacin which depends on the unique structure of its secondary amine groups. The formation and extraction of cupric complexed dithiocarbamic acids of actinospectacin permit quantification of undegraded antibiotic by spectrophotometric measurement of visible absorbance in the organic phase. The absorbance of the residual color in the aqueous phase measures degraded antibiotic.

3. The reliability of the bioassay (plate disk *vs. Klebsiella pneumoniae*) was shown to vary with phosphate buffer concentration so that a minimum of 0.05 *M* pH 7.85 phosphate buffer must be present.

4. The bioassay correlates well with the chemical assay.

5. Evidence is presented to demonstrate that the stereospecific relation of the secondary amines in actinospectacin is vital for its biological activity and response to the chemical assay.

6. Complete kinetic expressions have been determined for the alkaline solution degradation of actinospectacin at the various temperatures and a pKa *ca.* 12 for its hydrogen ion dissociation, probably of a sugar-like structure, has been kinetically observed.

Prediction of Stability in Pharmaceutical Preparations X

Alkaline Hydrolysis of Hydrocortisone Hemisuccinate

By EDWARD R. GARRETT†

The hydrolysis of hydrocortisone 21-hemisuccinate above pH 8 has been studied by constant pH titrations in aqueous solution and appears to involve specific hydroxyl ion catalyzed hydrolysis as the only significant reaction pathway. The apparent heat of activation for specific hydroxyl ion catalyzed hydrolysis when corrected for the heat of ionization of water is unusually low for hemisuccinate esters, 7.0 Kcal./mole. This implicates the configuration and structure of the steroid side chain in the facile hydrolysis of 21-steroid esters. The stability of hydrocortisone 21-hemisuccinate at storage and physiological conditions is predicted.

THE CLINICAL usefulness of hydrocortisone was enhanced by the formation of the water-soluble sodium salt of the 21-hemisuccinate ester (1, 2). The formulation of the water-soluble lyophilized sodium salt of hydrocortisone 21-hemisuccinate[1] permitted facile parenteral administration of hydrocortisone in an homogeneous solution where immediate high levels of circulating hydrocortisone are required.

This paper considers the kinetics of hydrolysis of sodium hydrocortisone hemisuccinate in aqueous solution above pH 7 as studied by constant pH titration. The experimental evidence should permit the prediction of stability of reconstituted solutions and should provide evidence for the understanding of the ester's utilization *in vivo* on parenteral administration.

EXPERIMENTAL

Experimental Procedure for Constant pH Titrations of 0.0165 *M* Hydrocortisone Hemisuccinate—The Cannon di-functional titrator (3) was standardized before each run with Beckman buffer solution which had been equilibrated for a minimum of 5 minutes in the temperature-controlled beaker of the titrator to be at the same temperature as the hydrocortisone hemisuccinate solution to be studied.

Hydrocortisone hemisuccinate which had been dried at 50° in high vacuum was weighed in a small weighing boat on a Gramatic balance. After the Cannon titrator had been standardized as above, the sample was transferred to the temperature-controlled beaker and 15 ml. of 0.0165 *M* sodium hydroxide from the constant temperature bath was added. The sodium hydroxide exactly neutralized the hydrocortisone hemisuccinate. A thick rubber band held a silicone covering over the beaker. Inserted into the silicone gasket were the glass-saturated calomel electrodes and a gas duct to blow nitrogen gently on the surface of the solution in the beaker. No carbon dioxide was absorbed by this system as tested for pH 10 for 1.5 hours.

The starting pH of the solution to be studied was recorded and the titration was then started. In general, the pH of the sodium salt of hydrocortisone hemisuccinate was 6.6. The syringe contained 2.011 *N* sodium hydroxide. The servomotor was used for the first few seconds to raise the pH quickly to the setting of the pH control and then the synchronous motor was used to maintain the solution at this pH. At the end of the run, the temperature and volume of solution in the beaker were recorded. Typical curves of volume of standard alkali consumed *vs.* time are given in Fig. 1. The controlled pH and observed temperature for the various runs are given in Table I. Solvent evaporation occurred, especially at the low rates encountered at low pH values.

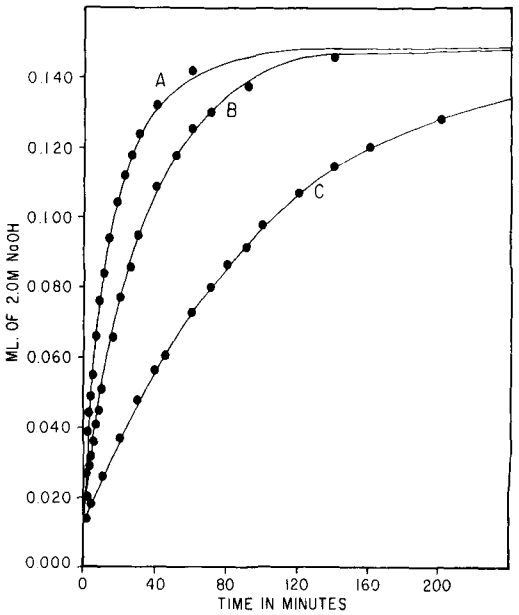

Fig. 1.—Typical curves for the consumption of standard alkali at constant pH by 0.0165 *M* hydrocortisone hemisuccinate at 48°. Curve A is at pH 10.0; curve B is at pH 9.5, and curve C is at pH 9.0.

9.0	29.5	0.203[b]		0.158

[a] Calculated from $k = k_{OH^-}[OH^-]$ where $\log k_{OH^-} = -1.53 \times 10^{-3}(1/T) + 5.12$ and $[OH^-] = 10^{-pOH}$ where pOH = pKw − pH where pKw is given in Table II. [b] Less than 10% loss of volume at 90% hydrolysis. [c] A 10–25% loss of volume at 90% hydrolysis.

The hydrocortisone hemisuccinate, theoretical molecular weight 462, was titrated in 50% ethanol and had a calculated molecular weight of 472, pKa = 5.64, and in 20% ethanol, pKa = 5.10.

CALCULATIONS

The Cannon titrator plots the consumption of standard alkali against time while the solution of hydrocortisone hemisuccinate is maintained at a given pH. Typical curves for the standard alkali consumptions for several pH values at 48° are given in Fig. 1.

The apparent first-order rate constant, k, for the hydrolysis of the hemiester was calculated by the Guggenheim method (4).

The basic equation is

$$\log (\lambda_{(t+\tau)} - \lambda_t) = -kt/2.303 + \text{constant} \quad \text{(Eq. 1)}$$

where k is the apparent first-order rate constant for the hydrolysis of hydrocortisone hemisuccinate at a specific pH, λ_t are the microliters of standard alkali titer consumed, $\lambda_{(t+\tau)}$ are the microliters of standard alkali titer consumed at time $t + \tau$ or τ time units later than time t, and τ is a time interval chosen to permit estimation of the first-order rate constant k in sec.$^{-1}$ without excessively weighting an extrapolated asymptotic value or a value of theoretical alkali consumption. The value τ should exceed the half-life of the reaction.

Typical first-order plots by this Guggenheim method are given in Fig. 2 for several pH values.

The determined rate constants and the pH and temperature of determination are given in Table I.

The rate of alkali consumption, $d[\text{NaOH}]/dt$, can be postulated as equal to the rate of hydrolysis of the hemisuccinate ester, $-d[\text{X}]/dt$, and may be proportional to the products of the concentrations of the hydroxyl ion concentration $[OH^-]$ and the ester concentration [X] so that

$$-d[\text{NaOH}]/dt = -d[\text{X}]/dt = -k[\text{X}] = -k_{OH^-}[OH^-][\text{X}] \quad \text{(Eq. 2)}$$

where at constant pH

$$k = k_{OH^-}[OH^-] \quad \text{(Eq. 3)}$$

and the k values listed in sec.$^{-1}$ in Table I are determined from the slopes of the plots of the Guggenheim Eq. 1 as demonstrated in Fig. 2.

The logarithmic expression derived from Eq. 3 is

$$\log k = \log k_{OH^-} + \log [OH^-] = \log k_{OH^-} - \text{pOH} \quad \text{(Eq. 4)}$$

but

$$\text{pOH} + \text{pH} = \text{pKw} \quad \text{(Eq. 5)}$$

so that

$$\log k = \log k_{OH^-} - \text{pKw} + \text{pH} \quad \text{(Eq. 6)}$$

where the pKw values at various temperatures are listed in Table II from Harned and Owen (5a).

A plot of $\log k$ against pH should be a straight line with an intercept of $\log k_{OH^-} - \text{pKw}$. Such plots are given in Fig. 3. The linearity of the plots is in good agreement with the *a priori* bases of Eq. (6).

The plots of Fig. 3 are fitted to a slope of one and permit the determination of the intercepts, $\log k_{OH^-} - \text{pKw}$, which are given in Table II for the average of the various temperatures studied. The actual temperatures varied among runs by about 0.5° (see Table I) so that the experimental error was actually less than appears from the scatter about the regressions of Fig. 3. Also, in Table I are listed the calculated k values as determined by

$$k = k_{OH^-}[OH^-] = k_{OH^-}[10^{-\text{pKw} + \text{pH}}] \quad \text{(Eq. 7)}$$

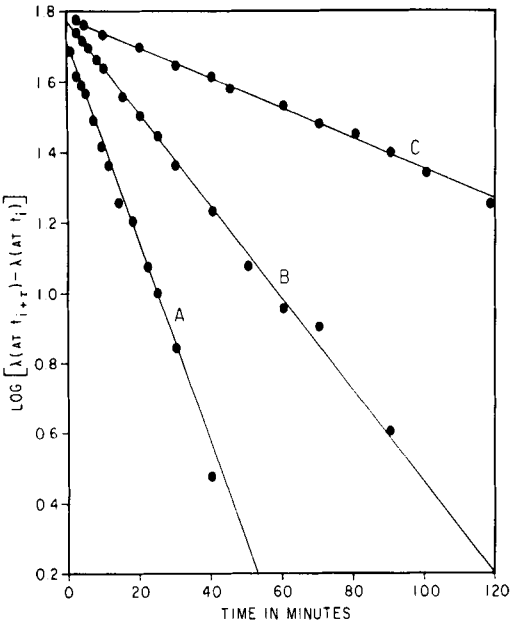

Fig. 2.—Typical first-order plots by the Guggenheim method for the hydrolysis of 0.0165 *M* hydrocortisone hemisuccinate at 48° at constant pH. Curve A is at pH 10.0, curve B is at pH 9.5, and curve C is at pH 9.0. The λ are the numbers of μl. of 2.0 *M* sodium hydroxide consumed at a particular time, *t*. τ is a constant time interval that exceeds the half-life of the reaction.

TABLE II.—ESTIMATES OF THE BIMOLECULAR RATE CONSTANT k_{OH^-} (1/*M*/sec.) FOR THE HYDROXYL ION CATALYZED HYDROLYSIS OF HYDROCORTISONE HEMISUCCINATE

°C.	log k_{OH^-} − pKw[a]	pKw[b]	log k_{OH^-}[c]	k_{OH^-} (1/*M*/sec.)
29	−13.82	13.87	0.05	1.12
38	−13.38	13.60	0.22	1.66
48	−12.96	13.32	0.36	2.29
57	−12.61	13.08	0.47	2.93
65	−12.32	12.89	0.57	3.72

[a] Intercept of the plots, Fig. 3, of the logarithm of the first-order rate constants, *k* (sec.$^{-1}$), at a given temperature, against the observed pH as per log *k* = pH + (log k_{OH^-} − pKw). [b] As given in Harned and Owen (5a). [c] Intercept of plot specified in footnote *a* + pKw.

where the pKw's are given in Table II and the k_{OH^-} is determined for the Arrhenius relation as discussed in the following section. These calculated values show reasonable agreement with the experimental.

Variation of Rate with Temperature.—Arrhenius plots of the logarithm of the apparent first-order rate constant in sec.$^{-1}$, i.e., log *k*, against 1/*T* for various controlled pH values are given in Fig. 4. The slopes of these plots are 4.327 × 10^3 so that the apparent heats of activation, ΔH_a, are 19.8 Kcal./mole as per the expression

$$k = Pe^{-\Delta H_a/RT} \qquad \text{(Eq. 8)}$$

or expressed logarithmically in accordance with the plot of Fig. 4

$$\log k = \log P - (\Delta H_a/2.303R)(1/T) \qquad \text{(Eq. 9)}$$

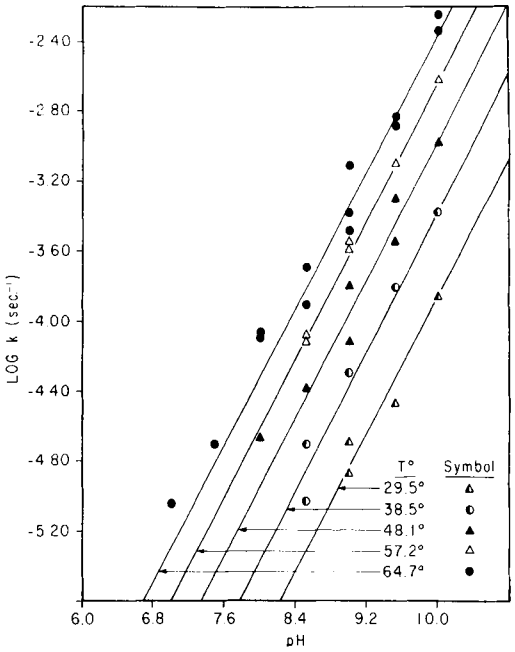

Fig. 3.—Logarithm of apparent first-order rate constants, *k* in sec.$^{-1}$, for the constant pH hydrolysis of 0.0165 *M* hydrocortisone hemisuccinate plotted against pH.

TABLE III.—LOG *P* VALUES FOR THE ARRHENIUS RELATION[a] BETWEEN TEMPERATURE AND THE LOGARITHMS OF THE APPARENT FIRST-ORDER RATE CONSTANTS FOR THE HYDROLYSIS OF HYDROCORTISONE HEMISUCCINATE AT VARIOUS pH VALUES

pH	log *P*
10.0	11.50
9.5	10.05
9.0	9.53
8.5	9.03
8.0	8.74

[a] $\log k = -\Delta H_a/2.303R(1/T) + \log P$, *k* in sec.$^{-1}$.

where *T* is in absolute degrees. The log *P* values for the various controlled pH values are given in Table III.

Now the apparent first-order rate constant, *k*, is the product of the specific hydroxyl ion rate constant, k_{OH^-}, and the hydroxyl ion concentration as shown in Eq. 3. Each of these factors can be expected to vary with temperature as expressed in Arrhenius relations

$$k_{OH^-} = P_1e^{-\Delta H_1/RT} \qquad \text{(Eq. 10)}$$

$$[OH^-] = Kw/[H^+] = P_2e^{-\Delta H_2/RT}/[H^+] \qquad \text{(Eq. 11)}$$

where ΔH_2 is the heat of ionization of water, 12.8 Kcal./mole at 40° (5b). Thus

$$k = k_{OH^-}[OH^-] = P_1P_2e^{-(\Delta H_1 + \Delta H_2)/RT}/[H^+] \qquad \text{(Eq. 12)}$$

and logarithmically

$$\log k = \log P_1P_2 + \text{pH} - \{(\Delta H_1 + \Delta H_2)/2.303R\}(1/T) \qquad \text{(Eq. 13a)}$$

$$= \log P - \{\Delta H_a/2.303R\}(1/T) \qquad \text{(Eq. 13b)}$$

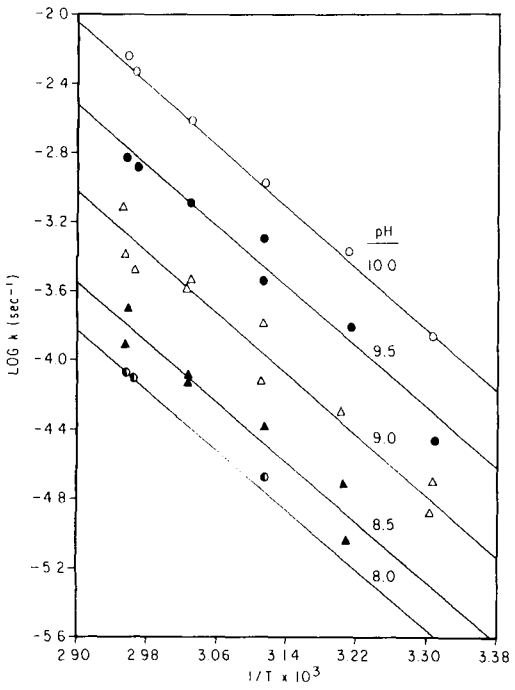

Fig. 4.—Arrhenius plot for the apparent first-order hydrolysis of 0.0165 *M* hydrocortisone hemisuccinate by constant pH titrations.

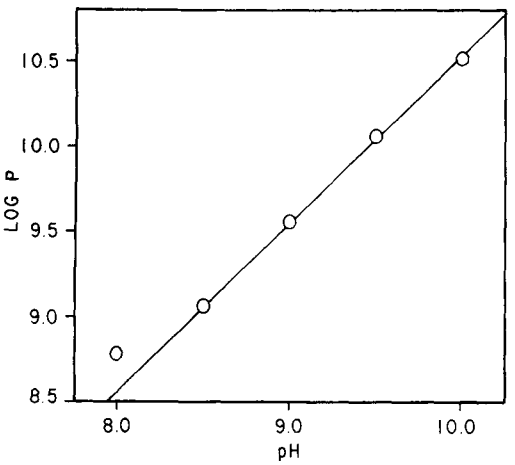

Fig. 5.—Plot of the intercept, log *P*, of the Arrhenius plots, log *k vs.* $1/T$, for the hydrolysis of hydrocortisone hemisuccinate against the pH of hydrolysis.

The intercepts of log *k vs.* $1/T$ in Fig. 4 for a given pH are log P = log P_1P_2 + pH, so that if these intercept values as given in Table III are plotted against pH, the result should be a straight line of unit slope and intercept log P_1P_2. Figure 5 demonstrates the validity of this rationale and permits an estimate of

$$\log P_1P_2 = \log P_1 + \log P_2 = 0.53 \quad \text{(Eq. 14)}$$

A plot of log Kw *vs.* $1/T$ from the data in the literature (5a) gives an apparent ΔH_2 as 12.8 Kcal./mole and log P_2 as −4.61. Thus log P_1 should be 5.14 from Eq. 14. Since ΔH_a for log *k vs.* $1/T$ for all pH values is 19.8 Kcal./mole, $\Delta H_1 = \Delta H_a - \Delta H_2$ should be 7.0 Kcal./mole for the bimolecular rate constant, k_{OH^-}.

The ΔH_1 and log P_1 can be determined directly from the k_{OH^-} values listed in Table II and plotted as per the logarithmic form of Eq. 10 in Fig. 6. The resultant expression is

$$\log k_{OH^-} = -1.53 \times 10^3(1/T) + 5.12 \quad \text{(Eq. 15)}$$

where ΔH_1 = 7.00 Kcal./mole in agreement with the ΔH_1 = 7.0 derived from the relations expressed in the Eqs. 13a and 13b, and log P_1 = 5.12 in agreement with the log P_1 = 5.14 derived from Eq. 14.

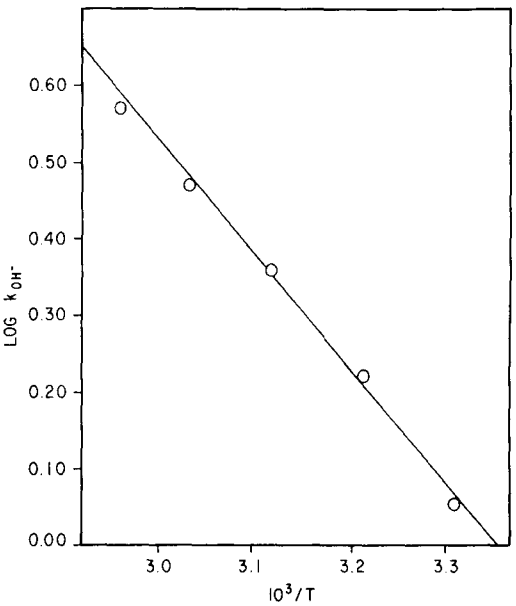

Fig. 6.—Arrhenius plot of the bimolecular rate constant, k_{OH^-} in L./*M*/sec., for the hydroxyl ion catalyzed hydrolysis of hydrocortisone hemisuccinate.

DISCUSSION

The rates of hydrolysis of hydrocortisone hemisuccinate, [X], can be calculated from the following expressions

$$dX/dt = -k[X] \quad \text{(Eq. 16)}$$

or

$$\log X/X_0 = -(k/2.303)t \quad \text{(Eq. 17)}$$

where

$$k = k_{OH^-}[OH^-] \quad \text{(Eq. 18)}$$

and

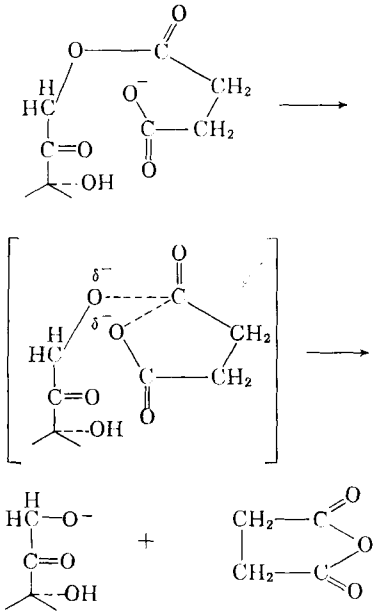
$$\log k_{OH^-} = -1.53 \times 10^3\,(1/T) + 5.12 \quad \text{(Eq. 19)}$$

and

$$[OH^-] = 10^{-pOH} \quad \text{(Eq. 20)}$$

where

$$pOH = pKw + pH \quad \text{(Eq. 21)}$$



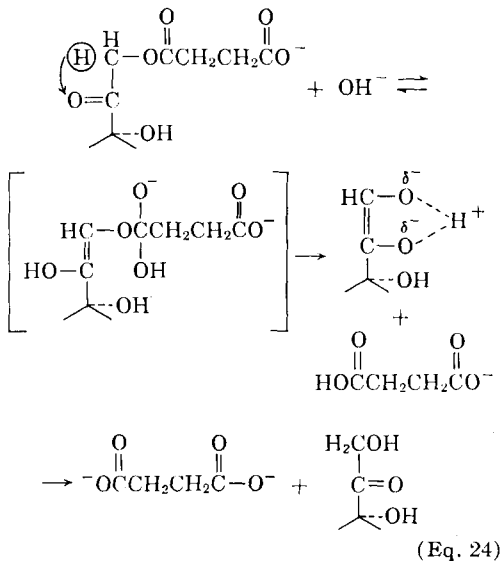
where pH is experimentally observed and pKw = $2.8 \times 10^{-3}(1/T) + 4.61$ (5a).

Rate constants calculated on these premises are compared with the experimental values in Table I and are reasonably consistent. The determination of alkaline hydrolysis rates by measurement of alkali consumption at constant pH in these studies is obviously not as precise as would be liked. The experimental setup was such that solvent evaporation was significant, especially at higher temperatures and for the lower rates at the lower pH values. However, the Guggenheim procedure for the evaluation of first-order reaction rate constants served to minimize the error due to the experimental variation of concentration for prolonged reaction times. Another possible source of error is anomalous pH reading in unbuffered solutions. The internal consistency of the kinetic and thermodynamic equations and the better agreement of the calculated rate with the averages of replicated studies shows that the technique is useful.

Great accuracy is obtained with faster reaction and, in the case of solutions of low ionic concentrations, at higher pH values. The obtained data describe the hydrolysis of hydrocortisone hemisuccinate as being specifically catalyzed by hydroxyl ion above a pH of 8.

Below a pH of 8, the apparent rates of hemisuccinate hydrolysis may be greater than the extrapolation of the specific hydroxyl ion catalysis rate expressions would predict. The values that can be calculated on the basis of these expressions should only be considered as the minimum estimate of the rates at pH values below 8.

Certain chemical phenomena that may produce rates below pH 8 that exceed prediction may be (*a*) the increase in the relative importance of spontaneous hydrolysis or intramolecular attack of the anion on the ester carbonyl carbon (6–10)



(Eq. 22)

or (*b*) a significant contribution of hydronium ion catalysis to hemisuccinate hydrolysis at pH values below 8 since this would involve a reaction accelerated by the attraction of opposite charges

$$H_3O^+ + R{-}OCOCH_2CH_2O^- \rightarrow R{-}OH + HOOCCH_2CH_2COOH \quad \text{(Eq. 23)}$$

The heat of activation for the specific hydroxyl ion catalysis of hydrocortisone hemisuccinate is 7.0 Kcal./mole and is significantly less than that found for the alkaline hydrolysis of hemisuccinic acid ester of secondary alcohols, i.e., 9–14 Kcal./mole (11–13). The rate constants for hydrocortisone hemisuccinate hydrolysis are also much higher than for other succinate esters. For example, at 40° the rate constant is *ca.* 200 times greater than that for the hydrolysis of cyclohexanol hemisuccinate (12).

These phenomena imply that the structure of the steroid side chain is such that it promotes 21 ester hydrolysis over and above possible repulsion of the attacking hydroxyl ion by a negative charge on the molecule. A possible explanation is that a leaving group is stabilized by resonance, a group such as an enediol anion

(Eq. 24)

The major conclusion is that a 21-steroid ester is highly susceptible to alkaline hydrolysis by virtue of the unique structure of the steroid side chain.[2]

The stability of hydrocortisone hemisuccinate can be predicted at 25° by application of Eq. 15 where k_{OH^-} at 25° = 1.0 and pKw = 14. The predictions of half-life are given in Table IV.

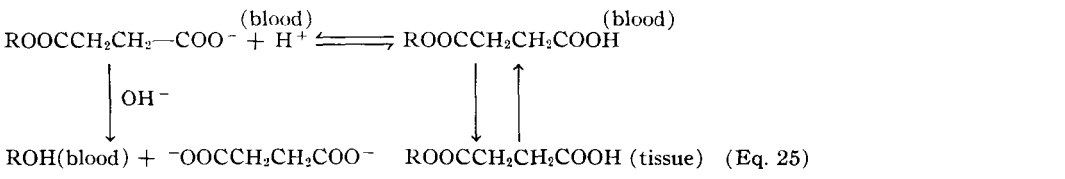
TABLE IV.—PREDICTED HALF-LIVES OF HYDROCORTISONE HEMISUCCINATE AT VARIOUS pH VALUES AT 25°

pH	$t_{1/2}$
7	80 days
8	8 days
9	19 hours
10	1.9 hours

[2] A possible alternative mechanism to postulate is one where the 17α-hydroxyl group is involved as an assisting group. Dr. S. Morris Kupchan of The University of Wisconsin suggests that this is consistent with his studies.

Recent studies on blood levels from parenterally administered hydrocortisone-21-hemisuccinate (14, 15) have shown that the steroid administered in this form is quickly available to the tissues. It was also shown that levels of free steroid after injections of the 21-phosphate ester were higher than those obtained after the 21-hemisuccinate esters were injected. Since comparative studies on biological activities are lacking, no conclusion as to medical significance could be drawn (15).

However, it was speculated (14) that a portion of the succinate ester was metabolically transformed without prior hydrolysis. Contrarily, no significant differences were observed between the phosphate and succinate esters studied in terms of percentage of injected steroid excreted in the urine.



A reasonable explanation for the blood level difference in free steroid is the greater deposition of hydrocortisone hemisuccinate in the tissues over that of the phosphate. Hydrocortisone hemisuccinate has a pKa *ca.* 5.0, and at the neutral pH of the blood, the sodium salt is in equilibrium with the free uncharged hemiester. In general, uncharged molecules exhibit higher lipoidal or fat solubility than charged molecules and penetrate cell membranes more rapidly

On the basis of Marcus' equation relating hydrolysis rate with pH and temperature (18), the apparent first-order rate constant for the production of free steroid from the phosphate ester is predicted as 2.5 $\times 10^{-4}$ hr.$^{-1}$ at 38° and pH 7.0. On the basis of the experimental data in this paper, and by use of Eq. 15 with pKw = 13.60 at 38° so that $[OH^-] = 2.51 \times 10^{-7}$ at pH 7, the apparent first-order rate constant for the hydrolysis of hemisuccinate ester is predicted to be 1.3 $\times 10^{-3}$ hr.$^{-1}$ at 38° and pH 7.0. It follows that, on the basis of solvolysis alone, free steroid should be produced from the succinate ester *ca.* five times faster than from the phosphate ester.

This fact is inconsistent with an assumption that 21-phosphate esters more readily produce free steroid in the blood than the 21-hemisuccinate esters by solvolytic mechanisms. This fact strongly validates the model proposed in Eq. 25.

(Eq. 25)

This fact has been well discussed in the literature (16, 17).

The doubly charged steroid phosphate is the major form of hydrocortisone phosphate at physiological pH values and has two pKa's, 6.2 and *ca.* 2 (18). At neutral pH the doubly charged phosphate anion is in equilibrium with the singly charged phosphate anion

$$R—OPO_2^{=} + H^+ \rightleftharpoons R—OPO_2H^- \quad \text{(Eq. 26)}$$

Thus, uncharged phosphate ester would be available for diffusion into lipid-like membranes only if the pH were decreased to *ca.* 4 and this is not physiologically feasible.

It follows, therefore, that increased tissue permeability of the hemisuccinate ester over the phosphate ester could account for the lower blood levels of free alcohol from the former.

Prediction of Stability in Pharmaceutical Preparations XI

Increased Stability of Soluble Steroid Hemiesters by Steric Hindrance

By EDWARD R. GARRETT† and MAX E. ROYER

Since alkyl substitution on the mono-esterified dicarboxylic acid of 21-steroid hemiesters decreases the rate of specific hydroxyl ion catalyzed hydrolysis, the kinetics of aqueous hydrolysis of prednisolone and 6α-methylprednisolone hemi-β,β′-dimethylglutarates have been studied by constant pH titration. The effect of steroid 6α-substitution on rate of 21-ester hydrolysis has been indicated. The stabilities of sodium salts of such esters at various pH values between 8 and 10 and at various temperatures have been predicted. It has been shown that steric hindrance due to alkyl substitution on the monoesterified dicarboxylic acid increases stability by more than tenfold over the previously reported stability of the nonhindered hydrocortisone hemisuccinate. A more precise procedure for constant pH titration is described.

THE PHARMACEUTICAL utility of a steroid has been enhanced by formation of a soluble derivative that still possessed biological potency and stability as the derivative. The criteria of solubility and biological potency have been well fulfilled by the sodium salt of the hemisuccinate ester of hydrocortisone (1–3). It has been shown that the stability of 21-steroid hemiesters is not significantly affected by increasing the chain length of the monoesterified dicarboxylic acid (4). Resistance to specific hydroxyl ion catalysis is promoted, however, by alkyl substitution on the dicarboxylic acid in accordance with Newman's rule of "six" (5, 6).

This paper reports on the detailed kinetic studies of the specific hydroxyl ion catalyzed hydrolysis of such sterically hindered esters, the hemi-β,β′-dimethylglutarate esters of prednisolone and 6α-methylprednisolone in aqueous media.

EXPERIMENTAL

The procedure for the constant pH titrations of the sodium salt of the hemi-β,β′-dimethylglutarate ester of prednisolone (Δ¹-hydrocortisone) was similar to that reported previously (4, 7). However, the experimental techniques for the constant pH titrations of the sodium salt of the hemi-β,β′-dimethylglutarate ester of 6α-methylprednisolone were considerably improved. The material was weighed and placed in a beaker fitted with a close-fitting rubber insert through which the single Beckman compound electrode extended to the bottom of the beaker. A metal clamp was also used to seal this rubber cap around the beaker. A needle was placed through the rubber insert and tubing led to another needle sealed in the electrode side orifice so that the pressure atop the electrode salt solution was the same as that within the beaker. The beaker containing the weighed material and a magnetic bar was submerged in the constant temperature bath atop a magnetic stirrer in a watertight can with a conduit periscoped above the water to permit egress for the insulated electric cord.

Fifteen milliliters of nitrogen-purged water, previously equilibrated in the temperature bath, was added by means of a syringe and needle thrust through the rubber cap. An additional needle had been thrust through the insert to act as a vent.

The resultant solution was *ca.* 0.004 *M* in hemiester. Both of these needles were removed and a 25-gauge 2-in. needle, bent at a right angle, was inserted. This was for the titrant delivery from a gas-tight 1-ml. "microliter" syringe.[1] The rubber cap bulged slightly from the internal vapor pressure but was definitely vaportight.

The Cannon difunctional titrator had been standardized previously as reported (4, 7).

CALCULATIONS AND RESULTS

Typical plots of the consumption of standard sodium hydroxide by hemi-β,β′-dimethylglutarate esters of a steroid alcohol are given in Fig. 1. These plots are for the hydrolysis of the 6α-methylprednisolone ester at 70.0° at several pH values and are given as chart divisions against time. Each chart division, *CD*, represents 0.008052 meq. of sodium hydroxide added as 1.0175 *M*. In some instances, as at pH 10.0, the possible rate of addition of alkali was slower than the consumption so that the only valid part of the curve is when the desired constant pH was attained and maintained.

The dashed lines in Fig. 1 represent the tangents to the curves at the origin and the apparent first-order rate constants, *k*, at the constant pH values can be calculated from

$$k(\text{sec.}^{-1}) = (N \times m)/(m' \times M) = (CD \times 0.008052)/(m' \times M) \quad \text{(Eq. 1)}$$

where *m* is the number of ml. of *N* normal sodium hydroxide consumed per second at the constant pH

[a] Calculated from slope of plot of first-order expression ($\log \lambda_\infty - \lambda$) = $-kt/2.303 + \log \lambda_\infty$ where λ_∞ is the theoretical volume of standard titer consumed on complete saponification and λ is the amount consumed at time, t. [b] Calculated from initial zero-order slope, m, of ml. of N normal titer consumed per second by m' ml. of M molar steroid hemiester, $k = (N \times m)/(m' \times M)$. [c] A different study than the one above it.

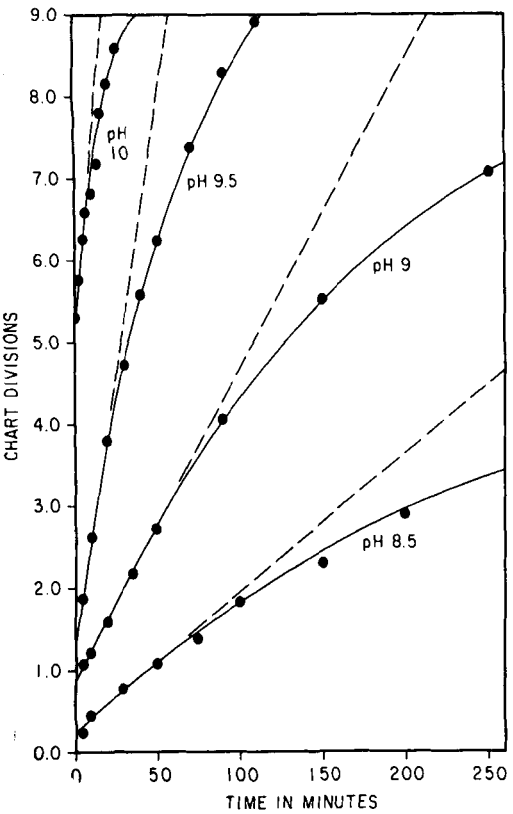

Fig. 1.—Typical plots of consumption of 1.000 M sodium hydroxide by 15 ml. of 0.004 M 6α-methylprednisolone hemi-β,β'-dimethylglutarate at constant pH and at 70.0° as a function of time. Each chart division represents 0.008052 meq. sodium hydroxide. The dashed lines are estimates of the initial rate of sodium hydroxide addition. At pH 10, the titer addition did not initially keep up with speed of reaction.

by m' ml. of M molar hemiester, or where CD is the number of chart divisions where each chart division represents 0.008052 meq. sodium hydroxide added.

The first-order rate constants, k in sec.$^{-1}$, derived from these tangents at the origin to the plots of alkali consumption with time are given in Table I for both 6α-methylprednisolone and prednisolone hemi-β,β'-dimethylglutarate.

Typical first-order plots are given in Fig. 2 as based on the expression

$$\log (CD_\infty - CD) = -kt/2.303 + \log CD_\infty \quad \text{(Eq. 2)}$$

where CD_∞ is the number of chart divisions which should be traveled at theoretically complete saponification of the *ca.* 0.004 M ester in the 15 ml. of water.

The apparent first-order rate constants, k in sec.$^{-1}$, estimated from the slopes of such plots are also given in Table I. The fine consistency of the rates determined by this method and calculated from the tangent to the origin is gratifying.

Plots of the logarithm of the rate constants against pH for the 6α-methylprednisolone and prednisolone hemiesters are given in Figs. 3 and 4, respectively.

These plots are characterized by the equation

$$k = k_{OH^-}[OH^-] \quad \text{(Eq. 3)}$$

or in logarithmic form

$$\log k = \log k_{OH^-} - \text{pOH} = \log k_{OH^-} + \text{pH} - \text{pKw} \quad \text{(Eq. 4)}$$

The intercepts of the plots of Figs. 3 and 4 are $\log k_{OH^-} - \text{pKw}$ and are given in Table II. The $\log k_{OH^-}$ can thus be calculated from the knowledge of the pKw at the given temperature as listed in the literature (8).

The Arrhenius plots of $\log k_{OH^-}$ against the reciprocal of the absolute temperature, $1/T$, are given in Fig. 5 as per the expression

$$\log k_{OH^-} = -S/T + \log P = \Delta H_a/2.303\ RT + \log P \quad \text{(Eq. 5)}$$

where for 6α-methylprednisolone hemi-β,β'-dimethylglutarate S = 2,995, $\log P$ = 8.506, and ΔH_a = 13.7 Kcal./mole and for prednisolone hemi-β,β'-dimethylglutarate S = 2,422, $\log P$ = 7.050, and ΔH_a = 11.1 Kcal./mole.

Values of $\log k_{OH^-}$ at 25, 30, and 40° can be calculated for both hemiesters from Eq. 5 with proper substitution of the derived parameters and they are given in Table II. The apparent first-order rate constants can be calculated from the derived values of Table II by insertion into Eq. 4 and are given for various pH values in Table III.

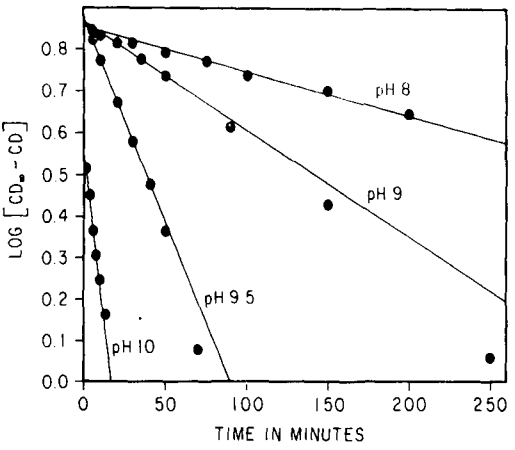

Fig. 2.—Typical first-order plots of hydrolysis of 6α-methylprednisolone hemi-β,β′-dimethylglutarate at constant pH and at 70°. Each chart division, *CD*, represents 0.008052 meq. sodium hydroxide added as 1 *M* to 15 ml. of *ca.* 0.004 *M* steroid hemiester. CD_∞ is the theoretical value at complete saponification.

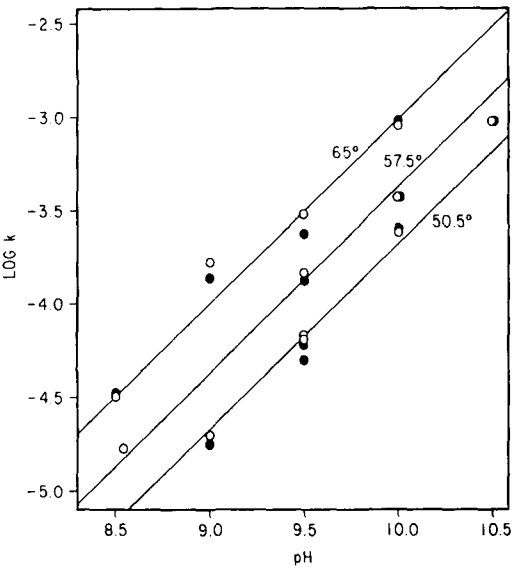

Fig. 3.—Logarithm of the apparent first-order rate constants, *k* in sec.$^{-1}$, for the hydrolysis of 6α-methylprednisolone hemi-β,β′-dimethylglutarate as a function of pH. The open circles represent *k* values derived from first-order plots; the solid circles represent *k* values derived from the initial zero-order rate of alkali consumption; the half-open circles are coincident values.

The half-life, $t_{1/2}$ in days, is calculated from

$$t_{1/2}(da) = 8.00 \times 10^{-6}/k(\text{sec.}^{-1}) \quad \text{(Eq. 6)}$$

The fraction, *f*, of nonhydrolyzed ester remaining at one year at the given temperature and pH and given in Table III is calculated from

$$\log f = -1.367 \times 10^{7} k(\text{sec.}^{-1}) \quad \text{(Eq. 7)}$$

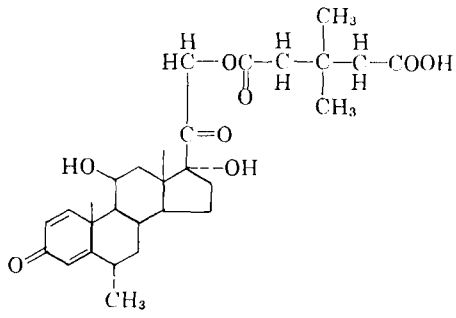

TABLE II.—ESTIMATES OF THE BIMOLECULAR RATE CONSTANT k_{OH^-} (1/*M*/sec.) FOR THE HYDROXYL ION CATALYZED HYDROLYSIS OF HEMIESTERS OF β,β′-DIMETHYLGLUTARATE

	°C.	log k_{OH^-} − pKw[a]	pKw[b]	log k_{OH^-}	(1/*M*/sec.) k_{OH^-}

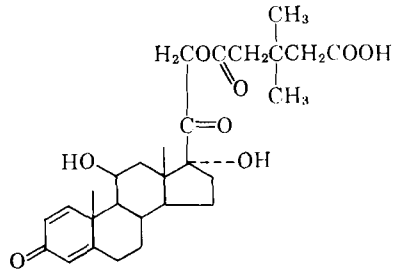
[a] Intercept of plot of logarithm of apparent first-order rate constant, *k* in sec.$^{-1}$, against pH by the expression log k = log k_{OH^-} − pKw + pH. [b] As determined from ref. 8. [c] The listed values for these temperatures were calculated from the derived Arrhenius' expression log $k_{OH^-} = -S/T + \log P$ where *S* and *P* for the 6α-methylprednisolone hemiester are $2.995 \cdot 10^3$ and 8.506, respectively, and for the prednisolone hemiester are $2.442 \cdot 10^3$ and 7.050, respectively. From these data and the pKw, the other values can be derived.



DISCUSSION

The specific hydroxyl ion catalyzed hydrolysis of 6α-methylprednisolone hemi-β,β′-dimethylglutarate (I) would be expected to have rates similar to the

I

specific hydroxyl ion catalyzed hydrolysis of prednisolone hemi-β,β′-dimethylglutarate (II) since the

II

former compound differs from the latter by only an α-methyl at the 6 position. Surprisingly, the latter compound hydrolyzes faster by an order of magnitude greater than two. Although the experimental conditions were not as elegant for the constant pH hydrolyses of the prednisolone compound as for the 6α-methylprednisolone since the improvements were subsequently introduced, the difference in magnitude of rates is considered significant.

[a] Log k_{OH^-} was calculated from log $k_{OH^-} = -2.995 \cdot 10^3(1/T) + 8.506$ for 6α-methylprednisolone hemiester, log $k_{OH^-} = -2.422 \cdot 10^3(1/T) + 7.050$ for prednisolone hemiester where T = °C. + 273°. Subsequently, k for a given pH and temperature was estimated by log k = log k_{OH^-} − pKw + pH, where pKw for a given temperature is given in Table II from the literature (8). [b] The ester of 6α-methylprednisolone hydrolyzes 0.029× as fast as hydrocortisone hemisuccinate at 25°, 0.036× as fast at 30°, and 0.051× as fast at 40°. The ester of prednisolone hydrolyzes 0.085× as fast as hydrocortisone hemisuccinate at 25°, 0.10× as fast at 30°, and 0.12× as fast at 40°. [c] Half-life in days at the given pH, $t_{1/2(da)} = 8 \times 10^{-6}/k$(in sec.$^{-1}$). [d] The fraction of nonhydrolyzed ester remaining at one year at the given temperature and pH.

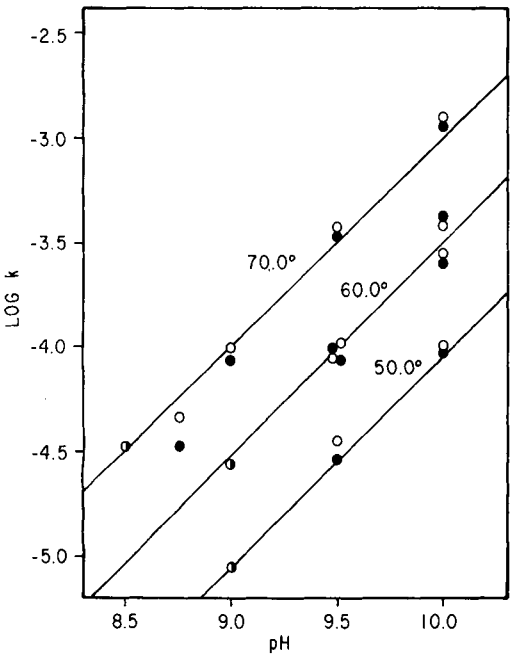

Fig. 4.—Logarithm of the apparent first-order rate constants, k in sec.$^{-1}$, for the hydrolysis of prednisolone hemi-β,β'-dimethylglutarate as a function of pH. The open circles represent k values derived from first-order plots; the solid circles represent k values derived from the initial zero-order rate of alkali consumption.

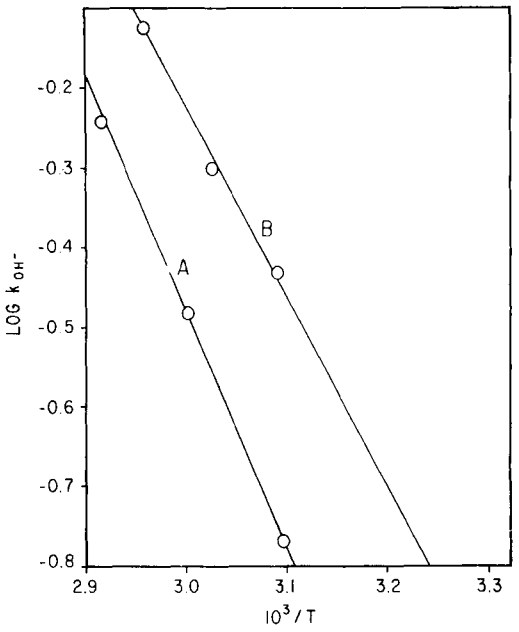

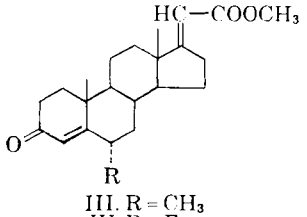

Fig. 5.—Arrhenius plot of the bimolecular rate constant, k_{OH^-}(1/M/sec.) for the hydroxyl ion catalyzed hydrolysis of steroid hemiesters of β,β'-dimethylglutarate. Curve A is for 6α-methylprednisolone; curve B is for prednisolone.

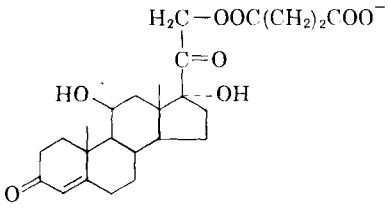
It is also significant that the coulometric bromination of methyl-6α-methyl-4,17(20)-[*cis*]pregnadien-21-oate (III) proceeds exceedingly fast whereas the coulometric bromination at fifty times the bromine concentrations as used for III is very much slower for methyl-6α-fluoro-4,17(20)-[*cis*]-pregnadien-21-oate (IV) (9).



III. R = CH_3
IV. R = F

In addition, it has been shown by derivative ultraviolet spectroscopy that a definitive interaction exists between the 3-keto-Δ^4 system of the A ring modified by a 6α-methyl substitution and an α-hydroxyl substituent at the 17 position (10).

The hydrolysis studies were conducted down to a pH of 8.5 and only specific hydroxyl ion catalysis was indicated. This does not permit rejection of intramolecularly abetted "spontaneous" hydrolysis or, its kinetic equivalent, specific hydroxyl ion catalyzed hydrolysis of the undissociated hemiester

which would make a significant contribution to the total hydrolysis rate at lower pH values, specifically in the neutral pH region 4–7 as a function of pKa. This phenomenon had been indicated previously for hydrocortisone hemisuccinate(V) (4).

V

Thus the predicted stabilities (Table III) of the β,β′-dimethylglutarate hemiesters of these steroids at pH values closer to neutrality are the most optimistic estimates. Intramolecular catalysis, if present, would tend to increase the hydrolysis rate at neutral pH values over that predicted from specific hydroxyl ion catalysis alone.

As was expected, stability to specific hydroxyl ion catalyzed hydrolysis is greatly enhanced by alkyl substitution over that for the hemisuccinate or other straight chain aliphatic hemiesters (4, 7) and is in accordance with Newman's rule (5, 6). It is interesting to note, however, that if intramolecular catalyzed hydrolysis is present, and significantly contributes in the neutral pH region 4–7, it would be predicted to be greater in the case of the alkyl substituted esters than for the nonalkylated hemiesters of dicarboxylic acids such as the straight chain glutaric or succinic acids (11).

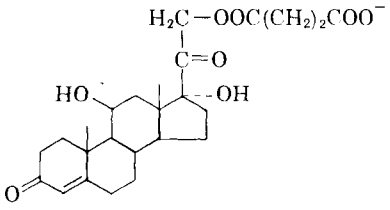
Solubilization in Nonpolar Solvents

Influence of the Chain Length of Solvent on the Solubilization of Water by Dioctyl Sodium Sulfosuccinate

By W. I. HIGUCHI and JAGDISH MISRA



The water solubilizing capacities of the solutions of dioctyl sodium sulfosuccinate (Aerosol OT, AOT) in normal aliphatic hydrocarbon solvents from *n*-heptane to *n*-octadecane were determined as functions of the AOT concentration and temperature. The method involved adding water to the AOT solutions up to the turbidity point. The solubilizing capacity was found to be strongly dependent on the solvent chain length, increasing with decreasing chain length. For example, in octane solutions at 30° about 50 moles of water per mole AOT can be solubilized while only 5 moles can be solubilized in hexadecane solutions. The thermodynamic activity of the solubilized water was determined by a modified isopiestic method. These data indicated that the binding of water in all systems studied was essentially the same. A tentative theory based on the solvation of the micelle exterior is proposed to explain the two sets of data.

THE PHENOMENON of micellar solubilization in aqueous systems has recieved considerable attention, this subject having recently been covered extensively in a book by McBain and Hutchinson (1). The applications of the principles and concepts of solubilization in aqueous media to pharmacy have been demonstrated (2). The drug activity, release characteristics, and stability (3, 4) may be improved by a suitable choice and amount of these solubilizing agents.

There appears to have been little or no study of micellar solubilization of drugs in nonaqueous systems. It is not implied by this statement that the practice of pharmacy has not involved the use of this type of solubilization. However, the mechanisms of incorporation of water and highly polar drugs in hydrophobic vehicles by agents have not received much consideration. One should know whether the formulation is

Solubilization in Nonpolar Solvents

Influence of the Chain Length of Solvent on the Solubilization of Water by Dioctyl Sodium Sulfosuccinate

By W. I. HIGUCHI and JAGDISH MISRA

The water solubilizing capacities of the solutions of dioctyl sodium sulfosuccinate (Aerosol OT, AOT) in normal aliphatic hydrocarbon solvents from *n*-heptane to *n*-octadecane were determined as functions of the AOT concentration and temperature. The method involved adding water to the AOT solutions up to the turbidity point. The solubilizing capacity was found to be strongly dependent on the solvent chain length, increasing with decreasing chain length. For example, in octane solutions at 30° about 50 moles of water per mole AOT can be solubilized while only 5 moles can be solubilized in hexadecane solutions. The thermodynamic activity of the solubilized water was determined by a modified isopiestic method. These data indicated that the binding of water in all systems studied was essentially the same. A tentative theory based on the solvation of the micelle exterior is proposed to explain the two sets of data.

THE PHENOMENON of micellar solubilization in aqueous systems has recieved considerable attention, this subject having recently been covered extensively in a book by McBain and Hutchinson (1). The applications of the principles and concepts of solubilization in aqueous media to pharmacy have been demonstrated (2). The drug activity, release characteristics, and stability (3, 4) may be improved by a suitable choice and amount of these solubilizing agents.

There appears to have been little or no study of micellar solubilization of drugs in nonaqueous systems. It is not implied by this statement that the practice of pharmacy has not involved the use of this type of solubilization. However, the mechanisms of incorporation of water and highly polar drugs in hydrophobic vehicles by agents have not received much consideration. One should know whether the formulation is

The authors are grateful to Professor T. Higuchi for helpful discussions.

truly physically stable thermodynamically or whether the system is an emulsion or a suspension capable of physical degradation. The questions of how much bound water and drug are there and what are their states of binding should be of concern. The results of an investigation along these lines would be helpful in the understanding and in the improvement of oil base formulations, e.g., ointments, lotions, oil injections, etc.

It was decided that a water-surfactant-hydrocarbon compatibility study would be a most worthwhile starting point. Specifically, the aims were to show how much water might be incorporated into an oil with the help of a surfactant and how available such water might be for drug solubilization. Results of this investigation are reported in this communication.

EXPERIMENTAL

General Considerations.—The surfactant used in these studies was dioctyl sodium sulfosuccinate (di-2-ethylhexyl sodium sulfosuccinate).[1] It was selected because some of its micellar characteristics in nonaqueous solvents had been studied by others (5–7). The oils used for this work were some of the normal aliphatic hydrocarbons from heptane to octadecane. These were chosen because preliminary studies had indicated a rather unusual chain length-solubilization limit relationship, *viz.*, that in shorter chain solvents a great deal more water could be solubilized by the same amount of AOT.

Materials.—In preliminary studies "100% pure" AOT was used after removing the methanol-insoluble fraction. However, the end points (turbidity point) in the water solubilization experiments were not reproducible[2] with this purification procedure despite the fact that the carbon, hydrogen, and sulfur analyses indicated better than 99% purity in these samples. Therefore, the following procedure was followed which is a modification of that reported by Williams, Woodberry, and Dixon (8).

About 400 Gm. of AOT was dissolved in 800 ml. of methanol. The insoluble solids were centrifuged and the supernatant removed by decantation and cooled to 3°. To this solution was added about 1.4 L. of water cooled to 3°. The resulting precipitate was centrifuged out at 5° and discarded. Then 0.2 L. more of water at 3° was added to the solution and about 100 to 150 Gm. of the resulting precipitate was recovered by, again, centrifugation. The material was dried under vacuum at 75° to 85° for 2 to 3 days until further drying showed no loss in weight of the material. Samples prepared in this manner always gave the same mole-mole (water-to-surfactant) ratio to within about ±2%.

All of the hydrocarbons used in this work were Eastman practical grade. These were dried and redistilled. Essential purity in all cases was established by melting point determinations. Doubly distilled water was used.

[1] Marketed as Aerosol OT by American Cyanamid Co.
[2] Variations in the results were as great as 30%.

Procedure for Solubilization Limit Study.—To determine the amount of water that could be solubilized before the system became two-phase the following procedure was adopted. Water was added to about 30 ml. of a magnetically stirred AOT-hydrocarbon solution in water-jacketed 250-ml. flasks until turbidity and two-phase formation occurred. In all cases the end point was sharp (within 1% of added water) and reversible. At the end point the systems were initially turbid, but after a few minutes, two separate, relatively nonviscous, layers formed which cleared after a few more minutes of standing. The smaller of the two phase volumes at the end point was always much greater than the amount that could be explained on the basis of only pure water coming out.

Procedure for Vapor Pressure of Water Determinations.—A rapid relative method was devised for determining the vapor pressures, and hence the thermodynamic activities, of the solubilized water. The isopiestic principle was utilized in a novel fashion.

The water vapor in the solubilized system was exposed to a salt solution (sodium chloride or calcium chloride) in a weighing bottle suspended from a glass hook attached to the male ground joint of the flask. The solubilized system was stirred magnetically from the outside, as in the solubilization limit studies. The vapor pressure of the water in salt solution was accurately known from standard tables (9). If after several hours the weighing bottle had gained or lost weight, a salt solution of different water activity was substituted. Generally after three such trials it was found that the water activity in the solubilized system could be matched to within about 0.01 unit of activity (activity = unity for pure water) with these "indicator" salt solutions. Thus, within a day or so a series of vapor pressure determinations was completed. Preliminary tests had shown that the usual procedure of equilibrating the solubilized system with an originally unmatched salt solution would have taken weeks.

RESULTS

Solubilization Limit Determinations.—The results of the mole water per mole AOT solubilizable in a single phase state at 30° are given in Fig. 1 as a function of the AOT concentration (w/w). The AOT concentration refers to the AOT-hydrocarbon solution prior to the addition of water. In Fig. 2 the corresponding results at different temperatures are given for octane, dodecane, and hexadecane.

As already mentioned, the precision of the end point determination for a given run was better than 1% but the reproducibility of a point for different AOT starting materials was about ±2%. Therefore, in order to minimize the effects of these sample variations upon both the temperature and the AOT concentration dependencies, the same stock AOT sample was used for the results given in Figs. 1 and 2.

The most interesting matter is the extreme sensitivity of the turbidity point to the chain length of the solvent. The behavior is somewhat surprising in view of the negligible chemical differences in the solvents.

Even for the heavy hydrocarbons, hexadecane and

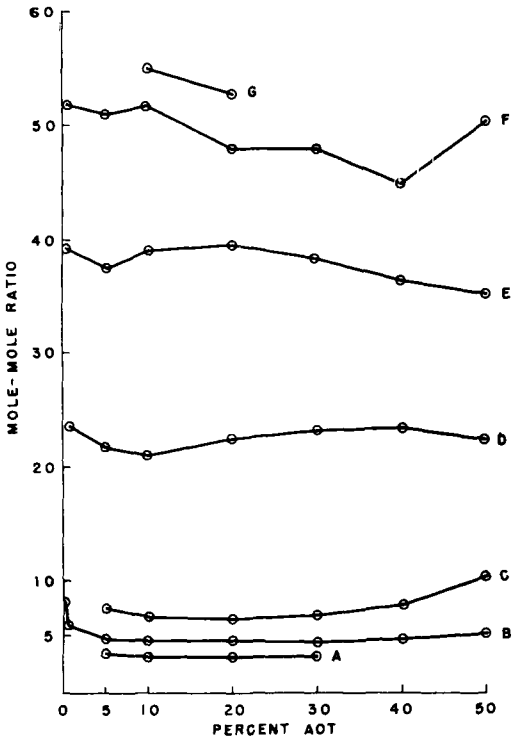

Fig. 1.—The solubilization limit for water in AOT-hydrocarbon systems at 30°. The ordinate is maximum moles of water solubilized per mole AOT. The abscissa is the per cent AOT in hydrocarbon solution prior to addition of water. A, octadecane; B, hexadecane; C, tetradecane; D, dodecane; E, decane; F, octane; and G, heptane.

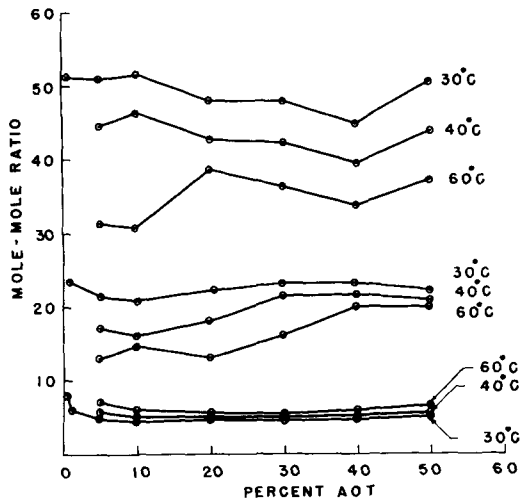

Fig. 2.—The solubilization limit for water in AOT-hydrocarbon systems at different temperatures.

octadecane, four to five moles of water per mole AOT can be sustained in a single phase system. Thus, for the 50% AOT case, it would mean that even here as much as 10% water may be incorporated in a clear preparation.

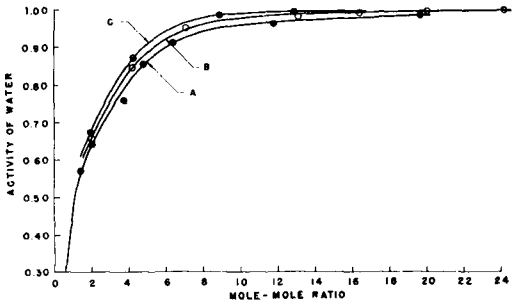

Fig. 3.—The activity of water in AOT-hydrocarbon-water systems as function of mole water per mole AOT solubilized in initially 10% AOT-hydrocarbon solution. A, Hexadecane; B, dodecane; C, octane.

Activity of Water Determinations.—In Fig. 3 the results of the determination of the activity of water (pure water = unit activity) are given for the octane, dodecane, and hexadecane systems at 30° and 10% AOT (in original hydrocarbon solution). The similarity of all three curves suggests that the state of binding of water in the three cases may not be too different, even when compared beyond the hexadecane turbidity point (~5 mole-mole ratio). This at first does appear surprising in view of the great differences in these systems with respect to their solubilization limit behavior.

In the data range reported in Fig. 3 for the octane system the possible condensation of octane in the weighing bottle to give erroneous values was discounted. However, a few activity determinations for the octane system beyond the turbidity point are not reported because there was fogging observed both on the weighing bottle walls and the walls of the flask. The condensing material appeared to be water, and the weighing bottle picked up weight even when pure water was placed in it. These observations suggest that water had just exceeded unit activity at the turbidity point for the octane system.[3]

Because of the fact that for hexadecane, and possibly for dodecane,[4] the turbidity point occurred below unit water activity, the solubilization limits as determined here cannot correspond to pure water coming out as the second phase, at least for hexadecane. Therefore, even up to about 20 moles water per mole AOT in the hexadecane case (see Fig. 3), water seems to be in the micellized state even though beyond 5 moles of water the system is no longer a single phase.

DISCUSSION

Mechanism of Solubilization and Solubilization Limit Behavior.—The ultracentrifuge and viscosity studies on the dodecane-AOT-water system by Mathews and Hirschhorn (5) have shown that in this system the water is bound in the interior of spherical monodispersed micelles. Studies by Aebi and Wiebush (7), also on the dodecane system, sug-

[3] The water in a water-in-oil emulsion may possess activity slightly greater than bulk water because of the surface-free energy of the droplets.

[4] As stated, the activity determinations were good to about 1%. For the dodecane system the turbidity occurred at a water activity of 0.99 ± 0.01, but no fogging of flask or bottle walls was observed at this point.

gest that about one or two moles of water per mole AOT in these micelles are very tightly bound by the polar heads of the AOT while the remainder of the water is "free." This free water is able to dissolve sodium chloride to essentially the same extent as bulk water, except for the common ion effect due to the Na^+ contribution from the AOT itself. In view of the activity data given in Fig. 3, this picture for the state of dispersion of the system should be appropriate for both octane and hexadecane, and therefore for probably all hydrocarbons studied here.

Why then are there such vast differences in the solubilization limits? An unambiguous answer to this question would require more work on this problem. The situation is complex to the extent that a single simple mechanism will not explain all of the facts. In the following paragraphs a tentative, reasonable picture consistent with the main observations is presented.

If it is first postulated that the turbidity point corresponds to the aggregation of intact swollen micelles and that the aggregation tendency is inversely related to the degree of solvation of the exterior of the micelles, the results of these studies can be rationalized. In essence, then, this theory states that the greater the amount of water in the micelle interior the greater the aggregation tendency, and the greater the micelle exterior solvation the lesser the tendency for aggregation. The "intactness" assumption seems reasonable in view of the similarity of the water activity data for hexadecane, dodecane, and octane beyond the hexadecane turbidity point. If the hexadecane turbidity point corresponded to some kind of micelle destruction and consequent rearrangement of hexadecane, water, and AOT molecules, this similarity would be fortuitous.

The tendency for micellar aggregation should be inversely related to how well the outside of the micelles are solvated. The stronger and thicker the solvated layer, the farther apart the polar cores of the micelles will be kept. Therefore, the type of attractive forces (10) responsible for suspension and emulsion aggregation would be minimized.

Solvation would generally be expected to be exothermic. Therefore increase in temperature should generally result in a decrease in solvation. This is consistent with the temperature dependence observed for octane and dodecane (see Fig. 2). If there is no solvation one would expect that an increase in temperature would lessen the tendency for aggregation. This is compatible with the small but positive temperature dependence observed with the hexadecane system.[5]

From a purely statistical point of view, it is reasonable (11) to except that the lower hydrocarbons might better solvate the micelle than the higher hydrocarbons. The local thermodynamic activity of the externally exposed functional groups of the micelles is greater for higher hydrocarbon systems because the kinetic units of the solvent are larger for the higher hydrocarbons. Therefore, their tendency to mix with the solvent should be less; the externally exposed groups of the micelle have a greater tendency for intramicellar association in higher hydrocarbons.

The lack of distinct AOT concentration dependence (see Fig. 1) at first thought appears to be contradictory to this theory, but it must be kept in mind that these are concentrated systems and intermicellar interactions are likely to be important. Actually the hexadecane system, for which some low AOT concentration runs were made, does show (see Fig. 1) a rapid increase in the mole-mole ratio with decreasing AOT concentration at low AOT concentrations. This is consistent with the aggregation theory and the mass action concept.

Because for the lower hydrocarbons the activity of micellized water was essentially unity at the turbidity point, there was the likelihood of the presence of emulsion droplets of water in these cases. It is possible that these emulsion droplets were able to nucleate the aggregation in the lower hydrocarbons.[6] Further discussion of this possibility would be only speculation at this point, however.

Pharmaceutical Significance.—These thermodynamically stable islands of water in oil should provide a means of incorporating ionic and other highly polar drugs into essentially nonpolar vehicles. An example already cited above is the solubilization of sodium chloride in micellized water.

A useful application for these systems should be found in the development of ointments. It would seem that a relatively nondrying ointment base could be designed on these concepts. For highly polar drugs the ointment of this type would, furthermore, possess slow but prolonged release characteristics.

This technique of solubilization might be utilized in the preparation of sustained-action formulations in which the drug can be uniformly and reproducibly dispersed into a wax. Investigations of this possibility are now under way in our laboratories.

[5] Temperature dependence for aggregation, *per se*, should be small since the energies involved are only the order of a few kT, where k = Boltzmann's constant and T = absolute temperature.

[6] Kinetics is not implied here, but that the droplets could provide surfaces for adsorption of micelles, and if some water is released by these micelles upon adsorption, this type of aggregation would perpetuate itself.

Physical Degradation of Emulsions Via the Molecular Diffusion Route and the Possible Prevention Thereof

By W. I. HIGUCHI and JAGDISH MISRA

The quantitative aspects of the rate of growth of the large particles and the rate of dissolution of the small particles in emulsions were theoretically examined for the case in which the process is diffusion controlled in the external phase. It was found that even if the miscibility of the dispersed phase is as low as about 1×10^{-7} Gm. per ml. the size distribution of micron size emulsion particles may change appreciably in 1 year. Furthermore, according to this mechanism the emulsion stability is approximately proportional to the particle volume. It is proposed that such unstable emulsions may be stabilized with respect to this process by the addition of small amounts of a third component which must distribute preferentially in the dispersed phase. Sedimentation experiments carried out with carbon tetrachloride emulsions in water with and without hexadecane and Nujol as additives support the theory.

WHEN one speaks of the instability of emulsions he most frequently has in mind the processes of creaming or sedimentation followed by coalescence, or the last process alone. Little thought, even at the qualitative level, has been given to examining the possible importance of molecular diffusion as a pathway in the degradation of emulsions.

This report presents a quantitative theoretical study of the various factors governing the degradation rate of emulsions when the process is strictly molecular diffusion controlled, i.e., when the coalescence rate is negligible. In Figs. 1A and 1B we illustrate the two processes of coalescence and molecular diffusion degradation, respectively. Coalescence then is the formation of a droplet from two smaller droplets, the significant step occurring when the two droplets get close enough to allow a contact of the droplet phases. Now in a molecular diffusion process two droplets may form a single droplet if conditions are such that one droplet is allowed to grow while the other dissolves. Hence, in the molecular diffusion process, the droplet phases are not required to come into contact.

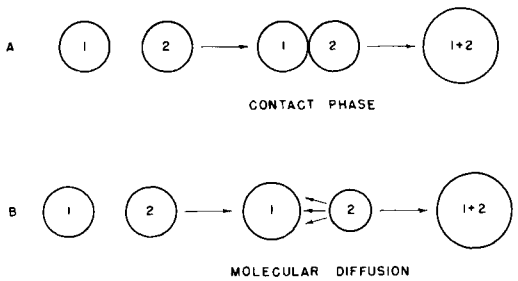

Fig. 1.—Illustration of emulsion degradation via coalescence (A) and via molecular diffusion degradation (B).

We can qualitatively visualize situations in which one mechanism will be more important than the other. For example an emulsion "stabilized" with respect to droplet contact by means of either a charge inducing agent or by means of a suitable protective colloid may yet yield to the mechanism of molecular diffusion degradation. On the other hand, an emulsion in which the internal phase is sufficiently immiscible in the external phase can only degrade by the droplet contact route.

THEORY

Case I. Simple Case of a Mixture of Two Sizes.—The differential equations for the rate of change of an arbitrary distribution of emulsion particle sizes cannot be solved by usual methods. For this reason it would be profitable to examine a specific simple case first so that a complete understanding of the situation in at least this one case might be obtained. We could then examine a more realistic case.

Consider an emulsion in which one finds particles of two sizes only. Let a_A and a_B be the radii of these particles and n_A and n_B their respective number concentrations. At time $t = 0$, let $a_A = a_{A0}$ and $A_B = a_{B0}$, with $a_{A0} < a_{B0}$.

The question we now would like to answer is, how do a_A and a_B vary with time? First let us examine the driving force responsible for degradation with which we are concerned.

It is well known (1) that the chemical potential of a component in a phase is a function of the molal interfacial area of the phase. Thus small crystals are more soluble than large ones, and the vapor pressures of small droplets are greater than the vapor pressures of large ones. Analogously, the miscibility of the internal phase material is a function of its molal interfacial area.

For a one-component droplet of radius r in equilibrium with the external phase solution the miscibility of the internal phase material with the external phase may be expressed by the following

Received April 28, 1961, from the School of Pharmacy, University of Wisconsin, Madison.

Supported in part by a grant from the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

equation in the Henry's law region

$$c_r = c_\infty \exp(K/r) \qquad \text{(Eq. 1)}$$

Here c_r is the miscibility of the r-size droplet, c_∞ is the miscibility of the infinitely large droplet, and K is given by

$$K = (2\gamma M)/(\rho RT) \qquad \text{(Eq. 2)}$$

where γ is the interfacial tension of the interface between the two phases, M and ρ are the molecular weight and density of the internal phase material, R is the molar gas constant, and T is the temperature in °K.

It is clear from Eq. 1 that if more than one droplet size is present in an emulsion the chemical potential of the internal phase material in all of the droplets cannot be equal, i.e., the smaller particles will be thermodynamically unstable with respect to the large ones. Thus the smaller ones will tend to dissolve, and the larger ones will tend to grow at the expense of the former.

Let us now examine the mechanism of the rate process which we call molecular diffusion degradation. For a quantitative analysis of the problem we must assume that the system is dilute, i.e., a few per cent or less volume fraction of the internal phase.[1] Also we must assume that the miscibility of the internal phase material in the external phase is low, i.e., $\lesssim 1\%$ or so. Another simplifying assumption is that each particle must seek an environment which is both a time average and a space average distribution of other particles. This is a good assumption for not too viscous emulsions (dilute oil-in-water or dilute water-in-light oil emulsions) but not so good for, say, most heavy base ointments. Even for the latter however, to the extent that we are interested in approximate degradation rates, the assumption does not endanger our conclusions.

Now the rate of dissolution or the rate of growth of a sphere of radius a may be expressed (2) by the following equation when the process is diffusion controlled in the external phase and when $(c_s - c_o)$ is smaller than *ca.* 1×10^{-2} Gm. per ml.

$$G = 4\pi Da(c_s - c_o) \qquad \text{(Eq. 3)}$$

Here G is the rate, D is the molecular diffusion coefficient of the internal phase material in the external phase, c_s is the miscibility of the dissolving or growing phase, and c_o is the concentration of the material at some distance from the sphere, large compared to a.

Implicit in the derivation of Eq. 3 are several assumptions which now must be discussed. First, Eq. 3 assumes that no interfacial barrier is present. Studies (3) have indicated that for micron-size droplets or greater, mass transfer between two liquid phases is governed primarily by diffusion rates in the external phase. Even relatively strong interfacial monolayer films provided by conventional low molecular weight surfactants probably do not affect these rates (3). Thick viscous films provided by polymeric surfactants or by polymolecular films of low molecular weight surfactants may be important, however. There is a great need for good experimental work to solve these problems satisfactorily. We can only state at the present that in many, and in probably most, cases interfacial barriers against molecular mass transfer are not important in emulsion systems. Second, Eq. 3 assumes that hydrodynamic effects are not important. Nielsen's recent studies (2) show that fluid flow effects upon dissolution rates or growth rates caused by sedimentation or creaming of aqueous emulsion (density difference between particle and water less than unity) are unimportant for particle sizes *ca.* 25 μ or less. The same conclusions apply to moderately agitated systems where local fluid accelerations and decelerations do not exceed by very much that due to gravity. By the same type of analysis it can be shown that velocity gradients in the system up to about 10 sec.$^{-1}$ remain unimportant.

Now c_s in Eq. 3 is given by Eq. 1, so that for particles of size a_A

$$c_s = c_A = c_\infty \exp\left(\frac{K}{a_A}\right) \qquad \text{(Eq. 4)}$$

and for particles of size a_B

$$c_s = c_B = c_\infty \exp\left(\frac{K}{a_B}\right) \qquad \text{(Eq. 5)}$$

We get by combining Eqs. 3, 4, and 5

$$G_A = 4\pi Da_A\left[c_\infty \exp\left(\frac{K}{a_A}\right) - c_o\right] \qquad \text{(Eq. 6)}$$

and

$$G_B = 4\pi Da_B\left[c_\infty \exp\left(\frac{K}{a_B}\right) - c_o\right] \qquad \text{(Eq. 7)}$$

which are the rates of dissolution (positive G) or growth (negative G) for particles of sizes a_A and a_B, respectively. It is a result of the assumption that all particles seek an average environment which makes Eqs. 6 and 7 applicable. Otherwise there should be a distribution of dissolution or growth rates even for particles of the same initial size.

We may now obtain a further relationship for c_o on the basis of the mass conservation law. Clearly mass balance requires that

$$n_A G_A + n_B G_B + (d\bar{c})/dt = 0 \qquad \text{(Eq. 8)}$$

where t is the time and $\bar{c}$ is the average amount of dissolved internal phase material in the external phase per unit volume of emulsion. Combining Eqs. 6, 7, and 8 we get

$$4\pi Da_A n_A\left[c_\infty \exp\left(\frac{K}{a_A}\right) - c_o\right] + 4\pi Da_B n_B\left[c_\infty \exp\left(\frac{K}{a_B}\right) - c_o\right] + d\bar{c}/dt = 0 \qquad \text{(Eq. 9)}$$

It can be easily shown from our final results that $d\bar{c}/dt$ is negligible in comparison to the other two terms. This greatly simplifies our task, since then from Eq. 9 we may write

$$c_o = \frac{c_\infty[n_A a_A \exp(K/a_A) + n_B a_B \exp(K/a_B)]}{n_A a_A + n_B a_B} \qquad \text{(Eq. 10)}$$

[1] However even up to high concentrations (~40%), the rates will probably not increase by more than a factor of two or so.

Now if the exponential terms in Eq. 10 are expanded in series form according to

$$\exp(x) = 1 + x + (x^2/2) + x^3/6 + \ldots \quad \text{(Eq. 11)}$$

we get from Eq. 10

$$c_o = c_\infty \left[1 + \frac{K(n_A + n_B)}{n_A a_A + n_B a_B} + \text{higher order terms}\right] \quad \text{(Eq. 12)}$$

When $K/a << 1$, as it is for emulsions in the size range of interest to us, the higher order terms are always negligible.

Now the c_o expression may be substituted into Eqs. 6 and 7. The exponentials in the resulting equations may be expanded again according to Eq. 11 to give

$$G_A = \frac{4\pi D c_\infty K n_B (a_B - a_A)}{n_A a_A + n_B a_B} \quad \text{(Eq. 13)}$$

and

$$G_B = \frac{-4\pi D c_\infty K n_A (a_B - a_A)}{n_A a_A + n_B a_B} \quad \text{(Eq. 14)}$$

Because the rate of growth or dissolution of a particle must be equal to its rate of change of mass, we may also write

$$G_A = -4\pi\rho a_A^2 \frac{da_A}{dt} \quad \text{(Eq. 15)}$$

and

$$G_B = -4\pi\rho a_B^2 \frac{da_B}{dt} \quad \text{(Eq. 16)}$$

When these last two equations are combined with Eqs. 13 and 14 we get

$$\frac{da_A}{dt} = \frac{D c_\infty K}{\rho a_A^2}\left[\frac{n_B (a_B - a_A)}{n_A a_A + n_B a_B}\right] \quad \text{(Eq. 17)}$$

and

$$\frac{da_B}{dt} = \frac{D c_\infty K}{\rho a_B^2}\left[\frac{n_A (a_B - a_A)}{n_A a_A + n_B a_B}\right] \quad \text{(Eq. 18)}$$

These Eqs. 17 and 18 give the rates of change of the radii of the two sizes in the emulsion.

In Fig. 2 plots of a_A and a_B are presented for the case $n_A = n_B, a_{Ao} = 0.5\ \mu$, and $a_{Bo} = 1.0\ \mu$. Here

$$t' = D c_\infty K t/\rho \quad \text{(Eq. 19)}$$

The curves in Fig. 2 were obtained by numerically solving Eqs. 17 and 18. These results show that at $t' \sim 9 \times 10^{-14}$, all of the originally 0.5 μ particles have completely disappeared. By means of Eqs. 19 and 2 let us see how small c_∞ must be in this case in order to have a_A change only slightly, say 10%. We have then

$$c_\infty = \frac{\rho^2 t' RT}{2Dt\gamma M} \quad \text{(Eq. 20)}$$

Let us select $t' = 4 \times 10^{-14}$ (about 10% change in a_{Ao}), $t = 3 \times 10^7$ seconds (1 year's time), $M = 100$, ρ = unity, $D = 5 \times 10^{-6}$ cm.^{2} sec.$^{-1}$ (water viscosity in the external phase), and $\gamma = 1.0$ dyne cm.$^{-1}$. Insertion of these values into Eq. 20 gives $c_\infty = 3 \times 10^{-8}$ Gm./ml. This rather low upper limit value for c_∞ indicates that this mode of emulsion degradation can be a very important one. Thus substances in the micron size range with $c_\infty > 3 \times 10^{-8}$ Gm./ml. may undergo appreciable change in size distribution.

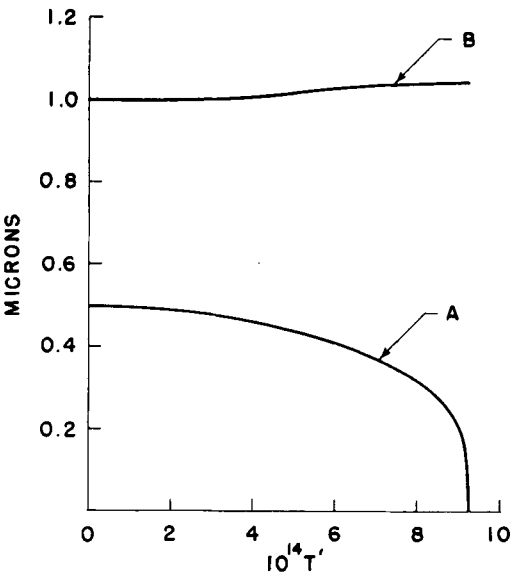

Fig. 2.—The degradation of an emulsion initially composed of a mixture of 0.5 μ and 1 μ radius droplets of equal number concentration. Curves A and B give droplet diameters as function of time (see Eq. 19 for definition of t').

Examination of Eq. 19 shows that the situation with respect to degradation can be improved by decreasing D which might be accomplished by increasing the viscosity of the external phase since, approximately

$$D = \frac{kT}{6\pi\eta\alpha} \quad \text{(Eq. 21)}$$

where η = viscosity of the external phase, α = molecular radius of diffusing material, and k = Boltzmann's constant.

Since the rate is proportional to γ, another way to retard degradation is to reduce γ by means of a suitable surfactant. However, one must avoid solubilization of the internal phase material in the external phase when using surfactants; otherwise the increase in c_∞ may offset the decrease in γ. Most water-oil interfacial tensions with surfactants are in the 0.1 to 10 dyne per cm. range.

The calculation for c_∞ just presented applies to the mixture of the 0.5 and 1.0 μ radii particles. If the emulsion is a mixture of 0.05 and 0.10 μ radii particles, the corresponding changes will occur a thousand times faster; i.e., the particle stability is proportional to the cube of its radius. Hence $c_\infty < 3 \times 10^{-11}$ Gm./ml. is the criterion for the 0.05–0.10 μ mixture, everything else remaining the same. This conclusion is apparent from Eqs. 17 and 18.

A careful examination of Eqs. 17 and 18 reveals that control of the size distribution in the preparation of the emulsion will not be too helpful with respect to the retarding of molecular diffusion degradation unless the distribution is made very nar-

row. Whether a_B is initially only a factor of two greater than a_A or whether it is many times greater makes only about a factor of two difference in the disappearance rate of the smaller particles. On the other hand, if $(a_B - a_A)$ is made very much smaller than a_A the rate will be inversely proportional to the narrowness of the distribution. Since most emulsions cannot be prepared with distributions so narrow, the narrowness of the distribution is generally not an important factor.

Fictitious as it may be, the emulsion composed of two particle sizes, $a_{Ao} = 0.5$ and $a_{Bo} = 1.0\ \mu$, of equal number concentration gives us a quantitative "feel" for the problem. The preceding analysis clearly shows that this route of degradation cannot be overlooked in emulsion stability studies.

Case II. More Complex Single Component Droplet Case.—To analyze a more realistic size distribution consider the emulsion with an initial ($t = 0$) distribution of radii following the law

$$n_i\, da_i = \frac{\bar{K}}{a_i^3}\, da_i \qquad \text{(Eq. 22)}$$

over the range $a_m \leq a_i \leq a_n$ at $t = 0$. For other, $t = 0$, a_i values assume $n_i = 0$. Here n_i is the concentration of particles in the size range between a_i and $a_i + da_i$ at $t = 0$, and $\bar{K}$ is a constant. The distribution given by Eq. 22 is a good approximation to the log-normal distribution.

The complexity of this problem limits the calculations to only the initial rate of degradation of the system. The rate of dissolution or growth of the ith particle at zero time is (analogous to Eqs. 6 and 7)

$$G_i = 4\pi\, Da_i \left[c_\infty \exp\left(\frac{K}{a_i}\right) - c_o \right] \qquad \text{(Eq. 23)}$$

where c_o is defined by a relationship similar to Eq. 10 but more general, *viz.*

$$\int_{am}^{an} 4\pi n_i Da_i \left[c_\infty \exp\left(\frac{K}{a_i}\right) - c_o \right] da_i = 0 \qquad \text{(Eq. 24)}$$

As before, the $d\bar{c}/dt$ term is neglected in deriving Eq. 24.

Substituting Eq. 22 into Eq. 24 and integrating for $t = 0$, we get

$$c_o = c_\infty \left[1 + \frac{K}{2}\left(\frac{1}{a_n} + \frac{1}{a_m}\right) \right] \qquad \text{(Eq. 25)}$$

with the neglect of higher order terms. Now if Eqs. 25 and 23 are combined we obtain

$$G_i = 4\pi\, Da_i\, c_\infty\, K\left(\frac{1}{a_i} - \frac{1}{2a_n} - \frac{1}{2a_m}\right) \qquad \text{(Eq. 26)}$$

for the ith particle at zero time. Equating G_i to the rate of change of mass of the ith particle

$$G_i = -4\pi\rho {a_i}^2 \frac{da_i}{dt} \qquad \text{(Eq. 27)}$$

and setting $a_i = a_m$ we get

$$\frac{da_m}{dt} = -\frac{Dc_\infty K}{2\rho a_m}\left(\frac{1}{a_m} - \frac{1}{a_n}\right) \qquad \text{(Eq. 28)}$$

which is the expression for the initial rate of size decrease of the smallest particles in the distribution.

Setting $a_i = a_n$ we get

$$\frac{da_n}{dt} = -\frac{Dc_\infty K}{2\rho a_n}\left(\frac{1}{a_n} - \frac{1}{a_m}\right) \qquad \text{(Eq. 29)}$$

which is the expression for the initial rate of growth of the largest particles in the distribution. It must be remembered that Eqs. 28 and 29 apply to only the initial rates while Eqs. 17 and 18 are valid for all times.

The quantitative similarity between Eqs. 28 and 29 and Eqs. 17 and 18 shows that a system with a continuous distribution of particle sizes does not behave too differently from the simple system consisting of only two sizes as far as the degradation rate is concerned. Thus, the general quantitative conclusions deduced for Case I are approximately applicable to more complex cases.

Case III. The Two Component Droplet Case.—While for both case I and case II the internal phase was treated as one component, in general one should consider the miscibility of the external phase material with the internal phase. Let us briefly outline the problem and discuss the conclusions for the case in which the external phase material is only slightly (say less than about 1%) miscible with the internal phase. The general case is much more difficult to analyze.

Figure 3 illustrates the problem. Component x makes up the bulk of the internal phase and component y makes up most of the external phase. c_{xl} and c_{yl} are the concentrations of the two components in the particle, c_{xs} and c_{ys} are the concentrations at the interface but on the external phase side, and c_{xo} and c_{yo} are the concentrations at some large distance from the particle.

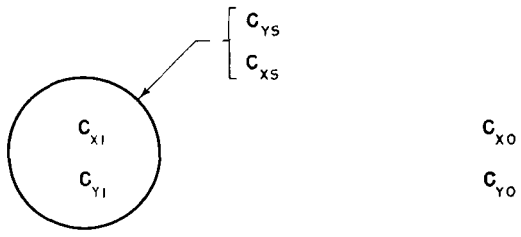

Fig. 3.—The two-component emulsion system. See text.

We may write for a particle of radius a

$$c_{xs} = k_x c_{xl} \exp\left(\frac{K_x}{a}\right) \qquad \text{(Eq. 30)}$$

and

$$c_{ys} = k_y c_{yl} \exp\left(\frac{K_y}{a}\right) \qquad \text{(Eq. 31)}$$

where k_x and k_y are the respective distribution coefficients, $K_x = 2\gamma \bar{V}_x/RT$, and $K_y = 2\gamma \bar{V}_y/RT$, with $\bar{V}_x$ and $\bar{V}_y$ the partial molal volumes of components x and y in the droplet. Equations 30 and 31 are simply the two component versions of Eq. 1. Both k_x and k_y can be expected to remain constant if each of the phases remain dilute with respect to one of the components (Raoult's law and Henry's law).

While we will not present the arguments, it can

be shown by Eqs. 30 and 31 and by the other conditions assumed above that the rate of growth or dissolution of the droplets in the emulsion is entirely controlled by the rate of diffusion of component x only. Furthermore it can be shown that

$$c_{ys} \simeq c_{yo} \qquad \text{(Eq. 32)}$$

in the steady state.

Therefore we may write

$$G_x = 4\pi D_x a\,(c_{xs} - c_{xo}) \qquad \text{(Eq. 33)}$$

for the rate of diffusion of component x toward or away from the particle. This becomes

$$G_x = 4\pi D_x a\left[k_x c_{xl} \exp\left(\frac{K_x}{a}\right) - c_{xo}\right] \qquad \text{(Eq. 34)}$$

when Eq. 30 is substituted for c_{xs}. Now because of Eq. 32

$$G_x = -4\pi a^2 c_{xl}\frac{da}{dt} \qquad \text{(Eq. 35)}$$

Then Eqs. 34 and 35 may be handled in the same way as was done in case I and the change in particle size may be evaluated as a function of time.

We may conclude that the two component droplet emulsion system behaves essentially the same as the one component droplet emulsion when the amount of the second component in the droplet is low, the second component being the predominant component of the external phase. This assumes, of course, that the appropriate γ and K_x are employed.

Case IV. Special Case of the Three Component Emulsion.—We shall not attempt a discussion of the general three component case. Let us, however, examine a special three component case which is of considerable importance to the question of emulsion stability.

In Fig. 4 the three component case is illustrated with the same symbolism as that used in Fig. 3 for the two component case but with addition of z values.

As before, let x and y represent the major internal phase and the major external phase components, respectively, with z being a minor component in both phases. As was found in case III (two component case) let the effect of y be negligible as far as the rates of change of the droplet sizes are concerned. These statements mean that

$$\left.\begin{aligned} &c_{yl} \ll c_{xl} \\ &c_{ys} \gg c_{xs} \\ &c_{yo} \gg c_{xo} \\ &c_{zs} \ll c_{ys} \\ &c_{zo} \ll c_{yo} \\ &c_{zl} \ll c_{xl} \end{aligned}\right\} \text{conditions (Eq. 36)}$$

and that

$$c_{ys} \simeq c_{yo} \text{ always}$$

We may write (as for the two component case)

$$c_{xs} = k_x c_{xl} \exp\left(\frac{K_x}{a}\right) \qquad \text{(Eq. 37a)}$$

and

$$c_{zs} = k_z c_{zl} \exp\left(\frac{K_z}{a}\right) \qquad \text{(Eq. 37b)}$$

Here k_x and K_x have the same meanings as before,

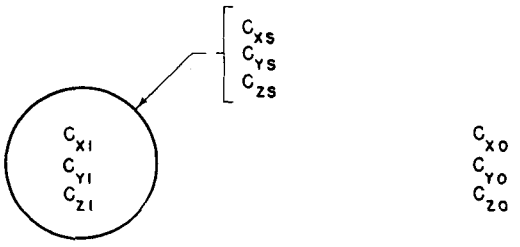

Fig. 4.—The three-component emulsion system. See text.

k_z is the corresponding distribution coefficient for the z component, and $K_z = 2\gamma \bar{V}_z/RT$ with $\bar{V}_z$ being the partial molal volume of component z in the droplet. The validity of Eqs. 37a and 37b may be easily demonstrated if it can be assumed that z does not interact with y to form a compound or complex in the internal phase and that z and x do not appreciably interact with each other in the external phase. In other words, for Eqs. 37a and 37b to apply, the solvent properties of each phase must be determined primarily by the major component in that phase. In the other extreme, i.e., when complex or compound formation between y and z in the internal phase or between x and z in the external phase occurs, more complex relationships than Eqs. 37a and 37b must be employed. However, even for these cases the general conclusions of this section will apply provided that the variations in k_x and k_y are taken into account.

Following the results for case III we may conclude that the condition, $c_{ys} \simeq c_{yo}$, is established very rapidly in any system for which $c_{ys} \neq c_{yo}$ initially. Then a period, τ, will ensue during which a pseudo-steady state is established. In the pseudo-steady state the rate of degradation of the system will depend upon either the rate of diffusion of x or that of z, or possibly upon both of these rates. If $k_x << k_z$ and if the diffusion coefficients for x and y are about the same, the degradation rate will not be markedly different from the one-component case. On the other hand, if $k_z << k_x$ the diffusion rate of z will govern the degradation rate of the particle at $t > \tau$. Physically what happens is that the relatively very slow rate of diffusion of z permits the x component to remain essentially equilibrated among all the droplets. Therefore, changes in the system occur only as fast as the change in the distribution of the slowest diffusing component. Thus, the degradation rate may be retarded by a factor

$$K_p = \frac{k_x}{k_z} \qquad \text{(Eq. 38)}$$

after a time τ. This result is significant to the extent that a system with a very large K_p value may be employed to stabilize emulsions which otherwise would degrade if the third (z) component were absent.

Having now established that in the pseudo-steady state ($t > \tau$) the degradation rate depends primarily upon K_p, let us now examine the period $t \lesssim \tau$, when K_p is infinitely large. For this purpose consider the three component emulsion containing only two sizes of particles. The situation is illustrated in Fig. 5. The symbolism is the same as in

Fig. 4 except the third subscripts A and B refer to the two particle sizes.

The initial boundary conditions ($t = 0$) for the two kinds of particles A and B or the number concentrations n_A and n_B are

$$a_A = a_{Ao} \qquad a_B = a_{Bo} \qquad \text{(Eq. 39)}$$

with

$$a_{Ao} < a_{Bo}$$

let also

$$c_{zlA} = c_{zlA_o} \text{ and } c_{xlB} = c_{xlB_o} \qquad c_{zlA} = c_{zlA_o} \text{ and } c_{zlB} = c_{zlB_o} \qquad \text{(Eq. 40)}$$

at $t = 0$.

Now immediately after the emulsion is prepared component y equilibrates rapidly to give $c_{ysA} \simeq c_{ysB} \simeq c_{yo}$. The main process with which we are now concerned is then that of the diffusion of x out of the A particles and into the B particles until the equilibrium condition

$$c_{xsA} = c_{xsB} \qquad \text{(Eq. 41)}$$

is reached. Since we have chosen $K_p \simeq \infty$, none of the z can leave or enter the droplets.

A practical and meaningful way to present the analysis is to determine the necessary initial concentration of z in the internal phase, $c_{zlo} = c_{zlA_o} = c_{zlB_o}$, which permits only a small change in a_A (say 10%) during the period, τ.

Substituting Eq. 37a into Eq. 41 we get

$$k_x\, c_{xlA_\infty} \exp\left(\frac{K_x}{a_{A_\infty}}\right) \simeq k_x\, c_{xlB_\infty} \exp\left(\frac{K_x}{a_{B_\infty}}\right) \qquad \text{(Eq. 42)}$$

where $c_{xlA_\infty} = c_{xlA}$, $c_{xlB_\infty} = c_{xlB}$, $a_{A_\infty} \neq a_A$, $a_{B_\infty} = a_B$, all at $t >> \tau$. Upon expansion of the exponential, Eq. 42 gives

$$\frac{c_{xlA_\infty}}{c_{xlB_\infty}} = 1 + K_x \frac{(a_{A_\infty} - a_{B_\infty})}{a_{A_\infty}\, a_{B_\infty}} + \ldots \qquad \text{(Eq. 43)}$$

we may also write

$$\bar{T} = \nu_{zl}\, c_{zl} + \nu_{xl}\, c_{xl} \qquad \text{(Eq. 44)}$$

Where $\bar{T}$ is a constant, and ν_{zl} and ν_{xl} are the partial specific volumes of z and x in the internal phase, respectively. Equation 44 is a good assumption for dilute solutions as specified under conditions (Eq. 36). It is valid for systems in which Raoult's law is obeyed for x and Henry's law is obeyed for z, i.e., for the case in which solute-solute interactions are unimportant.

Then for $t >> \tau$

$$\bar{T} = \nu_{zl}\, c_{zlA_\infty} + \nu_{xl}\, c_{xlA_\infty} \qquad \text{(Eq. 45)}$$

and

$$\bar{T} = \nu_{zl}\, c_{zlB_\infty} + \nu_{xl}\, c_{xlB_\infty}$$

where c_{zlB_∞} and c_{zlA_∞} are the c_{zlB} and c_{zlA} values at $t >> \tau$.

It is also apparent that

$$c_{zlA_\infty} = \frac{a_{A_o}^3}{a_{A_\infty}^3} c_{zlo} \qquad \text{(Eq. 46)}$$

and

$$c_{zlB_\infty} = \frac{a_{B_o}^3}{a_{B_\infty}^3} c_{zlo}$$

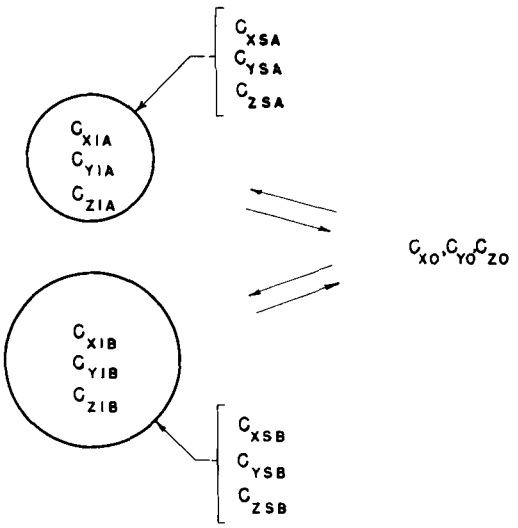

Fig. 5.—The three-component emulsion composed of a mixture of two sizes. See text for symbols.

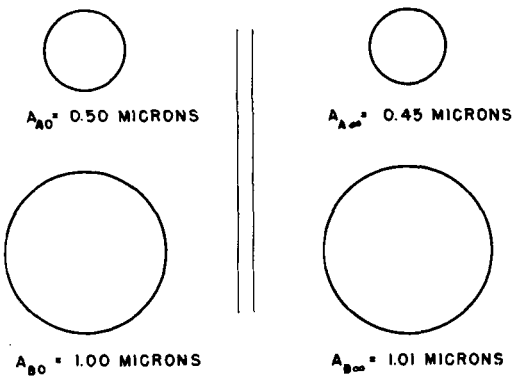

Fig. 6.—Illustration of the stabilization of an emulsion by a third component which is immiscible in the external phase. See text.

Now Eqs. 46, 45, and 43 may be combined to give

$$\frac{\bar{T} - \nu_{zl}(a_{A_o}^3/a_{A_\infty}^3)\, c_{zlo}}{\bar{T} - \nu_{zl}(a_{B_o}^3/a_{B_\infty}^3)\, c_{zlo}} = 1 + K_x \left(\frac{a_{A_\infty} - a_{B_\infty}}{a_{B_\infty}\, a_{A_\infty}}\right) \qquad \text{(Eq. 47)}$$

Then with the help of a final expression for the conservation of mass, *viz.*

$$n_A\, a_{A_o}^3 + n_B a_{B_o}^3 \simeq n_A a_{A_\infty}^3 + n_B a_{B_\infty}^3 \qquad \text{(Eq. 48)}$$

c_{zlo} may be evaluated.

Suppose as in case I we take $n_A = n_B$, $a_{Ao} = 0.5\ \mu$ and $a_{Bo} = 1.0\ \mu$ (See Fig. 6). Let us see what c_{zlo} must be so that $a_{A\infty} = 0.9\, a_{Ao}$, i.e., so that only a 10% change takes place during the period τ. Now $\bar{T} \sim$ unity, and for most organic compounds $\nu_{zl} \sim 1$. K_x will have values ranging from around 1×10^{-7} to 1×10^{-9}, depending primarily upon γ, since $\bar{V}_x \sim 100$, $RT \sim 2 \times 10^{10}$, and γ may generally vary from about 0.1 to 10 ergs per cm.^{2}. Employing these values with Eqs. 47 and 48 we find that $c_{zlo} \sim 3 \times 10^{-5}$ Gm. per ml. for $\gamma = 0.1$

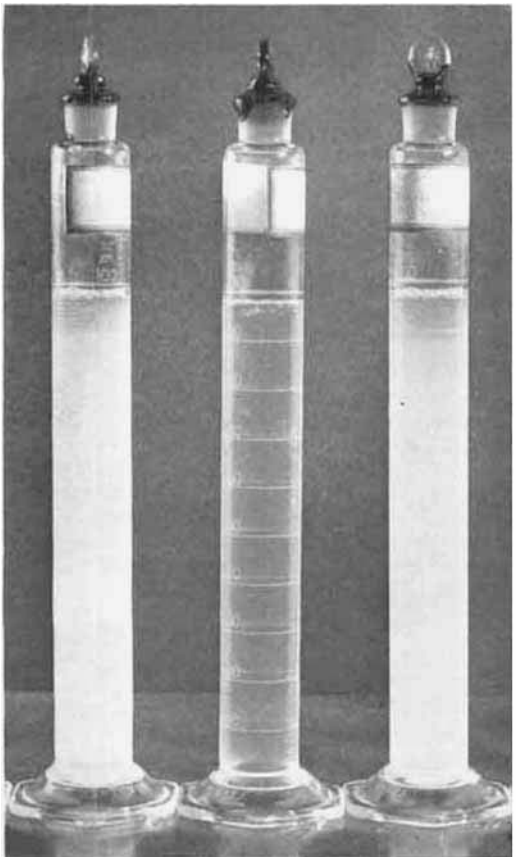

Fig. 7.—Photograph of 0.20% carbon tetrachloride-in-water emulsions containing 0.02% Aerosol OT, 12 hours after ultrasonic preparation. The center graduate, B, contains no other additive, while the graduates to the left, A, and right, C, contain 0.002% Nujol and hexadecane, respectively.

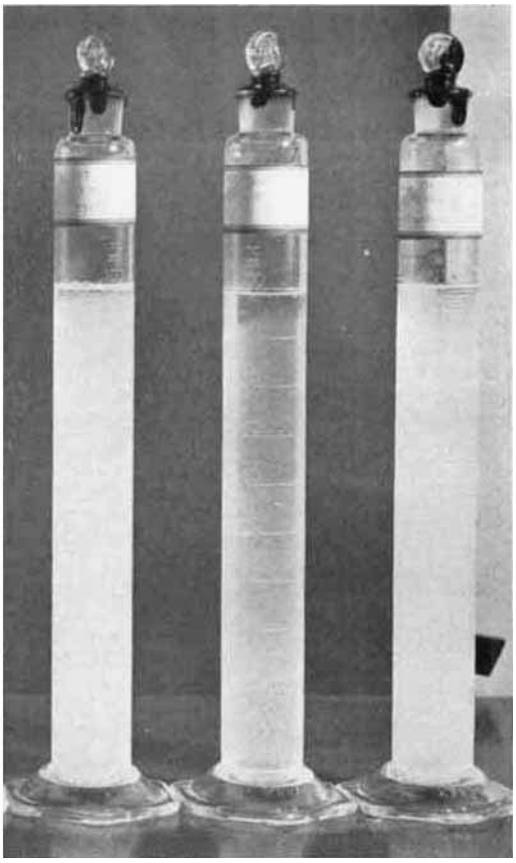

Fig. 8.—Photograph of 0.20% carbon tetrachloride emulsions containing 0.05% Aerosol OT 12 hours after preparation. Center graduate, B, contains no other additive while the graduates to the left, A, and right, C, contain 0.002% Nujol and hexadecane, respectively.

dyne per cm. and $c_{zlo} \sim 3 \times 10^{-3}$ Gm. per ml. for $\gamma = 10$ dynes per cm.

These values for c_{zlo} suggest that emulsions degrading via the molecular diffusion route may be stabilized by the incorporation of a small amount of a third component in the internal phase if this additive possesses a sufficiently large K_p value. About 1% additive should be more than ample for stabilizing most emulsions in the micron range. It is noteworthy that if γ is very low, say 0.01 dyne per cm., less than 0.01% additive is needed for stabilization.

For smaller size ranges Eq. 47 shows that c_{zlo} must be proportionately greater to provide the same stability. Therefore, if in the preceding calculations $a_{Ao} = 0.05\ \mu$ and $a_{Bo} = 0.10\ \mu$, the corresponding c_{zlo} values must be ten times greater.

EXPERIMENTAL STUDIES

Selection and Design of Experiment.—To test some of the ideas developed in the preceding sections of this report it was decided that dilute emulsions of carbon tetrachloride in water, stabilized against coalescence and aggregation, would be most appropriate for the following reasons: (*a*) According to Stokes' law the sedimentation rates of micron size particles of carbon tetrachloride in water would be great, i.e., *ca* 1×10^{-4} to 1×10^{-5} cm. sec.$^{-1}$. Thus, the presence or absence of submicron particles could be determined easily by visual observations. (*b*) The miscibility of carbon tetrachloride with water is high enough ($c_\infty \sim 1 \times 10^{-3}$ Gm. per ml.) so that submicron size particles in the presence of larger particles should disapear in about 1 hour according to our theory. (*c*) Additives such as hexadecane or Nujol may be employed to test the third component stabilization theory. These substances are miscible with carbon tetrachloride but possess very low miscibility with water, i.e., K_p is very great.

Materials and Procedure.—Carbon tetrachloride used was redistilled Baker reagent grade. Hexadecane was redistilled Eastman practical grade. Plough's pure Nujol was used without further purification. Aerosol OT (AOT) was purified (4) by fractional precipitation with methanol and a water-methanol solvent mixture. Water was redistilled with care to avoid any contamination by oil-miscible, water-immiscible materials.

The emulsions were prepared by ultrasonically emulsifying 0.2 ml. carbon tetrachloride (without

and with hexadecane or Nujol) in 100 ml. of water containing varying small amounts of Aerosol OT (0.02 to 0.10%). The carbon tetrachloride was pipetted into the detergent solutions in 100-ml. graduated cylinders (precleaned ultrasonically) with ground-glass stoppers. The stoppers were sealed with Cementyte to prevent any diffusion losses of the carbon tetrachloride vapor. The cylinders were then subjected to about 30 minutes of 40 kc. ultrasonic energy generated by the model DR-125AH Acoustica cleaning unit.[2] The emulsions were then removed from the ultrasonic bath and allowed to stand. The amount of sedimentation and the turbidity were observed from time to time for periods extending to several days.

Results.—In all cases where the additive, hexadecane or Nujol, was absent in the carbon tetrachloride the emulsion particles visibly coarsened relatively rapidly and settled. The rate of this process of coarsening and settling was greatest for the 0.02% AOT, in which case a clear liquid region at the top of several mm. formed in less than 1 hour. For the 0.10% AOT emulsions, the corresponding length of time was always several hours. Within about 8 hours nearly all of the particles in the 0.02% AOT emulsion settled completely, while it took several days in the case of the 0.10% AOT. Emulsions with intermediate concentrations (0.05%) of AOT showed intermediate rates.

In contrast to the above behavior, emulsions prepared from carbon tetrachloride containing 1% Nujol or hexadecane remained turbid longer and settled much more slowly than those emulsions free of these additives. It is noteworthy that the total hexadecane or Nujol in these cases was only 0.002%.

Figures 7 and 8 are photographs taken 12 hours after the preparation of emulsions for the 0.02 and 0.05% AOT, respectively. The center graduate, B, in each case is the emulsion without the additive; A and C containing Nujol and hexadecane, respectively. In the case of the 0.10% AOT, the situation was much like that of 0.05% AOT (Fig. 8) but after 4 days of standing.

The significant point here is that when the additive was present the small particles in the emulsion were most noticeably affected. Immediately after the preparation, the emulsions containing the same concentration of AOT had about the same appearance (turbidity). The large particles (1–10 μ) in the system, whether the additive was present or not, appeared to settle as expected (these can be seen in Figs. 7 and 8). The small particles (submicron) in the initial distribution were much more stable visibly, however, when the additive was present.

It was very difficult to ascribe these experimental findings to anything but molecular diffusion degradation and the prevention thereof. In all of these studies, visual examination of the sediment indicated that coalescence was unimportant, even for the 0.02% AOT cases. Even if some coalescence or aggregation were present, it is unreasonable to expect the presence of so little nonsurface-active ingredient as hexadecane or Nujol to influence coalescence or aggregation markedly over a wide range of surfactant concentration. Finally, the quantitative agreement (to an order of magnitude, of course) of the rate of degradation with theory should eliminate final doubts.

For emulsions not containing the additives, the increase in the apparent degradation rate with decreasing surfactant concentration may be explained on the following bases: first, the interfacial tension decreases with increasing surfactant concentration. The range of surfactant concentration employed, *viz.*, 0.02 to 0.10%, is commonly in the range in which γ changes rapidly. Thus, this is probably the main effect, following the theory. Second, it is possible that, at 0.10%, AOT may be involved in the formation of a polymolecular film at the interface. Cockbain (5) has proposed the multimolecular absorption idea to explain some of his findings on the aggregation of paraffin and benzene emulsions in AOT solutions. Mass transport through this film may be slow enough to affect the overall rate.

Eserine Potentiation of Streptomycin Activity in Bacteria-Infected Embryonated Chicken Eggs

By VERNON A. GREEN†

Increases in per cent egg-day survival of eggs treated with combined streptomycin and eserine above the summation of the per cent egg-day survival of the two used separately were interpreted as potentiation of the antibacterial activity of the antibiotic. An attempt was made to correlate the cholinesterase activity of the bacteria with the eserine potentiation of the antibiotic activity of the streptomycin.

POTENTIATIONS of drug activity by eserine have been reported by Lewis (1), Greig (2, 3), and Green, *et al.* (4). Green and Davis (5) found that eserine potentiated the toxicity as well as the antibacterial activity of chloramphenicol in embryonated chick eggs.

In this study, possible eserine potentiation of the antibacterial activity of streptomycin, in embryonated chicken eggs infected with *Salmonella typhosa* WLR1207, *Proteus vulgaris* ATCC93, *Shigella dysenteriae* WLR194, or *Pseudomonus aeruginosa* ATCC9027, was investigated using the technique of McKenna and Taylor (6) for growing bacteria in yolk sacs. The criterion for determining potentiation was an increase in the per cent egg embryo (egg-day) survival above the summation of the per cent egg embryo survival of the antibiotic and eserine administered separately. Cholinesterase activity of the bacterial cells was determined by the method of Hall and Lucas (7); each unit of esterase activity being equal to 1 ml. of 0.01 *N* acetic acid formed in 10 minutes on the hydrolysis of acetylcholine solution at pH 8.

EXPERIMENTAL

Bacterial Inhibition.—Using the method reported by Green and Davis (5), embryonated chick eggs were infected deep in the yolk sac with 0.2 ml. of bacteria suspension to be used in each investigation. See Tables I–IV for concentration of microorganisms in seed suspension. After incubating at 37° for 6 hours, the eggs with living embryos designated for the investigation with each microorganism were divided into four groups of 40 eggs each. For each microorganism the groups were as follows: (*a*) control group, received only 0.2 ml./egg of sterile saline; (*b*) received streptomycin 0.1 mg./egg; (*c*) received streptomycin, 0.1 mg., and eserine salicylate, 0.0015 mg./egg; and (*d*) received eserine salicylate 0.0015 mg./egg.

The streptomycin, eserine, and eserine-streptomycin combinations were contained in 0.2 ml. of solution and were injected beneath the shell over the blood vessels of the embryo without rupturing the yolk sac. Upon sealing the shell with paraffin, the eggs were returned to the incubator and maintained at 37°.

After 7 hours the eggs were again candled and, thereafter, candled twice daily at 9:00 a.m. and 4:00 p.m. The embryo survivals were determined for 14 days, at which time any surviving embryos were destroyed, and the total day survivals for each group were recorded. The mean egg-day survival for each group was calculated; and using the mean egg-day survival of the saline controls used as the base or 100%, the mean egg-day survival of each group was reported as a percentage of the controls (see Tables I–IV).

Cholinesterase Determination.—Bacterial cells grown in beef heart infusion at 37° were packed by centrifuging, then washed and resuspended in sterile 0.9% saline three times. When approximately 3 ml. of packed cells were obtained, the cells were ground with sterile powdered glass in a bacteria mill and the bacterial protein extracted with 5% ammonium sulfate solution after the method of Nachmansohn (8). No attempt was made to concentrate the enzyme, but an amount of the extract equivalent to 1 ml. of the packed cells was used to determine the cholinesterase activity. The esterase activity per ml. of packed cells was as follows: (*a*) *Salmonella typhosa*, 0.021 units; (*b*) *Proteus vulgaris*, 0.050 units; (*c*) *Shigella dysenteriae*, 0.000 units; and (*d*) *Pseudomonus aeruginosa*, 0.025 units

RESULTS

In this study of eserine potentiation of the activity of streptomycin in *S. typhosa*-infected eggs, it was noted that the summation of the per cent egg-day survival of streptomycin- and eserine-treated eggs was approximately 90% less than the per cent survival of eggs receiving a combination of the two agents (Table I). Further, the difference in the per cent egg-day survival of *P. aeruginosa*-infected eggs treated with combined streptomycin and eserine and the summation of the per cent survival of the two used separately was approximately 120% (Table IV). The cholinesterase activity of the packed cells of the above two organisms corresponded closely in this study.

The increase in per cent egg-day survival in combined streptomycin- and eserine-treated eggs was greatest in eggs infected with *P. vulgaris*, approximately 500% (Table II). Eggs infected with *S. dysenteriae* treated with combined streptomycin and eserine showed a per cent egg-day survival approximately 110% below the summation of the two used separately (Table III). These findings were in

TABLE I.—ESERINE POTENTIATION OF STREPTOMYCIN ACTIVITY IN CHICKEN EGGS INFECTED WITH *Salmonella typhosa*[a]

Agent Used	No. of Eggs	Egg-Day Survivals	% Egg-Day Survivals
Controls (saline)	40	56	100
Streptomycin, 0.1 mg.	40	176	300
Streptomycin, 0.1 mg., and eserine salicylate, 0.0015 mg.	40	288	500
Eserine salicylate, 0.0015 mg.	40	63	110

[a] Each egg infected with 0.2 ml. of a suspension of *Salmonella typhosa* containing 100,000 organisms per ml.

TABLE II.—ESERINE POTENTIATION OF STREPTOMYCIN ACTIVITY IN CHICKEN EGGS INFECTED WITH *Proteus vulgaris*[a]

Agent Used	No. of Eggs	Egg-Day Survivals	% Egg-Day Survivals
Controls (saline)	40	3	100
Streptomycin, 0.1 mg.	40	14	460
Streptomycin, 0.1 mg., and eserine salicylate, 0.0015 mg.	40	40	1300
Eserine salicylate, 0.0015 mg.	40	10	330

[a] Each egg infected with 0.2 ml. of a suspension of *Proteus vulgaris* containing 80,000 organisms per ml.

TABLE III.—ESERINE POTENTIATION OF STREPTOMYCIN ACTIVITY IN CHICKEN EGGS INFECTED WITH *Shigella dysenteriae*[a]

Agent Used	No. of Eggs	Egg-Day Survivals	% Egg-Day Survivals
Control (saline)	40	60	100
Streptomycin, 0.1 mg.	40	80	130
Streptomycin, 0.1 mg., and eserine salicylate, 0.0015 mg.	40	84	140
Eserine salicylate, 0.0015 mg.	40	72	120

[a] Each egg infected with 0.2 ml. of a suspension of *Shigella dysenteriae* containing 80,000 organisms per ml.

TABLE IV.—ESERINE POTENTIATION OF STREPTOMYCIN ACTIVITY IN CHICKEN EGGS INFECTED WITH *Pseudomonus aeruginosa*[a]

Agent Used	No. of Eggs	Egg-Day Survivals	% Egg-Day Survivals
Control (saline)	40	23	100
Streptomycin, 0.1 mg.	40	36	150
Streptomycin, 0.1 mg., and eserine salicylate, 0.0015 mg.	40	90	390

keeping with the cholinesterase activity of the packed cells, since *P. vulgaris* showed the highest esterase activity and *S. dysenteriae* showed the least esterase activity (no esterase activity by this method).

DISCUSSION

It appears from the data obtained in this study that eserine potentiation of streptomycin activity was greatest in eggs infected with *P. vulgaris* and least in eggs infected with *S. dysenteriae*. According to Schwartz, *et al.* (9), the minimal inhibitory concentration of streptomycin for *P. vulgaris* ATCC 93, *S. typhosa* WLRI 207, and *P. aeruginosa* ATCC 9027 is 37 mcg./ml., while the minimal inhibitory concentration of streptomycin for *S. dysenteriae* WLRI 94 is only 12.3 mcg./ml.

If the synergistic action of eserine on the antibacterial activity of streptomycin were linear, it appears that the increase in the per cent egg-day survivals of eggs infected with *P. vulgaris*, *S. typhosa*, and *P. aeruginosa* should have been of the same magnitude. Further, it appears that if the increase in embryo survivals in the above were due entirely to antibacterial action of the eserine salicylate, then the egg-day survival of the combined streptomycin- and eserine-treated eggs should have been at least equal to the summation of the two when used separately in *S. dysenteriae*-infected eggs.

Increases in the permeability of mouse brain and dog erythrocytes brought about by eserine was reported by Greig (2, 3). Further, this investigator found a 45% potentiation of the antibacterial activity of streptomycin on *E. coli* by eserine (4).

It appears probable that eserine, by some activity, may have increased the rate of absorption and, consequently, the concentration of the antibiotic in the tissues of the chick embryo. There appears, also, the probability that eserine, through its action with cholinesterase, may change the permeability of bacterial cells containing the enzyme, thus allowing the streptomycin to enter the cells more easily. At least, there appears to be some correlation between increases in per cent egg-day survivals and the cholinesterase content of the bacterial cells.

SUMMARY

In this study, the per cent egg-day survivals of eggs infected with *S. typhosa*, *P. vulgaris*, and *P. aeruginosa*, and treated with combined streptomycin and eserine were increased above the summation of the per cent egg-day survivals of streptomycin, 0.1 mg./egg, or 0.0015 mg./egg of eserine, used separately. The per cent egg-day survival of *S. dysenteriae*-infected eggs treated with combined streptomycin and eserine was less than the summation of the two agents used separately.

increase was greatest in *P. vulgaris*-infected eggs and least in *S. dysenteriae*-infected eggs. These findings appear to correlate with the esterase activity of the packed cells.

Synthesis of Compounds Containing the Isoindoline Ring System

By ABOO SHOEB and JAMES E. GEARIEN

In an attempt to gain further knowledge concerning the pharmacological properties inherent in the isoindoline ring system, a number of compounds containing this ring system were synthesized and screened for biological activity. These compounds are analogs of biologically active compounds. Only the amide of N-[3-(2-isoindolinyl)propyl]-beta-alanine demonstrated appreciable biological activity. The carbon-hydrogen absorption bands present in the infrared spectra of these compounds were related to their chemical structure.

ALTHOUGH isoindoline is a relatively unstable compound, N-substituted isoindolines are quite stable, easily prepared, and provide convenient intermediates for synthesis. The ganglionic blocking action of 4,5,6,7-tetrachloro-2-(dimethylaminoethyl)isoindoline dimethochloride (1) and the hypertensive action of a series of the quaternary salts of hydrogenated bis-(2-isoindolinyl)alkanes (2) have been extensively studied. Few other compounds containing the isoindoline ring system have been reported to contain biological activity. It therefore appeared desirable to synthesize a number of analogs of biologically active compounds in which the isoindoline ring system is substituted for the amino or substituted amino group.

Three esters which contain the isoindoline ring system and which are analogs of procaine, Trasentine, and eucatropine were synthesized. These esters were 2-isoindolinylethyl 4-aminobenzoate hydrobromide, 2-isoindolinylethyl diphenylacetate hydrochloride, and 2-isoindolinylethyl *dl*-mandelate hydrochloride. The first of these esters was prepared by reacting 2-(2-hydroxyethyl)isoindoline with *p*-nitrobenzoyl chloride. The resulting 2-isoindolinylethyl *p*-nitrobenzoate was catalytically reduced to 2-isoindolinylethyl *p*-aminobenzoate. 2-Isoindolinylethyl diphenylacetate hydrochloride was similarly synthesized by the reaction of 2-(2-hydroxyethyl)isoindoline with diphenylacetyl chloride. 2-Isoindolinylethyl *dl*-mandelate was prepared by reacting silver mandelate with 2-(2-chloroethyl)-isoindoline.

In order to introduce the isoindoline ring system into a molecule having the prerequisites for antihistamine activity, 2-(2-isoindolinyl)ethyl benzhydryl ether was synthesized by reacting benzhydryl bromide with 2-(2-hydroxyethyl)-isoindoline in the presence of metallic sodium. It was isolated as its hydrochloride.

1,6-Bis-(2-isoindolinyl)hexane was prepared by the lithium aluminum hydride reduction of 1,6-hexane diphthalimide.

It also appeared desirable to introduce this ring system into compounds which might possess antitumor activity. 2-[2-Bis-(2-chloroethyl)-aminoethyl]isoindoline was synthesized by first reacting 2-(2-chloroethyl)isoindoline with diethanolamine to yield crude 2-[2-bis-(2-hydroxyethyl)aminoethyl]isoindoline which was then converted to the nitrogen mustard analog by treatment with thionyl chloride. The second possible antitumor agent, 1-[3-(2-isoindolinyl)-propyl]dihydrouracil, was prepared by the following series of reactions

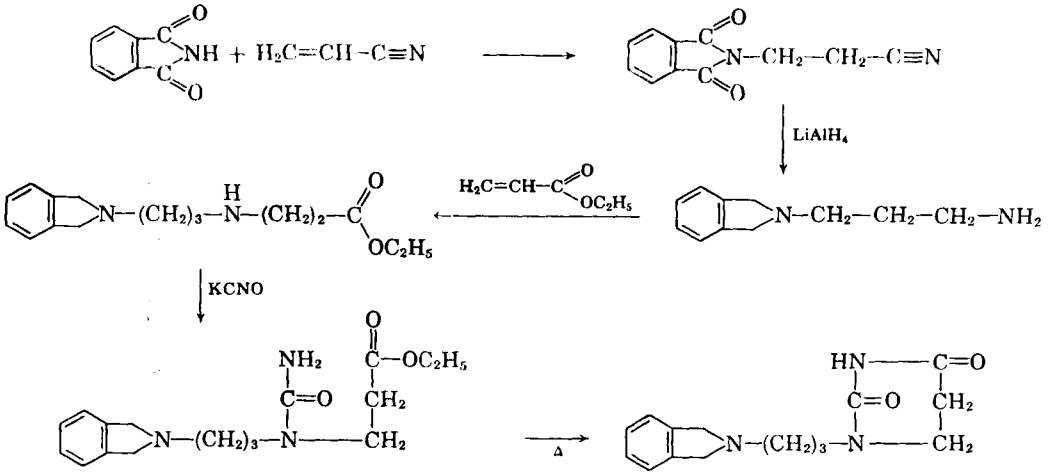
Synthesis of Compounds Containing the Isoindoline Ring System

By ABOO SHOEB and JAMES E. GEARIEN

In an attempt to gain further knowledge concerning the pharmacological properties inherent in the isoindoline ring system, a number of compounds containing this ring system were synthesized and screened for biological activity. These compounds are analogs of biologically active compounds. Only the amide of N-[3-(2-isoindolinyl)propyl]-beta-alanine demonstrated appreciable biological activity. The carbon-hydrogen absorption bands present in the infrared spectra of these compounds were related to their chemical structure.

ALTHOUGH isoindoline is a relatively unstable compound, N-substituted isoindolines are quite stable, easily prepared, and provide convenient intermediates for synthesis. The ganglionic blocking action of 4,5,6,7-tetrachloro-2-(dimethylaminoethyl)isoindoline dimethochloride (1) and the hypertensive action of a series of the quaternary salts of hydrogenated bis-(2-isoindolinyl)alkanes (2) have been extensively studied. Few other compounds containing the isoindoline ring system have been reported to contain biological activity. It therefore appeared desirable to synthesize a number of analogs of biologically active compounds in which the isoindoline ring system is substituted for the amino or substituted amino group.



Three esters which contain the isoindoline ring system and which are analogs of procaine, Trasentine, and eucatropine were synthesized. These esters were 2-isoindolinylethyl 4-aminobenzoate hydrobromide, 2-isoindolinylethyl diphenylacetate hydrochloride, and 2-isoindolinylethyl *dl*-mandelate hydrochloride. The first of these esters was prepared by reacting 2-(2-hydroxyethyl)isoindoline with *p*-nitrobenzoyl chloride. The resulting 2-isoindolinylethyl *p*-nitrobenzoate was catalytically reduced to 2-isoindolinylethyl *p*-aminobenzoate. 2-Isoindolinylethyl diphenylacetate hydrochloride was similarly synthesized by the reaction of 2-(2-hydroxyethyl)isoindoline with diphenylacetyl chloride. 2-Isoindolinylethyl *dl*-mandelate was prepared by reacting silver mandelate with 2-(2-chloroethyl)-isoindoline.

In order to introduce the isoindoline ring system into a molecule having the prerequisites for antihistamine activity, 2-(2-isoindolinyl)ethyl benzhydryl ether was synthesized by reacting benzhydryl bromide with 2-(2-hydroxyethyl)-isoindoline in the presence of metallic sodium. It was isolated as its hydrochloride.

1,6-Bis-(2-isoindolinyl)hexane was prepared by the lithium aluminum hydride reduction of 1,6-hexane diphthalimide.

It also appeared desirable to introduce this ring system into compounds which might possess antitumor activity. 2-[2-Bis-(2-chloroethyl)-aminoethyl]isoindoline was synthesized by first reacting 2-(2-chloroethyl)isoindoline with diethanolamine to yield crude 2-[2-bis-(2-hydroxyethyl)aminoethyl]isoindoline which was then converted to the nitrogen mustard analog by treatment with thionyl chloride. The second possible antitumor agent, 1-[3-(2-isoindolinyl)-propyl]dihydrouracil, was prepared by the following series of reactions

Received April 28, 1961, from the Department of Chemistry, University of Illinois, College of Pharmacy, Chicago.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

It was found that 2-(3-aminopropyl)isoindoline could be added to acrylamide as well as to ethyl acrylate. The addition of 2-(3-aminopropyl)-isoindoline to acrylamide produced the amide of N-[3-(2-isoindolinyl)propyl]-beta-alanine. This compound is analogous to a number of compounds (3) which possess oxytocic activity.

N^1 - [4 - (2 - Phenylisoindolinyl)]sulfanilamide was prepared by the usual synthesis employed for N^1-substituted sulfanilamides.

The compounds prepared in this study were screened for biological activity. Only the amide of N - [3 - (2 - isoindolinyl)propyl] - beta - alanine showed appreciable activity. This compound stimulated the contractions of isolated uterine muscles.

Most of the compounds prepared were found to contain three carbon-hydrogen absorption bands in the 2700–3200 cm.$^{-1}$ region of their infrared spectra. Since absorption in this area of the spectrum is usually the result of the absorption by carbon-hydrogen bonds and since there was present in these molecules three distinct types of carbon-hydrogen bonds, it was felt that with the aid of several simple model compounds, analysis of this region of their spectra would be possible. From a study of the spectra of the compounds listed in Table I it appeared that the three bands were the result of absorption by the carbon-hydrogen bonds of the aromatic ring, the carbon-hydrogen bonds of the heterocyclic ring, and the carbon-hydrogen bonds of the alkyl chain attached to the nitrogen atom.

The bands appearing at 3025–3050 cm.$^{-1}$ result from absorption by aromatic carbon hydrogen bonds. When only a single aromatic ring is present in the compound, the band occurs at 3025 as a shoulder on the stronger peak at 2940 cm.$^{-1}$. However, the addition of a second phenyl group as in 2 phenylisoindoline, 2-phenyl-4-aminoisoindoline, or 1,6-bis(2-isoindolinyl)hexane, increases the intensity of this band and it occurs as a separate peak. The absorption bands at 2940 to 2975 cm.$^{-1}$ were definitely established. These appeared to be due to absorption of the carbon-hydrogen bonds of the alkyl groups connected to the heterocyclic nitrogen atom. Substitution of a phenyl group for the alkyl group, 2-phenylisoindoline and 2-phenyl-4-amino-isoindoline, resulted in the loss of absorption peaks in this area. Furthermore, the substitution of an ethyl group for the methyl group of 2-methylisoindoline gave rise to a doublet rather than a single peak.

It appeared likely that the absorption bands occurring in the portion of the infrared spectra 2720 and 2800 cm.$^{-1}$ might be caused by the absorption of carbon-hydrogen bonds of the methylene group of the heterocyclic ring. It was, therefore, desirable to obtain the spectra of an isoindoline ring system that did not contain carbon-hydrogen bonds in that ring. Since it was difficult to obtain a 1,1,3,3 tetra-substituted isoindoline, the spectra of the compounds previously synthesized were compared to the spectra of N-methylphthalimide. While the previously identified peaks at 3050 and 2975 cm.$^{-1}$ were pres-

TABLE I.—STUDY OF THE SPECTRA

Compound	C—H Bond Aromatic Ring	C—H Bond Hetero-cyclic Ring	C-Bond Alkyl Chain
2-Methylisoindoline	3025[a]	2775	2940
2-Ethylisoindoline	3025[a]	2800	2940–2975
2-Phenylisoindoline	3050	2750	...
2-Phenyl-3-amino-isoindoline	3040	2720	...
1,6-Bis-(2-isoindo-linyl)hexane	3050	2780	2940
N-Methylphthalim-ide	3050	...	2975

[a] Occurs as a shoulder on the peak at 2940 cm.$^{-1}$.

ent, the peak at 2720 to 2800 was missing. This indicates that the peak usually occurring in this area is due to absorption of the methylene group of the heterocyclic ring.

EXPERIMENTAL[1]

2-(2-Hydroxyethyl)isoindoline.—A solution of 9.0 Gm. (0.047 mole) of N-(2-hydroxyethyl)phthalimide (4) in 25 ml. of tetrahydrofuran was slowly added to a previously cooled slurry of 5.4 Gm. (0.047 mole) of lithium aluminum hydride in 100 ml. of anhydrous ether. After the addition was completed, the cold reaction mixture was decomposed with absolute alcohol. Water was then added until the aluminum oxide was completely precipitated. The resulting suspension was filtered and the clear filtrate dried over anhydrous sodium sulfate. After the removal of the ether, the residue was distilled. It boiled at 167–169°/15 mm. The distillate weighed 4.6 Gm. (60%).

von Braun and co-workers (5) prepared 2-(2-hydroxyethyl)isoindoline by the reaction of ethylene oxide on isoindoline. They reported the isolation of an oil boiling at 162–164°/12 mm.

2-Isoindolinylethyl *p*-Nitrobenzoate.—To a stirred solution of 6.5 Gm. (0.04 mole) of 2-(2-hydroxyethyl)isoindoline in 50 ml. of dry benzene was added, dropwise, a solution of 7.5 Gm. (0.04 mole) of *p*-nitrobenzoyl chloride in 25 ml. of dry benzene. The reaction mixture was refluxed for 2 hours and the solvent removed. The remaining oil was neutralized with 10% sodium hydroxide and then extracted with benzene. After evaporation of the solvent, 9.3 Gm. (75%) of yellow crystals was obtained. These were recrystallized from an alcohol-water mixture.

Anal.—Calcd. for $C_{17}H_{16}N_2O_4$: C, 65.37; H, 5.16; N, 8.97. Found: C, 65.18; H, 4.96; N, 8.78.

2-Isoindolinylethyl *p*-Aminobenzoate Hydrobromide.—The reduction of 2-isoindolinylethyl *p*-nitrobenzoate to 2-isoindolinylethyl 4-aminobenzoate was carried out by shaking a solution of 3.0 Gm. (0.009 mole) of the nitro compound in 75 ml. of ether with 0.3 Gm. of Raney nickel catalyst at 15 pounds of hydrogen pressure. When the theoretical quantity of hydrogen had been absorbed, the hydrogenation was discontinued and the catalyst removed by filtration. The filtrate was treated with anhydrous hydrogen bromide. The precipitated hydrobromide salt was filtered and recrystallized from absolute alcohol by precipitation with anhydrous ether. The pure compound weighed 1.2 Gm. (42%) and melted at 239–240°.

Anal.—Calcd. for $C_{17}H_{19}BrN_2O_2$: C, 56.21; H, 5.26; N, 7.70. Found: C, 56.00; H, 5.26; N, 7.80.

2-(2-Chloroethyl)isoindoline Hydrochloride.—To 8.6 Gm. (0.053 mole) of 2-(2-hydroxyethyl)isoindoline dissolved in 20 ml. of chloroform was added slowly a solution of 8 ml. of thionyl chloride in 15 ml. of chloroform. The reaction mixture, after being refluxed for approximately 15 minutes, crystallized. After cooling in ice, the reaction mixture was filtered and the resulting crystalline solid washed with chloroform and then with ether. After recrystallization from absolute alcohol by the addition of a few drops of anhydrous ether, a yield of 10.6 Gm. (91%) of a white crystalline solid was obtained. It melted at 191–192°.

Anal.—Calcd. for $C_{10}H_{13}Cl_2N$: C, 55.06; H, 6.00; Cl, 32.51. Found: C, 55.21; H, 5.87; Cl, 32.43.

This compound has been previously reported by Gump, *et al.* (6). Its preparation and physical constants were not reported.

2-Isoindolinylethyl *dl*-Mandelate Hydrochloride.—Silver mandelate was prepared by neutralizing 10.0 Gm. of *dl*-mandelic acid with dilute ammonium hydroxide and adding a 10% solution of silver nitrate until the precipitation of the silver salt was complete. The silver mandelate was removed by filtration, washed with water, alcohol, and finally ether.

A mixture of 4.2 Gm. (0.016 mole) of silver mandelate, 3.5 Gm. (0.020 mole) of 2-(2-chloroethyl)isoindoline hydrochloride, and 20 ml. of dry benzene was refluxed for 8 hours. During this time the solution was protected from light. The resulting silver chloride was removed by filtration. Ether was added to the filtrate to produce a gummy mass which solidified upon standing in the refrigerator overnight. The solvent was decanted and the residue dissolved in absolute alcohol. The hydrochloride precipitated upon the addition of anhydrous hydrogen chloride. After recrystallization from isopropyl alcohol, 3.0 Gm. (58%) of a white solid melting at 151–152° was obtained.

Anal.—Calcd. for $C_{18}H_{20}ClNO_3$: C, 64.75; H, 6.00; Cl, 10.64; N, 4.20. Found: C, 64.27; H, 6.09; Cl, 10.28; N, 4.37.

2-Isoindolinylethyl Diphenylacetate Hydrochloride.—To a stirred solution of 7.0 Gm. (0.043 mole) of 2-(2-hydroxyethyl)isoindoline in 25 ml. of dry benzene was added slowly a solution of 10.0 Gm. (0.043 mole) of diphenylacetyl chloride (7) in 15 ml. of dry benzene. The reaction mixture was refluxed on a steam bath for 2 hours. After removal of the solvent on a flash evaporator, the residue was recrystallized from isopropyl alcohol. The pure compound melted at 194–195° and weighed 15 Gm. (92%).

Anal.—Calcd. for $C_{24}H_{24}ClNO_2$: C, 73.18; H, 6.14; Cl, 9.02; N, 3.56. Found: C, 73.16; H, 6.21; Cl, 9.00; N, 3.70.

2-(2-Isoindolinyl)ethyl Benzhydryl Ether Hydrochloride.—2-(2-Hydroxyethyl)isoindoline (8.0 Gm., 0.049 mole) was dissolved in 20 ml. of dry benzene. To this solution was added 1.3 Gm. (0.055 mole) of sodium cut in very small pieces. After the mixture was refluxed for 1 hour, a solution of 13.7 Gm. (0.055 mole) of benzhydryl bromide (8) was added and the resulting solution refluxed for 4 hours. The reaction mixture was filtered to remove the precipitated sodium bromide. After evaporation of the solvent in a flash evaporator, the residue was distilled. It boiled at 195°/0.35 mm. The viscous reddish-brown distillate was dissolved in the least possible amount of benzene and the solution was allowed to stand overnight. A small amount of tetraphenylethane (m.p. 200°) crystallized and was removed by filtration. An equal volume of ether was added to the filtrate and the resulting solution was saturated with anhydrous hydrogen chloride.

[1] Melting points are uncorrected. Microanalyses are by Weiler and Strauss, Oxford, England.

The hydrochloride precipitated and was removed by filtration. After recrystallization from absolute ethanol, 0.7 Gm. (38%) of a white solid melting at 204–204.5° was obtained.

Anal.—Calcd. for $C_{23}H_{29}ClNO$: C, 75.51; H, 6.56; Cl, 9.71. Found: C, 75.66; H, 6.72; Cl, 9.86.

1,6-Hexamethylenediphthalimide.—To 10.0 Gm. (0.085 mole) of 1,6-hexamethylenediamine in a round bottomed flask was added 25.5 Gm. (0.17 mole) of phthalic anhydride. After the vigorous reaction had subsided, the mixture was heated for 45 minutes at 100°, after which the temperature was increased to 160° for 10 minutes. The solid residue was treated with boiling 50% alcohol and the insoluble precipitate was removed by filtration. After recrystallization from tetrahydrofuran the crystals melted at 178–179°. It weighed 30.0 Gm. (97%).

Anal.—Calcd. for $C_{22}H_{20}N_2O_4$: C, 70.21; H, 5.32; N, 7.44. Found: C, 70.13; H, 5.31; N, 7.65.

1,6-Bis-(2-isoindolinyl)hexane Dihydrochloride.—A solution of 6.6 Gm. (0.018 mole) in 20 ml. of tetrahydrofuran was added, dropwise, to a slurry of 4.0 Gm. of lithium aluminum hydride in 75 ml. of anhydrous ether. The reaction mixture was refluxed for 15 minutes and then the reagent was decomposed by the addition of ethanol. Water was carefully added to precipitate the alumina which was filtered. The clear filtrate was evaporated to dryness and the resulting solid dissolved in benzene and treated with an equivalent of an alcoholic solution of hydrogen chloride. The precipitated hydrochloride, after recrystallization from methanol, melted at 297–298°. The crystals weighed 3.5 Gm. (50%).

Anal.—Calcd. for $C_{22}H_{30}Cl_2N_2$: C, 67.17; H, 7.63; N, 7.12. Found: C, 66.85; H, 7.13; N, 6.81.

2-[2-Bis(2-chloroethyl)aminoethyl]isoindoline Dihydrochloride.—To a 100-ml. mixture of equal parts alcohol and benzene was added 7.5 Gm. (0.034 moles) of 2-(2-chloroethyl)isoindoline hydrochloride and 4.6 Gm. (0.034 mole) of diethanolamine. The resulting solution was refluxed for 4 hours, after which the solvents were removed on a flash evaporator. The residue dissolved in 10 ml. of chloroform was added, dropwise, to a solution of 15 ml. of thionyl chloride in 15 ml. of chloroform. When the addition was completed the mixture was heated under reflux for 20 minutes and then cooled in an ice bath until crystallization was complete. The solid reaction product after filtration and recrystallization from a mixture of equal parts acetone and alcohol weighed 11.0 Gm. (90%) and melted at 270° (decompn.).

Anal.—Calcd. for $C_{14}H_{22}Cl_4N_2$: C, 46.66; H, 6.12; Cl, 39.45; N, 7.78. Found: C, 46.52; H, 6.26; Cl, 39.51; N, 7.85.

2-(3-Aminopropyl)isoindoline.—2-Cyanoethylphthalimide (9) (15.0 Gm. 0.087 mole) was placed in a Soxhlet thimble and extracted into a slurry of 10.6 Gm. of lithium aluminum hydride in 200 ml. of anhydrous ether. After the reaction was completed, the reaction mixture was cooled to 5°, decomposed first with absolute alcohol, and finally with sufficient water to precipitate the aluminum oxide. The suspension was filtered and the clear filtrate was dried over anhydrous sodium sulfate. The mixture was filtered and the solvent removed by distillation. The resulting oil was distilled under vacuum. The fraction distilling at 94–96°/0.6 mm. was collected. It weighed 9.8 Gm. (60%).

Anal.—Calcd. for $C_{11}H_{16}N_2$: C, 74.95; H, 9.15; N, 15.90. Found: C, 74.82; H, 9.34; N, 15.92.

The pure oil rapidly absorbed carbon dioxide from the air to form a solid carbonate. The free base was regenerated upon the addition of strong alkali.

N-[3-(2-Isoindolinyl)propyl]-beta-alanine Amide Dihydrochloride.—A solution of 1.8 Gm. (0.01 mole) acrylamide in 20 ml. of absolute ethanol was slowly added to a stirred solution of 2.1 Gm. (0.02 mole) of 2-(3-aminopropyl)isoindoline in 10 ml. of absolute ethanol. The mixture was allowed to stand for 1 week. After removal of the solvent in a flash evaporator, the dark residue was washed with anhydrous ether and then dissolved in absolute alcohol. The hydrochloride was precipitated by the addition of anhydrous hydrogen chloride. The resulting precipitate was recrystallized from a mixture of equal parts of isopropanol and 95% alcohol. The recrystallization gave 2.7 Gm. (85%) of a white crystalline precipitate that melted at 173–174°.

Anal.—Calcd. for $C_{14}H_{23}Cl_2N_3O$: C, 52.50; H, 7.24; Cl, 22.14; N, 13.13. Found: C, 52.43; H, 6.97; Cl, 22.31; N, 12.98.

N-[3-(2-Isoindolinyl)propyl]-beta-alanine Ethyl Ester.—A solution of 5.7 Gm. (0.057 mole) of ethyl acrylate in 10 ml. of absolute alcohol was added dropwise, with stirring, to a cooled solution of 10.0 Gm. (0.057 mole) of 2-(3-aminopropyl)isoindoline in 20 ml. of absolute alcohol. The mixture was allowed to stand at room temperature for 4 days, at which time the solvent was removed on a steam bath under *vacuum*. The residue distilled and a fraction weighing 14.2 Gm. (90%) and distilling at 156–158°/0.6 mm. was collected.

Anal.—Calcd. for $C_{16}H_{24}N_2O_2$: C, 69.53; H, 8.75; N, 10.15. Found: C, 69.28; H, 8.52; N, 10.11.

1-[3-(2-Isoindolinyl)propyl]dihydrouracil.—To a stirred solution of 8.8 Gm. (0.032 mole) of N-[3-(2-isoindolinyl)propyl]-beta-alanine ethyl ester in a mixture of 3 ml. of hydrochloric acid and 10 ml. of water was added, dropwise, a solution of 3.4 Gm. (0.042 mole) of potassium cyanate in 10 ml. of water. The resulting solution was stirred for 1 hour and then allowed to stand overnight at room temperature. During this time a second layer formed. The upper layer was separated and treated with sufficient alcohol to precipitate the potassium cyanate present completely. After filtration of the solid, the filtrate was evaporated to dryness. A solid remained which, after recrystallization from absolute alcohol, gave 2.2 Gm. (25%) of a white crystalline solid melting at 184–185°.

Anal.—Calcd. for $C_{15}H_{19}N_3O_2$: C, 65.91; H, 7.00; N, 15.38. Found: C, 65.63; H, 7.29; N, 15.38.

N-Phenyl-3-nitrophthalimide.—To 3-nitrophthalic anhydride (10) (66.0 Gm., 0.45 mole) was added, dropwise, 42.0 Gm. (0.45 mole) of redistilled aniline. After the addition was completed and the reaction had subsided, the reaction mixture was heated at 210° for 20 minutes. The resulting orange liquid solidified on cooling and was recrystallized from a mixture of equal parts of acetone and ethanol. It

yielded a yellow crystalline solid which melted at 136–138°. The yield was 107.0 Gm. (82%).

Anal.—Calcd. for $C_{14}H_8N_2O_4$: C, 62.68; H, 3.01; N, 10.52. Found: C, 62.43; H, 2.89; N, 10.32.

N-Phenyl-3-aminophthalimide.—N-Phenyl-3-nitrophthalimide (10.0 Gm., 0.037 mole) dissolved in 100 ml. of equal parts tetrahydrofuran and ethanol, was reduced over Raney nickel catalyst in a Parr hydrogenator at 30 pounds of hydrogen pressure. After approximately 8 hours of shaking, the theoretical quantity of hydrogen had been absorbed. The solvent was then removed on a flash evaporator and the solid residue was recrystallized from benzene to yield 7.5 Gm. (85%) of a white crystalline solid. It melted at 185–187°.

Anal.—Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.58; H, 4.23; N, 11.76. Found: C, 70.63; H, 4.02; N, 11.88.

2-Phenyl-4-aminoisoindoline.—A solution of 13.0 Gm. (0.054 mole) of N-phenyl-3-aminophthalimide in 100 ml. of tetrahydrofuran was added, dropwise, to a suspension of 6.2 Gm. of lithium aluminum hydride in 75 ml. of tetrahydrofuran. The addition required 45 minutes. The reaction mixture was then refluxed for an additional 10 minutes, cooled in an ice bath, and the excess lithium aluminum hydride decomposed with absolute alcohol. The alumina was precipitated by the careful addition of water and the reaction mixture was filtered. The filtrate was dried over anhydrous sodium sulfate. After removal of the solvent, a greenish solid remained. After recrystallization from ethanol it weighed 10.0 Gm. (87%) and melted at 123–124°.

Anal.—Calcd. for $C_{14}H_{14}N_2$: C, 79.96; H, 6.71; N, 13.33. Found: C, 79.72; H, 6.83; N, 13.55.

N^1-[4-(2-Phenylisoindolinyl)]-N^4-acetylsulfanilamide.—To a refluxing solution of 2.1 Gm. (0.010 mole) of 2-phenyl-4-aminoisoindoline and 0.8 Gm. (0.010 mole) of pyridine in 30 ml. of benzene was added, dropwise, a solution of 2.6 Gm. (0.011 mole) of 4-acetamidobenzenesulfonyl chloride in 20 ml. of equal parts benzene and acetone. After the addition was completed, the resulting solution was refluxed for 10 minutes. Upon cooling, an oil settled to the bottom of the flask. The supernatant liquid was decanted and the oil was washed with ether and finally with cold water. Upon standing it solidified and was recrystallized from 50% isopropanol to give 3.3 Gm. (81%) of a white crystalline solid. The solid melted at 230–231°.

Anal.—Calcd. for $C_{22}H_{21}N_3O_3S$: C, 64.84; H, 5.19; N, 10.31; S, 7.86. Found: C, 64.78; H, 5.55; N, 10.41; S, 7.51.

N^1-[4-(2-Phenylisoindolinyl)]sulfanilamide.—N^1-[4-(2-Phenylisoindolinyl)]-N^4-acetylsulfanilamide (2.8 Gm., 0.007 mole) was refluxed for 1 hour with a solution of 2 ml. of hydrochloric acid in 4 ml. of water. The reaction mixture was then neutralized with sodium carbonate and the precipitated product collected on a Buchner funnel. After recrystallization from isopropanol to which a few drops of acetone was added, 1.8 Gm. (69%) of a white crystalline solid was obtained. It melted at 234–236°.

Anal.—Calcd. for $C_{20}H_{19}N_3O_2S$: C, 65.73; H, 5.25; N, 11.49; S, 8.77. Found: C, 65.50; H, 5.51; N, 11.22; S, 8.68.

2-Methylisoindoline.—2-Methylisoindoline was prepared by the lithium aluminum hydride reduction of N-methylphthalimide, following the procedure employed for the preparation of 2-(2-hydroxyethyl)isoindoline. It distilled at 85–86°/15 mm. [lit. (11) b.p. 81–82°/13 mm.].

2-Ethylisoindoline.—The compound was prepared by the lithium aluminum hydride reduction of N-acetylphthalimide, following the procedure of Rabjohn, Drumm, and Elliott (12). A fraction distilling at 217–220° was collected [lit. (12) b.p. 219–220°].

2-Phenylisoindoline.—N-Phenylphthalimide was reduced with lithium aluminum hydride as described by Wittig, Closs, and Mindermann. It melted at 168–169° [lit. (13) b.p. 169–170°].

SUMMARY

A series of compounds containing the isoindoline ring system, which are analogs of biologically active compounds, were prepared and screened for pharmacological activity. Only the amide of N-[3-(2-isoindolinyl)propyl]-beta-alanine showed appreciable biological activity. This compound increased the contractions of the isolated guinea pig uterus.

The carbon-hydrogen absorption bands occurring in 2700–3200 $cm.^{-1}$ region of their infrared spectra were examined and related to their molecular structure. The absorption bands occurring from 3025 to 3050 were the result of absorption of carbon-hydrogen bonds in the aromatic ring. Those occurring in the 2940–2975 region were the results of absorption of carbon-hydrogen bonds in the alkyl chain attached to the heterocyclic nitrogen atom. The band occurring at 2750 to 2780 was caused by absorption of the methylene group in the heterocyclic ring.

Polarographic Method of Analysis for Pharmaceuticals

By A. FRANCIS SUMMA

Polarographic methods for the determination of acetazolamide, chlorothiazide, and nitrofurantoin, and their application to pharmaceutical dosage forms, are described. These methods are satisfactory for the assay of pharmaceutical preparations official in U.S.P. XVI. The polarographic methods have the desired accuracy and precision for routine control procedures.

SINCE the introduction of polarography by Heyrovsky in 1920, there have been a number of reports in the literature concerning its application to pharmaceutical dosage forms (1–5). As with other new analytical techniques, there has been a tendency among some of the more enthusiastic supporters to be uncritical of polarographic methods and to use a polarographic procedure whether or not some other more satisfactory method existed. Some of the polarographic analyses suggested in the literature are quite complex and do not compare favorably with simpler colorimetric, volumetric, and spectrophotometric methods available. A polarographic approach should be considered whenever new and more accurate methods of analysis for pharmaceuticals are being sought. For many pharmaceutical analytical problems, polarography may well offer a method that has advantages over all other techniques.

There are some official pharmaceutical preparations for which the present method of analysis does not provide for the separation of excipients prior to analysis. In some cases, the compound cannot be separated from its excipients by partition between immiscible solvents and there is no other convenient physical or chemical means of separation. These excipients may interfere with a particular assay and lead to erroneous results. This is especially a danger in an ultraviolet spectrophotometric assay. In some cases, excipients will not interfere with the polarographic analysis, for polarography will produce a wave which is specific for a given compound with an electroreducible or oxidizable group. Acetazolamide, chlorothiazide, and nitrofurantoin were chosen as examples.

EXPERIMENTAL

Apparatus

The polarographic waves were obtained with the Sargent model XXI recording polarograph. The cells used were either large (20-ml. sample volume) or small (3-ml. sample volume) H-type cells containing a saturated calomel electrode (S.C.E.) separated from the sample compartment by an agar plug and fritted-glass diaphragm. The electrode capillary delivered 1.136 mg. of mercury per second at a column height of 45 cm. with a drop-time of 4.20 seconds.

Received July 18, 1961, from the Department of Health, Education, and Welfare, Food and Drug Administration, Bureau of Biological and Physical Sciences, Division of Pharmaceutical Chemistry, Washington 25, D. C.
Accepted for publication August 2, 1961.

Acetazolamide Tablets

Acetazolamide produces a polarographic wave having a half-wave potential ($E_{1/2}$) of -0.518 volts in 0.1 N hydrochloric acid solution *vs.* S.C.E. The diffusion current was found to be linear with concentration in the range between 8×10^{-5} M and 4×10^{-4} M.

Procedure.—Weigh and finely powder not less than 20 acetazolamide tablets. Weigh accurately a portion of the powder, equivalent to about 50 mg. of acetazolamide, transfer to a 100-ml. volumetric flask, and dissolve in about 40 ml. of boiling water. Heat the mixture on a steam bath for 15 minutes, cool to room temperature, add water to volume, and mix. Filter a portion of this solution, discarding the first 10 ml. of filtrate, and then pipet a 3-ml. aliquot of the filtrate, accurately measured, to a 25-ml. volumetric flask, add 2 ml. of 1 N hydrochloric acid, dilute to volume with water, and mix. Transfer a portion of this solution to an electrolytic cell, place in a constant temperature bath regulated at 25.0 ± 0.5° and remove the dissolved oxygen by aerating the solution with nitrogen for approximately 10 minutes. Insert the electrolytic cell under the capillary tip of the dropping mercury electrode assembly having a drop time of 4 to 5 seconds. Trace the polarogram from -0.20 to -0.75 volt vs. S.C.E. at a sensitivity which will give a suitable curve. Extrapolate the residual curve and draw parallel to it a line through the diffusion current plateau. Measure the height of the diffusion wave as the difference between the residual current and the diffusion current plateau. Calculate the quantity in mg. of $C_4H_6N_4O_3S_2$ in the portion of the tablets taken by the formula $C\,(I_{d\,\text{sample}}/I_{d\,\text{std.}})$ in which $I_{d\,\text{sample}}$ is the diffusion current value of the sample, C is the concentration of the standard solution, and $I_{d\,\text{std.}}$ is the diffusion current value of U.S.P. Acetazolamide Reference Standard determined similarly in a solution of the same composition containing about 60 mcg. in each ml.

Chlorothiazide Tablets

Chlorothiazide produces a polarographic wave having a half-wave potential ($E_{1/2}$) of -1.528 volts in an equimolar solution of 1 N ammonium chloride solution and 1 N ammonium hydroxide solution *vs.* S.C.E. The diffusion current was found to be linear

with concentration in the range between 1.2×10^{-4} M and 6×10^{-4} M.

Procedure.—Weigh and finely powder not less than 20 chlorothiazide tablets. Weigh accurately a portion of the powder equivalent to 100 mg. of chlorothiazide and transfer to a 100-ml. volumetric flask. Add 20 ml. of dimethylformamide, agitate for 5 minutes, and make to volume with an equimolar solution of 1 N ammonium chloride solution and 1 N ammonium hydroxide solution. Pipet a 3-ml. aliquot of this solution, measured accurately, to a 25-ml. volumetric flask and make to volume with distilled water. Transfer a portion of this solution to an electrolytic cell, place in a constant temperature bath regulated at 25.0 ± 0.5°, and remove the dissolved oxygen by aerating the solution with nitrogen for approximately 10 minutes. Insert the electrolytic cell under the capillary tip of the dropping mercury electrode assembly having a drop time of 4 to 5 seconds. Trace the polarogram from −1.25 to −1.75 volts *vs.* S.C.E. at a sensitivity which will give a suitable curve. Extrapolate the residual current curve and draw parallel to it a line through the diffusion current plateau. Measure the height of the diffusion wave as the difference between the residual current and the diffusion current plateau. Calculate the quantity, in mg., of $C_7H_6ClN_3O_4S_2$ in the portion of the tablets taken by the formula $C\,(I_{d\ \text{sample}}/I_{d\ \text{std.}})$, in which $I_{d\ \text{sample}}$ is the diffusion current value of the sample, C is the concentration of the standard solution, and $I_{d\ \text{std.}}$ is the diffusion current value of U.S.P. Chlorothiazide Reference Standard determined similarly in a solution of the same composition containing about 125 mcg. in each ml.

Nitrofurantoin Oral Suspension

Nitrofurantoin produces a polarographic wave having a half-wave potential ($E_{1/2}$) of −0.384 volt in an equimolar solution of 1 N ammonium chloride solution and 1 N ammonium hydroxide solution *vs.* S.C.E. The diffusion current was found to be linear with concentration in the range between 8×10^{-5} M and 4.8×10^{-4} M.

Procedure.—Pipet accurately an amount of nitrofurantoin oral suspension equivalent to approximately 50 mg. of nitrofurantoin into a 100-ml. volumetric flask. Add 20 ml. of dimethylformamide, agitate for 5 minutes, and make to volume with an equimolar solution of 1 N ammonium chloride solution and 1 N ammonium hydroxide solution. Pipet a 3-ml. aliquot of this solution, accurately measured, into a 25-ml. volumetric flask. Add 0.10 ml. of a 0.1% gelatin solution and make to volume with distilled water. Transfer a portion of this solution to an electrolytic cell, place in a constant temperature bath regulated at 25.0 ± 0.5°, and remove the dissolved oxygen by aerating the solution with nitrogen for approximately 10 minutes. Insert the electrolytic cell under the capillary tip of the dropping mercury electrode assembly having a drop time of 4–5 seconds. Trace the polarogram from −0.20 to −0.70 volt *vs.* S.C.E. at a sensitivity which will give a suitable curve. Extrapolate the residual current curve and draw a line parallel to it through the diffusion current plateau. Measure the height of the diffusion wave as the difference between the residual current and the diffusion current plateau. Calculate the quantity, in mg., of $C_8H_6N_4O_5$ in the portion of the suspension taken by the formula $C\,(I_{d\ \text{sample}}/I_{d\ \text{std.}})$, in which $I_{d\ \text{sample}}$ is the diffusion current value of the sample, C is the concentration of the standard solution, and $I_{d\ \text{std.}}$ is the diffusion current value of U.S.P. Nitrofurantoin Reference Standard determined similarly in a solution of the same composition containing about 60 mcg. in each ml.

Nitrofurantoin Tablets

Procedure.—Weigh and finely powder not less than 20 nitrofurantoin tablets. Weigh accurately a portion of the powder, equivalent to about 50 mg. of nitrofurantoin, and transfer to a 100-ml. volumetric flask. Proceed as directed in the assay for nitrofurantoin oral suspension, beginning with "add 20 ml. of dimethylformamide." Calculate the quantity in mg. of $C_8H_6N_4O_5$ in the portion of the tablets taken by the formula $C\,(I_{d\ \text{sample}}/I_{d\ \text{std.}})$, in which $I_{d\ \text{sample}}$ is the diffusion current value of the sample, C is the concentration of the standard solution, and $I_{d\ \text{std.}}$ is the diffusion current value of U.S.P. Nitrofurantoin Reference Standard determined similarly in a solution of the same composition containing about 60 mcg. in each ml.

DISCUSSION

The intersection-point method of measuring the diffusion current, as shown in Figs. 1, 2, and 3, was used for all polarographic waves. When the diffusion current so measured was plotted against concentration, a straight line was obtained (Fig. 4). Each point on the graph represents an average of three determinations. The experimental error by this method of analysis was found to be ±1%. It was felt that the greatest source of error in the analyses resulted from the measurement of the diffusion current height from the polarographic wave.

The results obtained by both polarography and U.S.P. XVI methods of analysis for each dosage form are listed in Table I. The table shows that

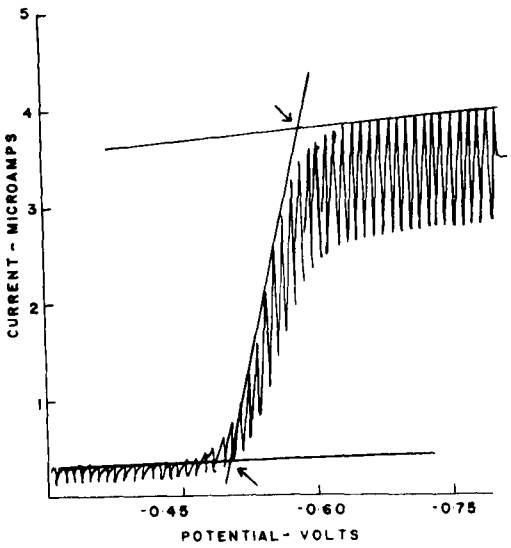

Fig. 1.—Acetazolamide polarogram in 0.1 N hydrochloric acid solution.

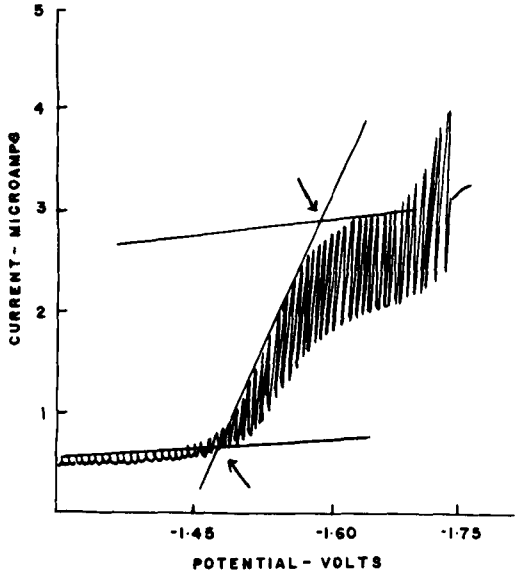

Fig. 2.—Chlorothiazide polarogram in equimolar ammonium chloride-ammonium hydroxide solution.

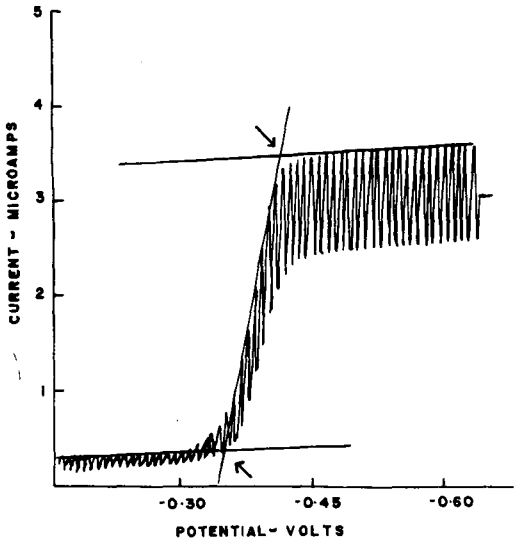

Fig. 3.—Nitrofurantoin polarogram in equimolar ammonium chloride-ammonium hydroxide solution.

the methods are in good agreement and that the results obtained by the polarographic method show greater precision than those obtained by the U.S.P. XVI method. In all cases, excipient material present in the commercially available preparations did not interfere with the polarographic and U.S.P. analysis and, therefore, no attempt was made to separate them prior to analysis. The average volume occupied by the undissolved tablet excipients was approximately 0.05 ml. so that the error introduced by leaving the tablet excipient in the solution is less

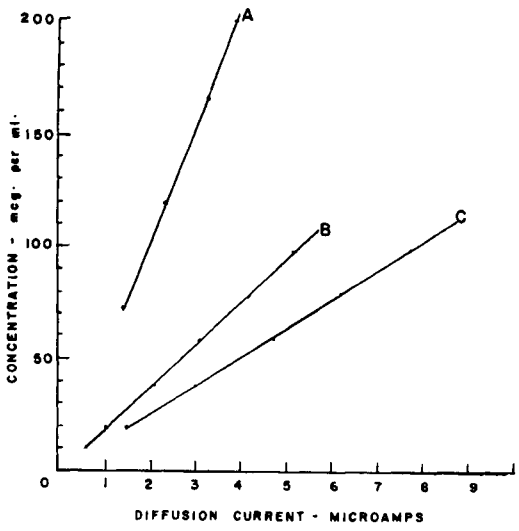

Fig. 4.—Plot of diffusion current *vs.* concentration for chlorothiazide (A), acetazolamide (B), and nitrofurantoin (C) solutions.

TABLE I.—RESULTS OF POLAROGRAPHIC AND U.S.P. XVI ANALYSES

Sample	% of Declared	
	Polarography	U.S.P. XVI

[a] U.S.P. XVI method modified by centrifuging sample after filtration.

than 0.2%, considerably less than the errors involved in measuring the diffusion current.

No difficulties were encountered with the polarographic analysis for acetazolamide, chlorothiazide, or nitrofurantoin in tablets and, therefore, outside of the development of a quantitative procedure no further investigation was undertaken. However, it was found that with the U.S.P. XVI spectrophotometric assay for nitrofurantoin oral suspension, a strong background was produced. This background can be attributed to the colloidal suspension produced by the Veegum present in the formulation which is not eliminated by simple filtration. The results obtained by the U.S.P. XVI method (Table I) for nitrofurantoin oral suspension are somewhat higher than those obtained by polarography. Modification of the U.S.P. XVI method by centrifuging the sample after filtration produced results which agreed more closely.

To determine whether the U.S.P. XVI or the polarographic method was at fault, a simulated nitrofurantoin oral suspension was prepared. Again, as shown in Table I, the polarographic and the modified U.S.P. XVI methods are in good agreement. It can be concluded that the spectrophotometric method is more susceptible to interference from extraneous materials than the polarographic method.

SUMMARY

Samples of acetazolamide, chlorothiazide, and nitrofurantoin were reduced at the dropping-mercury electrode. Their diffusion currents were found to be linear with concentration in the ranges investigated and therefore can be used for a quantitative polarographic assay.

A 0.1 *N* hydrochloric acid solution was found suitable for the polarographic determination of acetazolamide. A solution of dimethylformamide, 1 *N* ammonium chloride solution, and 1 *N* ammonium hydroxide solution were found suitable for the polarographic determination of both chlorothiazide and nitrofurantoin.

Similar experimental conditions were maintained throughout each assay to keep the variables at a minimum. The temperature was held within $\pm 0.5°$ by a constant temperature bath.

Polarographic analyses of dosage forms were compared with U.S.P. XVI analyses and proved to be quite satisfactory.

Metal Chelates of Oxazolidinones as Central Nervous System Stimulants

By WINTHROP E. LANGE, BASIL H. CANDON, and MAX CHESSIN

In an attempt to determine the effect of chelation upon central nervous system activity, a series of metal chelates have been prepared of 2-imino-5-phenyl-4-oxazolidinone, 2-imino-5,5-diphenyl-4-oxazolidinone, and 2-imino-5-*p*-biphenyl-4-oxazolidinone, using Cu^{++}, Ni^{++}, Mg^{++}, and Fe^{+++} ions. Spectral and analytical evidence has indicated a 1:1 ratio of metal to oxazolidinone in the respective chelates of all four metals. The magnesium chelate of 2-imino-5-phenyl-4-oxazolidinone exhibited the selective central nervous system stimulating characteristics of the parent compound and it also provided two therapeutic advantages, an earlier onset of action and a relatively shorter span of activity.

In 1913 Traube (1) reported the synthesis of a series of oxazolidinones, but it was not until 1956 that Schmidt (2) called attention to the central stimulant activity of one of the compounds, 2-imino-5-phenyl-4-oxazolidinone. In 1957 Lienert and Janke (3) in a further study of the same compound showed an activity similar to one parameter of caffeine activity, namely central nervous system stimulation, without the objectionable side-effects of the alkaloid.

The presence of a center for chelation in the oxazolidinone molecule suggested that chelates could be prepared. The possibility then exists that metal chelates of an oxazolidinone might provide a water-insoluble compound with more desirable pharmacological activity. This then would be a start in a study of the effects of chelation on drugs which must cross the blood-brain barrier. Accordingly, various oxazolidinones were reacted with a number of metal salts capable of forming chelates, and several metal chelates have been prepared.

Received April 28, 1961, from the Massachusetts College of Pharmacy, Boston, and Nordson Pharmaceutical Laboratories, Inc., New York, N. Y.
Accepted for publication August 14, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

DISCUSSION

In order to determine the influence of substitution on the central nervous system stimulant activity of the oxazolidinone molecule, the following oxazolidinones were prepared.

To determine whether the U.S.P. XVI or the polarographic method was at fault, a simulated nitrofurantoin oral suspension was prepared. Again, as shown in Table I, the polarographic and the modified U.S.P. XVI methods are in good agreement. It can be concluded that the spectrophotometric method is more susceptible to interference from extraneous materials than the polarographic method.

SUMMARY

Samples of acetazolamide, chlorothiazide, and nitrofurantoin were reduced at the dropping-mercury electrode. Their diffusion currents were found to be linear with concentration in the ranges investigated and therefore can be used for a quantitative polarographic assay.

A 0.1 *N* hydrochloric acid solution was found suitable for the polarographic determination of acetazolamide. A solution of dimethylformamide, 1 *N* ammonium chloride solution, and 1 *N* ammonium hydroxide solution were found suitable for the polarographic determination of both chlorothiazide and nitrofurantoin.

Similar experimental conditions were maintained throughout each assay to keep the variables at a minimum. The temperature was held within $\pm 0.5°$ by a constant temperature bath.

Polarographic analyses of dosage forms were compared with U.S.P. XVI analyses and proved to be quite satisfactory.

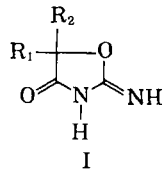
Metal Chelates of Oxazolidinones as Central Nervous System Stimulants

By WINTHROP E. LANGE, BASIL H. CANDON, and MAX CHESSIN

In an attempt to determine the effect of chelation upon central nervous system activity, a series of metal chelates have been prepared of 2-imino-5-phenyl-4-oxazolidinone, 2-imino-5,5-diphenyl-4-oxazolidinone, and 2-imino-5-*p*-biphenyl-4-oxazolidinone, using Cu^{++}, Ni^{++}, Mg^{++}, and Fe^{+++} ions. Spectral and analytical evidence has indicated a 1:1 ratio of metal to oxazolidinone in the respective chelates of all four metals. The magnesium chelate of 2-imino-5-phenyl-4-oxazolidinone exhibited the selective central nervous system stimulating characteristics of the parent compound and it also provided two therapeutic advantages, an earlier onset of action and a relatively shorter span of activity.



In 1913 Traube (1) reported the synthesis of a series of oxazolidinones, but it was not until 1956 that Schmidt (2) called attention to the central stimulant activity of one of the compounds, 2-imino-5-phenyl-4-oxazolidinone. In 1957 Lienert and Janke (3) in a further study of the same compound showed an activity similar to one parameter of caffeine activity, namely central nervous system stimulation, without the objectionable side-effects of the alkaloid.

The presence of a center for chelation in the oxazolidinone molecule suggested that chelates could be prepared. The possibility then exists that metal chelates of an oxazolidinone might provide a water-insoluble compound with more desirable pharmacological activity. This then would be a start in a study of the effects of chelation on drugs which must cross the blood-brain barrier. Accordingly, various oxazolidinones were reacted with a number of metal salts capable of forming chelates, and several metal chelates have been prepared.

Received April 28, 1961, from the Massachusetts College of Pharmacy, Boston, and Nordson Pharmaceutical Laboratories, Inc., New York, N. Y.
Accepted for publication August 14, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

DISCUSSION

In order to determine the influence of substitution on the central nervous system stimulant activity of the oxazolidinone molecule, the following oxazolidinones were prepared.

I

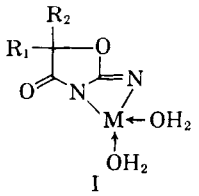
Ia. $R_1 = C_6H_5$, R_2 = H 2-imino-5-phenyl-4-oxazolidinone

Ib. $R_1 = C_6H_5$, $R_2 = C_6H_5$ 2-imino-5,5-diphenyl-4-oxazolidinone

Ic. $R_1 = C_6H_5—C_6H_5$, R_2 = H 2-imino-5-*p*-biphenyl-4-oxazolidinone

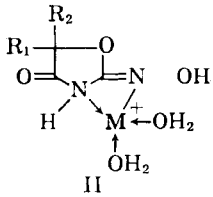
Chelates (1:1) with cupric, nickel, ferric, and magnesium ions were isolated and the analytical results are recorded in Table I. A stable 1:1 chelate with neither zinc nor ferrous iron could be obtained.

Structural Considerations.—The results of elemental analyses of the chelates, as shown in Table I, indicate a structure containing one metal atom per molecule of oxazolidinone. The presence of water of chelation was shown by a loss of weight corresponding to approximately the calculated number of molecules of water without a change in color when the chelates were dehydrated at 225°. In the case of the magnesium chelate, the additional molecule of water of hydration was determined by Karl Fischer titration without drying at 110° as was done with the other chelates. Saturated aqueous solutions of the nickel and copper chelates gave negative tests for the metal ions. A positive test was given by magnesium and ferric iron indicating the ionic character of these complexes.



The infrared spectral characteristics of the oxazolidonones and their chelates were compared in an attempt to show the site of chelation. Owing to the complexity of the spectra of amide chelates in the 3 μ region, it is not suitable for detailed study. However, in the 6 μ region the intense amide I band can easily be identified. This band is usually considered to be a stretching wavelength of the amide carbonyl in resonance with the C—N band. In the oxazolidinone compounds the amide II band thought to be due to C—N stretching or N—H deformation is also present. Table II lists the wavelengths of the absorption bands for the various oxazolidinones and their chelates.

TABLE II.—INFRARED ABSORPTION BANDS, μ, OF OXAZOLIDINONE CHELATES[a]



Compound	Bands		
	Amide I	Amide II	NH or OH
Ia	5.95	6.35[b]	7.73
Ia-Copper chelate	6.25	...	7.67
Ia-Nickel chelate	6.18	...	7.69
Ia-Magnesium chelate	6.00	6.35, 6.62	7.80
Ia-Ferric chelate	6.00	6.35, 6.42	7.75, 7.82
Ib	6.00	6.30	7.65
Ib-Copper chelate	6.10	...	7.70
Ic	6.00	6.38	7.80
Ic-Copper chelate	6.20	...	7.72

[a] The compounds were examined as solids in Nujol mulls using a Perkin-Elmer model 137 recording spectrophotometer. [b] A broad band extending to 6.65 μ.

It will be noted that in the case of the copper and nickel chelates the band corresponding to the amide I has a higher wavelength than the parent compound and the amide II band disappears. This could be due to a definite shift of the resonance equilibrium of the amide group and the formation of covalent bonds. The fact that there is no change in the intensity of the carbonyl or amide I band could indicate structure I as the most likely for the copper and nickel chelates.

I

II

In the case of the ferric and magnesium chelates, the amide I band remains unchanged while the amide II band shows two maxima. This could be due to coordination with the imino group giving rise to definite bands rather than the broad amide II band of the parent compound. These compounds then could have a structure corresponding to II which might indicate either a cyclic complex or a chelate. In general, chelate bonding of the alkaline earth ions is primarily ionic and the bond

[a] The carbon-hydrogen analyses were determined by Weiler and Strauss, Oxford, England, and by Dr. C. K. Fitz, Needham, Mass. [b] Ia = 2-imino-5-phenyl-4-oxazolidinone; Ib = 2-imino-5,5-diphenyl-4-oxazolidinone; Ic = 2-imino-5-*p*-biphenyl-4-oxazolidinone. [c] The metal content of the chelates was determined by ashing to constant weight at 1000°. [d] This quantity is the loss of weight on dehydration at 225° after initial drying at 110°. [e] Determined gravimetrically as the pyrophosphate. [f] This sample was determined by the Karl Fischer method without drying at 110°.

strength is related to the ratio of charge of the ion to its ionic radius. The charge/radius ratio for magnesium is 2.44 which is at the lower limit for chelate formation. Thus, the relatively weak bonding of magnesium as compared with the strong bonding of copper accounts for the difference in the infrared spectra of the two chelates.

The band at 7.73 μ for 2-imino-5-phenyl-4-oxazolidinone, as may be seen in Table II, was found to undergo a regular shift from one chelate to another. It is interesting to note that the relative order of stability of the various divalent chelates was found to parallel the wavelength shifts of this band (Cu > Ni > Mg). The results agree with those obtained by Harkins and co-workers (4) with five membered chelate ring imidazole derivatives except for the position of the magnesium.

Examination of another physical property, the oil-water partition coefficient, was made not only to discover differences between the chelates and cyclic complexes or ionic chelates, but also to obtain information regarding the capabilities of the metal derivatives to penetrate the bloodbrain barrier. Oleyl alcohol was selected for this determination in accordance with the advantages ascribed by Albert (5). The coefficients were obtained by measuring spectrophotometrically the percentage of compound extracted by oleyl alcohol in the manner described by Foye and Duvall (6). Reference to Table III shows that the copper chelate is considerably more fat-soluble than any of the others. It will be noted in respect to biological applications that the increased liposolubility modifies the onset of action of these compounds. However, this effect does not appear to be the only determinant of central nervous system stimulant activity.

TABLE III.—OIL-WATER PARTITION COEFFICIENTS AT 25°

Ia-Nickel chelate	1.3	6.6	11.0

[a] Ia = 2-imino-5-phenyl-4-oxazolidinone.

Biological Results.—Initial tests on 2-imino-5-phenyl-4-oxazolidinone, known generically as pemoline, confirmed the findings of Schmidt (2). This compound induces central nervous system stimulation in various laboratory animals while the homologs described by Traube (1) were inactive. The results of preliminary pharmacological screening of related compounds and their chelates which we had prepared are given in Table IV. The compounds were screened in male albino mice (18–22 Gm.) for pharmacological activity. Attention was especially directed toward central nervous system stimulant action determined by visual observation. The compounds were tested at dose levels of 250 and 500 mg./Kg., p.o. It is apparent from the results shown in Table IV that substitution at position 5 is critical while chelation does not effect activity *per se*.

[a] The results were obtained by visual observation. [b] The 5-position substituents of the 2-imino-4-oxazolidinone molecule is given and the metal when chelates are referred to. [c] The dosage is in mg./Kg., p.o. [d] A, active; I, inactive.

The relative lack of toxicity of magnesium in comparison with the other metals led to the selection of the magnesium chelate for further study. The compound induced central nervous system stimulation in monkeys, dogs, cats, rabbits, rats, and mice. Due to the insoluble nature of the compound, the oral route of administration was used throughout these studies except in rare instances. The duration and degree of central nervous system stimulatory activity in laboratory animals appears to be directly related to dosage. Although the acute oral LD_{50} value in mice was approximately 1500 mg./Kg. it was possible to note increased locomotor activity in doses as low as 15 mg./Kg. The profile of central nervous system stimulation noted does not resemble that induced by sympathomimetic amines, i.e., pilomotor erection, salivation, and widening of the palpebral fissures. Antihistiminic, cholinolytic, and adrenolytic effects were not observed in the pharmacological evaluation of this compound.

Unlike the monamine oxidase inhibitors, the serotonin and norepinephrine levels of the brains of the mice pretreated with magnesium pemoline did not differ from those of untreated control animals. Female albino mice weighing 18–24 Gm. were pretreated with magnesium pemoline (100 mg./Kg., p.o.) and sacrificed at scheduled times (1 hour, 3 hours, and 24 hours). Whole brains were removed and pooled. Serotonin and norepinephrine measurements were carried out by spectrophotofluorimetric methods (7, 8).

To measure the onset and duration of effect of the magnesium chelate compared to the base compound, screening studies were undertaken in mice, measuring the response to supramaxial electroshock by the methods of Toman and co-workers (9, 10).

Mice received supramaximal electroshock through cranial electrodes. The latency period was measured for convenience from onset of shock to onset of tonic extensor phase. It normally includes a

phase of increasing limb flexon. The threshold for tonic extensor convulsions is 7–10 ma. The latency period between shock and the extensor component of the convulsion was recorded to the nearest 0.2 sec. following 20 ma. (approximately twice the threshold shock).

After establishing that pemoline and magnesium pemoline significantly prolonged the supramaximal electroshock latency period following oral administration, each drug was administered orally to mice, generally in groups of 20. The dose of each compound was 100 mg./Kg., p.o. Treated groups and control groups were challenged at specified intervals and onset and duration of action were determined. Analysis of data presented in Table V reveals that the onset of activity of magnesium pemoline was more rapid. Statistically significant responses were obtained at 15 minutes while the parent compound was inactive at 15 minutes and 30 minutes, but was active at the 1-hour test period.

TABLE V.—ELECTROSHOCK SEIZURE LATENCY EXPERIMENTS

Expt. No.	Time of Electroshock Challenge after Drug, hr.[a]	No. of Mice/ Group	Increase in Seizure Latency Time Over Control Group Mg-Pemoline	Pemoline

[a] The dosage used was 100 mg./Kg. orally. [b] S, Statistically significant increase in latency seizure time; N.S, not significant statistically (*t* test).

EXPERIMENTAL

2-Imino-5-phenyl-4-oxazolidinone.—This product was obtained by the procedure of Traube (1). A 83% yield of colorless needles was obtained which melted at 254–256° (decompn.) which agrees with the reported value.

2-Imino-5,5-diphenyl-4-oxazolidinone.—This compound was prepared by the procedure of Iwaya and workers (11). A white solid was obtained which melted at 250–252° (decompn.) which agrees with the reported value.

Ethyl-*p*-xenylglyoxalate.—This intermediate was prepared by the procedure of Blicke and Grier (12). Recrystallization of the product from an ether-petroleum ether mixture gave a white solid which melted at 38–39° which agrees with the reported value.

Ethyl-*p*-xenylhydroxyacetate.—In a pressure bottle was placed 25.4 Gm. (0.1 mole) of ethyl-*p*-xenylglyoxalate in 175 ml. of anhydrous ethanol, 0.85 Gm. platinized charcoal, and 6 ml. of water containing 0.35 Gm. of palladium chloride. The mixture was hydrogenated for 8 hours at three atmospheres pressure. The catalyst was removed by filtration and the solvent evaporated under reduced pressure. The residue was recrystallized from aqueous alcohol to give 23.0 Gm. (90%) of ethyl-*p*-xenylhydroxyacetate; m.p. 160–162°.

Anal.—Calcd. for $C_{16}H_{16}O_3$: C, 74.97; H, 6.29. Found: C, 74.81; H, 6.50.

2-Imino-5-*p*-biphenyl-4-oxazolidinone.—A solution of 12.8 Gm. (0.05 mole) of ethyl-*p*-xenylhydroxyacetate and 9.2 Gm. (0.05 mole) of guanidine nitrate in 50 ml. of ethanol and sodium ethoxide (1.5 Gm. sodium) was heated 30 minutes on a water bath. The ethanol was removed *in vacuo* and the residue dissolved in sodium bicarbonate. The aqueous solution was washed with ether and acidified with dilute hydrochloric acid to give 9.0 Gm. (70%) of 2-imino-5-*p*-biphenyl-4-oxazolidinone as a crystalline solid melting at 283–286° with decomposition.

Anal.—Calcd. for $C_{15}H_{12}N_2O_4$: C, 71.43; H, 4.79. Found: C, 71.11; H, 4.92.

Preparation of the Metal Chelates.—The chelates of the various oxazolidinones were all prepared by the same procedure. The metal salts which were employed were: cupric chloride, magnesium sulfate, ferric sulfate, nickel nitrate.

To a mixture of the oxazolidinone (0.025 mole) in 50 ml. of ethanol was added sufficient 20% sodium hydroxide solution to solubilize the oxazolidinone. The solution was diluted with 100 ml. of water and the metal salt (0.025 mole) in 20 ml. of water was slowly added with constant stirring. A sufficient quantity of 20% sodium hydroxide solution was added from time to time to maintain the pH at 10.5. The mixture was stirred for 1 hour after the final addition of the metal salt solution and the product collected by filtration. The yields of the various chelates ranged from 83 to 95% of the theoretical. Analyses and colors of the various chelates are shown in Table I.

Manually Sorted Punched Card System for Pharmaceutical Literature

By JOHN G. WAGNER

A 5 × 8 inch punched card and direct coding system for pharmaceutical literature is illustrated and described. Use of the cards for a cooperative literature searching system and for a separate complete article file is discussed. Although the punched card system was designed for use in a department of product research and development in a pharmaceutical house, it would probably serve equally well for the faculty of a college of pharmacy.

A NUMBER of authors (1–9) have reported on the use of hand-sorted punched cards for bibliographic, data storage, and data processing purposes. Specific articles have been written on the use of such cards for a chemical bibliography (1), an instrumentation bibliography (7), storage of infrared absorption spectra (6), storage of medical research data (8), and processing of psychological data (9).

Keeping track of literature in the pharmaceutical field is becoming an increasing burden. It has become almost a necessity to have a cooperative effort with central filing of abstracts and/or references in order to be able to keep up with the new literature. This is true not only in industrial research and development but also in the academic field. The punched card system for pharmaceutical literature to be described was designed for use in a department of pharmacy or product research and development in a pharmaceutical house, but it would probably serve equally well for the faculty of a college of pharmacy.

The most useful property of punched cards is that of providing a means of cross indexing without the necessity of duplicating entries (4). In initiating the system to be described, most attention was paid to the facility in getting references and abstracts out of the file as in the system proposed by Cox, *et al.* (1).

THE PUNCHED CARD AND CODING SYSTEM

A 5 × 8 inch card sold by the Royal McBee Corporation (10) is used. Although the 155 holes around the perimeter of this card are divided into a series of numbered fields, the latter are not used in the system to be described. The numbers printed on the face of the card are completely ignored and only direct coding utilized, as shown in Fig. 1. This figure shows the back of the card. The material shown is printed directly on the cards in lots of one thousand by an offset printing process.

The "D" opposite a word such as Endocrine means deep punch, while the "S" opposite a word such as Agriculture means shallow punch. There are 58 pairs of "D" and "S" categories, making a total of 116 possibilities for direct coding. One additional hole is utilized if the reference is a patent or specification for a patent. Eight other holes near the cut corner of the card are used for the last two digits of the year; the last digit of the year of publication is placed in the set of four holes nearest the cut corner. The remaining 30 holes, 20 at one edge of the card and 10 at the other edge of the card, are numbered. The categories assigned to 29 of these 30 holes are shown in Table I.

In Fig. 1 there are several heavier black lines which divide the categories into several groups. Referring to the left-hand side of the back of the card, the groups of categories from top to bottom may be titled: pharmacologic classification, method of administration, type of dosage form, nature of process, assay and instrument classification, and source of reference. Referring to the right-hand side, the groups of categories from top to bottom may be titled: chemical and pharmaceutical nature of substance, stability and compatibility group, and a miscellaneous group which starts with "clinical testing" and ends with "drug combination(s)."

The cards may be filed by year and into "patent" and "nonpatent" sections. However, the cards could be filed randomly in one group or into any other specific groups. For example, if the card deck becomes large enough one might wish to segregate a group of categories, such as the assay and instrument classification.

A COOPERATIVE LITERATURE SEARCHING SYSTEM

Since we are now adding to the file of cards at the rate of about 1,200 cards per year, cooperative abstracting has been initiated in our department. Patents present no problem since we merely cut out pertinent abstracts of the patents from the *Official Gazette* and paste them on the cards. When a rubber cement is used a card will be perfectly flat after the abstract is pasted onto it. Most of the

Received September 6, 1961, from the Pharmacy Research Section, Product Research and Development Unit, The Upjohn Co., Kalamazoo, Mich.

articles to be abstracted are chosen from *Current Contents* (11). The title of each article, the surnames and initials of the authors, and the journal reference is typed onto the front of the card. The cards are then assigned for abstracting and a simple record kept of the number of cards assigned to each scientist on a given day. When the cards are returned with the abstracts on them, an entry of the date they were returned is made and then the number of days required for abstracting is noted. When about 50 to 100 cards have been returned, the cards are coded using a china red marker to indicate where "D" or "S" cuts are to be made in the cards. Since only the abstractor would often know whether there are any categories involved in the numbered holes (Table I), the scientist doing the abstracting is requested to have Table I with him when he reads the article and to mark the appropriate holes with a china red marker.

The cards bearing abstracts are circulated to about fifteen scientists. Hence each scientist gets the benefit of the others' abstracting. When each deck of coded cards has completed the circuit of scientists, they are punched appropriately and filed in drawers.

RESULTS OF THE LITERATURE SEARCHING SYSTEM

The growth of the punched card file of pharmaceutical literature in the Product Research and Development Unit of The Upjohn Co. is shown in Fig. 2. The system was initiated on October 15, 1956. There has been steady growth in the number of cards added to the file in each subsequent year. At the present time the rate of addition is greater

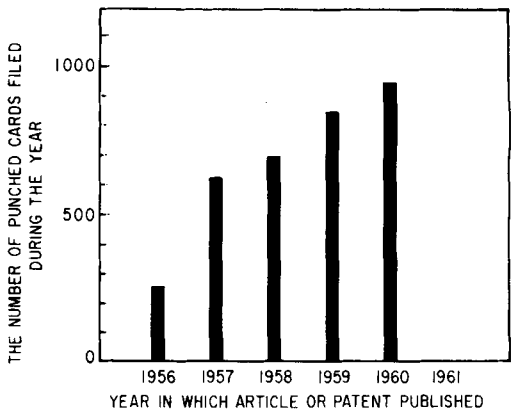

Fig. 2.—The growth of the punched card file of pharmaceutical literature in the Product Research and Development Unit of The Upjohn Co.

than 1,200 cards per year. It is estimated that by the end of 1962 there will be between 5,000 and 6,000 cards in the file.

The average time and range of time required for abstracting[1] articles varies widely, depending upon the particular scientist doing the abstracting and his duties at the time the cards are assigned. Average abstracting times for individual scientists range from 2 to 40 days with corresponding ranges from 1 to 7 days, and 13 to 72 days. During 1960 a total of 975 abstracted cards were circulated to 14 to 15 scientists. The average time for a deck of cards to circulate among the 14 or 15 scientists was 48 days, with a range of 16 to 82 days.

The usefulness of the file of punched cards may be illustrated by a few examples. When the author was requested to write a recent review article (12), it required only about 1 day to retrieve about 500 pertinent references and abstracts from the file. Reduction of these to about 200 references resulted in the principal material from which the review was written. When a scientist is assigned the task of writing an Invention Report for the Patent Law Unit, preparatory to the filing of a patent application, most of the pertinent patent and other literature references can be obtained readily from the file. The file has been used to answer some of the myriad of questions one is asked by personnel within and without his own unit of the Company during a working year; the file has even been used to answer telephone queries while the line has been held open.

A CARD SYSTEM FOR COMPLETE ARTICLE RETRIEVAL

The same type of card as shown in Fig. 1 may be used as an index to a complete article (reprint or photostat) file also. In this case only the title, author(s), reference, a code number, and the year of publication is placed on the front of the card. The code number is written large in the upper right-hand corner with the year of publication in brackets beneath the number. Reprints or photostats added to the file are numbered consecutively by attaching a red-bordered label to the upper right-hand corner of the first page of the article and stapling the label

[1] Time between assignment of the card and its return.

to the page in case the adhesive becomes weak in later years. The articles are filed consecutively by number. Each year's articles are placed in a separate hanging file in a conventional file drawer. The cards are coded after reading the article and are then filed. Retrieval of the articles via the card index has been found to be very rapid and efficient.

Cellulose Acetate Succinate as an Enteric Coating for Some Compressed Tablets

By L. O. WILKEN, Jr., M. M. KOCHHAR, D. P. BENNETT, and F. P. COSGROVE

The preparation and testing of compressed tablets of barium sulfate and sodium chloride coated with cellulose acetate succinate (CAS) are described, and the statistical evaluation of the data obtained is presented. The most satisfactory coatings were obtained when the test material, in an acetone-ethyl acetate solution, was applied by a modified "pan" method using talc as a dusting powder. Generally, CAS coatings which were stable for 3 1/2 hours in Simulated Gastric Fluid USP XVI dissolved sooner than control coatings of CAP applied and treated in the same manner. Disintegration times were slightly lower for most tablets placed directly into Simulated Intestinal Fluid, USP XVI than they were for tablets first treated with Simulated Gastric Fluid USP XVI for 3 1/2 hours and then tested in the former solution. None of the tablet coatings showed signs of cracks as a result of storage at −2 ± 2° for 21 days or 45 ± 2° for 10 days; however, some of these showed statistically significant differences in average disintegration time when compared with samples stored at room temperature. When test and control tablets were stored at 40 ± 2° and approximately 81% humidity, the majority of coatings were unsatisfactory. Tablets lost less than 3.56% tablet weight as a result of the simulated gastric fluid treatment. Preliminary *in vivo* tests with human subjects indicate that CAS has merit as an enteric coating. Pancreatin appears to have little effect on the disintegration times of the test coating.

THE IMPORTANCE of a good enteric coating for compressed tablets has been long recognized (1–3). Recently, the interest in this area has been stimulated by reports (4–6) of new enteric coatings and improved methods of evaluating enteric coatings. While considerable studies have been reported on the use of cellulose acetate phthalate (CAP) (4, 7–9) as an enteric coating, little experimental work has been published on the use of cellulose acetate succinate (CAS) for this purpose. Malm, *et al.* (10), prepared some cellulose succinate compounds as early as 1940; however, the authors did not fully study the enteric coating properties of the compounds.

Since CAS and CAP appear to possess similar solubility properties, and since there still exists a need for more efficient and inexpensive enteric coating material, as well as more data on the substances presently employed for this purpose, this study was undertaken. Also, it was felt that CAS might be less toxic than corresponding phthalate products, if the former proved to be a satisfactory enteric coating material, since succinic acid is normally found in the body.

EXPERIMENTAL

Material.—The cellulose acetate phthalate and cellulose acetate succinate used were obtained from Eastman Kodak Co., Rochester, N. Y. CAS has the following composition (11): combined acetyl, 20.6%; combined succinyl, 33.6%; No. of acetyls per anhydroglucose unit, 1.65%; No. of succinyls per anhydroglucose unit, 1.15%; No. of hydroxyls per anhydroglucose unit, 0.20%; free succinic acid, 0.21%; free carboxyl (corrected for free succinic acid), 15.0%.

Received April 28, 1961, from the College of Pharmacy, University of Texas, Austin.
Accepted for publication July 18, 1961.
The authors wish to thank Distillation Products Industries for the generous samples of CAS and CAP used in this study.

to the page in case the adhesive becomes weak in later years. The articles are filed consecutively by number. Each year's articles are placed in a separate hanging file in a conventional file drawer. [a] End point for all sodium chloride tablets was taken when 100% of tablet passed through screen of disintegration apparatus. End point for subcoated barium sulfate tablets was taken at the first appearance of core tablet. End point for plain barium sulfate tablets was taken when the tablet edges showed definite erosion. [b] Weight and standard deviations of the average weights of 20 samples consisting of 10 tablets each. [c] Slight cracks observed in a few coatings after simulated gastric fluid treatment.

Other Materials Used.—Dimethyl phthalate (Eastman); ethyl acetate, N.F. and reagent; acetone, N.F. and technical; talc, U.S.P.; simulated gastric fluid U.S.P. XVI; simulated intestinal fluid U.S.P. XVI; sucrose U.S.P.; starch U.S.P.; calcium carbonate U.S.P.; amaranth U.S.P.; barium sulfate U.S.P., and sodium chloride, technical.

Preparation of Tablets.—Tablets of sodium chloride and barium sulfate-sucrose (5:2) were compressed on a power-driven Stokes model F single-punch machine using 3/8 in. deep concave punches. The weights of 10 tablets of sodium chloride and barium sulfate were maintained at approximately 3.60 and 4.60 Gm., respectively. The total weight of each granulation compressed was about 20 lb. Each batch was divided into two groups and designated as: (*a*) tablets to be enteric coated without a subcoat and (*b*) tablets to be subcoated prior to enteric coating. Simple syrup, subcoating powder (consisting of varying amounts of calcium carbonate, starch, and sucrose) and the conventional coating pan were used to apply the subcoats. For the barium sulfate tablets a small amount of amaranth, as an indicator, was added to some of

the subcoating powder and this mixture applied as the first two or three subcoats.

Tablets of each of the above two groups were then divided as follows: (*a*) tablets to be enteric coated without a dusting powder and (*b*) tablets to be enteric coated using talc as a dusting powder.

At a later date, another batch of sodium chloride (2n) was compressed as before, coated with CAP and talc, and used as a second control.

Enteric Coating.—The enteric coating solution used had the following composition: cellulose acetate succinate, 9.0 Gm.; dimethyl phthalate (plasticizer), 3.4 Gm.; ethyl acetate, 84.4 Gm.; acetone, 84.4 Gm. A solution containing the same concentration of commercially available CAP was used as the control.

The compressed tablets were enteric coated with the CAS or CAP solution using a modified "pan" coating technique. In place of the copper pan, a small porcelain container was used because the conventional pan was not suitable for small experimental lots of approximately 700 to 1500 tablets.

Twelve to fifteen milliliters of enteric coating solution were employed for each coat. The total number of coats applied per batch was 15 or 20. When a dusting powder was employed, approximately 12 to 15 Gm. of talc were used for each application. Controls were coated in a similar manner. It is estimated that the weight ratio of polymer to talc for tablets coated by this technique ranged from 1:10 to 1:15. Some properties of plain and enteric coated tablets are given in Tables I and II.

Enteric Coated Tablets.—*In vitro* tests were carried out by using the disintegration apparatus, simulated gastric fluid, and simulated intestinal fluid of the U.S.P. XVI.

Tablets coated only with 20 coats CAS or CAP did not resist the action of simulated gastric fluid U.S.P. XVI for $3^1/_2$ hours; therefore, they were rejected and not studied further.

All other enteric coated tablets were tested for disintegration in simulated intestinal fluid by two procedures: (*a*) by placing tablets directly into this fluid and (*b*) by placing the tablets in the simulated gastric fluid U.S.P. XVI for $3^1/_2$ hours prior to transferring them to the simulated intestinal fluid U.S.P. XVI. All disintegration times were recorded to the nearest minute.

The behavior of the tablets in the simulated gastric fluid, their disintegration times in simulated intestinal fluid, their end points for disintegration, and some of their physical properties are shown in Table II.

Effect of Storage.—Since it was observed by investigators that some enteric coatings may crack when subjected to various storage conditions, it was of interest to investigate the effect of cold, heat, and high humidity upon the test coatings. Eighteen to twenty-two tablets from each group of enteric coated tablets were exposed in open containers to: (*a*) refrigerator temperature of $-2 \pm 2°$ for 21 days, (*b*) oven temperature of $45 \pm 2°$ for 10 days, and (*c*) oven temperature of $40 \pm 2°$ and approximate humidity of 81%[1] for 10 days. At the end of the storage periods, tablets were allowed to return to room temperature, examined for cracks, weighed (except those rejected due to the action of high humidity chamber), and tested for disintegration as soon as possible. The condition in the humidity chamber was purposely made much more extreme than any which might be ordinarily found. With all sodium chloride test and control samples, a considerable amount of water was found in the storage containers and many of the coatings were broken. Most of the CAS and CAP coats on barium sulfate tablets containing no subcoats showed cracks; however, with the corresponding subcoated tablets, no breaks in the coatings were observed. These latter tablets increased in weight, but no further work was done with them. Test and control coatings stored in the heat and cold showed no cracks. The disintegration times for the samples are found in Table III.

Loss of Tablet Weight.—It was observed that many of the tablets gained weight during the simulated gastric fluid treatment and during the humidity storage period. This indicated that some liquid had entered into the tablets. Also, it was shown from the results of the humidity storage experiment that considerable sodium chloride was present in the water which had accumulated in the storage containers holding the nonsubcoated enteric coated sodium chloride tablets. These observations appear to substantiate Gakenheimer's (13) conclusion that CAP coatings may act as a semipermeable membrane. Therefore, it was of interest to determine whether the simulated gastric fluid caused any loss of tablet material during the testing procedure. Representative samples stored at room temperature, $-2 \pm 2°$ and $45 \pm 2°$ were weighed, placed in the simulated gastric fluid for $3^1/_2$ hours, and then dried to constant weight at $105 \pm 5°$. Corresponding samples not treated with the above solution but dried to constant weight at $105 \pm 5°$ served as controls. Considerable variation in tablet weight loss of both treated and control samples was observed. Results indicate, however, that not more than 3.56% tablet weight is lost as a result of the simulated gastric fluid treatment. Findings expressed as per cent weight loss of tablet material appear in Tables IV, V, and VI.

Effect of Different Solutions on Disintegration Times.—Bauer and Masucci (14) found that the disintegration of CAP coatings in the intestinal contents, which is on the acid side, is the result of the hydrolytic action of intestinal esterases and not upon the alkalinity of the solution. *In vitro* tests carried out in this study indicated that the per cent of pancreatin in the simulated intestinal fluid U.S.P. XVI had little effect upon the disintegration times of CAS or CAP coatings.

Findings suggest that if the pancreatic enzymes of the simulated intestinal fluid solubilize the coats by cleaving the ester linkages, the process is slow and overshadowed by the alkalinity of the solution. Results are given in Table VII.

In Vivo Test.[2]—Wagner (4) has pointed out that an adequate evaluation of an enteric coating necessitates both *in vitro* and *in vivo* tests. While a com-

[1] The proper humidity was maintained by placing in the bottom of a desiccator a saturated solution of ammonium sulfate containing an excess of the salt (12).

[2] We are indebted to Dr. J. H. Lawson, Consulting Radiologist, Health Center, University of Texas, for his help in evaluating the X-ray films.

plete *in vivo* study on CAS as an enteric coating was beyond the scope of this work, it was felt that a preliminary *in vivo* study on humans would be of interest to those working in the field of enteric coatings.

Two subjects were given CAS talc sc barium sulfate (20 coats) No. 1 tablets in the following manner: subject 1 fasted 6 hours before and during the experiment except for a cup of coffee at 10:00 a.m. A tablet was taken at 7:30 a.m. and again at 11:00 p.m. X-rays were taken at 11:05 a.m. and at 2:05 p.m. The radiologist's report states, "the 11:05 a.m. film shows an opacity resembling a medicinal coated tablet in the right lower quadrant which is probably in the ileum. On the 2:04 p.m. film fragmented density in the right lower quadrant indicates dissolution of the enteric coating with the material still in the ileum. A new tablet is observed in the right upper quadrant which is either in the distal end of the stomach or in the descending duodenum."

Subject 2 took food at 7:30 a.m. and at 12:15

TABLE VII.—EFFECT OF DIFFERENT SOLUTIONS ON TABLET DISINTEGRATION TIME

Tablet	Coats	Solution	Disintegration Times, min. ± S. D.[a]
CAS Talc subcoated $BaSO_4$	15	Simulated intestinal fluid U.S.P. XVI	17 ± 0.9
CAS Talc subcoated $BaSO_4$	15	Simulated intestinal fluid U.S.P. XVI less pancreatin	19 ± 0.6 14 ± 0.6
CAS Talc subcoated $BaSO_4$	15	Simulated intestinal fluid U.S.P. XVI less NaOH (pH 5.15)	No significant disintegration in 150 min.
CAP Talc subcoated $BaSO_4$	15	Simulated intestinal fluid U.S.P. XVI	28 ± 2.4
CAP Talc subcoated $BaSO_4$	15	Simulated intestinal fluid U.S.P. XVI less pancreatin	25 ± 3.8
CAP Talc subcoated $BaSO_4$	15	Simulated intestinal fluid U.S.P. XVI less NaOH	No significant disintegration in 150 min.

[a] Standard deviation of a single observation of disintegration times of six tablets.

p.m., only one tablet was taken at 8:00 a.m. X-rays were taken at 11:38 a.m. and at 2:10 p.m. The radiologist reported, "that both films show an undissolved medicinal coated tablet in the stomach."

A third subject also took food at breakfast and lunch. This subject received three CAS talc sc barium sulfate (15 coats) No. 2 tablets in the following way: one tablet was taken at 7:45 a.m., another at 10:00 a.m., and the third at 12:15 p.m. Only one X-ray was taken at 2:05 p.m. The results reported by the radiologist states, "A fairly homogeneous opaque material is noted in the caecum on the film. There is no indication of separation of the opaque material and this could be one or three tablets. There is one density at the top of the film overlying the spine which appears to be a tablet in the stomach, however, the stomach is not sufficiently included on the film for this determination to be definite."

Evaluation of Results.—Statistical evaluation of the results was performed using the *t*-test for determination of significant differences between two means. The *t* values that are greater than 95% probability *t* value at the appropriate degrees of freedom are considered significant. Results are given in Table VIII.

DISCUSSION

Generally, duplicate batches of each type of tablet were enteric coated and tested in an attempt to obtain reliable results.

Measurements of tablet thickness on the edge and side were made only for plain sodium chloride; plain barium sulfate; nonsubcoated, enteric coated sodium chloride; and nonsubcoated, enteric coated barium sulfate tablets because it was difficult to achieve satisfactory measurements with the subcoated, enteric coated tablets. Although the enteric coats of the latter tablets were quite evenly applied, the subcoats were not completely smooth. However, the weights of subcoats and enteric coats of these tablets were fairly uniform, and the tablets in general had an acceptable appearance. Overcoming the coating inconsistencies appeared to be a matter of developing a better coating technique.

While an attempt was made during the coating procedure to keep constant the volumes of enteric coating solution, the weight of dusting powder, the time between the addition of enteric coating solutions and the addition of talc, and the drying time between coats, it was noted that the movement of the tablets in the coating container had an effect upon the quantity of talc adhering to the tablets per application. When tablets were mixed frequently by hand while they were in the coating container, it appeared that less dusting powder adhered to the coatings. Two batches were rejected because it was felt they were not coated correctly. With one of these, the coatings contained some clear spots where little or no talc appeared to be present. The weight and instability of CAS talc plain barium sulfate No. 1 tablets in simulated gastric fluid appears to substantiate this observation. While this batch received the same number of coats as CAS talc plain barium sulfate No. 2, there was less enteric coating material on the tablets. A minimum amount of tablet stirring should be done during the coating procedure in order to prevent erosion of talc from the coatings. Wagner, *et al.* (4), has reported the importance of the talc concentration in three modern enteric

[a] t was calculated by $t = \frac{|X_1 - X_2|}{\sqrt{(S\bar{x}_1)^2 + (S\bar{x}_2)^2}}$ as found in Martin, E. W., and Cook, E. F., "Remington's Practice of Pharmacy," 12th ed., Mack Publishing Company, Easton, Pa., 1961, pp. 109–110.

coatings. Sheffield, *et al.* (15), also, found some differences between tablets enteric coated in small lots and those enteric coated in pilot-size batches. These differences might be reflected in the amount of extra rubbing caused by the increase in number of tablets used.

While high humidity affected most of the coatings, this problem does not appear to be a serious one. Water-proof coatings can be applied to either the plain or finished tablet without too much difficulty. A desiccant can also be packaged with the finished product.

Some test and control tablets stored in the cold and heat showed significant changes in disintegration times when compared statistically with those kept at room temperature; however, it is felt that the differences were not too serious from a practical aspect. It should be noted that some water could have come in contact with the tablets stored at $-2 \pm 2°$ for 21 days inasmuch as they were stored in open containers directly under the freezing unit of the refrigerator.

Significant differences in disintegration times in simulated intestinal fluid were observed between CAS and CAP coated tablets. These results might be due to the differences in the chemical structure

of the two coating materials. Hiatt (16) stated that those cellulose acetate phthalates having a free carboxyl content between 9 and 15% by weight are most preferable for enteric coating. The CAS used in this report had a free carboxyl content of 15% by weight.

Wagner, *et al.* (17), also reported that the minimum pH at which starch acetate phthalates dissolve depends upon the percentage of free carboxyl groups on the polymer molecule.

Our findings on the disintegration times for tablets in simulated intestinal fluid following treatment in simulated gastric fluid, as compared with disintegration times for tablets placed directly into the former solution, generally agree with data reported by Wagner, *et al.* (4). Further work on this phase of the problem will be considered at a later date.

Pancreatic enzymes may cleave the ester linkages of CAS; however, this was not demonstrated in this study chiefly because of the relatively high pH of the solutions used. Further work using buffer solutions at pH values from 1.2 to 6.9 might indicate the pH dependency and stability of CAS.

Wagner and Long (4) point out that an adequate *in vitro* comparison of two or more enteric coatings as done here with CAP and CAS requires testing the tablets coated with the enteric material at several levels. The slopes and positions of lines obtained by plotting disintegration times against mean weight of coating per tablet or mean weight of enteric substance per tablet should then be compared. These investigators also state that the amounts of enteric material and dusting powder employed are equally as important as the nature of the enteric substance when comparisons are made.

In this study the two different coatings were compared only at two levels of enteric substance; however, an attempt was made to control the amount of talc applied so that test and control tablets would receive the same amount of dusting powder per tablet. Our results, at the levels tested, showed that CAS coatings dissolved faster than CAP coatings in simulated intestinal fluid; however, it is possible in light of the work of Wagner, *et al.* (4), at higher or lower levels of coating, the reverse might take place.

Preliminary *in vivo* tests show that CAS has merit as an enteric coating. While considerable *in vivo* testing is still required before definite conclusions can be drawn, it is of interest to note that with one test subject a CAS coated tablet remained in the stomach for a period of more than 6 hours. X-ray films of two other test subjects indicated that the CAS coated tablets dissolved shortly after entering the intestines.

SUMMARY AND CONCLUSIONS

1. The preparation and testing of cellulose acetate succinate coated tablets of sodium chloride and barium sulfate are described and the statistical evaluation of the data obtained is presented.

2. Satisfactory enteric coated tablets were obtained, in most instances, when CAS, in an acetone-ethyl acetate solution, was applied by a modified "pan" method using talc as a dusting powder.

3. None of the test coatings showed signs of cracks as a result of storage at $-2 \pm 2°$ for 21 days or at $45 \pm 2°$ for 10 days; however, some test and control coatings showed differences in disintegration times in simulated intestinal fluid U.S.P. XVI when compared statistically with samples kept at room temperature.

4. CAS coatings which were stable for $3^1/_2$ hours in simulated gastric fluid dissolved sooner than control coatings of CAP applied and treated in the same manner.

5. Disintegration times are slightly lower for most tablets placed directly into simulated intestinal fluid than for tablets first treated with simulated gastric fluid for $3^1/_2$ hours and then tested in the former solution.

6. Of the tablets tested, none lost more than 3.56% tablet weight as a result of the $3^1/_2$ hours treatment in simulated gastric fluid.

7. The presence of pancreatin in the simulated intestinal fluid appeared to have little effect upon the rate at which the coatings dissolved.

8. Preliminary *in vivo* tests with human subjects indicate that CAS has merit as an enteric coating.

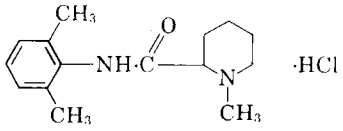
Qualitative and Quantitative Tests for Mepivacaine Hydrochloride



By M. E. AUERBACH, J. J. HEFFERREN, H. M. KOEHLER, and E. L. PRATT

A series of qualitative tests and quantitative methods are presented for mepivacaine hydrochloride. These data result from a cooperative laboratory study by research personnel of the drug firm and the American Dental Association. The methods chosen are discussed, their particular applications noted, and their limitations described.

MEPIVACAINE HYDROCHLORIDE[1] is a local anesthetic agent which is used in dentistry alone or with a vasoconstrictor such as levonordefrin (1). The chemical tests have been developed to provide data on those drugs appearing in "Accepted Dental Remedies." The limits set for these tests seem to be reasonable with expected normal analytical and manufacturing variation for mepivacaine hydrochloride and its preparations. It is to be expected that there may be or will be dosage forms of mepivacaine hydrochloride where these tests will not apply without appropriate modifications.

MEPIVACAINE HYDROCHLORIDE

1-Methyl-2,6-pipecoloxylidide hydrochloride; N-(2,6-dimethylphenyl)-1-methylpiperidine-2-carboxamide hydrochloride; $C_{15}H_{22}N_2O \cdot HCl$; mol. wt. 282.82. The structural formula of mepivacaine hydrochloride may be represented as follows

Physical Properties.—Mepivacaine hydrochloride is a white, odorless, crystalline solid, m.p. 255–262° (decompn.), U.S.P. class 1. It is freely soluble in methanol and water, very slightly soluble in chloroform, and practically insoluble in ether. The pH of a 2% aqueous solution is about 4.6.

Identity Tests.—Dissolve about 100 mg. of mepivacaine hydrochloride in 10 ml. of water and add 2 drops of nitric acid, followed by 1 ml. of silver nitrate T.S.; a white precipitate forms. This precipitate is insoluble in diluted nitric acid but soluble in diluted ammonia solution (presence of chloride).

Dissolve about 100 mg. of mepivacaine hydrochloride in 10 ml. of water, heat almost to the boiling point, and add with stirring 1 ml. of a saturated solution of picric acid in 20% alcohol. Collect the precipitate and wash with a few small portions of water and dry. The picrate melts with decomposition at 197–199°, U.S.P. class I. (Caution! Picrates may be explosive.)

Dissolve about 150 mg. of mepivacaine hydrochloride in 10 ml. of water, and transfer to a small separator. Add 10 ml. of chloroform and 3 ml. of ammonium hydroxide T.S. Shake the separator, allow the layers to separate, and carefully transfer the chloroform layer to a small flask containing 0.5 Gm. of sodium sulfate. Shake the contents until the chloroform solution is clear. Filter the solution and collect the filtrate in a small beaker. Evaporate the chloroform and dry the residue at 60° in vacuum. The yellow-white mepivacaine base melts at 149–153°, U.S.P. class I.

Absorption Characteristics.—A 0.03% solution of mepivacaine hydrochloride in water exhibits ultraviolet absorbance maxima at about 263 and 271 mμ [absorptivity (1%, 1 cm.) about 16.5 and 13.4, respectively] and minima at 254 and 270 mμ.

The infrared absorption spectrum of a 0.3% mixture of mepivacaine hydrochloride in potassium bromide, in a disk of about 0.83 mm. thickness, is shown in Fig. 1.

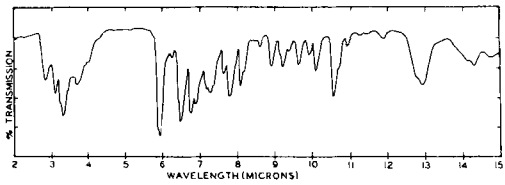


Fig. 1.—Infrared absorption of mepivacaine hydrochloride.

Purity Tests.—Dry about 1 Gm. of mepivacaine hydrochloride, accurately weighed, at 105° for 4 hours: the loss in weight does not exceed 1.0%.

Char about 1 Gm. of mepivacaine hydrochloride, accurately weighed, cool the residue, add 1 ml. of concentrated sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh. The residue does not exceed 0.1%.

Assay.—Transfer to a 200-ml. tall form beaker about 350 mg. of mepivacaine hydrochloride, ac-

Received January 8, 1962, from the Division of Chemistry, American Dental Association, Chicago, Ill., and Sterling-Winthrop Research Institute, Rensselaer, N. Y.

Accepted for publication January 17, 1962.

Analysis of Local Anesthetics VII. For the preceding paper in this series, see THIS JOURNAL, 50, 347(1961).

[1] The trade name for mepivacaine hydrochloride is Carbocaine Hydrochloride.

curately weighed. Dissolve in 50 ml. of glacial acetic acid and add 10 ml. of a 6% solution of mercuric acetate in glacial acetic acid. Titrate potentiometrically with 0.1 *N* perchloric acid in glacial acetic acid, or titrate to a green end point using 2 drops of crystal violet in glacial acetic acid as an indicator. A blank should be run on all reagents. Each milliliter of 0.1 *N* perchloric acid is equivalent to 28.28 mg. of mepivacaine hydrochloride. The amount of mepivacaine hydrochloride, $C_{15}H_{22}N_2O \cdot HCl$, is not less than 98.0 nor more than 102.0%.

MEPIVACAINE HYDROCHLORIDE AND LEVONORDEFRIN INJECTION

Identity Tests.—The solution responds to the identity tests for mepivacaine hydrochloride.

Assay.—*Mepivacaine Hydrochloride.*—Transfer to a 60-ml. separator an amount of solution, accurately measured, equivalent to about 40 mg. of mepivacaine hydrochloride. Add 8 ml. of water and 1 ml. of 1 *N* sodium hydroxide and extract the mixture with three 10-ml. portions of chloroform. Wash the combined chloroform extracts with 10 ml. of water. Filter the chloroform extracts through a tight cotton plug, using additional chloroform to complete the transfer. Titrate metachromatically to a red end point with 0.01 *N* perchloric acid in dioxane, using 2 drops of 0.1% methyl red in methanol as an indicator. Alternately, add sufficient acetonitrile to the combined, washed chloroform extracts to give a chloroform-acetonitrile ratio of about 4 to 1 and titrate potentiometrically. Each milliliter of 0.01 *N* perchloric acid is equivalent to 2.828 mg. of mepivacaine hydrochloride. The amount of mepivacaine hydrochloride, $C_{15}H_{22}N_2O \cdot HCl$, is not less than 95.0 nor more than 105.0% of the labeled amount.

Levonordefrin.—The concentration of levonordefrin may be determined using the U.S.P. colorimetric assay procedure for epinephrine (U.S.P. XVI, p. 895). When the ferro-citrate solution and the glycine-bicarbonate buffer are mixed with a solution containing levonordefrin and mepivacaine hydrochloride, a fine precipitate forms. This precipitate should be removed by centrifuging before the colorimetric measurements of the iron complex with levonordefrin at 530 mμ are taken. This precipitate does not interfere with the reaction. The amount of levonordefrin is not less than 95.0 nor more than 110.0% of the labeled amount.

DISCUSSION

U.S.P. terminology for solubility, melting points, and reagents have been used wherever feasible.

Identity Tests.—The paper chromatographic R_f values for mepivacaine hydrochloride in hydrochloric acid and acetic acid systems described by Koehler and Feldmann (2) are 0.69 and 0.81, respectively.

Mepivacaine hydrochloride readily forms a reineckate salt in aqueous solutions. Tetraphenyl borate of mepivacaine hydrochloride forms with difficulty, thus it is not included in the identity caine base reacts with cobalt chloride T.S. to give a green color and a fine precipitate (3). A negative test with Millon's mercuric nitrate reagent can be used to determine absence of local anesthetics derived from *p*-aminobenzoic acid or other compounds with a primary amino group. The diazotation reaction with sodium nitrite and hydrochloric acid followed by a coupling reaction with beta-naphthol can be used to determine the presence of any impurities which have a primary aminophenyl group.

Quantitative Methods.—Mepivacaine hydrochloride, being the hydrochloride salt of a basic cyclic tertiary amine, can be determined by a number of the usual methods such as the Kjeldahl nitrogen, volumetric, or other chloride methods, the titration in a water-alcohol or nonaqueous medium of the amine base which has been extracted from an alkaline solution, and the direct perchloric acid colorimetric or potentiometric titration of the hydrochloride salt in a mixture of glacial acetic acid and mercuric nitrate, Fig. 2. This last method does not require a standard and offers a convenient, precise (standard deviation, 0.2%) method for the determination of the active ingredient, mepivacaine hydrochloride.

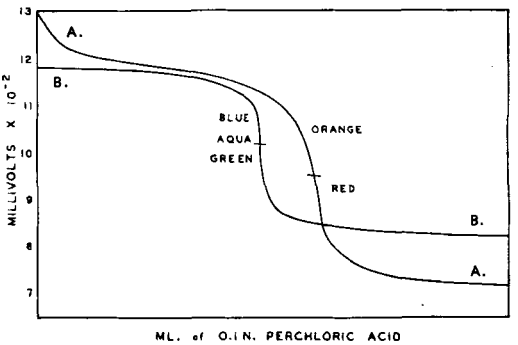

Fig. 2.—Potentiometric titration of mepivacaine base in a 4:1 mixture of chloroform-acetonitrile with 0.01 *N* perchloric acid in dioxane as a titrant and methyl red as an indicator, curve A. Potentiometric titration of mepivacaine hydrochloride in glacial acetic acid with 0.1 *N* perchloric acid in glacial acetic acid as a titrant and with mercuric acetate and crystal violet indicator added, curve B.

The common parenteral forms of mepivacaine hydrochloride used in dentistry are 1.8-ml. cartridges which contain 3% local anesthetic or 2% local anesthetic with a vasoconstrictor at a concentration of 1:20,000. For types of anesthesia other than dental, 1 and 2% mepivacaine hydrochloride solution are available in single and multiple-dose vials containing as much as 50 ml.

The ultraviolet absorption of local anesthetic solutions is frequently a convenient and accurate method of assay. While the ultraviolet absorption of mepivacaine hydrochloride is distinctive (Fig. 3), even the more intense band at 263 mμ with an $E(1\%, 1\text{ cm.})$ of 16.5 is somewhat low for assay purposes. The absorption spectrum of the base and the hydrochloride salt in methanol are essentially identical with that of the hydrochloric salt in

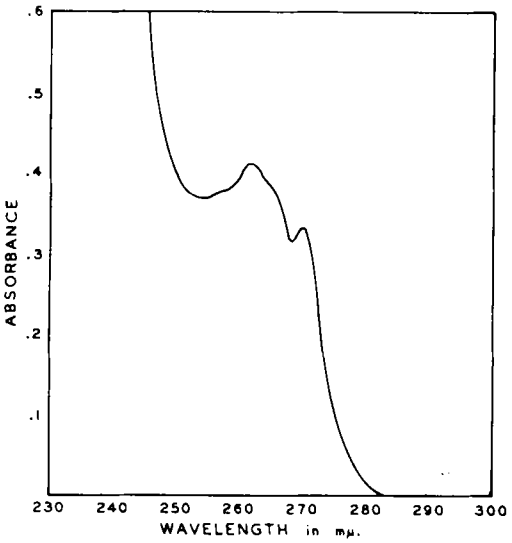

Fig. 3.—Ultraviolet absorption of mepivacaine hydrochloride in water.

The *cis*-aconitic anhydride method for tertiary amines (4) has been used successfully to determine mepivacaine hydrochloride in the usual aqueous solutions as well as blood and serum samples. Mepivacaine base has been used as a standard for this colorimetric procedure. This method may not be suitable for routine analysis, especially for the assay of the usual mepivacaine hydrochloride solutions where the advantages of this method are not fully utilized.

The mepivacaine hydrochloride in the usual local anesthetic solution can be determined gravimetrically as mepivacaine base by extraction with methylene chloride or chloroform of a solution of the hydrochloride which has been made alkaline with sodium carbonate. In such a procedure, the phenolic vasoconstrictors form water-soluble sodium salts which remain in the alkaline aqueous phase while the mepivacaine base is extracted into the organic phase.

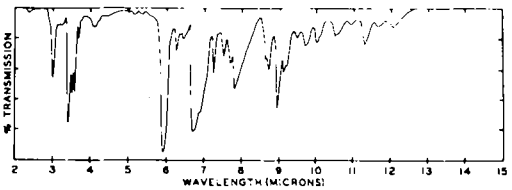

Fig. 4.—Infrared absorption of mepivacaine base in chloroform.

The mepivacaine base obtained from an extraction procedure can be determined by infrared absorption (Fig. 4). The absorption of mepivacaine base in chloroform at 5.97 μ in a 1.0-mm. sodium chloride cell obeys Beer's law in the range 0–6 mg./ml. The method involves the extraction of the base from an alkaline solution with chloroform. The chloroform extract is evaporated in a jet of warm air to less than 10 ml. and then diluted with chloroform to 10 ml. in a volumetric flask. The absorption at 5.97 μ of this solution in a 1.0-mm. cell *vs.* a chloroform-containing reference cell is compared with a standard. This standard, which is a sample of mepivacaine hydrochloride of known purity, is carried through the same procedures as the unknown. Using the baseline technique, the standard deviation of this method is 1.0%.

Mepivacaine base, subsequent to an extraction procedure, can be determined by metachromatic or potentiometric titration with 0.01 *N* perchloric acid in dioxane (Fig. 2). The direct titration of the base in the chloroform extraction solvent makes this a rapid, convenient method. The standard deviation of this titrimetric method is 1.0% and, unlike the ultraviolet and infrared methods, does not require a mepivacaine reference standard.

Gas Chromatography of Barbiturates II. Application to the Study of Their Metabolism and Excretion in Humans

By A. BAERHEIM SVENDSEN and E. BROCHMANN-HANSSEN

Five different barbiturates were administered to adult humans and their urine analyzed for the unchanged and metabolized products by gas chromatography. Barbital was easily identified in urine collected 16 days after administration. The demethylation of N-methyl substituted barbiturates could be followed. *p*-Hydroxy phenobarbital was detected by gas chromatography after administration of phenobarbital and mephobarbital.

DEVELOPMENT of new and more specific methods of analysis has repeatedly led to reinvestigation of problems associated with the metabolism and excretion of barbiturates. The earliest studies were based on gravimetric methods which, for the most part, lacked specificity and sensitivity (1–7). More recently, ultraviolet spectrophotometry has been extensively used (7–23). Occasionally, erroneous results have been reported due to the fact that the spectrophotometric method usually does not differentiate between an unchanged barbiturate and its metabolic product. Paper chromatography (24–26) and liquid-liquid partition systems (20, 27) have been used for separation of such mixtures. Gas chromatography has been shown to be a rapid and selective method for analysis of barbiturates in complex mixtures (28–30). It seemed to be of interest to study the applicability of this method to biological systems, particularly with regard to the urinary excretion of certain barbiturates and their metabolites.

EXPERIMENTAL

The experiments were carried out with adult humans. A single, therapeutic dose of the barbiturate in powder or tablet form was taken in the evening, and the urine collected the next morning and at intervals during the following 24 to 40 hours. In the case of barbital, urine samples were also collected 6 and 16 days after administration.

Purification.—The total volume collected during each time interval was acidified with dilute hydrochloric acid and extracted several times with ether. The combined ether extracts were washed with a 1% solution of sodium bicarbonate which removed much of the colored impurities. The bicarbonate wash was shaken once with a little ether, which was then combined with the total ether extract. The barbiturates were extracted from the ether solution with 0.1 *N* sodium hydroxide. Each alkaline extract was filtered through a pledget of cotton into an excess of dilute hydrochloric acid. The combined and acidified aqueous extracts were shaken several times with ether, the ether extracts dried over anhydrous sodium sulfate and evaporated to dryness in a rotating vacuum evaporator. The residue was dissolved in 1 to 5 ml. acetone, and this solution was used for analysis.

Gas Chromatographic Analysis. The instrument and experimental conditions described previously were used (30). The quantitative determinations were based on planimetric measurements of peak areas and internal standardization. Most of the work was carried out on a column containing 1.7% of neopentyl glycol sebacate on acid- and alkali-washed Chromosorb W, 60–80 mesh. However, *p*-hydroxy phenobarbital could not be eluted from this column. Apiezon L was found to be a satisfactory stationary phase for separation of phenobarbital and its *p*-hydroxy derivative.

The results are given in Tables I to V.

DISCUSSION

Although the present work is based on only a single administration of each drug, the results are in good agreement with earlier reports. Of the five barbiturates investigated, only barbital appears to be excreted quantitatively in unchanged form. Thus, following a single dose of 1500 mg., Lous (15) reported a recovery from urine of 33% after 48 hours and of 75 to 95% after 10 to 14 days. Our own work also confirms this slow elimination of barbital. Even after 16 days, detectable amounts were present in the urine.

No metabolite has ever been isolated from aprobarbital. Although Fabre (4) has reported to have recovered 46 to 90% of the dose after 6 to 10 days, more recent work (15) shows recoveries of less than 20% after 5 to 8 days. In our experiment, 8% of the dose was found unchanged after 48 hours. These low recoveries of aprobarbital would lead one to suspect that a major portion of this barbiturate may be metabolized to substances that are not detected by the methods used so far.

Butler, *et al.* (21), have shown that dogs excrete phenobarbital mainly as the *p*-hydroxy derivative. Later Curry (24, 25), Algeri and McBay (26), and Butler (20) have found that this conversion also takes place in humans, although to a lesser extent. In dogs, *p*-hydroxy phenobarbital is almost completely conjugated, mainly with glucuronic acid, while humans excrete about one-half of the metabolite in the free form, the other half as a conjugate other than the glucuronide (20). *p*-Hydroxy phenobarbital interferes with the U.V. spectrophotometric determination of phenobarbital unless a separation is carried out prior to the determination (27). By gas chromatography on a polyester column, only phenobarbital was eluted and determined. However, a column containing Apiezon L as the stationary phase (1.4% on Chromosorb W, 60–80 mesh) gave a well-defined peak for the *p*-

hydroxy derivative. At 187° the retention time was 5.5 minutes for phenobarbital and 20 minutes for the metabolite. Authentic samples of *p*-hydroxy phenobarbital isolated from dog urine[1] and synthesized according to Butler (20) were used to identify the metabolite in urine collected after administration of phenobarbital and mephobarbital. No attempts were made to determine the amounts of the *p*-hydroxy compound quantitatively. However, a visual inspection of the chromatograms showed the amounts of the unconjugated material to be smaller than those of phenobarbital.

[1] The authors are indebted to Dr. Thomas C. Butler for supplying us with a sample of this material.

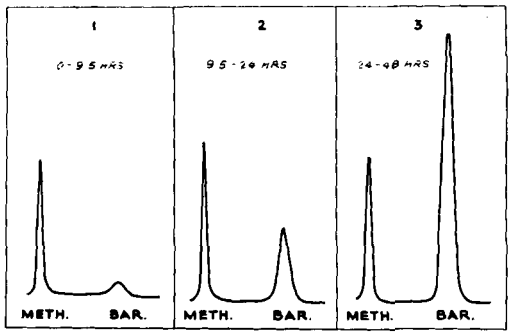

Fig. 1.—Gas chromatograms of urine extracts after administration of metharbital. METH., metharbital; BAR., barbital.

N-Methyl derivatives of barbiturates are demethylated in the body. Butler (16, 18, 22) has shown that mephobarbital is much more rapidly demethylated than metharbital. Our results confirm this (Tables II and IV, Fig. 1).

CONCLUSION

The gas chromatographic method of analysis has been found to be suitable for identification and quantitative determination of barbiturates and their metabolites excreted in the urine. Results obtained with five barbiturates are in good agreement with earlier reports.

Study of the Color Reaction of Streptomycin Sulfate with Procaine Hydrochloride

By A. V. PUCCINI and A. J. SPIEGEL

The cause of the increased color of streptomycin sulfate solution in the presence of procaine hydrochloride was studied. It was determined that the carbonyl function of the streptomycin reacted with the *p*-amino group of the procaine causing a discoloration beyond that of a normal streptomycin solution.

THE PURPOSE of this study was to investigate the cause of an increased darkening of streptomycin sulfate solution in the presence of procaine hydrochloride and to determine the functional groups responsible for this reaction.

This was of interest since procaine hydrochloride is frequently added to streptomycin sulfate solutions used for intramuscular or subcutaneous injection to alleviate pain at the injection site.

The streptomycin molecule is composed of three parts: streptidine, streptose, and N-methyl-L-glucosamine, connected to one another by glycosidic linkages (1). The presence of a reactive carbonyl group can be shown by its ability to undergo typical aldehyde reactions such as the formation of the oximes and semicarbazones (2). The preparation of biologically active N'-alkylstreptomycylamines have also been reported (3). Dihydrostreptomycin, due to the absence of this carbonyl group, is, therefore, a more stable, less reactive compound.

Streptomycin solution is subject to irreversible destruction by acid or alkali, and the rate of decomposition increases as the pH is lowered below 3.0 or elevated above 8.0. This decomposition is due to the hydrolysis of streptomycin producing streptidine and streptobiosamine (4). Streptomycin solutions normally darken upon standing. The extent and rate of color change depend in part on the purity of the preparation; however, this change in color is not necessarily accompanied by loss of activity.

EXPERIMENTAL

The streptomycin sulfate and dihydrostreptomycin sulfate used in this study were U.S.P. grade. The solutions used contained 400 mg. of antibiotic activity per ml. of an aqueous citrate solution, buffered at pH 6.0. The samples were stored at 50° in a constant temperature oven for various periods of time to accelerate reaction conditions. The absorbance was read on a Bausch and Lomb Spectronic 20 colorimeter at 450 mμ. The increase in absorbance under these conditions was a measure of the rate of color formation.

Solutions of streptomycin sulfate with procaine hydrochloride, tetracaine hydrochloride, and lidocaine hydrochloride in 2% concentrations were studied to determine their effect on the color formation of streptomycin in solution. Controls of the aforementioned compounds were also investigated. Figure 1 indicates that tetracaine hydrochloride and lidocaine hydrochloride had no effect on the color formation of streptomycin solutions. Procaine hydrochloride, however, greatly increased the color intensity of these solutions. This indicated that the primary amino group in the procaine hydrochloride molecule was the functional group involved

Received October 30, 1961, from the Pharmaceutical Research Department, Chas. Pfizer & Co., Inc., Brooklyn, N. Y.
Accepted for publication December 8, 1961.

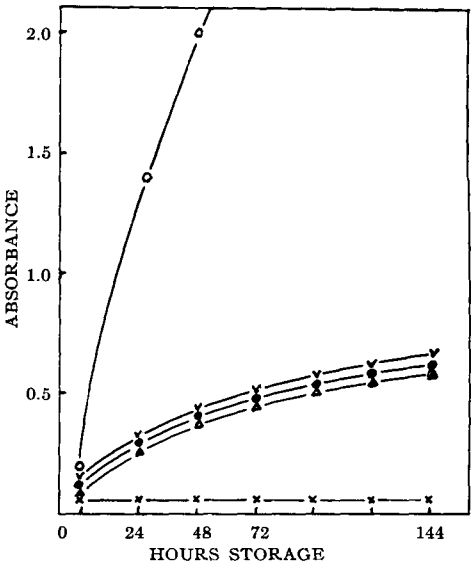

Fig. 1.—The effect of amines on streptomycin color formation. O, Streptomycin sulfate and 2% procaine hydrochloride; V, streptomycin sulfate and 2% tetracaine hydrochloride; ●, streptomycin sulfate; △, streptomycin sulfate and 2% lidocaine hydrochloride; x, 2% procaine hydrochloride, 2% tetracaine hydrochloride, and 2% lidocaine hydrochloride.

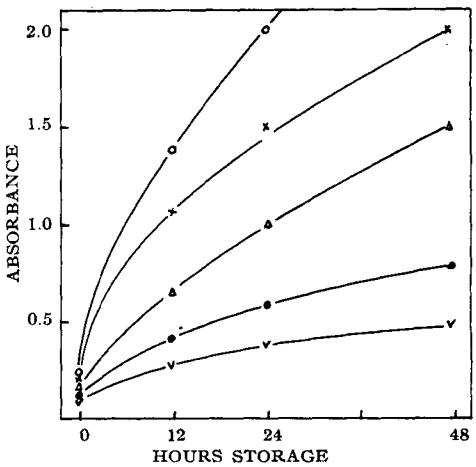

Fig. 2.—The effect of various concentrations of procaine hydrochloride on streptomycin color formation. V, Streptomycin solution; ●, streptomycin and 0.5% procaine hydrochloride; △, streptomycin and 1.0% procaine hydrochloride; x, streptomycin and 2.0% procaine hydrochloride; O, streptomycin and 4.0% procaine hydrochloride.

in this reaction. The effects of various concentrations of procaine hydrochloride on streptomycin solutions are shown in Fig. 2. The color of these solutions was intensified as the concentration of procaine hydrochloride was increased.

Since procaine hydrochloride upon hydrolysis forms *p*-aminobenzoic acid (5), solutions of streptomycin sulfate containing either 2% procaine hydrochloride or an equimolar quantity of *p*-aminobenzoic acid were comparatively evaluated. It has been reported that caffeine complexes with procaine (6) and *p*-aminobenzoic acid (7). Accordingly, the effect of caffeine on the color formation of these solutions was also investigated. The results are summarized in Fig. 3 and show that *p*-aminobenzoic acid has a more adverse effect upon the color stability of streptomycin solutions than does procaine hydrochloride. The addition of caffeine in no way affected the color formation of these solutions.

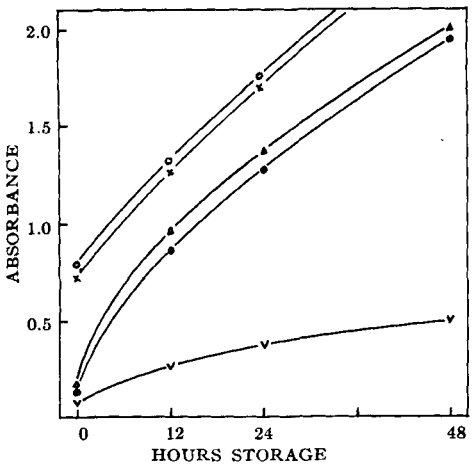

Fig. 3.—Effect of *p*-aminobenzoic acid, procaine hydrochloride, and caffeine on streptomycin color formation. ∨, Streptomycin; ●, streptomycin and 2% procaine hydrochloride; △, streptomycin, 2% procaine hydrochloride, and 2.0% caffeine; x, streptomycin and PABA; ○, streptomycin, PABA, and 2% caffeine.

To determine whether the carbonyl group of streptomycin was involved in this color reaction, dihydrostreptomycin was studied, since in this compound the carbonyl group is reduced to an alcohol. Upon the addition of procaine hydrochloride, tetracaine hydrochloride, or *p*-aminobenzoic acid to solutions of dihydrostreptomycin, no color was formed under accelerated conditions, thereby indicating that the carbonyl group of streptomycin was the active color-forming moiety involved in this reaction.

SUMMARY AND CONCLUSIONS

A study of the color reaction between procaine hydrochloride and streptomycin sulfate has shown that the darkening of this mixture beyond the normal colorless to light yellow color of a streptomycin solution was due to an interaction between the *p*-amino group of the procaine and the carbonyl group of the streptomycin. If the *p*-amino group was substituted as in the case of tetracaine hydrochloride, or absent as in lidocaine hydrochloride, or the carbonyl group reduced as in dihydrostreptomycin, this color formation did not occur under the conditions of this experiment.

The addition of caffeine in no way affected the color formation of these solutions.

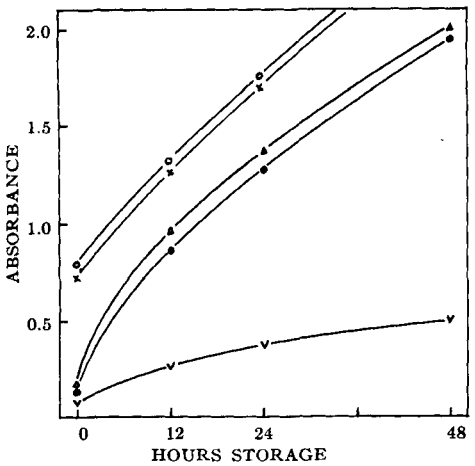

Fig. 3.—Effect of *p*-aminobenzoic acid, procaine hydrochloride, and caffeine on streptomycin color formation. ∨, Streptomycin; ●, streptomycin and 2% procaine hydrochloride; △, streptomycin, 2% procaine hydrochloride, and 2.0% caffeine; x, streptomycin and PABA; ○, streptomycin, PABA, and 2% caffeine.

To determine whether the carbonyl group of streptomycin was involved in this color reaction, dihydrostreptomycin was studied, since in this compound the carbonyl group is reduced to an alcohol. Upon the addition of procaine hydrochloride, tetracaine hydrochloride, or *p*-aminobenzoic acid to solutions of dihydrostreptomycin, no color was formed under accelerated conditions, thereby indicating that the carbonyl group of streptomycin was the active color-forming moiety involved in this reaction.

SUMMARY AND CONCLUSIONS

A study of the color reaction between procaine hydrochloride and streptomycin sulfate has shown that the darkening of this mixture beyond the normal colorless to light yellow color of a streptomycin solution was due to an interaction between the *p*-amino group of the procaine and the carbonyl group of the streptomycin. If the *p*-amino group was substituted as in the case of tetracaine hydrochloride, or absent as in lidocaine hydrochloride, or the carbonyl group reduced as in dihydrostreptomycin, this color formation did not occur under the conditions of this experiment.

Book Notices

Instrumental Methods for the Analysis of Food Additives. Edited by William H. Butz and Henry J. Noebels. Interscience Publishers Inc., 250 Fifth Ave., New York 1, N. Y., 1961. viii + 288 pp. 15 × 23 cm. Price $11.

Timely and useful information is presented in this book. The text is divided into four major parts under the headings: Introduction, Sampling and cleanup, Identification, and Analytical procedures. The introduction is a 41-page coverage of the Food Additive Petition and discussions of the Food Additive Amendment and how to operate with it. An index is included.

The Fire of Life. By Max Kleiber. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. xxii + 454 pp. 15 × 22.5 cm. Price $11.50.

An introductory textbook on animal energetics, this book aims to present the fundamental concepts (i.e., heat, latent heat, chemical energy, etc.) and their basic relationships. The book title indicates that the text is essentially limited to the classical rather than the newer aspect of metabolism and nutrition. The text is divided into six parts under the headings: Evolution of bioenergetics, Total starvation, Physical aspect of metabolism, Metabolism of the starving animal, Food as fuel, Food and population. Practice problems and an index are appended.

Carbon-14 Compounds. By John R. Catch. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1961. vii + 128 pp. 14 × 21.5 cm.

Intended as a guide to the literature and not as a practical textbook nor a comprehensive index of C^{14}-compounds, this book touches on: The production of C^{14}, Chemical synthesis, Biological methods of labeling, Peculiar features of C^{14}-compounds, Analysis, Measurement of C^{14}, and Precautions in the use of C^{14}-compounds.

in this reaction. The effects of various concentrations of procaine hydrochloride on streptomycin solutions are shown in Fig. 2. The color of these solutions was intensified as the concentration of procaine hydrochloride was increased.

Since procaine hydrochloride upon hydrolysis forms *p*-aminobenzoic acid (5), solutions of streptomycin sulfate containing either 2% procaine hydrochloride or an equimolar quantity of *p*-aminobenzoic acid were comparatively evaluated. It has been reported that caffeine complexes with procaine (6) and *p*-aminobenzoic acid (7). Accordingly, the effect of caffeine on the color formation of these solutions was also investigated. The results are summarized in Fig. 3 and show that *p*-aminobenzoic acid has a more adverse effect upon the color stability of streptomycin solutions than does procaine hydrochloride. The addition of caffeine in no way affected the color formation of these solutions.

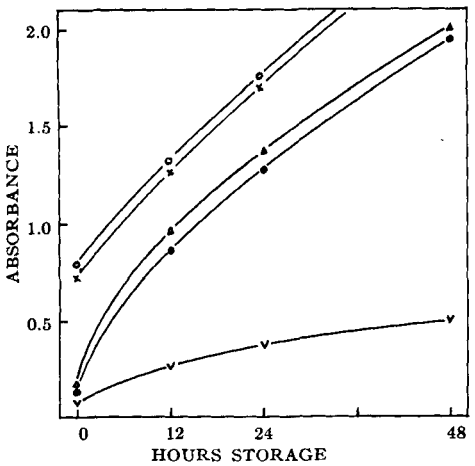

Fig. 3.—Effect of *p*-aminobenzoic acid, procaine hydrochloride, and caffeine on streptomycin color formation. ∨, Streptomycin; ●, streptomycin and 2% procaine hydrochloride; △, streptomycin, 2% procaine hydrochloride, and 2.0% caffeine; x, streptomycin and PABA; ○, streptomycin, PABA, and 2% caffeine.

Carbon-14 Compounds. By John R. Catch. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1961. vii + 128 pp. 14 × 21.5 cm.

Intended as a guide to the literature and not as a practical textbook nor a comprehensive index of C^{14}-compounds, this book touches on: The production of C^{14}, Chemical synthesis, Biological methods of labeling, Peculiar features of C^{14}-compounds, Analysis, Measurement of C^{14}, and Precautions in the use of C^{14}-compounds.

Progress in Medicinal Chemistry. Vol. 1. Edited by G. P. ELLIS and G. B. WEST. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1961. ix + 262 pp. 15.5 × 25 cm. Price $11.25.

The purpose of this new series is to present surveys of selected topics. This volume includes contributed chapters on: Pharmacological screening tests, Hypotensive agents, Tranquilizers, Diuretic drugs, Oral hypoglycemic drugs, and Antifungal agents. A general index is appended.

La Cinetica Dei Farmaci E Dei Traccianti Radioattivi. By ALDO RESCIGNO and GIORGIO SEGRE. Editore Boringhieri s.p.a., Via Broffeiro 3, Turino, Italy, 1961. 209 pp. 13.5 × 20.5 cm. Paperbound. Price L. 3,000.

Chapter headings are: Assorbimento, eliminazione e curve di distribuzione, Gli scompartimenti, Gli scompartimenti e i sistemi in equilibrio dinamico, Teoria dei modelli di sistemi a scompartimenti, Il rinnovamento, I precursori.

The Givaudan Index. 2nd ed. Givaudan-Delawanna, Inc., 321 West 44th St., New York 36, N. Y., 1961. 431 pp. 15 × 23 cm. Price $7.50.

This edition contains monographs on 288 commercially available chemicals commonly used in perfumery. In addition to the type of specifications given in the first edition, flash points and color index numbers are now included. Descriptions of analytical procedures are appended and are referred to in the individual monographs. Appended is a color classification based upon various concentrations of potassium dichromate in 2% sulfuric acid; also an index of odor types, and a classification of chemicals by functional groups. A general index is included.

Chromatography. Edited by ERICH HEFTMANN. Reinhold Publishing Corp., 430 Park Ave., New York 22, N. Y., 1961. xxv + 753 pp. 15 × 22.5 cm. Price $17.50.

Theory, techniques, and applications of chromatography and electrochromatography are presented in this reference text by authoritative contributors. The first half of the book develops the theories and techniques; the second half covers the applications to classes of compounds and is of particular value to advanced students and researchers. Specific areas treated are: adsorption, partition, ion exchange, electro-, column, slab, paper, and gas chromatography. References are given for each chapter, and author and subject indexes are appended.

Ponencias, Conferencias y Conclusiones de la la Convención Bienal de la Indústria Farmacéutica Española. Sociedad Española de Farmacotecnia, Barcelona 14, Spain, 1961. 339 pp. 17 × 24 cm. Paperbound.

The proceedings of the 1961 convention of the Sociedad Española de Farmacotecnia held in Barcelona are printed in Spanish except for two reports in French. Discussions include descriptions of the Spanish and French pharmaceutical industries, and one report (French) covers research in synthetic medicaments.

Biochemistry. 3rd ed. By ABRAHAM CANTAROW and BERNARD SCHEPARTZ. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. xxviii + 938 pp. 16 × 25 cm. Price $13.

This book is designed for use as a textbook in biochemistry for the first year medical student. It contains much recent information that would interest anyone in this and related fields. New material relates to: absorption, transport, mobilization, and intermediary metabolism of lipids; structure and biosynthesis of proteins; structure and metabolism of nucleic acids; abnormal hemoglobins; biochemical genetics; metabolic antagonism; classification and mechanism of action of enzymes; enzyme kinetics; regulation of the volume and composition of body fluid compartments; calcium homeostasis and skeletal mineralization; metabolism of steroid and adrenal medullary hormones; neurohormones; metabolism in nervous and adipose tissue.

Textbook of Physiology and Biochemistry. 5th ed. By GEORGE H. BELL, J. NORMAN DAVIDSON, and HAROLD SCARBOROUGH. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1961. xi + 1,117 pp. 16.5 × 24 cm. Price $13.50.

A comprehensive British textbook for students in the health sciences. It is liberally provided with graphs and figures as visual aids to understanding and illustrating the text. A good index is appended.

Nervous Inhibition. Edited by ERNST FLOREY. Pergamon Press Ltd., Headington Hill Hall Oxford, England, 1961. xv + 475 pp. 15 × 23 cm. Price $15.

A compilation of 31 papers presented at the May 31, 1960 symposium held at the University of Washington, Friday Harbor Laboratories. General topics covered include the development of theories of inhibition, inhibition in the mammalian spinal cord, inhibition of receptor nerve cells, nervous inhibition of endocrine systems, and presynaptic inhibition. Author and subject indexes are appended.

Hypertension—Recent Advances. Edited by ALBERT N. BREST and JOHN H. MOYER. Lea & Febiger, 600 South Washington Square, Philadelphia 6, Pa., 1961. xxi + 660 pp. 15 × 23 cm.

The papers in this compilation were presented at the second Hahnemann Symposium on Hypertensive Disease in Philadelphia, May 1961. The seven main groups include related papers on: Natural history of hypertension, Etiological mechanisms, Atherosclerosis, Pharmacology, Catecholamine metabolism and Drugs affecting it, Therapeutic considerations (22 papers in latter group). A general index is appended.

Abriss der Laboratoriumstierkunde. Edited by G. HOFFMANN. Veb Gustav Fischer Verlag, Jena, Villengang 2, Germany, 1961. xviii + 270 pp. 16.5 × 24 cm. Price DM 39.50.

This book (German) describes the various laboratory animals and gives in detail their utilization in animal experimentation.

Progress in Medicinal Chemistry. Vol. 1. Edited by G. P. ELLIS and G. B. WEST. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1961. ix + 262 pp. 15.5 × 25 cm. Price $11.25.

Abriss der Laboratoriumstierkunde. Edited by G. HOFFMANN. Veb Gustav Fischer Verlag, Jena, Villengang 2, Germany, 1961. xviii + 270 pp. 16.5 × 24 cm. Price DM 39.50.

This book (German) describes the various laboratory animals and gives in detail their utilization in animal experimentation.

Progress in Medicinal Chemistry. Vol. 1. Edited by G. P. ELLIS and G. B. WEST. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1961. ix + 262 pp. 15.5 × 25 cm. Price $11.25.

The purpose of this new series is to present surveys of selected topics. This volume includes contributed chapters on: Pharmacological screening tests, Hypotensive agents, Tranquilizers, Diuretic drugs, Oral hypoglycemic drugs, and Antifungal agents. A general index is appended.

La Cinetica Dei Farmaci E Dei Traccianti Radioattivi. By ALDO RESCIGNO and GIORGIO SEGRE. Editore Boringhieri s.p.a., Via Broffeiro 3, Turino, Italy, 1961. 209 pp. 13.5 × 20.5 cm. Paperbound. Price L. 3,000.

Chapter headings are: Assorbimento, eliminazione e curve di distribuzione, Gli scompartimenti, Gli scompartimenti e i sistemi in equilibrio dinamico, Teoria dei modelli di sistemi a scompartimenti, Il rinnovamento, I precursori.

The Givaudan Index. 2nd ed. Givaudan-Delawanna, Inc., 321 West 44th St., New York 36, N. Y., 1961. 431 pp. 15 × 23 cm. Price $7.50.

This edition contains monographs on 288 commercially available chemicals commonly used in perfumery. In addition to the type of specifications given in the first edition, flash points and color index numbers are now included. Descriptions of analytical procedures are appended and are referred to in the individual monographs. Appended is a color classification based upon various concentrations of potassium dichromate in 2% sulfuric acid; also an index of odor types, and a classification of chemicals by functional groups. A general index is included.

Chromatography. Edited by ERICH HEFTMANN. Reinhold Publishing Corp., 430 Park Ave., New York 22, N. Y., 1961. xxv + 753 pp. 15 × 22.5 cm. Price $17.50.

Theory, techniques, and applications of chromatography and electrochromatography are presented in this reference text by authoritative contributors. The first half of the book develops the theories and techniques; the second half covers the applications to classes of compounds and is of particular value to advanced students and researchers. Specific areas treated are: adsorption, partition, ion exchange, electro-, column, slab, paper, and gas chromatography. References are given for each chapter, and author and subject indexes are appended.

Ponencias, Conferencias y Conclusiones de la la Convención Bienal de la Indústria Farmacéutica Española. Sociedad Española de Farmacotecnia, Barcelona 14, Spain, 1961. 339 pp. 17 × 24 cm. Paperbound.

The proceedings of the 1961 convention of the Sociedad Española de Farmacotecnia held in Barcelona are printed in Spanish except for two reports in French. Discussions include descriptions of the Spanish and French pharmaceutical industries, and one report (French) covers research in synthetic medicaments.

Biochemistry. 3rd ed. By ABRAHAM CANTAROW and BERNARD SCHEPARTZ. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. xxviii + 938 pp. 16 × 25 cm. Price $13.

This book is designed for use as a textbook in biochemistry for the first year medical student. It contains much recent information that would interest anyone in this and related fields. New material relates to: absorption, transport, mobilization, and intermediary metabolism of lipids; structure and biosynthesis of proteins; structure and metabolism of nucleic acids; abnormal hemoglobins; biochemical genetics; metabolic antagonism; classification and mechanism of action of enzymes; enzyme kinetics; regulation of the volume and composition of body fluid compartments; calcium homeostasis and skeletal mineralization; metabolism of steroid and adrenal medullary hormones; neurohormones; metabolism in nervous and adipose tissue.

Textbook of Physiology and Biochemistry. 5th ed. By GEORGE H. BELL, J. NORMAN DAVIDSON, and HAROLD SCARBOROUGH. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1961. xi + 1,117 pp. 16.5 × 24 cm. Price $13.50.

A comprehensive British textbook for students in the health sciences. It is liberally provided with graphs and figures as visual aids to understanding and illustrating the text. A good index is appended.

Nervous Inhibition. Edited by ERNST FLOREY. Pergamon Press Ltd., Headington Hill Hall Oxford, England, 1961. xv + 475 pp. 15 × 23 cm. Price $15.

A compilation of 31 papers presented at the May 31, 1960 symposium held at the University of Washington, Friday Harbor Laboratories. General topics covered include the development of theories of inhibition, inhibition in the mammalian spinal cord, inhibition of receptor nerve cells, nervous inhibition of endocrine systems, and presynaptic inhibition. Author and subject indexes are appended.

Hypertension—Recent Advances. Edited by ALBERT N. BREST and JOHN H. MOYER. Lea & Febiger, 600 South Washington Square, Philadelphia 6, Pa., 1961. xxi + 660 pp. 15 × 23 cm.

The papers in this compilation were presented at the second Hahnemann Symposium on Hypertensive Disease in Philadelphia, May 1961. The seven main groups include related papers on: Natural history of hypertension, Etiological mechanisms, Atherosclerosis, Pharmacology, Catecholamine metabolism and Drugs affecting it, Therapeutic considerations (22 papers in latter group). A general index is appended.

Abriss der Laboratoriumstierkunde. Edited by G. HOFFMANN. Veb Gustav Fischer Verlag, Jena, Villengang 2, Germany, 1961. xviii + 270 pp. 16.5 × 24 cm. Price DM 39.50.

Discussions include descriptions of the Spanish and French pharmaceutical industries, and one report (French) covers research in synthetic medicaments.

Biochemistry. 3rd ed. By ABRAHAM CANTAROW and BERNARD SCHEPARTZ. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. xxviii + 938 pp. 16 × 25 cm. Price $13.

This book is designed for use as a textbook in biochemistry for the first year medical student. It contains much recent information that would interest anyone in this and related fields. New material relates to: absorption, transport, mobilization, and intermediary metabolism of lipids; structure and biosynthesis of proteins; structure and metabolism of nucleic acids; abnormal hemoglobins; biochemical genetics; metabolic antagonism; classification and mechanism of action of enzymes; enzyme kinetics; regulation of the volume and composition of body fluid compartments; calcium homeostasis and skeletal mineralization; metabolism of steroid and adrenal medullary hormones; neurohormones; metabolism in nervous and adipose tissue.

Textbook of Physiology and Biochemistry. 5th ed. By GEORGE H. BELL, J. NORMAN DAVIDSON, and HAROLD SCARBOROUGH. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1961. xi + 1,117 pp. 16.5 × 24 cm. Price $13.50.

A comprehensive British textbook for students in the health sciences. It is liberally provided with graphs and figures as visual aids to understanding and illustrating the text. A good index is appended.

Nervous Inhibition. Edited by ERNST FLOREY. Pergamon Press Ltd., Headington Hill Hall Oxford, England, 1961. xv + 475 pp. 15 × 23 cm. Price $15.

A compilation of 31 papers presented at the May 31, 1960 symposium held at the University of Washington, Friday Harbor Laboratories. General topics covered include the development of theories of inhibition, inhibition in the mammalian spinal cord, inhibition of receptor nerve cells, nervous inhibition of endocrine systems, and presynaptic inhibition. Author and subject indexes are appended.

Hypertension—Recent Advances. Edited by ALBERT N. BREST and JOHN H. MOYER. Lea & Febiger, 600 South Washington Square, Philadelphia 6, Pa., 1961. xxi + 660 pp. 15 × 23 cm.

The papers in this compilation were presented at the second Hahnemann Symposium on Hypertensive Disease in Philadelphia, May 1961. The seven main groups include related papers on: Natural history of hypertension, Etiological mechanisms, Atherosclerosis, Pharmacology, Catecholamine metabolism and Drugs affecting it, Therapeutic considerations (22 papers in latter group). A general index is appended.

Abriss der Laboratoriumstierkunde. Edited by G. HOFFMANN. Veb Gustav Fischer Verlag, Jena, Villengang 2, Germany, 1961. xviii + 270 pp. 16.5 × 24 cm. Price DM 39.50.

This book (German) describes the various laboratory animals and gives in detail their utilization in animal experimentation.

Review Article

Crystallography. Part I

By JOHN A. BILES

"The impossible we do at once—miracles take a little longer." (1)

INTRODUCTION

WILLIAM H. WERKMEISTER, a philosopher, once compared the advances of the sciences with those of the humanities (2). He showed that advances in travel could be illustrated by plotting velocity of travel by man or machine with date of discovery. The resulting plot was roughly exponential. The advances in the humanities with time, he suggested, would represent a zig-zag line which does not show the long range upswing. Since the discovery of crystallography, advances with time would fit the exponential-type curve. With little or no imagination, one concludes that X-ray crystallographers in the near future will be performing routine studies in structural analysis without the use of chemical properties. With increasing effort they will help to predict or substantiate hypotheses in reaction mechanisms. They have already helped to solve the riddle of life; scientists recognize the worth of the crystallographer when discussing RNA and DNA. X-ray crystallographers, through their reports, will allow scientists to utilize imaginations with increasing tempo. It is little wonder then that Grenville-Wells reminded the readers of the optimistic advertisement quoted above (1).

Cannon recorded a discussion with Gamgee, a British biological chemist who visited Cannon's laboratories at Harvard University at the turn of the century (3). After Cannon apologized for the physical facilities, Gamgee responded, "I have never noticed that the nature of the cage determined the singing of the bird." Today, the pharmaceutical crystallographer has been termed a "rare bird" (4), but this bird is the first to admit that the cage is important. The refinement of methods and X-ray equipment and the development of computors have contributed to a most rapid advance.

Crystallography was first developed as a branch of mineralogy. It was concerned with the study of three-dimensional bodies and the laws which governed their growth, shape, and geometric character. Crystallography soon reached such proportions that it became a separate science. To review crystallography in total would require volumes. Faced with this dilemma, the reviewer took the easy way out by limiting the pages of words to some aspects of X-ray and optical crystallography. To review just two of the total number of different phases of crystallography and application to pharmaceutical research does not allow one to conclude that there are but two important phases—it just provides an opportunity for other experts to write review articles.

Received from the University of Southern California, Los Angeles 7.

The author wishes to express his appreciation for the assistance offered by J. W. Shell, T. Higuchi, W. I. Higuchi, and J. G. Wagner.

Editor's note: Other important aspects of crystallography, including optical crystallography and crystalline properties, will be discussed by Dr. Biles in Part II of this review which will appear in the July issue of THIS JOURNAL.

NOMENCLATURE

An ideal crystal is a regular polyhedral solid bounded by plane faces which represents an extended array of atoms arranged in a definite order in all directions. This body contains a unit cell or unit of structure, repetition of which, in three dimensions, produces the crystal. Each unit cell is the same size for the specific crystal and contains the same number of particles similarly arranged. Even though size and shape of such a crystal may vary, the angles between the faces will remain constant. At times many of the crystal faces may not be evident, but there still remains an orderly internal arrangement of the atoms. A measurement of the interfacial angles reveals a number of faces of the same type. Faces of the same type are referred to as a form. In some instances, one form is all that is needed to define the three-dimensional solid. In other instances and at times demanded, two or more forms are present. The crystals of a given substance may vary in size, relative development of given faces, and the number and kind of faces or forms present. Crystals showing such variations have different habits. Thus, some crystals are described as needles, others are tabular, equant, columnar, or lamellar. The habit acquired depends upon the solvent used, the temperature, concentration, impurities, and the rate of precipitation.

The crystal faces are identified using Miller indexes. These indexes consist of a series of whole numbers which have been derived from the parameters by their inversion and, if necessary, the subsequent clearing of fractions. The numbers are so given so that the three numbers refer to the *a*, *b*, and *c* crystallographic axes, respectively. The possible faces from various planes of molecules or atoms, as identified by the Miller indexes may be illustrated by either two- or three-dimensional figures. Imagine looking down the *c* axis of a crystal and at the *a-b* plane of the crystal. Some different crystal faces which parallel and do not intersect the *c* axis are identified by Miller indexes, as shown in Fig. 1.

Crystal faces intersect at definite angles to each other and the faces of the crystal parallel the internal planes of the crystal. Thus, one may compare Fig. 1 with the observation of the density of trees in the various rows of trees in a fruit orchard. The next time you are driving down the highway and pass a fruit orchard, try to visualize the different planes and guess the Miller indexes for each of the rows. Perhaps, though, it would be simpler to consider the

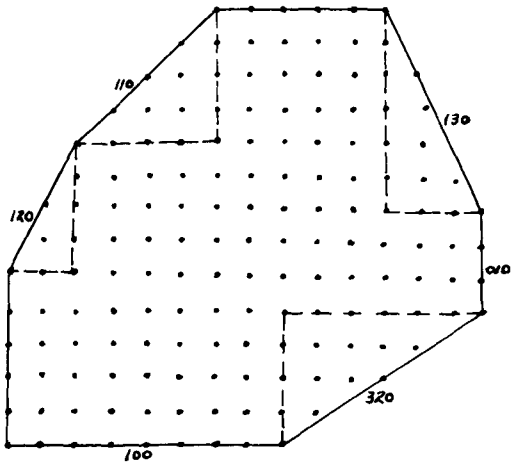

Fig. 1—A cross section of a crystal perpendicular to the *c* axis.

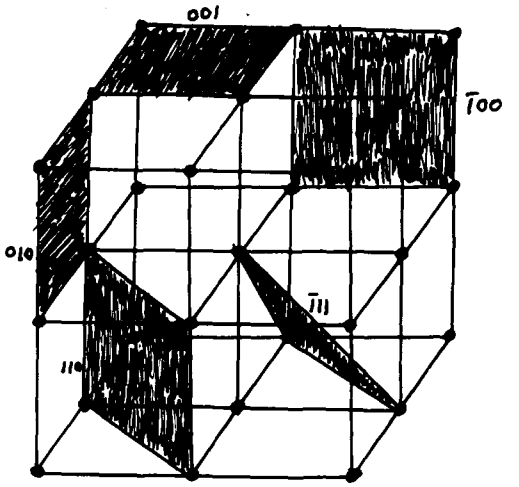

Fig. 2—Some possible crystal faces of the sodium chloride crystal.

structure of the sodium chloride crystal in which one sodium ion is surrounded by six chloride ions, and each chloride ion surrounded by six sodium ions. The possible faces could be identified by the three-dimensional diagram illustrated in Fig. 2.

Examining Fig. 2, it is observed that there is a perfectly regular arrangement of the cations and anions. The three-dimensional network of sodium ions represents the space lattice of the sodium ions in the crystal of sodium chloride. Similarly, there is a space lattice of chloride ions. The space lattice of sodium chloride represents the interpenetration of the sodium and chloride lattices. Each ion in the lattice has exactly the same environment as any other point representing the same ion. The space lattice of the crystal is built up of a three-dimensional basic pattern

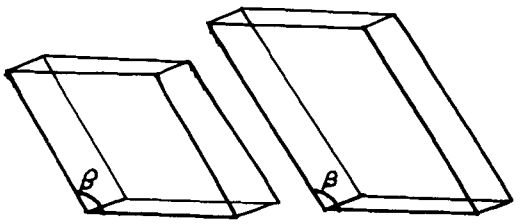
which is called the unit cell. The external appearance of the crystal is determined by the shape and dimensions of the unit cell.

By the application of geometry, it has been shown that only 14 different kinds of simple space lattices are possible. That is, there are only 14 ways in which similar points can be arranged in a regular three-dimensional order. By taking combinations of the various lattices that are possible for each crystallographic system, there have been built up 230 different space groups. The space-group symbols and the procedure for deducing the space groups are described in crystallography textbooks (5). For purposes of review, most of the readers recall that crystals vary in their angular relationships and symmetry. On this basis, a crystal is classified into one of six crystal systems. Each system is defined in terms of the crystallographic axes, which are imaginary lines used to describe the position of the plane faces in space. The systems, depending on the symmetry, are subdivided into 32 classes.

X-RAY CRYSTALLOGRAPHY

The increasing importance of this science can be felt by reading the excellent reviews. One could read the fascinating reports of molecules in crystals (6), the motion of the atoms in crystals (6, 33), crystallographic studies of compounds of biological interest (34, 35), the application of crystallography to chemistry (36), the use of X-ray crystallography in the pharmaceutical industry (37, 38), and British achievements in X-ray crystallography (39). Should the scientist become a convert to this science, in a few sentences Lonsdale could tell him the required background (40). If a few hundred pages are necessary to convert the scientist, then out of the many excellent textbooks written, the books of Bunn (41) and Robertson (42) would prove interesting material.

The Unit Cell



The arrangement of the molecules in the space lattice and the relationship of the molecules to the crystal shape was predicted before the use of X-ray procedures. Hodgkin (6) and Robertson (7) have called attention to the observations of Hooke in 1664. Hooke noted the crystal shape of alum. He considered that the shape resulted from "three or four several positions or postures of globular particles . . . by these kinds of texture or position of globular bodies, may you find out all the variety of regular shapes into which the smooth surfaces of Alum are form'd. . . nor does it hold in superficies but in solidity also, for it's obvious that a fourth Globule laid upon the third in this texture, composes a regular Tetrahedron, which is a very usual Figure of the Crystals of Alum."

By X-ray analysis, it has been determined that each unit cell contains four aluminum ions, four potassium ions, 48 water molecules, and eight sulfate ions. Hodgkin commented that, remarkably enough, the relative positions of the positive ions in the crystal conform with Hooke's suggestions but, in total, the structure of alum is considerably more complicated than Hooke's drawings propose (6).

One of the first insights into the unit cell structure was presented by W. H. Bragg when he measured the unit cells of naphthalene and anthracene (8). The measurements were also reported by Robertson in 1933 (9, 10). The cell dimensions for the two compounds are shown in Table I and Fig. 3.

TABLE I.—UNIT CELL DIMENSIONS OF SOME AROMATIC HYDROCARBONS

	a, Å.	*b*, Å.	*c*, Å.	*β*
Naphthalene	8.34	6.05	8.69	122°49′
Anthracene	8.58	6.02	11.18	125°
Diphenyl	8.22	5.69	9.5	94.8°
p-Diphenylbenzene	8.08	5.60	13.59	91.9°
p-Diphenyl-diphenyl	8.05	5.55	17.81	95.8°

(A) (B)

Fig. 3—The unit cell dimensions for naphthalene (A) and anthracene (B).

It should be noted that two sides of the unit cells in Fig. 3 are almost the same distance. Also the angle beta (obtuse angle) for both cells are very close. The two cells differ with respect to the *c* axis, which is 2.49 Å. longer in anthracene than in naphthalene. It may be recalled that the diameter of the benzene ring is almost this distance (8).

The unit cell dimensions have also been determined for diphenyl (11), *p*-diphenylbenzene (12), and *p*-diphenyldiphenyl (13). The unit cell dimensions for these compounds are also listed in Table I. Again two sides of the cells are very similar (also similar to those of naphthalene and

anthracene); the angle beta for the three compounds are similar, but the difference lies along *c*. The bond distance between the benzene rings was found to be 1.48 Å. Adding the 1.48 Å. to the 2.49 Å., the sum is found to be approximately the same value as the differences between the values along *c*.

The unit cell dimensions of long chain organic compounds have been the subject of discussion for approximately 30 years. Francis, Collins, and Piper (14) determined the unit cell dimensions for a number of saturated fatty acids, alcohols, alkyl iodides, and ethyl esters, as well as some dicarboxylic acids. A definite correlation was obtained when the molecular weight of the compounds of each of the homologous series was plotted against the melting point. A straight line relationship was also obtained when the crystal spacings were plotted against the carbon content. Francis, *et al.*, reported that when the fatty acids containing the even numbered carbon atoms were crystallized from glacial acetic acid, C-type crystals were obtained. The specific spacings were noted. When the same fatty acids were crystallized from either benzene or acetone, different spacings were noted. These were referred to as B crystals. When the fatty acids containing odd numbered carbon atoms were crystallized from glacial acetic acid, acetone, or benzene, only spacings corresponding to B crystals were observed. Abrahamsson and von Sydow (15) reported the variation of unit cell dimensions of long chain fatty acids of form C. For the acids with 12, 14, 18, 22, and 26 carbon atoms, it was found that all dimensions in the monoclinic cell were found to be dependent on the number of carbon atoms in the chain. The *a* and *b* axes and angle beta decreased asymptotically with increasing chain length. The *c* axis and long spacings, *d* (001), obeyed linear laws.

Warren and Matthews (16) noted the straight line relationship of *d* spacings and molecular weight for alcohol derivatives of the xanthates. They used the strong inner line as the *d* distance of choice. They also investigated the unit cell dimensions of the anilides of acids from formic acid through stearic acid (17). The patterns of the even members of series C_8 to C_{18} show a marked similarity, suggesting a uniformity of crystal structure which may be described as isostructural. Their results were in agreement with Slagle and Ott (18). Matthews, Warren, and Michell continued this line of investigation (19). When the first-order reflections of the silver salts of fatty acids were plotted against the number of carbon atoms in the fatty acid, a straight line was obtained. The equation was determined to be

$$X = 9.85 + 2.44\,(y - 2) \qquad \text{(Eq. 1)}$$

The value of 2.44 represented the increment of the —CH_2 group, and the value of 9.85 represented the combined value for the —CH_3 and —COOAg group. Similarly, in a study of the amides of the fatty acids, the straight line relationship of the first-order reflection was given by

$$X = 6.25 + 1.85\,(y - 2) \qquad \text{(Eq. 2)}$$

The value of 1.85 for the amides represented the increment for the —CH_2 group.

Merritt and co-workers identified alkyl halides as the alkyl 6-nitrobenzothiazolyl-2-sulfides and sulfones (20). Their differentiation of the halides was made by observation of the three strongest reflection lines. Wurz and Sharpless studied the amides of saturated aliphatic acids (21). A straight line relationship was correlated for the odd and even series. The line for the even series had a greater *y* intercept than that for the odd series. Garska, *et al.*, recently reported that when the fatty alcohol could not be identified with gas chromatography or mass spectrometry, the alcohol benzoate could be prepared and X-ray analysis performed (22). They too reported an apparent correlation existing between length of the carbon chain attached to the 3,5-dinitrobenzoate radical and the size of the largest *d* spacing in the diffraction pattern of the ester.

Sharma and Biswas reported the X-ray diffraction study of *n*-alkyl malonic acids (23). The melting points of the acids and the characteristic long spacings were recorded. Their work is quite similar to those reported by Francis, *et al.* (14). The saw tooth arrangement of the melting points and long spacings for the odd and even membered series was reported. The spacings in the alkyl fatty acids corresponding to the length of the molecules suggest that the molecules are interlinked as dimers. Sharma and Biswas reported that such spacings in the alkyl malonic acids were approximately equal to the calculated extended length of a single molecule. They suggested that the alkyl malonic acids existed as a single unit, presumably due to internal saturation through intramolecular hydrogen bonding. Additional reports on relationships between the unit cell dimensions and chain length include those of Brock and Hannum (24), Lutz and co-workers (25), Guertin, *et al.* (26), and W. S. Singleton (27).

Pharmaceutical scientists could very well apply the knowledge obtained from unit cell dimensions. Such data can be used for purposes of

identification. The crystallographer may compare his diffraction pattern with the values in the A.S.T.M. file (28). In one of the laboratories it was reported that one of the liquid multivitamin preparations produced had a wine base as a major constituent. Upon changing the source of supply for the wine, a precipitate began to appear in the finished product. X-ray patterns were taken of the precipitate and checked against an A.S.T.M. file. The precipitate was identified as calcium tartrate tetrahydrate (29). Purity determinations can be determined. Concentration and stability has been suggested for suspensions (30). Shell states, since the crystalline material has a definite size unit cell, that this fact can be used as a general quantitative method of analysis which offers a combination of specificity and precision. The completeness or progress of a chemical reaction could be followed by X-ray diffraction methods since the unit cell dimensions of the product would, in all probability, be different from those of the reactants (31).

Mott has discussed the role of vacant lattice sites in crystalline solids. He believes that the vacant lattice site allows the diffusion in solids, and particularly when two metals are welded together. During the welding, a region intermediate between the two metals is formed which is occupied by an alloy of the two. Diffusion has taken place, which means that two adjacent atoms in a crystalline solid are able to change places if the temperature is high enough. This exchange can come about only with the help of a vacant lattice site. It was also expressed that vacancies play a role in metallic fatigue (32).

X-Ray Diffraction

In 1949, Kaufman and Fankuchen, reviewing the reports on X-ray diffraction, stated that in a matter of 10 to 15 years diffraction had been established as a most useful tool for analytical purposes. The tool was not self-sufficient; it was incapable by itself of replacing chemical analysis; but it had proved useful for identification of crystalline substances (43). Later reviews were written by Fankuchen, Kaufman, and Post (44–47). Post and Fankuchen also reported on low temperature X-ray crystallography (48). In 1936 there was concern about the filing of diffraction data. Hanawalt and Rinn suggested an effective use of a large library of standard X-ray diffraction patterns for the identification of unknowns (49). In 1938 Hanawalt, *et al.*, published information concerning classification and use of diffraction patterns. They included data on 1000 compounds (50). Frevel, Rinn, and Anderson then tabulated the diffraction data for 705 cubic substances (51), 447 tetragonal substances (52), and 1287 hexagonal substances (53). Matthews (54) recommended the use of a punched card system, and Ashley and Newton (55) suggested the use of a Kardex system. The American Society of Testing Materials (A.S.T.M.) card index file of X-ray diffraction data is widely used (56). Recently, Beukelman discussed the efficient use of an I.B.M. file of A.S.T.M. powder X-ray diffraction data (57). The literature sources for the X-ray diffraction patterns for different series of compounds of pharmaceutical interest are listed in Table II.

TABLE II.—REFERENCES TO X-RAY DIFFRACTION PATTERNS OF COMPOUNDS OF POSSIBLE PHARMACEUTICAL INTEREST

Compound Type	Compound Type
Aromatic hydrocarbons (58)	Azoic coupling components (77)
Aromatic hydrocarbons-trinitrofluorenone (59)	Cobalt ammine azides (78)
Alkyl halides (20)	Guanidine derivatives (79)
Aldehydes and ketones (60)	Explosives (80)
Surface-active agents (61)	Penicillins (81)
Fatty acids (27, 62)	Dyestuffs (82)
Fatty acid silver salts (26)	Barbiturates (83–85)
Aliphatic acid amines (21)	Sedatives and anticonvulsants (86)
Alkyl dithiol esters of sebacic acid (25)	Boron compounds (87)
Alcohol benzoate esters (22)	Phosphorous nitrogen compounds (88)
Substituted benzoic acids (63)	Sodium phosphates (89)
Aliphatic and aromatic amines (64)	Calcium phosphates (90)
Sterols and their digitonides (65, 66)	Strontium phosphates (91)
Steroids (67–70)	Crystalline ferrocenes (92)
Fructose dinitrophenylhydrazone (71, 72)	Copper chelates (93)
Phenols (73, 74)	Porphyrins (94)
Tetrazole derivatives (75)	Alcohols (95)
Oxadiazoles (76)	Bacterial viruses (117)

Some comments concerning the reports listed in Table II are warranted. Hofer and Peebles (58) reported that impurities lowering the melting point of the hydrocarbons as much as 15° did not modify the diffraction patterns appreciably. Rose and Van Camp (63) showed that benzoic acid derivatives having the same empirical formulas and same melting points could be differentiated with X-ray diffraction. Gaebler, Parsons, and Beher (65) detected differences in the X-ray diffraction analysis of digitonin polymorphs, whereas the infrared spectra of the samples used were virtually identical below 9.2 and above 9.7 μ. In the second study, Beher and co-workers reported that X-ray diffraction definitely established sterol digitonides as chemical com-

pounds, whereas infrared analysis did not distinguish between a simple mixture and a corresponding digitonide. Baker, Beher, and Parsons (67–70) reported the diffraction patterns for 138 steroids. Moore and Burkardt (75) stated that failure of X-ray patterns of the same compound to correlate may arise from polymorphism or preferential orientation of sample particles. In the reporting of the *d* distances for the various barbiturates, Williams (83) criticized the values reported by Penprase and Biles (84). Williams was justified in so doing if the *d* distances are required for pure solids, or for inclusion in the A.S.T.M. file. However, the report of Penprase dealt with a rapid identification of barbiturates using specific methods. With such methods polymorphism is evident and is, in fact, an aid for rapid identification. North and Rich (117) examined the T2 virus which has a very substantial tail structure and the T7 virus which has a small tail. Experiments suggested that some of the DNA inside the bacteriophage T2 virus head is oriented parallel to the tail. Furthermore, evidence suggested that the DNA may be organized into crystalline domains about 140 Å. across in T2 and 120 Å. in T7. The reports of the diffraction patterns of the various phosphates are indicative of the complexity of phosphate chemistry (89–91). The diffraction patterns of the calcium phosphates and strontium phosphates can undoubtedly be utilized in the study of strontium deposition in the bone. The review of the X-ray work of the fatty acids by O'Connor should be considered a masterpiece considering the complexity of the subject (62).

Quantitative Diffraction Method

Space will not permit the discussion of the use of X-ray diffraction analysis in a number of different analytical techniques. These techniques include emission spectroscopy (96–102), absorption (103, 104, 108), analysis combining absorption and diffraction (105), photoelectron spectra for surface analysis (106), low angle scattering analysis of particle size (107), and scattering methods (109,110). The selected references listed above are offered as a substitute for a discussion.

Single Crystal Analysis

Kaufman and Fankuchen (43) stated that single crystal diagrams may give more information than powder diagrams. In addition to a set of *d* spacings, one can obtain the unit cell size rather simply and, from a consideration of the systematic extinction, determine the space group. Bunn (41) has stated that the unit cell dimensions can be determined from powder diffraction data for the crystals of high symmetry. However, it is quite difficult to determine the unit cells from powder data for crystals of low symmetry. Nevertheless, Azaroff and Buerger have made available directions for the determination of unit cell dimensions from powder diagrams (111). This text is written in a manner which is easily understood. There are limitations in determining the unit cell dimensions. These limitations depend on the amount of data collected, particularly for a series of compounds. Examination of Table I will indicate the limitations and the value obtained from the unit cell determinations. Structural analysis is both much more complex and much more revealing.

Single crystal analysis is of great value in the determination of molecular weight. Douglass and Cook (112) reported that there was a question whether the lycoctonine monohydrate was represented by the empirical formula of $C_{25}H_{40}NO_7 \cdot H_2O$ or twice this value. The molecular weight determination by single crystal analysis was used to clarify the mystery. Straumanis (113) reported that the molecular weight determination by X-ray analysis may surpass the accuracy values obtained by chemical methods. The molecular weight of beta-lactoglobulin was determined by X-ray (114). Crystallographers in the pharmaceutical industry have been called upon to determine molecular weights by X-ray single crystal analysis (115, 116). Shell has described a method which requires a relatively small investment of time, yet with errors usually no greater than one hydrogen atom (116).

Structural Analysis

With continued refinement of methods used in the study of structural analysis, compounds have been restudied. It has become common in the past few years to calculate the electron density in crystals in three dimensions. With this study, the positions and modes of vibration of the atoms in the crystal may be studied (6). Cox, *et al.*, in a series of papers, studied the crystal structure of benzene (118–120). The positions of the hydrogens were determined and it was reported that the benzene molecule, as a whole, was oscillating with a root mean square amplitude of approximately 7.9° about the sixfold axis. Such a movement is allowed by the nondirected character of the intermolecular forces and the cog-wheel packing of the molecules in the crystal (6). The crystal structures of 3,4-benzpyrene (121) and 9,10-dimethyl-1,2-benzanthracene (122) were studied. Both molecules were found not to be planar. It was found that two ab-

normally short bonds and one very long bond were present in 3,4-benzpyrene. In 9,10-dimethyl-1,2-benzanthracene, ring D was found to be bent down out of the general plane by about 20° and atom C_{15} up by about 12°. On the other hand, in a study of the crystal structure of 1,2-benzanthracene, the molecule was found to be planar within experimental error (123). Perhaps a relationship can be established from X-ray analysis concerning carcinogenic activity of these type compounds.

Aromatic hydrocarbon complexes have been studied (59, 124–127). Aromatic nitro compounds have been found to complex with hydrocarbons. The stability of the complex has been ascribed to "polarization bonding" (125) between components. The complexation of 1,3,7,9-tetramethyl uric acid, T.M.U.A., and pyrene has been studied by De Santis and co-workers. The T.M.U.A. solubilizes polycyclic aromatic hydrocarbons in water to form 1:1 and 1:2 crystalline complexes from organic solvents. It was found that the T.M.U.A. molecules in pure form in the crystal state stack up with alternate molecules similarly arranged. Neighboring molecules are not mirrored but rotated 180° with respect to each other. When a 1:1 complex of T.M.U.A. and pyrene crystallized out, the molecules were found to be stacked in alternating fashion. Every other molecule in a stack was a T.M.U.A. molecule. The orientation of these molecules was similar. A 1:2 complex has been isolated. The author would anticipate that the arrangement in the crystal will be a 1:2:1:2 arrangement. Of course it would be interesting to see if a 1:3 complex and a 2:3 complex could be isolated.

De Santis (127), *et al.*, suggested, that in the T.M.U.A. crystal the second molecule paired was rotated from the other molecule by 180° since the $\overset{+}{N}—\overset{-}{O}$ bonds (dipoles) are roughly perpendicular to the long axis of the molecules and that interaction between dipoles is the main factor responsible for pairing. Thus dipole-dipole interaction may predominate over the hydrogen bonds. When a methyl or a keto group is attached to the nitrogen, the dipole bond is weakened. The report of Sutor (128, 129) may be related to this discussion. It was found by Sutor that caffeine and theophylline molecules pair up in the same plane. The paired molecules are illustrated in Fig. 4. The arrows identify the dipoles.

Since the methyl group on the nitrogen reduces the strength of the dipole, and since the unit cell of caffeine is slightly greater in volume than that of theophylline, the greater solubility in water

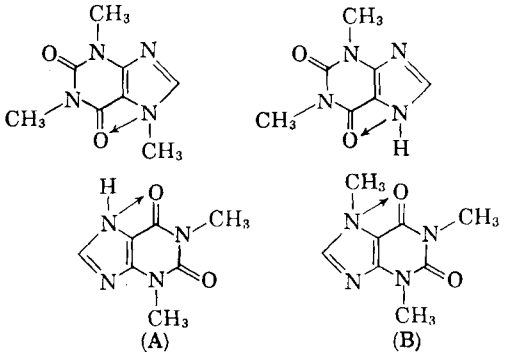


Fig. 4—The paired molecules of theophylline (A) and caffeine (B).

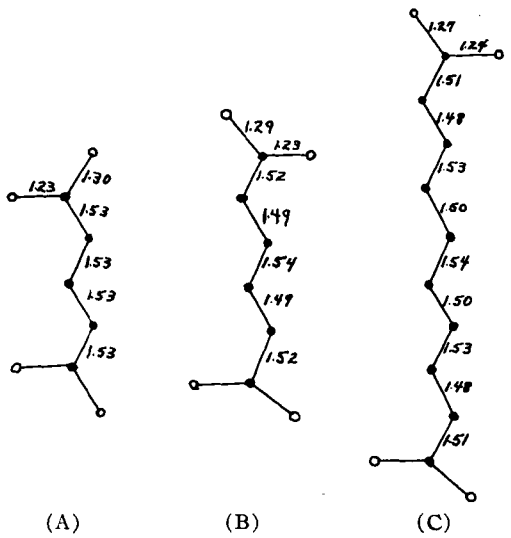

and lower melting point of caffeine, in comparison to theophylline, is better appreciated. Sutor points out that the disordering of the molecules along the *c* (of the unit cell) is the difference in the strength in which water is held. Theophylline does not effloresce even though there are chains of water molecules running through the structure. If the water molecules are disordered in their arrangement along *c*, only a fraction of them would be hydrogen bonded to the caffeine molecule. Thus, water is more firmly linked to a theophylline molecule. Gerdil and Marsh suggested an alternate proposal for the placement of water in the caffeine structure (130). With the information proposed concerning the relative positions of the molecules of caffeine and theophylline and the effect of the dipoles, the reader might want to make a comparison with the study of caffeine complexation by the Higuchi group (131–135).

The crystal structures of uracil (136), adenine hydrochloride (137), guanine hydrochloride (139), and thymine monohydrate (138) have been reported. Parry draws attention to the close similarity between the dimensions of the pyrimidine ring in adenine hydrochloride and in uracil. Broomhead reported that the cell dimensions of guanine hydrochloride and adenine hydrochloride are different, but the structures are strikingly similar. The structures of various nucleotides have been reported (140–142). Bryan and Tomita (143) emphasized the value of the study of purines and pyrimidines for use in the formulation of structures for nucleic acids. For this formulation the identification of sites of protonation of the bases at acid pH, knowledge of the molecular geometry of the various bases, and a possible model for the geometry of interbase hydrogen bonding in polynucleotides would be most valuable. The reading of Spencer's report on the stereochemistry of DNA should be a must for

those interested in cell development (144). The Crick and Watson model has suggested a fascinating mechanism for the process of heredity (39). The structure analysis of proteins has been reviewed by Kendrew and Perutz (35). A most recent review on proteins by Kendrew was published (145).

The difference in solubility in water and melting points for the aliphatic dibasic acids has been the subject of reports by X-ray crystallographers (146–150). Morrison and Robertson (150) stated that several factors could account for the saw tooth type arrangement. The carboxyl groups in beta-glutaric acid deviate further from the plane of the carbon atoms than in the even numbered series studied. The end-to-end hydrogen bridge connections between the carboxyl groups are 2.69 Å., which is almost the same as in the even structures, but the lateral connection is 3.6 Å., which is much weaker than in the even series. In addition, the bond lengths are more closely normal in beta-glutaric acid than those found in the even series. The bond distances of some of the dibasic acids studied (147–150) are shown in Fig. 5.

Bragg, Perutz, *et al.* (151–153), examined the structure of hemoglobin. They reported that the pleochroism of sheep hemoglobin varied considerably. On this basis they suggested that structural differences are evident between fetal and adult sheep hemoglobin (152). In a later paper they reported that reduced, oxy, carboxy, or methemoglobin existed in three polymorphic forms, whereas the hemoglobin of normal adult man crystallizes in six different forms. Patterson projections of horse and human hemoglobin possess similarities which imply a close relationship between the internal architecture of these two proteins (153). Partial X-ray crystallographic studies have been reported for the sterols (154) and three trimethylsteroids (155). The structural analysis has not been performed for these complex molecules. The unit cell dimensions have been published. This is also true of prednisolone acetate (155). Gafner, *et al.*, reported that the trimethyl steroids had many similarities. He cautioned, however, that the intensities of the diffraction patterns could be misleading since powder samples were not free from preferred orientations (155).

(A) (B) (C)

Fig. 5—The bond distances for glutaric acid (A), adipic acid (B), and sebacic acid (C).

A major accomplishment in X-ray structural analysis was performed by the Hodgkin group in England with the help of White, Prosen, and Trueblood in the United States (157–160). They determined the structure of vitamin B_{12} without the use of chemical analysis. The various techniques used in determining the structure would prove interesting reading.

X-ray structural analysis has been used to aid in the determination of molecule stability and in explaining organic reactions. Three examples will be discussed (161–166). The structure of benzene and *p*-chlorobenzene iododichloride has been studied (161, 162). Archer and van Schalkwyk reported that the ICl_2 group in benzene iododichloride was linear and symmetrical. The direction of this group is approximately at right angles to the *ac* plane. Bekoe and Hulme (162) stated that the electrophilic group in the *para* position gave rise to a dipole moment directed away from the iodine atom. It is possible that a tendency of electrons to drift away from the iodine atom partially increased the positive charge on the iodine and so makes a greater resonance stabilization of the molecule. In the linear ICl_2 group the third valence is at right angles to the halogen group. Presumably dsp^3 or d^3sp bonds are formed, but not fully used. The main cohesive forces in the crystal are between the iododichloride groups. Watson, in studying the crystal stuctures of 1-chloro-2,4-dinitrobenzene and 1-bromo-2,4-dinitrobenzene stated that the relative positions of the nitro group should be studied since this group affected the rate of reaction for nucleophilic aromatic substitution (163). A maximum activation through electron transfer is attained if the nitro group is planar with the benzene ring. It was reported that the nitro group in the 1-chloro derivative was rotated 39° and the nitro group was rotated 40° for the 1-bromo derivative.

Thus, the activating effect of the nitro group is greatly diminished by this steric effect and may result in a net deactivation. Donohue and co-workers have examined the polymorphs of sulfur (164–166). Donohue (164) suggested that the geometrical considerations of some of the allotropic forms of sulfur should be included in discussions concerning reactions of compounds containing the S—S bond, especially with regard to transition states or activated complexes, even though the precise energetics are not known. Thus the structural data of sulfur will undoubtedly be of increasing importance.

Recently, developments in techniques have allowed a reinvestigation of bond distances. Refinement of the structure of anthraquinone was reported by Murty (167). Refinement was done utilizing two-dimensional synthesis, three-dimensional synthesis, and three-dimensional differential synthesis. The hydrogen atoms were detected and their positions verified. Thus the hydrogen carbon bond distance was measured and compared to that obtained by other methods. The structure of chlortetracycline hydrochloride was also analyzed by X-ray procedures (168). From the analysis of this antibiotic Hirokawa, *et al.*, proposed that (*a*) the fourth ring takes a partial quinone structure, (*b*) C_{11} and O_{11} are single bonded, (*c*) C_{10a}—C_{12} is conjugated and no double bond is localized on the C_{11a}—C_{12} bond, (*d*) carbon sequence C_1—C_3 is also conjugated, (*e*) carbon sequence C_4—C_6 is completely saturated, (*f*) the dimethylamino group takes the polar configuration with respect to the first ring. Point (*f*) represents an exception to the structure found on chemical grounds. Thus the X-ray structure corresponds to the conformation assigned on chemical grounds to epi-chlortetracycline. The organic portions of the molecules exhibit only van der Waals contacts except for the hydrogen bonds around the anion. Only intramolecular hydrogen bonds are found. The chloride ion, which lies near the apex of the pyramid made by the dimethylamine group and C_4 is surrounded by six atoms which form a distorted octahedron. Those six atoms are N_4, O_6, $CH_{3(6)}$, O_{12}, O_{12a}, and N_{amide}.

Crystallographic studies of the biuret reactions have been made by Freeman and co-workers (169). They report that the metal-peptid complexes appear to be involved *inter alia* in the transition states of metal-activated proteolytic enzyme reactions. The metal contributes to the color formation. In some studies for metal binding the peptid nitrogen atoms were the donor atoms while in other studies the donor atoms were the peptid oxygens. When copper II was chelated and involved the nitrogen atom, the complex was anionic divalent; when chelation occurred with the oxygen, the complex was cationic divalent. The crystal structure of isosteric compounds was studied. Giacomello and co-workers determined the orientations and stucture of 2,4-dihydroxybenzoic acid and 2-hydroxy-4-aminobenzoic acid. It was found that even though the compounds were isosteric, crystallization occurred and different lattices were formed. The relationship of the isosteres in the crystalline state was illustrated. The reader should refer to the original reference for full appreciation (170, 171). X-ray studies of additional compounds of pharmaceutical interest are listed in Table III.

TABLE III.—SOME COMPOUNDS OF PHARMACEUTICAL INTEREST ANALYZED BY X-RAY

Acridine polymorphs (172–174)	Chelates (179)	Penicillin (185,186)
dl-Alphaprodine HCl (175)	Colchicine (180)	Strychnine (187,188)
Antihistamines (176)	Cycloseri ne(181)	Liquid water (189)
Biotin (177)	Fatty acids (62, 191)	Ice (190)
Cellobiose (178)	Formic acid (182)	
	Glycine polymorphs (183, 184)	

The X-ray analysis of colchicine (180) was helpful in the determination of the structure of the molecule. von Sydow (191) illustrates the various forms of the fatty acids referred to as A, A′, B, B′, C. Malenkow proposed that in liquid water the importance of the dodecahedron formation from water molecules is evident.

Influence of the Absorption Rate of Tolbutamide on the Rate of Decline of Blood Sugar Levels in Normal Humans

By EINO NELSON, E. L. KNOECHEL, W. E. HAMLIN, and J. G. WAGNER

The absorption of tolbutamide and several of its salts was studied by means of carboxytolbutamide excretion rate measurements following the oral ingestion of the drugs in nearly constant surface dosage forms by normal adult humans. Lowering of blood sugar levels produced in normal adult humans after the oral ingestion of the same preparations was also studied. Initial rate of decline of blood sugar level could be correlated with either the absorption rate of tolbutamide or the amount of tolbutamide in the body 1 hour after drug ingestion; increasing with increasing absorption rate or increase in amount of tolbutamide in the body. In most instances, increases in *in vitro* dissolution rate were reflected in increases in rate of decline of blood sugar level, absorption rates, or amounts of tolbutamide in the body at 1 hour.

THE RELATIONSHIP between the rate of absorption of the antidiabetic drug tolbutamide[1] and resulting depression in blood sugar level has not beeen previously studied. The availability of several salts of tolbutamide with different dissolution rates and, hence, different absorption rates, made possible the present study which was concerned with the nature of this relationship.

Received June 7, 1961, from the School of Pharmacy, University of California Medical Center, San Francisco 22, and the Research Laboratories, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication August 21, 1961.
The authors wish to acknowledge the aid of Dr. H. L. Upjohn, who arranged the blood sugar tests; Dr. John H. Flokstra and Miriam Barnes, who carried out the blood sugar analysis; Dr. O. S. Carpenter, who obtained the coefficients of the polynomials; and Mrs. Inge O'Reilly, who conducted the carboxytolbutamide assays.
Tolbutamide is 1-butyl-3-*p*-tolylsulfonylurea.

Influence of the Absorption Rate of Tolbutamide on the Rate of Decline of Blood Sugar Levels in Normal Humans

By EINO NELSON, E. L. KNOECHEL, W. E. HAMLIN, and J. G. WAGNER

The absorption of tolbutamide and several of its salts was studied by means of carboxytolbutamide excretion rate measurements following the oral ingestion of the drugs in nearly constant surface dosage forms by normal adult humans. Lowering of blood sugar levels produced in normal adult humans after the oral ingestion of the same preparations was also studied. Initial rate of decline of blood sugar level could be correlated with either the absorption rate of tolbutamide or the amount of tolbutamide in the body 1 hour after drug ingestion; increasing with increasing absorption rate or increase in amount of tolbutamide in the body. In most instances, increases in *in vitro* dissolution rate were reflected in increases in rate of decline of blood sugar level, absorption rates, or amounts of tolbutamide in the body at 1 hour.

THE RELATIONSHIP between the rate of absorption of the antidiabetic drug tolbutamide[1] and resulting depression in blood sugar level has not beeen previously studied. The availability of several salts of tolbutamide with different dissolution rates and, hence, different absorption rates, made possible the present study which was concerned with the nature of this relationship.

Received June 7, 1961, from the School of Pharmacy, University of California Medical Center, San Francisco 22, and the Research Laboratories, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication August 21, 1961.
The authors wish to acknowledge the aid of Dr. H. L. Upjohn, who arranged the blood sugar tests; Dr. John H. Flokstra and Miriam Barnes, who carried out the blood sugar analysis; Dr. O. S. Carpenter, who obtained the coefficients of the polynomials; and Mrs. Inge O'Reilly, who conducted the carboxytolbutamide assays.
Tolbutamide is 1-butyl-3-*p*-tolylsulfonylurea.

EXPERIMENTAL

Materials.—Pharmaceutical grade tolbutamide and its sodium salt were used.

The 2-amino-2-methyl-1-propanol salt of tolbuta-

mide was prepared in the following manner: 100 Gm. (0.37 mole) of tolbutamide was added to about 1200 ml. of deionized water, previously heated to 50°. To this slurry was added, in small portions, 34.8 Gm. (0.37 mole) of 2-amino-2-methyl-1-propanol (tech. grade). Stirring and heating were continued and a small additional amount of the amine (1.0 Gm.) was added to effect complete solution of the acid. The hot solution was filtered, placed in a lyophilizing flask, and frozen.

Following the removal of the solvent by lyophilization, the resulting light, fluffy, white solid was triturated with successive portions of ether in a porcelain mortar. The resulting slurries were filtered and the filter cake was washed with fresh portions of ether. The solid was dried for 48 hours *in vacuo;* yield, 131 Gm., m.p. 150.2–153.8°.

Anal.—Calcd. for $C_{16}H_{29}N_3O_4S$: C, 53.46; H, 8.13; N, 11.69; S, 8.92; equiv. wt., 359. Found: C, 53.77; H, 8.36; N, 11.52; S, 8.99; equiv. wt., 353; % H_2O (Karl Fischer), none.

The 1-amino-2-propanol salt of tolbutamide was prepared by the following procedure: to 1200 ml. of deionized water heated to 50° was added 100 Gm. (0.37 mole) of tolbutamide. To the resultant slurry 28 Gm. (0.37 mole) of 1-amino-2-propanol (tech. grade) was added in small portions with constant agitation. An additional amount (1 Gm.) of the amine was added to effect a complete solution. The hot solution was filtered, placed in a lyophilization bottle, and frozen.

The white, fluffy solid produced upon removal of the aqueous phase by lyophilization was triturated with small portions of ether in a porcelain mortar. Following filtration of the resulting slurries, the filter cake was washed with fresh portions of ether. The solid was dried *in vacuo* for 68 hours; yield, 90 Gm., m.p. 91.4–94.6°.

Anal.—Calcd. for $C_{15}H_{27}N_3O_4S$: C, 52.15; H, 7.88; N, 12.16; S, 9.28; equiv. wt., 345. Found: C, 52.17; H, 7.91; N, 11.75; S, 9.37; equiv. wt., 345; % H_2O (Karl Fischer), none.

Dosage Forms.—The sodium, 2-amino-2-methyl-1-propanol, and 1-amino-2-propanol salts of tolbutamide, as well as tolbutamide free acid, were compressed into thin cylindrical disks at a pressure of about 40,000 p.s.i., using commercial tableting equipment. The disks were 1.28 cm. in diameter and their thickness varied from 0.168 cm. to 0.229 cm., depending on the form of tolbutamide used. Each disk contained 250 ± 10 mg. tolbutamide equivalent and had a surface area of 3.38 ± 0.09 cm.[2].

Test Subjects and Conduction of Tests.—Two separate test panels were used: one for the studies on the absorption and excretion rates of carboxytolbutamide[2] following the ingestion of 0.5 Gm. tolbutamide in the various forms, and the other for studying blood sugar level following ingestion of 1.0-Gm. doses of tolbutamide in the same forms. The test subjects for all experiments were normal adult humans. Drug was ingested on fasting stomachs in the morning and no food was taken until 1 hour had lapsed from the time of drug ingestion in the absorption experiments. In the blood sugar lowering tests the compounds were administered after overnight fasting and no food was taken during the active course of the experiments (10 hours).[3]

Analytical Methods.—Urine was assayed for carboxytolbutamide by a previously described method (1). Blood sugar determinations were made on blood obtained from the antecubital veins by means of an Autotechnicon. The analytical method was that of Hoffman (2).

In Vitro Dissolution Rate Studies.—Dissolution rates of each of the forms were determined in 0.1 *N* hydrochloric acid and 0.2 *M* tris(hydroxymethyl)-aminomethane (adjusted to pH 7.2 with hydrochloric acid) solutions at 37° using a method previously described to study dissolution rates of slightly soluble weak acids and their sodium salts (3).

RESULTS

Excretion Experiments.—Cumulative excretion of carboxytolbutamide following the ingestion of tolbutamide in the several hours is given in Table I.

Blood Sugar Level Studies.—Results of blood sugar tests in 23 normal subjects are shown in Tables II and III.

In Vitro Dissolution Rate Studies.—The dissolution rates *in vitro* determined by the method described are summarized in Table IV.

DISCUSSION

Treatment of Excretion Data.—Cumulative amounts of carboxytolbutamide excreted in 1, 2, 3, and 4 hours by each of the test subjects in each test were fitted to polynomials with powers of time of the form

$$Y = at + bt^2 + ct^3 + dt^4 \qquad \text{(Eq. 1)}$$

where Y was the amount excreted in mg. and t was time in hours. The coefficients of Eq. 1, for each of the tests, are listed in Table V.

It has been previously reported that absorption rate (A.R.) may be calculated from excretion measurements by the following expression (4)

$$\text{A.R.} = \frac{1}{f}\left(\frac{dAe}{dt} + \frac{1}{K}\frac{d^2Ae}{dt^2}\right) \qquad \text{(Eq. 2)}$$

In Eq. 2, dAe/dt is excretion rate, d^2Ae/dt^2 its derivative, K the rate constant for elimination of drug, and f the fraction of drug reaching circulation that is excreted unchanged. All quantities in Eq. 2 refer to unchanged drug. Tolbutamide is nearly quantitatively oxidized to carboxytolbutamide *in vivo* and this metabolite is quantitatively excreted in the urine about 12 times more rapidly than it is formed (5). Therefore, even though carboxytolbutamide excretion was followed, this very closely represented tolbutamide's oxidation and application of Eq. 2 to calculate absorption rate should not result in the introduction of any substantial error. In order to calculate absorption rate of tolbutamide by Eq. 2 the first and second derivatives of Eq. 1 were taken at 1.0, 1.5, and 2.0 hours. A mean value of K for each of the subjects used in the excretion experiments was available from other work (5), hence absorption rate could be calculated at the

[2] Carboxytolbutamide is *p*-[(butylcarbamoyl)sulfamoyl]-benzoic acid.

[3] The experimental design used in the blood sugar lowering tests is shown in the Appendix.

	...	97.7	97.4	97.0	97.8	99.7	101.7

[a] Adjusted for difference in initial blood sugar level by covariance analysis. The zero-hour blood sugar level was used as a covariate. [b] 23 Normal subjects for disks and 5 normal subjects for placebo. [c] Top row, average blood sugars in mg. %; bottom row, per cent of placebo group average.

indicated times for each of the preparations. The calculated rates are listed in Table VI in terms of tolbutamide equivalent (1 Gm. tolbutamide = 1.11 Gm. carboxytolbutamide). The value of K for subjects E, I, B, and C in Tables I, V, VI, and VII were, respectively, 0.139, 0.105, 0.133, and 0.124 hours^{-1}.

When the mean values of absorption rate, following ingestion of the sodium or 1-amino-2-propanol salts of tolbutamide were plotted *vs.* time on semilogarithmic graph paper, the line was linear indicating that absorption was by an apparent first-order process. This is shown in Fig. 1. With the 2-amino-2-methyl-1-propanol salt, the absorption

rate was nearly constant in the 2-hour period where the calculations were made. The differences in the nature of absorption processes was not unexpected. Both the sodium and 1-amino-2-propanol salts of tolbutamide dissolve rapidly in mediums possessing hydrogen ion concentrations in the physiological range (Table IV). The 2-amino-2-methyl-1-propanol salt of tolbutamide and tolbutamide free acid dissolve substantially slower and, since the dosage forms could be expected to have presented a nearly constant surface to dissolution fluids *in vivo* due to their geometry, this dissolution process was apparently rate limiting in absorption in the time period under consideration.

The excretion rate of carboxytolbutamide is very nearly directly proportional to the amount of tolbutamide in the body (5). That is,

$$dTe/dt \cong KT \qquad \text{(Eq. 3)}$$

where dTe/dt is the excretion rate of carboxytolbutamide, K the rate constant for the *in vivo* oxidation of tolbutamide in hours^{-1}, and T is the amount of tolbutamide in the body at any time. The value of T for each of the subjects in each of the tests was calculated at 1 hour and these are listed in Table VII in terms of tolbutamide equivalent. This was done by using the first derivative of Eq. 1.

Correlation Between Absorption Rate or Body Level of Tolbutamide and Initial Lowering of Blood Sugar Level.—The rate of lowering of blood sugar level was examined in respect to two parameters concerned with tolbutamide absorption. One of these was the rate of initial depression of blood sugar level compared to the half-life for absorption. This

comparison was only applicable in the case of the sodium and the 1-amino-2-propanol salts of tolbutamide since it was only with these materials that an apparent first-order absorption resulted (Fig. 1). From Table II the average rate of lowering of blood sugar level during the first hour was 27.2 and 19.1 mg. %/hr. for the 1-amino-2-propanol and sodium salt of tolbutamide, respectively. From Fig. 1, the half-lives for absorption were 0.46 and 0.68 hours, respectively; indicating the dependency of blood sugar level lowering on absorption rate.

In order to include all four test preparations in a correlation, lowering of blood sugar level at the end of the first hour of experiments is compared to the logarithm of the calculated amount of tolbutamide in the body at the same time on Fig. 2. The tendency for linearity indicates that a diminishing rate in blood sugar lowering is obtained with higher levels of tolbutamide. Examination of data on extent of initial lowering of blood sugar level as a function of dose of tolbutamide published by West and Johnson (6) indicates that the same general relationship between extent of lowering and dose holds.

Results obtained with the disks of tolbutamide (free acid) in these studies should not be taken as indicative of results which would be obtained with commercial tablets. In these studies the surface area of the tolbutamide was restricted to a very low

value. The commercial tablets[4] disintegrate in the gastrointestinal tract liberating drug in fine particle size, and the results (7) are distinctly different.

Correlation Between Initial Lowering of Blood Sugar Level or Amount of Tolbutamide in Circulation and *In Vitro* Dissolution Rate of the Preparations.—The biological response obtained in these experiments is related to the physical chemical property of dissolution rate of the preparations. This may be seen from an examination of Fig. 3 where extent of blood sugar lowering after 1 hour is compared to the *in vitro* dissolution rates of the disks that served as dosage forms in the experiments. The *in vitro* dissolution rates used in the plot were from determinations in the nearly neutral mediums (Table IV). A generally similar relationship holds if the rates in acidic mediums are used in the plot. Comparison of data in Table IV to corresponding data in Tables I, II, and III also indicates the dependency of extent of carboxytolbutamide excretion or blood sugar level lowering, respectively, on dissolution rate.

SUMMARY

A study was made of the influence of the rate of absorption of tolbutamide on the initial depression of blood sugar levels in normal adult humans. Initial depression in blood sugar level is related to the absorption rate (increasing with increasing rate of absorption), amount of tolbutamide in the body in the time taken for comparison (increased with increased amounts of tolbutamide in the body), and to the *in vitro* dissolution rate of the various salts of tolbutamide used in the tests. Ultimately, differences in either depression of blood sugar level or amount of tolbutamide in the body during the times at which the comparisons were made was dependent on the *in vitro* dissolution rate of the preparations which surely determined *in vivo* absorption rate in this *in vivo*, solution rate-limited absorption.

APPENDIX

Experimental Design Used in the Blood Sugar Lowering Tests.—A pool of 35 normal human subjects were used. Subjects were assigned at random to one of three treatments, namely; T, one of the test preparations in the form of cylindrical disks; O, a compressed tablet of tolbutamide; P, a placebo tablet. Nine subjects (39% of the 23 receiving the test preparations) were administered all four of the test preparations. The schedule of treatments is shown in Table VIII.

Separation of Amino Acids on Ion Exchange Resin Papers

Dependence of R_f Values on pH and Ionic Strength

By A. BAERHEIM SVENDSEN and E. BROCHMANN-HANSSEN

Fifteen amino acids have been chromatographed on paper impregnated with an ion exchange resin of the sulfonic acid type. The R_f values have been determined at various pH and ionic strengths of the buffer eluant. By means of several chromatograms of appropriate pH values and ionic strengths, most amino acids can be separated and identified in about 2 hours. The ion exchange resin papers can be regenerated and used again.

DURING our studies of the amino acid composition of opium (1–3), various methods of separation and quantitative determination of amino acids have been investigated. Two-dimensional paper chromatography is satisfactory for most qualitative work, whereas the ion exchange procedure of Moore and Stein (4–6) is often preferred for quantitative analysis because of its accuracy and reproducibility.

In recent years papers impregnated with ion exchange resins have become available. These combine many of the advantages of paper chroma-

Separation of Amino Acids on Ion Exchange Resin Papers

Dependence of R_f Values on pH and Ionic Strength

By A. BAERHEIM SVENDSEN and E. BROCHMANN-HANSSEN

Fifteen amino acids have been chromatographed on paper impregnated with an ion exchange resin of the sulfonic acid type. The R_f values have been determined at various pH and ionic strengths of the buffer eluant. By means of several chromatograms of appropriate pH values and ionic strengths, most amino acids can be separated and identified in about 2 hours. The ion exchange resin papers can be regenerated and used again.

DURING our studies of the amino acid composition of opium (1–3), various methods of separation and quantitative determination of amino acids have been investigated. Two-dimensional paper chromatography is satisfactory for most qualitative work, whereas the ion exchange procedure of Moore and Stein (4–6) is often preferred for quantitative analysis because of its accuracy and reproducibility.

tography with those of the ion exchange method, and several investigators have reported on the application of such papers to the separation of amino acids. Lautsch, Manecke, and Broser (7), as well as Tuckerman, Osteryoung, and Nachod (8), separated certain amino acids on carboxylated ion exchange paper. Myhre and Smith (9), using an aqueous-organic solvent, obtained results that were quite different from those which one would expect on the basis of ion exchange phenomena alone. Partition effects apparently modified the migration rates. Tuckerman (10) separated arginine, histidine, and lysine in casein hydrolysates by means of paper impregnated with a sulfonated ion exchange resin. This method was later used for quantitative determinations by Roberts and Kolor (11).

In the column chromatographic method, all the major amino acids are separated by increasing the pH, the ionic strength, and the temperature during the elution. This paper reports the effect of pH and ionic strength on the separation of amino acids on ion exchange paper.

EXPERIMENTAL

Materials.—Amberlite SA-2 ion exchange paper was used. This is prepared from alphacellulose pulp and finely ground ion exchange resin of the sulfonic acid type (Amberlite IR-120). Citrate buffer solutions were prepared in the pH range of 2.2 to 6.5 with sodium ion concentrations ranging from 0.1 to 0.8 *N*. The buffer solutions described by Moore, Spackman, and Stein (6) were used as starting points and adjustments made as needed to include a wider range of pH and ionic strength.

Procedure.—Sheets of ion exchange papers were cut into sections, 22 inches long and 9 inches wide. The lower edge was cut in a saw-tooth fashion so as to facilitate the flow of liquid off the paper. The papers were placed in a chromatographic cabinet and washed overnight with a buffer solution of the same pH and ionic strength to be used for elution. The buffer was then replaced with water to rinse out the excess of salts, and finally the papers were suspended in air until they were almost dry. Five microliters of 0.02 *M* solutions of the various amino acids were applied as small round spots four inches from the upper edge of the papers and about one inch apart. The papers were again placed in the chromatographic cabinet and developed with appropriate buffer solutions. The descending method was used for this as well as for the previous activation and washing. After about 2 hours, when the solvent front had progressed about 15 inches beyond the point of sample application, the papers were removed from the cabinet, air-dried, and sprayed with a 0.5% solution of ninhydrin in ethanol. The papers were left for 1 hour at room temperature and then heated at 100° for 10 minutes. The R_f values were calculated on the basis of six to eight chromatograms for each amino acid. At pH values where the neutral and acidic amino acids travelled closely behind the liquid front, the spots tended to become diffuse and poorly defined.

The ion exchange papers could be used again several times. The amino acid spots and excess of ninhydrin were removed with alcoholic hydrochloric acid (about 1 *N* hydrochloric acid in ethanol). The papers were washed with water and treated with buffer as described above. Care must be exercised in handling the wet papers as they tear very easily.

RESULTS AND DISCUSSION

The R_f values obtained for 15 amino acids at various pH values and ionic strengths are given in Table I. The effect of pH is also illustrated in Fig. 1, while Figs. 2 to 5 show the effect of the ionic strength. It is apparent that both factors, pH and ionic strength, have a pronounced effect on the rate of migration of the amino acids. No complete separation of all amino acids can be achieved in one single run. However, by running several chromatograms of appropriate pH and ionic strengths, most amino acids can be separated and identified in a relatively short time.

For a preliminary, exploratory examination of an amino acid mixture of unknown composition, a buffer solution of relatively low pH and concentration will yield much information. At a pH of 3.5 and a sodium concentration of 0.2 *N*, a reasonably good separation of the majority of common amino acids may be accomplished (*cf.* Fig. 1). If several acidic and neutral amino acids are present, these are best separated at a still lower pH value, for example 2.2, and at sodium concentrations of 0.6 and 0.8 *N* (Fig. 2). Basic amino acids are easily separated in the pH range of 5 to 6 (Figs. 1 and 5).

The R_f value of γ-aminobutyric acid is very much affected by pH between 4.5 and 6.5, while phenylalanine and tyrosine show greater response to pH

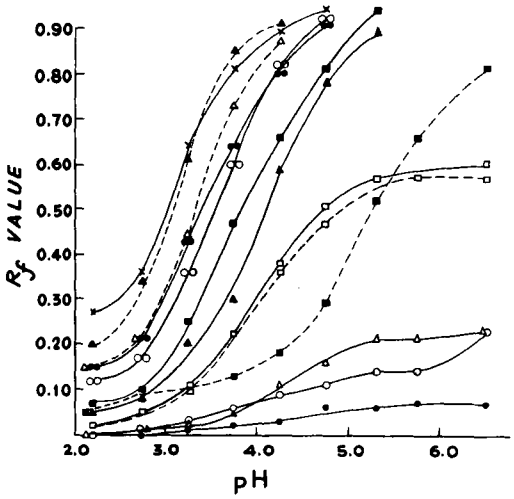

Fig. 1.—Influence of pH on the R_f values of arginine (—●—●—), histidine (—○—○—), lysine (—△—△—), tyrosine (--□--□--), phenylalanine (—□—□—), leucine (—▲—▲—), isoleucine (—■—■—), γ-aminobutyric acid (--■--■--), valine (—○○—○○—), alanine (—●●—●●—), glutamic acid (--△--△--), aspartic acid (--▲--▲--), and threonine (—×—×—).

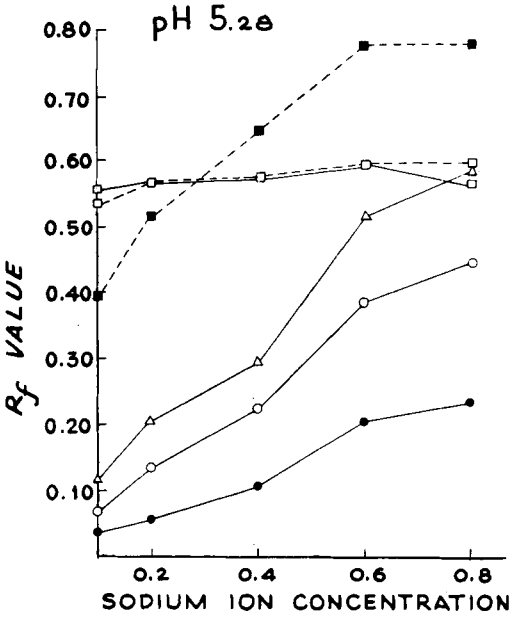

Fig. 5.—Influence of ionic strength of the R_f values of arginine (—●—●—), histidine (—○—○—), lysine (—△—△—), γ-aminobutyric acid (--■--■--), tyrosine (--□--□--), and phenylalanine (—□—□—)

changes at lower pH values. Thus, the curves for these amino acids in Fig. 1 intersect at about pH 3.25 and again at about pH 5.5.

Certain amino acids, such as leucine and isoleucine, which are difficult to separate by conventional paper chromatography show good separation on ion exchange papers, particularly at a high ionic strength in the pH range of 2.2 to 3.25. Phenylalanine and tyrosine, on the other hand, are more difficult to separate on ion exchange paper than on ordinary filter paper. Although they are affected to a somewhat different extent by changes in pH and ionic strength, it is difficult to obtain a clear-cut separation of the two amino acids in a mixture. The temperature, undoubtedly, plays an important role in ion exchange separations of amino acids. Thus, in column chromatography, tyrosine, phenylalanine, β-aminoisobutyric acid, and glucosamine appear together in the same fractions when eluted at 30° (12). When the temperature is raised to 50°, all four compounds are nicely separated (5, 6, 12). It is probable that similar improvements may be obtained by increasing the temperature in ion exchange paper chromatography.

Alkaloids of *Vinca rosea* Linn. (*Catharanthus roseus* G. Don.) XII

Preparation and Characterization of Trace Alkaloids

By GORDON H. SVOBODA, MARVIN GORMAN, ALBERT J. BARNES, Jr., and A. THORNTON OLIVER

The processing of this plant (1) for the four new oncolytic agents, vincaleukoblastine, leurosine, leurosidine, and leurocristine, has resulted in obtaining eight new companion dimeric alkaloids, these latter being obtained in yields of not more than 1.5×10^{-4} %. To date, a total of 24 new alkaloids have been reported from these laboratories. Procedural details and preliminary characterization of carosidine, carosine, pleurosine, neoleurosidine, vincarodine, catharicine, vindolidine, and neoleurocristine are described.

As a result of the search for the active antitumor principles contained in various alkaloidal fractions from this plant, 20 crystalline alkaloids, 16 of them being new, have been obtained in these laboratories[1] (2–6). Four of these, leurosine, vincaleukoblastine (VLB),[2] leurosidine, and leurocristine have demonstrated varying degrees of oncolytic activity in experimental tumors, the latter two being capable of producing "indefinite" survivors in DBA/2 mice infected with the P-1534 leukemia, a transplanted acute lymphocytic leukemia (7, 8). Clinically, VLB and leurocristine have elicited responses in human neoplasms, the former being commercially available as the sulfate[3] for the treatment of Hodgkin's disease and choriocarcinoma

The alkaloids obtained from this plant can be categorized into three groups. The first group consists of dimeric indole-indoline alkaloids of approximate composition of $C_{46}H_{52-62}N_4O_{8-10}$. Spectral studies (9) indicate a common structural relationship to the $C_{21}H_{24}N_2O_2$ indole, catharanthine, and the $C_{25}H_{32}N_2O_6$ indoline compound, vindoline, both of which are also obtained from this plant. The second group contains a number of miscellaneous smaller alkaloids ranging in molecular weight of 325–500. This group would include catharanthine and vindoline. A number of symmetrical dimeric alkaloids, primarily dihydroindoles, comprise the third group.

The eight alkaloids reported herein represent minor constituents obtained during the preparation of the four biologically active alkaloids mentioned above, and in no case were they found in greater amounts than 1.5×10^{-4} %. Five of these are members of the first group, while the remaining three, carosidine, vincarodine, and vindolidine, belong to the third class.

Carosidine was obtained by rechromatography of the residues remaining in the VLB sulfate mother liquors, while carosine and pleurosine were obtained by rechromatography of certain mixtures of leurosine and isoleurosine. Neoleurosidine resulted from rechromatography of impure leurosidine. The presence of this compound was suspected because of an abnormal pK'a ratio determined by electrometric titration.

Vincarodine was obtained by gradient pH extraction (6) of a fraction resulting from rechromatography of post-VLB column eluate, as were catharicine and vindolidine. Neoleurocristine was found by subjecting leurocristine sulfate mother liquors to the same type of gradient pH technique.

These new alkaloids are listed in Table I, which shows their empirical formulas, m.p.'s, pK'a's, specific rotations, and ultraviolet absorption maxima. Their infrared spectra are reproduced in Fig. 1 as an additional aid to their identification.

DISCUSSION

Carosidine.—Alumina chromatography of the bases obtained from the VLB sulfate mother liquors yielded this alkaloid by elution with chloroform-benzene (3:1). The ultraviolet spectrum is that of a typical substituted dihydroindole. The infrared spectrum (mull) shows the presence of

Received March 20, 1962, from the Organic Chemical Development and Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, Ind.

Accepted for publication April 3, 1962.

Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

The authors wish to thank the following individuals for their aid in the course of this investigation: Messrs. D. R. Bedwell, R. J. Armstrong, G. Johnson, and Miss R. Miller for laboratory assistance; Dr. R. Pfeiffer for crystallographic data; Dr. H. E. Boaz, Messrs. L. G. Howard, P. W. Landis, L. A. Spangle, Miss M. L. Hofmann, and Mrs. D. Stephens for physical data; Messrs. W. L. Brown, G. M. Maciak, H. L. Hunter, and R. Hughes for microanalysis.

[1] For the sake of brevity, experimental techniques repeated from earlier work are not described in detail. A reference is given to the previous paper.

[2] In compliance with the decision of the A.M.A. Council on Drugs, the name vincaleukoblastine should be replaced by vinblastine as the generic name for this alkaloid.

[3] Supplied as Velban, vinblastine sulfate, Lilly.

TABLE I.—NEW TRACE ALKALOIDS FROM *Vinca rosea* LINN.

Name	Formula[a]	M.P., °C.	$[\alpha]_D^{25}$ ($CHCl_3$)	pK'a in 33% DMF	U.V. $\lambda_{max.}^{EtOH}$, mμ
Carosidine	...	263–278, 283[b]	−89.8°	...	212, 254, 303
Carosine	$C_{46}H_{56}N_4O_{10}$	214–218	+6.0°	4.4, 5.5	255, 294
Pleurosine	$C_{46}H_{56}N_4O_{10}$	191–194[b]	+61.0°	4.4, 5.55	267, 308
Neoleurosidine	$C_{48}H_{62}N_4O_{11}$	219–225[b]	+41.6°	5.1	214, 268
Vincarodine	$C_{44}H_{52}N_4O_{10}$	253–256[b]	−197.4°	5.8 (66%)	230, 272, 298
Catharicine	$C_{46}H_{52}N_4O_{10}$	231–234[b]	+34.8°	5.3, 6.3	214, 268, 293, 315
Vindolidine	$C_{48}H_{64}N_4O_{10}$	244–250[b]	−113.2°	4.7, 5.3	261, 311
Neoleurocristine	$C_{46}H_{56}N_4O_{12}$	188–196[b]	−57.87°	4.68	220, 257, 298

[a] While these molecular formulas agree well with the analytical results for each particular alkaloid, it should be noted that they are to be considered as proximate at this time, in light of our experience with the other dimeric alkaloids (9). [b] With decomposition.

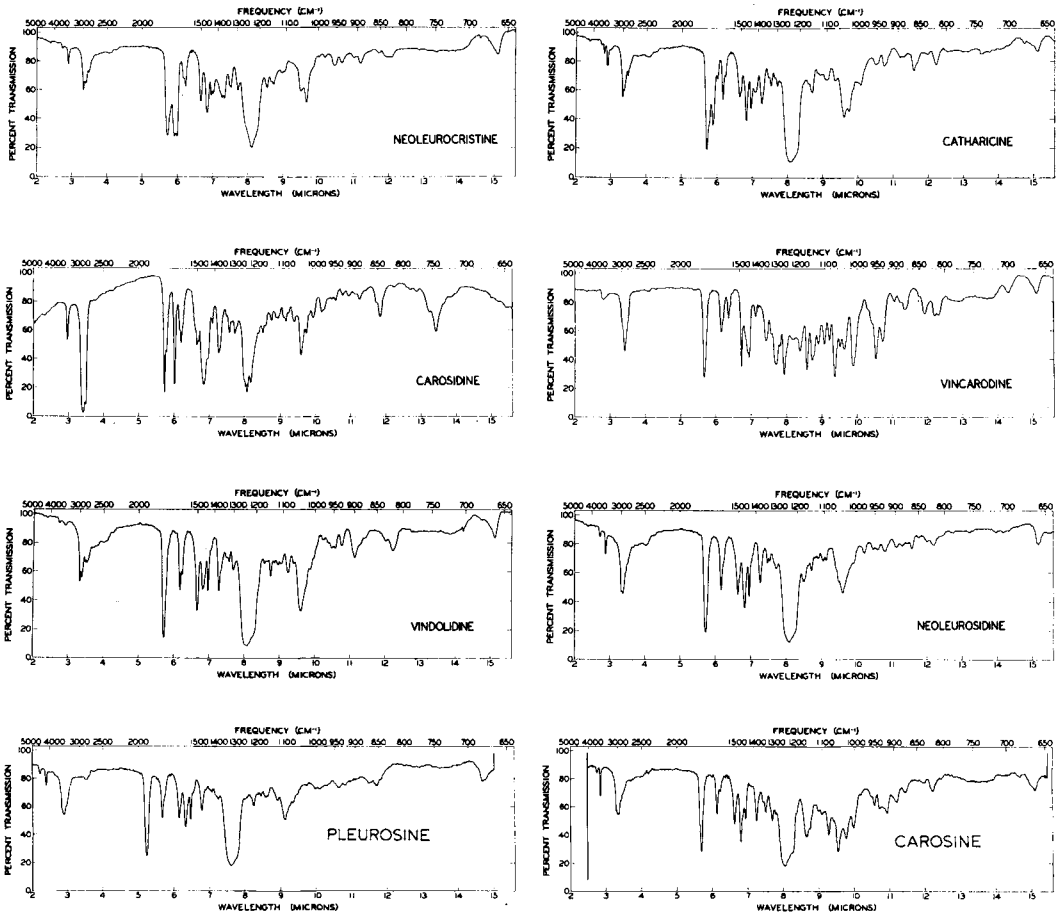

Fig. 1.—Infrared spectra of new alkaloids.

NH at 2.95 μ and carbonyl functions at 5.75 and 6.02 μ.

Carosine and Pleurosine.—Rechromatography of crude leurosine-isoleurosine mixtures described previously (5) yielded these two alkaloids, carosine from benzene-chloroform eluates (1:1) and pleurosine from chloroform.

The ultraviolet spectrum of carosine differs from those of the other dimeric alkaloids. Its infrared spectrum shows it to be a dimeric alkaloid containing hydroxyl, indole NH, and ester carbonyls. The NMR spectrum indicates the presence of two methyl esters, an aromatic methoxyl, an N-CH_3, and an O-acetyl group.

The ultraviolet spectrum of pleurosine is similar to those of the other dimeric alkaloids except that it does not shift in acid. The infrared spectrum resembles those of the other group 1 dimeric alkaloids.

Neoleurosidine.—The presence of this compound was suspected when an abnormal pK'a ratio was found to be associated with a particular crude

crystalline leurosidine sample. Leurosidine exhibits two pK'a groups at approximately 5.0 and 8.8, in equal mole per cent. The presence of neoleurosidine was thus indicated by an increased molar percentage of the lower pK'a. Electrometric titration of this sample, however, in 33% DMF gave the following data: 1.0 mole for pK'a 8.93 and 4.33 moles for pK'a 5.15. Rechromatography gave the new compound from the 1% methanol–99% chloroform eluate.

The ultraviolet spectrum is similar to those of the other dimeric alkaloids except that it does not shift to lower wavelength in acid as do the others. The infrared spectrum is consistent with those of the other related dimeric alkaloids of group 1 and contains the same type of hydroxyl as does leurosidine.

Vincarodine.—This alkaloid was obtained by chromatography of the bases from the VLB sulfate mother liquors and subjecting the benzene-chloroform (1:3) eluate to the gradient pH separation. It was found in the pH 4.40, 4.90, and 5.40 extracts.

The ultraviolet spectrum appears to be that of a substituted dihydroindole and closely resembles the alkaloid vincine from *Vinca minor* Linn. (10, 11). The infrared spectrum substantiates the relationship to vincine, showing the presence of a methyl ester and methoxyl substitution on the aromatic portion of the molecule, as well as an N-H.

Catharicine.—This new dimeric alkaloid was obtained by rechromatography of the chloroform-soluble post VLB eluate resulting from the commercial production of VLB sulfate (4) and by subjecting an early chloroform cut to gradient pH separation. It was found at pH 2.85 and 3.40.

Its ultraviolet spectrum is similar to those of the dimeric alkaloids which are composed of catharanthine-like and vindoline-like moieties, the slight bathochromic shift in acid, typical of the ultraviolet spectrum of leurosine, VLB, etc., is not found. The infrared spectrum is similar to that of VLB, but shows evidence of additional unsaturation which appears to be in the neighborhood of the basic nitrogen of the indole moiety (which titrates with a pK'a of 7.0 in VLB but does not in catharicine).

Vindolidine.—This alkaloid was obtained in the same manner as was catharicine, from the same starting material. The last two benzene-chloroform (1:3) fractions were treated with the gradient pH technique, and vindolidine was found to be present in the pH 3.90 and 4.40 extracts, the bulk of it being associated with the lower level. (Leurosidine was also obtained from these two fractions, but was found at pH levels of 5.40, 5.90, and 6.40.)

The ultraviolet spectrum is that of a typical substituted dihydroindole. The infrared spectrum supports a close structural relationship to vindolicine and vindoline and suggests the possibility that both this alkaloid and vindolicine are dimeric indoline alkaloids.

Neoleurocristine.—The presence of this alkaloid in the leurocristine sulfate mother liquors was demonstrated by paper chromatographic examination which indicated a less mobile material than leurocristine. Subjecting these mother liquors to gradient pH separation yielded the new alkaloid from the pH 3.40 fraction. The ultraviolet spectrum is quite similar to that of leurocristine, showing the anomalies to the other dimeric alkaloids that the latter does. The infrared spectrum contains an additional carbonyl band at 6.05μ, which may be due to an amide. As with leurocristine, no N-CH_3 is found in the NMR spectrum (1).

EXPERIMENTAL

Carosidine.—A quantity of VLB sulfate crude mother liquors was converted to the base, and 3.6 Kg. of this amorphous alkaloidal residue was chromatographed on 119 Kg. of alumina, deactivated in the usual manner (4). The column results are listed in Table II.

The crude methanol-crystallized carosidine obtained from fractions 32–35 was further purified by warming with 200 ml. of chloroform. The chloroform-insoluble material was filtered off and discarded. Concentration of the clear filtrate *in vacuo* to approximately 40 ml., followed by the addition of 400 ml. of acetone, with subsequent chilling produced 1.54 Gm. of the alkaloid in the form of blades having parallel extinction; gradual decompn. 263–278°, m.p. 283°, $[\alpha]_D^{26}$ −89.8° (c = 1, $CHCl_3$).

Anal.—Found: C, 67.75; H, 6.72; N, 8.22; O, 17.46.

Electrometric titration data were not available because of the insolubility of this alkaloid in the systems investigated. The solubility of this compound did not allow for calculation of extinction coefficients; $\lambda_{max.}^{EtOH}$ 212, 254, 303 mμ.

Carosine and Pleurosine.—Chromatography of a benzene solution containing 25 Gm. of a crude leurosine-isoleurosine mixture, corresponding to fractions 10 and 11 as described in an earlier paper (5), on 1000 Gm. of alumina, deactivated with 60

TABLE II.—CHROMATOGRAPHY OF BASES FROM VLB SULFATE MOTHER LIQUORS, YIELDING CAROSIDINE

Fraction	Eluting Solvent	Compound	Wt., Gm.	Crystallizing Solvent

ml. of 5% acetic acid gave the results as listed in Table III.

Carosine.—Recrystallization of the crude crystalline base from methylene chloride-ether produced 0.240 Gm. of the base as needles with parallel extinction; m.p. 214–218°; $[\alpha]_D^{26}$ +6.0° (c = 1, $CHCl_3$).

Anal.—Calcd. for $C_{46}H_{56}N_4O_{10}$: C, 66.97; H, 6.84; N, 6.79; O, 19.39. Found: C, 66.71, 66.71; H, 7.02, 6.88; N, 6.52; O, 19.61.

pK'a 4.4, 5.5, electrometric titration, 33% DMF; mol. wt., 934; $\lambda_{max.}^{EtOH}$ 255 mμ [log E(1%, 1 cm.) 2.21], 294 mμ [log E(1%, 1 cm.) 2.19].[4]

Pleurosine.—Recrystallization of the base from methanol yielded 0.175 Gm. of long blades having parallel extinction; m.p. 191–194° (decompn.); $[\alpha]_D^{26}$ −61.0° (c = 1, $CHCl_3$).

Anal.—Calcd. for $C_{46}H_{56}N_4O_{10}$: C, 66.97; H, 6.84; N, 6.79; O, 19.39. Found: C, 67.04; H, 7.08; N, 6.49; O, 19.44.

pK'a 4.4, 5.55, electrometric titration, 33% DMF; mol. wt., 908; $\lambda_{max.}^{EtOH}$ 267 mμ [log E(1%, 1 cm.) 2.32], 308 mμ [log E(1%, 1 cm.) 1.87].

Neoleurosidine.—A benzene solution of 8.5 Gm. of impure leurosidine, exhibiting the abnormal pK'a ratio described above, was chromatographed on 343 Gm. of alumina (Alcoa, Grade F-20) deactivated with 11.5 ml. of 10% acetic acid in the usual manner (see Table IV).

The crude methanol-crystallized neoleurosidine from fractions 75–90 were combined and were recrystallized from methanol, yielding 1.017 Gm. of pure alkaloid in the form of rods with inclined extinction; m.p. 219–225° (decompn.); $[\alpha]_D^{26}$ + 41.6° (c = 1, $CHCl_3$).

Anal.—Calcd. for $C_{48}H_{62}N_4O_{11}$: C, 66.18; H, 7.17; N, 6.43; O, 20.20. Found: C, 66.20; H, 7.26; N, 6.49; O, 20.14; OCH_3, 13.4; OAC, 8.65; (C)-CH_3, 4.21.

pK'a 5.1, electrometric titration, 33% DMF; mol. wt., 452 × 2 = 904; $\lambda_{max.}^{EtOH}$ 214 mμ [log E(1%, 1 cm.) 2.77], 268 mμ [log E(1%, 1 cm.) 2.29]; shoulders at 285 mμ [log E(1%, 1 cm.) 2.19], 295 mμ [log E (1%, 1 cm.) 2.12], 310 mμ [log E(1%, 1 cm.) 1.83].

Vincarodine.—The gradient pH technique (6) used to prepare this alkaloid from the benzene-chloroform (1:3) eluate of columned bases from the VLB sulfate mother liquors is as follows: a total of 182 Gm. of amorphous base was dissolved in 7 L. of benzene and filtered. The clear solution was mixed with 9 L. of 0.1 *M* citric acid and the mixture was distilled *in vacuo* to remove the benzene. The aqueous phase was filtered and subsequently extracted with one 9-L. portion of benzene at each of the following pH levels: 3.2, 3.9, 4.4, 4.9, 5.4, 5.9, and 8.0, the pH being raised after each extraction by the addition of 28% ammonia.

The crude cuts from pH 4.4, 4.9, and 5.4 (40.4 Gm.) crystallized from methanol, yielding 3.0 Gm. of crude crystalline vincarodine. Recrystallization from chloroform-methanol yielded 2.55 Gm. of base as blades having parallel extinction; m.p. 253–256° (decompn.); $[\alpha]_D^{26}$ −197.4° (c = 1, $CHCl_3$).

Anal.—Calcd. for $C_{44}H_{52}N_4O_{10}$: C, 66.31; H, 6.58; N, 7.03; O, 20.08. Found: C, 66.56; H, 6.62; N, 7.20; O, 20.12.

pK'a 5.8, electrometric titration, 66% DMF; mol. wt., 400 if monomeric, 800 if dimeric. The molecular weight by vapor pressure lowering indicated that the dimeric formulation was correct.

[4] Because of the high degree of solvation of these molecules, the samples taken for pK'a determination and ultraviolet spectral measurements at times did not give the same molecular weight as those specially dried for analysis. Therefore, we report the ultraviolet absorption intensities as log $E_{1\%}$ rather than as log ϵ_M.

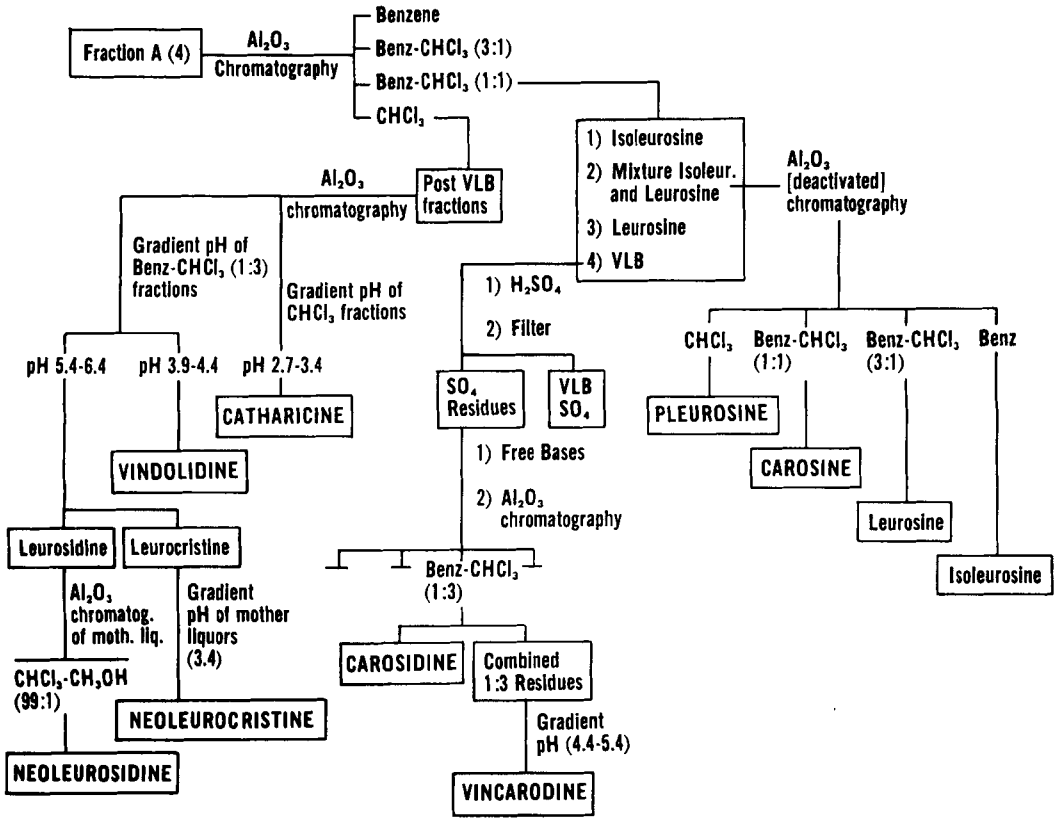

Fig. 2.—Flow diagram.

$\lambda_{max.}^{EtOH}$ 230 mμ [log E(1%, 1 cm.) 2.82], 272 mμ [log E(1%, 1 cm.) 2.30], 298 mμ [log E(1%, 1 cm.) 2.04].

Catharicine.—Rechromatography of the chloroform-soluble post-VLB eluate from fraction 1 and subjecting 256.55 Gm. of an early chloroform fraction, corresponding to fraction 47 as described in (6), to the gradient pH technique previously recorded, yielded this dimeric indoline alkaloid from pH cuts 2.70 and 3.40. The amorphous residues from each cut readily crystallized from acetone, yielding 1.1805 and 4.535 Gm. of crude crystalline base, respectively. Recrystallization from acetone, or from any of the commonly-used solvents, was ineffectual, always producing a gel. It was necessary to rechromatograph the base to obtain a pure entity.

The pure base crystallizes from acetone as irregular plates; m.p. 231–234° (decompn.), $[\alpha]_D^{26}$ + 34.8° (c = 1, $CHCl_3$).

Anal.—Calcd. for $C_{46}H_{52}N_4O_{10}$: C, 66.97; H 6.84; N, 6.79; O, 19.39. Found: C, 66.20; H, 6.70; N, 6.55; O, 20.00.

pK'a 5.3, 6.3, electrometric titration, 33% DMF; mol. wt., 894; $\lambda_{max.}^{EtOH}$ 214 mμ [log E(1%, 1 cm.) 2.81], 268 mμ [log E(1%, 1 cm.) 2.29], 293 mμ [log E(1%, 1 cm.) 2.12], 315 mμ [log E(1%, 1 cm.) 1.74]; shoulder at 283 mμ [log E(1%, 1 cm.) 2.23].

Vindolidine.—Rechromatography of the chloroform-soluble post-VLB eluate from fraction 1 and subjecting 69.25 Gm. of the late chloroform-benzene (3:1) fractions, corresponding to fractions 43 and 44 as described in (6) to gradient pH separation gave 0.642 Gm. of crude crystalline vindolidine from pH cut 3.92 and 0.037 Gm. from pH cut 4.42. Recrystallization from methanol yielded microcrystals; m.p. 244–250° (decompn.); $[\alpha]_D^{26}$ −113.2° (c = 1, $CHCl_3$).

Anal.—Calcd. for $C_{48}H_{64}N_4O_{10}$: C, 64.84; H, 7.26; N, 6.30; O, 21.60. Found: C, 64.90, H, 7.22; N, 6.56; O, 21.56; OCH_3, 17.45; (N)CH_3, 3.38; (C)CH_3, 4.94; OAC, 4.52.

pK'a 4.7, 5.3, electrometric titration, 33% DMF; mol. wt., 880; $\lambda_{max.}^{EtOH}$ 261 mμ [log E(1%, 1 cm.) 2.33], 311 mμ [log E(1%, 1 cm.) 2.12].

Neoleurocristine.—Subjecting 4.786 Gm. of leurocristine sulfate crude mother liquors to gradient pH separation in the usual manner resulted in obtaining 0.181 Gm. of this new alkaloid from the 0.40 Gm. of crude amorphous residue in the pH 3.40 cut by crystallization from methanol, from which it crystallizes as irregular plates; m.p. 188–196° (decompn.); $[\alpha]_D^{26}$ −57.87° (c = 1, $CHCl_3$).

Anal.—Calcd. for $C_{46}H_{56}N_4O_{12}$: C, 64.47; H, 6.59; N, 6.54; O, 22.41. Found: C, 64.62, 64.82; H, 6.55, 6.72; N, 6.57, 6.34; O, 22.05; OCH_3, 10.36; (C)CH_3, 4.50; OAc, 4.42.

pK'a 4.68, electrometric titration, 33% DMF; mol. wt., 827; $\lambda_{max.}^{EtOH}$ 220 mμ [log E(1%, 1 cm.) 2.74], 257 mμ [log E(1%, 1 cm.) 2.23], 298 mμ [log E(1%, 1 cm.) 2.29]; shoulders at 264 mμ [log E(1%, 1 cm.) 2.23], 290 mμ [log E(1%, 1 cm.) 2.24].

A flow diagram illustrating the manner in which these alkaloids were obtained is shown in Fig. 2.

Stability of Potassium Phenethicillin I

Kinetics of Degradation in Aqueous Solution

By M. A. SCHWARTZ, A. P. GRANATEK, and F. H. BUCKWALTER

Kinetic studies of the degradation of potassium phenethicillin in aqueous solution have been carried out and presented with a view toward stability prediction. Phenethicillin, an acid with pKa 2.9, is hydrolyzed by both acid and base with minimum rate of degradation at about pH 6.5 at 35°. In acid solution the ionic form of phenethicillin is hydrolyzed about 13 times as fast as the free acid. The $HPO_4^=$ ion was found to be a general base catalyst. The effect of temperature in the neutral pH region has been determined, and from this data the aqueous solution stability of potassium phenethicillin at 25 and 4° has been predicted.

Potassium phenethicillin[1] is the first commercially produced semisynthetic penicillin.

Its chemical, microbiological and pharmacological properties have been described (1–3). Clinical studies have also been reported (4, 5). The present work was undertaken to enable the prediction of the optimum stability formulating conditions for potassium phenethicillin in aqueous solution.

EXPERIMENTAL

One lot of commercially produced potassium phenethicillin containing approximately 60% of the L-form was used throughout this study. All buffer materials were reagent grade.

The kinetic studies were carried out as follows: 90 ml. of buffer (pH range given in Table I) in a 100-ml. volumetric flask was brought to bath temperature and then 1.0 ml. of a freshly prepared 0.1 *M* aqueous solution of potassium phenethicillin was added with mixing. At appropriate intervals, 2.0-ml. samples of the reaction mixture were taken and added to 8.0 ml. of cold 0.5 *M* pH 6 citrate-phosphate buffer to quench the reaction. These solutions were immediately frozen and kept in this state until just before assay. The phenethicillin potency of these samples was determined by the microbiological turbidimetric assay method with *Staph. aureus* strain FDA209-P as the inoculum.

In order to determine the effect of freezing the quenched samples until assay, a solution of 80 mcg./ml. of potassium phenethicillin in the strong pH 6 buffer was divided into 10-ml. samples and frozen. One sample was assayed each day for 13 days. No significant loss of potency was observed despite a day-to-day variability of 14.5%. To avoid this, all samples from a single kinetic run were assayed on the same day. The maximum time these were kept frozen was 6 days.

The ionic strength of all the buffers was adjusted to 0.5 with potassium chloride. The pH was determined with a Beckman Zeromatic pH meter using glass and calomel electrodes.

The pKa of phenethicillin was determined in 0.5 *M* potassium chloride by taking the pH of a half-neutralized 0.01 *M* solution.

Received August 14, 1961, from the Research Division, Bristol Laboratories, Syracuse, N. Y.
Accepted for publication September 18, 1961.
The authors wish to thank Mrs. Irene Rubycz for her valuable technical assistance and Mr. K. L. Teegarden for his assistance in the statistical evaluation.

[a] Approximate molar concentrations, calculated from the following pKa: H_3PO_4 = 1.96, $H_2PO_4^-$ = 6.70, $H_3Cit.$ = 3.08, $H_2Cit.^-$ = 4.75, $HCit.^=$ = 5.40. [b] Observed first-order constant. [c] Extrapolated value. [d] Initial pH. [e] Initial Concentration. [f] Second-order rate constant (L. $mole^{-1}$ $hr.^{-1}$).

RESULTS AND DISCUSSION

Order of Reaction.—At constant temperature and pH the hydrolysis of phenethicillin is an overall first-order reaction as shown by the linear log concentration-time plots of Fig. 1. These are typical of the results obtained throughout this study.

Runs 18 through 20 in Table I were made using 0.001 *M* potassium phenethicillin with 0.001, 0.002, and 0.003 *M* hydroxyl ion. The data are plotted as second-order reactions as in Fig. 2. The rate constants were determined from the slopes by the method of least squares.

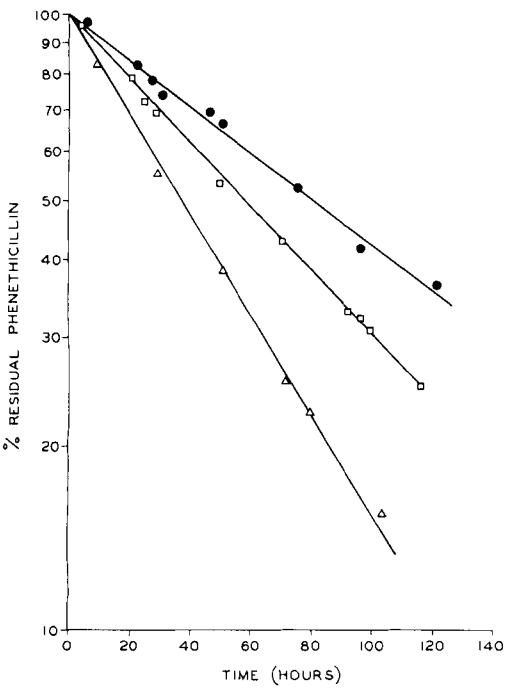

Fig. 1.—First-order plots of degradation of phenethicillin at 35° at several pH's. Δ, pH 3.9; ● pH, 6.7; □, pH 7.4.

Table I lists the buffers used and the observed results. The k' values were all calculated by the method of least squares. The standard deviations, $\sigma k'$, were obtained essentially by the method described by McLeod, *et al.* (6).

pH Dependence.—Figure 3 shows the dependence of the rate of hydrolysis of phenethicillin on pH. The dashed curve shows the actual values found while the solid curve is corrected for buffer effects. The effect of buffers is discussed in a subsequent section.

The curvature on the acid side indicates that more than one species is involved in the reaction. Since phenethicillin is an acid with pKa 2.9, one may calculate the proportions of unionized and ionized material as a function of pH from the following relationships

$$f_{HP} = \frac{[H^+]}{[H^+] + Ka} \text{ and } f_{P^-} = \frac{Ka}{[H^+] + Ka} \quad \text{(Eq. 1)}$$

where f_{HP} = fraction of phenethicillin as the free acid [HP] and f_{P^-} = fraction of phenethicillin ionized [P^-].

The overall hydrogen ion catalyzed reaction may be written in the form

$$-\frac{dP_T}{dt} = k_1 [H^+] [HP] + k_2 [H^+] [P^-] = k' P_T \quad \text{(Eq. 2)}$$

where k_1 and k_2 are the rate constants for the hydrolysis of acid and ion, respectively, P_T is the total drug concentration, and k' is the observed pseudo first-order rate constant. Dividing through by $P_T[H^+]$

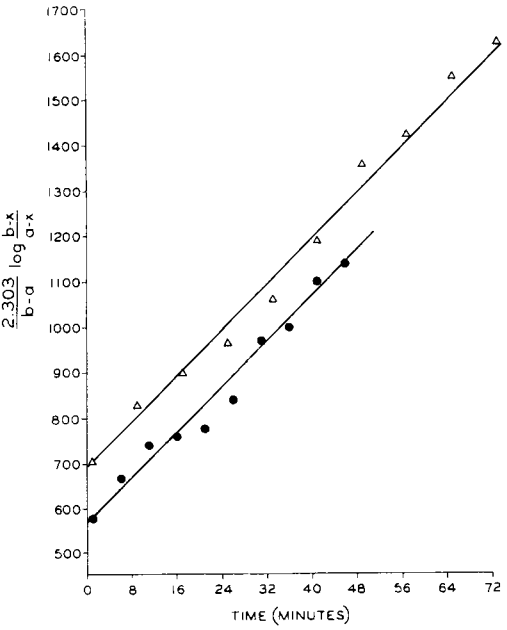

Fig. 2.—Second-order plots of reaction of phenethicillin with hydroxyl ion at 35°. a = Initial molar concentration of phenethicillin, b = initial molar concentration of $[OH^-]$. ●, b = 0.003, a = 0.001; Δ, b = 0.002, a = 0.001.

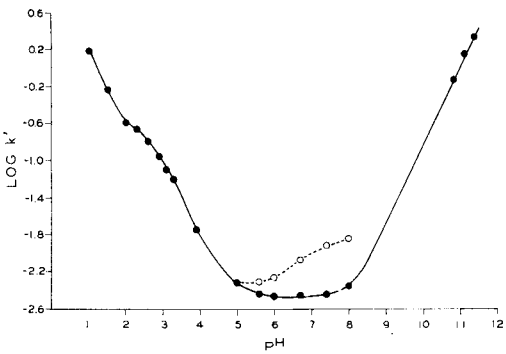

Fig. 3.—pH dependence of rate of hydrolysis of phenethicillin at 35°.

$$\frac{k'}{[H+]} = k_1 f_{HP} + k_2 f_{P^-} \qquad \text{(Eq. 3)}$$

Since $f_{HP} + f_{P^-} = 1$, we may rearrange Eq. (3) to

$$\frac{k'}{[H^+]} = (k_1 - k_2) f_{HP} + k_2 \qquad \text{(Eq. 4)}$$

A plot of $k'/[H^+]$ as a function of f_{HP} should give a straight line with slope $k_1 - k_2$ and intercept k_2. Such a plot is shown in Fig. 4. The constants derived from the best fit line as determined by the method of least squares are[2]: k_1 = 12.5 ± 5.7 L. mole^{-1} hr.$^{-1}$ and k_2 = 162 ± 6.5 L. mole^{-1} hr.$^{-1}$ at 35°. The greater affinity of the negatively charged ion for proton probably accounts for its faster reaction rate.

[2] The errors noted here and subsequently in this paper represent the standard deviation.

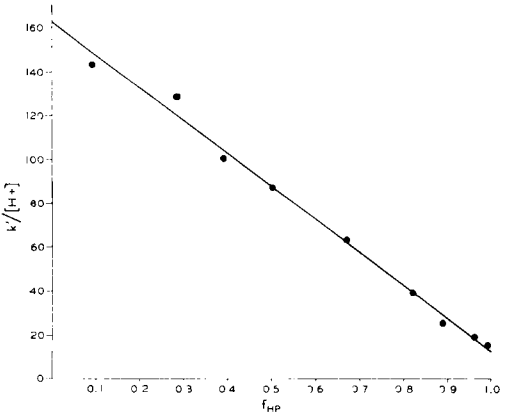

Fig. 4.—Plot of Eq. 4 from which was determined k_1 and k_2 at 35°.

The second-order constant for alkaline hydrolysis was determined directly to be 758 ± 28 L. mole^{-1} hr.$^{-1}$.

From these values the pH of minimum degradation rate may be determined as follows

$$k' = k_2 [H^+] + k_{OH^-} [OH^-] = k_2 [H^+] + \frac{K_w k_{OH^-}}{[H^+]} \qquad \text{(Eq. 5)}$$

since all the phenethicillin is in the ionic form in this pH region. Differentiating k' with respect to $[H^+]$, we obtain

$$\frac{dk'}{d[H^+]} = k_2 - \frac{K_w k_{OH^-}}{[H^+]^2} = 0 \qquad \text{(Eq. 6a)}$$

$$[H^+]_{min.} = \sqrt{\frac{k_{OH^-} K_w}{k_2}} \qquad \text{(Eq. 6b)}$$

At 35° this results in $pH_{min.}$ = 6.5. This, incidentally, is the same value observed in the case of benzyl penicillin (7).

Effect of Buffers.—In the pH range 5.5 to 7.0 where specific acid and base effects were calculated to be negligible, appreciable rates of degradation were observed. This led to the conclusion that water and/or one or more of the buffer ingredients were catalytic species. Examination of the results indicated that the $HPO_4^=$ ion was a general base catalyst. This effect may be formulated as follows

$$k' = k_2[H^+] + k_{OH^-}[OH^-] + k_0 + k_{HPO_4^=} [HPO_4^=] \qquad \text{(Eq. 7a)}$$

which when transposed becomes

$$k' - k_2[H^+] - k_{OH^-}[OH^-] = k'' = k_0 + k_{HPO_4^=} [HPO_4^=] \qquad \text{(Eq. 7b)}$$

A plot of k'' against $HPO_4^=$ should therefore be linear with slope $k_{HPO_4^=}$ and intercept k_0, where k_0 represents the rate of reaction with H_2O. Figure 5 is such a plot, and by the method of least squares the 35° values of k_0 = 0.00325 ± 0.0001 and $k_{HPO_4^=}$ = 0.094 ± 0.003 were obtained. Unprotonated citrate ion appears to have no catalytic effect on the reaction rate.

Effect of Temperature.—For purposes of stability prediction the rate of reaction was run at pH 6.7 as a function of temperature. The Arrhenius plot

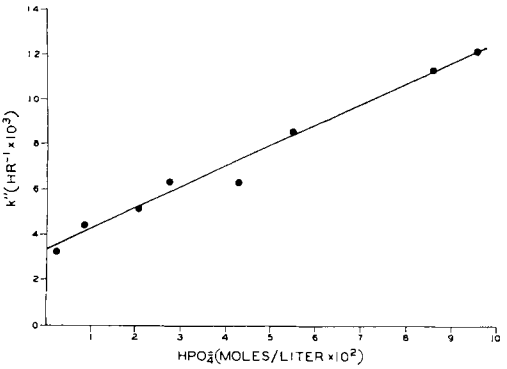

Fig. 5.—Plot showing catalytic effect of $HPO_4^=$ ion on rate of hydrolysis of phenethicillin at 35°

from these data is shown in Figure 6. The energy of activation was calculated to be 17.6 ± 0.3 Kcal. per mole.

Prediction of Stability.—For a solution of phenethicillin not containing phosphate the rate of degradation at room and refrigerator temperatures may be calculated from k_0 determined at 35° and the heat of activation at pH 6.7. This assumes that the latter is the same as the heat of activation for the reaction with water.[3] In this way the following values were calculated k_0 = 0.00134 hr.$^{-1}$ at 25° (room temperature) and k_0 = 0.000129 hr.$^{-1}$ at 4° (refrigerator temperature).

Further application of this data to product formulation will be considered in a subsequent paper.

SUMMARY AND CONCLUSIONS

Degradation rates for potassium phenethicillin have been determined over the pH range 1–11 and as a function of temperature in the neutral region. On the acid side, both the free acid and ionized species undergo degradation at different rates with the constant for the ion being about 13 times that of the acid. The half-life of potassium phenethicillin at 35° and pH 1.5 is about 1 hour. A comparable value for penicillin G is about 4 minutes (7). This fifteenfold increase in potassium phenethicillin stability over penicillin G at pH 1.5 and 35° may account for the greater serum levels achieved with oral administration of potassium phenethicillin.

The pH of the minimum rate of degradation of potassium phenethicillin is 6.5, although the rate of degradation does not increase appreciably until the pH is brought below 5.5 or above 7. Secondary phosphate ion catalyzes the hydrolysis while unprotonated citrate ion does not have a catalytic effect. Optimum aqueous solution stability conditions for potassium phenethicillin would therefore be provided by maintaining the pH of the preparation between 6 and 6.5 using a buffer such as citrate which has no effect on its hydrolysis in this pH range. Applications of these data to product formulation are considered in a subsequent paper (8).

[3] This was found to be true as will be shown in a subsequent paper.

Derivatives of Thiazolo[5,4-d]thiazole

By HIKMAT T. FIKRAT and J. F. ONETO

A series of bis-2,5-substituted thiazolo[5,4-d]thiazoles has been prepared and examined for biological activity.

THE CONDENSATION of dithio-oxamide with aromatic aldehydes was first described by Ephraim (1). Recently, Johnson and Ketcham (2) reported on studies concerning this reaction and established the structure of the resulting parent heterocycle as thiazolo[5,4-d]thiazole, I, with substituents at the two and five positions being equivalent.

I

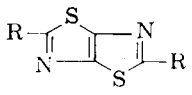
The purpose of our investigation was to prepare a number of hitherto undescribed thiazolothiazole derivatives for biological examination. Compounds of this class were considered to be of empirical interest because of the included thiazole moiety which occurs in a wide variety of agents exhibiting diverse biological activities.

The synthesis was effected in low to moderate yields (10–88%) through condensation of dithio-oxamide with appropriate aldehydes following essentially the published procedure (2). Of particular interest was the development of an alternate preparative method which was studied in the preparation of the previously described benzaldehyde derivative (2), and the pyridine-3-aldehyde and 2,2-dimethyl-4-cyanobutyraldehyde derivatives (Table I). The condensation was carried out in refluxing pyridine and indicated that in the above instances high reaction temperatures were not essential for successful results. However, the yields obtained by this approach were invariably lower than those realized from the published procedure.

Received May 1, 1961, from the School of Pharmacy, University of California Medical Center, San Francisco 22.
Accepted for publication July 28, 1961.
This paper represents part of a dissertation submitted by Hikmat T. Fikrat in partial fulfillment of the requirements for the Ph.D. degree, 1959.
Portions of the paper are adapted from the honorable-mention winning manuscript submitted by Hikmat T. Fikrat in the Western Region, 1959, Lunsford-Richardson Pharmacy Award competition.
The authors are indebted to Dr. L. A. Strait and Mr. M. Hrenoff for the spectral analyses and interpretations. They also wish to express their gratitude to Dr. Leonard Daub and his staff, Parke Davis and Co., for the antimicrobial evaluations, and to Dr. Roger Ketcham for his continued interest and valuable counsel. The pharmacological study of compound 14 was carried out with the cooperation of Dr. Frederick Meyers, Department of Pharmacology, University of California Medical Center, San Francisco.

The apparent limitation of the reaction to aromatic type aldehydes has been reported (2). Our investigation of a number of saturated and α,β-unsaturated aliphatic aldehydes, in addition to the aldehydes studies by Johnson and Ketcham, supports this observation with the exception of the previously mentioned 2,2-dimethyl-4-cyanobutyraldehyde. As this cyano aliphatic aldehyde is devoid of α hydrogen, it was of interest to investigate the reaction behavior of the analogous hydroxypivaldehyde-(2,2-dimethyl-3-hydroxypropionaldehyde) and its acetyl and benzoyl derivatives. Efforts to obtain the corresponding thiazolothiazole derivatives from these aldehydes were unsuccessful.

The reaction of quinoline-2-aldehyde with dithio-oxamide yielded an acid-soluble compound melting at 109–111°, and an acid-insoluble compound which melted over a wide range (230–265°) after several recrystallizations from chloroform. Neither of the products proved to be thiazolothiazole derivatives.



During the course of the investigation, the diamide, dihydrazide, and diisopropylidenehydrazide derivatives of thiazolothiazole-2,5-dicarboxylic acid were prepared and studied.

Inasmuch as bis-(1,1-dimethyl-3-cyanopropyl)-thiazolo[5,4-d]thiazole is the only compound to have been prepared from an aliphatic aldehyde, its structure in addition to analyses was further confirmed by comparing its ultraviolet and infrared spectra with those reported for the parent heterocycle (3).

The ultraviolet absorption of the compound was measured with a Cary model 11 spectrometer at a concentration of 2.5 mg. % in 95% ethanol. Bands appearing at 244 mμ (log ϵ = 3.85) and 251 mμ (log ϵ = 4.11) correspond in shape and contour with the reported thiazolothiazole bands at 242 and 255 mμ (log ϵ = 3.94). A strong band appearing at 278 mμ corresponds with the 260 mμ (log ϵ = 3.87) of thiazolothiazole.

The infrared absorption of the compound was measured in a potassium bromide disk (3 mg. per 400 mg. KBr) with a Perkin-Elmer model 21 spectrophotometer. The observed characteristic vibrational frequencies lead to the following assignments: a broad unresolved band at 3.41 μ in the C—H stretching region is understandable due to the increased variety of C—H bonds as compared with the sharp 3.31 μ band due to the

[a] Compounds 1, 2, 3, 4, 7, and 12 were recrystallized from pyridine; 5 from ethanol; 6 and 8 from phenol-ethanol; 10 from pyridine or benzene-alcohol; 11 from pyridine, chloroform or benzene; 13 from chloroform, and 14 from acetone, benzene, ethanol, or ether. [b] Molar ratio of aldehyde to dithio-oxamide. [c] Time of heating during the indicated internal temperature range. [d] Melting points were determined on a Nalge m.p. apparatus and are uncorrected. [e] Analyses were performed at the Microanalytical Laboratory, Department of Chemistry, University of California, Berkeley. [f] Procedure B. [g] The crude product was hydrolyzed with hydrochloric acid in butanol to the bis-4-aminophenyl derivative; m.p. 296–300° [Lit. (2) 301–303°]. [h] The reaction mixture was then cooled to 180–200° and maintained at that temperature range for 20 minutes. [i] The 2,2-dimethyl-4-cyanobutyraldehyde was supplied through the courtesy of Eastman Chemical Products, Inc., Kingsport, Tenn.

C—H stretch in thiazolothiazole. The presence of the nitrile group is indicated by a characteristic stretching band at 4.5 μ. Peaks at 6.7, 6.8, and 6.9 μ can be assigned to the $-CH_2-$ and $-CH_3$ deformation vibrations. Peaks at 7.14 and 7.26 μ are assigned to the deformation vibrations of the $=C(CH_3)_2$ grouping. The assigned structure appears to be in general agreement with the infrared spectrum.

BIOLOGICAL RESULTS

The compounds appearing in Table I, with the exception of compound 9, were screened at the Parke Davis and Co. Laboratories for antibacterial activity. In addition, the screening program included bis-(4-aminophenyl)thiazolothiazole and thiazolothiazole-2,5-dicarboxylic acid and its dihydrazide and diisopropylidenehydrazide derivatives.

The compounds were tested against representative strains of *Streptococcus pyogenes*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, *Salmonella typhimurium*, and *Mycobacterium tuberculosis*. None of the compounds showed antibacterial activity.

Compound 7 and thiazolothiazole-2,5-dicarboxylic acid were tested for antiviral activity with negative results.

Compounds 1, 2, 3, 4, and 14 showed no effect when tested for amebacidal activity.

Bis-(4-aminophenyl)-thiazolothiazole produced a 20% increase in blood cholesterol when administered to rats by intubation at a 5-mg. daily dose level for 7 days.

Compound 14, the 1,1-dimethyl-3-cyanopropyl derivative, was subjected to a preliminary pharmacological screening and appears to differ in its action from the usual central nervous system depressants.

The acute LD_{50} determined in mice is greater than 1250 mg./Kg. subcutaneously.

When given to dogs, rats, mice, and guinea pigs, orally or intramuscularly in doses of 2–200 mg./Kg., the compound induced normal sleep; that is, animals could be awakened by stimulation, but would subsequently return to sleep even in the laboratory environment. No excitement, respiratory depression, or general anesthesia was seen. Onset of action was 15–30 minutes; duration 2–3 hours. The electroencephalogram showed an ordinary sleep pattern during the action of the drug. The compound appeared qualitatively similar to trimeglamide (4) when directly compared.

The effect of sodium pentobarbital was intensified by the simultaneous administration of compound 14 whether measured by prolongation of sleeping time after anesthetic doses of pentobarbital or augmentation of the effect of subanesthetic doses. The tested compound was given in doses of 25–200 mg./Kg. intraperitoneally.

No autonomic or cardiovascular effects were demonstrable in anesthetized dogs with the smaller (50 mg./Kg.) doses tolerated by the unanesthetized animals.

No analgetic effect, strychnine antagonism, or protection against apomorphine emesis were demonstrable. Minor protection against pentylenetetrazol convulsions was shown.

The compound appears to have highly selective effects on the central nervous system, manifested almost purely by induction of sleep. However, it differs from the sedative-hypnotics in that an ex-

citement is not seen nor can anesthesia and medullary depression be induced by increasing the dose. Unlike the tranquilizers, this thiazolothiazole derivative does not alter autonomic function or exhibit evidences of central stimulation.

EXPERIMENTAL

General Procedures.—The molar ratio of reactants and other reaction data appear in Table I. *Procedure A.*—Following the published procedure (2), a mixture of dithio-oxamide and the aldehyde was heated under a stream of nitrogen in a wax bath. The reaction mixture was cooled and treated with ethanol. The product was filtered and recrystallized.

Procedure B.—Procedure A was modified by refluxing the reactants in dry pyridine for 60 hours. After cooling, the product was filtered and recrystallized.

Dihydrazide of Thiazolo[5,4-d]thiazole Dicarboxylic Acid.—A mixture of 0.5 Gm. (2 mmoles) of bis-(carbomethoxy)-thiazolothiazole, prepared from the corresponding acid (2) and diazomethane, 325 mg. (6 mmoles) of hydrazine hydrate (85% aqueous solution) and 125 ml. of ethanol was refluxed for 6 to 7 hours. The reaction mixture was concentrated by distillation under reduced pressure, filtered, and the product washed with ethanol. The yield was practically quantitative. A suitable recrystallization procedure was not achieved. The crude washed product, m.p. > 400°, gave the following analytical results.

Anal.—Calcd. for $C_6H_6N_6O_2S_2$: N, 32.56; S, 24.84. Found: N, 31.20; S, 24.78.

Diisopropylidenehydrazide of Thiazolo[5,4-d]thiazole Dicarboxylic Acid.—Five drops of glacial acetic acid was added to a suspension of 0.5 Gm. (2 mmoles) of the dihydrazide of thiazolothiazole dicarboxylic acid in 100 ml. of reagent acetone. After refluxing for 1 hour, the reaction mixture was concentrated under reduced pressure and filtered. The yield was practically quantitative. After recrystallization from acetone-ethanol, the product melted at 296–298°.

Anal.—Calcd. for $C_{12}H_{14}N_6O_2S_2$: N, 24.84; S, 18.95. Found: N, 25.28; S, 18.60.

Diamide of Thiazolo[5,4-d]thiazole Dicarboxylic Acid.—A fine suspension of bis-(carbomethoxy)-thiazolothiazole was prepared by dissolving 0.2 Gm. (0.78 mmole) of the ester in 5 ml. of boiling dioxane, followed by rapid cooling in an ice bath. Five milliliters of ammonium hydroxide (27%) was added and the mixture allowed to stand overnight at room temperature. After concentrating the mixture to one-half volume under reduced pressure, the white precipitate was filtered and washed with water and ethanol. The yield was practically quantitative. A suitable recrystallization procedure was not achieved. The crude, washed product did not melt when heated to 400°.

Anal.—Calcd. for $C_6H_4N_4O_2S_2$: N, 24.55; S, 28.00. Found: N, 24.30; S, 27.86.

Pantothenyl Alcohol Effect on Delta-1-Cortisol-Induced Gastric Ulcers

By THOMAS A. LYNCH, WILBUR L. HIGHLEY, and ALBERT G. WORTON

The development of a standardized technique in assessing the ulcerogenic side effects of the corticosteroid drugs has provided an effective means of evaluating antiulcer agents. Approximately 90% incidence of gastric ulcers can be produced in fasting female rats by daily subcutaneous administration of 40 mg./Kg. delta-1-cortisol (D1C) for 4 days. Pantothenyl alcohol, extensively used in treating postoperative intestinal atony, was evaluated for antiulcer activity in such treated animals by two methods: (*a*) oral feeding during the 4 days induction period to determine effect on development on ulcers and (*b*) oral feeding after induction of ulcers to determine the effects on spontaneous healing. Pantothenyl alcohol did not reduce the degree of ulceration during the induction period, but markedly accelerated spontaneous ulcer healing.

THE IMPORTANCE of pantothenic acid to gastrointestinal integrity has been demonstrated by studies involving pantothenic acid deprivation and the pituitary axis. In 1943, Bly, *et al.* (1), demonstrated a 50% reduction of intestinal motility in pantothenic acid-deficient dogs. About the same time, Jurgens and Pfaltz (2) observed atony and distention of the gastrointestinal tract of pantothenic acid-deficient rats. These observations helped establish the basis for the use of pantothenic acid in the treatment of postoperative intestinal atony and gaseous intestinal distention (3–6). The discovery by Lipmann, *et al.* (7), that pantothenic acid formed an integral part of coenzyme A, and the pantothenic deficiency studies in humans by Bean,

Pantothenyl Alcohol Effect on Delta-1-Cortisol-Induced Gastric Ulcers

By THOMAS A. LYNCH, WILBUR L. HIGHLEY, and ALBERT G. WORTON

The development of a standardized technique in assessing the ulcerogenic side effects of the corticosteroid drugs has provided an effective means of evaluating antiulcer agents. Approximately 90% incidence of gastric ulcers can be produced in fasting female rats by daily subcutaneous administration of 40 mg./Kg. delta-1-cortisol (D1C) for 4 days. Pantothenyl alcohol, extensively used in treating postoperative intestinal atony, was evaluated for antiulcer activity in such treated animals by two methods: (*a*) oral feeding during the 4 days induction period to determine effect on development on ulcers and (*b*) oral feeding after induction of ulcers to determine the effects on spontaneous healing. Pantothenyl alcohol did not reduce the degree of ulceration during the induction period, but markedly accelerated spontaneous ulcer healing.

THE IMPORTANCE of pantothenic acid to gastrointestinal integrity has been demonstrated by studies involving pantothenic acid deprivation and the pituitary axis. In 1943, Bly, *et al.* (1), demonstrated a 50% reduction of intestinal motility in pantothenic acid-deficient dogs. About the same time, Jurgens and Pfaltz (2) observed atony and distention of the gastrointestinal tract of pantothenic acid-deficient rats. These observations helped establish the basis for the use of pantothenic acid in the treatment of postoperative intestinal atony and gaseous intestinal distention (3–6). The discovery by Lipmann, *et al.* (7), that pantothenic acid formed an integral part of coenzyme A, and the pantothenic deficiency studies in humans by Bean,

Received June 29, 1961, from the Department of Pharmacology, The Warren-Teed Products Co., Columbus, Ohio. Accepted for publication October 10, 1961.

et al. (8), were important in establishing the link between pantothenic acid and intestinal formation of acetylcholine.

The relationship of pantothenic acid in resistance to stress and adrenocortical function has been presented by numerous workers (9–14). These studies implicate pantothenic acid as a protective factor against certain nonspecific stress effects.

Evidence for the correlation of the ulcerogenic effects of stress and adrenocortical activity has been demonstrated (15–21). However, Zucker (22) was the first to implicate pantothenic acid as a factor in ulcerogenesis. He demonstrated the formation of duodenal ulcers in rats on a pantothenic acid-deficient diet, which were healed by pantothenic acid administration. Evidence was presented in his study to show that the intact adrenal cortex and pituitary gland were necessary for development of these ulcers. An increase in sensitivity and vulnerability of the duodenal mucosa, as a target area, to the effects of adrenocortical hormone was suggested as a mode of ulcerogenesis.

Since there appeared to be good evidence that pantothenic acid deficiency was implicated in the etiology of experimental ulcers, it was decided to study the effect of pantothenyl alcohol in the prevention and treatment of such experimental ulcers in rats without a pantothenic acid depletion.

EXPERIMENTAL

The method of producing gastric ulcers was that of Robert and Nezamis (17), which consisted of administering daily subcutaneous doses of D1C for 4 days to fasted female rats. The animals were sacrificed with chloroform, the stomach removed, cut along the lesser curvature, and the mucosa grossly examined for incidence and severity of ulcers. A composite ulcer index was devised which measured the number, size, and per cent incidence of the ulcers.

Preventive Effects of Pantothenyl Alcohol in D1C-Induced Gastric Ulcers in Rats.—The method of producing ulcers in this study was essentially the same as described by the original workers (17). In the first part of this experiment, pantothenyl alcohol was administered during the ulcer induction period. Thirty female Wistar rats, weighing 167–236 Gm., were used. The animals were divided into three groups using five rats per cage. D1C suspended in a Tween base[1] was administered subcutaneously to two groups of 10 animals each, using a dosage of 1 ml. (40 mg.)/Kg. daily. Ten control rats were given an equivalent dosage of the vehicle by the subcutaneous route. Of the D1C-treated animals, 10 were given 1 mg./ml. of pantothenyl alcohol in their drinking water. All animals were sacrificed with chloroform after 4 days of steroid treatment and fasting, the stomachs removed, and the ulcer index determined. In addition, the adrenal glands were removed and weighed.

Pantothenyl Alcohol Treatment of D1C-Induced Gastric Ulcers in Rats.—Under similar conditions, the effect of pantothenyl alcohol was determined on the healing rate of gastric ulcers after the 4 days ulcer induction period. Thirty female Wistar rats, weighing 160–195 Gm., were used. All animals were given D1C subcutaneously under the same conditions as above. Following 4 days of ulcerogenic treatment, 25 mg./Kg. of pantothenyl alcohol was administered subcutaneously to 15 rats, which thereafter were given 1 mg./ml., of pantothenyl alcohol in their drinking water. Control animals were given an equivalent volume of normal saline subcutaneously. All animals were on Purina laboratory chow diet for the first day, followed by powdered whole milk[2] the remainder of the time. Animals were then sacrificed with chloroform at daily intervals for 3 days to determine the ulcer indexes. Thymus and adrenal gland weights were recorded throughout the experiment. Hemoglobin, erythrocyte, and leucocyte levels were determined on the third day of treatment.

An additional 52 rats (151–191 Gm.) were studied as above to confirm the 3 days pantothenyl alcohol treatment results and to extend the observations over a longer period. The procedure was the same as before, except that Purina laboratory chow was resumed as the diet on the ninth day, and pantothenyl alcohol was withdrawn from the rats on the thirteenth day of the 16 days treatment period. Hematologic tests were not made.

RESULTS

Preventive Effects of Pantothenyl Alcohol in D1C-Induced Gastric Ulcers in Rats.—When pantothenyl alcohol was given during the D1C gastric ulcer induction period, no improvement in the ulcer index was observed. Fasted rats, treated with D1C for 4 days, showed an ulcer index of 16.7, compared to 18.4 for rats on D1C and pantothenyl alcohol (Table I). The ulcer index, as determined by the method of Robert and Nezamis (17), is broken down for the individual rat to demonstrate the severity and incidence. The incidence of ulcers was 95% for the 20 D1C treated rats. These ulcers were found in the pyloric part of the stomach only. An ulcer index of 9.05 was also calculated for the control animals receiving the vehicle alone. Here the ulcers were found in the forestomach only. The results in Table I agree very favorably with those of Robert and Nezamis (17).

As shown in Table II, D1C reduced the adrenal gland weight by about 15%, but pantothenyl alcohol did not significantly influence this change. The mean body weight losses of the control, D1C and D1C-pantothenyl alcohol groups, during the 4 days fast period, were 25.4, 32.3, and 35.5%, respectively. The mean daily water consumption was about 100 ml./Kg. in all groups.

Pantothenyl Alcohol Treatment of D1C-Induced Gastric Ulcers in Rats.—Failure of pantothenyl alcohol administration to affect the development of D1C-induced gastric ulcers, prompted the in-

[1] Tween base, 5 mg. methylcellulose, 4 mg. Tween 80, 9 mg. sodium chloride, and 9 mg. of benzyl alcohol per 1 ml. of aqueous solution.

[c] One rat with perforated ulcer.

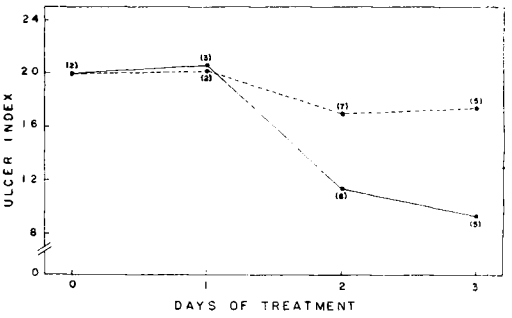

Fig. 1.—Effect of pantothenyl alcohol following the development of gastric ulcers in female Wistar rats. Ulcers induced by 40 mg./Kg. of D1C subcutaneously per day for 4 days in 30 fasted rats. Dotted line represents control animals. Unbroken line represents animals given 25 mg./Kg. of pantothenyl alcohol subcutaneously, immediately after the 4 days ulcer induction period, followed thereafter by 1 mg./ml. in the drinking water (equivalent to about 300 mg./Kg. daily). Number of animals in parentheses.

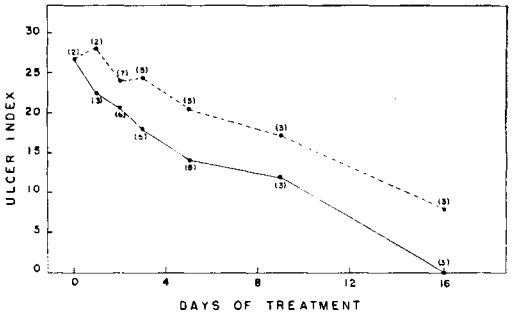

Fig. 2.—Effect of pantothenyl alcohol following the development of gastric ulcers in female Wistar rats. Ulcers induced by 40 mg./Kg. of D1C subcutaneously per day for 4 days in 52 fasted rats. Dotted line represents control animals. Unbroken line represents animals given 25 mg./Kg. of pantothenyl alcohol subcutaneously, immediately after the 4 days ulcer induction period, followed thereafter by 1 mg./ml. in the drinking water (equivalent to about 300 mg./Kg. daily). Number of animals in parentheses.

vestigation of pantothenyl alcohol effects on the spontaneous healing of ulcers. When pantothenyl alcohol was given on a treatment regimen to rats with D1C-induced gastric ulcers, definite declines below the control ulcer indexes were observed. Table III and Fig. 1 show a decrease of 32% in the ulcer index of pantothenyl alcohol-treated rats after 2 days of treatment and a 46% decrease after 3 days.

Hemoglobin, erythrocyte, and leukocyte levels on the third day of treatment were essentially the same in control and treated groups. Determination of thymus and adrenal gland weights failed to reveal a definite pattern.

Water consumption during the 4 days D1C treatment period was approximately 50% greater than before, but increased about twofold in both groups when food and treatment were instituted. Body weight, reduced about 33%, remained at this level in both groups even though the animals were

receiving food during the treatment period. Unabsorbed D1C remained in the subcutaneous site in all of the animals after 3 days of treatment and may have accounted for the absence of weight gain.

The results of the additional 52 rats tabulated in Table IV and depicted in Fig. 2, show an initially higher ulcer index than before, but essentially the same reduction of ulcer index by pantothenyl alcohol during the first 3 days of treatment. The ulcer indexes of the pantothenyl alcohol-treated rats were consistently lower than the controls and averaged about 23% below controls during the first 9 days of treatment. On the sixteenth day, no ulcers were found in the pantothenyl alcohol group, while one perforated ulcer was found in the control group. Extensive multiple erythematous eruptions of the forestomach occurred in both treated and control groups on the fifth day of treatment only. These were more severe in the control rats. No significant changes in thymus and adrenal gland weight patterns were noted.

The relative water consumption and weight change pattern during the first 3 days of treatment was essentially the same as noted earlier. Water consumption continued at about the same rate until the end of the experiment. After the fifth day of treatment, control rats began to gain weight, concomitant with the disappearance of D1C deposits in the subcutaneous tissues; however, on the ninth day, pantothenyl alcohol-treated animals showed obvious signs of alopecia and became emaciated, even though their ulcer index was declining more rapidly. When pantothenyl alcohol was withdrawn from the drinking water on the thirteenth day of treatment, the animals rapidly regained 10% of their body weight in 2 days to match that of the controls, and signs of emaciation disappeared.

DISCUSSION

The production of gastric ulcers in fasting rats by use of D1C confirms the work of Robert and Nezamis (17), and illustrates the efficacy of the method.

The failure of pantothenyl alcohol to prevent D1C-induced gastric ulcers, in contrast to its apparent accelerating effect on healing, may be due to the overwhelming action of the massive doses of steroid during the ulcer induction period.

The sustained depression of body weight, following the 4 days ulcer induction period, corresponds to the presence of D1C deposits in the subcutaneous tissue, and probably prevented a more rapid spontaneous ulcer healing.

The mechanism of pantothenyl alcohol in accelerating the healing of experimental gastric ulcers is obscure. Zucker (22) has suggested as the etiology of the experimental rat duodenal ulcer during pantothenic acid deficiency, that the target area or duodenal mucosa becomes sensitized to the ulcerogenic effect of the adrenocortical steroids. In D1C-induced gastric ulcers, existing levels of mucosal pantothenate may be less adequate in maintaining and restoring cellular integrity. Pantothenyl alcohol may aid in the maintenance and reparative processes of the gastric mucosa by providing a greater level of tissue pantothenate.

The emaciation and the alopecia observed in the rats on the ninth day of treatment is unusual in that the effects appeared as a result of the pantothenyl alcohol treatment. Unna and Greslin (23) found no toxicity when 200 mg. of calcium pantothenate was fed daily to rats for a period of over 6 months. Their average dosage was roughly three times that of pantothenyl alcohol used in the present experiment. The observed toxic effects further emphasize the role of pantothenic acid under stress conditions.

SUMMARY

1. Gastric ulcers were experimentally produced in fasted female rats by subcutaneous administration of D1C for 4 days.

2. Pantothenyl alcohol given during the induction period did not significantly alter the development of D1C-induced gastric ulcers.

3. Pantothenyl alcohol markedly accelerated the healing of gastric ulcers when given during the recovery period. Complete healing was observed by 16 days in the pantothenyl alcohol group, but required a longer period in the control animals.

4. Pantothenyl alcohol-treated animals showed obvious evidence of toxicity, characterized by emaciation and alopecia on the ninth day of treatment, which disappeared upon withdrawal of the drug.

5. The possible role of pantothenyl alcohol, relative to its effect on D1C-induced gastric ulcers, is discussed.

Quantitative Study of Chelates of Pyridine-2-aldoxime

By SANFORD BOLTON and ROBERT I. ELLIN†

Acid dissociation constants of pyridine-2-aldoxime and its affinity for various metal ions were determined by means of potentiometric titrations. Stable chelates were formed with the following metal ions, listed in order of stability: ferric > cupric > cobaltous > ferrous > nickelous > mercuric > zinc > cadmium >manganous. Calcium and magnesium ions showed no evidence of chelate formation. The unusually high stabilities of the cobaltous and ferrous chelates suggest that the oxime exhibits a specific affinity for these ions. All of the 1:1 chelates showed a strong tendency to hydrolyze, as indicated by results obtained from titrations of solutions containing the reactants in a 1:1 ratio. Colored species were formed in the ferrous, ferric, cobaltous, nickelous, and cupric systems. In particular, the ferrous chelate formed an intense red solution, suggesting possible application of the oxime as an analytical reagent for ferrous ion.

THE CHELATING ability of the oxime group has been recognized for some time; however, relatively little work on the stability of oxime chelates has been reported in the literature. A notable exception is dimethylglyoxime which, because of its analytical applications, has been the subject of extensive investigations (1–3). Recently a few papers have appeared which were particularly concerned with oxime chelation. Murmann has calculated stability constants of chelates of 2-methyl-2-amino-3-butanone oxime and some of its derivatives (4). Proposed chelate structures demonstrated formation of hydrogen bonded species, similar to those observed for dimethylglyoxime chelates. Banerjea and Tripathi noted the intense colors of cuprous and ferrous chelates of methyl-2-pyridyl ketoxime and described the use of this oxime as an analytical reagent for these metals (5). During the course of the present investigation, a paper by Krause and Busch was published, which described in detail the isolation of and formulas for nickelous, palladium, and platinum chelates of pyridine-2-aldoxime (6).

The primary purpose of this investigation was to study the ability of pyridine-2-aldoxime to form chelates with selected metal ions. These metal complexes may be of value in the treatment of poisoning by organophosphate anticholinesterases. Wagner-Jauregg and associates (7) demonstrated that the hydrolysis rate of diisopropylphosphorofluoridate (DFP) is greatly accelerated in the presence of various cupric chelates; the α,α'-dipyridyl chelate, which is related structurally to pyridine-2-aldoxime, showed the strongest catalytic activity. A similar study by Courtney and associates (8) described a number of metal chelate compounds which acted as catalysts in hydrolyzing DFP and isopropyl methylphosphonofluoridate (sarin). Although these complexes are efficient for decomposing organophosphate anticholinesterases, only a few appear to have been tested *in vivo* (9).

EXPERIMENTAL PROCEDURE

Reagents.—Pyridine-2-aldoxime, recrystallized from 50% ethanol, m.p. 113°; potassium nitrate, analytical reagent; sodium hydroxide solution (carbonate free) and hydrochloric acid, both standardized by conventional methods; ferric nitrate ferrous chloride, cobaltous nitrate, nickelous nitrate, cupric nitrate, mercuric chloride, cadmium nitrate, zinc nitrate, manganous nitrate, calcium chloride, and magnesium nitrate, all analytical reagent grade. Purities of the metal salts, with the exception of ferrous chloride, were checked by titrating with an 0.05 *M* solution of the disodium salt of EDTA, analytical reagent, according to methods suggested by Chaberek and Martell (10), using Eriochrome-schwartz T and murexide as indicators. Ferrous chloride was analyzed by a conventional method.

Procedure.—The experimental method consisted of potentiometric titrations of the oxime alone and in the presence of various metal ions. The ratio of ligand to metal salt in solution was varied to determine both the qualitative and quantitative nature of the interaction (11). The ionic strength for all solutions was maintained at 0.1 *M* by the addition of potassium nitrate. To insure the exclusion of carbon dioxide, nitrogen was passed through the solutions during the course of the titrations. During each titration, enough time was allowed between addition of increments of base to make certain that equilibrium was attained. This precaution was especially critical in the cobaltous and ferrous systems, where in many instances a considerable period of time elapsed before the pH readings became constant. All measurements were made at 24 ± 0.5° with a Beckman model G pH meter, equipped with extension electrodes. Spectrophotometric measurements were made with a Bausch and Lomb Spectronic 20 colorimeter.

THEORY

Chelate Formation.—Chelates of pyridine-2-aldoxime may take either of the two forms illustrated in Fig. 1. If equilibrium 2 is predominant it is possible that the resulting chelate may act as a relatively weak acid

$$C_5H_4N{-}CH{=}NOH + M \rightleftarrows [(C_5H_4N{-}CH{=}NOH)M] \rightleftarrows (C_5H_4N{-}CH{=}NO^-)M + H^+$$

However, analysis of titration data on the basis of complete dissociation of the aldoxime hydrogen yielded constant values of chelate stability constants. This observation suggests that the intermediate, undissociated form represented above (bracketed) is either absent or present in only negligible amounts in these systems. Therefore, it is impossible to distinguish between the two equilibria represented in Fig. 1 by means of potentiometric titrations.

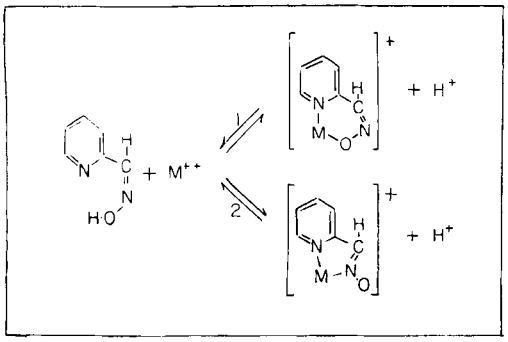

Fig. 1.—Chelates of pyridine-2-aldoxime.

Acid Dissociation Constants.—A method suggested by Chaberek and Martell (12) was used to determine the acid dissociation constants of pyridine-2-aldoxime (pa) from titration data (Fig. 2). The relevant constants are

$$K_{a1} = (HA)(H^+)/(H_2A^+) = 2.05 \times 10^{-4} \quad \text{(Eq. 1)}$$

$$K_{a2} = (A^-)(H^+)/(HA) = 9.50 \times 10^{-11} \quad \text{(Eq. 2)}$$

where $(H_2A^+) = C_5H_4NH^+{-}CH{=}NOH$, $(HA) = C_5H_4N{-}CH{=}NOH$, and $(A^-) = C_5H_4N{-}CH{=}NO^-$. The first dissociation constant (K_{a1}) is of significance in solutions of pH less than 6. When calculating chelate stability constants at higher pH's this equilibrium may be neglected.

Chelate Stability Constants.—The applicable equilibria involved in chelate formation may be expressed as follows

$$M^n + A^- \rightleftarrows MA^{n-1} \qquad K_{MA} = (MA^{n-1})/(M^n)(A^-) \quad \text{(Eq. 3)}$$

$$MA^{n-1} + A^- \rightleftarrows MA_2^{n-2} \qquad K_{MA2} = (MA_2^{n-2})/(MA^{n-1})(A^-) \quad \text{(Eq. 4)}$$

$$MA_2^{n-2} + A^- \rightleftarrows MA_3^{n-3} \qquad K_{MA3} = (MA_3^{n-3})/(MA_2^{n-2})(A^-) \quad \text{(Eq. 5)}$$

where M^n = metal ion of charge n and A^- is defined above. The stability constants were calculated from potentiometric data by an adaptation of Bjerrum's method (13). Derivations of the equations involved have been reported elsewhere (12).

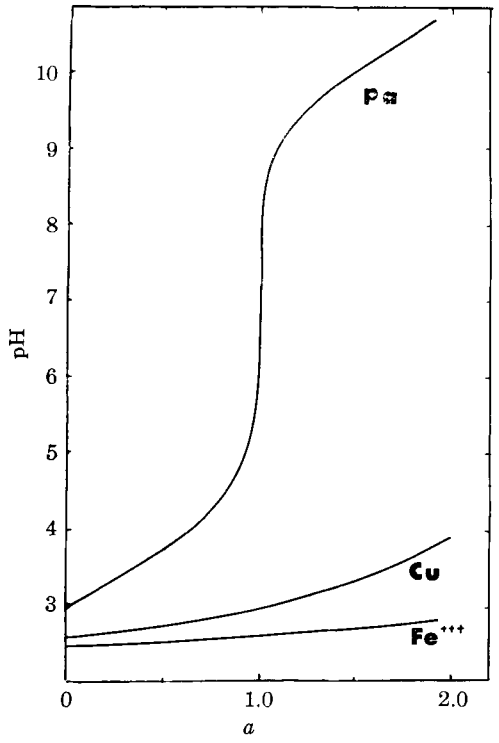

Fig. 2.—Titration curves of pyridine-2-aldoxime (pa) plus one equivalent of HCl. $C_{pa} = 0.008$ *M*. $C_{pa}/C_M = 0.004/0.004$ *M* = 1. *a*, Moles of base per mole of metal ion.

The value of (A^-) may be determined from titration data as follows

$$(A^-) = \frac{(C_A) - a(C_A) - (H^+) + (OH^-)}{\frac{(H^+)}{K_{a2}} + \frac{2(H^+)^2}{K_{a1}K_{a2}}} \quad \text{(Eq 6)}$$

where C_A = total molar concentration of ligand in the system and a = moles of base added per mole of ligand.

The number of moles of ligand bound per mole of metal ion, $\bar{n}$, has been called the "formation function" by Bjerrum (13).

$$\bar{n} = \frac{(C_A) - (A_{free})}{(C_M)} = \frac{(C_A) - (A^-)[1 + (H^+)/K_{a2} + (H^+)^2/K_{a1}K_{a2}]}{(C_M)} \quad \text{(Eq. 7)}$$

where (A_{free}) = total concentration of all free ligand species and (C_M) = total concentration of metal ion in the system; $\bar{n}$ may be calculated from Eqs. 6 and 7.

Bjerrum has shown that log K_{MA}, log K_{MA2}, and log K_{MA3} may be determined from a plot of $\bar{n}$ *vs.* pA, where pA = $-\log (A^-)$, if the successive K values are sufficiently different

$$\log K_{MAn} = p\text{A}, \text{ when } \bar{n} = n - 0.5 \quad \text{(Eq. 8)}$$

$$\log (K_{MAn}K_{MAn-1}) = 2p\text{A}, \text{ when } \bar{n} = n - 1 \quad \text{(Eq. 9)}$$

If the K values, as obtained by this method, do not

differ greatly in magnitude, a method of successive approximations may be used to determine more exact values of the stability constants (13). In the present investigation, K_{MA} and K_{MA2} for the mercuric, zinc, and cadmium chelates were determined by the latter method.

Spectrophotometric measurements may be employed to determine stability constants if the absorption of all pertinent species is known. In the present work, K_{MA} for the ferric chelate was determined by this method. The extinction coefficient for the 1:1 chelate was determined by measuring the absorption of a solution containing ferric ion and oxime, in which the ferric ion was present in large excess to insure complete formation of the 1:1 chelate. The concentration of chelate formed in solutions where chelation was not complete could then be determined from spectrophotometric measurements and K_{MA} calculated according to the following relationship

$$K_{MA} = [(x)/(C_M - x)(C_A - x)] \times [(1 + (H^+)/K_{a2} + (H^+)^2/K_{a1}K_{a2}] \quad \text{(Eq. 10)}$$

where x = molar concentration of chelate.

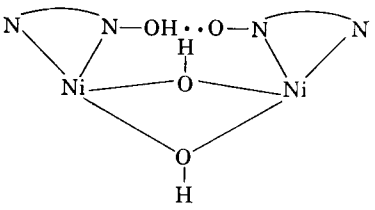
RESULTS AND DISCUSSION

Titration Curves.—The formulas and stability constants of the metal chelates were determined from potentiometric titration curves illustrated in Figs. 2–7. Although manganous ion showed evidence of a weak interaction, precipitation occurred early in the titration, and stability constants could not be calculated. Calcium and magnesium ions showed no evidence of chelate formation. Therefore, the results for the manganous, calcium, and magnesium ions have been omitted from the data.

Figure 2 shows the titration curves for pyridine-2-aldoxime alone and in the presence of equimolar concentrations of ferric and cupric ions. One equivalent of hydrochloric acid was added to the titration mixtures in order to determine the first dissociation constant for the oxime (K_{a1}). Since more than half of the oxime was bound to both ferric and cupric ions before the addition of the acid, the titrations illustrated in Fig. 2 were necessary to determine values of (A^-) at lower values of $\bar{n}$.

Titration curves for a 1:1 ratio of reactants are shown in Fig. 3. Precipitation is indicated by the letter x. In all cases where precipitation did not occur before the completion of the titration, a definite inflection was observed at some point after the addition of one equivalent of base. Such results indicate hydrolysis and/or polymerization of the chelate species (14). In the cases of the cadmium, zinc, and nickelous ions, the end point observed at two equivalents of base suggests one of the following reactions

$$H_2O\text{—}MA^+ + OH^- \rightleftharpoons HO\text{—}MA + H_2O$$



$$2H_2O\text{—}MA^+ + 2OH^- \rightleftharpoons AM\begin{matrix}O\text{—}H\\ \diagup\ \diagdown\\ O\text{—}H\end{matrix}MA + 2H_2O$$

The titration curve for the nickelous ion is also characterized by the appearance of a break at one and one-half equivalents of base. Possible explanations of this phenomenon are: (*a*) dimerization is occurring stepwise

$$2H_2O\text{—}MA \underset{}{\overset{OH^-}{\rightleftharpoons}} \left[\begin{matrix}H\\ |\\ AM\text{—}O\text{—}MA\\ |\\ H_2O\end{matrix}\right]^+ + H_2O$$

$$\overset{OH^-}{\rightleftharpoons} AM\begin{matrix}O\text{—}H\\ \diagup\ \diagdown\\ O\text{—}H\end{matrix}MA + H_2O$$

and (*b*) a stable, dimeric, hydrogen-bonded species is formed

The breaks at approximately one and one-quarter and one and two-thirds equivalents of base for copper are very difficult to rationalize. It would appear that formation of a complex polymeric species is occurring in these solutions. Titration of the ferric chelate was complete upon addition of three equivalents of base, and this fact suggested that a stable dihydroxo-ferric chelate was formed.

When the reactants were present in a molar ratio of two aldoximes to one metal ion, an end point was observed at two equivalents of base (Fig. 4). These

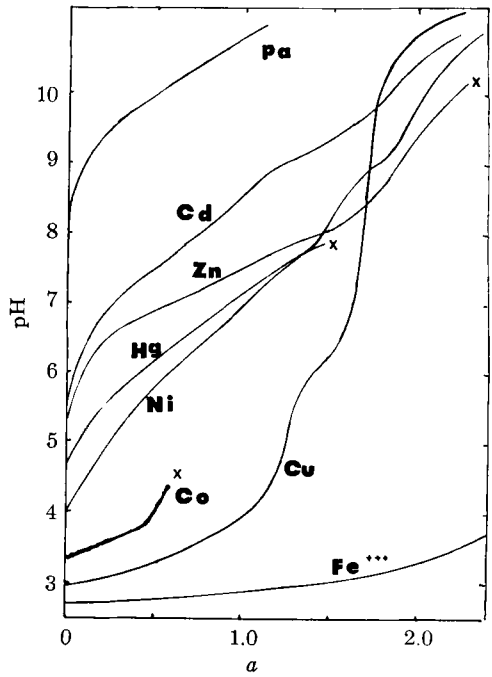


Fig. 3.—Titration curves of pyridine-2-aldoxime (pa). $C_{pa} = C_M = 0.004$ *M*. *a*, Moles of base per mole of metal ion; *x*, precipitation.

curves are indicative of the formation of stable 2:1 chelates. The ferric ion again showed a break at three equivalents of base, an indication of formation of a hydroxo-2:1 chelate. The sharp breaks at one and two equivalents of base for the copper chelate is indicative of a large "spreading factor" (13) between the first and second chelate stability constants.

Figure 5 illustrates titration of the nickelous,

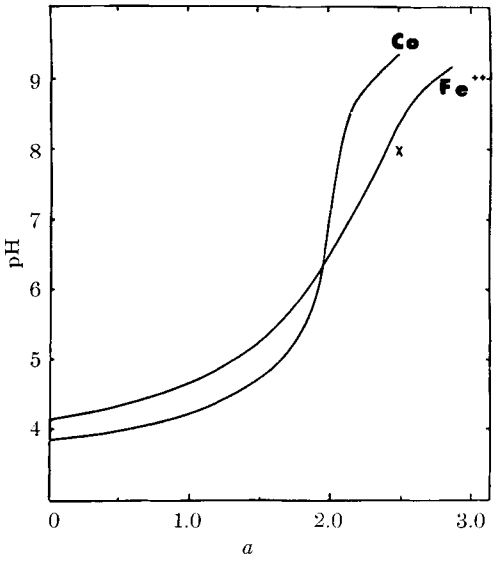

Fig. 6.—Titration curves of pyridine-2-aldoxime. C_{pa} = 0.0032 *M*. C_M = 0.00048 *M*. *a*, Moles of base per mole of metal ion; *x*, precipitation.

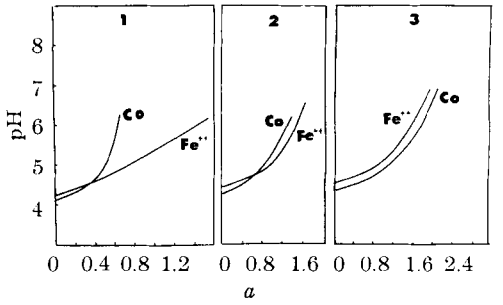

Fig. 7.—Titration curves of pyridine-2-aldoxime. 1, C_{pa} = C_M = 0.00032 *M*. 2, C_{pa} = 0.00032 *M*. C_{pa}/C_M = 2. 3, C_{pa} = 0.00032 *M*. C_{pa}/C_M = 3. *a*, Moles of base per mole of metal ion.

cupric, and ferric systems, containing the reactants in a ratio of three ligand to one metal ion. The single break at three equivalents for the nickelous and ferric ions indicates formation of 3:1 chelates. The curve for the cupric ion shows that stable chelates of an order higher than 2:1 are not being formed. Because zinc, cadmium, and mercuric ions showed no evidence of forming 3:1 chelates under similar conditions, the results are not shown here.

The ferrous and cobaltous interactions (Figs. 6 and 7) have been treated separately for several reasons. Precipitation of a chelate species occurred before completion of the titration in solutions comparable in strength to those illustrated in Figs. 3–5. Further, equilibrium occurred very slowly and it was extremely difficult to determine the point at which the pH of these solutions remained steady. To overcome these difficulties, studies were made at a larger ratio of ligand to metal ion (Fig. 6). These results show the formation of a 2:1 cobaltous and a 3:1 ferrous chelate. In the ferrous system, the

fact that after the addition of two equivalents of base the buffer region occurred at lower pH values was indicative of formation of a 3:1 species. An end point at three equivalents of base was not observed because precipitation occurred before this point was reached. Although equilibrium occurred rather quickly in these systems, cobaltous chelation was virtually complete before the addition of base and stability constants could not be determined. Therefore, studies were made at lower concentrations of reactants (Fig. 7). Again, precipitation occurred in some cases and the equilibrium pH could not be determined at elevated pH readings (pH 5–6) but enough values were obtained at lower pH values to yield reproducible stability constants.

Analysis of Colored Species.—The above discussion does not take into account the possibility that the end points observed in the 2:1 and 3:1 systems could also be due to titration of hydroxo-chelates. The method of Job (15) was used to demonstrate that 2:1 and 3:1 chelates were indeed forming in these systems. This method was applicable to those chelates which formed colored solutions (Table I.)

TABLE I.—COLORS OF CHELATE SOLUTIONS

Chelate	Color		
	Low pH		High pH
Ferric	Deep orange		Brown-red
Cupric	Light green		Deep green
Cobaltous	Yellow		Yellow orange
Ferrous	Red		Deep red
Nickelous	Yellow		Orange
Mercuric		Colorless	
Cadmium		Colorless	
Zinc		Colorless	

Among these solutions only the ferrous chelate showed an absorbance peak in the visible spectrum (515 mμ). [The ferrous chelate formed an intense red solution under alkaline conditions. In dilute, alkaline (pH 10–11) solutions of ferrous ion containing excess oxime, no precipitation occurred and the color was stable for approximately 12 hours. These facts suggest possible use of the oxime as an analytical reagent for ferrous ion.] For the other solutions, a convenient wavelength was selected for analysis as indicated in Fig. 8. Although the data are not included here, the nickelous ion showed evidence of 2:1 chelate formation at high pH values, according to the method of Job. This fact seems to suggest that under these conditions the 3:1 species dissociates to the 2:1 chelate. Otherwise, the results shown in Fig. 8 are completely compatible with the previous discussion.

Isolation of Chelate Species.—A mixture of 0.02 *M* mercuric chloride and 0.02 *M* pyridine-2-aldoxime yielded a white, crystalline precipitate.

Anal.—Calcd. for $(C_5H_4N{-}CH{=}NOH)HgCl_2$: N, 7.15; O, 4.07; Hg, 51.0, Cl, 18.0. Found: N, 7.3; O, 4.2; Hg, 50.4; Cl, 17.8.

It is interesting to note that this insoluble species probably contains the oxime in an undissociated form, since insoluble chelates usually have a zero net charge. However, as mentioned previously, this undissociated form is probably present in negligible amounts in more dilute solutions in which the chelate is soluble.

Attempts to isolate pure chelates formed by cobaltous and ferrous ions failed because the insoluble species precipitated in a colloidal form. Extreme conditions of pH and temperature applied to more concentrated solutions (0.02 *M*) of these chelates resulted in appreciable precipitation. However, analysis showed that these precipitates probably were either mixtures of chelate and metal hydroxides or complicated polymeric forms. Analysis of precipitates obtained by adding excess base to 0.02 *M* solutions of the zinc and cupric chelates also showed no correspondence to a single, simple species. No insoluble chelates could be isolated from the other systems.

Formation Functions.—The formation functions illustrated in Fig. 9, were calculated according to Eq. 7 from data derived from Figs. 2–7. This plot clearly shows the relationship of the stability constants of the various chelates. With one exception, $\bar{n}$ *vs.* *p*A values calculated from titration curves of different ligand:metal ratios were in good agreement. In the nickelous system, results obtained from the 1:1 curve, which described K_{MA}, were different from corresponding results derived from the 2:1 and 3:1 curves. Since the 2:1 and 3:1 titration curves yielded data which were in good agreement, the nickelous chelate formation curve in Fig. 9 was constructed from these data.

The large breaks for the ferrous chelate at $\bar{n}$ = 2 and for the cupric chelate at $\bar{n}$ = 1 indicate a large value for the "spreading factor" between successive stability constants. The other curves show no such inflections, indicating relatively small differences between successive stability constants.

Stability Constants.—Table II lists the Stability constants determined in this study. Previously reported values for dimethylglyoxime are included for purposes of comparison. The constants were determined from the formation functions by methods previously described. Values of $\bar{n}$ greater than 2.3 could not be determined for the ferrous system. Therefore, the value of log K_{MA2} reported in Table II is an approximation, determined from the value of (A^-) at $\bar{n}$ = 2 (Eq. 9). K_{MA} for the ferric chelate was also determined at pH 2 by a spectrophotometric method outlined in the calculations section (Eq. 10) and was in good agreement with the value determined potentiometrically (Table III). The fact that formation of a 1:1 chelate is the predominant equilibrium in solutions of pH 2 was demonstrated by Job's method (Fig. 8). This check was

$(C_A)/[(C_{pa}) + (Fe^{+++})]$	Absorbance, 400 mμ (Corrected)	Log K_{MA}
0.33	0.295	11.27
0.40	0.306	11.23
0.50	0.326	11.25
0.60	0.291	11.21
0.67	0.264	11.20

[a] pH = 2. Molar absorbance of chelate (400 mμ) = 556. $(Fe^{+++}) + (C_{pa}) = 0.0096$ *M*.

made because large errors may be introduced in the determination of a very large stability constant when a relatively small amount of (A^-) is in equilibrium with the chelate.

As previously noted, analysis of the 1:1 titration curve for the nickelous chelate resulted in values of K_{MA} which differed from values obtained from the 2:1 and 3:1 curves. Algebraic calculation of log K_{MA} (12) from 1:1 data at low values of $\bar{n}$ (where chelate hydrolysis does not interfere with the calculations) yielded values which were not constant, varying from approximately 7.5 to 7.0 at $\bar{n}$ equal to 0.21 and 0.36, respectively. These low, inconsistent results are difficult to explain; but they may possibly be due to incomplete dissociation of the oxime hydrogen from the chelate in these solutions. For example, the formation of a dimeric species of a structure similar to that previously suggested (see under discussion of the 1:1 titration curve of the nickelous chelate) could account for the inconsistency of these calculations.

The relative stabilities of transition metal chelates have been correlated with the atomic number of the metal ion (16). This relationship is shown graphically in Fig. 10 for chelates of EDTA, ethylenediamine, and pyridine-2-aldoxime; for which the maximum value of the stability constant occurs for the copper system. A further increase of the

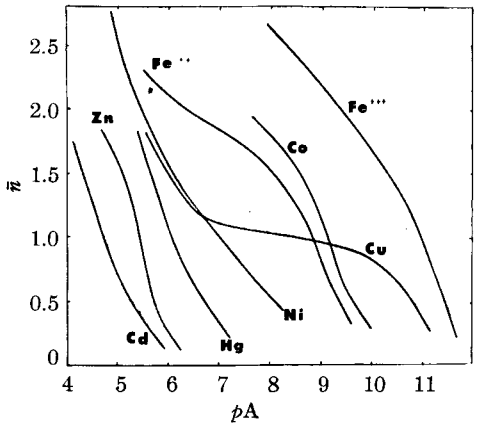

Fig. 9.—Formation functions. pA = log [1/(A$^-$)]. $\bar{n}$ = (Ligand$_{bound}$)/(C_M).

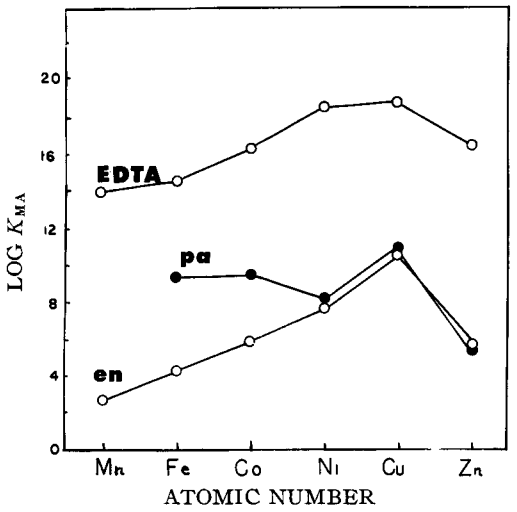

Fig. 10.—Correlation of log K_{MA} with atomic numbers of transition metals (and zinc). en, Ethylenediamine; pa, pyridine-2-aldoxime.

atomic number by one, going to zinc, results in a decrease of the stability constant. It should be noted that the ferrous and cobaltous chelates of pyridine-2-aldoxime show large deviations from the usual results; the affinity of the oxime for these ions is greater than that which would be expected from results observed in other chelate systems. It has been previously noted that complexation may occur through either the oxime nitrogen or oxygen (Fig. 1). The actual configuration may depend on particular circumstances such as pH and the properties of the metal ion. The "specificity" observed for the ferrous and cobaltous chelates may be due to an optimum set of such conditions for the formation of a chelate ring.

SUMMARY

1. The acid dissociation constants of pyridine-2-aldoxime and its chelate stability constants with various metal ions have been determined by means of potentiometric titrations. The stabilities of the 1:1 chelates were in the following order: $Fe^{+++} > Cu^{++} > Co^{++} > Fe^{++} > Ni^{++} > Hg^{++} > Zn^{++} > Cd^{++} > Mn^{++}$. Ferrous and cobaltous ions appeared to have unusually high affinities for the oxime. Calcium and magnesium ions showed no evidence of complexations. Cu^{++}, Co^{++}, Hg^{++}, Zn^{++}, and Cd^{++} ions formed stable 2:1 complexes, while Fe^{+++}, Fe^{++}, and Ni^{++} ions formed 3:1 species.

2. One to one titration curves indicated that hydrolysis and/or polymerization of the 1:1 chelates was occurring at elevated pH values.

3. Colored species were formed in the Fe^{+++}, Cu^{++}, Co^{++}, Ni^{++}, and Fe^{++} systems. In particular, the ferrous chelate formed an intense stable red solution at high pH values.

Thiophosphoric Acid Derivatives of Ethylamine, DL-Methionine, and L-Proline Ethyl Esters III

Biological Activities in Fruit Flies

By FLORENCE C. KLEE† and ERNST R. KIRCH

Biological responses of the flies which eventually did not survive suggest that the compounds are cholinesterase inhibitors. Male fruit flies are the most susceptible in 0.01 and 0.001% w/v solutions. Concentration-toxicity and structure-toxicity relationships are discussed.

THE SYNTHESIS of thiophosphoric acid derivatives of ethylamine, DL-methionine, and L-proline ethyl esters (1) and their biological activities in guppies (2) have been published recently.

The purpose of this investigation was to observe the biological responses of fruit flies (*Drosophila melanogaster*) exposed to 0.1, 0.01, and 0.001% w/v aqueous solutions or suspensions of thiophosphoric acid derivatives which have structures similar to those of known acetylcholinesterase inhibitors. The derivatives have the general formula $-\overset{|}{N}-\overset{S}{\overset{\|}{P}}(X)_2$ where N represents the amine or amino acid ester moiety and $(X)_2$ = $(O\text{-alkyl})_2$, $(O\text{-}C_6H_5)_2$, $(C_2H_5O)Cl$, or $(Cl)_2$.

If these derivatives are anticholinesterases certain biological responses should be observed such as secretion of saliva, dizziness, evacuation of rectum, convulsions, and total paralysis (death).

EXPERIMENTAL

A cornmeal-molasses agar medium (3) was prepared, poured into Erlenmeyer flasks, and autoclaved after cotton stoppers were inserted. Several pairs of red eye and white eye female and male flies were introduced into each flask, and within 11 days many flies developed. One or two-day old flies were used in the investigation of the insecticidal activity of the compounds.

Aqueous suspensions or solutions (0.1, 0.01, and 0.001% w/v) of each compound listed in Table I were tested with 100 flies consisting of 50 males and 50 females in different test tubes. By separating the sexes the biological responses of each sex could be easily observed.

A 9-cm. filter paper was inserted into a 6-inch Pyrex test tube and firmly pressed against the glass surface about one inch from the top of the tube. Young flies were anesthetized with ether and transferred to the paper-lined tubes. Cotton stoppers were inserted and the flies were allowed to recover from the ether. The solution to be tested (0.9 ml.) was slowly introduced onto the filter paper by means of a syringe supplied with a long needle. The flies were periodically observed and the results at the end of 24 hours are presented in Table I. When distilled water was used instead of a suspension or solution of a compound under test it was observed for control purposes that both sexes survived after 24 hours.

Inhibition of cholinesterase is suggested from observations of the fruit flies which eventually did not survive in test tubes containing aqueous suspensions or solutions of the compounds. The flies were extremely agitated and frequently exhibited muscle contractions (of the proboscis and leg) and wing flutter (convulsions). Later they fell on their dorsal side and remained in this position for many hours due to dizziness and leg unsteadiness. All attempts to place them on their feet were unsuccessful.

Sex Differences.—Neither sex survived in 0.1% w/v aqueous suspensions or solutions of 10 of the 17 compounds in Table I.

Ethylamine Series.—Three of the esters which are extremely toxic to male fruit flies are not as toxic to the female flies. About 37% of the females survived after being in contact for 24 hours with 0.1% suspensions of the dichloro derivative or the tertiary ester, and 74% survived after being subjected to the isobutyl ester. The phenyl ester is somewhat toxic (32%) to males and has no effect on female fruit flies.

Amino Acid Series.—The diethyl esters in both amino acid series and the dichloro derivative in the methionine series are relatively less toxic to both sexes since about 45% of the males and about 87% of the female fruit flies survived.

The 0.01% aqueous solutions of all the compounds are more toxic to the male flies with the exception of the isopropyl ester (ethylamine series), ethoxychloro ester (methionine series), and dichloro derivative (proline series) which apparently are not toxic.

Received April 28, 1961, from the College of Pharmacy, University of Illinois, Chicago.
Acccepted for publication August 21, 1961.
This paper is abstracted in part from a dissertation submitted to the Graduate College at the Chicago Professional Colleges of the University of Illinois by Florence C. Klee in partial fulfillment of the requirements for the degree of Doctor of Philosophy in pharmaceutical chemistry.
Presented to the Scientific section A.PH.A., Chicago meeting, April 1961.
The authors wish to thank Dr. Katsuyuki Yokoyama for his suggestions concerning the culturing and handling of large numbers of fruit flies. The authors also wish to thank Dr. Halina Presley for Drosophila cultures consisting of two stocks, wild or red eye, and white eye.

17	$(C_2H_5O)_2P(S)Cl$[b]	100	100	100	5	10	0	0	0	0

[a] X = $C_2H_5NHP(S)$; Y = DL-$CH_3SCH_2CH_2CH(CO_2C_2H_5)NHP(S)$; Z = L-$CH_2CH_2CH_2CH(CO_2C_2H_5)N$-P(S). For control purposes, distilled water was used instead of an aqueous suspension or solution of a compound under test; it was observed that both sexes survived after 24 hours. [b] Reference standard.

Both sexes are unaffected by 0.001% aqueous solutions of the compounds with the exception of five derivatives in the ethylamine series (phenyl, ethyl, normal, tertiary, and isobutyl esters) and the dichloro derivative in the methionine series which are somewhat toxic to the male flies.

DISCUSSION

The biological responses of the fruit flies indicate to the authors that these compounds are acetylcholinesterase inhibitors.

Concentration-Toxicity Relationship

Varying the Concentration of Compounds in the Ethylamine Series, $C_2H_5N(H)-P(S)(X)_2$.[1]—The greatest decrease in toxicity after one tenfold dilution of the 0.1% w/v aqueous suspension or solution is observed with the two and three carbon chain esters and no change in toxicity is observed with the phenyl ester (Table I). The ethoxychloro, ethyl, and normal propyl esters are 87% as effective, whereas the isopropyl ester is no longer toxic to fruit flies. Following a second tenfold dilution, only the diethyl and phenyl esters are somewhat toxic (about 17%) to males.

The four carbon straight-chain ester (normal butyl) and the dihalo derivative are about 74 and 9% as effective after each tenfold dilution.

Only a 46% decrease in toxicity is observed upon one tenfold dilution of the 0.1% suspensions of the four carbon branched-chain esters. After the second tenfold dilution, the decrease in toxicity is 43% for the secondary butyl ester, and about 18% for the tertiary and isobutyl esters. The most toxic compound in 0.01% solution is the *sec*-butyl ester, and the *tert*-butyl ester is the most lethal in 0.001% solution.

Varying the Concentration of Compounds in the DL-Methionine Series, DL-$CH_3SCH_2CH_2CH(CO_2C_2H_5)NHP(S)(X)_2$.[2]—The ethoxychloro derivative is not toxic to flies after one tenfold dilution of the 0.1% suspension.

The dihalo derivative exhibits a 7% decrease in toxicity for each tenfold dilution of the 0.1% suspension and is toxic to males in 0.01% and 0.001% solutions.

The diethoxy ester, which is slightly toxic to both sexes as a 0.01% solution, decreases in toxicity 25 and 6% per tenfold dilution of the 0.1% suspension.

Varying the Concentration of Compounds in the L-Proline Series L-$CH_2CH_2CH_2CHN(CO_2C_2H_5)-P(S)(X)_2$.[2]—The order of decreasing toxicity upon one tenfold dilution is the dichloro derivative (94%), followed by the ethoxychloro (86%), and diethoxy (35%) esters. The latter two esters are toxic to males as 0.01% solutions, the ethoxychloro ester being twice as potent as the diethoxy ester.

These compounds are not toxic when a second tenfold dilution is made.

Structure-Toxicity Relationship

Varying X[1] Groups: Ethylamine Series $C_2H_5N(H)-P(S)(X)_2$.—Observations of the results obtained with the 0.1% suspensions or solutions indicate that with the exception of the isobutyl and concentration %, w/v phenyl esters, all of the esters are more toxic than the dihalo derivative (Table II).

The compounds display a greater range of toxicity when tested as 0.01% solutions. Branching of the four carbon atom chain enhances toxicity to fruit flies since the four carbon branched-chain esters are more toxic than the corresponding straight-chain ester.

[1] $(X)_2$ = $(O\text{-Alkyl})_2$, $(O\text{-}C_6H_5)_2$, $(C_2H_5O)Cl$, or $(Cl)_2$.

[2] $(X)_2$ = $(OC_2H_5)_2$, $(OC_2H_5)Cl$, or $(Cl)_2$.

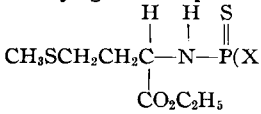
[a] The compounds at each dilution are arranged according to decreasing toxicity. [b] (O-Alkyl)$_2$, (O-C_6H_5)$_2$, (OC_2H_5)Cl, or (Cl)$_2$. [c] Ethylamine, DL-methionine, or L-proline ethyl esters. [d] X = $C_2H_5NHP(S)$; Y = DL-$CH_3SCH_2CH_2CH(CO_2C_2H_5)NHP(S)$; Z = L-$CH_2CH_2CH_2CH(CO_2C_2H_5)N$-P(S). [e] Reference standard.

Apparently there is no differentiation as far as toxicity to male flies is concerned when ethoxy or phenoxy groups are substituted for the normal

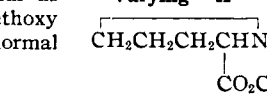
butoxy groups attached to the C_2H_5N— nucleus (Tables I and II). These esters are toxic to male fruit flies to the extent of 30%.



The normal propyl ester is somewhat toxic (12%) to male flies. Branching of this chain, unlike the butyl series, causes a decrease in toxicity and the resulting isopropyl ester is not toxic to flies.

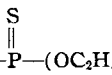
The ethoxychloro and dichloro derivatives are as toxic to male flies as the normal propyl ester.

The tertiary butyl ester, representing maximum branching of a four carbon chain is the most toxic compound to both sexes in 0.001% solution, and the secondary butyl, halo, and three carbon chain derivatives are the least toxic since the latter have no effect on flies at this concentration.

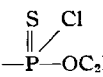


The normal and isobutyl esters are about one-third as toxic and the phenyl and ethyl esters are about two-thirds as toxic to males as the tertiary butyl ester.

Varying X[2] Groups: DL-Methionine Series, DL-



—The results obtained with the 0.1% suspensions of the compounds indicate that when C_2H_5O, Cl groups are attached to this nucleus, maximum toxicity to both sexes results since there are no survivors (Tables I and II). The replacement of the halogen atom by an ethoxy group causes a 90% loss in toxicity to the females and a 42% decrease in toxicity to males. Similarly, when two chlorine atoms are attached to this nucleus the compound is not toxic to females and there is a 54% decrease in toxicity to males. The dichloro derivative is toxic to males to the extent of 18% even after two tenfold dilutions.



Varying X[2] Groups: L-Proline Series, L-

—In contrast to what is observed in the methionine series, equally potent derivatives are obtained when C_2H_5O, Cl groups or two Cl atoms are attached to this nucleus. There are practically no survivors of either sex. Two ethoxy groups on this nucleus produces a decrease in the toxicity to the males and females of about 40 and 80%, respectively. The toxicity of the dichloro derivative is lost upon further dilution. The diethoxy and ethoxychloro derivatives are no longer toxic to females upon one tenfold dilution, but weakly toxic to males.

Varying the Amine:[3]  **Nucleus.**—When the amine attached to this nucleus is ethylamine, an ester is obtained which is quite toxic to both male and female flies when tested in a 0.1% solution and somewhat toxic to males after two tenfold dilutions (Table III). Substituting methionine or proline for ethylamine results in approximately 40% loss in toxicity to males and about 84% loss in toxicity to females. The 0.01% solutions of the amino acid esters are somewhat toxic to male fruit flies but have no effect on flies after a tenfold dilution.

Apparently, substituting methionine for proline makes very little difference in the toxicity of the ester obtained, but substituting ethylamine for either amino acid enhances its toxicity.

Varying the Amine:[3]  **Nucleus.**—All of the amines produce esters which are equally potent in 0.1% suspensions or solutions and nontoxic in 0.001% solutions.

[3] Ethylamine or the DL-methionine and L-proline ethyl esters.

TABLE III.—PER CENT EXPIRED OF FRUIT FLIES IN 24 HOURS VARYING THE AMINE[a] ATTACHED TO THE —P(S)(X)$_2$[b] NUCLEUS

Amine[a]	Concentration, % w/v: 0.1 Total %	0.1 Male %	0.1 Female %	0.01 Total %	0.01 Male %	0.01 Female %	0.001 Total %	0.001 Male %	0.001 Female %
				P(S)(OC$_2$H$_5$)$_2$ Nucleus					
Ethylamine	100	100	100	15	28	2	7	14	0
Methionine	34	58	10	9	10	8	3	4	2
Proline	42	62	22	7	12	2	1	2	0
				P(S)(OC$_2$H$_5$)Cl Nucleus					
Ethylamine	100	100	100	8	14	2	1	2	0
Methionine	100	100	100	0	0	0	2	0	4
Proline	100	100	100	14	26	2	0	0	0
				P(S)Cl$_2$ Nucleus					
Ethylamine	75	90	60	5	10	0	0	0	0
Methionine	26	46	6	19	32	6	11	18	4
Proline	94	96	92	0	0	0	1	2	0

[a] Ethylamine or the DL-methionine and L-proline ethyl esters. [b] (X)$_2$ = (OC$_2$H$_5$)$_2$, (OC$_2$H$_5$)Cl, or (Cl)$_2$.

A difference in toxicity can be noted only with the 0.01% solutions where L-proline produces a derivative more toxic than that of ethylamine or DL-methionine. The methionine derivative is not toxic at this concentration.

Varying the Amine:[3] —P(S)(Cl)$_2$ **Nucleus.**—The order of decreasing toxicity in 0.1% suspensions or solutions is proline, followed by ethylamine, and then methionine. When proline is attached to this nucleus, a derivative results which is toxic to both sexes. Replacement of proline by ethylamine produces a derivative which retains the same toxicity to males but is about 30% less toxic to females. Methionine attached to this nucleus produces a derivative which is not toxic to females and, compared to the proline derivative, is 50% less toxic to males.

The order of decreasing toxicity for the 0.01% solutions is reversed, that is, methionine, followed by ethylamine, and then proline, because ethylamine is only weakly toxic to males and proline is no longer toxic to flies at this concentration.

It is interesting to observe that the methionine derivative in 0.001% solution retains its toxicity to males to the extent of 18%.

SUMMARY

Biological responses of the fruit flies indicate that the thiophosphoric acid derivatives are anticholinesterases.

Results on mature fruit flies show that neither sex survives in 0.1% w/v suspensions of most of the derivatives. The 0.01% solutions are more toxic to the male flies than to the females. Both sexes are unaffected by 0.001% solutions, with the exception of five esters of the ethylamine series (*n*-propyl, *n*-, *tert*-, isobutyl, and phenyl esters), and one methionine derivative (dichloro), which were somewhat toxic to the male flies.

Concentration-toxicity and structure-toxicity relationships are discussed.

Thiophosphoric Acid Derivatives of Ethylamine, DL-Methionine, and L-Proline Ethyl Esters IV

Biological Activities in Seeds of *Hyoscyamus niger*

By FLORENCE C. KLEE† and ERNST R. KIRCH

The effect of certain thiophosphoric acid derivatives on germination and seedling growth of hyoscyamus seeds was observed. All of the compounds as 0.1% w/v suspensions or solutions inhibited the growth of the seedlings. Four ethylamine and two DL-methionine derivatives inhibited germination, whereas two esters stimulated germination. Inhibition and stimulation of germination and growth were observed with some of the 0.01% solutions. The 0.001% solutions had no effect on germination, but seven promoted the growth of the seedling. Structure-toxicity relationship is discussed.

THE SYNTHESIS of thiophosphoric acid derivatives of ethylamine, DL-methionine, and L-proline ethyl esters (1) and their biological activities in guppies (2) and fruit flies (3) have been reported recently.

These thiophosphoric acid derivatives have structures similar to known anticholinesterases.

$$\begin{array}{c} \quad\quad S \\ | \quad \| \\ -N-P(X)_2 \end{array}$$

Their general formula is —N—$P(X)_2$, where N represents the amine or amino acid ester moiety and $(X)_2$ = $(O\text{-alkyl})_2$, $(O\text{-}C_6H_5)_2$, $(C_2H_5O)Cl$, or $(Cl)_2$. The observed biological responses of guppies and fruit flies which have been in contact with aqueous solutions of these compounds seem to indicate that these compounds are indeed acetylcholinesterase inhibitors.

There exists the possibility of these thiophosphoric acid derivatives inhibiting other enzymes since Aldridge has shown that organophosphorus compounds are not specific inhibitors for the cholinesterases but rather inhibitors for enzymes possessing carboxylic esterase activity (4). Seeds contain many enzymes playing a role in the synthesis and hydrolysis of carbohydrates, proteins, and lipids (5). The purpose of this investigation is to observe the effect of 0.1, 0.01, and 0.001% w/v aqueous suspensions or solutions of certain thiophosphoric acid derivatives on the germination and seedling growth of *Hyoscyamus niger* L. seeds.

Accepted for publication August 21, 1961.

This paper is abstracted in part from a dissertation submitted to the Graduate College at the Chicago Professional Colleges of the University of Illinois by Florence C. Klee in partial fulfillment of the requirements for the degree of Doctor of Philosophy in pharmaceutical chemistry.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

The authors wish to thank Dr. Katsuyuki Yokoyama for the supply of *Hyoscyamus niger* seeds for this investigation. The authors are grateful to Dr. Allan M. Burkman for his helpful suggestions concerning statistical calculations.

† Present address: University of Illinois, Navy Pier, Chicago.

EXPERIMENTAL

Two milliliters of an aqueous suspension or solution (0.1, 0.01, and 0.001% w/v) of each compound in Table I was slowly introduced with a syringe on a filter paper containing 80 seeds (*Hyoscyamus niger*) in a 9-cm. Petri dish. For a control, two ml. of distilled water was used instead of the aqueous solution of the compound to be tested.

The Petri plates were covered and placed in the dark for 2 days. On the second day, two ml. of distilled water was introduced into each dish. After 4 days, the number of seedlings which had germinated was recorded and the length of each seedling was measured.

Table I shows the per cent germination, the average height of the seedling observed for each compound at three concentrations, and the standard deviation. The percentages of inhibition or stimulation of germination and seedling growth as compared to the control are presented in Tables II and III, respectively.

Germination.—Germination of the seeds was inhibited to various extents by 0.1% w/v aqueous suspensions or solutions of six compounds, four of which are in the ethylamine series and two in the DL-methionine series (Table II). The dichloro derivative in the ethylamine series is the strongest inhibitor (86%), whereas the diethyl ester (ethylamine series) and dihalo derivative of the methionine series are only half as effective. The ethoxychloro derivative (ethylamine series) is much less effective (16% inhibition), and the weakest inhibition is observed with the tertiary butyl ester (ethylamine series) and the diethyl ester in the methionine series (about 9% inhibition).

It was interesting to observe that the secondary butyl and phenyl esters in the ethylamine series stimulated germination to the extent of 10 and 5%, respectively.

The 0.01% solution of diethoxyethylamidothiophosphate is 17% inhibitory, whereas the diethyl ester in the methionine series is a weak inhibitor (6% inhibition). The normal butyl ester stimulated germination to the extent of 10%.

The 0.001% solutions of the compounds had no effect on the germination.

Growth.—All of the compounds as 0.1% suspensions or solutions inhibited the growth of the *Hyoscyamus niger* seedlings (Table III). Maximum

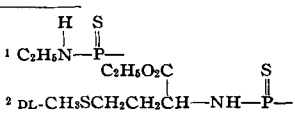
growth inhibition (average of 94%) was caused by the ethoxychloro ester in the ethylamine series and all of the dihalo derivatives.

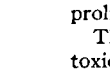


Almost all of the 0.01% solutions of compounds in the three series had an effect on seedling growth. Maximum inhibition (about 20%) was observed with derivatives in the ethylamine series, namely, the diethyl, tertiary butyl, and dichloro derivatives. Stimulation of seedling growth was caused by two esters in the ethylamine series, isopropyl (16%), secondary butyl (11%), and the diethyl ester (7%) in the proline series.

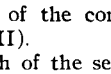
Seven of the 0.001% solutions promoted the growth of the seedling. In the ethylamine series, the isopropyl and normal butyl esters stimulated the seedling growth to the extent of 25%, and the secondary butyl and dichloro derivatives were 12% stimulatory. The diethyl esters in both amino acid series promoted growth to about 17%, whereas the dichloro derivative in the proline series was about 9% less stimulatory. Only one ester, diethoxyethylamidothiophosphate, inhibited seedling growth to the extent of 6%.

DISCUSSION

The effect of various derivatives of thiophosphoric acid on the germination and seedling growth of seeds of *Hyoscyamus niger* was primarily inhibition, however, some stimulation was also observed (Tables II and III).



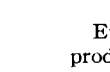
Structure-Toxicity Relationship.—The effects of the 0.1% suspensions or solutions on the germination of hyoscyamus seeds indicate that derivatives which have two chlorine atoms or two ethoxy groups attached to the ethylamine[1] or methionine[2] nucleus



cause inhibition of germination. The ethylamine derivatives are more potent than the corresponding methionine derivatives. The ethoxychloro and tertiary butyl esters in the ethylamine series are weak inhibitors. It is interesting to note that the proline derivatives have no effect on germination.

The following relationships between structure and toxicity are based on the results obtained with the 0.1% suspensions or solutions of the compounds on the seedling growth (Table III).

Varying the Amine.[3]—Growth of the seedling is inhibited to the extent of about 92% irrespective of the particular amine that is attached to the



—$P(Cl)_2$ nucleus.

Ethylamine attached to the —$P(=S)(Cl)OC_2H_5$ nucleus produces a derivative which is 98% inhibitory to growth. When ethylamine is replaced by methionine or proline, much of the inhibitory effect of the derivative is lost since the two amino acid derivatives inhibit growth only to the extent of about 34%.

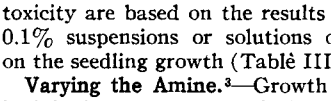
The amine imparting the most toxicity to the

—$P(OC_2H_5)_2$ nucleus is ethylamine (82% inhibition). A 47% decrease in inhibition of growth is observed when proline is substituted for ethylamine. The methionine derivative is 65% less inhibitory than the ethylamine derivative.

Varying the $(X)_2$ Groups[4]

C_2H_5N—P— **Nucleus.**—The order of decrease in the inhibition of growth when the X groups of this nucleus are varied is mono and dichloro (96%), ethyl, *n*-propyl (81%), tertiary (65%), secondary, isobutyl (58%), *n*-butyl (50%), phenyl, and isopropyl (17%).

The halogen derivatives are the most potent growth inhibitors. Two and three carbon straight-chain esters also are very effective; however, the three carbon branched-chain ester has much less inhibitory effect on the growth of the seedling.



Unlike the three carbon esters, branching of the four carbon chain esters enhances the inhibitory effect since the branched-chain esters are more inhibitory to growth than the corresponding straight-chain ester.

Replacement of the two and three carbon straight-chains by a four carbon straight-chain results in an ester which is 31% less inhibitory.

A phenyl ring in place of a halogen or an alkyl group (with the exception of a three carbon branched-chain) greatly decreases the inhibitory action of the compound.

DL-$CH_3SCH_2CH_2C$—N—P— **Nucleus.**—In the methionine series, two chlorine atoms attached to this nucleus produces a derivative which inhibits seedling growth to the extent of 97%. The replacement of one chlorine atom with an ethoxy group results in a 70% loss in the inhibitory action, and when both chlorine atoms are replaced, 80% of this effect is lost.

L-$CH_2CH_2CH_2CHN$—P— **Nucleus.**—As was observed in the methionine series, two chlorine atoms on this nucleus result in a potent growth-inhibitory substance. The inhibitory effect is greatly diminished (by more than 40%) upon substitution of the halogen atoms with one or two ethoxy groups.

[3] Ethylamine or the DL-methionine and L-proline ethyl esters.

[4] $(X)_2$ = $(O\text{-Alkyl})_2$, $(O\text{-}C_6H_5)_2$, $(C_2H_5O)Cl$, or $(Cl)_2$.

SUMMARY

Primarily, inhibition and, to some extent, stimulation were the effects of certain derivatives of thiophosphoric acid on the germination and seedling growth of the seeds of *Hyoscyamus niger*.

Seed germination was inhibited to various extents by the 0.1% suspensions of four ethylamine (dichloro, diethoxy, ethoxychloro, and tertiary butyl) and two methionine (dichloro and diethoxy) derivatives. In contrast, germination was stimulated by three esters, the 0.1% suspensions of the secondary butyl and phenyl esters, and the 0.01% solution of the normal butyl ester. The 0.01% solutions of the diethyl esters in the ethylamine and methionine series had an inhibitory effect. The 0.001% solutions of all the compounds had no effect on germination. Germination was unaffected by any of the solutions of the proline derivatives.

All of the compounds as 0.1% suspensions or solutions inhibited, to various extents, the growth of the seedling. Maximum growth inhibition was caused by the ethoxychloro ester in the ethylamine series and all of the dihalo derivatives. Ten of the 0.01% solutions had an inhibitory effect and three of the solutions had a stimulatory effect on seedling growth. Growth was promoted by seven of the 0.001% solutions.

The relationship between structure and toxicity is discussed.

Comparison of Anticonvulsant and Psychopharmacologic Drugs

By GREGORY B. FINK† and EWART A. SWINYARD

Four anticonvulsant drugs were compared with seven psychopharmacologic agents by a battery of tests designed to detect possible tranquilizing activity. The drugs tested were found to have only one property in common, the ability to prolong hexobarbital sleep time. Five psychopharmacologic agents, chlorpromazine, promazine, trifluprom azine, reserpine, and hydroxyzine, blocked conditioned avoidance responses and reduced amphetamine toxicity in aggregated mice, whereas the two sedative anticonvulsants, phenobarbital and trimethadione, and two psychopharmacologic agents, meprobamate and phenaglycodol, were inactive by these tests. The two nonsedative anticonvulsants, diphenylhydantoin and phenacemide, markedly reduced amphetamine toxicity in aggregated mice, which suggests that these two anticonvulsant drugs may have mild tranquilizing properties.

IN PREVIOUS reports from our laboratories, the anticonvulsant activity of several psychopharmacologic drugs with tranquilizing properties were compared with those of conventional antiepileptic agents (1, 2). In the present report, the tranquilizing activities of four antiepileptic drugs are compared with those of some clinically useful psychopharmacologic agents. This study was prompted by the fact that some conventional anticonvulsant drugs not only control epileptic seizures, but also may exert a salutary effect on the behavioral disturbances which often accompany convulsant disorders (3). Furthermore, anticonvulsant drugs have been used successfully in the treatment of nonepileptic, mentally ill patients (3–7). These observations suggest that anticonvulsant drugs may possess some central properties which are common to those of the psychopharmacologic agents. The experiments described in this communication were designed to test this hypothesis.

METHODS

Adult male albino mice (CF No. 1 strain) obtained from the Carworth Farms were used as experimental animals. They were allowed free access to food and water except during the experimental test period. All drugs were given orally in aqueous solution, except that phenacemide, trimethadione, meprobamate, and phenaglycodol were given as suspensions in 6% acacia solution. The mean neurotoxic dose (TD_{50}) and the time of peak activity were determined for each drug as described elsewhere (2). Equitoxic doses (multiples of the TD_{50}) were given to groups of animals as described below, and the animals subjected to the particular test at the time of peak drug activity. The various drugs examined, their times of peak activity, and their TD_{50}s are listed in Table I.

TABLE I.—TIME OF PEAK EFFECT AND NEUROTOXIC DOSES (TD_{50}) OF SOME ANTICONVULSANT AND PSYCHOPHARMACOLOGIC DRUGS IN MICE

Drug	Time of Peak Drug Effect, min.	Neurotoxic Dose[a] (TD_{50})
Diphenylhydantoin sodium (Dilantin sodium)	180	84 (74–95)
Phenacemide (Phenurone)	45	660 (545–799)
Phenobarbital sodium	180	70 (58–84)
Trimethadione (Tridione)	120	1150 (1055–1253)
Meprobamate (Equanil; Miltown)	30	228 (196–262)
Phenaglycodol (Ultran)	60	170 (119–241)
Hydroxyzine hydrochloride (Atarax hydrochloride)	30	490 (434–553)
Reserpine	240	16.5 (11.6–23.4)
Chlorpromazine hydrochloride (Thorazine hydrochloride)	90	15.7 (10.6–23.2)
Promazine hydrochloride (Sparine hydrochloride)	60	23.5 (15.0–36.9)
Trifluprom azine hydrochloride (Vesprin)	90	7.8 (5.3–11.5)

[a] Values expressed in mg./Kg. with 95% fiducial limits in parentheses.

Hexobarbital Potentiation.—The drugs were administered to groups of 8 mice each. At the time of peak drug effect, hexobarbital sodium (100 mg./Kg.) was injected intravenously. The sleeping time, in minutes, was measured from the end of the injection until the animal regained its righting reflex. The per cent increase in the sleep time of the drug-treated group over that of the corresponding control group run concurrently was calculated and the results were analyzed by the *t* test.

Accepted for publication September 28, 1961.

This investigation was supported by a research grant from the National Institute of Neurological Diseases and Blindness (B-381), National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

This paper is a portion of a thesis submitted by Gregory B. Fink in partial fulfillment of the requirements for the degree of Doctor of Philosophy at the University of Utah.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

† Predoctoral trainee under National Institutes of Health Pharmacology Training Grant (2G-153). Present address: School of Pharmacy, Washington State University, Pullman.

Conditioned Response Test.—A shuttle box (20 in. by 4 in. by 11 in.) was divided into two compartments (one black and one white) of equal length and width, by a barrier formed by elevating the smooth white floor of the white compartment 2 in. The black compartment had walls 9 in. high and a grid floor composed of stainless steel rods (1/8 in. diameter, placed 1/4 in. apart) through which an electric shock (60-cycle a.c.; 50 v., delivered through a grid scrambler) could be applied to the feet of the mouse. An electric buzzer was placed beneath the grid floor of the black compartment and a 25-w. light bulb with a reflector was placed above it. Mice were placed individually in the black compartment. After 15-seconds exposure to the environment, the buzzer and light were activated for 10 seconds. An animal could avoid the electric shock that would follow by escaping to the white compartment (conditioned response, CR). Each mouse was further conditioned until it would escape to the white compartment when placed in the box (secondary conditioned response, SCR). Three end points were used to determine drug activity: abolition of (*a*) the SCR (exposure to 15 seconds of the environment), (*b*) the CR (exposure to 15 seconds of environment alone, and 10 seconds of buzzer and light), and (*c*) the unconditioned response (UR, exposure to 15 seconds of environment alone, 10 seconds of buzzer and light, and, finally, 5 seconds of shock associated with the buzzer and light). The response of each mouse was graded according to an arbitrary point system: a mouse exhibiting a SCR was awarded 3 points; a CR, 2 points; a UR, 1 point; nonresponders to 5 seconds of shock were assigned 0 points. Drug activity was determined in groups of 8 mice. Each mouse was given a block of 4 consecutive trials at 1-minute intervals (a fully conditioned mouse would score 12 points in this control response) and then administered the drug to be tested. At selected times after drug administration, the mice were given another block of trials and the responses recorded. A control group was always tested concurrently with the drug-treated groups to insure that the SCR and CR were not extinguished spontaneously, despite the fact that preliminary experiments indicated that there were no significant differences in the total scores of a group of 8 control mice given successive blocks of trials over a 4-hour period. The data were statistically analyzed by the Walsh test (8).

Amphetamine Toxicity Tests.—The drugs were initially tested by the 3-mice-per-cage test described by Lasagna and McCann (9), except that an intraperitoneal dose of 97.5 mg./Kg. of amphetamine, equivalent to 3 times the LD_{50} determined in aggregated mice, was employed as previously reported (10). This test was so severe that even reserpine, a drug known to have tranquilizing properties, was ineffective in nontoxic doses. Therefore, amphetamine toxicity was also studied in aggregated mice by a modification of the 10-mice-per-cage test described by Burn and Hobbs (11). Fifty mice were randomly divided into 5 groups of 10 mice each. A different drug at a selected dose level was administered to each of four groups, and the requisite volume of vehicle was given to the fifth group, which served as a control. Thirty minutes before the time of peak effect for each drug (15 minutes for drugs with a time of peak effect of 30 minutes), each animal was given 25 mg./Kg. of amphetamine sulfate intraperitoneally. Each group of mice was then placed in a clear plastic cage (27 cm. by 17 cm. by 12 cm.) with a screen bottom. Twenty-four hours later the number of dead mice in each box was recorded. The above procedure was repeated until 20 mice (2 groups of 10 mice each) had received the selected dose of each drug. The data were statistically analyzed by the Chi-square method, and drug activity was expressed as a ratio (% of deaths in control group/% of deaths in drug-treated group).

RESULTS

The effects of some anticonvulsant and psychopharmacologic drugs on hexobarbital sleep time in mice are summarized in Table II. As indicated in the table, all of the agents significantly increased hexobarbital sleep time. The increase in sleep time ranged from 40% for meprobamate to 240% for diphenylhydantoin.

TABLE II.—EFFECTS OF SOME ANTICONVULSANT AND PSYCHOPHARMACOLOGIC DRUGS ON HEXOBARBITAL SLEEP TIME IN MICE

Drug	Dose mg./Kg.	Dose Multiples TD_{50}	Increase in Sleep Time,[a] %
Diphenylhydantoin	42	1/2	240
Phenacemide	330	1/2	177
Phenobarbital	35	1/2	53
Trimethadione	575	1/2	81
Meprobamate	114	1/2	40
Phenaglycodol	85	1/2	207
Hydroxyzine	122	1/4	117
Reserpine	8.2	1/2	55
Chlorpromazine	7.8	1/2	184
Promazine	11.7	1/2	71
Trifluprom azine	3.9	1/2	168

[a] All values in this column are significantly different from controls ($P < 0.05$).

The effects of these same drugs on conditioned responses in mice are shown in Table III; these effects are expressed as activity ratios (total points in predrug blocks of trials/total points in postdrug blocks of trials). Ideally, a drug that blocks only the secondary conditioned response (SCR) in all animals has an activity ratio of 1.5 (12/8), whereas a drug that blocks the conditioned response (CR) in all animals has a ratio of 3.0 (12/4). Ratios above 3.0 indicate that the unconditioned response (UR) is also blocked in some animals. The four anticonvulsant drugs (diphenylhydantoin, phenacemide, phenobarbital, and trimethadione) did not significantly suppress either the SCR or the CR even after doses up to the TD_{50}. Meprobamate and phenaglycodol, in doses equivalent to the TD_{50}, partially blocked the SCR, although only the activity ratio of meprobamate, 1.28, was significant. Hydroxyzine at 1/2 the TD_{50} blocked the SCR in all animals, whereas 8.2 mg./Kg. of reserpine (1/2 TD_{50}) abolished the CR in all animals and blocked the UR in some animals, as indicated by an activity ratio of 3.39. Chlorpromazine exhibited greater activity as the dose level was increased. At dose levels of 3.9 and 7.8 mg./Kg., the SCR and the CR were successively

TABLE III.—EFFECTS OF SOME ANTICONVULSANT AND PSYCHOPHARMACOLOGIC DRUGS ON CONDITIONED RESPONSES IN MICE

Triflupromazine	3.8 (2.4–6.1)	3.8	1/2	3.5[c]

[a] Values expressed in mg./Kg. with 95% fiducial limits in parentheses. [b] % of deaths in control group/% of deaths in drug-treated group. [c] Significantly different from controls ($P < 0.05$).

suppressed (activity ratios, 1.35 and 1.96, respectively). At the TD_{50} (15.7 mg./Kg.), the drug absolished the CR and occasionally blocked the UR, as indicated by a ratio of 3.10. Trifluprom azine was more active and promazine was less active than chlorpromazine at dose levels equivalent to 1/2 the TD_{50}; the ratios were 2.58, 1.26, and 1.96, respectively.

The effects of some anticonvulsant and psychopharmacologic drugs on amphetamine toxicity in aggregated mice are summarized in Table IV. It is evident that the drugs were less effective against amphetamine toxicity in the 3-mice-per-cage test than in the 10-mice-per-cage test. Except for the three phenothiazine derivatives, all the drugs were ineffective in nontoxic doses by the former test, whereas only phenobarbital, trimethadione, meprobamate, and phenaglycodol were ineffective as measured by the latter test. Thus, chlorpromazine, promazine, and trifluprom azine effectively reduced amphetamine toxicity in both situations, whereas diphenylhydantoin, phenacemide, hydroxyzine, and reserpine effectively reduced the toxicity of this substance only in the less severe 10-mice-per-cage test.

DISCUSSION

Three tests were employed to measure the tranquilizing activity of the drugs selected for study; namely, hexobarbital potentiation, a conditioned avoidance response, and protection against amphetaminetoxicity in aggregated mice. It is well known that many diverse agents, including tranquilizers, sedatives, anesthetics, antihistaminics, and other substances, increase the duration of sleep induced by barbiturates (12). However, this is one of few tests which gives positive results with all drugs claimed to have tranquilizing properties (12). Although conditioned responses are extensively used to evaluate psychotropic substances, the ability to alter conditioned behavior in animals is not limited to tranquilizing agents. For example, morphine, 5-hydroxytryptamine, mescaline, and iproniazid have been shown to block the secondary conditioned response (SCR) and/or conditioned response (CR) (13–15). On the other hand, there have been no reports which indicate that agents other than those with tranquilizing activity can reduce amphetamine toxicity in aggregated mice in nontoxic doses. These facts emphasize that no single method can be relied upon to detect the tranquilizing properties of a drug. The above battery of tests was selected because it appeared broad enough to include all agents with tranquilizing properties and selective enough to delineate drugs with mild tranquilizing activity from those with potent activity.

The data presented indicate that the anticonvulsant and psychopharmacologic drugs studied may be divided into 3 distinct groups: (I) phenobarbital, trimethadione, meprobamate, and phenaglycodol, (II) diphenylhydantoin and phenacemide, and (III) hydroxyzine, reserpine, chlorpromazine, promazine, and trifluprom azine. The drugs in group I are reported to have similar profiles of action (1, 2, 16–18) and all possess sedative-anticonvulsant properties. They are characterized herein by having activity in only one test, hexobarbital potentiation. Thus, this group of drugs probably possesses little tranquilizing activity. The drugs in Group II are nonsedative, anticonvulsant agents and are characterized by ability to potentiate hexobarbital and to reduce amphetamine toxicity in aggregated mice. Thus, the two drugs in this group, diphenylhydantoin and phenacemide, appear to have some properties in common with the drugs in Group III, the tranquilizers, which are characterized by giving positive results in all three tests employed. Of the drugs in Group III, chlorpromazine, promazine, and trifluprom azine appear to be more potent tranquilizers than hydroxyzine and reserpine because they are the only agents

effective by the 3-mice-per-cage amphetamine toxicity test.

The published data on the effects of psychopharmacologic drugs on conditioned avoidance responses in rats are in agreement with those presented herein for mice. In rats, chlorpromazine and reserpine block the SCR and CR (13, 14, 19), whereas hydroxyzine blocks only the SCR (14). Trifluprom azine is more potent (20) and promazine is less potent (14) than chlorpromazine when compared for ability to block the CR in rats. Meprobamate and the barbiturates have little effect on the CR as long as the rats are capable of responding to the UR (electric shock) (13, 16, 19). Because these drugs also have essentially the same profiles of action against conditioned avoidance responses in mice, this species appears to be as useful as rats for evaluating drugs by this technique. In addition, the data reported by Lasagna and McCann (9) and Burn and Hobbs (11) on the effects of psychopharmacologic drugs on amphetamine toxicity in aggregated mice are in agreement with those presented herein. This technique appears to be a useful one for discerning tranquilizing properties in candidate psychotropic substances.

The data indicate that two of the anticonvulsant drugs studied, diphenylhydantoin and phenacemide, may have mild tranquilizing activity. In similarity to the tranquilizers (Group III, above) they lack hypnotic activity and may improve mood and behavior in epileptic patients (3, 21). Clinical reports indicate that diphenylhydantoin also calms disturbed nonepileptic psychotic patients (3–6), conditions in which the phenothiazines are effective (22). Phenacemide may improve behavioral disorders; but, in certain cases, it also causes adverse psychic changes (3, 21, 23). On the basis of these observations, it would appear that diphenylhydantoin and phenacemide do indeed possess some tranquilizing properties and that this property should be investigated more fully in human patients.

SUMMARY

Four anticonvulsant drugs and seven psychopharmacologic agents were tested in mice for ability to increase hexobarbital sleep time, to abolish a conditioned avoidance response (CAR), and to reduce amphetamine toxicity in mice aggregated 3 per cage (more severe test) and 10 per cage (less severe test). All drugs significantly increased hexobarbital sleep time. Chlorpromazine, promazine, trifluprom azine, reserpine, and hydroxyzine blocked the conditioned response and/or secondary conditioned response. Meprobamate, phenaglycodol, and the anticonvulsant drugs (diphenylhydantoin, phenacemide, phenobarbital, and trimethadione) had little effect on CAR in nontoxic doses. Only the phenothiazine derivatives were effective by the 3-per-cage amphetamine toxicity test. The phenothiazines, reserpine, and hydroxyzine were active in the 10-per-cage test; two nonsedative-anticonvulsant drugs, diphenylhydantoin and phenacemide, were also effective by this test, which suggests that they may have some tranquilizing properties. The sedative-anticonvulsant drugs (phenobarbital, trimethadione, meprobamate, and phenaglycodol) were inactive by both amphetamine toxicity tests. The significance of these findings is discussed.

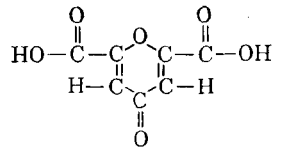
Dissociation Constants of Certain γ-Pyrone Dicarboxylic Acids

Meconic Acid and Chelidonic Acid



By SADAICHI MIYAMOTO† and EINAR BROCHMANN-HANSSEN

Meconic acid and chelidonic acid are very strong acids having dissociation constants of the same order of magnitude as sulfuric acid. This high acidity is explained on the basis of the resonance structure of the γ-pyrone molecule.

THE TWO MAIN acids of opium are meconic acid and sulfuric acid, which together account for 60 to 80% of the total acid content (1). In the course of our studies of the acid composition of opium it became apparent that meconic acid is an exceptionally strong acid, from the point of view of being an organic carboxylic acid. Search of the literature failed to reveal any information about the extent of its acid strength. This led to an investigation of the dissociation constants of meconic acid and the closely related chelidonic acid.

Meconic acid

Chelidonic acid

EXPERIMENTAL

Preparation of Meconic Acid.—Ten grams of powdered opium was mixed with 50 Gm. of Dowex 50-X2(H^+), 50–100 mesh, and 500 ml. of hot water in a 1 L. Erlenmeyer flask. The mixture was shaken mechanically for 30 minutes. The alkaloids, amino acids, and most of the colored materials were adsorbed on the resin, while the organic and inorganic acids were liberated. The supernatant liquid was decanted, 250 ml. of hot water was added to the resin, and the shaking was continued for 15 minutes. This process was repeated. The combined acid extracts were concentrated to about 100 ml. under reduced pressure, and powdered barium hydroxide was added until the solution was distinctly basic to litmus. The precipitate which formed was collected by centrifugation and washed several times by suspension in a little cold water, followed by centrifugation. It was treated repeatedly with small portions of 1 *N* hydrochloric acid to dissolve barium meconate, leaving a residue of barium sulfate. A test for complete removal of barium meconate was made by means of ferric chloride reagent (5% ferric chloride in 0.1 *N* hydrochloric acid). This reagent gives a red color with meconic acid. The combined extracts of barium meconate were neutralized with 10% ammonia, whereby barium meconate again precipitated out. The suspension was centrifuged, the precipitate washed several times with small amounts of cold water, and then transferred to a 250-ml. Erlenmeyer flask with the aid of about 100 ml. of water. Ten grams of Dowex 50-X_2 (H^+), 50–100 mesh, was added and the mixture was shaken mechanically for 30 minutes. The solution, containing free meconic acid, was filtered through a pledget of glass wool and the ion exchange resin was washed with water. The combined filtrate and washings were concentrated under reduced pressure at a temperature below 50°. Meconic acid crystallized and was recrystallized several times from water as the trihydrate. Titration with 0.02 *N* sodium hydroxide gave a purity of 99.8%. Anhydrous meconic acid was obtained by heating to constant weight at 102°. Upon titration the anhydrous sample showed a purity of 100 ± 0.2%.

Preparation of Chelidonic Acid.—Chelidonic acid was synthesized from ethyl oxalate and acetone according to the method described by Riegel and Zwilgmeyer (2). It was recrystallized from water as the monohydrate with a purity of 99.5%. Anhydrous chelidonic acid was obtained by heating at 160° to constant weight.

Determination of Dissociation Constants.—*Titration Method.*—Solutions of meconic acid and chelidonic acid (10^{-3} *M*) were titrated potentiometrically at 25° using a Beckman model W pH meter in combination with a Brown recording potentiometer, the scale of which was graduated in pH units. The titrant, 1 *N* sodium hydroxide, was added at a slow, constant rate by means of a synchronous clock motor driving the plunger of a small syringe. A polyethylene capillary tubing led from the syringe into the solution being titrated. The titration curves, which are illustrated in Fig. 1, show that both acids are very strong acids giving a sharp

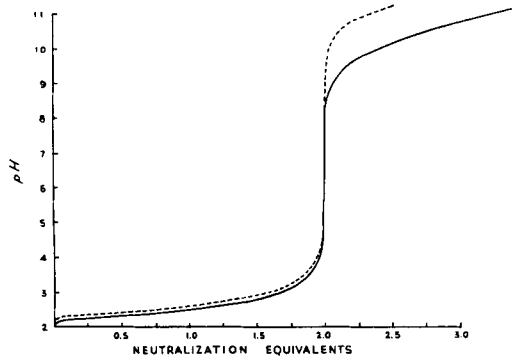

Fig. 1.—Titration curves for meconic acid (solid line) and chelidonic acid (broken line).

change in pH at the neutralization point. Chelidonic acid produces a single break after the addition of two equivalents of alkali, indicating that the two dissociation constants are relatively close. Meconic acid exhibits a second, but much less distinct potential change after addition of three equivalents of base.

The dissociation constants were calculated from the following equation

$$K_a = \frac{[H^+]\left[(Na^+) + (H^+) - \frac{Kw}{(H^+)}\right]}{M - \left[(Na^+) + (H^+) - \frac{Kw}{(H^+)}\right]}$$

where M is the total molar concentration of the acid. Calculations were made at the 0.25, 0.5, and 0.75 neutralization points (Table I). No value could be obtained for pK_1, since the calculations yielded negative results for this constant.

Spectrophotometric Method.—The results obtained by the titration method were checked by a spectrophotometric procedure (3). Meconic acid and chelidonic acid were found to obey Beer's law in the range of 230 to 315 mμ in both acidic, neutral, and basic solutions. Buffer solutions were prepared in range of pH 1 to 11.5. These were adjusted to constant ionic strength by means of sodium chloride and diluted with water to an ionic strength of 0.015 to 0.03 (Table II). Solutions of hydrochloric acid and sodium hydroxide in concentrations of 0.1 N and 1 N were also used for pH adjustment.

The determinations were carried out as follows: in a 25-ml. volumetric flask was placed 0.25 ml. of a solution of meconic acid or chelidonic acid, 5×10^{-3} M, and the volume was adjusted to the mark with buffer solution (or with hydrochloric acid or sodium hydroxide). Thus, a final concentration or 10^{-5} M was obtained. The final pH of the solution was determined with a Beckman model G pH meter and the absorbance was read in a Beckman DU spectrophotometer at 25°. The following wavelengths were chosen to give maximum change in absorbance with a change in pH; for meconic acid: 295, 305, and 315 mμ (Fig. 2); for chelidonic acid: 250, 260, and 270 mμ.

TABLE II.—BUFFER SOLUTIONS USED

pH Range	Composition	Ionic Strength
1.0–2.8	HCl + KCl	0.015
3.0–5.6	CH_3COOH + CH_3COONa	0.02
6.0–7.8	KH_2PO_4 + NaOH	0.02
8.0–11.47	H_3BO_3 + NaOH	0.03

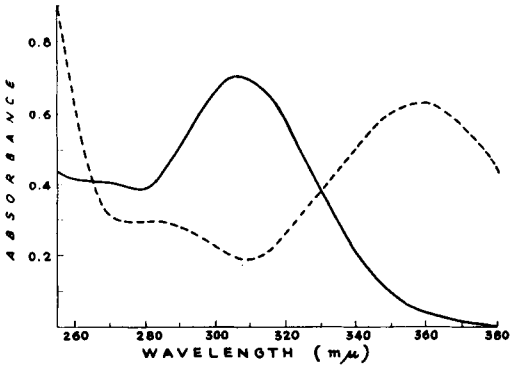

Fig. 2.—Ultraviolet spectrum of meconic acid in 0.1 N hydrochloric acid (solid line) and in 0.1 N sodium hydroxide (broken line).

The degree of ionization (α) was calculated from the following equation

$$\alpha = (k_\alpha - k_m)/(k_i - k_m)$$

where k_m = molar absorptivity of the unionized form, k_i = molar absorptivity of the completely ionized form, and k_α = molar absorptivity of the partly ionized form. Then, pK was calculated as follows

$$pK = pH - \log [(\alpha)/(1 - \alpha)]$$

In the region of low pH values there was very little change in absorbance with a change in pH. It was, therefore, not possible to differentiate

clearly between the molecular form and the ionized form on the basis of spectral changes for the first and second dissociation constants. Consequently, no dependable values could be obtained. The third dissociation constant for meconic acid was readily calculated and gave results that agreed closely with those obtained by the titration method (Table III).

Determination of Dipole Moment.—The dipole moment of anhydrous meconic acid was measured in dioxane at 30° (4). No measurement was made for chelidonic acid because it was not sufficiently soluble in dioxane or any other solvent suitable for dipole moment studies.

RESULTS AND DISCUSSION

The overall results are summarized in Table IV. The ionization constants reported are mean values based on Table I and Table III.

The results show that both meconic acid and chelidonic acid are very strong acids having dissociation constants very close to those given for sulfuric acid (5). This high acidity is probably due to the peculiar character of the γ-pyrone structure favoring a separation of charge by participation of the benzenoid form in a resonance hybrid

The positive charge on the ring oxygen will be expected to increase the acidity by the inductive effect. The high dipole moment for meconic acid also supports this hypothesis.

γ-Pyrone itself has a dipole moment of 4D (6). It has been calculated that if γ-pyrone were completely in the form with a separation of charge, its dipole moment would be 22D (6). Likewise, it has been estimated that its keto form would have a dipole moment of 1.75D (7). The actual situation is, therefore, a resonance hybrid to which both forms contribute.

pK_3	10.10[a] (10.08[b])	...
μ	5.19 D	...

[a] Titration method. [b] Spectrophotometric method.

The inductive effect of the hydroxyl group and hydrogen bonding between the hydroxyl group and the carboxyl group would tend to increase the acid strength of the latter. This would explain why meconic acid is a stronger acid than chelidonic acid.

Infrared spectra indicated the presence of hydrogen bonding in meconic acid, but were otherwise not very helpful for characterization of the structure.

Opium contains about 7 to 13% meconic acid and 2 to 4% sulfuric acid (1). The presence of such high concentrations of very strong acids is probably biologically significant in view of the high alkaloidal content of opium. In the same connection, it is interesting to note that *Chelidonium majus* L., in which the alkaloids also are localized in the latex, contains chelidonic acid, another strong dibasic acid.

Histological Study of *Aristolochia triangularis*, *Casearia sylvestris*, and *Schinopsis balansae*

By PHILIP A. BABCOCK and MAYNARD W. QUIMBY

The content of this paper is concerned with the external and internal morphology of three little-known South American plant drugs: the dried stems of *Aristolochia triangularis* (*Aristolochiaceae*), the dried stem bark of *Casearia sylvestris* (*Flacourtiaceae*), and the dried leaves of *Schinopsis balansae* (*Anacardiaceae*). Stained and unstained sections were employed in this study, as were temporary and permanent mounts. The results of histological studies of powdered and macerated materials are also reported.

THERE is little information in the literature concerning the histology of *Aristolochia triangularis* Chamisso, of *Casearia sylvestris* Swartz, and of *Schinopsis balansae* Engler. Parts of these plants are reportedly used in a ground drug mixture employed by some South American Indians as a remedy for arthritic conditions. This problem was undertaken in order to enter macroscopic and microscopic descriptions of these crude drugs into the literature. The crude drug materials used in this problem were authenticated by Professor Heber W. Youngken.

The histologies of the stems of *Aristolochia triangularis*, the bark of *Casearia sylvestris*, and the leaves of *Schinopsis balansae* have been worked out and are described in this paper.

ARISTOLOCHIA TRIANGULARIS CHAMISSO

Description of the Plant.—*Aristolochia triangularis* Chamisso, family *Aristolochiaceae*, is a tropical woody vine indigenous to Brazil. Bailey (1) reports that it has been cultivated in California. There are about 300 species of *Aristolochia* found in the tropical and the temperate regions of the world. Most members of this genus are woody climbers that commonly possess irregular and grotesque flowers. These flowers often have an equally strange odor. According to Standley (2) the roots of a related species, *A. grandiflora* Swartz, have reportedly been used to poison human beings and animals in the West Indies and that they possess sudorific, abortive, and emmenagogue properties. He further reports that the roots of this and of several other species are used in preparing antidotes for snake bite.

The stems of *Aristolochia*, according to Schenke (3), are soft and tortuous because the ray parenchyma tissue is extensively developed. The soft phellem is thick and possesses numerous longitudinal fissures. Bailey (1) describes the plant as follows: the leaves are simple, deltoid, and glabrous, and have acute apices. They are pellucid-punctate and are palmately veined with three main veins. The lamina is averagely 4 inches long by 6 inches wide, and the petioles are prehensile. Each flower is borne singly and possesses a purple-spotted calyx. A corolla is absent. The fused sepals of the calyx form a bent tube with an oval, basal swelling. The termination of the tube is somewhat constricted, and at this point it widens out into a flat flare. The ovary of the flower is inferior with a lobed and fleshy style. The general floral shape is shown by the flowers of the common Dutchman's pipe, *A. macrophylla* Lam. The fruit is a 6-valued capsule.

Crude Drug.—The material used in this investigation was received as a bundle of dried stems, approximately 2 feet long by 8 inches in diameter. Pieces of stem varied in length from 1 foot to 4 feet and in diameter from 0.25 to 1 inch. The bundle had evidently been made from fresh material and was tied with a young stem. The ends of the stem segments were either cut diagonally or twisted off. The longer stems were bent double. The stem segments were very light in weight. The periderm is thick and very soft and possesses numerous deep longitudinal fissures. The bark is easily separated from the wood and is from tan to brown in color. The wood is light gray. There are occasional white patches of fungal growth on the periderm. The stems are rarely branched. The fracture is complete, brittle, and splintery. The severe drying that this material had been subjected to resulted in some breaking down of tissues and in considerable shrinkage.

Stem Histology.—In transverse section the arrangement of the vascular tissue is indicative of an abnormal woody dicotyledonous stem (Fig. 1). The periderm is layered and is fairly thick. Directly within the periderm lies a sclerenchymatous pericyclic zone made up of lignified cells arranged in an unbroken ring. The phloem consists of dome-shaped patches separated by large fan-shaped rays. The cambial zone is somewhat irregular, for it curves inward at the radii of the xylem rays. This results in a wavy general appearance. The xylem consists of wedge-shaped segments as well as broad rays, arranged in a ring. The xylem segments are usually seven in number and are penetrated by later-formed rays in the older stems. This vascular arrangement is known as an anomalous structure. The pith is small and irregular.

The phellem comprises the broadest area of the periderm. This region is layered with alternating light and dark colored layers. These layers are due

Received August 21, 1959, from the Division of Pharmacognosy and Allied Sciencies, Department of Biological Sciences, Massachusetts College of Pharmacy, Boston 15.

Accepted for publication August 10, 1961.

This paper is based on a portion of a thesis submitted by Philip A. Babcock to the Faculty of the Massachusetts College of Pharmacy in partial fulfillment of the requirements for the degree of Master of Science.

Presented to the Scientific Section, A.PH.A., Cincinnati meeting, August 1959.

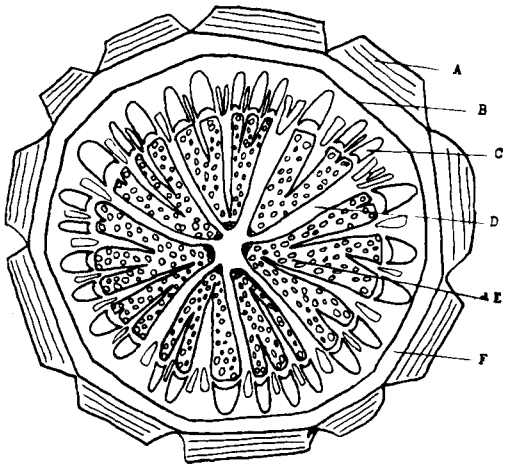

Fig. 1.—Transverse sectional diagram of *Aristolochia triangularis* stem. A, Phellem; B, pericycle; C, phloem; D, xylem ray; E, xylem "segment"; F, phelloderm.

to the variation in the radial dimensions of the cells. The light colored layers are composed of cells, each with a broad radial dimension. The more compact zone is composed of cells, each with a short radial dimension. These phellem layers are not uniform in width throughout. The phellem cells are laid down in radial rows and vary from large, nearly cubical cells to small cells that are nearly rectangular when viewed in transverse section. The cell walls are thin and often wavy. However, the outer walls of the cells are generally thicker than the radial and inner walls. The cells of the phellem contain a large amount of dark brown extractive matter.

The phellogen zone is fairly distinct and is characterized by somewhat compressed rectangular thin-walled cells arranged in radial rows. It is a narrow zone of only a few cells in width.

The cells of the phelloderm are arranged in radial rows and are tangentially elongated. These cells are relatively thin walled. Stone cells are also abundant in this region. These cells are scattered, or are found singly, or in clusters of from two to five cells. These stone cells are tangentially elongated and are characterized by having thick, lignified secondary cell walls with simple pits and branching pit canals. Secretory cells are found scattered throughout the phelloderm. These cells are three to four times larger and less elongated and possess walls that are thin but more sharply defined than the other parenchyma cells of this tissue. The secretory cells contain usually one globular, yellow-orange body, presumed to be oleoresinous.

The inner border of the periderm lies adjacent to an unbroken band of sclerenchyma cells averaging between five and eight cells in breadth. This pericyclic band exhibits two types of cells. That is, it is made up of a band of small, nearly isodiametric, compactly arranged stone cells that is often interrupted by patches of thin-walled fibers. When viewed longitudinally, the pericyclic fibers are seen often to possess septations. The thin walls of the fibers take only a light lignin stain, and have small, oval to slit-like, simple pits. The fibers are long and narrow, and have blunt, tapering ends. One average-sized septate fiber was found to be 1140 μ long with an average width of 27 μ. The stone cells of this region are small and possess thick, heavily lignified walls. Starch grains are rarely observed in the pericyclic sclerenchyma cells.

Stone cells are abundant in the phloem patches, but phloem fibers are absent. The stone cells are found in groups or are scattered. These stone cells possess heavily lignified thick walls. The stone cells in the phloem are fairly isodiametric with four to six sides and a somewhat rounded outline, except those adjacent to the cambial zone, where they are elongated. These are generally three to four times longer than they are wide, with their long axes in sections at right angles to the radius. These elongated stone cells are thinner walled than the scattered stone cells and they possess larger lumina. Furthermore, they are sharply rectangular in outline and are arranged in compact tangential rows, two to four cells in width. The cell walls exhibit numerous simple pits with unbranched pit canals.

Many secretory cells are present, scattered among the cells of the phloem. The secretory cells are large, thin walled, cubical cells with fairly regular outlines. They contain yellow-orange globular cell inclusions.

Phloem parenchyma cells and sieve elements are scattered, and they are indistinct in outline because of the extensive drying to which the material has been subjected. The large fan-shaped rays that separate the phloem patches contain numerous stone cells. These stone cells are thick walled and sharply rectangular in outline when examined in transverse section. The stone cells in the proximity of the cambial zone are more elongated and are arranged end to end in rows which follow the general contour of the phloem rays. The scattered stone cells of the phloem rays are usually situated with their long axes in a radial plane. The ray parenchyma cells contain starch grains more commonly than do the parenchyma cells of the phloem patches. Rarely, small druses are found in the phloem parenchyma.

The cambial zone dips inward between the xylem wedges, and this gives a scalloped appearance in transverse section to the wood region. The cambial zone is composed of a few rows of delicate compressed cells.

The fluted xylem, that is typical of *Aristolochia* and *Menispermum* and of some other vines, is due to abnormal secondary xylem formation. The xylem tissue of *A. triangularis* is divided into wedge-shaped segments, usually seven in number. These segments are often dichotomously divided by the formation of later formed rays. The number of later formed rays increases with the age of the stem. The xylem wedges of the young stems exhibit few of these later formed rays, whereas these rays become increasingly numerous in the older stems until the outer region of the xylem is composed of nearly equal, alternating areas of xylem wedges and rays. Growth rings are not evident.

Two general sizes of vessels are present. The more prominent size is up to 300 μ in diameter. The vessels are numerous and are distributed uniformly throughout the xylem segments. The wood is therefore ring-porous. The vessel members

(elements) here are as broad as or broader than they are high. Vessels with smaller diameters are more numerous. The members of these vessels are more elongated, being two to four times as high as they are wide. These members possess nearly transverse end walls that are characterized by large single pores. The side wall pitting is profuse. The pits are reduced and bordered, varying from large oval pits with distinct borders to small slit-like pits with indistinct borders. Tyloses are present in some vessels of the older regions of the xylem. Occasionally the lumina of some vessels are completely filled by the tyloses. The tyloses are commonly lignified and possess many simple pits that vary from small and slit-like to large and circular.

Full-bordered pit-pairs between vessels as well as between vessels and fibers appear in face view as circles, each enclosing a cross. A longitudinal section showing a vessel wall junction reveals that the pits have small lenticular pit cavities and broad pit canals leading into the cell lumina. These are somewhat similar to the bordered pits of the conifers but they are much reduced.

In transverse view the numerous fibers appear angular in outline, while in longitudinal view they are usually long and tortuous, and they possess characteristically tapering ends. For the most part these fibers have walls that are approximately one-sixth as thick as the cell is broad. This was determined from examination of macerated material. These narrow fibers are, on the average, 1 mm. long. On their side walls they possess many slit-like pits with indistinct borders.

The presence of primary xylem is evidenced by the presence of vessels with annulo-spiral wall thickenings. The primary xylem elements are found on the inner extremities of the xylem wedges adjoining the pith area.

Sparsely scattered wood parenchyma cells occur both singly and in small clusters. These cells are relatively large. They are elongated up to eight or ten times their width. In macerated preparations they often show a distorted outline. The walls of these cells are thickened and lignified. Numerous round or oval simple pits occur in the walls. Even on the same wall these pits vary considerably in size. Small clusters as well as single, very small starch grains are commonly found within these cells.

According to Schenke (3) there are eight initial xylem rays extending from the cambium to the pith. In this investigation seven rays were found to be the more common number. The formation of younger rays divides the initial xylem segments as the stem increases in age. Many older stems show equal, alternating areas of ray and xylem wedge areas in the proximity of the cambial zone.

Ray parenchyma cells, secretory cells, and stone cells are present in the xylem rays. The parenchyma cells are thin walled and rectangular in longitudinal section. In transverse section they appear slightly elongated radially. Stone cells are usually found scattered through the deeper third of some of the rays near the pith. These stone cells are nearly isodiametric and most commonly occur singly, although occasional clusters of two or three are present.

The secretory cells found in the xylem rays are much larger than the ray parenchyma cells. They possess thin but clearly defined walls. Most of them contain a globular, yellow-orange body. These secretory cells are scattered and are not so numerous as the ray parenchyma cells, and they are generally larger but less elongated.

Starch grains are more abundant within the ray parenchyma cells than within any other cells of the xylem.

Crystals in the form of small druses and, rarely, prisms are often present as cell inclusions in the xylem ray cells. Druses of very fine crystals and irregular prisms are not commonly situated within the parenchyma cells bordering the fibers of the xylem. Commonly, only one crystal is present within a single cell, but near the pith region more are sometimes present.

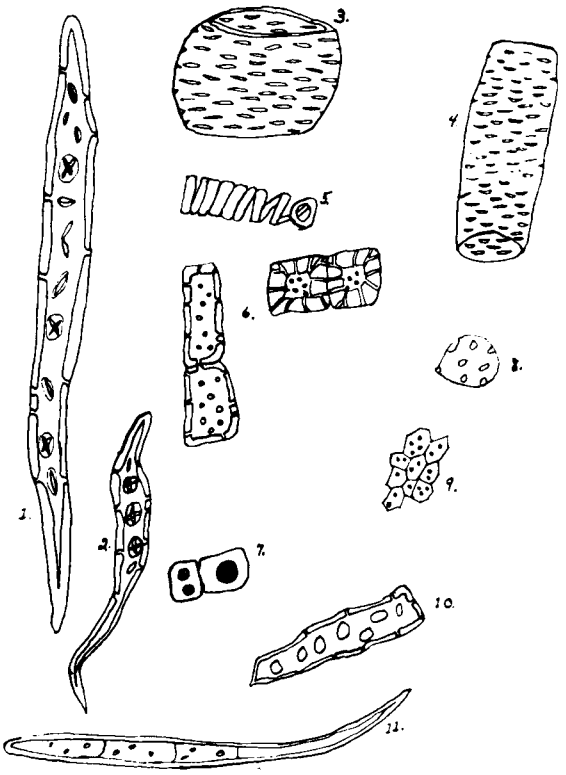

Fig. 2.—Elements of macerated and powdered *A. triangularis* stem. 1 and 2, Wood fibers; 3 and 4, vessel elements; 5, spiral element; 6, stone cells; 7 secretory cells; 8, tyloses; 9, periderm cells; 10, wood parenchyma; 11, septate pericyclic fiber.

The pith area is relatively small and it is irregular because the inner portions of the xylem wedges are not equidistant from the center of the stem. It is composed of typical thin-walled parenchyma cells with coarse simple pits. The cells are loosely arranged. Stone cells occur both singly and scattered in small clusters. They are fairly isodiametric, thick walled, and heavily lignified. Crystals occur more abundantly in the pith than in other tissues of the stem. These crystals are coarser than those of other tissues. They are prismatic or diamond-shaped, and are thin.

Powdered and Macerated Material.—Stem seg-

ments were broken and then ground in a drug mill. The resulting powder was screened through a 40-mesh screen. This resulted in a homogeneous brown powder with no odor.

Other portions of stem material were treated according to the Schulze maceration process. Stem segments were cut into thin longitudinal slices and were put into a beaker. A mixture of one part nitric acid and three parts water was added, and this was followed by a few crystals of potassium chlorate. The beaker was then warmed until bubbles and yellow fumes arose from the liquid. The reaction was allowed to continue until the pieces of wood became white. The material was then removed, washed with running water, and shaken with glass beads to dissociate the cellular elements. Microscopic examination of the powdered and macerated materials revealed the following (Fig. 2): in mounts of the powder, fragments of xylem are prominent. These are composed mostly of clusters of wood fibers and some small vessels. Fragments from the walls of the larger vessels are fairly numerous. Occasional tyloses lignified with numerous large simple pits are present. These have been separated from the walls of the older, large vessels. Fragments of periderm are easily detected because of the characteristic thin and wavy-walled cells of the phellem. Fragments of parenchyma tissue from the rays, pith, and phloem are present. Secretory cells are often present in the parenchymatous tissue fragments. There is usually only one yellow-orange body within any single secretory cell. Occasionally these cell inclusions are found separated from the secretory cells. Stone cells are either associated with parenchyma tissue or they are discrete. There are two general types of stone cells. One type is nearly isodiametric and thick-walled. The other type is elongated. A few small starch grains are present which vary from 3 to 5 μ in diameter. They are angular and possess a faint oval eccentric hilum. Occasional fragments as well as whole crystals are present as rectangular and diamond-shaped platelets and prisms.

Large barrel-shaped vessel elements are readily seen in macerated material. They show numerous bordered pits on their side walls. The pits vary from small slits to large ovals, within rounded borders. The end walls are nearly transverse, each with a single large pore. Many of these large vessels measure up to 300 μ in diameter and are sometimes broader than they are high. One vessel element was found to be 340 μ broad by 290 μ high. The smaller vessels are not nearly so broad, and they are commonly two to four times higher than they are broad. Xylem fibers are thick-walled and are, on the average, 750 μ long by 25 μ wide. They are commonly tortuous and possess numerous slit-like bordered pits. Less common are the thin-walled septate fibers of the pericycle. These average a little over 1000 μ in length by 25 to 30 μ in width. They have small, rounded, simple pits on their thick walls. Stone cells are numerous. An elongated stone cell of average size measures 100 by 36 μ. The other type of stone cell is more nearly isodiametric, thicker-walled, and possesses branching pit canals. The lumen is much smaller in the latter type. Small segments of phellem tissue are present, as are some thin-walled parenchyma cells.

CASEARIA SYLVESTRIS SWARTZ

Description of the Plant.—*Casearia sylvestris* Swartz, family *Flacourtiaceae*, occurs as a shrub or tree that ranges from 3 to 20 meters in height. It is indigenous to the West Indies and to Central and South America. The genera *Hydnocarpus* and *Taraktogenos*, some species of which yield chaulmoogra oil, are also members of this family.

According to Standley (4) the branches of this tree are slender and bear simple alternate leaves that are usually entire. The leaves are glabrous or nearly so with lanceolate to lanceolate-oblong outlines and acute apices. They are from 6 to 10 cm. in length by 2 to 3 cm. in width, and they are thin and densely pellucid-punctate.

Small greenish-white flowers of this plant are borne in umbels on pedicels which are 2 to 4 cm. The fruit is small and obovoid and is 3 to 4 cm. in length.

The pale yellow wood of the tree is hard, heavy, and compact. The tree is used as a source of lumber in Cuba.

Many common names have been given to this plant in the countries of its origin. Some of these are as follows: *comido de culebra*, Nicaragua; *cafeillo cimarron* and *laurel espada*, Puerto Rico; *sarne de perro*, Cuba and Puerto Rico; *rompe-hueso* and *sarnilla*, Cuba.

Crude Drug.—The part used is the stem bark which occurs as curved chips up to 6 inches long. Usually the pieces are not nearly so wide as they are long and they are, on the average, $^1/_4$ inch in thickness. The convex outer surface is brownish-tan with a scaly appearance caused by the sloughing off of small platelets of periderm. Small white areas of fungal growth and some adherent moss and lichens are sometimes evident. The fracture is complete, short, and sharp. The broken transverse surface shows narrow alternating tangential layers of light-brown sclerenchyma tissue and dark brown nonlignified tissue. The concave inner surface is grayish-tan. It is smooth except for slight longitudinal striations. Small white areas of fungal growth are rarely present on this surface. The odor is slightly musty.

Histological Data.—Beneath a thin layer of periderm are alternating strata of nonlignified and of lignified cells. There are numerous, but narrow, phloem rays present. Because of the nature of this material, its histology is essentially that of secondary phloem. The amount of periderm tissue present is usually slight (see Fig. 3).

The phellem is $^1/_8$ inch thick, on the average, and varies from 6 to 20 cells in thickness. The inner and radial walls of these cells are thickened and lignified. They are narrow, tangentially elongated cells with small lumina and are arranged in definite radial rows. The phellogen is indistinct and no phelloderm can be demonstrated. The later formed periderms arise in the outer regions of the secondary phloem, and this results in the sloughing off of the outer tissue in some areas.

The lignified layers of the phloem are made up predominately of stone cells that are elongated vertically. These cells are one and one-half times as high as broad. Tangential bands of stone cells course through the phloem in a regular manner with only occasional dividing or joining. Because the

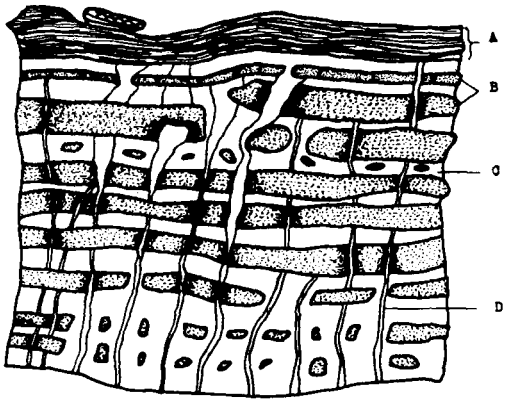

Fig. 3.—Transverse sectional diagram of *Casearia sylvestris* bark. A, Periderm; B, stone cell strata; C, parenchymatous stratum; D, phloem ray.

cells of these areas are very similar in size and shape, they form a regular pattern of rows both tangentially and radially. This pattern is referred to as a "storied arrangement." In transverse section the stone cells of these bands possess fairly regular outlines and have thickened, heavily lignified walls. The walls are densely pitted with simple pits and have unbranched pit canals. The majority of these stone cells contain a single large crystal that often completely fills the cell lumen. The strata of stone cells vary from 2 to 25 cells in radial dimension. The strata are continuous in the inner region of the phloem, but they become increasingly discontinuous in the regions nearer the periderm. These discontinuous strata of lignified cells are interrupted by phloem ray cells and by other cells of the nonlignified strata. Included in the lignified strata are also definite aggregations of nearly isodiametric stone cells. These stone cells are thicker-walled than the other stone cells of the strata and they possess branching pit canals but they rarely contain crystals. Similar stone cells are occasionally found singly or in small clusters among the cells of the nonlignified strata. These cells are infrequently found in the lignified strata. These cells are five to eight times longer than wide, with walls about $^1/_6$ as thick as the cell is wide. Each possesses a broad lumen. One end wall is often oblique, and the other end wall is at a right angle to the longitudinal walls. All the walls of these cells possess numerous simple pits with branched pit canals.

The outermost stratum of lignified cells is made up of thinner-walled stone cells with larger lumina and fewer crystals than the stone cells of the inner strata.

The strata of nonlignified cells are composed of phloem parenchyma, sieve elements, ray parenchyma, and sparsely scattered stone cells. The sieve tube elements are thin-walled and possess oblique end walls. Their sieve plates are compound as seen in a radial longitudinal view. The phloem parenchyma cells are numerous. In longitudinal section these cells are seen to be from two to three times as high as they are broad. In transverse view these cells appear nearly square in outline.

The phloem rays are very numerous and their regular arrangement is often interfered with by the stone cell strata. Rays vary from two to five cells in width at an expanded middle portion, and they commonly possess a many-celled elongation on the top and on the bottom that is evident in tangential sections. These elongations of the rays are one cell in width. The ray cells vary in size, and each exhibits a rounded outline in a tangential view.

Starch grains occur in small clusters within some of the phloem parenchyma cells and rarely within the ray parenchyma cells. They are two- to four-compound.

Powdered and Macerated Material.—The chips of bark were ground in a drug mill and the powder was then put through a number 40-mesh sieve. The resulting powder was homogeneous and light tan in color, with no noticeable odor. Material prepared by the Schulze maceration process was also examined. The following elements were observed during a microscopic examination (see Fig. 4).

The most prevalent element present is the crystals. These crystals are greatly varied in shape and give a play of colors with polarized light. Some of the crystals still remain within the stone cells. Stone cells are very numerous. These occur singly and in clusters. The clusters are most commonly composed of one or more rows of cells. Solitary crystals are usually present in the lumina of the stone cells in these rows. Two types of stone cells are present. Thick-walled nearly isodiametric stone cells are present. They possess branching pit canals and

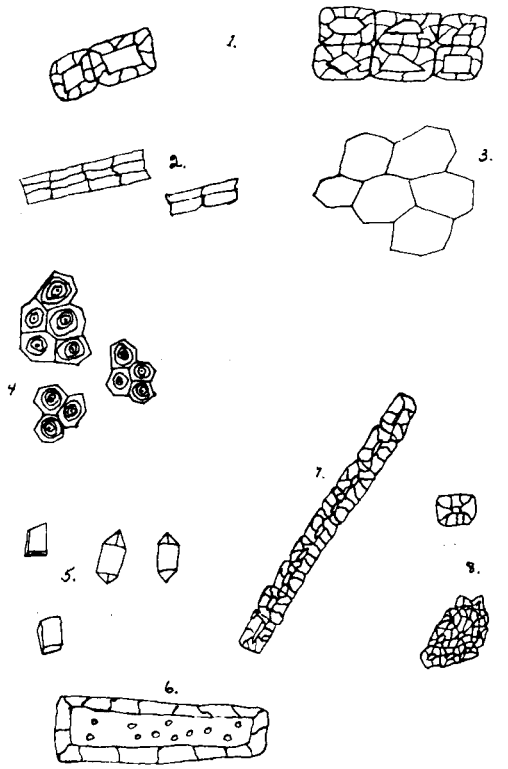

Fig. 4.—Elements of macerated and powdered *C. sylvestris* bark. 1, Crystal-bearing stone cells; 2 and 3, periderm fragments; 4, starch; 5, crystals; 6, elongated stone cells; 7, row of stone cells (crystals lacking); 8, stone cell cluster.

small lumina. These are, on the average, 30 μ in diameter. The thinner-walled stone cells are elongated. They average from 50 to 60 μ in length by 25 to 30 μ in width. These cells have unbranched pit canals and many simple pits. Their lumina are often angular because of the crystals that completely fill them. Clusters of phloem parenchyma cells and sieve elements are also found. Fragments of phellem are composed of narrow, tangentially elongated cells of about 10 by 30 μ. Phellem fragments in surface view appear as clusters of three- to six-sided cells. In macerated preparations they appear rounded, with clear, refractive cell walls and nonrefractive lumina. Small angular starch grains are present in small numbers. They occur commonly as three- to many-compound grains. The individual grains are, on the average, 3 to 4 μ in diameter. They possess tiny, faint, central hila and concentric lamellae.

SCHINOPSIS BALANSAE ENGLER

Description of the Plant.—*Schinopsis balansae* Engler is an anacardiaceous tree attaining a height of from 10 to 20 meters, indigenous, according to Cabrera (5), to the hot, dry forests of the southern Matto Grosso in Paraguay and northeastern Argentina.

Engler described the plant in 1885 (6). The bark of the trunk is ash gray in color and the wood is dark red and very hard. The young branches are light gray and sometimes possess sharp spines that are stout and straight, and from 1 to 2 cm. long. Simple leaves are borne alternately, and the twigs have short internodes. Each leaf possesses a semicylindrical petiole varying from 4 to 10 cm. in length. They are coriaceous, glabrous, and oblong to oblong-lanceolate. Their apices are very short and mucronate. The margins are entire and somewhat undulate, and the obtuse bases are rounded. The midrib is reddish, thick, and hard. There are numerous thin, but prominent, lateral veins. The leaf is from 4 to 8 cm. long by 1.5 to 2 cm. wide. The flowers are borne in terminal, pyramidal panicles having a length of 6 to 7 cm. Bractioles of the panicles are concave and ciliate, and about 1 mm. long. The pedicels are slightly pubescent. The fruit is a lustrous and woody single samara. It is knife-shaped and possesses an ovoid "seed body."

Leaves of this plant contain a considerable amount of a catechol-type tannin that is water soluble and that gives a dark green color with ferric chloride solution.

According to Youngken (7), the dried heartwood of *Schinopsis balansae* Engler and *S. lorentzii* (Grisebach) Engler are the sources of *Quebracho Colorado* which has been valued for its high tannin content. The name *Quebracho* means "axe-breaker." Therefore, the name *Quebracho Colorado* means "red axe-breaker wood." *Quebracho Colorado* is not related to *Quebracho blanco* which refers to the bark of *Aspidosperma quebracho-blanco* Schlectendal, family *Apocynaceae*. Preparations of the last named bark were once used as respiratory stimulants.

Cabrera (5) reports that the natural range of *S. lorentzii* borders on the north of that of *S. balansae*. The simple leaves of *S. balansae* enable one to distinguish this species easily from *S. lorentzii*, which possesses imparipinnate leaves, each with 7 to 15 leaflets.

Histological Data.—As seen in transverse section, the arrangement of tissues of the lamina is indicative of a bifacial leaf. The midrib area is somewhat semicircular in this view, the dorsal side of the midrib being more prominent than the ventral side (see Fig. 5).

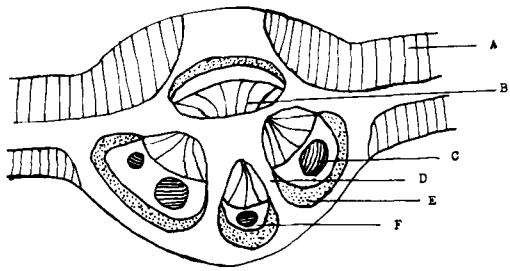

Fig. 5.—Transverse sectional diagram through the midrib of *Schinopsis balansae* leaf. A, Palisade zone; B, xylem; C, secretory canal; D, parenchyma; E, sclerenchyma fibers; F, phloem.

The upper epidermis of this leaf consists of a single layer of cells which are rectangular in outline. Their outer walls and the outer third of their radial walls are considerably thickened. In many instances these epidermal cells have lignified walls. There is a very well developed cuticle present. Stomates are present in about the same number as in the lower epidermis. The neighboring cells in this view appear somewhat L-shaped, with the base of the L forming a flange upon which the guard cells are situated.

Palisade cells are oriented with their long axes perpendicular to the epidermis. The palisade cell regions are each composed of from two to three layers. The palisade zones constitute three-fourths of the mesophyll of the lamina. The palisade regions are separated by a narrow region of fairly compact spongy mesophyll cells.

The lateral veins possess well developed bundle sheaths. The sheaths of the small veins are parenchymatous. Those of the larger veins are sclerenchymatous and they extend to both epidermises. A small group of fibers whose walls are thick and slightly lignified is usually associated with the phloem of the bundle. A single secretory canal is commonly present within the phloem of these large veins. Prismatic or diamond shaped solitary crystals are found in many of the cells of the bundle sheath. Characteristically large, coarse druses are sometimes present within the bundle sheath cells of the small veins.

The cells of the lower epidermis are very similar to those of the upper epidermis.

The epidermal cells of the midrib are about one-third the size of those on the rest of the leaf blade, but they are of similar shape. The palisade region within the upper epidermis extends into the midrib from each side to a distance of about one-third of the width of the midrib region. Beneath the upper epidermis of the midrib and between the palisade cell regions is an area of well developed collenchyma tissue. The most striking characteristic of the histology of this leaf is the arrangement of the

vascular tissue in the midrib. It is arranged in a broken semicircle of five vascular strands. Two inverted strands with the phloem regions toward the upper epidermis are situated ventrally, the other three strands are oriented with their phloem regions toward the lower epidermis. These strands form an arc under the upper strands. The secondary development of the xylem is fairly extensive, whereas the phloem region is not as well developed. The cambium of the bundles is indistinct.

Secretory canals are present within the phloem regions of the three lower vascular strands of the midrib and rarely within those of the upper vascular strands. From two to three canals occur within the two lateral strands, and one canal is found in the lowest strand. The content of these canals is presumed to be oleoresinous (see Fig. 5).

Transverse sections through the midrib at the base of the lamina show five vascular strands. Similar sections cut close to the apex show but one strand.

The center of the midrib is composed of parenchyma cells with thickened lignified walls that are marked by round simple pits. Narrow zones of parenchyma cells radiate out between the vascular strands and encircle the stele. Between this parenchymatous region and the lower epidermis is an extensive area of collenchyma. Many of these cells contain solitary crystals that vary from diamond-shaped to prismatic.

A region of thick-walled fibers is associated with the phloem region of each vascular strand. Commonly only the outer walls of these cells are lignified.

In surface sections of the lamina the epidermal cells present a fairly regular outline although the cell walls are irregularly thickened. Patches or small areas exhibit epidermal cells with lignified walls. These areas have no definite pattern. The lignified walls of these cells possess simple pits. Stomates occur about equally in each of the two epidermises. The guard cells of the stomates are surrounded by narrow neighboring cells. The number of neighboring cells is seven, on the average, but varies from a minimum of five to a maximum of nine. There are usually two neighboring cells along each side of the paired guard cells, two neighboring cells at one end of the pair, and only one at the other end. Rows of crystal-bearing cells accompany most of the veins. Such rows are parallel to the veins with which they are associated. The crystals are commonly diamond shaped or prismatic. Occasional one-celled, appressed, nonglandular hairs are associated with the epidermal cells of the midrib and of the larger lateral veins. These hairs are thick-walled and possess narrow lumina that extend about one-half the length of the hairs. The bases are only slightly enlarged. The hairs vary from about 35 to 90 μ in length. The average length of these hairs is approximately 60 μ and their bases are about 13 μ wide.

In transverse sections of the petiole one can see five leaf traces entering the base of the petiole. These traces are arranged in the semicircular pattern (see Fig. 6). There are three traces in an arc and their phloem regions face the lower epidermis. There are two small ventral traces across the top of the arc, and they are inverted so that their phloem regions face the upper epidermis. The xylem regions of the traces are separated by regions of

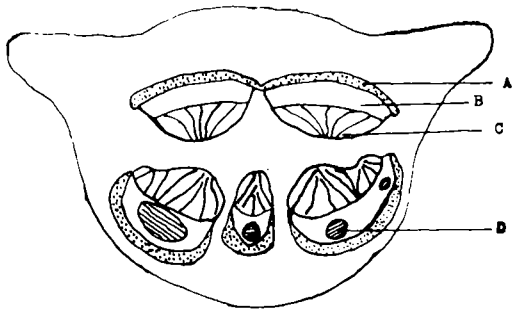

Fig. 6.—Transverse sectional diagram of *S. balansae* petiole. A, Sclerenchyma fibers; B, phloem; C, xylem; D, secretory canal.

parenchyma cells. The central portion of the midrib is composed of parenchyma cells whose walls are thickened and lignified. These cells are relatively large and have conspicuous intercellular spaces. In the phloem region of each of the three dorsal traces one or more secretory canals are situated. Each of the five traces possesses a definite sclerenchymatous cap of thick-walled fibers. The walls of these fibers seldom are lignified. Collenchyma is extensively developed between the vascular tissue and the epidermises. Many of these collenchyma cells contain crystals of the types found in the midrib. Crystals are sometimes found also within

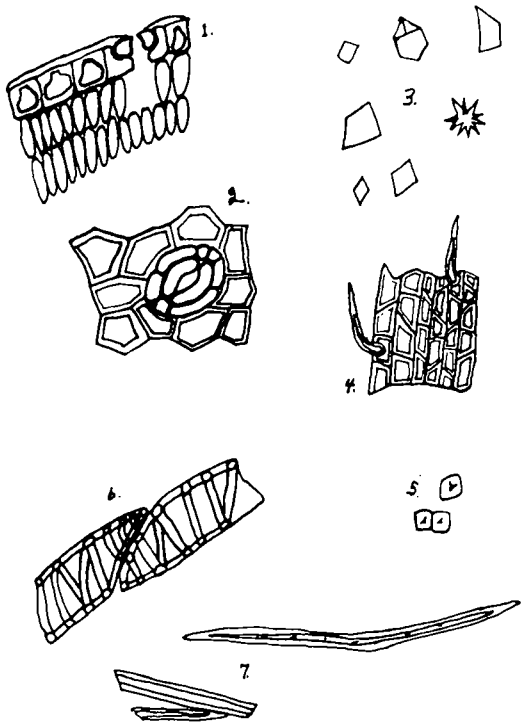

Fig. 7.—Elements of macerated and powdered *S. balansae* leaf. 1, Epidermal fragment with stomate and attached palisade cells; 2, epidermal fragment in surface view; 3, crystals; 4, hairs on epidermal fragment of petiole or midrib; 5, starch grains; 6, xylem elements; 7, sclerenchyma fibers.

the cells of the phloem regions and within the parenchyma cells in the center of the midrib.

Some slightly developed periderm can be found to have replaced the epidermis in scattered areas on the dorsal surface of the petiole base. It is formed from the subepidermal layer. Nonglandular hairs of the type found on the midrib are occasionally present on the dorsal surface of the petiole. The petiole has a normal clasping base. A short distance from the base the petiole becomes semicylindrical with the ventral side flattened. Its firmness is due to the extensive development of collenchyma tissue.

Powdered Material.—A sample of dried leaves was crumbled and then was screened through a 40-mesh sieve. The resulting powder was greenish and possessed a very slight musty odor. The following elements were observed in microscopic examination (Fig. 7): fragments of epidermis from the lamina are prevalent. The epidermal cells are polygonal and possess thick walls when seen in surface view. Occasionally some of the walls of the epidermal cells are lignified. Stomates are prominent in these epidermal fragments. The guard cells are long and elliptical. The number of neighboring cells varies from five to nine but is, on the average, seven. There are usually two neighboring cells along each side of the paired guard cells, two neighboring cells at one end of the pair, and only one at the other end. Fragments of mesophyll tissue are commonly associated with epidermal tissue.

Fragments of epidermis from the midrib and the petiole are composed of cells that are smaller than those found on the lamina, and these are arranged in rows with their end walls sometimes oblique when seen in a surface view. These epidermal cells have thick, but nonlignified, walls. No stomates are present in this tissue. One-celled, appressed, nonglandular hairs are often present on these fragments of epidermal tissue.

Broken clusters of thick-walled fibers with sparse, small, simple pits are present. Sometimes crystal-bearing cells accompany these fibers.

Fragments of xylem elements show spiral wall thickenings or scalariform pitting.

Occasional tissue fragments contain portions of the secretory canals with an amorphous red-brown content. Fragments of collenchyma tissue made up of cells with characteristic unevenly thickened walls are present. These cells are elongated. Crystals are a prominent element. They occur as fragments and as entire prisms, rarely as druses. The prisms are on the average 15 μ long. Starch grains are not common, but some do occur as simple or two-compound grains with diameters of from 4 to 5 μ.

SUMMARY

This paper contains reports on the histologies of the stem of *Aristolochia triangularis* Chamisso, the bark of *Casearia sylvestris* Swartz, and the leaf of *Schinopsis balansae* Engler. The following characteristics are noteworthy.

1. *Aristolochia triangularis* stem. This stem exhibits an anomalous vascular structure. The wood is diffuse porous. Wood parenchyma is sparse and diffuse. Thick-walled wood fibers are abundant. Stone cells occur scattered in the broad xylem rays. Some of the vessels contain tyloses. Some of the ray and pith cells contain prismatic and thin diamond-shaped crystals. The fan-shaped phloem rays consist, in part, of stone cells. The pericycle consists of stone cells and fibers. The extensively developed phellem is deeply fissured.

2. *Casearia sylvestris* bark. This bark consists mainly of secondary phloem, only a small amount of periderm being present. In the phloem numerous tangential bands of stone cells alternate with bands of nonlignified cells. Most of the stone cells contain crystals. The crystals are prismatic, nearly rectangular, or diamond-shaped. Sieve tube elements possess compound sieve plates on their radial walls. The small starch grains are usually two- to many-compound. Two types of stone cells are present. No fibers are present.

3. *Schinopsis balansae* leaf. This leaf possesses a well developed cuticle and the stomates are rather evenly distributed in the two epidermises. Stomates most commonly have seven neighboring cells. In scattered areas of the epidermis the cell walls are lignified. The lamina exhibits a bifacial structure. The midrib exhibits five vascular strands arranged in a semicircle. The two upper strands are inverted. The phloem areas of many vascular strands possess secretory canals. Fibers that accompany vascular strands are often nonlignified. Coarse druses and prismatic crystals are often associated with the vascular strands. Appressed nonglandular hairs are sometimes present on the dorsal surface of the petiole.

Bioassay of Estradiol 17-Cyclopentylpropionate

By W. F. BEYER, D. H. EMMONS, and M. L. PABST

The immature mouse uterus has been utilized for the bioassay of a long-acting estrogen, estradiol 17-cyclopentylpropionate. The compound was dissolved in cottonseed oil and injected in a single subcutaneous dose of 0.10 ml. The uteri were removed and weighed 72 hours after the injection. Statistical analysis of uterine weights, using a 2 × 2 balanced bioassay, gave an approximate average standard error of potency of 12%. Similar uterine weights were produced by estradiol 17-cyclopentylpropionate when given in a single subcutaneous injection or when given in divided doses over a 3-day period. In the case of estrone and estradiol, a single dose was considerably less effective than divided daily doses. The similarity in response to one and three doses of estradiol 17-cyclopentylpropionate and its ability to maintain an increase in uterine weight following a single dose has been utilized as the basis of the assay for a long-acting estrogen.

RUBIN, *et al.* (1), reported a bioassay for estrogens using the increase in uterine weight of immature mice as the response. This method involved the use of a divided dose schedule and uterine ratios (100 times the uterine weight in mg. divided by the body weight in Gm.) as the response. Modifications of the method resulted in a shorter assay procedure for estradiol 17-cyclopentylpropionate (ECP).[1] The modified method is described for a single dose schedule and the use of uterine weights of immature mice. Uterine responses to estrone U.S.P. and estradiol U.S.P. are presented along with dose response curves and assay results for ECP.

ANIMALS AND METHOD

Twenty-one to twenty-five-day old immature mice of the CFW or CF No. 1 strain were used. No significant differences were noted in responses of the two strains. All mice utilized for a single test were of the same age group and strain. Commercial mouse diet and tap water were permitted *ad libitum*.

A cottonseed oil solution of ECP was injected subcutaneously in a single dose of 0.10 ml. The mice were sacrificed and the uteri were removed 72 hours after the injection. The uteri were separated from the ovaries, severed at the uterocervical junction, stripped of extraneous tissue, blotted free of contained fluid, and rapidly weighed to the nearest 0.10 mg. In many cases the body weights were obtained at the time the animals were sacrificed. This made it possible to obtain uterine ratios as well as uterine weights.

The log dose-uterine response relationship with a constant ratio of two between successive doses was used to calculate potency. The 2 × 2 assay design of Bliss (2) or U.S.P. XVI (3) was used. When more than one sample was assayed against a single standard, calculations for the joint assay of several preparations (4) were used.

RESULTS AND DISCUSSION

It was necessary to obtain dose response data and to test the duration of response before establishing an assay procedure. The duration of response was tested using both single and multiple dose schedules. By repeated trials it was found that a total dose of 0.32 mcg. of ECP per mouse resulted in a useful uterine weight response. For the single dose schedule, 0.32 mcg. of ECP was contained in a volume of 0.10 ml. of cottonseed oil. For the multiple dose schedule, 0.32 mcg. of the compound was contained in 0.30 ml. of cottonseed oil and 0.10 ml. was administered daily for 3 days. The uteri were removed at varying intervals after the injections to determine the duration of response.

The results in Table I show that the largest uterine weights and ratios occurred during the 48 to 120-hour period after a single injection and approximately 72 to 144 hours after the initial injection using multiple doses. Although the uterine weights remained fairly constant over most of the test period for both dosage schedules, the uterine ratio values decreased as the body weights of the mice increased. The body weights increased as the interval between initial injection and uterine removal was lengthened.

Dose response data for the single and multiple dose schedules were obtained using an interval of 72 hours from beginning of injection to uterine removal. At this time, uterine weights of mice receiving a total dose of 0.32 mcg. per mouse (Table I) were near maximal and were approximately five times that of uninjected controls (Table II). This period was also the earliest time for uterine removal when an injection interval of 24 hours was maintained for the multiple dose schedule.

The mean uterine weights and uterine ratios for the dosage levels tested are shown in Table II. The responses over a dose range of 0.08 to 0.64 mcg. of ECP per mouse exhibited a graded dose response relationship. There was a significant difference between the average responses for successive dosage levels tested, with the dose range suitable for bioassay extending over an eightfold difference in dose.

The data used in Table II were analyzed by linear regression methods yielding slopes (b),

Index of precision (λ)	0.2866	0.2734
Three Doses		
Standard Deviation (s)	12.49	80.22
Slope (b)	44.98	305.33
Index of precision (λ)	0.2779	0.2620

standard deviations (s), and indexes of precision (λ) shown in Table III. Tests for curvature indicated a linear response over the dose range used. The results in Table III show a similarity in response for single and multiple dose schedules. The standard deviations, slopes, and indexes of precision using either method compare favorably.

Estrone U.S.P. and estradiol U.S.P. were used as examples to compare the effects of ECP to that of more rapidly acting estrogens. Table IV shows that single doses of either estrone or estradiol, with uterine removal 72 hours later, have little effect, whereas multiple doses given over a 3-day period produce significantly larger uteri.

[a] Uteri removed 72 hours after beginning of injection.

The prolonged effect of ECP on the mouse uterine weight permits determination of potency by a single injection method. To test the validity and reproducibility of this method, replicate assays using both the uterine weight and uterine ratio methods were done on a preparation containing ECP assayed against a house standard of ECP.

The data of Table V show that results of replicate assays are comparable when either uterine weights or ratios are used. The averages for potency, index of precision, and standard error were similar. Assay No. 4 exceeded the tabular value of 4.03 for the test of parallelism (F) at $P = 0.05$ using uterine weights. However, the same assay using ratios had a relatively high, although acceptable, value of 3.59.

Tests for homogeneity of log potencies of indi-

7	94	0.2050	12	38.55	5.33	0.1382
8	95	0.3020	17	49.31	6.33	0.1284
9	91	0.2060	12	49.87	6.90	0.1451
10	99	0.2050	12	49.87	6.90	0.1451
Averages	98	0.2333	14	44.85	6.43	0.1486

vidual assays by both uterine weight and ratio methods were performed; no evidence of heterogeneity was found at $P_{0.05}$ level of significance. Weighted mean potencies, calculated by weighting each log potency inversely as its variance, gave mean potencies of 103 and 101% for uterine weights and ratios, respectively. Since the use of uterine weights and ratios gave very similar results, an analysis of covariance was used to determine whether this would give appreciably better assay precision. Table V shows results using uterine weight as the variate (y) and body weight as the covariate (x) in a covariance analysis. The assumption that body weight had an important influence on uterine weight was not borne out. Although the mean standard error for the covariance method was comparable to that by the ratio method and slightly smaller than that by the weight method, this small increase in precision was not felt to warrant obtaining body weights for subsequent assays.

Numerous preparations containing ECP were assayed by the single dose-mouse uterine weight method. The assays were calculated using statistical methods as outlined in U.S.P. XVI (3) for 2 × 2 balanced assay designs. Table VI shows the results of representative assays of 10 preparations containing ECP assayed at dosage levels of 0.12 and 0.24 mcg., with eight mice at each dosage level. When more than one sample was assayed against a common standard, calculations for the joint assay of several preparations were used (4).

An average log confidence interval (L) of 0.2333 was obtained for the 10 preparations shown in Table VI. Using the value of 0.1486 for the average index of precision (λ), and eight mice per dose, the average standard error of potency was calculated as 12%.

No heterogeneity of assay variance (s^2) was found at $P_{0.05}$ for the independent assays of Table VI when analyzed using Bartlett's test (5). There was also no evidence of heterogeneity of assay slopes for the same group of assays, as determined using the chi square test at the same level of significance.

SUMMARY AND CONCLUSIONS

The method of Rubin, *et al.* (1), using the immature mouse for the bioassay of estrogens has been modified for the assay of a long acting estrogen, estradiol 17-cyclopentylpropionate (ECP). The modifications consist of administering the hormone in a single subcutaneous dose, removing the uteri 72 hours later, and using uterine weights as responses. The results were analyzed according to U.S.P. XVI (3) for a 2×2 balanced assay. When eight mice were used on each dose, the average log confidence interval was 0.2333.

Similar results were obtained by injecting ECP in single or divided doses. This was not the case with estrone or estradiol which were much more effective when multiple injections were given.

It is suggested that the method described for the assay of ECP may be utilized as a rapid bioassay for other long acting estrogens. It may also be used for identification of long acting estrogens and to differentiate between those that are either long or short acting.

Liquefaction Time of Rectal Suppositories

By IVO SETNIKAR and SERGIO FANTELLI

An apparatus reproducing the conditions of the environment of the rectum is described. With this apparatus, the liquefaction time of rectal suppositories, either with fatty or water-soluble bases, can be measured. The liquefaction times found for a series of suppositories with fatty bases and with so-called water-soluble bases are reported. It is proposed that a maximum limit should be established for the liquefaction time of rectal suppositories carrying drugs with general action.

The United States Pharmacopeia XVI defines suppositories as "solid bodies of various weights and shapes, adapted for introduction into orifices of the human body and usually melting, softening, or dissolving at body temperature."

However, no method is described for testing these characteristics on the whole suppository. The method for the determination of the melting temperature of fatty (class II) substances is useful for suppository bases but not always applicable to the nonhomogeneous drug-base mixtures of which suppositories are often made. Since the drugs present may alter the melting point (m. p.) of the bases and since the m. p. of the drug-base mixtures may change considerably over a period of time (1), the determination of the m. p. of the suppository base alone is clearly not sufficient for the control of the characteristics mentioned in the U.S.P. definition of suppositories.

Several researchers have felt the need and proposed methods by which these characteristics, and particularly the m. p. can be controlled on the whole suppository. These methods can be classified into two groups: (*a*) m.p. determinations in a dry environment (2, 3) and (*b*) m.p. determinations on suppositories in a water bath (4–7).

With both kinds of methods the m.p. is measured in an environment very different from that of the rectum, for the latter is neither anhydrous nor aqueous. Both give useful information on fatty bases only, because almost all of the so-called water-soluble bases melt at a temperature above body temperature with the first technique, while they dissolve independently of the temperature with the second. Further, with neither method is it possible to record a very important datum, i. e., a representative time of melting, softening, or dissolving at body temperature.

The knowledge of this time is essential in suppositories which include a drug for a general action and must, therefore, be absorbed. Indeed, a suppository which takes too long to liquefy may be expelled before liquefaction, together with the drug it includes. Beside this, it may exert a mechanical irritant action on the rectal ampulla even if the base and the drug, *per se*, are not irritant. The U. S. P. should,

Liquefaction Time of Rectal Suppositories

By IVO SETNIKAR and SERGIO FANTELLI

An apparatus reproducing the conditions of the environment of the rectum is described. With this apparatus, the liquefaction time of rectal suppositories, either with fatty or water-soluble bases, can be measured. The liquefaction times found for a series of suppositories with fatty bases and with so-called water-soluble bases are reported. It is proposed that a maximum limit should be established for the liquefaction time of rectal suppositories carrying drugs with general action.

The United States Pharmacopeia XVI defines suppositories as "solid bodies of various weights and shapes, adapted for introduction into orifices of the human body and usually melting, softening, or dissolving at body temperature."

However, no method is described for testing these characteristics on the whole suppository. The method for the determination of the melting temperature of fatty (class II) substances is useful for suppository bases but not always applicable to the nonhomogeneous drug-base mixtures of which suppositories are often made. Since the drugs present may alter the melting point (m. p.) of the bases and since the m. p. of the drug-base mixtures may change considerably over a period of time (1), the determination of the m. p. of the suppository base alone is clearly not sufficient for the control of the characteristics mentioned in the U.S.P. definition of suppositories.

Several researchers have felt the need and proposed methods by which these characteristics, and particularly the m. p. can be controlled on the whole suppository. These methods can be classified into two groups: (*a*) m.p. determinations in a dry environment (2, 3) and (*b*) m.p. determinations on suppositories in a water bath (4–7).

With both kinds of methods the m.p. is measured in an environment very different from that of the rectum, for the latter is neither anhydrous nor aqueous. Both give useful information on fatty bases only, because almost all of the so-called water-soluble bases melt at a temperature above body temperature with the first technique, while they dissolve independently of the temperature with the second. Further, with neither method is it possible to record a very important datum, i. e., a representative time of melting, softening, or dissolving at body temperature.

The knowledge of this time is essential in suppositories which include a drug for a general action and must, therefore, be absorbed. Indeed, a suppository which takes too long to liquefy may be expelled before liquefaction, together with the drug it includes. Beside this, it may exert a mechanical irritant action on the rectal ampulla even if the base and the drug, *per se*, are not irritant. The U. S. P. should,

Received May 8, 1961, from Recordati S.p.A., Research Dept., Milano, Italy.
Accepted for publication July 27, 1961.

therefore, recommend, for suppositories including a general-acting drug, a maximum liquefaction time, just as it fixes maximum times for the disintegration of tablets. Also, as in the case of the latter (U. S. P. XVI, p. 830), it should emphasize that "sure disintegration (or rather sure liquefaction) is an essential attribute for suppositories including a general acting drug."

Obviously, if an apparatus is to give a reliable indication on the liquefaction of rectal suppositories, it must reproduce the mechanical and physicochemical conditions of the rectum as faithfully as possible.

The human rectum, or distal portion of the intestine, is 12–14 cm. long and has a maximum diameter of 5–6 cm. The following conditions are present: (*a*) In healthy subjects the average temperature (8) is 36.9° (from 36.2 to 37.6°). (*b*) Water is not present in the liquid state; the feces are semisolid and contain 77–82% water (9). (*c*) Water may issue from the blood through a process of osmosis. Although the rectal mucosa tends to absorb water and transfer it to the blood, it may be regarded as a semipermeable membrane since it also permits the passage of water in the opposite direction, provided that there are osmotic forces to attract it. This process is, however, antiphysiological and may be both irritating and painful. (*d*) There are practically no peristaltic movements (10) to churn and mix up the contents of the ampulla of the rectum. (*e*) The pressure on the contents of the rectum is, according to posture, from 0 to 50 cm. water (10, 11). (*f*) Feces may be present.

Nearly all these conditions (temperature, heat transmission, semipermeability of the walls, pressure) may be reproduced in a semipermeable cellophane dialyzer tube immersed in a water bath at 37.0°.

EXPERIMENTAL

Apparatus.—The apparatus (Fig. 1) consists of a glass cylinder with an external diameter of 50 mm., narrowing down to 22 mm. at either end for a length of 30 mm. The cylinder is fitted with two connections through which water circulates from a circulating water pump, thermoregulated to 37.0°.

The apparatus is prepared in the following way: a 34–35-cm. length of cellulose dialyzer tubing, size inflated diameter 1 1/8 in.,[1] is moistened, opened, and placed in the glass cylinder. The tube is drawn out of either end of the cylinder and secured thereto with two elastic bands. Then the rubber tubes of the thermoregulated pump are attached to the connections of the apparatus and water is made to circulate in it. The apparatus is raised or lowered, keeping it vertical, until the level is found at which the lower half of the cellophane tube is collapsed and the upper half gaping. At the level at which the tube starts to close in, the hydrostatic pressure of the water in the apparatus is about zero.

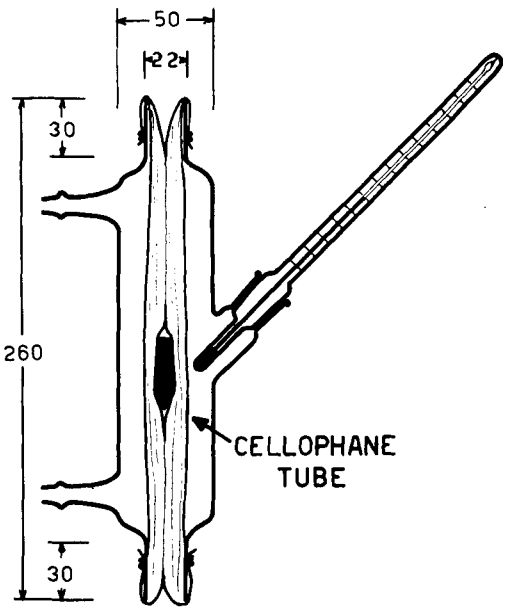

Fig. 1.—Apparatus for measuring the liquefaction time of rectal suppositories; the dimensions are in millimeters. The thermometer scale is divided into tenths of a degree and a scale ranging from 32 to 45° is adequate.

When the thermometer reaches a stable temperature of 37.0°, a suppository is dropped in, the apparatus is lowered about 30 cm., and measurement of the liquefaction time begins.

If the suppository contains a small quantity of drug, or if the drug is dissolved in the base, one can gauge to a high degree of accuracy the moment in which the suppository has entirely liquefied. When the suppository contains large quantities of undissolved drugs, e.g., 0.5 Gm. of aminophylline, it is more difficult to determine the moment of complete liquefaction. In this case it may be helpful to raise the apparatus every 2–3 minutes so as to open up the cellophane tube at suppository level in order to facilitate dispersion of the material already liquefied. Another device is to place a metal spiral, with a diameter of about 5 mm. and a pitch of 3–5 mm., near the suppository in order to promote upward and downward dispersion of the liquefied material. In the most difficult cases, the difference in the assessment of the moment of complete liquefaction by independent observers does not exceed 10–30 seconds.

The apparatus can also be used for the determination of the m.p. of suppositories made by water-insoluble bases. For this purpose the temperature is raised at a speed of 1° every 10 minutes until the suppository melts.

When the experiment is over, the apparatus is raised until the cellophane tube gapes, the inner walls of the tube are washed with water containing a detergent, then with distilled water, and allowed to drip for a few minutes. The apparatus is then ready for use again.

[1] Fisher Catalog No. 8–667.

Results.—Suppositories consisting of commercially available bases, the compositions of which are reported by Pennati and Steiger-Trippi (12), were prepared and kept at room temperature for 1–6 months. The liquefaction time was then measured and the results are given in Table I.

The error of observation was determined by repeating the measurements of ten identical suppositories. For the theobroma oil base the follow-

[a] Softening after 10–20 minutes, no liquefaction during 1 hour.

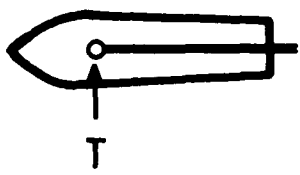

Fig. 2.—Actual shape and size of the suppositories used. *T* indicates the position of the thermocouple inserted in the suppository to measure the speed of heating.

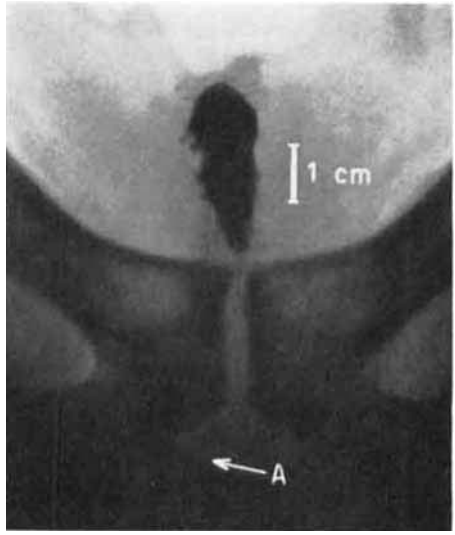

Fig. 3.—Roentgenograph of the pelvic inlet of 34-year-old man, in the supine position, 5 minutes after insertion of a type A suppository. The suppository has completely disintegrated. Arrow *A* marks the position of the anal orifice, to which in this and in the following figures, a lead strip piece was juxtaposed. The dimension of 1 cm. on the plane of the suppository is also marked. The size and shape of the suppository were the same as in Fig. 2.

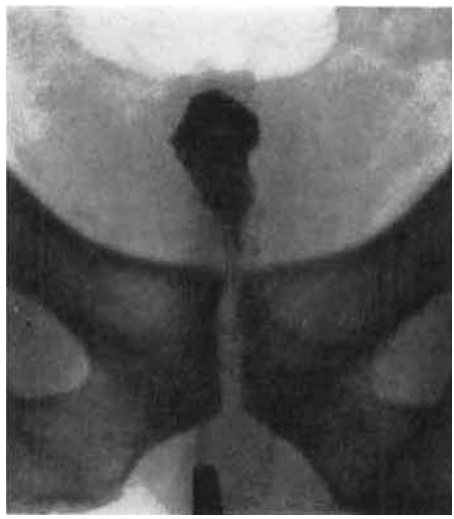

Fig. 4.—Type A suppository, 10 minutes after insertion. The contrast medium tends to spread and rise up the rectum.

ing results were obtained: average liquefaction time 245 seconds, standard deviation ± 10 seconds (4.1% of the average time), standard error 3.2 seconds (1.3% of the average time). Comparable percentage standard deviation and errors were obtained for other bases. The data naturally depend, to some extent, upon the size and shape of the rectal suppositories used. The ones used in these experiments are reproduced in their actual size in Fig. 2.

To check whether the values found by the *in vitro* method were representative of what actually occurs in the ampulla of the human rectum, two types of suppositories were prepared with the following compositions: *Type A Suppositories (Fatty Base).*—theobroma oil, 1.6 Gm.; barium sulfate, 0.5 Gm.

Type B Suppositories (Water-Soluble Base).—Carbowax 1540, 0.8 Gm.; Carbowax 6000, 1.1 Gm.; Polyethylene glycol 400, 0.5 Gm.; barium sulfate, 0.5 Gm.

These suppositories were of the size and shape represented in Fig. 2. The liquefaction time of these suppositories was tested on five healthy male subjects kept throughout the experiment in a supine position. The pelvic inlet was roentgenographed at set intervals. The pictures obtained in one of these experiments are reproduced in Figs. 3–9 and the results summarized in Table II. The agreement between the *in vitro* and *in vivo* results is sufficiently satisfactory to show that the proposed method represents the course of events within the ampulla of the human rectum.

TABLE II.—LIQUEFACTION TIMES *In Vitro* AND *In Vivo*

	Softening Temp.,[a] °C.	M.P.,[a] °C.	Liquefaction Time *in vitro* min.	Liquefaction Time in the Human Rectum, min.
Suppository A	30	34	4.5	between 3 and 7
Suppository B	52	58	40	between 30 and 50

[a] Determined by a modified Bogs method.

Fig. 5.—Suppository type A, 15 minutes after insertion. The upward movement and spread of the contrast medium are even more marked.

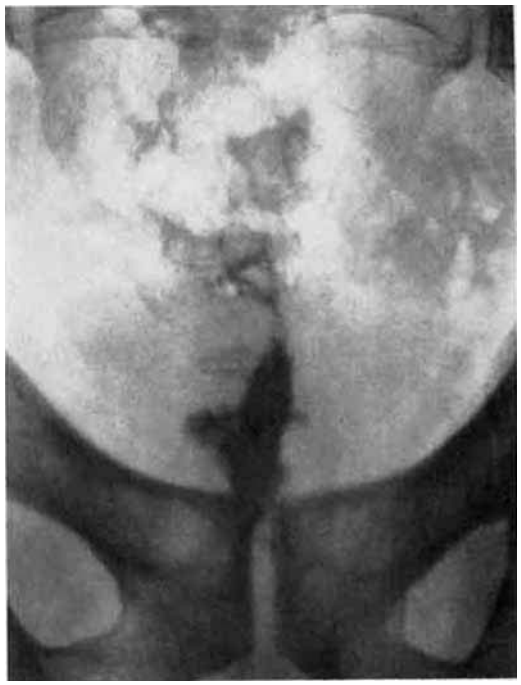

Fig. 6.—Roentgenograph of the pelvic inlet of the same subject as that of Fig. 3, 10 minutes after insertion of a type B suppository. The disintegration of the suppository and the spread of the contrast medium have hardly begun.

When the apparatus is used for the determination of the m.p. of fatty-base suppositories it must be known at what rate the temperature of the suppository comes into equilibrium with that of the apparatus in order to regulate the speed at which the temperature of the apparatus should be raised. For this purpose, suppositories of Imhausen H were prepared and a thermocouple was inserted at the level marked T in Fig. 2 (Imhausen H is a mixture of hydrogenated natural fats, mostly triglycerides of laurinic acid, with a monoglyceric ester as emulsifier). One suppository prepared in this way was put in the apparatus kept at 34.7°. The temperatures measured by the thermocouple in the center of the suppository during 1 hour of experiment are given in Fig. 10*A*.

As the rise in temperature (dT) in the time (dt) is, in all probability, proportional to the difference between the environment temperature (T_e) and the temperature of the suppository (T), the following equation may be written

$$dT/dt = k(T_e - T) \qquad \text{(Eq. 1)}$$

where k is a constant depending on the heat capacity and conductivity of the suppository. By integration, Eq. 1 becomes

$$kt = \log (T_e - T_0)/(T_e - T) \quad \text{(Eq. 2)}$$

where T_0 expresses the temperature of the suppository at the beginning of the experiment.

Equation 2 shows that plotting the logarithm of $(T_e - T_0)/(T_e - T)$ on the ordinate and the time on the abscissa of a diagram of Cartesian axes, a straight line should be obtained with a slope equal

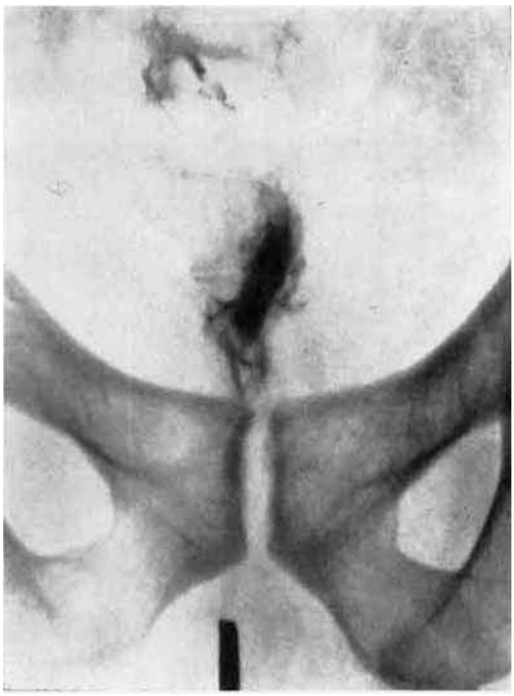

Fig. 7.—Type B suppository, 30 minutes after insertion. The disintegration of the suppository and the spread of the contrast medium are already very evident.

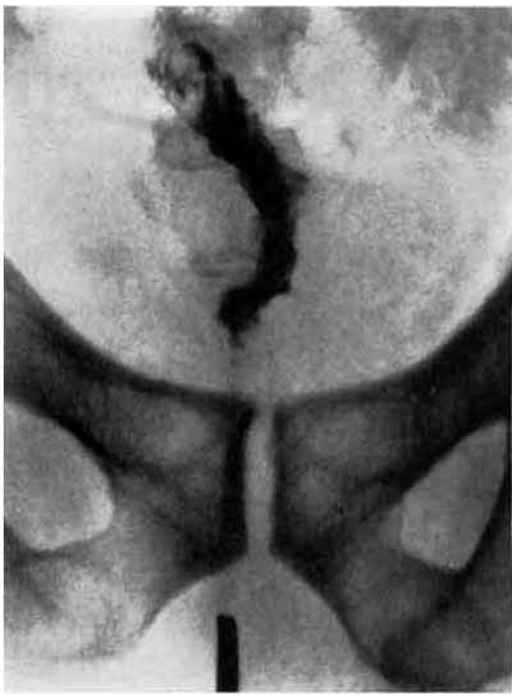

Fig. 8.—Type B suppository, 45 minutes after insertion. Disintegration is complete.

to k. The data of Fig. 10*A* were recalculated in this way (in this experiment T_e was equal to 34.7° and T_0 equal to 18.3°) and the results are reported in Fig. 10*B*.

One notes that the rise in temperature proceeds at first at a higher speed ($k = 0.141$) and then, when in all likelihood a more uniform temperature gradient has formed throughout the thickness of the suppository, the rise proceeds more slowly ($k = 0.053$). The half-equilibrium time is reached in 2 minutes, the 99% equilibrium time in 27.5 minutes.

It may also be calculated that, when the temperature in the apparatus is raised by 1° every 10 minutes, the temperature at the center of the suppository remains behind that of the apparatus by 0.1–0.3°. Under these conditions the error of appreciation of the m.p. is smaller than 0.3°. If one considers that when the suppository begins to melt its diameter is reduced and the transmission of heat is facilitated, the difference between the temperature inside the suppository and that of the environment becomes still smaller and likewise the error.

This method of analysis of the temperature transmission may be useful also in order to know how size, method of preparation, and composition may affect the temperature-equilibrium time and to choose the best conditions from this point of view.

DISCUSSION

In Table I the bases studied are divided into fatty and water-soluble, though the distinction is not always accurate because many commercial bases consist of mixtures of fats and more-or-less water-

Fig. 9.—Type B suppository, 60 minutes after insertion. Disintegration is complete and the spread of the contrast medium considerable. If this figure is compared with Fig. 5, it will be seen that the spread of the contrast medium is greater. This is probably due to the longer time (15 minutes in Fig. 5 and 60 minutes in Fig. 9). In this figure the contrast medium begins at a distance of about 4 cm. from the anal orifice and extends for about 5 cm. up the rectum. In 60 minutes it has risen on the average about 2 cm. up the rectum.

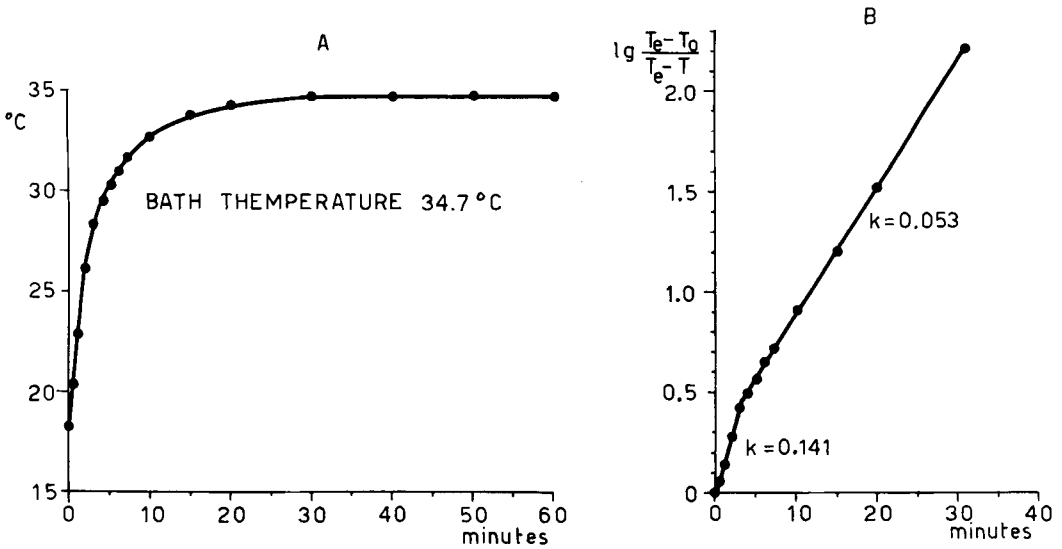

Fig. 10.—Speed of the rise in temperature at the center of the suppository measured with a thermocouple situated in the way described in Fig. 2. The data of Fig. 10*A* are transferred on to Fig. 10*B* to convert Eq. 2 of the text into a linear equation in order to calculate the constant, *k*, of the speed by which the temperature in the center of the suppository increases.

soluble substances which help the fats to emulsify and contribute to the liquefaction process. Indeed, if the base is purely fatty as, e.g., theobroma oil, in order to liquefy it must have a m.p. of 37° or less. This does not happen with Neo Suppostal and Lipomassa C.F.M., which liquefy in the cellophane tube even though they have a m.p. higher than 37°. Therefore, to know whether suppositories liquefy in the rectum, it is not enough to know the m.p. only, even of the so-called fatty bases. Further, as the m.p. of the so-called water-soluble bases is higher than 37°, it must be concluded that, for rectal suppositories, the m.p. tells us very little about the capacity of bases for liquefaction in the rectum.

On the strength of their high m.p., suppositories made with water-soluble bases may, at first sight, seem peculiarly suited to hot or tropical climates. Actually, however, other factors have to be borne in mind, i.e., that liquefaction often takes some considerable time (although it can be shortened by the addition of drugs, propylene glycol, water, etc.) and that these bases dissolve by attracting water from the blood by an antiphysiological process of osmosis which may be irritating and painful. Other disadvantages of these bases have already been noted by Czetsch-Lindenwald (13). Suppositories with water-soluble bases should, therefore, be always subjected to extensive pharmaceutical and biological testing.

We would like also to comment on the definition of suppositories given in the U. S. P. The term "softening" is vague, and the terms "melting" or "dissolving" refer to the base rather than to the suppository, for the drug included does not always melt or dissolve. The reference to "body temperature" is not applicable to dissolving, which depends rather on the presence of water. Further, it seems to us that for rectal suppositories a distinction should be made between those with a local action, e.g., glycerinated gelatin suppositories U. S. P., for which the softening or liquefying is not always essential, and those including a drug for a general action, release of which depends in first instance on the liquefaction of the suppository.

For these suppositories, the liquefaction time is of such great biological importance that a maximum limit should be fixed for it, e.g., 10 minutes, as proposed by Czetsch-Lindenwald (14).

Characterization and Mode of Degradation of the Neurophysiologically Important Transaminase Inhibitors, the α-Aminooxyalkanoic Acids

By EDWARD R. GARRETT†

The α-aminooxyalkanoic acids such as aminooxyacetic acid have shown extraordinary properties of inhibition of the γ-aminobutyric acid-α-ketoglutaric acid enzymatic transamination to glutamate-succinic semialdehyde *in vivo* whereas the β-aminooxyalkanoic acids such as β-aminooxypropionic acid are of low potency. The unexpected lack of significant basicity of the aminooxy group in aminooxyacetic acid and its nondipolar ion nature implies a cyclic form in solution which may be responsible for its ability to cross cell walls and exhibit *in vivo* activity. The aminooxyacetic and β-aminooxypropionic acids are degraded in mild alkali at 60° to form ammonia and nitrite ion in the ratio of 2:1, and a mechanism of hydroxylamine release is postulated to account for this stoichiometry where the rate determining step is the release of hydroxylamine and a carboxylic acid. Hydroxylamine itself is quickly transformed by mild alkali at 60° to ammonia and nitrite ion. This mode of degradation is significant since hydroxylamine itself is a known transaminase inhibitor.

THE IMPORTANCE of the enzymatic transamination of γ-aminobutyric acid, GABA, with α-ketoglutaric acid to form glutamate and succinic semialdehyde in brain tissue and the potential effect on neurological activity has been stressed in the literature (1–3). Thus, inhibition of this transamination is of interest in the possible correlation of GABA levels in the brain with physiological properties such as definite depression of the central nervous system (4). Although suitable doses of hydroxylamine have been shown to increase the GABA levels in the brain of rats (5), a potent inhibitor *in vitro* and *in vivo* of the transaminase involved has been recently shown by Wallach (4) to be aminooxyacetic acid (AOAA), H_2NOCH_2COOH. Recent studies on various analogs have shown that good *in vivo* activity was generally limited to the α-aminooxyalkanoic acids or their easily hydrolyzed derivatives such as esters (6). None of the compounds studied was superior to aminooxyacetic acid (6).

The studies reported in this paper include the titrimetric characterization, stability, and possible modes of degradation of two representative compounds, aminooxyacetic acid and β-aminooxypropionic acid. The purposes were to obtain data for the possible rationalization of the observed difference in *in vivo* activity of these compounds.

Received August 7, 1961, from the Research Division, The Upjohn Co., Kalamazoo, Mich.

Accepted for publication August 23, 1961.

The author is greatly indebted to Mrs. Lillian G. Snyder for excellent technical assistance. Grateful appreciation is given to Dr. R. V. Heinzelman for discussions which led to many of the rationales expressed in this paper.

† Present address: College of Pharmacy, University of Florida, Gainesville.

EXPERIMENTAL

Purity by Titration.—Aminooxyacetic acid hemihydrochloride (7) ($H_2NOCH_2COOH.{}^1/_2HCl$, mol. wt. = 109.3) 0.10 mmole, was dissolved in 10.00 ml. solvent and was titrated with 2.000 *N* sodium hydroxide in the Cannon automatic titrator (8) (see Fig. 1). A minor inflection (pH 3.4) was observed at an amount of titer which was $^1/_3$ of the total titer consumed up to a large inflection (pH 6–10). This was equivalent to the $^1/_2$ HCl per molecule. The titer between the minor and major inflections was equivalent to the number of moles.

Fifteen titrations showed that the material was of high purity by titration, 100.0 ± 0.3%.

Similarly, 10.00 ml. of 0.0050 *M* β-aminooxypropionic acid hydrochloride (9) ($H_2NO—CH_2CH_2COOH.HCl$, mol. wt. = 141.6) was titrated (see Fig. 2). The minor inflection was at pH 4.2, and 8 titrations conducted in water and in various aqueous alcohol solvents showed that the material was of high purity by titration, 100.0 ± 1.0%.

The apparent pKa values of these compounds as functions of per cent ethanol by volume are given in Table I. These pKa values are estimated from the pH at half-neutralization of the apparent prosthetic groups.

The compounds studied were provided by E. L. Schumann (6) of these laboratories.

Stability at 60° in Acid and Neutral Regions.—Solutions of 0.01 *M* aminoooxyacetic acid hemihydrochloride as studied up to 554 hours in water (pH 2.75), up to 22 hours at pH 9.5, up to 280 hours in 0.1 *N* hydrochloric acid at pH 1.20 were completely stable as evidenced by no change in the titration curves. Solutions of 0.005 *M* β-aminooxypropionic acid hydrochloride as studied up to 300 hours at pH 8.0 and up to 280 hours in 0.1 *N* hydrochloric acid at pH 1.20 were also completely stable by titration. No differences were observed in the shape of the curves or the apparent equivalent weight for aliquots taken up to these stated times.

Although β-aminooxypropionic acid hydrochloride in aqueous solution *ca.* pH 5.1 was stable up to the

TABLE I.—pKa AS FUNCTIONS OF PER CENT ETHANOL BY VOLUME

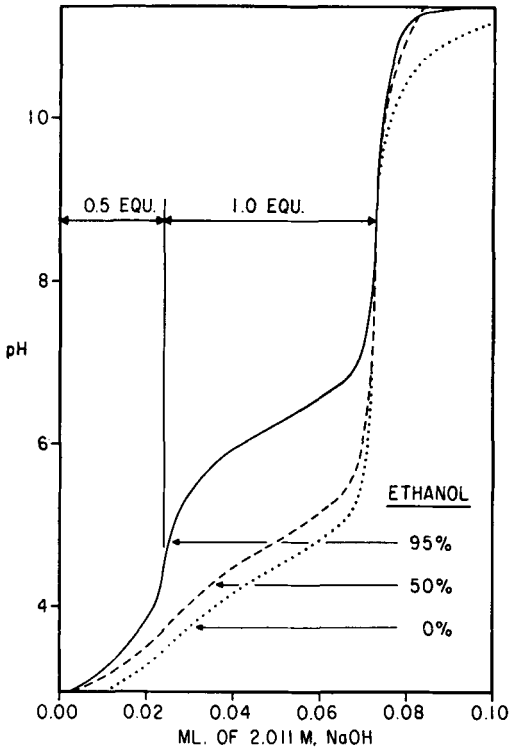

Fig. 1.—Potentiometric titrations of 0.010 *M* aminooxyacetic acid hemihydrochloride in varying per cent ethanol-water solutions.

17 hours studied at room temperature by titration, a change in the titration curve was observed when the solutions were subjected to 60°. This had not been observed with aminooxyacetic acid hemihydrochloride in aqueous solution at 60°. The change in the titration curves resulted in an apparent increase in pKa_2 from 5.22 to 6.0 at 100 hours with a significant decrease in the amount of titer necessary to reach the major inflection at pH 8 by 5% at 18 hours and 10% by 100 hours. This same phenomenon occurred when β-aminooxypropionic acid was subjected to pH 4 at 60°.

Stability in Alkaline Media.—Degradation of the aminooxyalkanoic acids occurred in mild alkali at 60°. Ten-milliliter aliquots of 0.0101 *M* sodium aminooxyacetate in 0.01 *M* sodium hydroxide were acidified with 1 ml. 0.25 *N* hydrochloric acid and potentiometrically titrated with 2.00 *M* sodium hydroxide. In another study, aliquots were directly titrated with 1.904 *M* hydrochloric acid. Typical curves of such titrations as a function of time of subjection to 60° are given in Fig. 3 and pertinent information is tabulated in Table II.

Similarly, typical curves for the titrations with time by 1.904 *M* hydrochloric acid of 10-ml. aliquots of 0.01 *M* sodium β-aminooxypropionate maintained at 60° in 0.01 *M* sodium hydroxide are given in Fig. 4 and pertinent information for such a degradation is given in Table III.

[a] Estimated from point of half-neutralization of between apparent inflection at pH 10.7 and definite inflection at pH 7 (see Fig. 2). [b] Portions of titration curves above pH 10 are superimposed over zero-time curve. The titer difference between the major inflections at pH 7 permits quantification of the amount of pKa 9.4 material appearing.

Hydroxylamine was also subjected to 0.01 *M* sodium hydroxide at 60° and aliquots were titrated at intervals. The pKa = 6.00 of hydroxylamine disappeared within 10–15 minutes and an apparent pKa of 9.3 appeared with a significant loss of free alkali.

The degraded alkaline solutions of both aminooxyalkanoic acids and hydroxylamine showed the presence of large amounts of nitrite ion as tested by the method of Forist (10).

RESULTS AND DISCUSSION

Ionic Nature of Aminooxyalkanoic Acids.—In general, pKa values of carboxylic acids increase with decreasing aqueous content of miscible solvents, whereas the pKa values of ammonium ions show little change or tend to decrease (11). The rationale is that a decrease in dielectric constant should not favor the dissociation of an uncharged species such as a carboxylic group whereas it should show no effect or slightly favor the dissociation of a protonated amine. This latter dissociative equilibrium does not involve a change in the number of ions. The pKa data of Table I indicate very little change in pKa_1 values with increasing alcohol content, whereas the pKa_2 values increase, and the increase is especially large between 50 and 95% (by volume)

ethanol content of the solvent. These facts permit the postulation of a nondipolar ion for the aminooxyalkanoic acids in solution, i.e., pKa_1 is assigned to the aminooxy group and pKa_2 is assigned to the carboxyl group. The smaller increase in pKa_2 between 0 and 50% ethanol content of the solvent than between 50 and 95% suggests that unusual molecular interactions may occur in solutions of high dielectric. The presence of a hemihydrochloride is in itself unique and implies that aminooxyacetic acid exists as the dimer in the crystalline form: $Cl^- \cdot NH_3^+—OCH_2COO^- \cdot NH_3^+—OCH_2COOH$.

The apparent pKa_1 values are determined on the premise that pKa_1 = pH at half-neutralization. Actually, the acidity of aminooxyacetic acid hemihydrochloride solutions is no less than what an equivalent molarity of hydrochloric acid would produce and thus strongly indicates that if any aqueous pKa_1 of this compound exists, it is very much less than the 2.75 estimated from half-neutralization and listed in Table I.

These facts indicate that aminooxyacetic acid may exist in cyclic form in solution where the aminooxy group is unavailable for ready protonation, as

If the number of methylene groups is increased between the carbonyl and the aminooxy group, cyclicization is inhibited and the aminooxy group becomes more readily protonated, as in the case of the real pKa_1 of β-aminooxypropionic acid hydrochloride.

Mode of Alkaline Degradation.—When aminooxyacetic acid is subjected to mild alkali and titrations of aliquots are made as a function of time (Fig. 3 and Table II), a new titratable group appears at *ca.* pKa 9.4 and the acidity of the reacting solution increases, indicative of free alkali consumption. The increase in molarity of the new 9.4 pKa func-

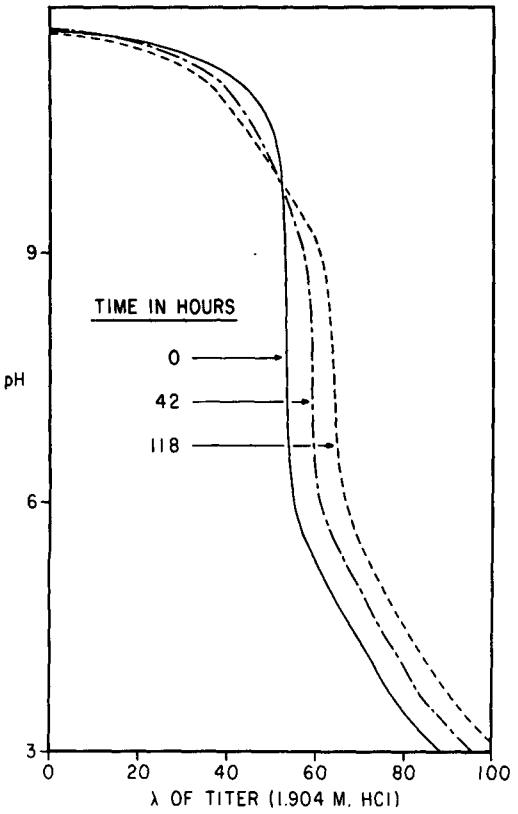

Fig. 4.—Titrations of 0.003 *M* sodium β-aminooxypropionate in 0.01 *M* sodium hydroxide maintained at 60°. The titer is 1.904 *M* hydrochloric acid.

tion was estimated by superimposition of the titration curve above pH 10 and estimating the differences in titer between the major inflection of a titration curve at any time with inflection of the titration curve taken at zero time (12). The loss of free alkali was estimated from differences in standard acid titer necessary to achieve the initial pH (12) and is given in Table II from the data on standard acid titration of aliquots. Standard alkaline titration of acidified aliquots gave variable results and indicated that the strong acid anion produced by basic treatment was unstable in acidic solutions.

These facts were consistent with the assignment of ammonia to the observed pKa 9.4 (NH_3, pKa = 9.25) and nitrite ion (pKa 3.6), produced in the ratio of 2:1 (see Tables II and III). The possible explanation of this degradation in this ratio is given in the following equations

$$H_2NO{-}CH_2COOH \xrightarrow[HOH]{OH^-} H_2NOH + HOCH_2COOH \quad \text{(Eq. 1)}$$

$$3NH_2OH + OH^- \rightarrow NO_2^- + 2NH_3 + 2H_2O \quad \text{(Eq. 2)}$$

Equation 2 predicts the formation of NH_3 and NO_2^- in the ratio of 2:1. The formation of the latter would lower the apparent acidity and consume free alkali. Chemical tests have unambiguously shown the presence of nitrite. Hydroxylamine (pKa = 6.00) was not observed by titration. This indicates that the possible reaction shown in Eq. 2 is the fast one and that reaction shown in Eq. 1 is rate determining. This fact was substantiated by subjecting hydroxylamine to 0.01 *M* sodium hydroxide at 60°. Within several minutes the pKa 6.0 disappeared, a pKa of 9.3 appeared with an alkali consumption in

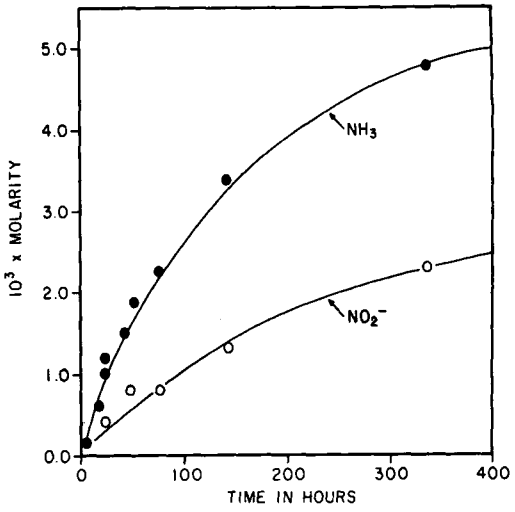

Fig. 5.—Appearance of NH_3 and NO_2^- as a function of time from the degradation of 0.010 *M* sodium aminooxyacetate in 0.010 *M* sodium hydroxide.

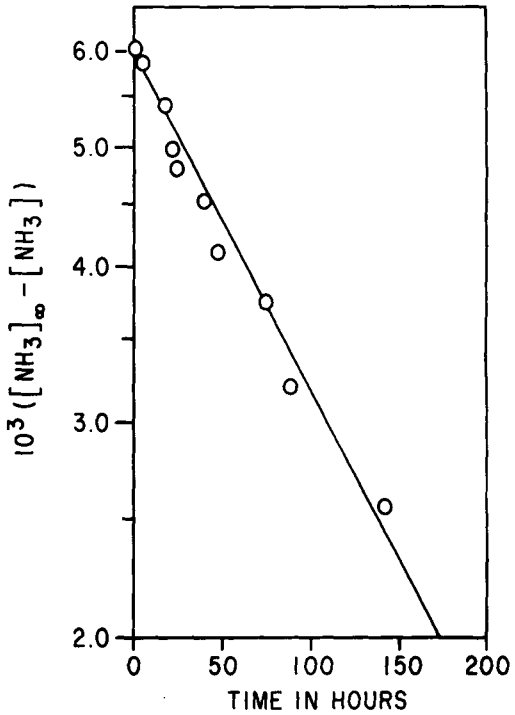

Fig. 6.—First-order plot for the appearance of $[NH_3]$ from the degradation of 0.010 *M* sodium aminooxyacetate in 0.010 *M* sodium hydroxide. The $[NH_3]_\infty$ is taken as 6.0×10^{-3}.

the ratio 1:2 with the pKa 9.3, and nitrite ion was conclusively identified as present.

The same phenomena were observed for the alkaline degradation of β-aminooxypropionic acid (Table III).

It can be concluded that carbonate or hydroxylamine is not an end product of the mild alkaline degradation of aminooxyalkanoic acid (no pKa's 6.0–6.5 are observable) and that the most probable sequence is the hydrolysis to hydroxylamine and some carboxylic acid, with a subsequent fast degradation of hydroxylamine to ammonia and nitrite ion.

Figure 5 plots the ammonia and nitrite produced as a function of time in 0.01 *M* sodium hydroxide at 60° as based on the above discussion. Apparent first-order plots for the production of ammonia and nitrite are given in Fig. 6 for aminooxyacetic acid with an apparent half-life of 110 hours under these conditions.

It is interesting to note that although β-aminooxypropionic acid is quite stable at 60° below pH 2 and between pH 7–10, degradation other than alkaline also occurs with an apparent maximum at pH values of *ca.* 3–4. This implies a significant acid catalyzed hydrolysis of the neutral molecule where

$$H_2NO{-}CH_2CH_2COOH + H_3O^+ \rightarrow H_3\overset{+}{N}OH + HOCH_2CH_2COOH \quad \text{(Eq. 3)}$$

the hydroxylamine was identified by the appearance of a pKa 6.0 since hydroxylamine does not readily degrade at this pH. It may be inferred that at a pH less than 2 the protonated compound, $^+H_3NO{-}CH_2CH_2COOH$, is the major species and resists hydrogen ion attack. At a pH greater than 7, the hydrogen ion and hydroxyl ion concentrations are insufficient for catalytic action.

Biological Activity and the Chemistry of Aminooxyalkanoic Acids.—The increased biological activity of aminooxyacetic acid over all other compounds studied (4, 7) can be assigned to its unusual chemical characteristics which include the absence of any apparent basicity of the aminooxy group in aqueous solution, perhaps due to a tendency to exist in the form of a five-membered ring. This in turn may be responsible for its ability to cross cell walls.

The ability of these α-aminooxyalkanoic acids to release hydroxylamine *in vitro* is of interest in light of the known action of hydroxylamine as an inhibitor of transaminase. This suggests that these α-aminooxyalkanoic acids may uniquely carry and release hydroxylamine at the physiological site, wheras hydroxylamine itself is too readily metabolized or not readily transportable. Of course, the possibility that the intact acids are the primary agent is not refuted.

Sulfide Derivatives of Cysteine II

Some Sulfonamide Derivatives of Cysteine and Methionine

By MATTHEW VERDERAME

Seven new sulfide derivatives of cysteine have been prepared. In addition sulfonamides of cysteine, L-3-mercapto-N-sulfanilylalanine, and methionine, DL-N-sulfanilylmethionine, among others, have also been prepared. Except for L-3-[(3′-hydroxy-4′-carboxyphenyl)-carbamylmethylthio]-alanine (compound 2), which was slightly effective against a *Klebsiella pneumoniae* infection in Swiss mice, all other compounds tested for various activities showed a lack of physiological effectiveness.

A PREVIOUS paper (1) was concerned with the synthesis and physiological testing of several new amide derivatives of L-3-carboxymethylthioalanine as possible antiviral agents. This paper is, in part, involved with the synthesis and testing of seven additional sulfide derivatives of cysteine. The second half of this publication essentially deals with the preparation and biological study of L-3-mercapto-N-sulfanilylalanine, DL-N-sulfanilylmethionine, and other related compounds.

Received August 28, 1961, from the Chemistry Department, Albany College of Pharmacy, Union University, Albany, N. Y.
Accepted for publication October 16, 1961.
The author wishes to express special thanks to Dr. C. M. Suter for his assistance rendered in this work. Appreciation is also extended to the Sterling-Winthrop Research Institute for the use of their facilities and also for providing financial support toward this work.

DISCUSSION

The sulfide derivatives of cysteine, L-3-(substituted)-methylthioalanines (Table I), were made by

the ratio 1:2 with the pKa 9.3, and nitrite ion was conclusively identified as present.

The same phenomena were observed for the alkaline degradation of β-aminooxypropionic acid (Table III).

It can be concluded that carbonate or hydroxylamine is not an end product of the mild alkaline degradation of aminooxyalkanoic acid (no pKa's 6.0–6.5 are observable) and that the most probable sequence is the hydrolysis to hydroxylamine and some carboxylic acid, with a subsequent fast degradation of hydroxylamine to ammonia and nitrite ion.

Figure 5 plots the ammonia and nitrite produced as a function of time in 0.01 *M* sodium hydroxide at 60° as based on the above discussion. Apparent first-order plots for the production of ammonia and nitrite are given in Fig. 6 for aminooxyacetic acid with an apparent half-life of 110 hours under these conditions.

It is interesting to note that although β-aminooxypropionic acid is quite stable at 60° below pH 2 and between pH 7–10, degradation other than alkaline also occurs with an apparent maximum at pH values of *ca.* 3–4. This implies a significant acid catalyzed hydrolysis of the neutral molecule where

$$H_2NO{-}CH_2CH_2COOH + H_3O^+ \rightarrow H_3\overset{+}{N}OH + HOCH_2CH_2COOH \quad \text{(Eq. 3)}$$

the hydroxylamine was identified by the appearance of a pKa 6.0 since hydroxylamine does not readily degrade at this pH. It may be inferred that at a pH less than 2 the protonated compound, $^+H_3NO{-}CH_2CH_2COOH$, is the major species and resists hydrogen ion attack. At a pH greater than 7, the hydrogen ion and hydroxyl ion concentrations are insufficient for catalytic action.

Biological Activity and the Chemistry of Aminooxyalkanoic Acids.—The increased biological activity of aminooxyacetic acid over all other compounds studied (4, 7) can be assigned to its unusual chemical characteristics which include the absence of any apparent basicity of the aminooxy group in aqueous solution, perhaps due to a tendency to exist in the form of a five-membered ring. [c] The analytical data were determined at the Sterling-Winthrop Research Institute.

the alkylation of cysteine according to procedures previously described (1-3).

The new sulfonamides of cysteine and methionine (Table II) were made in the usual manner starting with N-acetylsulfanilyl chloride (ASC) to acylate the amino groups of these amino acids, followed by the acid hydrolysis of the acetamido grouping. In the case of cysteine, the acylation was first performed on cystine and the resulting product then reduced to free the mercapto group, according to the following reactions

EXPERIMENTAL

Most of the starting materials were obtained from Eastman. Others were purchased from Matheson (*p*-aminosalicylic acid and DL-methionine) and Merck (sulfathiazole).

L-3-(Substituted)-methylthioalanines (Table I).—Compounds 1 and 6 were recrystallized from water. Compound 4 was recrystallized from water and alcohol. Number 3 required two recrystallizations from water and a third from equal parts absolute ethanol and methanol, followed by the addition of ether. Number 7 was purified from acetic acid plus water. For compound 5, equal parts of alcohol and water was used initially, and then water and acetic acid. Compound 2 required alternate treatment with dilute hydrochloric acid and sodium bicarbonate solutions. The base, added to the filtered, acid solution of the crude material, yielded the amphoteric compound, which redissolved by the addition of more bicarbonate solution. Acidification of the filtered, basic solution produced a pure compound.

L - N,N' - Bis - (*p* - acetamidobenzenesulfonyl)-cystine.—A mixture consisting of 39.2 Gm. (0.168 mole) of ACS, 20.0 Gm. (0.084 mole) of L(−)cystine, 13.6 Gm. (0.336 mole) of sodium hydroxide dissolved in 500 ml. of water, and 300 ml. of ether was vigorously agitated for 45 minutes at room temperature. The layers were separated and the aqueous portion chilled and acidified with concentrated hydrochloric acid to pH 1. The product was reduced at once without further purification. For analysis, a portion was recrystallized once from isopropyl alcohol and twice from alcohol; m.p. 216° (decompn.).

Anal.—Calcd. for $C_{22}H_{26}N_4O_{10}S_4$: N, 8.83; S, 20.20. Found: N, 8.82; S, 19.6.

TABLE II.—SOME SULFONAMIDE DERIVATIVES OF CYSTEINE AND METHIONINE

No.	X	Formula	Nitrogen, % Calcd.	Nitrogen, % Found	Sulfur, % Calcd.	Sulfur, % Found
8	—CH(COOH)CH$_2$SH	$C_9H_{12}N_2O_4S$	10.14	10.29	23.21	23.40
9	—CH(COOH)CH$_2$SCH$_2$CH$_3$	$C_{11}H_{16}N_2O_4S_2$	9.20	9.08	21.07	21.5
10	—C$_6$H$_4$—SO$_2$NHCH(COOH)CH$_2$SC$_2$H$_5$	$C_{17}H_{21}N_3O_6S_3$	9.14	8.75	20.93	20.03
11	—CH(COOH)CH$_2$CH$_2$SCH$_3$	$C_{11}H_{16}N_2O_4S_2$	...	[a]	21.07	22.38

[a] Carbon and hydrogen were also determined. *Anal.*—Calcd.: C, 43.40; H, 5.30. Found: C, 43.77; H, 5.17.

L - 3 - Mercapto - N - acetylsulfanilylalanine.—The crude L-N,N′-Bis-(*p*-acetamidobenzenesulfonyl)-cystine was treated with 9.0 Gm. (0.138 mole) of zinc dust, 90 ml. (0.168 mole) of a 10% solution of hydrochloric acid, 110 ml. methyl alcohol, and 75 ml. of water. The mixture was then heated at about 55° for 1.5 hours, with shaking. To effect a solution of the product, the mixture was heated to near boiling, filtered, and chilled. The white product thus obtained was essentially pure and amounted to 14.6 Gm., or 27.4%, based on the quantity of ASC used initially. A sample, recrystallized twice from alcohol, melted at 214–217°.

Anal.—Calcd. for $C_{11}H_{14}N_2O_5S_2$: N, 8.80; S, 20.14. Found: N, 8.85; S, 19.9.

L-3-Mercapto-N-sulfanilylalanine (Compound 8).—The previously isolated 14.6 Gm. (0.046 mole) of L-3-mercapto-N-acetylsulfanilylalanine was refluxed for 30 minutes with 125 ml. of 6 *N* hydrochloric acid solution. The mixture was filtered while hot, cooled, and neutralized with a solution of 20% sodium hydroxide. The 8.0 Gm. of product, obtained by two recrystallizations from hot water, corresponded to a 63% yield; m.p. 170–173°. For analytical data, see Table II.

L - 3 - Ethylthio - N - (N′ - acetylsulfanilyl)-alanine.—By the procedure previously described, a mixture of 13.4 Gm. (0.090 mole) of L-3-ethylthioalanine (2), 22.2 Gm. (0.095 mole) of ASC, 7.6 Gm. (0.190 mole) of sodium hydroxide in 150 ml. of water, and 150 ml. of ether, stirred for 2 hours at room temperature, yielded 17.4 Gm. of product, which was recrystallized twice from alcohol and water. Yield, 55.9%; m.p. 190–193°.

Anal.—Calcd. for $C_{13}H_{18}N_2O_5S_2$: N, 8.09; S, 18.51. Found: N, 8.02; S, 18.69.

L-3-Ethylthio-N-sulfanilylalanine (Compound 9).—From the hydrolysis of 17.4 Gm. (0.051 mole) of L-3-ethylthio-N-(N′-acetylsulfanilyl)-alanine with 125 ml. of 6 *N* hydrochloric acid solution for 30 minutes was obtained 11.1 Gm. of product, following two recrystallizations from alcohol and water. Yield, 70.6%; m.p. 182–184°.

L - 3 - Ethylthio - N - [(N′ - sulfanilyl) - sulfanilyl]-alanine (Compound 10).—As previously described, the crude product obtained from a mixture of 7.7 Gm. (0.025 mole) of L-3-ethylthio-N-sulfanilylalanine, 6.5 Gm. (0.028 mole) of ASC, 2.2 Gm. (0.056 mole) of sodium hydroxide in 80 ml. of water, and 80 ml. of ether, was hydrolyzed directly with 60 ml. of 6 *N* hydrochloric acid solution for one-half hour. The product thus obtained was recrystallized three times from alcohol and water, yielding 1.5 Gm. or 12%, based on L-3-ethylthio-N-sulfanilylalanine; m.p. 127° (decompn.).

DL-N-(N′-Acetylsulfanilyl)-methionine.—A mixture of 13.9 Gm. (0.093 mole) of DL-methionine, 21.6 Gm. (0.093 mole) of ASC, 6.8 Gm. (0.186 mole) of sodium hydroxide dissolved in 110 ml. of water, and 110 ml. of ether, agitated for 1 hour, yielded an oil, upon acidification of the aqueous phase. The oil solidified in a desiccator over calcium chloride after 3 days. Partial purification was effected by triturating the solid in a mortar three times with 50-ml. portions of ether, the mixture being filtered each time. The undissolved substance was then recrystallized once from ethyl acetate and again from water. The 12.0 Gm. of product thus obtained corresponded to a 37.6% yield; m.p. 163–164°.

Anal.—Calcd. for $C_{13}H_{18}N_2O_5S_2$: C, 45.07; H, 5.24; N, 8.09; S, 18.51. Found: C, 44.98; H, 4.97; N, 7.92; S, 18.67.

DL-N-Sulfanilylmethionine (Compound 11).—Hydrolysis of 12.0 Gm. (0.035 mole) of DL-N-(N′-acetylsulfanilyl)-methionine with 95 ml. of 6 *N* hydrochloric acid solution in the usual way produced 4.2 Gm. of product (39.8%), after two recrystallizations from ethyl acetate; m.p. –144146°.

BIOLOGICAL RESULTS[1]

Compounds 2, 5, 7, 8, and 10 were ineffective intraperitoneally or subcutaneously against a *M. pyogenes* infection in Swiss mice. Also, compounds 8, 9, 10, and 11 were inactive *in vivo* against a staphylococcus infection orally and subcutaneously. Against a *Trichomonas gallinae* infection in hamsters, compound 7 was without effect.

[1] The author wishes to express his thanks to A. J. Arrowsmith, S. D. Sobell, D. A. Berberian, and R. G. Slighter, among others, of the Sterling-Winthrop Research Institute for performing the biological studies on these compounds.

As possible antimetabolites for calcium pantothenate, phenylalanine, cysteine, and folic acid, compounds 3, 4, 5, 6, and 11 were ineffective. Given intraperitoneally to Swiss mice having a *D. pneumoniae I* infection, compounds 2, 3, 4, and 6 were of no value. Compound 1 was ineffective as a possible spermatocidal agent. Also ineffective against a *Klebsiella pneumoniae* infection in Swiss mice given by various routes were compounds 1, 3, 4, 5, and 6. Compound 2, however, did show slight effectiveness.

Effect of Phentolamine and Tolazoline on Some Metabolic Processes of Heart Homogenates

BY HARRY C. FROEDE and HAROLD C. HEIM

The addition of phentolamine enhances oxygen uptake of rat heart homogenates respiring in the presence of added succinate, but evokes an inhibitory effect with pyruvate as the substrate. These effects are not observed when phentolamine is replaced by tolazoline. Oxidation of α-ketoglutarate is not affected by either drug nor is the activity of a purified malic dehydrogenase. The addition of oxaloacetate to homogenates inhibits oxygen uptake and the inhibitory effect is not abolished by the prior addition of phentolamine. The total α-keto acid content of homogenates respiring in the presence of succinate was found to be somewhat higher than in those homogenates to which both succinate and phentolamine were added at the beginning of the experiments.

TOLAZOLINE and phentolamine are both 2-substituted imidazolines which evoke adrenergic blocking effects. It has been reported that the most pronounced side effects elicited by these drugs are related to a direct stimulation of the myocardium and include cardiac arrhythmias, anginal pain, tachycardia, and fibrillation (1–4).

A survey of the literature reveals that no studies have been undertaken to determine whether phentolamine or tolazoline affect metabolic processes of the heart, *in vitro*. Therefore, because of the widely held belief that drugs produce effects on tissues, at least in part, through an alteration of intracellular reactions, an investigation of the effects of these two drugs on oxidative processes of heart homogenates was conducted.

EXPERIMENTAL

Conventional manometric techniques were used to determine the effect of phentolamine and tolazoline on oxygen uptake in the presence of different added substrates including succinate, α-ketoglutarate, and pyruvate. Hearts from adult Sprague-Dawley rats of both sexes were used. The animals were stunned and decapitated, following which the hearts were immediately removed, cut open, and washed in cold 0.1*M* phosphate buffer. The ventricles were then dissected free, blotted dry on filter paper, weighed, and placed in a glass homogenizer immersed in ice and containing sufficient buffer so that 1.0 ml. of homogenate contained 50 mg., wet weight, of ventricle. The homogenates were centrifuged for 10 minutes at 480 × g in a Servall RC-2 centrifuge with an SS-34 rotor and at a temperature of 3°. The sediment was discarded and the supernatant was used as the homogenate. Ten animals were used in each experiment and each determination of oxygen uptake was performed in duplicate. No more than 10 minutes elapsed between the time the animals were killed and the preparation of the homogenates.

The concentrations of reagents added to the flasks are included in *Results*. The temperature of the bath was 37° and the gas phase was air. After a 10-minute equilibration period, the side arm contents were tipped into the vessels, the manometers closed, and readings taken at 15-minute intervals for a total of 90 minutes.

Keto-acid determinations were performed according to the method of Friedemann (5). The contents of the main compartments of two Warburg vessels were pooled and 2.0 ml. of the ensuing mixture was pipetted into 8.0 ml. of cold, 10% trichloroacetic acid solution. After centrifugation at 3000 × g for 15 minutes, 3.0 ml. of the clear supernatant

The authors are most grateful for the generous amounts of phentolamine and tolazoline supplied by the Ciba Pharmaceutical Co.

As possible antimetabolites for calcium pantothenate, phenylalanine, cysteine, and folic acid, compounds 3, 4, 5, 6, and 11 were ineffective. Given intraperitoneally to Swiss mice having a *D. pneumoniae I* infection, compounds 2, 3, 4, and 6 were of no value. Compound 1 was ineffective as a possible spermatocidal agent. Also ineffective against a *Klebsiella pneumoniae* infection in Swiss mice given by various routes were compounds 1, 3, 4, 5, and 6. Compound 2, however, did show slight effectiveness.

Effect of Phentolamine and Tolazoline on Some Metabolic Processes of Heart Homogenates

BY HARRY C. FROEDE and HAROLD C. HEIM

The addition of phentolamine enhances oxygen uptake of rat heart homogenates respiring in the presence of added succinate, but evokes an inhibitory effect with pyruvate as the substrate. These effects are not observed when phentolamine is replaced by tolazoline. Oxidation of α-ketoglutarate is not affected by either drug nor is the activity of a purified malic dehydrogenase. The addition of oxaloacetate to homogenates inhibits oxygen uptake and the inhibitory effect is not abolished by the prior addition of phentolamine. The total α-keto acid content of homogenates respiring in the presence of succinate was found to be somewhat higher than in those homogenates to which both succinate and phentolamine were added at the beginning of the experiments.

TOLAZOLINE and phentolamine are both 2-substituted imidazolines which evoke adrenergic blocking effects. It has been reported that the most pronounced side effects elicited by these drugs are related to a direct stimulation of the myocardium and include cardiac arrhythmias, anginal pain, tachycardia, and fibrillation (1–4).

A survey of the literature reveals that no studies have been undertaken to determine whether phentolamine or tolazoline affect metabolic processes of the heart, *in vitro*. Therefore, because of the widely held belief that drugs produce effects on tissues, at least in part, through an alteration of intracellular reactions, an investigation of the effects of these two drugs on oxidative processes of heart homogenates was conducted.

EXPERIMENTAL

Conventional manometric techniques were used to determine the effect of phentolamine and tolazoline on oxygen uptake in the presence of different added substrates including succinate, α-ketoglutarate, and pyruvate. Hearts from adult Sprague-Dawley rats of both sexes were used. The animals were stunned and decapitated, following which the hearts were immediately removed, cut open, and washed in cold 0.1*M* phosphate buffer. The ventricles were then dissected free, blotted dry on filter paper, weighed, and placed in a glass homogenizer immersed in ice and containing sufficient buffer so that 1.0 ml. of homogenate contained 50 mg., wet weight, of ventricle. The homogenates were centrifuged for 10 minutes at 480 × g in a Servall RC-2 centrifuge with an SS-34 rotor and at a temperature of 3°. The sediment was discarded and the supernatant was used as the homogenate. Ten animals were used in each experiment and each determination of oxygen uptake was performed in duplicate. No more than 10 minutes elapsed between the time the animals were killed and the preparation of the homogenates.

The concentrations of reagents added to the flasks are included in *Results*. The temperature of the bath was 37° and the gas phase was air. After a 10-minute equilibration period, the side arm contents were tipped into the vessels, the manometers closed, and readings taken at 15-minute intervals for a total of 90 minutes.

Keto-acid determinations were performed according to the method of Friedemann (5). The contents of the main compartments of two Warburg vessels were pooled and 2.0 ml. of the ensuing mixture was pipetted into 8.0 ml. of cold, 10% trichloroacetic acid solution. After centrifugation at 3000 × g for 15 minutes, 3.0 ml. of the clear supernatant

was used for determination of total keto-acid content. The color which developed upon addition of 2,4-dinitrophenylhydrazine was measured at 435 mμ, with redistilled pyruvic acid being used as the standard keto-acid.

Malic dehydrogenase activity was determined according to the method of Ochoa (6). The oxidation of dihydro-β-diphosphopyridine nucleotide (DPNH) to diphosphopyridine nucleotide (DPN), with the concomitant reduction of oxaloacetate to malate, was measured by observing the decrease in absorbance (A_s) at 340 mμ with a Beckman model DU spectrophotometer. The enzyme concentration was adjusted so that 3.0 ml. of reaction mixture contained 40 units. The final concentration of DPNH and oxaloacetate were both 5×10^{-6} *M*. Malic dehydrogenase, DPNH, and oxaloacetate solutions were freshly prepared prior to each experiment.

RESULTS

Figure 1 shows that the oxygen consumption by rat heart homogenates in the presence of added succinate proceeds at a rapid rate for approximately 30 minutes, after which a decline in rate occurs. This is confirmatory to the results obtained by other investigators (7, 8). Figure 1 also shows, however, that if phentolamine is added at the start of the experiment in sufficient amount so that the final concentration is 7×10^{-4} *M*, oxygen consumption is much greater than in the absence of phentolamine. The rate is initially quite rapid and declines somewhat after about 30 minutes, but still remains greater than in the control flasks. The prior addition of tolazoline, so that final concentrations ranged between 1.4×10^{-2} *M* and 3.6×10^{-4} *M*, did not significantly alter the rate of oxygen uptake.

It has been established that oxaloacetate markedly inhibits the oxidation of succinate (9, 10) and it has been suggested that the decline in rate of oxygen uptake might be due to accumulation of oxaloacetate (7). Table I shows that the addition of oxaloacetate inhibited oxygen uptake in the presence of succinate by approximately 57% and that this inhibitory effect was not significantly altered by either phentolamine or tolazoline. In flasks containing pyruvate as the substrate, the addition of phentolamine, at final concentration of 7×10^{-4} *M*, caused a 70% inhibition of oxygen uptake, but this effect was not observed with tolazoline. When malate and succinate were both present, the oxygen uptake was somewhat less than that obtained when no malate was present, and the addition of phentolamine caused a 210% increase in oxygen consumption. Similar results were obtained with phentolamine in the experiments in which fumarate was present together with succinate. Tolazoline did not significantly alter oxygen consumption. When α-ketoglutarate was added as the substrate, the oxygen consumption was not changed by either phentolamine or tolazoline.

Analysis of flask contents at the end of the experiments revealed that total α-keto acids were present

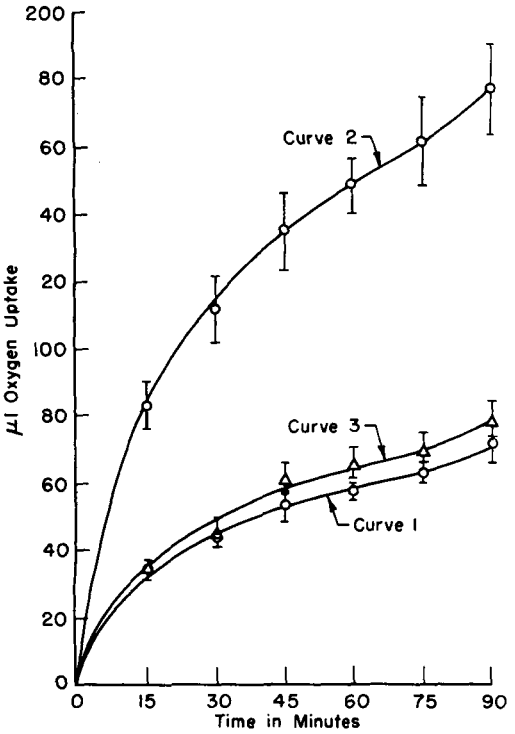

Fig. 1.—Effect of phentolamine and tolazoline on rate of oxygen uptake in the presence of added succinate. Curve 1, no drug; curve 2, phentolamine (7×10^{-4} *M*); curve 3, tolazoline (7×10^{-4} *M*). Experimental conditions are the same as shown in Table I.

TABLE I.—EFFECT OF PHENTOLAMINE AND TOLAZOLINE ON OXYGEN UPTAKE

Substrate	Drug	O_2 Uptake, mm.³/25 mg. Tissue/90 min.	Increase (+) or Decrease (−) Due to Drug, %
Succinate[a]	None	72 ± 5.7[g]	
	Phentolamine	176 ± 12.6	+140

[a] Flasks contained 0.4 ml. 0.1 *M* succinate tipped from sidearm. [b] Flasks contained 0.4 ml. 0.1 *M* pyruvate containing 7.5×10^{-3} *M* ATP, 2.5×10^{-4} *M* DPN, and 2.5×10^{-3} *M* $MgCl_2$ added from sidearm. Main compartment contained 0.1 ml. 1.5×10^{-2} *M* nicotinamide. [c] Flasks contained 0.4 ml. 0.1 *M* succinate and 0.2 ml. 2×10^{-2} *M* malate, both added from sidearm. [d] Flasks contained 0.4 ml. 0.1 *M* succinate and 0.2 ml. 2×10^{-2} *M* fumarate, both added from sidearm. [e] Flasks contained 0.4 ml. 0.1 *M* succinate in sidearm, 0.1 ml. 10^{-2} *M* oxaloacetate in main compartment. [f] Flasks contained 0.4 ml. 0.1 *M* α-ketoglutarate and 0.1 ml. 10^{-3} *M* DPN, both added from sidearm. In addition, all flasks contained 0.5 ml. homogenate (25 mg. tissue), 0.3 ml. 5×10^{-4} *M* cytochrome C, 1.0 ml. 0.1 *M* phosphate buffer, pH 7.4 and water to make a total volume of 3.0 ml. Center wells contained 0.2 ml. 10% potassium hydroxide and filter paper strips. [g] Standard deviation = $\sqrt{\frac{\Sigma d^2}{n-1}}$.

TABLE II.—TOTAL KETO ACIDS IN FLASK CONTENTS AFTER 90 MINUTES

Substrate	Keto Acids, mcg./25 mg. Tissue[a]
Succinate	46.0 ± 2.2
Succinate + phentolamine	31.6 ± 3.7

[a] Results represent average of six determinations.

in greater amounts in flasks containing succinate than in those containing succinate plus phentolamine. These results are set forth in Table II.

Neither phentolamine nor tolazoline produced any significant effect on the activity of a purified malic dehydrogenase obtained from commercial sources.[1]

DISCUSSION

Although phentolamine and tolazoline are related chemically, tolazoline did not produce the *in vitro* metabolic effects observed with phentolamine. A slight inhibition of pyruvate oxidation was observed with tolazoline, but the effect was not nearly so marked as that observed with phentolamine.

Several investigators (7, 9, 10) have reported that very low concentrations of oxaloacetate strongly inhibit the oxidation of succinate. In this study it was found that the inhibitory effect of oxaloacetate could not be abolished by the prior addition of phentolamine. It has been suggested that oxaloacetate inhibits the oxidation of succinate through a competitive inhibition of succinic dehydrogenase (9–11) and at least one study has been conducted in which this phenomenon was observed with a purified succinic dehydrogenase preparation (12). It seems likely, however, that mass action effects might account for some of the inhibition when homogenates are used as the enzyme source because such preparations contain many enzymes other than succinic dehydrogenase and which could conceivably be affected by oxaloacetate. For example, the oxidation of succinate proceeds according to the pathway

$$\text{succinate} \xrightarrow{\text{DPN}} \text{fumarate} \rightarrow \text{malate} \xrightarrow{\text{DPN}} \text{oxaloacetate}.$$

The equilibrium constant (K') for the fumarate-malate system has been reported to be $8 \times 10^{-13}\ M$ (13). In view of the fact that the equilibrium lies far in the direction of malate, only minute amounts of oxaloacetate would be necessary to stop the conversion of malate to oxaloacetate.

The α-keto acid content, after 90 minutes incubation with succinate, was reduced by about 33% in those flasks to which phentolamine had been added at the beginning of the experiment. Wolff and Ball (7), in their studies on the effect of thyroxine on succinate metabolism, found that thyroxine inhibited malic dehydrogenase and concluded that thyroxine prevented the accumulation of oxaloacetate. The concentration of succinate used in these studies was much greater than that used by Wolff and Ball. Thus, if oxaloacetate is a competitive inhibitor of succinic dehydrogenase, a greater quantity would be required to inhibit oxygen uptake in the experiments reported herein. It was found, however, that the total amount of α-keto acids which accumulated in the flask contents is in close agreement with the values reported by Wolff and Ball. Furthermore, the rate of oxygen uptake during the first 15 minutes was about 140% greater in the flasks containing phentolamine, whereas thyroxine has been reported to produce no change in the initial rate (7). It would not appear conceivable, therefore, that phentolamine increases the oxygen uptake in the presence of added succinate by preventing the accumulation of oxaloacetate.

Close correlation cannot as yet be drawn between the effects observed *in vitro* and the response elicited by drugs *in vivo*. It has been established that even slight alterations in the structural configuration of many drugs produce marked changes in pharmacological activity. Although phentolamine and tolazoline are both imidazoline derivatives, they differ structurally to a considerable extent. This structural difference could possibly be related to the different effects produced by the two drugs on the *in vitro* systems used in this study and to the effects produced on the heart, *in vivo*.

It should be stressed that, with the exception of the experiments involving purified malic dehydrogenase, this study was conducted with homogenates as the enzyme source. In such preparations there are many reactions occurring which evoke indirect, rather than direct, effects on the enzymatic reactions of the citric acid cycle. In describing the effects of a drug on aerobic processes one cannot neglect the possibility that the drug might alter reactions which are indirectly involved with the cycle and which, therefore, escape observation when studies are performed using citric acid cycle intermediates as substrates. It is, therefore, not possible to elaborate a mechanism of action of phentolamine on the basis of the effects produced by this drug on enzymes of the citric acid cycle, *in vitro*. However, since phentolamine inhibits oxygen uptake with pyruvate as substrate, enhances oxygen uptake in the presence of succinate, evokes no effect on α-ketoglutarate oxidation, and has no effect on malic dehydrogenase, it could conceivably act at the level of the electron transport system or the accompanying phosphorylation system.

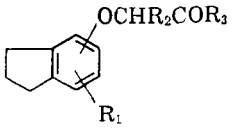
Indanols V



Indanoxyacetic Acid Derivatives

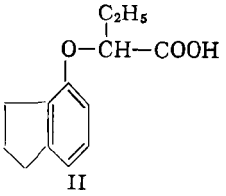
By SEYMOUR L. SHAPIRO†, THEODORE BAZGA, and LOUIS FREEDMAN

Indanoxyacetic acid derivatives (I) yielded compounds with adrenergic blocking and potentiating effects, tranquilizing activity, and anti-inflammatory activity. Of particular interest was the hypocholesteremic effect with α-(indan-4-oxy)butyric acid.

In the preceding paper, indanoxy ethers (1) were projected as simple structural analogs (2, 3) of steroids and related compounds.

Herein, we evaluate indanoxyacetic acid analogs of the type I

I



which were varied as shown in Table I. Such structures show formal analogies to the α-biphenylbutyric acids evaluated as hypocholesteremic agents by Garattini and co-workers (4), as well as the auxins (5).

Group variation, as for example R_1 as benzyl and *p*-chlorobenzyl, provided enhanced lipid solubility (6) whereas employment of R_2 from hydrogen through *n*-butyl assessed structures with increasing molecular crowding about the carboxyl group (7). The R_3 group, in turn, was inspected as the indanoxyacetic acids and derived amides and dialkylaminoalkylamides.

Reaction of the appropriate indanol with the substituted ethyl-α-bromoacetate in refluxing acetone (8), employing anhydrous potassium carbonate as an acid binder, gave the ester I, $R_3 = OC_2H_5$. The esters were hydrolyzed to the corresponding acids or converted to the amides.

On oral administration, cholesterolytic activity (8) was noted as follows: compound No./$LD_{min.}$ mg./Kg. s.c./oral dosage mg./Kg., for 3 days/% reduction in serum cholesterol at end of three days: 54/750/250/37; 55/1000/200/31; 56/300/100/51; 57/500/166/none; 58/450/150/none; 12/750/250/12. The 5-position isomer of compound 55, compound 14 ($LD_{min.}$ 500 mg./Kg.) showed 18% reduction in cholesterol after three daily doses at 30 mg./Kg. s.c. Compound 54 afforded lasting hypotension whereas compounds 55 and 56 were without effect on blood pressure (9).

The high order of hypocholesteremia obtainable with compound 56 (II), in the absence of hypotensive activity

II

has suggested additional explorations associated with the steric factor at R_2, along with the influence of substituents *ortho* to the phenoxy oxygen.

Other pharmacological effects of interest were noted as follows: potentiation of adrenaline (compounds 21, 22, 25, 31, and 39), and adrenergic block (compounds 68 and 69); ganglionic block (compound 68); reduction in motor activity (compounds 23, 25, and 72); significant inhibition of mescaline scratch test, with no inhibition of motor activity (compounds 29, 69, and 76); anti-inflammatory effects (compounds 31 and 77).

EXPERIMENTAL[1]

Ethyl α-(Indan-4-oxy)butyrate. (Compound 44).—A mixture of 26.8 Gm. (0.2 mole) of 4-indanol, 39 Gm. (0.2 mole) of ethyl α-bromobutyrate, and 27.6 Gm. (0.2 mole) of anhydrous potassium carbonate in 80 ml. of acetone was stirred and heated under reflux for 4 hours. When cool, the solid was removed by filtration and the filtrate diluted with 250 ml. of ice water and extracted with three 100-ml. portions of ether. The ethereal extracts were combined, washed successively with *N* sodium hydroxide and water, and then dried (anhydrous magnesium sulfate). After filtration, the ether was removed and the residue distilled to give 24 Gm. (48%) of product, b.p. 114–118° at 0.2 mm.

N - Diethylaminoethyl - α - (indan - 4 - oxy)-butyric Acid Amide. (Compound 69.)—A mixture

[1] Typical experimental procedures are given.

Melting and Freezing Behavior of Methyl Stearate

By A. P. SIMONELLI† and T. HIGUCHI

Investigations into the mechanism and kinetics of melting and crystallization of the stable form of methyl stearate as followed by changes in its specific volume have shown that: (*a*) the melting behavior was a sensitive function of its immediate history in a manner not associated with polymorphic transitions, (*b*) the thermodynamic equilibrium point was apparently displaced by stirring and that this displacement was proportional to the rate of stirring, (*c*) the rate of crystal growth for the present system was governed largely by the intrinsic rate of two-dimensional nucleation of a crystal plane, and (*d*) the rate of melting was a function of heat transport at higher temperature potentials. The extreme sensitivity of the method used allows the measurement of phase changes where they were of the order of parts per million and enabled the study under very small temperature potentials.

THE RESULTS of an investigation on the rates of melting and freezing are presented. These changes are often of great fundamental importance in altering the appearance of some and the rates of release of other pharmaceutical dosage forms. Although they are extremely common and apparently simple phenomena, relatively little effort seems to have been directed towards the construction of a clear and comprehensive picture of the underlying principles. Past studies in this area have been largely confined to metallic organic or simple organic systems which involve comparatively small entropy changes upon melt-

ing. The present study, on the other hand, has been concerned with the transition rates of systems which are composed of relatively large organic molecules possessing a greater entropy of melting.

The present investigation has dealt specifically with the solidifying and melting rates of methyl stearate as followed by measuring changes in its specific volume. On freezing, the ester exhibits a substantial change in volume corresponding to 30 ml. per mole, and permits the detection of an extremely small phase conversion, changes of the order of 2 p.p.m. being easily followed. These studies include (*a*) the influence of a thermal gradient on the rate of crystal growth, (*b*) melting characteristics of methyl stearate crystals formed under a moderate and extremely small temperature gradient, (*c*) the influence of a thermal gradient on the rate of melting, and (*d*) the apparent influence of stirring on the crystallization rate.

FACTORS INFLUENCING CRYSTAL GROWTH RATE

The growth of crystals involves several steps among which are transport of material to the surface, plane nucleation, growth of plane nuclei, and abstraction of the heat evolved. The overall net rate, it is evident, is dependent on the relative rates of the individual processes, the rate determining step being the slowest process. During the crystallization process, material from the melt at the interface is deposited upon the crystal and this requires, of necessity, that material must be transported from the bulk of the melt to the surface. The transport of impurity away from the surface of the crystal is also very important. If the rate of crystallization occurs at a slow rate, the concentration of impurity at the interface (molten zone) and the bulk of the melt will not appreciably differ. In the event crystallization is sufficiently rapid, however, the rate of impurity rejection occurring at the rapidly growing interface can overcome the rate of diffusion of impurity away from the interface and cause the impurity concentration at the interface to be appreciably greater than that of the bulk of the melt. This enrichment lowers the melting point and can cause the rate of rapidly growing surfaces to decrease markedly.

The rate of crystal growth is also sensitively dependent on the temperature at the interface. This temperature and the temperature existing in the melt can differ significantly if the heat of fusion which is liberated upon crystallization is not quickly dissipated. The rate of heat transfer from the sample to the bath, dQ/dt, can be estimated for simple geometric forms of sample vessel immersed in a constant temperature bath. It can be shown that the rate is greatly increased by subjecting the sample to stirring.

Even in the event that the rate of mass and heat transfer is infinitely rapid, the rate of crystallization will be limited by the finite rate of formation of the crystalline structure. According to the literature there are four known mechanisms of crystal growth (1–4): upon a rough surface, by a screw dislocation, by two-dimensional nucleation upon a smooth surface, and by three-dimensional nucleation. The rate laws for these mechanisms are

$$\text{rough surface growth rate} = K_1\Delta T + A_1 \quad \text{(Eq. 1)}$$

$$\text{screw dislocation growth rate} = K_4\Delta T^2 \quad \text{(Eq. 2)}$$

$$\text{2-D nucleation growth rate} = K_2 \exp\left[-A_2/\Delta T\right] \quad \text{(Eq. 3)}$$

$$\text{3-D nucleation growth rate} = K_3 \exp\left[-A_3/\Delta T^2\right] \quad \text{(Eq. 4)}$$

where ΔT is the temperature potential and K_x and A_x are characteristic constants of the particular system studied. The rate laws derived in the literature, however, have been derived for ideally pure materials, and for this reason the temperature potential can be represented by the temperature difference between the freezing point and the water bath. This assumption tacitly assumes that the equilibrium temperature of the sample is remaining constant as freezing proceeds and is valid only for pure systems.

It would be most difficult to account for the effect of impurity upon the system due to adsorption and occlusion, but the effect of impurity upon the potential can be obtained by considering the thermodynamic equation used in equilibrium dilatometry (5), $N_2 = A_0\Delta T_f[f/(1-f)]$, where N_2 is equal to the mole fraction of impurity, A_0 is the cryoscopic constant, f is the fraction of the sample that is melted, and ΔT_f is equal to the difference between the freezing point of the mixture, T_m, and the equilibrium temperature of the sample, T_s, at the particular fraction melted, f. The fraction melted can be obtained from a dilatometric curve (5) and is equal to the melting dilation, H, divided by the dilation coefficient, D, of the sample. The dilation coefficient, D, is equal to the total change in height of the mercury in the constant-bore tubing of the dilatometer recorded for complete melting of the sample from the solid state. The melting dilation, H, on the other hand, is equal to the change in height recorded for only a partial melting of the sample from the solid state. The equilibrium temperature of the sample is easily obtained from these relationships, i.e., $T_s = T_m - [N_2/A_0][(1-f)/f]$. The temperature potential of the system, then, is given by the difference between the equilibrium temperature of the sample and the temperature of the water bath, T_b; therefore

$$\Delta T = T_s - T_b = T_m - T_b - \left[\frac{N_2(1-f)}{A_0 f}\right] \quad \text{(Eq. 5)}$$

This equation shows that the temperature potential of an impure system is equal to the temperature potential if it were pure plus a correction factor to account for the effect of the impurity. If Eq. 5 is substituted for the temperature potential, the resulting rate equation can be applied to impure systems

$$\text{rough surface growth rate} = K_1\left(C - \frac{E}{f}\right) + A_1 \quad \text{(Eq. 6)}$$

$$\text{screw dislocation growth rate} = K_4\left(C - \frac{E}{f}\right)^2 \quad \text{(Eq. 7)}$$

smooth surface growth rate =

$$K_2 \exp\left[\frac{A_2}{C}\left(\frac{f}{f - E/C}\right)\right] \quad \text{(Eq. 8)}$$

3-D nucleation growth rate =

$$K_3 \exp\left[\frac{A_3}{C^2}\left(\frac{f}{f - E/C}\right)^2\right] \quad \text{(Eq. 9)}$$

In the above: $C = (T_m - T_b + N_2/A_0)$ and $E = N_2/A_0$.

The above equations predict that the mechanism can be identified by obtaining rate *vs.* height data at a constant water bath temperature and plotting rate *vs.* $1/f$, $(\text{rate})^{1/2}$ *vs.* $1/f$, log (rate) *vs.* $f/(f - E/C)$, and log (rate) *vs.* $(f/[f - E/C])^2$, as only one plot should yield a straight line.

EXPERIMENTAL

Apparatus.—The apparatus essentially consisted of a water bath controlled to ±0.001° and a dilatometer. The latter apparatus was similar to that previously described (5) with the exception that it was constructed in one piece.

Procedure.—The dilatometer was prepared in the following manner. The sample and stirrer were loaded into a test tube and the open end was sealed to constant-bore tubing as previously described. The end of the dilatometer thus formed was connected by means of a T-tube to an ampul of mercury and to a vacuum pump. After evacuating the system, mercury was introduced by lifting the ampul of mercury until the desired amount of mercury was introduced into the dilatometer. The T-tube was removed and the dilatometer placed into the water bath at a temperature within the melting point range of the mixture to temper the sample overnight. The temperature of the water bath was then slowly dropped to room temperature. The dilatometer was then placed into a high pressure bomb and subjected to a pressure of 3,000 lbs./in.^{2}. This step was necessary in order to eliminate void space which otherwise obscures the data. Finally the dilatometer was placed into the water bath. To investigate transition rates the temperature of the water bath was changed sharply and the mercury height read with a micrometer microscope at intervals of 1 to 5 minutes. From an equilibrium melting curve the readings were converted to fractions of the sample melted, f. The rates as a function of the fraction melted were obtained from the slopes of the fraction melted *vs.* time plots of this data. In another method the temperature of the water bath was varied by increments. Fraction melted-time readings were recorded at each temperature setting for short intervals in order to limit the change in the fraction of the sample melted. By alternately applying a freezing and melting potential, the variation of the fraction melted was held to a minimum. In this way the fraction of the sample melted was approximately constant, and the slopes of the various fraction melted-time plots at each temperature setting yielded the rate at the particular temperature of the water bath This method allowed the simultaneous study of melting and freezing as a function of the temperature.

The first method, which maintained a constant water bath temperature and a varying fraction melted, was preferred as the water bath temperature was rigidly controlled and the fraction melted can be measured very accurately. The second method, on the other hand, requires a constant fraction melted and a varying temperature; yet the fraction melted must be allowed to vary in order to obtain a rate; in addition, heat transfer and mercury expansion can affect the results if the fraction melted-time readings are taken for too short a time. This method, however, enjoys the advantage of requiring much less time to complete a rate study.

Sources of Materials.—Three lots of methyl stearate were used in this study. Eastman Kodak reagent grade methyl stearate was recrystallized several times from methanol. This methyl stearate is obtained by fractional distillation of natural products, but a gas chromatogram indicated that it was contaminated by methyl palmitate. The melting point of this sample was 38.33° and it was estimated from a dilatometric melting curve that it contained 0.065 mole fraction of impurity. Methyl stearate was also obtained by the reduction of methyl oleate. A gas chromatogram showed that the sample obtained in this manner was relatively free from methyl palmitate. The melting point of this sample was 38.60° and it was estimated that it contained 0.042 mole fraction of impurity. Recrystallization from methanol three times and then from Skelley C three times increased the melting point to 39.05° and decreased the impurity to 0.004 mole fraction.

RESULTS AND DISCUSSION

Establishment of Mechanism of Crystal Growth.—Dilatometric investigations on the rate of crystal growth as a function of the degree of supercooling were carried out on the three relatively pure lots of methyl stearate. Essentially the method employed was based on continual determination of the fraction melted of a partly solidified and slowly freezing sample of the lipid. The measurements are reported in terms of the fraction of the sample melted obtained by measuring the heights of the mercury column as observed in the dilatometer, the total height change for complete freezing from the liquid state being of the order of 40 cm. The sample was brought to near equilibrium at such temperature 38.75° that approximately 75% was in the liquid state. The temperature was then dropped sharply by a few tenths of a degree and the capillary height of the dilatometer was observed from time to time. A plot of the fraction melted *vs.* time was prepared and the rates at various degrees of crystallization were recorded.

In Figs. 1 and 2 these rates of crystal growth have been plotted as several functions of f, the melting dilation expressed as fractions of the sample melted. It is evident that according to preceding discussions, the rates appear to obey Eq. 8 or 9, based on the two- or three-dimensional nucleation as the rate determining step.

Since the above run was determined on a system largely melted, a run at a lower degree of melting was carried out to differentiate between these two

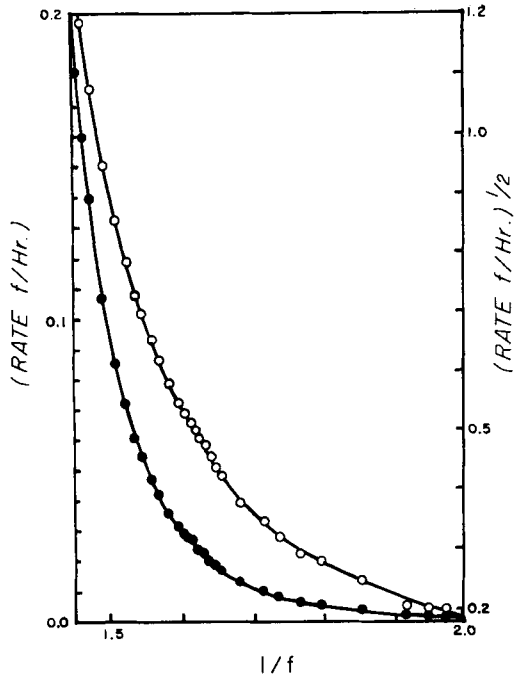

Fig. 1.—The rate data of the same experiment plotted according to Eqs. 6 and 7. ●, rate *vs.* $1/f$. ○, $(\text{rate})^{1/2}$ *vs.* $1/f$.

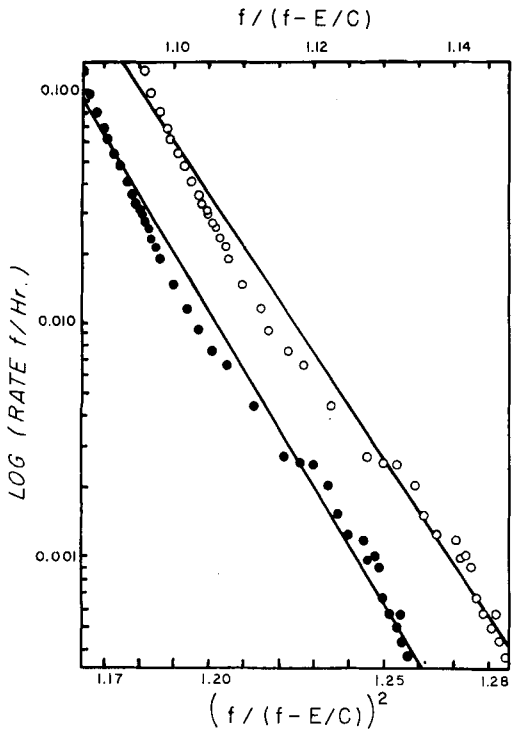

Fig. 2.—The rate data of the same experiment as Fig. 1 plotted according to Eqs. 8 and 9. ●, log(rate) *vs.* $[f/(f - E/C)]$. ○, log(rate) *vs.* $[f/(f - E/C)]^2$.

mechanisms. The results are shown by Fig. 3 and indicate that the crystal growth is governed largely by the intrinsic rate of formation of crystal planes.

To substantiate this the rate of phase transformation under fixed conditions except for temperature was determined as a function of temperature. In this method the equilibrium temperature of the sample at its observed height was first obtained from its dilatometric melting curve (5). A freezing potential was then applied to the system by sharply dropping the water bath temperature, the fraction melted-time readings being taken, however, only for a sufficient time to establish the rate. The sample then was remelted until the fraction of the sample melted had increased to its initial point and then the temperature of the water bath was again sharply dropped to another temperature. In this manner the rates of crystallization were obtained directly as a function of the supercooling, $T_a - T_b$. Figure 4 shows that a plot thus determined of the log (rate) *vs.* $1/\Delta T$ is a straight line verifying the previous results that the rate law which governs this system is that the rate $= K_2 \exp(-A_2/\Delta T)$. This strongly suggests that the rate determining process for crystal growth in this system was nucleation of crystal planes, the extension of the nucleus to the edges being relatively rapid. Figures 1 to 4 were determined using the sample containing 0.004 mole fraction of impurity. All samples, however, displayed the same behavior.

Melting Characteristics of Methyl Stearate Crystals Formed under a Moderate and Extremely Small Temperature Gradient.—The melting behavior of methyl stearate was found to be a rather sensitive function of its immediate history in a

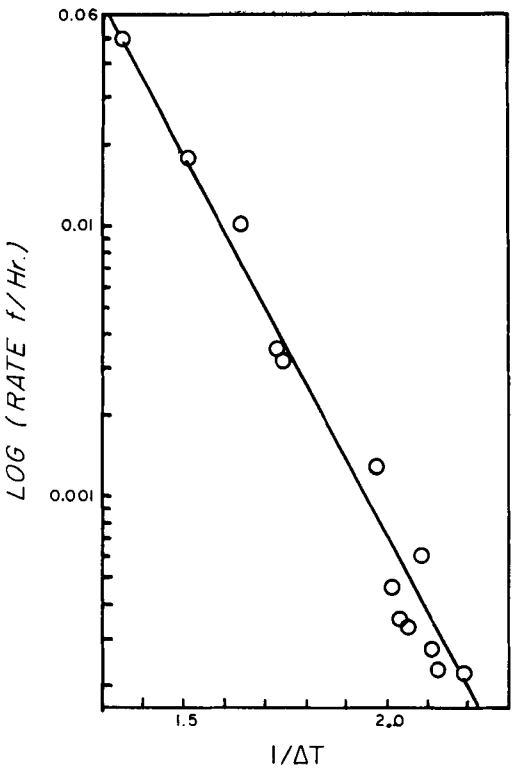

Fig. 4.—The log(rate) as a function of $1/\Delta T$.

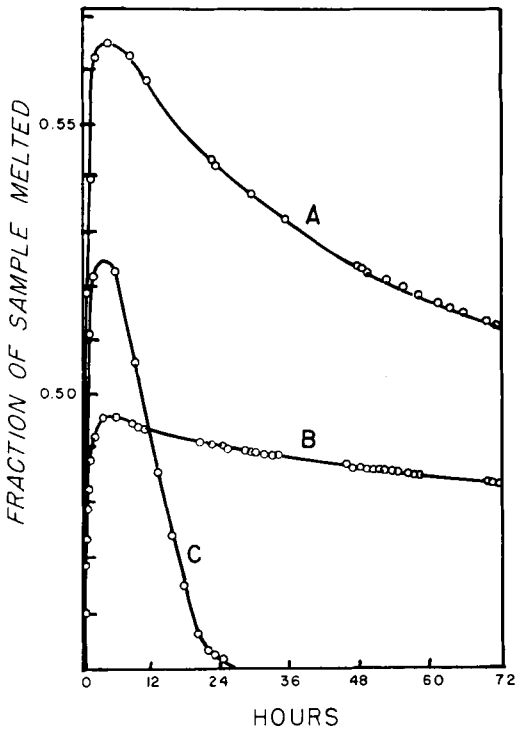

Fig. 5.—The effect of past history upon "after-melting" contraction. Curve A, initial run where $T°$ was changed from 37.08 to 37.50°. Curve B, rerun after freezing the sample very slowly with the aid of stirring where $T°$ was changed from 37.08 to 37.50°. Curve C, third run after freezing the sample very rapidly without any stirring where $T°$ was changed from 36.76 to 37.29°.

manner not associated with polymorphic transitions. When the system was exposed to a melting potential, the sample was observed to contract after initially expanding for a period of time. Although the rate of contraction decreased with time, the recovery process persisted as long as 7 days without stopping. This peculiar behavior will be referred to as "after-melting" contraction, and is illustrated by curve A of Fig. 5 which shows the fraction of the sample melted readings recorded after applying a melting potential to the system.

This phenomenon can be possibly rationalized as being due to imperfections in the crystal structure induced by excessive growth rates. The crystal eliminates these stresses by overmelting and then refreezing. Impurity can exert the same effect if its distribution is not thermodynamically stable within the solid sample as it will redistribute itself during melting.

If either of the above is responsible for "after-melting" contraction, then, crystallizing the sample under equilibrium conditions should tend to diminish its effect. The sample was melted and then solidified using a small temperature potential and with the aid of stirring. The results of the rerun are shown by curve B in Fig. 5. Comparison with A shows that "after-melting" contraction was significantly eliminated. To check this further the sample was again melted and solidified using a large temperature potential without the aid of stirring. Curve C in Fig. 5 shows that the effect of these harsh conditions greatly increased "after-melting" contraction and seems to indicate that the above explanations may be true. Although samples of varying purity were used, the effect always appeared. This seems to indicate that "after-melting" contraction may be largely due to the presence of crystal imperfections.

Influence of a Thermal Gradient on the Rate of Melting.—The mechanism of melting was investigated, and it was found that a plot of the melting rate *vs.* the reciprocal fraction melted yielded a straight line. Some of the runs, however, revealed a break in the curve between the rates of 3,000 to 5,000 mg./min. This suggests that the determining factor at high melting rates differs from that which is operative at the lower rates. This is illustrated by Fig. 6.

According to Eqs. 1 and 6, a plot of the rate *vs.* the reciprocal fraction melted will be straight in the event the rate is first order with respect to the temperature potential. In this case, either melting from a rough surface is occurring or heat transfer is the governing factor. For this study the rate of heat transfer from the bath to the sample, dQ/dt, in the presence of stirring can be calculated from

$$\frac{dQ}{dt} = \frac{K_g A \Delta T}{n} \text{ cal./sec.} \qquad \text{(Eq. 10)}$$

where n is the thickness of glass in dilatometer, K_g is the heat conductivity of glass, A is the area of the glass, and ΔT is the temperature potential. The theoretical rate of heat transfer calculated from

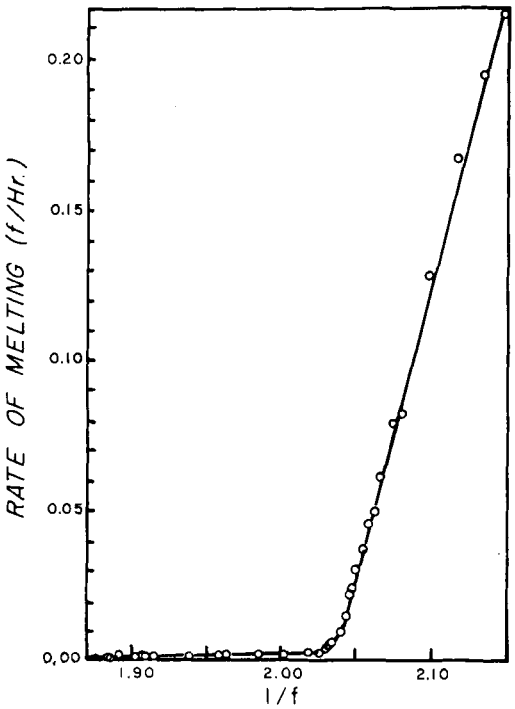

Fig. 6.—The rate of melting as a function of the reciprocal fraction melted.

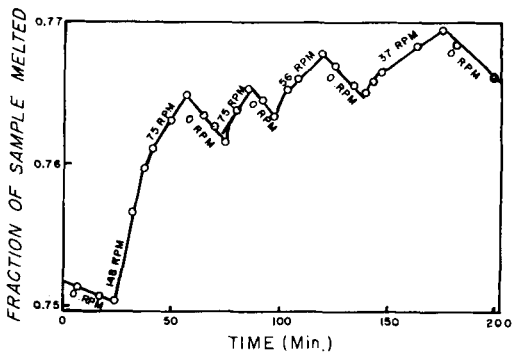

Fig. 7.—The effect of stirring upon the fraction of the sample melted *vs.* time curve.

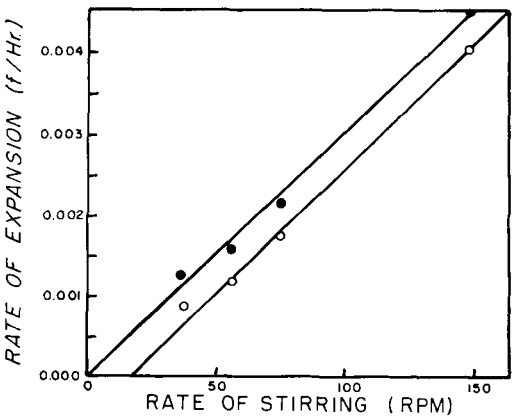

Fig. 8.—The rate of expansion as a function of the rate of stirring. O, the observed rate; ●, the net rate (the observed rates with stirring less the observed rate of the unstirred sample).

the above is approximately 100 cal./°C./min. If the governing rate is the rate of heat transfer, then Eq. 10 predicts that the value of K_1 in Eq. 1 will be equal to $(K_0A)/n$ or 100 cal./°C./min. At the same time, Eq. 6 predicts that the value of K_1 can be calculated from the slope of the rate *vs.* reciprocal fraction melted curve as the slope is equal to $(K_1N_2)/A_0$. The values of K_1 which were calculated from the beginning slopes of a few runs seem to indicate that heat transfer is the governing factor at fast rates of melting as the values of K_1 were approximately 100 cal./min.

The slope of the straight line after the break varied greatly, indicating that the slope may depend upon experimental conditions. A possible cause may be the effect of "after-melting" contraction, which varies in degree from one run to another depending on the past history. It may also be possible that the rate is not proportional to ΔT in this region, but may be proportional to some other function of ΔT.

Since the first part of the curve was not determined by the rate of melting, only the slower rates can be used to determine the rate law; at low potentials, however, the rates become very sensitive to the effects of heat transfer, "after-melting" contraction, temperature, surface area, and other experimental conditions. Since these variables complicate the rate data, the mechanism of melting was not investigated any further.

Apparent Influence of Stirring on the Crystallization Rate.—An unstirred sample which was solidifying at a slow rate was observed to undergo the reverse process when stirring was initiated and refreeze when stirring was stopped. A system of pulleys which allowed the rate of stirring to be varied over a wide range was utilized to study this peculiar behavior further. A typical plot of the height *vs.* time with a varying rate of stirring is shown by Fig. 7. The slopes of the curve at the various rates of stirring were obtained, and the rates were plotted *vs.* the rate of stirring expressed as revolutions per minute (r.p.m.). The plot of the observed and net rates are shown in Fig. 8, revealing straight line relationships. The exact reason for this behavior has not been established.

Discussion.—Previous studies involved measurements of the linear rate upon one plane of the crystal, maintained a constant surface area, utilized highly purified substances, and relied upon diffusion for all transport processes. This study, however, utilized samples whose purity varied over a wide range and involved dilatometric measurements of the combined growth of all planes of a variable number of crystals. Most important, however, the conditions of this study more closely resemble those of industry (free growth with stirring) which permit the results to be more readily applied to industrial systems.

The study of the rates of phase transitions can yield useful information which can be utilized to advantage in the production and storage processes

by the pharmaceutical industry. Many of the substances used in the formulation of medicinals are polymorphic and frequently exhibit melting points, solubilities, pharmacological activities, and other important properties which differ markedly from each other; as a result, the conversion of one form to another upon aging presents an important problem, as it can often curtail the shelf life of products.

Chemical Effect of High Level Gamma Irradiation on Blood Glucose *in Vitro*

By LINDA KAY RAMES† and HAROLD S. BAILEY

Furan-2,5-dicarboxylic acid is one of the decomposition products of blood glucose subjected to high energy gamma irradiation.

THE EFFECT of ionizing radiation on materials of biological interest is important to our understanding of radiation hygiene. Pioneering studies have been made on the changes produced in amino acids, proteins, carbohydrates, and other biochemicals upon bombardment with nuclear radiation.

Changes in aqueous solutions of biochemicals upon irradiation are complex. Due to free radical formation, a large quantity of hydrogen is formed upon irradiation of water containing traces of halides. Also, dissolved oxygen in irradiated water will react with (H) radicals present to form the free radical (HO_2). Therefore, oxidizable or reducible solutes present in an irradiated aqueous medium may be readily oxidized or reduced.

Because of its importance to living organisms, we have been interested in the effect of ionizing radiation on blood glucose.

It is possible that the effect of irradiation of blood glucose and other blood constituents may provide an insight into the mechanism of radiation sickness. Since blood acts as a transportation agent for the body and as a solvent for so many complex compounds, it could be the source or carrier of toxic decomposition products resulting from irradiation.

Radiation effects on blood glucose have been noted both *in vitro* and *in vivo* (1–4). Irradiation of both dogs and rats has resulted in the development of hypoglycemia.

One could expect that the effects of ionizing radiation on blood might produce several by-products from blood glucose since blood would yield many other ions and radicals besides those of water upon irradiation. These other substances may alter the process of decomposition or react quickly with the products.

Previous research by us indicated that furan-2,5-dicarboxylic acid might be one of the irradiation decomposition products of glucose solutions. The objective of this study, therefore, was to show whether furan-2,5-dicarboxylic acid is produced upon irradiation of blood.

EXPERIMENTAL

Irradiation of Blood Plasma.—Rabbit blood plasma was chosen as the medium in which the effects of gamma radiation on blood glucose would be studied. Heparinized blood was centrifuged, the plasma decanted, and kept under refrigeration. Some hemolysis occurred.

A total of 9.01 mg. of radioactive glucose randomly-labeled with carbon^{14} was added to 8 ml. of the blood plasma contained in a small beaker. The specific activity of the radioglucose was 1.0 mc. per mmole, and a total activity of 50 μc. was present. After solution was evident, the blood plasma was poured into a half-ounce prescription bottle, and the beaker was rinsed twice with approximately 4-ml. portions of blood plasma, the rinsing combined with the original solution in the bottle.

For irradiation, the bottle containing the labeled blood plasma was fastened to a pegboard constructed in such a manner that the cobalt^{60} irradiation source could be positioned at a known distance by remote control. The source was placed exactly 3 inches from the bottle.

The Co^{60} source had a gamma ray activity of 103.6 curies. At a distance of 3 inches the blood plasma received an approximate dose of 23,760 roentgens per hour or a total of approximately 1,200,000 roentgens in the 50.5 hours of irradiation.

Radiochemical Analysis by the Carrier Technique.—A 100-mg. portion of synthesized furan-2,5-dicarboxylic acid was added to the irradiated plasma. The carrier furan-2,5-dicarboxylic acid was then solated from the irradiated system by the following process.

The irradiated blood plasma was heated until a brownish-gray, dry mass was produced and, after cooling, 100 ml. of 50% sulfuric acid was added to the residue. After heating at 180° for 1 hour, the resulting mixture was cooled and diluted with distilled water, filtered, and the carbonaceous material on the filter washed with two portions of a 1:1 ethanol-water solution.

The filtrate was heated to remove some of the ethanol in which the furan-2,5-dicarboxylic acid is very soluble. When the volume was reduced to 100 ml., heating was stopped and the solution cooled. The acid filtrate was then successively extracted in a continuous liquid-liquid extractor with 75-ml. portions of ether. A total of 525 ml. was used for the extraction. After evaporation of the ether extract, the residue was dissolved in 50 ml. of hot alcohol, filtered, and evaporated down to dryness in a tared counting planchet.

A radioassay of the residue in the planchet was performed using a windowless gas counter. The weight of the residue assayed was 58.7 mg. and the activity was 89,456 c.p.m., corresponding to a specific activity of 1,524 c.p.m. per mg.

The planchet was then placed in a beaker and the residue dissolved in hot alcohol, activated charcoal was added and the material boiled, filtered hot, evaporated, and radioassayed in the same manner as the first sample.

The white crystalline residue weighed 11 mg. with an activity of 14,424 c.p.m., corresponding to a specific activity of 1,311 c.p.m. per mg.

The residue was purified a third time with a final sample weight of 10.7 mg. with an activity of 14,775 c.p.m. corresponding to a specific activity of 1,381 c.p.m. per mg.

A distilled water solution of the final residue showed ultraviolet absorption characteristics similar to that of irradiated glucose solutions and synthesized furan-2,5-dicarboxylic acid.

DISCUSSION

Though furan-2,5-dicarboxylic acid was isolated as a metabolic product by Flashentrager, *et al.* (5), as early as 1937, its physiological action and biochemical transformation have not been extensively studied.

Research (6, 7) has indicated that the formation of furan-2,5-dicarboxylic acid in a biological system is dependent on the presence of glucuronic acid or galacturonic acid rather than that of glucose. This indicates that the first step in the metabolic formation of furan-2,5-dicarboxylic acid from glucose would require oxidation to glucuronic acid or rearrangement and oxidation to galacturonic acid.

The formation of radicals from the ionization of water provides a medium in which these oxidative processes are probable.

The formation of radicals during the irradiation of blood would be enhanced by the presence of halide ions. Of course, the complexity of blood would lead to the formation of ions and other radicals besides (H) and (OH).

Evidence indicates that the second step in the formation of furan-2,5-dicarboxylic acid would be formation of ketohexose by further oxidation or rearrangement of glucuronic acid (7).

Ring closure of the ketohexose would yield a heterocyclic ring containing oxygen with substituents on carbons 2 and 5. Dehydration of this structure by removal of two hydrogen and two hydroxyl groups would yield the furan ring. Evidence has already been produced proving that oxidation of the substituents on carbons 2 and 5 of the furan ring occurs readily (7).

Under the conditions of our experiment it is apparent that furan-2,5-dicarboxylic acid is a decomposition product of blood glucose upon irradiation of blood plasma *in vitro*.

The presence of radioactivity in the sample of furan-2,5-dicarboxylic acid indicates beyond a doubt that this product resulted from a transformation of the radioglucose added to the blood plasma.

The difference in activity of the purified and unpurified samples was probably due to large quantities of degradative fragments of radioglucose and possibly other organic substances formed by the action of the concentrated sulfuric acid. Since other radioactive compounds can be formed, it is essential that the furan-2,5-dicarboxylic acid isolated be purified to a constant specific activity in order to state that the activity is due mainly to radioactive furan-2,5-dicarboxylic acid. It can be seen from a comparison of the specific activities of the second and third isolations (1,311 c.p.m./mg. *vs.* 1,381 c.p.m./mg.) that purification of the furan-2,5-dicarboxylic acid was adequate for our conclusions. In addition, the ultraviolet absorption characteristics of the isolated product agreed with those of synthesized furan-2,5-dicarboxylic acid.

CONCLUSIONS

1. A study of a chemical effect of high level gamma irradiation on blood glucose *in vitro* using the radioactive tracer technique has been made.
2. Furan-2,5-dicarboxylic acid was shown to be one of the decomposition products formed from high level gamma irradiation of blood glucose *in vitro*.
3. A further study of the effect of irradiation of blood on blood glucose with radioactive glucose would be feasible to prove the identity of other possible decomposition products.

Effects of the Potassium and Magnesium Salts of Aspartic Acid on Metabolic Exhaustion

By H. ROSEN, A. BLUMENTHAL, and H. P. K. AGERSBORG

Two groups of 40 rats were placed in a swim test situation designed to produce metabolic exhaustion. The provision of potassium and magnesium aspartates to one group at a dose of 1 Gm./Kg. significantly delayed the onset of metabolic exhaustion as evaluated by swimming time. It is considered that this alteration in swim time occurred as a result of the material's affecting those animals which would ordinarily have swum for less than 196 minutes rather than altering the times of the group as a whole.

THE SCIENTIFIC literature is replete with reports on various rat swim test situations. Included are the effects of age and sex differances (1), fatigue, practice and drug effects (2), the shortening of swim time by the application of weights (3, 4), and the ability that diet has to alter performance (5, 6).

Some of the most impressive data relating to swim tests have been reported by Richter (7). In these experiments it was demonstrated that a direct relationship exists between duration of swim time and the temperature of the water in which the animals are swimming. Additionally, a presentation of a possible causal relationship between those animals swimming "indefinitely" and for "very short" periods was made.

None of the publications reviewed made a point of evaluating metabolic exhaustion. It is assumed that an animal, faced with a swim or drown situation, will perform to his utmost ability. Although this assumption must be true, there are no data to indicate whether this level of ability is dictated by emotional factors (7), availability of metabolic substrate, or accumulation of toxic end products.

EXPERIMENTAL

To determine these points and to determine the size and type of container, temperature, optimum number of animals per volume of container and, most important, to establish sufficient knowledge leading to a recognizable and reproducible end point, numerous orientation studies were made prior to final experimentation.

The "swimming pool" finally adopted was a rectangular, custom-made aquarium 36 in. long, 24 in. wide, and 24 in. deep; the tank was equipped with a thermoregulator and heater to maintain constant temperature and a water circulator to facilitate maintenance of constant temperature without either aiding or antagonizing the normal swimming efforts of the rats. The water depth in all reported tests was 20 inches.

In preliminary tests, male rats ranging in weight from 150–300 Gm. were used. It was concluded that any male rats within this range would be satisfactory. However, for the reported experiments, this range was narrowed to 180 to 245 Gm.

When rats are placed in water they first swim in a horizontal position on the surface; then, looking for a means of escape, they often go as deep as the bottom of the tank; next they assume a vertical position at the surface and use all four legs vigorously, with occasional second-long rest periods. In short order, they must work continuously to keep their heads above water. At this stage, while the hind legs pump steadily, the animals fold their forelegs in front of the chest in an apparent effort to use them as wings or fins to avoid the sinking process. As work continues, they frequently sink and must struggle to reach the surface. Eventually loss of control of movements is observed and the animals sink to a depth of 10 to 20 in. with an inability to fight to the surface; some will walk the perimeter of of the tank bottom, some will remain almost motionless at a depth of 10 or more inches, while others flail aimlessly without rising. These are variations of the end point. Rats removed from the water at this time usually recover. A rat in this condition is finished swimming as far as physical ability is concerned; he is fatigued and apparently near exhaustion. This is the first reproducible and constant symptom which is always observed; hence it was selected as the end point.

If rats are allowed to remain in the water when the end point is reached, a few recover sufficiently in about 30 seconds to make a few more trips to the surface. Those that show no recovery remain under water and drown. These latter observations are not routine; the rats were removed from the tank at the end point, but early in the series some were allowed to remain in order to provide terminal observations.

It was found that a census of 8 to 10 rats was optimum for the tank used; thus, when the number of rats was reduced below eight, additional rats were added to maintain that number.

Preliminary observations concerning onset of metabolic exhaustion were made by exposing the animals to various ambient water temperatures, observing the swim time, resting for either 15 or 30 minutes, and exposing the same animals to the same conditions of temperature and swim. At the lower temperatures, 20°, the animals were capable of approximately 20 minutes of swim; this could be reproduced for several exposures. As the water temperature was increased, it was found that swim time increased in accordance with Richter, but that duration of time of subsequent exposures was appreciably reduced. This was taken to mean that metabolic involvement in the initial swim was such that complete recovery had not taken place by the time the second effort was required.

Since normal temperature regulating mechanisms are considered to be in balance at approximately 85° F. (29° C. environmental), and, since metabolic activity would be neither inhibited nor enhanced by

Accepted for publication October 18, 1961.

exposure to such an ambient temperature, the reported tests were done at a water temperature of 28.0 ± 0.25° C. Control animals, after swimming to exhaustion and given 15-minutes rest, were usually unable to swim at all when exposed for the second time to the water temperature. It was concluded, therefore, that a situation producing metabolic exhaustion had been produced.

Laborit (8, 9) has demonstrated that several agents have the ability to prolong the duration of rat swim time. The most active substance reported was a combination of the potassium and magnesium salts of aspartic acid. Since control rats, in the Laborit technique, were able to swim for appreciably shorter times than those in this study, and, since second exposure resulted in an observed time approximating that of the first, there was felt to be a need for additional data more directly related to metabolic exhaustion as described.

For the actual test, 10 male rats apparently healthy and ranging in weight between 180 and 245 Gm. were selected on the afternoon preceding the test day. They were arranged into two groups of five each, weighed, and small slits made in the ears for purposes of identification. One group was treated twice by stomach tube with 500 mg./20 ml./Kg. each of potassium aspartate and magnesium aspartate (1000 mg./20 ml./Kg. total) in one solution. The first dose was given 17 hours before the test and the second 45 to 60 minutes before the test. The control rats were handled in a like manner using water only; both groups were allowed food and water *ad libitum* until actually placed in the tank for swimming.

At zero time, both groups of rats were placed in the pool under the conditions previously described and allowed to swim until each, in turn, reached the end point of fatigue. As each rat reached his end point he was removed from the water, identified, and his total elapsed swim time recorded.

It should be remembered that only swim time is assayable by this test; no attempt at measurement of work output is possible.

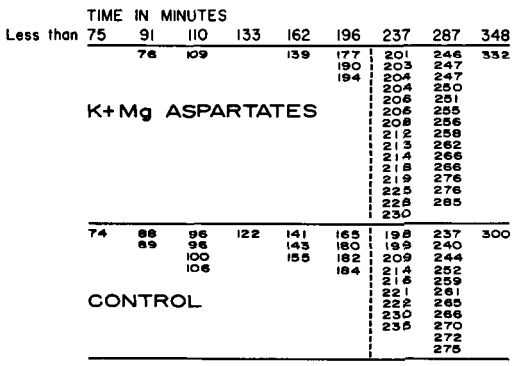

Fig. 1.—Average of the control times and aspartate animals times.

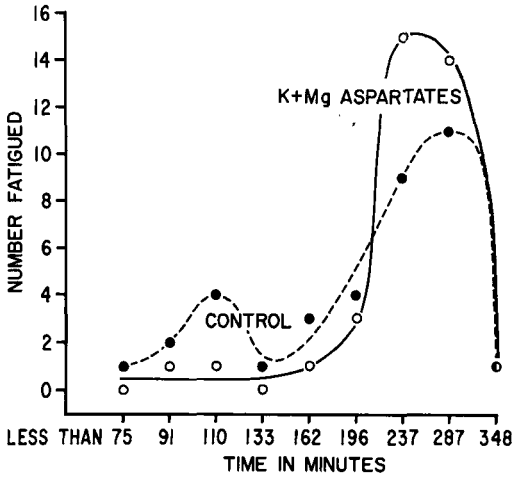

Fig. 2.—Plots of data in Fig. 1.

RESULTS AND DISCUSSION

The accompanying figures present the results obtained from eight cumulative experiments; they offer similar data, in a different way. Thirty-six control and 36 aspartate treated rats are included; the remaining eight will be discussed later. The rats are divided into log-spaced swim time groups.

An average of the control times and aspartate animals' times in Fig. 1 indicates that the control rats swam 194.6 ± S.E. 7.96 min. and that the drug-treated rats swam 223.6 ± S.E. 8.05 min., an increase of 15% in swimming time.

If the data presented in Fig. 1 are plotted graphically (Fig. 2), the distribution of the controls is seen to be bimodal. In both groups there appears to be a line of demarcation at 196 minutes; 41.7% of the controls swim less and 58.3% swim more than 196 minutes. On the other hand, the aspartate-treated rats shift to a unimodal frequency; 16.7% swim less and 83.3% swim more than 196 minutes. Application of the chi square test indicated that this shift was significant at a level less than 5%. It is felt that this is a strong indication that the swimming times of rats which have longer endurance are not altered by the aspartates while the swimming time of animals of lesser endurance are prolonged.

The eight rats which are not represented in the figures but which are included in the calculations were discarded for reasons as follows: one aspartate rat was obviously incapable of coordinated swimming; he was removed from the water in about 20 minutes and expired shortly thereafter. Four control rats and three aspartate rats were interminable swimmers; they were swimming well after 6 hours and were discarded. As a check on our interpretation, one of the control rats and one aspartate rat were timed further; they were still swimming after 8 hours and were removed from the tank.

Determination of Nikethamide with Cyanogen Bromide and Barbituric Acid

By O. PELLETIER and J. A. CAMPBELL

Two procedures are presented for the determination of nikethamide which involve its reaction with cyanogen bromide and barbituric acid. The first method is highly specific while the second is more rapid but slightly less specific. These methods have the advantage of being simpler, more rapid, and more specific than the present N.F. procedure.

WHILE testing various pyridine derivatives in the cyanogen bromide-barbituric acid method recently developed in this laboratory for the determination of niacinamide (1), it became evident that under certain conditions the diethylamide of nicotinic acid (nikethamide) also produced a pink color with these reagents which might be useful for its estimation.

The present N.F. method (2) involves a titration of the diethylamine after digestion and distillation without differentiating other nitrogen-containing compounds. Since this procedure was not specific it was decided to investigate the color reaction. This paper describes two possible methods for determining nikethamide and the studies that were made in developing these methods.

METHOD

Reagents.—*Cyanogen Bromide,* 10%.—Prepare and use under hood. Do not let cyanogen bromide or solution come in contact with skin. Dissolve a weighed amount of cyanogen bromide in warm water at about 40°. Allow to come to room temperature and dilute to 10% solution. Store in refrigerator and bring to room temperature before using.

Potassium Phosphate, Monobasic, 3%.—Dissolve 15 Gm. KH_2PO_4 in water to make 500 ml.

Potassium Phosphate, Monobasic, 0.3%.—Dilute 100 ml. of 3% KH_2PO_4 to 1000 ml. with water.

Barbituric Acid Buffered Solution, Saturated (2%).—Prepare volume required for each batch of assays by adding 100 ml. of 3% KH_2PO_4 to each 2 Gm. of reagent grade barbituric acid and shaking vigorously at intervals for about 1 hour. Filter before using.

Assay.—*Nikethamide Standard Solution.*—Dilute an aliquot of nikethamide N.F. 25% standard[1] with 0.3% KH_2PO_4 to 3.0 mcg. per ml.

Assay Solution.—Dilute to 3 mcg. per ml. with 0.3% KH_2PO_4.

Reaction.—Run in duplicate. To 1.0 ml. of standard or assay solution in colorimeter tube, add 0.5 ml. cyanogen bromide, mix, stopper, and let stand 10 minutes. Add 10 ml. barbituric acid, mix, and let stand 5 minutes. Place tubes in water bath at 50° for 25 minutes and then transfer to another bath at 20° for 5 minutes. Within the next 15 minutes set spectrophotometer at 0 absorbance at 560 mμ with a standard blank in which cyanogen bromide is replaced by water and measure absorbance of reaction product.

Calculations.—Mcg. per aliquot = $Au \times 3/As$, where Au = absorbance of unknown and As = absorbance of standard.

RAPID METHOD

Dilute standard with 0.3% KH_2PO_4 to 1.0, 1.5, 2.0, 2.5, and 3.0 mcg. per ml., respectively, and dilute sample to about 2 mcg. per ml. To 1.0-ml. standard solution or assay solution (in duplicate) in colorimeter tube, add 0.5 ml. cyanogen bromide, mix, stopper, and let stand 10 minutes. Add 10 ml. of barbituric acid, mix by swirling, and read maximum absorbance which remains stable from 10 to 15 minutes after addition of barbituric acid. Set spectrophotometer at 0 absorbance at 505 mμ with a standard blank in which cyanogen bromide is replaced by water. Plot absorbance of standard *vs.* concenration and draw line of best fit but do not consider the origin as a point in drawing the line. Read from curve the number of mcg. per ml. corresponding to absorbance of sample.

EXPERIMENTAL RESULTS AND DISCUSSION

Factors Affecting the Reaction.—Modifications of the niacinamide method previously presented (1) were thoroughly investigated. The optimum time of cyanogen bromide reaction was 10 (±1) minutes. When the reaction was conducted at room temperature, maximum absorbance was obtained at 505 mμ 10 minutes after addition of barbituric acid. There was also a minor peak at 560 mμ which reached its maximum in about 2.5 hours. Development of the latter peak could be accelerated by incubating 25 minutes at 50° after allowing the barbituric acid reaction to proceed 5 minutes at room temperature. The use of other temperatures offered no advantages for this determination.

Concentration of Nikethamide.—At 560 mμ there was a linear relation between absorbance and concentrations up to 10.0 mcg. which passed through

TABLE I.—PERCENTAGE OF ABSORBANCE OF NIACIN DERIVATIVES IN COMPARISON TO NIKETHAMIDE (100%)

Substance	Regular Method,[a] %	Rapid Method,[b] %
Nikethamide	100	100
Niacin	none	0.5
Niacinamide	none	7.4
Pyridine-3-sulfonic acid	1.2	1.9
Nicotinic acid dimethylamide	none	9.1
Nicotinic acid methylamide	none	3.6
Nicotinic acid ethylamide	1.2	1.4
Nicotinic acid methyl ester	none	2.5
Nicotinic acid ethyl ester	none	2.5

[a] Substance tested at 3 mcg. [b] Substance tested at 2 mcg.

Received July 6, 1961, from the Food and Drug Laboratories, Department of National Health and Welfare, Ottawa, Canada.

Accepted for publication September 13, 1961.

[1] Proposed standard, containing 25% nikethamide according to the N.F. requirements (2).

the origin. At 505 mμ, concentrations from 1.0 to 3.5 mcg. gave a straight line which did not pass through the origin. In this latter case a standard curve was used to calculate the results. The mean recoveries at different levels were 100.4 ± 2.7% for 7 determinations with the first method and 100.1 ± 2.5% for 6 determinations with the second method.

Reaction of Related Compounds.—To test the specificity of the methods, compounds most likely to react similarly to nikethamide were assayed at the 3-mcg. level for the regular method and at 2 mcg. for the rapid method. Results are reported in Table I in terms of percentage of absorbance of related compound in comparison to nikethamide. For the regular method, the highest percentage was 1.2% for pyridine-3-sulfonic acid and nicotinic acid ethylamide; other substances tested gave no absorbance. For the rapid method, the highest percentages were 9.1% for nicotinic acid dimethylamide and 7.4% for niacinamide; others were below 4%. The fact that nikethamide is practically the only compound giving a colored product seems to be due (*a*) to the different rate of reaction of various pyridine derivatives with cyanogen bromide and (*b*) to the difference in stability of the colored compound formed upon reaction of the pyridinium derivative with barbituric acid unsubstituted in the 5 position.

It may be concluded that the regular method is more specific than the rapid method although the latter would be quite satisfactory for most routine checking purposes.

Citrinin from *Penicillium steckii* Zaleski

By A. JABBAR and A. RAHIM

The antibiotic substance isolated from cultured *Penicillium steckii* Zaleski was identified as citrinin.

PENICILLIUM STECKII Zaleski[1] was shown to have antibiotic activity against *Staph. aureus* and *Ps. pyocyanes* (1). It was later found that the same strain formed a penicillin-like antibiotic (2). In this paper the isolation, characterization, and crystallization of the antibiotic is described and it is confirmed that the antibiotic is citrinin.

The organism *Penicillium steckii* Zaleski was cultivated in Czapek-Dox solution containing 0.25% yeast extract; the active principle from the potent greenish culture broth was isolated by chloroform, and purified by adsorption chromatography on acid-washed alumina. The antibiotic was crystallized in prismatic needles and in plates from chloroform and petroleum ether mixture. The crystalline sample, melting at 165–169° (with decompn.), is readily soluble in chloroform and acetone. LD_{50} is 100 mg. The determination of its functional groups and the studies of its physicochemical properties show that the antibiotic is citrinin.

EXPERIMENTAL

Culture Media.—Czapek-Dox solution; sucrose, 20 Gm.; sodium nitrate 2.0 Gm.; potassium dihydrogen phosphate, 1 Gm.; potassium chloride, 0.5 Gm.; magnesium sulfate, heptahydrate, 0.5 Gm.; ferrous sulfate, heptahydrate, 0.01 Gm.; water to 1 L. The only source of nitrogen in the medium is sodium nitrate which corresponds to 0.3296 Gm. of nitrogen per L. Czapek-agar medium was the best for sporulation.

Production and Isolation of the Antibiotic on Czapek-Dox Solution.—For the production of the antibiotic, the surface culture was found to be better than the shake culture. Of the different carbon sources such as glucose, sucrose, lactose, and galactose, sucrose was the best. Grain extract, beef extract, and yeast extract were found to have a stimulatory effect both on the growth of the organism and on the production of the antibiotic.

Czapek-Dox solution containing 0.25% yeast extract was distributed in 50-ml. amounts in 250-ml. conical flasks which were plugged with cotton and sterilized at 15 lb. pressure for 20 minutes. The contents of the flask were then inoculated with spore-suspension in water, prepared from Czapek-agar slopes of *Penicillium steckii*, one flask being sown from each slope. The flasks were incubated at room temperature for 4 days. The culture fluids were separated from the mycelia by decantation. The filtrates were then extracted with an equal volume of chloroform. For the isolation of the antibiotic present in the mycelia, the thoroughly washed mycelia were crushed with sand and extracted with alcohol. The extracts were evaporated to dryness at 50° under reduced pressure, taken into chloroform, and chromatographed on acid-washed alumina to remove the coloring matter. The antibiotic was crystallized from chloroform and petroleum ether mixture. Repeated crystallization gave lemon-yellow prismatic needles, sometimes lemon-yellow plates, melting at 165–169° with decomposition.

The purified product is readily soluble in chloroform and acetone, very sparingly soluble in water. It is soluble in alcohol, aqueous alkali, less soluble in ether, still less in petroleum ether.

[1] *Penicillium steckii* Zaleski was isolated from local soils and has been identified by Dr. A. H. S. Brown and deposited in Herb IMI as 61422.

The antibiotic was found to be active *in vitro* against the following test organisms

Organisms	Activity[a]
Bacillus subtilis (CN663)	4+
Proteus vulgaris (CN2770)	+
Streptococcus aureus (CN2)	+
Staphylococcus aureus (CN4108)	2+
Pseudomonas aeruginosa (NCIB8295)	+
E. coli (CN311)	+
Vibrio cholerae	
Ogwa strain	3+
Inaba strain	2+
Paratyphoid B	+

[a] The plus signs indicate the degree of inhibition effect of the antibiotic.

The antibiotic substance in the broth is stable for a long time both at room temperature and under refrigeration. It is stable at acid pH and less stable at alkaline pH. It is quite stable up to 80° and gets partially inactivated at 100°. Copper ions have no effect on it. It is toxic; 100 mg. substance per Kg. body weight of rat, kills the rat when given intraperitoneally.

Structure of the Antibiotic Molecule.—The molecular weight is 256 (Rast method). It contains carbon, hydrogen, and oxygen, but nitrogen, halogens, and phosphorus are absent. The product decolorized acidified potassium permanganate solution and bromine in carbon tetrachloride. It gave a brown color with aqueous ferric chloride and deep blue color (first brown) with sodium nitrite in concentrated sulfuric acid, indicating the presence of phenolic group in the molecule. Carboxyl group was detected by the evolution of carbon dioxide when a few crystals of the substance were added to a solution of sodium bicarbonate.

The physicochemical and antibacterial properties of the compound compared favorably with those of citrinin described (3–5). Both of them have the same functional groups, i. e., phenolic and carboxyl, both are active against *V. cholera* and Gram-positive organisms, and activities of both are completely destroyed by cysteine (6). It was therefore concluded that the new antibiotic might be identical with citrinin. Paper chromatographic studies with the authentic sample of citrinin as a standard (7) and color test for citrinin as described by Tauber, *et al.* (8), showed that the antibiotic is citrinin. In the chromatographic studies, the antibiotics were located by the bioautographic technique using *B. subtilis* as the test organism. It failed to depress the m.p., 165–169°, of the authentic specimen on admixture with it.

Analogs of Tetrahydrofolic Acid VI

N-[1-(2-Amino-4-hydroxy-6-methyl-5-pyrimidyl)-3-propyl]-*p*-aminobenzoyl-L-glutamic Acid, an Inhibitor of Folic Reductase

Sir:

Fifteen enzymes utilizing folic acid, tetrahydrofolic acid (I), or derivatives of tetrahydrofolic acid are known (1–3). A number of these enzymes are inhibited by aminopterin (4-amino-4-deoxyfolic acid) (4–7), but nearly as many are not (6, 8–10). 5,6,7,8-Tetrahydroaminopterin (II) can inhibit some of the enzymes not inhibited by aminopterin (10, 11). 5,8-Dideaza-5,6,7,8-tetrahydroaminopterin (IV) has been recently synthesized (12) and found to have inhibitory properties similar to tetrahydroaminopterin (12, 19). In addition, 5,8-dideaza-5,6,7,8-tetrahydrofolic acid (III) (13) has been found to bind to folic reductase eight times stronger than the substrate, folic acid (14).

I. R = OH, X = —NH—
II. R = NH_2, X = —NH—
III. R = OH, X = —CH_2—
IV. R = NH_2, X = —CH_2—

The folic cofactor area should be a prime target for utilization of recent developments in nonclassical antimetabolite theory (15–17) since larger differential effects on inhibition of these enzymes might be obtained by the bulk principle of specificity (15), the exo-alkylating irreversible inhibition phenomenon (16), and the bridge principle of specificity (17). In order to use

It is quite stable up to 80° and gets partially inactivated at 100°. Copper ions have no effect on it. It is toxic; 100 mg. substance per Kg. body weight of rat, kills the rat when given intraperitoneally.

Structure of the Antibiotic Molecule.—The molecular weight is 256 (Rast method). It contains carbon, hydrogen, and oxygen, but nitrogen, halogens, and phosphorus are absent. The product decolorized acidified potassium permanganate solution and bromine in carbon tetrachloride. It gave a brown color with aqueous ferric chloride and deep blue color (first brown) with sodium nitrite in concentrated sulfuric acid, indicating the presence of phenolic group in the molecule. Carboxyl group was detected by the evolution of carbon dioxide when a few crystals of the substance were added to a solution of sodium bicarbonate.

The physicochemical and antibacterial properties of the compound compared favorably with those of citrinin described (3–5). Both of them have the same functional groups, i. e., phenolic and carboxyl, both are active against *V. cholera* and Gram-positive organisms, and activities of both are completely destroyed by cysteine (6). It was therefore concluded that the new antibiotic might be identical with citrinin. Paper chromatographic studies with the authentic sample of citrinin as a standard (7) and color test for citrinin as described by Tauber, *et al.* (8), showed that the antibiotic is citrinin. In the chromatographic studies, the antibiotics were located by the bioautographic technique using *B. subtilis* as the test organism. It failed to depress the m.p., 165–169°, of the authentic specimen on admixture with it.

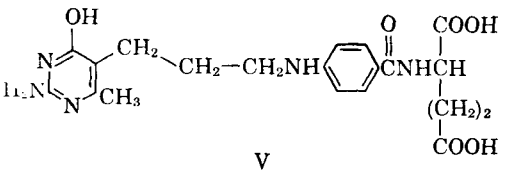
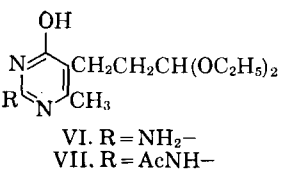
Analogs of Tetrahydrofolic Acid VI

N-[1-(2-Amino-4-hydroxy-6-methyl-5-pyrimidyl)-3-propyl]-*p*-aminobenzoyl-L-glutamic Acid, an Inhibitor of Folic Reductase



Sir:

Fifteen enzymes utilizing folic acid, tetrahydrofolic acid (I), or derivatives of tetrahydrofolic acid are known (1–3). A number of these enzymes are inhibited by aminopterin (4-amino-4-deoxyfolic acid) (4–7), but nearly as many are not (6, 8–10). 5,6,7,8-Tetrahydroaminopterin (II) can inhibit some of the enzymes not inhibited by aminopterin (10, 11). 5,8-Dideaza-5,6,7,8-tetrahydroaminopterin (IV) has been recently synthesized (12) and found to have inhibitory properties similar to tetrahydroaminopterin (12, 19). In addition, 5,8-dideaza-5,6,7,8-tetrahydrofolic acid (III) (13) has been found to bind to folic reductase eight times stronger than the substrate, folic acid (14).



I. R = OH, X = —NH—
II. R = NH_2, X = —NH—
III. R = OH, X = —CH_2—
IV. R = NH_2, X = —CH_2—

The folic cofactor area should be a prime target for utilization of recent developments in nonclassical antimetabolite theory (15–17) since larger differential effects on inhibition of these enzymes might be obtained by the bulk principle of specificity (15), the exo-alkylating irreversible inhibition phenomenon (16), and the bridge principle of specificity (17). In order to use

V

VI. R = NH_2–
VII. R = AcNH–

these three corollaries of nonclassical antimetabolite theory, it would be advisable to have an inhibitor that can be made by a relatively short sequence and the sequence should be one that lends itself to the placing of substituents in a variety of positions. Synthesis of compound V, which satisfies both the inhibitor and synthetic requirements, is the subject of this communication.

Ethyl 2-acetylglutaraldehydate, prepared in 47% yield from Michael addition of ethyl acetoacetate to acrolein (18), was converted in boiling ethanolic ammonium chloride in 63% yield to its diethyl acetal (VIII), b.p. 110–112° (0.2 mm.).

Anal.—Calcd. for $C_{13}H_{24}O_5$: C, 60.1; H, 9.64. Found: C, 60.0; H, 9.70.

Reaction of the keto ester acetal (VIII) with guanidine in boiling absolute ethanol afforded a 76% yield of VI, m.p. 179–180°.

Anal.—Calcd. for $C_{12}H_{21}N_3O_3$: C, 56.6; H, 8.31; N, 16.5. Found: C, 56.5; H, 8.10; N, 16.7.

Treatment of VI with acetic anhydride in pyridine at 85° gave a 57% yield of VII, m.p. 150°.

Anal.—Calcd. for $C_{14}H_{23}N_3O_4$: C, 56.6; H 7.81; N, 14.1. Found: C, 56.8; H, 7.94; N, 14.3.

Hydrolysis of VII by short boiling in water afforded 46% of 2-acetamido-4-hydroxy-6-methyl-5-pyrimidinepropionaldehyde (IX), m.p 159–160°.

Anal.—Calcd. for $C_{10}H_{13}N_3O_3$: C, 53.8; H, 5.87; N, 18.8. Found: C, 53.6; H, 5.95; N, 18.6.

Condensation of the pyrimidinepropionaldehyde (IX) with *p*-aminobenzoyl-L-glutamic acid in boiling alcohol, reduction of the resultant anil (X) with sodium borohydride, and basic hydrolysis of the N-acetyl group gave, after full purification, 15% of V as a white solid,[1] m.p. >250°; $\lambda_{max.}^{pH\ 1}$ 222 (ε 27,800), 270 (ε 19,200), and 303 mμ (ε 11,400); $\lambda_{max.}^{pH\ 8.4}$ 295 mμ (ε 15,100); $\lambda_{max.}^{pH\ 13}$ 284 mμ (ε 20,500).

Anal.—Calcd. for $C_{20}H_{23}N_5O_6$: C, 55.8; H, 5.85; N, 16.3. Found: C, 56.2; H, 5.66; N, 16.5.

Compound V inhibited (14) folic reductase with $K_i = 7 \times 10^{-6}$, about the same as the K_m of folic acid. Since this compound is constructed from ethyl acetoacetate, acrolein, guanidine, and *p*-aminobenzoyl-L-glutamic acid, it is obvious that a variety of derivatives of V can be made by modifying the four components or by transformations of VI; in this way, compounds could be obtained that, by use of nonclassical antimetabolite theory, might selectively inhibit some of the 15 enzymes in the folic acid cofactor area. In addition, considerable information could be obtained about the relative binding and conformational requirements of these substrates to their respective enzymes (19). Such a program is continuing in these laboratories.

Chamazulene from *Artemesia caruthii*

Sir:

In a recent survey of terpene-bearing plants of the Sonoran desert, it was reported (1) that the steam distillate of common sagebrush (*Artemesia caruthii* Wood var. *wrightii* A. Gray) contained a blue oil. Because of the widespread interest (2*a*, 2*b*) in the azulenes of the Compositae family, and in particular the Artemesia species, we undertook to identify the blue component of this oil. It has now been characterized as chamazulene (1,4-dimethyl-7-ethylazulene).

Stems, leaves, and flowers of *A. caruthii* were collected in August 1961 at elevations above 6000 ft. in the Graham Mountains of Arizona. The wet plant material was steam distilled; the blue distillate was taken up in petroleum ether and extracted into 85% phosphoric acid. The concentrated acid solution was diluted with water, regenerating the blue oil, which was then partitioned into petroleum ether again. After being dried over magnesium sulfate, the petroleum ether solution was evaporated to dryness under vacuum. A viscous blue oil remained; from 1.0 Kg. of wet plant material, 0.50 Gm. of azulenic compound was obtained.

After further purification by chromatography over alumina, the oil was converted to a trinitrobenzene addition compound; m.p. 130.5–131.0°, uncor. [Lit. (3), 132° for chamazulene TNB compound].

Anal.—Calcd. for $C_{14}H_{16}.C_6H_3(NO_2)_3$: C, 60.45; H, 4.82. Found: C, 60.35; H, 4.77.

The ultraviolet, visible, and infrared spectra were identical to the reported values (4) for chamazulene. As might be expected, these spectra were almost superimposable on those of an authentic sample of guaiazulene (1,4-dimethyl-7-isopropylazulene) measured in this laboratory. However, the critical data for the guaiazulene TNB compound [m.p. 151–152° (4); anal. calcd.: C, 61.31; H, 5.15] clearly differentiate it from the chamazulene compound.

Only a few plant species yield chamazulene on simple steam distillation. One of these is *Artemesia absynthium* (5). The precursors of this blue oil have been shown to be a group of closely-related sesquiterpene lactones (5). Because of the recent scientific interest in these sesquiterpene compounds, as well as local interest in the medicine and taxonomy of the Artemesia species in southwestern United States, we are now engaged in isolating and characterizing the lactones of *A. caruthii*.

Screening Antifatigue Agents by Radiorespirometry

Sir:

Over the past 5 years a number of publications have appeared on the use of the potassium and magnesium salts of aspartic acid in the treatment of human fatigue (1–3). To measure the effect of various agents on fatigue in animals, the rat swim test has been found useful (4). Ideally, the mechanisms whereby these substances modify the energy-yielding processes in fatigue should be studied in the exercising animal. However, the many technical difficulties this would present led us to develop instead the following assay based on the utilization of glucose, a primary source of energy, during recovery from fatigue.

Male white rats, weighing 280 to 350 Gm. were burdened with lead amounting to 3% of their body weight and permitted to swim in tanks containing 18 inches of water at 28° until no longer able to surface.

Prior treatment consisted of 30 mg. per Kg. oral doses, beginning with a single dose 2 days before the experiment, two doses on the day before, and one or two on the day of the experiment, depending on whether the animal was to be used in the morning or afternoon, respectively. The last dose was given immediately before the animal was placed in the tank. Upon removal

Chamazulene from *Artemesia caruthii*

TABLE I.—EFFECT OF ASPARTATE SALTS ON RESPIRATORY $C^{14}O_2$ PRODUCTION

Treatment	No. of Animals	Respired CO_2[a] 30 min.	60 min.	90 min.
Rested controls	5	2.18 ± 0.44	2.36 ± 0.62	1.75 ± 0.40
Swum controls	15	0.36 ± 0.15	0.62 ± 0.11	0.62 ± 0.25
K Asp. 30 mg./Kg.[b]	8	0.58 ± 0.32	0.96 ± 0.54	0.71 ± 0.25
P[c]		0.025	<0.025, >0.01	0.20
Mg Asp. 30 mg./Kg.	6	0.47 ± 0.32	0.66 ± 0.36	0.58 ± 0.22
P		0.15	0.35	...
K Asp. 15 mg./Kg. + Mg Asp. 15 mg./Kg.[d]	9	0.65 ± 0.40	0.91 ± 0.40	0.87 ± 0.18
P		0.05	<0.025, >0.01	<0.025, >0.01

[a] Means and standard deviations in $\mu c. \times 10^{-3}$ registered at the times indicated after injection of C^{14}-glucose. [b] Aspartate salts were given orally. [c] Significance of mean increase compared with swum controls by one-tailed *t*-test. [d] Spartase, Wyeth.

from the tank (discarding those which did not swim at least 15 minutes) 0.4 ml. of a solution containing 1.7 $\mu c.$ per ml. of uniformly labeled C^{14}-glucose in 2% nonradioactive glucose was injected into the external saphenous vein and the rat was placed in a closed glass chamber swept by 140 ml. of air per minute. The C^{14} content of the respired carbon dioxide was measured by passing the effluent air through the 250-ml. ionization chamber of a Nuclear-Chicago "Dynacon" electrometer connected to a 1 ma. linear recorder.

Representative data from the respired $C^{14}O_2$ curves for the controls and animals receiving individual and mixed aspartate salts are tabulated in Table I. The mean values for the control animals and those receiving the mixed salt are illustrated in Fig. 1, which demonstrates the essential factors observed in these experiments: (*a*) the length of the induction period before appreciable $C^{14}O_2$ is excreted (considerably prolonged in fatigued animals as compared with rested controls); (*b*) the considerably lower maximal rate of $C^{14}O_2$ evolution in the fatigued animals and the longer time taken to reach the maximal rate; (*c*) the differences in total $C^{14}O_2$ output as indicated by the areas under the curves; (*d*) the elevation of the curves of the treated animals above those of the fatigued controls.

Studies on the method are being continued in view of the fairly high degree of individual variation encountered, and glucose-1-C^{14} and glucose-6-C^{14} are being tried in the hope that one of these will result in a more specific response and also help to elucidate the mechanism.

l-N-Norarmepavine

Sir:

Recent reports have described the isolation from Asiatic lotus, *Nelumbo nucifera* Gaertn. (*Nymphaeaceae*), of the alkaloids nuciferine (1, 2, 4), roemerine (2, 4), nornuciferine (2–4), and *dl*-armepavine (5). We report herewith the isolation from American lotus, *Nelumbo lutea* (Willd.) Pers. (*Nymphaeaceae*)[1] of the alkaloids nuciferine (0.046%), *dl*-armepavine (0.0046%), and an apparently new alkaloid (0.047%), to which we assign structure I and the name *l*-N-norarmepavine.

The new alkaloid, m.p. 152–153°, $[\alpha]_D^{25}$ − 23°

[1] Air-dried leaves and stems, collected in Wisconsin in 1959–1961. We thank Professor H. H. Iltis of the University of Wisconsin for confirming the identity of the plant. A voucher specimen is deposited in the University of Wisconsin Herbarium.

l-N-Norarmepavine

Sir:

Recent reports have described the isolation from Asiatic lotus, *Nelumbo nucifera* Gaertn. (*Nymphaeaceae*), of the alkaloids nuciferine (1, 2, 4), roemerine (2, 4), nornuciferine (2–4), and *dl*-armepavine (5). We report herewith the isolation from American lotus, *Nelumbo lutea* (Willd.) Pers. (*Nymphaeaceae*)[1] of the alkaloids nuciferine (0.046%), *dl*-armepavine (0.0046%), and an apparently new alkaloid (0.047%), to which we assign structure I and the name *l*-N-norarmepavine.

The new alkaloid, m.p. 152–153°, $[\alpha]_D^{25}$ − 23°

[1] Air-dried leaves and stems, collected in Wisconsin in 1959–1961. We thank Professor H. H. Iltis of the University of Wisconsin for confirming the identity of the plant. A voucher specimen is deposited in the University of Wisconsin Herbarium.

(c 1.33, $CHCl_3$), $[\alpha]_{546}^{26}$ − 40° (c 1.03, $CHCl_3$), λ_{max}^{EtOH} 228 mμ (ε 15,400), 282 mμ (ε 5,000), 287 mμ (ε 4,900), was shown to have the formula $C_{16}H_{15}NO(OCH_3)_2$.

Anal.—Calcd. for $C_{18}H_{21}NO_3$: C, 72.21, H, 7.07; N, 4.68; OCH_3, 20.73. Found: C, 72.06; H, 7.02; N, 4.89; OCH_3, 20.15; equiv. weight by titration with perchloric acid, 304.

Acetylation of I with acetic anhydride-pyridine, followed by chromatography on neutral alumina, gave an amorphous O,N-diacetate (III), IR bands at 5.70, 6.18 μ, and a crystalline N-acetate (II), m.p. 237–238°, IR band at 6.20 μ but none in the 5.6–6.0 μ region, soluble in dilute sodium hydroxide.

Anal.—Calcd. for $C_{20}H_{23}NO_4$: C, 70.36; H, 6.79; N, 4.10. Found: C, 69.95; H, 6.82; N, 3.92.

The foregoing facts established that I possesses a phenolic hydroxyl group and an acylable amino group.

Exhaustive methylation of I gave the 1-(4′-methoxybenzyl) - 6,7 - dimethoxy - 2 - methyl-1,2,3,4-tetrahydroisoquinoline methiodide (IV), m.p. 127–129° (6–9). Treatment with alkali yielded the methine V, m.p. 86–87°, characterized by direct comparison (mixed m.p., IR) with an authentic sample (10). Methylation of I with formalin and formic acid yielded *d*-armepavine (VI), m.p. 139–140°, $[\alpha]_D^{25}$ + 91° (c 1.19, $CHCl_3$). The infrared spectrum of the methylation product in chloroform was superimposable upon that of a sample of *l*-armepavine, m.p. 140–141°, prepared by sodium-liquid ammonia reduction of cycleanine (11). Mixture of equal quantities of *d*- and *l*-armepavine and crystallization from acetone yielded *dl*-armepavine, m.p. 166–167°. The melting point was undepressed by admixture of the sample isolated from *N. lutea*, and the infrared spectra of the respective samples in chloroform were identical. Hence, the name *l*-N-norarmepavine is proposed for the new phenolic secondary base. A total synthesis of *dl*-1-(4′-hydroxybenzyl) - 6,7 - dimethoxy - 1,2,3,4 - tetrahydroisoquinoline has been reported (12).

Diazomethane methylation of *d*-armepavine (derived from *l*-N-norarmepavine) yielded a nonphenolic base, m.p. 62–63°, $[\alpha]_D^{28}$ + 79° (c 0.84, $CHCl_3$) which was identified as *d*-l-(4′-methoxybenzyl) - 6,7 - dimethoxy - 2 - methyl - 1,2,3,4-tetrahydroisoquinoline by direct comparison with an authentic sample (10). The latter compound has recently been shown to possess the L-configuration at C-1 (13).[2] Consequently, the absolute configuration of L-(*l*)-N-norarmepavine may be represented as in I.

Crystallography. Part II

By JOHN A. BILES

OPTICAL CRYSTALLOGRAPHY

Optical Indicatrix

The manner in which light is affected by crystals arises from the internal structure. Crystals are placed in one of two classes depending on the effect of the transmission of light in different directions through the crystals. These classes are isotropic and anisotropic. Fletcher (192) introduced the optical indicatrix to explain the effect of light when passing through a nonopaque substance. In relation to this, Wooster (193) has discussed the geometrical properties of a triaxial ellipsoid.

To visualize the optical indicatrix one can consider a point source of light in the center of a crystal. Allow the light to propagate in every direction of the crystal. After an elapse of time, draw wave fronts for all of the waves. The result of all of the wave fronts is either a sphere, spheroid, or ellipsoid (triaxial). The sphere is termed an isoaxial indicatrix; solids producing such a figure are termed isotropic. These solids are also termed isometric. The spheroid, either prolate or oblate, is termed a uniaxial indicatrix; solids producing such a figure are termed anisotropic and belong to the tetragonal and hexagonal systems. The triaxial ellipsoid is termed a biaxial indicatrix; solids producing such a figure are termed anisotropic and belong to the orthorhombic, monoclinic, and triclinic crystal systems.

In order to determine the orientation of the optical indicatrix within the crystal, the crystallographer will examine the interference figures. These figures are defined as telescopic images of convergent light passing through anisotropic crystals between crossed nicols. The theory of formation of interference figures has been proposed by Kamb (194).

Refractive Index and Molar Refraction

The velocity of the light on passing through the crystal is determined by measuring the refractive index of the section of the crystal viewed. Meaningful refractive indexes are termed principal indexes. The principal indexes are determined by viewing sections which lie in the planes of the indicatrix coordinates. This is done by looking for centered interference figures.

The refractive index depends on the velocity of the light which, in turn, depends upon the atoms, ions, or aggregates present and their position occupied in the lattice. This index is proportional to the polarizability of the molecule. The ease of displacement of positive and negative charges with respect to each other in an electric field is called polarizability. Thus, the refractive index is governed by the kind of atoms present in the molecule and the packing of the molecules, atoms, or ions in the crystalline state. The polarizability is the same in any direction in the crystal for isotropic solids. The polarizability will vary with the direction of propagation of light in anisotropic crystals. The net effect is the polarization of light which is

Received from the University of Southern California, Los Angeles 7.

Editor's note: Part 1 of this review appeared in the June issue; THIS JOURNAL, 51, 499(1962).

quite evident when anisotropic crystals are examined under the microscope between crossed nicols.

It has been shown that the mathematical relationship of the total induced polarization which is caused by the distortion of the electron shells in the molecule is equivalent to the molar refraction (195, 196). Brühl found that conjugated unsaturated groups caused an increase of the molecular refractive and dispersive power (197). This optical exhaltation was quantitative and dependent on the nature and number of unsaturated atomic groups.

Bragg (198) was able to calculate the refractive index values for calcite and aragonite utilizing the specific refractions of the carbonate and calcium ions. This calculation was aided with an X-ray analysis which showed that carbonate ions were flat and the planes of the ions normal to the direction of the least refractive index. Under the influence of an electric field an atom develops a doublet of moment *se*, corresponding to the relative displacement to a distance *s* of elementary charges $\pm e$

$$s = E'e\lambda \qquad \text{(Eq. 3)}$$

where E' = strength of field in neighborhood of atom and λ = characteristic constant of atom. This does not depend on the direction of the local field if isotropic.

In each ml. of polarized medium, let there be N_1 atoms which form doublets of moments, e, N_2 forms doublets of moment s_2e, etc. It can be shown that

$$(K - 1)\bar{E} = P = (N_1s_1e + N_2s_2e + \ldots) \qquad \text{(Eq. 4)}$$

where $\bar{E}$ = average value of electric density throughout medium, P = total polarization per unit volume, and K = dielectric constant of the medium.

The strength of a doublet is

$$s_1/\lambda_1 \qquad \text{(Eq. 5)}$$

Strength of the doublet is also

$$(\bar{E} + {}^1/_3P)e \qquad \text{(Eq. 6)}$$

Thus

$$K - 1 = \frac{P}{\bar{E}} = \frac{\Sigma Ne^2\lambda}{1 - {}^1/_3 \Sigma Ne^2\lambda} \qquad \text{(Eq. 7)}$$

$$K = n^2 \qquad \text{(Eq. 8)}$$

$$n^2 - 1 = \frac{\Sigma Ne^2\lambda}{1 - {}^1/_3 \Sigma Ne^2\lambda} \qquad \text{(Eq 9)}$$

Or

$$\frac{n^2 - 1}{n^2 + 2} = {}^1/_3 \Sigma Ne^2\lambda \qquad \text{(Eq. 10)}$$

If both sides of Eq. 10 are multiplied by M/ρ

$$\frac{M}{\rho} \cdot \frac{n^2 - 1}{n^2 + 2} = a\,({}^1/_3 N_0e^2\lambda_1) + b\,({}^1/_3 N_0e^2\lambda_2) + \ldots \qquad \text{(Eq. 11)}$$

This additive law is obeyed approximately for isotropic material. The law would be exactly obeyed were it not for the fact that all other atoms around any given atom are not arranged at random, since those which form part of the same molecule have a definite relationship to it.

Bragg considered the polarization of the ions in the three directions; he also considered that the polarization in the y and z directions affected the polarization in the x direction. Allowance for these effects yielded an equation for the refraction index, n, for any given direction of the electric vector as

$$n^2 - 1 = \frac{(c_1N_1e^2\lambda_1 + c_2N_2e^2\lambda + \ldots)}{1 - {}^1/_3(c_1N_1e^2\lambda_1 + c_2N_2e^2\lambda_2 + \ldots)} \qquad \text{(Eq. 12)}$$

The polarization of the calcium ion in calcite or aragonite is not too important since the ion contributes about 15% of the total refractivity. The value for the calcium ion is given as 1.99. The value for the calcium in calcite and aragonite is determined with the knowledge of the density of the solid. Thus

$$Ne^2\lambda = \frac{3\rho}{M} I_{Ca^{++}} \qquad \text{(Eq. 13)}$$

The value for Eq. 13 is 0.165 for calcite and 0.175 for aragonite. The I value for carbonate was determined utilizing the molecular refractions of Al_2O_3, NO_3^-, CO_3^-, and SO_3. The I_0 for the three oxygens is between 3.3 and 3.7. When the I value for $CO_3^=$ is substituted into Eq. 13, the value of 0.822 is obtained for calcite and 0.873 for aragonite. The value for e^2 may be calculated and then substituted back into Eq. 9. When corrections were made for neighboring interactions, Bragg found that the observed and calculated refractive indexes were similar. These values are reported in Table IV.

TABLE IV.—CALCULATED AND OBSERVED REFRACTIVE INDEX VALUES FOR CALCITE AND ARAGONITE

Calcite	Calcd.	Observed
ϵ	1.488	1.486
ω	1.631	1.658
Aragonite		
α	1.538	1.530
β	1.694	1.681
γ	1.680	1.686

It is to be noted from the data recorded in Table IV that the calculated value for beta in aragonite is greater than the value for gamma. Those who have a knowledge of the biaxial indicatrix know that this is impossible. It does indicate, however, that at an early date there was developed a quantitative relationship for the calculation of refractive indexes of solids.

Bragg also pointed out that the oxygens surrounding the sulfur in the sulfate ion were uniformly distributed in the three-dimensional pattern. He thus stated that this tetrahedral arrangement of oxygen atoms was the cause of the small difference in the principal refractive indexes. This does point to the use of refractive indexes or molar refractions in prediction of coordination complexes. Dachille and Roy used infrared absorption and molar refractions to check coordination (199). The investigators related primary coordination, atomic number, atomic weight, and ionic charge to absorption wavelengths for the major bands. For AX_2 compounds, a K value of 0.168 was obtained where K was found to be

$$K = \frac{(\text{C.N.})(\mu)(A_A + A_X)^{1/3}}{Z_A Z_Z \cdot \lambda^2} = 0.168 \quad \text{(Eq. 14)}$$

where C. N. = coordination number, $Z_A Z_Z$ = valence, μ = reduced mass term, $A_A + A_X$ = sum of atomic numbers, and λ = main absorption wavelength in microns.

Equation 14 was applied to ABO_4 type compounds and the K value did not agree for the different compounds studied as well as the value agreed for the AX_2 compounds. The molar reactivities supported the conclusions reached using the infrared data.

Batsanov (200) calculated the electronic polarizability of atoms with intermediate bond character. The determination of the effect of the change of bond polarity on the atomic refraction was discussed. The study was quantitated by comparing the ionic and atomic refractivities of the elements. After finding the change in the atomic size with changing ionization and by using the proportionality of refractions to atomic volumes, a law was proposed which governs the change in the electronic polarizabilities of the atoms with a change in the bond polarity. Nutt (201) has reported a correlation and prediction of the optical and thermodynamic properties of saturated liquid hydrocarbons by the group contribution method. Such a relationship can be applied to the solid hydrocarbons which are nonpolar without too much error. Nutt used the Sellmeier-Drude equation for calculations.

The molar refractions of molecules in the solid state have been experimentally determined and compared with the calculated values. When reports were submitted for "Crystallographic Data," molar refraction values were included (202). The molar refractions have been experimentally determined for the antihistamines (203), sulfonamides (204), antitubercular compounds (205), and steroids (206). The experimental values were in close agreement with the calculated values. The reader should recall that Bragg, in calculating the refractive indexes of calcite and aragonite, stated that experimental and calculated molar refractions could be identical were it not for the fact that all other atoms around any given atom are not arranged at random (198). In some cases the experimental molar refraction showed a negative deviation from the calculated value; the deviation was by as much as 14%. Compounds showing such deviation included thiamine hydrochloride (207), α-pyridine sulfonic acid (208), cyclotrimethylenetrinitramine (209), cyclotetramethylenetetranitramine (210), and streptidine sulfate monohydrate (211). On the other hand, it was observed that some highly conjugated systems showed a positive deviation from the calculated molar refraction. This deviation occurred with *trans*-azobenzene (212), *trans*-stilbene (213), *trans*-diethylstilbestrol (214), and 1,3,5-tri(*p*-chlorophenyl)benzene (215). The positive deviation was shown also by 4-aminosalicylic acid (216), vanillin (217), 2-mercaptobenzothiazole (218), gliotoxin (219), and 2-naphthoic acid (220). The observed and calculated molar refraction for *l*-naphthoic acid agreed within 1% (221).

Brasseur applied the Lorentz and Lorenz equation to the study of inorganic materials (222). The results obtained were satisfactory for the carbonates of calcium, magnesium, manganese, zinc, ferrous, barium, strontium, and lead.

A comparison between the square of the geometric mean refractive index of crystals and the dielectric constant determined in solvents can be made. Maxwell derived a relationship of the refractive index for light of long wavelength to the dielectric constant (223). This relationship is given by Eq. 8. This relationship is close when the molecules are far apart. A comparison of the dielectric constant calculated from refractive indexes of compounds in the solid state to the dielectric constant of the molecule in solution is shown in Table V. The dielectric constant of acetanilid and D.D.T. was determined using different solvents, and the value changed with each solvent. In addition, D.D.T. was liquefied and the dielectric constant was deter-

mined at different temperatures. The values for two such temperatures are included in the table.

Kleber (230) reported the relation between the dielectric constant and the structure of a crystal. The relation was based on the polarizability of the lattice, the anisotropic nature of the lattice, and the presence of dipoles in the crystal lattice. He related the dielectric constant to the number of structural units on 1 ml. of the lattice and the molar polarizability by

$$\frac{\epsilon - 1}{\epsilon + 2} \cdot \text{v.} = \frac{4\mu}{3} N \left[\alpha \frac{\mu^2}{3kt}\right] \quad \text{(Eq. 15)}$$

Pulou (231) measured the specific inductive capacities for 60 crystals. The dielectric constant of the crystal was measured relative to the characteristic cleavage plane or optic axis. McMahon (232) noted that the dielectric constant of certain organic compounds became higher than normal when solidified in either alternating or undirectional electric fields. In a magnetic field an anisotropic change resulted in an increase in the direction of applied field and decreased perpendicular to the field. Allen (233) related the refractive index to the specific gravity for some crystalline compounds. He stated that the geometric mean of the three principal refractive indexes was proportional to the specific gravity as given by

$$k = \frac{\alpha\beta\gamma}{d} \quad \text{(Eq. 16)}$$

He reported that his equation was good for some polymorphs but not others.

The refractive index has also been used in establishing the conformation of cyclohexane derivatives (234–236). *Cis-trans* pairs of disubstituted cyclohexanes can be differentiated by measuring the refractive index of the melt. The isomer having the higher index of refraction and higher density would be the isomer with the less conformational stability. Kelly (237) proposed that for isomeric cyclohexanes and tetrahydropyran derivatives similarly substituted on corresponding ring carbon atoms, the refractive indexes and densities increase with increasing number of axial substituents.

The refractive index of solids has been used for the identification of mixtures (238), and as a supplement to X-ray analysis of solid solutions to detect any possible heterogeneity (239). The difference between the highest and lowest refractive index values, the birefringence, has been used to predict molecular orientations (240), specific strength of cotton fibers (238), and the nature of montmorillonite complexes (241). In studying the birefringence of aromatic complexes of clays, it was noted that the polarizability of the aromatic molecule would affect the overall polarizability of the complex. When the aromatic nucleus complexed parallel to the silicate sheet, the negative birefringence increased.

Chemical Microscopy and Optical Crystallographic Properties

The development of chemical microscopy and optical crystallography in the United States was largely the result of the works of Chamot and Mason, Keenan, McCrone, and Witt and Poe. Review articles on chemical microscopy have appeared periodically (242–249). Mason has justified chemical microscopy in the technical organization (250). Hartshorne has discussed the value of optical crystallography in industry (238). During the first and middle part of the first half of the twentieth century there was no standard practice in reporting crystallographic properties. As a result, recommended practices were published (251). Through the efforts of McCrone, optical crystallographic data were published monthly beginning in 1948 (202). This practice ceased in *Analytical Chemistry* with the report of alpha-D-talose (252). Similar reports are now appearing in THIS JOURNAL (253). Winchell has tabulated the optical properties for many compounds (224) and at the peak of the interest in optical crystallographic properties, Kirkpatrick suggested punched cards for the filing of such information (254). McCrone also suggested a punched card system (255).

Keenan and his workers contributed a large amount of data to the literature. Largely through his efforts, data were collected on U.S.P. XII compounds (225). Optical crystallographic

properties were determined for N.F. X compounds (256). Witt and Poe and co-workers contributed to the development of optical crystallographic properties of organic compounds of pharmaceutical interest (203–205,257–260). Plein and Dewey have contributed particularly in the identification of amines (261–264). The optical crystallographic studies of Bryant and Mitchell remain a classic (265–269). Bryant prepared the *p*-bromanilides of acetic acid and propionic acid and found that the acids could be semiquantitated in binary mixtures by determining the optic axial angles using five monochromatic radiations of the mercury arc. With the aid of dispersion of the optic axes and the melting points, the weights of the components could be calculated. Their additional reports emphasized various types of dispersion including crossed axial plane, inclined, horizontal, crossed, and ellispoidal dispersion. In reporting optical crystallographic data of different compounds, McCrone and co-workers had to resort to some imaginative work. Deffner and McCrone (270) reported the problems involved in the determination of the refractive indexes of *p*-dimethylaminobenzaldehyde since the compound was soluble in all of the refractive index oils. McCrone found polymorphism to be prevalent with some of the compounds tested. The relationship between temperature and transition was reported for salicylamide (271). Rose, Van Camp, and Williams have contributed to the literature. Their studies include the Rauwolfia alkaloids (272–276), alkaloids from *Vinca rosea* (277), antibiotics (278, 279), and other compounds of pharmaceutical interest. Shell (280, 281) and Clarke and Krc (282) have contributed also. Shell refined some of his studies by utilizing the universal stage (203, 204). He also stated that the orientation of the biaxial indicatrix in triclinic crystals could be determined only with the use of the universal stage (283).

The work of Prien and Frondel should not go unnoticed by crystallographers. Their original work was important in solving the toxicology of sulfonamide therapy. Through the use of optical crystallographic properties, they were able to prove that acetylsulfathiazole crystallized in the kidney. They also studied the acetyl derivatives of sulfanilamide and sulfapyridine (284–286). These investigators continued their studies with an emphasis on urinary calculi (287–289). Prien reported the structure and comparison of some 6000 human urinary calculi studied by crystallographic techniques. He was able to correlate the optical crystallographic studies with pathogenesis, and found that it was often possible to reconstruct the clinical history by an optical study of the calculus obtained from the patient. In a paper concerning the deposition of solids in the body, Pfeiffer discussed the use of X-ray diffraction, optical crystallography, and infrared absorption spectrophotometry (290). Pfeiffer suggested that the physical chemist could devote greater time to help solve the problem of cholesterol deposition. Stewart made an attempt to examine atherosclerotic and normal tissues and plasma in the fresh state and at temperatures up to 37° with the thought that results might have some bearing on the problem of the integration of certain forms of lipid in tissue. Stewart discussed the significance of the birefringent material observed (291).

Optical crystallographic properties have been used to aid in predicting molecular orientations in the solid state. Studies have been published for purines and pyrimidines (260), and dicarboxylic acids (292, 293). The limitations of the use of optical crystallographic properties in helping to determine molecular orientations has been discussed by Krishnan and Lonsdale and coworkers (294, 295).

Fusion Methods

The Kofler group has been responsible for the development of "Thermo-Mikro-Methoden" (296). L. Kofler, holder of the Magister in Pharmacy, Ph.D., and M.D., was a pharmacognosist but had to turn to microscopy because of lack of facilities. His wife, Adelheid, was a mineralogist who received an M.D. (297). McCrone and co-workers have been responsible for the development of fusion methods in the United States (298). McCrone pointed out that both methods were influenced by publications of Otto Lehmann. The two methods were developed apparently independently (298). Reports utilizing Koflers' procedures continue to be published. These include studies of glutamic acid antipodes (299), thermomicromethod studies of polymorphic modifications of organic compounds (300), studies of ergot alkaloids (301), ergothionein (302), binary mixtures of some medicinal agents (303), and ternary mixtures (304). With the Thermo-Mikro-Methoden procedures, the eutectic temperatures of 16 hormones were studied, using benzil, acetanilid, phenacetin, benzanilid, salophen, or dicyandiamid. It was noted that 11 of the 16 hormones were polymorphic and that three were present in commercial products in an unstable modifica-

tion (305). Arceneaux has reported that the polymorphic character of trichlorophenoxyacetic acid and related compounds made it difficult to develop a quantitative microscopic fusion method of analysis for commercial products (306). Arceneaux also presented a study of the microthermal analysis of the binary mixture of 1,2,3,4-tetrachlorobenzene-pentachlorobenzene (307).

The great amount of work that McCrone has done with fusion methods can be appreciated by referring to his text (298). His methods have been applied to pharmaceuticals. These include the sterols (308) and esters of 2,4,6-trinitrobenzoic acid (309). The naphthalene molecular addition compounds of these esters melted incongruently, whereas most of the phenanthrene molecular addition compounds melted congruently. Trinitrofluorenone was found to be capable of forming molecular addition compounds with aromatic hydrocarbons (310). From the study, it was concluded that those substituent groups known to release electrons to the benzene ring either by inductive mechanisms or by a resonance mechanism generally led to a molecular addition compound with the reagent. Bulky groups on the benzene ring prevented complex formation. The study was extended to polynuclear aromatics (311), which included the examination of adlehydes, esters, acids, amides, phenols, and aniline derivatives. The reagent is of more limited applicability to the benzene series than to the polynuclear series. The value of trinitrofluorenone was recognized, but a sub-reagent was also desirable for the identification within a series of compounds. Quinones were investigated as possible sub-reagents. Of nine quinones studied, 2,5-biphenyl-1,4-benzoquinone offered the greatest potential (312).

The use of fusion methods was extended to the identification of high explosives (313). For the identification of these compounds, thymol functioned as the solvent for the solute (explosive) crystallizations. Seven different physical characteristics were noted depending on the solubility of the compounds in thymol. It is interesting that McCrone, in this study, stated that fusion methods ensure that a given compound will always show the same morphological characteristics. West and Granatelli utilized 8-quinolinol in developing a fusion method for the microscopic identification of inorganic ions (314).

The fusion method was used in the determination of 2,2-bis-*p*-chlorophenyl-1,1,1-trichloroethane in technical D.D.T. (315). In a complete study of the problem of the impurity in D.D.T., the investigators applied the Arrhenius rate equation to the rate of crystallization of technical D.D.T. with varying percentages of impurity. When the log rate of crystallization was plotted against the reciprocal of the temperature, straight line plots were obtained. Utilizing methods of fusion techniques, the purity of compounds can be estimated by sublimation procedures (316). Petrucci and Weygandt reported that the impurity content could be determined if about 1% or greater. The same method can be used for removing trace impurities from organic solids.

CRYSTALLINE PROPERTIES

Crystallization

Bush reviewed the separation and purification of compounds by crystallization on a small scale (317). Tipson believes that often the best method for separation and purification of organic compounds is by recrystallization (318). He outlined schemes for batchwise, countercurrent fractional recrystallizations, and investigated the distribution of the components in the phases after each recrystallization. He illustrated his theory, scope, and methods with binary and triangular phase diagrams.

Classical multicrystal growths from solution still receives little attention (319). No comprehensive treatment of the batch process has been reported in spite of its wide commercial application. Caldwell reported that crystals of commercially acceptable size could be produced by (*a*) circulation of crystals in the supersaturation zone, (*b*) removal of excess fines, and (*c*) maintaining high magma density (320). He considered these factors in relation to a continuous crystallizer which produces supersaturation by vacuum cooling, rather than by evaporation. The continuous crystallizer, known as the draft tube, which utilizes the above listed factors will produce crystals up to about 16 mesh. Caldwell called attention to the mechanism of crystal formation. He discussed the postulates of Meir, and of Rumford and Bain, concerning nuclei formation. Crystal growth was considered from the viewpoint of bulk diffusion.

Whether crystal growth is bulk diffusion controlled, surface reaction controlled, or interface process controlled has been the subject of study by various workers. Doremus (321) showed that crystal growth rate of ionic salts was controlled by an interface process rather than by bulk diffusion of solute. He proposed an adsorbed layer on the growing crystal, and argued

mation was a fourth-power step. When growth of a constant number of small particles of the same size and concentration was greater than 0.4 mM, the precipitation was diffusion controlled and the kinetics was measured according to the following equation

$$k_0 t = \int_0^a a^{-1/3}(1 - a)^{-1}\, da \qquad \text{(Eq. 22)}$$

When the concentration was less than 0.4 mM, then the kinetics was expressed by

$$k_R t = \int_0^a a^{-2/3}(1 - a)^{-4}\, da \qquad \text{(Eq. 23)}$$

In the above equations a is represented by the degree of reaction (precipitation). Thus, at low concentrations the crystal growth is increased with the fourth power of the concentration. The changes of the order of 0.4 mM can be observed microscopically. When the initial concentration was less than 0.5 mM the crystals were small prisms. When the initial concentration was between 0.5 and 1.5 mM, the crystals were more or less distorted prisms, the corners having grown more than the middle of the faces. When the concentration was greater than 1.5 mM, the corners had grown far more than the other parts of the crystals, giving them appearance of stars. Nielsen stated that the stars were to be expected in the case of diffusional control of growth rate since the concentration then is greatest at the corners. Rectangular growth is obtained when the concentration is approximately the same all over the surface and it cannot be so when the consumption of matter is fast compared with diffusion.

Schlichtkrull has studied the nucleation and growth of insulin crystals (339–344). Nuclei were formed by freeze drying a crystalline mixture containing dissolved insulin. Monodisperse insulin crystal suspension with crystal sizes of 5, 25, and 40 μ were obtained. The rate of nucleation and growth of the crystals as functions of concentration of insulin in crystal mixtures were reported. The rate of growth of pig insulin from a clear solution containing sodium citrate and acetone could be represented by

$$dc/dt = 2.8 \times 10^{-7} \times c\,(95.8 - c)^3 \qquad \text{(Eq. 24)}$$

where C represents the crystalline fraction in per cent of total insulin and is measured in minutes. The linear rate, R_d, of deposition of insulin on crystal faces is

$$R_d = 1.63(C_i - 0.080)^2 \text{ u./min. for saline, beef} \qquad \text{(Eq. 25)}$$

$$R_d = 0.38(C_i - 0.066)^3 \text{ u./min. for citrate, pig} \qquad \text{(Eq. 26)}$$

The concentration, C_i, of dissolved insulin was expressed in mmoles per L. The shape of the crystals could be related to the species. Using ordinary methods, recrystallized pig insulin precipitated as single, sharp, and perfect rhombohedral bodies. Cattle and sheep insulin crystals were often of a twinned appearance. When urea or a halogenide was present in the mother liquid of all three insulins, perfectly shaped rhombohedral crystals were obtained. A patent was issued to Schlichtkrull for obtaining uniform insulin crystals for injection (345). A relationship between the weight of seeds (P), the weight of product desired (I), the size of seed crystals (d_p), and the size of the product crystals desired (d_i) was found to be

$$P = I\left(\frac{d_p{}^3}{d_i{}^3 + d_p{}^3}\right) \qquad \text{(Eq. 27)}$$

Choi and co-workers (346) found that β-lactose could be determined from its rate of crystallization in a saturated lactose solution abundantly seeded with crystalline α-lactose hydrate. In a mixture of β- and α-lactose, the α-lactose could then be determined as the difference between the total lactose and the crystallized β-lactose. The rate of crystallization of β-lactose was represented by

$$k_2 t = \log \frac{c_0 - s_\infty}{c_t - s_\infty} \qquad \text{(Eq. 28)}$$

where the total initial lactose concentration after seeding was C_0, the final solubility S_∞, and the concentration C_t, at any given time t.

Crystal Habit

Crystallographers describe the habit of a crystal as acicular, lamellar, tabular, equant, and columnar (347). The habit of pharmaceutical compounds has been used for purposes of identification. However, this method of identification has definite limitations. It has been stated that "it is virtually impossible to duplicate the crystallization pattern of a single compound on two slides" (348). The angles between any two faces of a crystal will remain the same even if the crystal growth is accelerated or retarded in one direction or another. Should crystal habits be used to identify compounds, the habits from various solvents should be used for differentiation of compounds. The microscopic identification is more reliable the greater the number of crystallizations from various solvents or the greater the number of crystallizations of different derivatives. Identification by this method has been used considerably by chemical toxicologists (349, 350).

In a series of articles Shead discussed the use of profile angles for the identification of compounds.

that fitting a solute unit directly into the crystal lattice from solutions would be difficult. It would be an improbable event for uncharged molecules to collide at a kink in a growth step with just the right orientation to fit into the crystal lattice. For ionic solutes, the difficulties would be even greater because at least two different particles would have to collide simultaneously or alternately in a kink. Furthermore, the ions would have to be desolvated at the same time as they fitted into the lattice. Thus, the concept of an adsorbed layer which permitted desolvation and partial orientation before incorporation into the lattice seemed reasonable.

Bauer (322) considered the general mechanism of crystal growth from a thermodynamic point of view. He stated that the atom layer growth through surface nucleation occurred only for growth on material of the same composition. Growth on a material of different component can occur by original formation of a mono or polymolecular layer without nucleation which then leads to formation of three-dimensional nuclei or through formation of three-dimensional nuclei directly on the foreign substrate. Hoffman (323) called attention to the free energy difference between the rate of nucleation and growth of crystallites in supercooled liquids. The free energy difference was approximated by the expression

$$\Delta F = \Delta H_f \cdot \frac{\Delta T}{T_m} \qquad \text{(Eq. 17)}$$

The equation was derived assuming that ΔH and ΔS in the thermodynamic relation

$$\Delta F = \Delta H - T\Delta S \qquad \text{(Eq. 18)}$$

is constant with temperature, and equal to ΔH_f and $\Delta H_f/T_m$, respectively. In many cases ΔH and ΔS depend on temperature. Hoffman derived a simple expression for the thermodynamic driving force in nucleation and growth processes that takes into account the temperature variation of ΔH and ΔS

$$\Delta F = \left(\Delta H_f \cdot \frac{\Delta T}{T_m}\right)\left(\frac{T}{T_m}\right) \qquad \text{(Eq. 19)}$$

Those interested in the theory of crystal nucleation from vapor, liquid, and solid systems should read Dunning's discussion of the matter as well as the work of Higuchi and O'Konski (324, 325).

Stranski (326), among various workers, developed a classical theory for the growth of crystals. The growth of a crystal depended upon the molecules depositing in layers on a crystal surface. Gibbs (327) stated that a perfect crystal surface could only grow by repeated two-dimensional nucleation of new layers. According to this, a crystal can only grow if the supersaturation amounts to at least 25%. However, Volmer and Schultze succeeded in 1931 in getting iodine crystals to grow further from a 1% supersaturated vapor. This unusually great discrepancy between calculation and experiment was the cause for new investigations. In 1949 Frank succeeded in explaining the discrepancy. He stated that instead of growth occurring by growth in layers, growth occurred in the form of spirals (328, 329). Frank's theory has been tested and positive results have been reported by many investigators. Most recently, Dash and Tweet reviewed the methods of observing dislocations in crystals and discussed the work of Frank and others (330). Studies of growth steps on sucrose crystals (331), paraffin (332), diphenylamine, phenanthrene, and borneol (328) provide interesting reading. The reader should refer also to Buckley's text on "Crystal Growth" (333). Cottrell stated that to understand work-hardening, creep, fatigue, fractures, and recrystallization, one has to study the collective behavior of large, complex assemblies of dislocations, and the theory of this can go forward only when experiments have shown what are the decisive aspects of this behavior in practice (334).

Kinetics

In a study of the kinetics of barium sulfate precipitate formation, Johnson and O'Rourke said the precipitation process is interpreted as being initially controlled by nucleation reaction and finally controlled by growth reaction (335). They reported that the rate of growth of a single crystal could be represented by

$$da/dt = -k(c_0 - c)^{2/3} \cdot a^q \qquad \text{(Eq. 20)}$$

where a = mean ionic activity of Ba^{++} and SO_4^{--}, b = time, and c_0 and c = molar concentration of barium sulfate available at t_0 and t. The kinetic constant and shape factor is incorporated in k. The rate of change of the mean ionic activity as well as the surface of the particle is proportional to some power q. The growth equation for a constant number of particles becomes

$$da/dt = -k_v^{1/3}(c_0 - c)^{2/3}(a - a_s)^q \qquad \text{(Eq. 21)}$$

Further studies on the kinetics of crystal growth in barium sulfate precipitations were reported (336–338). Nielsen found that the work of Johnson and O'Rourke was valid for precipitations of certain electrolytes. In Nielsen's original work he reported that the rate of growth of barium sulfate was controlled by some sort of chemical reaction in which the crystal for-

Using sublimation procedures, he specified the conditions necessary to obtain thin crystal plates of simple goemetric form suited for measurement of profile angles (351–354). McCrone stated, however, that profile angles are not sufficient for identification except in limited cases (355), and suggested that using profile angles along with fusion, optical-crystallographic and polymorphic studies, and rates of crystal growth would be more conclusive. In a series of articles dealing with "organic chemical microscopy," Dunbar and associates developed tests for organic classes of compounds using specific reagents. They prepared derivatives which could be identified microscopically. They reported methods for the identification of amines (356, 357), carboxylic acids, anhydrides and acid chlorides (358, 359), aldehydes and ketones (360), hydroxy compounds (361), amino acids (362), and cations (363). Van der Wegen reported the microchemical identification of some alkaloids, barbiturates, sulfonamides, and new synthetic drugs. Sixty-nine compounds and 29 reagents were tabulated with 42 drawings of crystal forms (364). Sandri has reported that bromoplatinic acid is more sensitive as a reagent for identification of organic bases than is chloroplatinic acid. Bromobismuthic acid was also studied as a reagent. In addition, Sandri used a special potassium bismuth iodide solution for the microchemical detection and differentiation of β-phenylisopropylamine and N-methylphenylisopropylamine (365–367). Berisso utilized potassium iodobismuthate to characterize and differentiate piperazine and α-methylpiperazine. Mixtures could be detected in any proportion (368). Tenger was able to distinguish derivatives of pyridine used in medicine with a modified Dragendorff reagent (369).

The use of chlortetracycline hydrochloride as a reagent for the qualitative detection or quantitative estimation of common cations or anions has been reported (370). The antibiotic did not show any promise. The characterization of certain cations with isoquinoline has been the subject of some reports (371–373). For a detailed study of the identification of elements in the periodic table, the text of Chamot and Mason should be consulted (374).

A differential method using crystalline habits has been reported for the identification of barbiturates and sedatives (84, 86). Other investigators have reported that solvents may greatly affect the habit of the crystal (375, 376). In a study of crystal habit, Stroitelev reported that a less viscous media favored more coarse and more equidimensional crystals for pregmatities and pneumatolytic, in comparison with magmatic and hydrothermal deposits (377). In a study of the crystal habit of salol, Malkin reported the dependence of the form of crystal growth on the rate of growth (378). Transition to an acicular shape occurred when the rate of growth of a crystal of salol increased. When undercooling was decreased, the rate of growth decreased and the growth of acicular crystals was replaced by growth of crystals of regular shape. The various habits of ice crystals obtained at various temperatures under an atmosphere of oxygen, nitrogen, or air with carbon dioxide have been reported (379–381).

Hartman and Perdok (382) related crystal structure and crystal morphology on an energy basis. They concluded that the morphology of a crystal is governed by chains of strong bonds running through the structure. The effective period of such a chain of strong bonds is called a periodic bond chain vector, a P.B.C. vector. The faces of a crystal are classified as (*a*) F-faces or flat faces, each of which is parallel to at least two P.B.C. vectors, (*b*) S-faces or step faces, each of which is parallel to at least one P.B.C. vector, and (*c*) K-faces or kinked faces which are not parallel to any P.B.C. vector. The faces described are listed in order of decreasing importance. In a later paper Hartman reported on his studies of the equilibrium forms of crystals (383). The F-faces were found to be the most important faces. For nonionic crystals it was found that the equilibrium form may also exhibit S and K faces. Hartman stated mathematically under what conditions S and K faces might exist.

Jackson developed an equation which permits a prediction of which faces of any crystals are smooth or rough and hence a prediction of growth morphology (384). The equation permitting this prediction is

$$\alpha = \frac{L_0}{kT_E} \cdot \frac{n_i}{V} \qquad \text{(Eq. 29)}$$

where

$$\frac{L_0}{kT_E} = \frac{\Delta S}{R} \qquad \text{(Eq. 30)}$$

L_0/kT_E represents the entropy change associated with the crystal transformation divided by the gas constant, and n_i/V is the fraction of the total bonding energy of an atom that can be associated with an atomic layer parallel to the face under consideration. When $\alpha < 2$, faces are rough and initiation of new layers is easy. When $\alpha > 2$, faces are smooth and initiation of new layers is difficult and growth on screw locations is important.

Rules have been established for twinning (385). Hartman (386) derived seven possible twin laws. He applied the periodic bond chain theory of crystal morphology to growth twins. He concluded that when twinnng starts on a face, this face must be an F-face or, less probably, an S-face. He stated that the difference of habit between twins and single individuals can be understood from enhanced growth at the twin boundary. This enhancement takes place only where F-faces or eventually S-faces must meet at a reentrant angle of the twin boundary. The twin plane of contact twins should be an F-face. With penetration twins, a certain F-face or S-face can be indicated that acted originally as a composition plane. Hartman stated that the existence of threefold, fourfold, and sixfold twin axes is to be doubted. The elbow twinning that occurs in calcium carbonate has been diagramed by Bragg (387).

The crystal habit has been used to correlate crystal structure with the thixotropic behavior of aliphatic urethanes (388). Hendrickson and Shulman found that all of the long chain aliphatic urethanes showing thixotropic characteristics had fine needle or cluster of needles type structures. The more pronounced the structure of the cluster of needles, the better the thixotropic properties. Compounds showing no thixotropic properties had rod-like crystal structures. One has to examine the photomicrographs to fully appreciate the relationship between the habit and thixotropy.

Shell (389) has emphasized the role that crystal habit often exerts in the development of stable suspensions. Shell stated that in tableting "the mechanical influence of crystal shape . . . is one factor, but there is another, sometimes dominant one, which results from the anisotropy of cohesion and of hardness which is possessed by organic crystals . . . It is significant that this anistropy bears a fixed relation to the fundamental crystallographic directions. Therefore, as crystal habit varies, the dominant faces may vary in their relation to this anisotropy, and it is the influence of the dominant faces which tends to orient the crystals during a packing or compression process. Thus, major habit variations of an active ingredient can influence greatly the ease or the difficulty of making satisfactory compressed tablets." Shell quantitated the crystal habit of various batches utilizing preferred orientation measurements.

Crystal Adsorption

Some of the recent work published concerning the modification of crystal habit by the addition of impurities or poisons should provide a real stimulus. The early studies of crystal habit modifications were summarized by Whetstone (390). Whetstone reported that the crystal habit modification by dyes depended on the anionic and cationic substituent groups and the nature of the substitution. Dyes were adsorbed in a majority of conditions when sulfonic acid groups were present. Several sulfonic acid dyes were used in a study of the alteration of crystal habits of ammonium, sodium, and potassium nitrate, as well as ammonium sulfate. The effects of pH and dye presence on the crystal habit of these salts were correlated. In additional publications, Whetstone illustrated the orientation of the dye molecule in relation to the cations and anions on the crystal face where the adsorption occurred. Pleochroism was utilized in determining the face for dye adsorption (391–393). Michaels, Colville, and Tausch studied the effect of cationic and anionic surface-active agents on the growth of adipic acid crystals (394, 395). The effect of cationic and anionic surface-active agents on the growth of adipic acid crystals was studied. X-ray analysis indicated that the linear 6-carbon dicarboxylic molecules are aligned end-to-end in parallel array in the crystal with their long axes parallel to the 010 face so that the 001 face is made up entirely of carboxyl groups, while the 010 and 110 faces contain both carboxylic and hydrocarbon portions of the molecule. Trimethyldodecylammonium chloride (TMDAC) in concentrations of 0.364 mmole was twice as effective in hindering the growth on the 001 face as on the 110 or 010 face. High concentrations of TMDAC caused the formation of very thin plates or flakes. Concentrations of 50 p.p.m. sodium dodecylbenzenesulfonate (SDBS) were three times more effective in reducing growth rates on the 110 and 010 faces than on the 001 face. Higher concentrations of SDBS caused extreme habit modification, the crystals changing from hexagonal plates to long thin rods or needles. Michaels and Tausch reported that the effect of additive depends strongly on the supersaturation level of adipic acid. At low supersaturation, increasing additive concentration results in drastic reduction or cessation of growth on certain faces, while at high supersaturation levels, the additives have relatively little effect on growth, regardless of concentration. Anionic additives significantly accelerated the growth on the 001 face. Additives increased the supersaturation level at which extensive 3-dimensional nucleation occurred, and resulted in better-formed crystals. Michaels and Tausch interpreted their results in terms of 2-dimensional

nucleation and dislocation theories of crystal growth. Mechanisms for growth and habit modification were developed.

Sears reported that lead chloride in a few p.p.m. altered the growth behavior of potassium chloride (396). Sears attributed this alteration to the inhibition of the rate of growth at unit steps and that the rate of two dimensional nucleation was markedly increased by the presence of the impurity. In a second paper Sears stated that the observed alteration of crystal growth by specific soluble impurities was inexplicable by the Frank theory of crystal growth (397). He proposed that the poison was adsorbed at growth steps to give monostep coverage at each step. The growth rate from a step was then controlled by the equilibrium concentration of single unfilled sites in the line of adsorbed atoms. As the concentration of poison increased the number of open sites along a step decreased, and the rate of step motion then decreased. Sears further proposed that if a poison was adsorbed at a step, it reduced the step energy. Thus a growth poison will reduce the critical free energy for two-dimensional nucleation and increase the nucleation rate. Comer presented evidence that cations including stannic, chromium III, and ferric were adsorbed on the surface of primary ammonium phosphate and primary ammonium arsenate (398). The tapering of the crystals in the presence of the foreign cations was explained by the presence of the foreign cation at the intersection of the 100 and 101 plane and the 010 and 011 plane. This inhibited the growth and caused successive layers to deposit at a slight distance in from the intersection of these planes. McCartney and Alexander reported that the rate of nucleation and crystal growth of calcium sulfate dihydrate was most strongly reduced by colloidal materials having regularly ionized carboxyl groups on a chain structure (399). The anionic polymers were most strongly adsorbed on the 111 faces of the crystals.

Polymorphism and Lattice Energy

In 1821 Mitscherlich discovered polymorphism with his work on the dimorphism of calcium carbonate. Since that time a considerable amount has been reported in the literature. In 1958 Eitel reviewed the importance of polymorphism in geological problems; his review included 700 references (400). O'Conner's chapter on the polymorphism of fatty acids represents an excellent review of the massive literature on the subject (62). Additional sources concerning polymorphism include Hartshorne and Stuart (401), Kofler and Kofler (296), McCrone (298), and Jelley (192).

The importance of polymorphism has increased in recent years in pharmaceutical research for several reasons. Analytical errors may develop when analytical methods utilizing physical properties change with a change in crystal structure (306). Polymorphs of a drug differ in total solubility in a given solvent (402). The absorption rate can vary with different polymorphs of a given drug (403). Polymorphism can create problems in terms of crystal growth in suspensions (404). Polymorphic forms can create problems involving differences in filterability (405). The thermal stability can vary with different polymorphs of a drug (298). The success of a new product is seldom independent of its physical form (406).

Polymorphism or transitions from one polymorph to another can be detected by various methods. Observation of transitions with temperature can be easily detected using the Kofler melting point block. Dilatometry has been used to study polymorphism of fats and other compounds (407, 408). Cini and co-workers believe that changes in magnetic anisotropy provide a valuable tool in the study of polymorphism (409). Optical crystallography has been a most valuable tool (253), as has X-ray crystallography (410). Electron microscopy has been utilized for such identifications (411). Infrared spectroscopy has been used with success (412). Surface tension measurements have been utilized in determining the transition temperatures (413, 414).

Various methods can be used for the preparation of various polymorphs of a given compound. Pressure has been used (415, 416). This reviewer has not read any articles dealing with the polymorphism of drugs as affected by pressures used in tablet compression. Temperature changes have been widely used for the preparation of polymorphs and phase diagrams for the temperature variable have been discussed (192, 296, 298, 401). Impurities have been known to cause polymorphism (191), as well as mode of crystallization (191). Solvents have been used for the preparation of polymorphs.

Some fundamental studies of polymorphism are lacking. However, von Sydow (191) attempted to study the dipole effect of the solvent on the polymorphic form of fatty acids isolated, and reported that the study was difficult because the rate of crystallization was not controlled. A second way that the solvent could affect the crystallization was related to the vapor pressure

of the solvent. Two polymorphs of chloracetamide have been isolated using solvents (417). The difference between the cell dimensions was found to be only in the value of the obtuse angle in the unit cell. The alpha form was obtained from nonpolar solutions. These crystals were hard to dissolve in benzene or in carbon tetrachloride. Katayama suggested that these molecules become stable in these solutions by making dimers by hydrogen bonds, and the dimers thus formed come into the crystals having the alpha configuration. These crystals are quite soluble in water or ethyl alcohol and the molecules make hydrogen bonds with the solvent molecules. Katayama concluded that "this will be the reason why the crystals obtained from these solutions have a different structure." In a study of the polymorphism of 17-β estradiol, Smakula, *et al.*, stated that the ability of molecules of a compound to associate in alternate modes of hydrogen bonding of comparable stability can be expected to be a major cause of polymorphism, thereby causing differences in the solid-state spectra of polymorphic substances (418). W. Higuchi, *et al.*, in a study of the polymorphism of methylprednisolone, reported that the lack of structural information on the methylprednisolone system precluded a single interpretation of the entropy of transition. But they suggested that the entropy difference was a result of greater localization of the functional groups in the side chain in form I resulting either from intermolecular or intramolecular interactions (419).

Because of the similarity in structures, the polymorphism of hydrocortisone terbutylacetate and prednisolone terbutylacetate was studied (420). Four polymorphs of each system were isolated, but the isolation methods were not similar.

The transition rates of some polymorphic systems have been studied. Hartshorne and Thackray have studied the α-and β-sulfur systems (421). The activation energy for the transfer of molecules from the beta to the alpha form corresponded closely to the heat of sublimation of the beta form. Thus the molecules in the transition layer at the interface were energetically equivalent to the molecules in the vapor state. Johansson (422) suggested that should the formation of nuclei be a homogeneous process and that all crystals be of the same size, the probability of transition should be the same for each crystal. The course of the transition could be described as

$$-dN/dt = KN \qquad \text{(Eq. 31)}$$

$$N = N_0 e^{-kt} \qquad \text{(Eq. 32)}$$

where N is the number of nontransformed crystals and N_0 is the number of crystals when time is zero. However, when log N was plotted against time, a straight line was not obtained. Thus, the reaction must be heterogeneous and described by

$$N = N_1 e^{-k_1 t} + N_2 e^{-k_2 t} + \ldots \qquad \text{(Eq. 33)}$$

The heat of activation could not be determined for the various nuclei so no conclusions could be made concerning whether or not the number of nuclei was proportional to the surface or the volume of the crystals. Johansson examined the kinetics of the polymorphic transformation since such an investigation might elucidate the influence of a lattice transition on the velocity of reactions in the solid state. In a study of the growth of crystals in the alpha to beta transition in paradichlorobenzene, Bykhovskii, *et al.*, found that the linear growth rate was a function of temperature (423). The temperature dependence of the rate was not in agreement with Hartshorne's supposition that the rate of displacement of the boundary between the phases was determined solely by the difference between the rates of evaporation. Bykhovskii's conclusion was that the material was transferred directly in the solid state as a result of thermal agitation. In the study of the transition rates the results agreed best with the supposition that the alpha to beta, or vice versa, transition in paradichlorobenzene involved a dislocation mechanism in growth.

The rate constant for the reaction of phenylhydrazine with the stable and unstable modification of *o*-methoxybenzaldehyde was determined by Urazovskii (424). Using the metastable form of the aldehyde the rate constant was found to be 4.15 at 3.5°, and persisted at 5, 15, and 25°. The stable form has a much higher rate constant than that of the metastable form. In aqueous dioxane the difference was greater than in aqueous ethanol. The stable form was apparently a hydrogen bonded dimer, whereas the metastable form was chelated by a hydrogen bond. The heat of activation for the stable form was 11,400 cal. per mole and 11,200 cal./mole for the metastable form.

Structural analysis has been valuable in the study of polymorphism. The crystal structure and polymorphism of N-methylacetamide has been reported by Katz and Post (425). The low temperature form changed to the high temperature phase at 10°. Below the transition temperature the unit cell was found to be orthorhombic with 4 molecules per cell. Above the transition temperature, the orthorhombic unit cell contained 2 molecules per unit cell. Along with

this transition there was a reduction in cell size which was brought about by the existence of molecular orientational disorder. The polymorphism of glycine has been studied in detail (183, 184, 426). Three forms, alpha, beta, and gamma, have been isolated. The beta form is unstable. The molecular volume of the three forms was the same within one cubic Å. β-Glycine consisted of hydrogen bonded molecular layers extending parallel to the 010 plane. The layers have the same configuration of molecules as the alpha form. Single layers in the beta form were connected geometrically by the twofold screw axis and held together by hydrogen bonds extending in the *b* direction. In α-glycine the nitrogen atom was buried within the double layer in such a way that very close contact of these two layers occurred. Where molecular layers were discovered in the β-glycine parallel to the *c* axis, molecular double layers held together by hydrogen bonds were found parallel to the *c* axis in α-glycine. γ-Glycine, which showed a marked piezoelectric property along the *c* axis, was found to have a crystal structure nearly the same as that of α-glycine. The bond distances and bond angles were compared with γ- and α-glycine and with α- and β-glycine. The crystal structures of the three forms of the even-numbered fatty acids, *A*, *B*, and *C*, and the four polymorphs of the odd-numbered fatty acids, namely *A'*, *B'*, *C'*, and *D'* are illustrated and discussed by von Sydow (191, 427).

The crystal structures for the polymorphs of acridine have been studied. Acridine was reported to have five distinct polymorphic forms (428). It was found that acridine I was a hydrate. Acridine II and III appeared to have nearly the same free energies at room temperature since neither showed any great tendency to transform to the other and both were produced by the decomposition of I. At higher temperatures II was the stable form. The sizes of the unit cells, lattice energies, and volumes per molecule were almost equal (172–174). A comparison of the packing of anthracene and acridine III was shown. The acridine II consisted of two molecules in the asymmetric unit cell and exhibited significant departure from planarity. This was also evidenced from the lack of fluorescence of the crystal. Birks and Cameron reported that fluorescence in aromatic compounds is associated with planarity (429). The fluorescence was determined by the presence and configuration of the π electrons in the molecule. Phillips, *et al.*, reported that the apparent molecular thermal motions in I, II, and III were of the same type but that the translational components of the mean square amplitudes of vibration appeared to be higher in the acridines than in the anthracenes. This result may explain the lower melting point of the acridines than anthracene. Phenazine has been found to be dimorphic (430, 431). Indigo has been found to be dimorphic. The value of $a \cdot \sin \beta$ was found to be the same for the two forms. However, the change of one form to the new form occurred by a slip of about $c/4$ of the molecular plates parallel to the *YOZ* plane (432).

One of the most difficult polymorphic problems to solve was that of cortisone acetate. Several patents have been issued (433–440). The polymorphs of cortisone acetate were detected by infrared spectra (441, 442). Most recently, Callow and Kennard correlated the previous work (443). There is evidence of six crystalline modifications or solvates of cortisone acetate. Five forms of cortisone acetate and methods of their isolation along with photomicrographs were presented by Callow and Kennard. They reported that forms II, III, IV, and V as intact crystals are stable for some time in the presence of water, but when shaken or ground, transformation to form I takes place rapidly. Crystals of form II were apparently unchanged in water after 126 hours, whereas in a shaking machine a change was seen after 20 hours and was complete after 60 hours. If the crystals were ground, transformation could take place in 4 hours, but probably because of caking of suspensions, complete transformation still took about 56 hours. Form IV was found to be a dihydrate which was found to be unstable in water at room temperature. This reviewer, in a study of the polymorphism of cortisone acetate, noted that crystals from aqueous alcohol, presumably form IV, gradually changed to another form when stored at room temperature free from solvent. This change was followed easily by noting the change in the refractive indexes of the crystals.

Polymorphism has been recorded for many steroids and natural and synthetic drugs. It would be impossible to list all of the forms of the various drugs that have been reported in the literature. Though temperature studies have been reported, infrared patterns interpreted, speculations on hydrogen bonding made, little or nothing can be said of the exact molecular orientations. Much work must be done, and perhaps it is up to the X-ray crystallographers to move in.

Polymorphism has been investigated from a thermodynamic point of view. Staveley discussed, in length, the transitions in solids and liquids (444). Hurst obtained a second-order differential equation in the variable p and T which is valid for all phase equilibria of the first and second orders (445). A first-order phase transition is accompanied by the absorption or evolution of latent heat. Second-order transitions differ from first-order transitions in that there is no evolution or absorption of latent heat. Hurst says that a second-order transition is to be regarded as the limiting case of a first-order transition with infinitesimally small ΔV. The heat, entropy, and temperature of transition have been calculated for the forms I and II of methylprednisolone (419). The escaping tendency, or fugacity, for the two polymorphs was determined by solubility studies. It was found that the transition temperature was 118°, that the $\Delta H^{\circ}_{I,II}$ was 1600 cal. per mole, and that the entropy change at the transition point was 4.1 e.u. Exploratory studies involving cloud point determinations indicated that much more energetic crystal forms were probable.

Frederick (404) reported that one of the most important elements of polymorphs is that the different forms of the same drug differ in their solubility properties. Wagner (446) pointed out the significance of differences in dissolution rate *in vivo* of drugs (of different brands of dosage forms of the same drug). The dissolution rate of a compound is proportional to the solubility of the drug in the solvent (447). From these relationships it can be concluded that one polymorphic form may have a greater activity than a second polymorphic form. Higuchi, *et al.* (419), stated that the activity of the more energetic form of methylprednisolone was found to be of the order of 80% greater than that of the more stable form. In an *in vivo* study of the forms I and II of methylprednisolone, Ballard and Nelson (403) found that the mean absorption rate in mg. per hr. per cm.^{2} was approximately 1.7 times as great with form II than with form I. This study was performed by preparing pellets of the drug for implantation. Rats were used in the investigation. In discussing the physical chemical analysis of percutaneous absorption, Higuchi stated that substances showing lower melting points generally permitted higher concentration in solution and would thus tend to give faster penetrating systems. He stated that it would be difficult to produce rapid absorption of high melting point compounds (448). Higuchi also pointed out that different crystalline modifications may exist having different free energies, thus different thermodynamic activities at room temperature. As to the choice of polymorphs of a given drug, it may be pointed out that in 1952 Dale received a patent for the development of a polymorph of riboflavin which possessed much greater solubility and therefore a more useful form of the vitamin (402).

One can conclude then that the lattice forces are important in terms of the availability of the drug for utilization. Pirsch has contributed to the question of the lattice forces of organic molecules (449). In recognition that the form of the spatial filling of organic molecules is of decisive influence on the magnitude of the molar heat of fusion, Pirsch arranged organic molecules into three large spatial types, according to the magnitude of their molar heat of fusion. These three spatial groups were classified as (*a*) chain molecules, (*b*) disk molecules, and (*c*) spherical molecules.

Organic compounds of the spherical structures show small fusion entropy values and low molar heats of fusion. As a rule, these types of compounds demonstrate no polymorphic changes near the melting point. Closely above the melting point, liquid crystals should persist. The molar heat of fusion is greater for the disk and chain compounds, with the latter showing the highest values. A relationship was presented characterizing the linear dependence of the molar heat of fusion on the position of the melting point

$$\Delta_E H = k(T_e - a) \qquad \text{(Eq. 34)}$$

in which k and a are characteristic constants for each spatial form type. Just as a higher energetic form would be desirable for drug availability *in vivo*, a higher energetic form may not be the most suitable form for drug stability. Higuchi and Guillory determined the stabilities of derivatives of vitamin A (450). The investigators found that the relative rates of degradation of series of similar solid derivatives measured at any temperature were such that the logarithm of the rates was a linear function of the reciprocal of their melting points. Thus a strong lattice offers a stabilizing effect.

An additional consideration in drug availability from the crystalline state would be solvates. Rose, *et al.*, have reported that *trans*-diethylstilbestrol forms solvates when crystallized from chloroform, benzene, ether, 2-propanol, methanol, and acetic acid (214). Rose also reported that erythromycin formed an acetone and chloroform solvate which readily lost solvent

on exposure to air and converted to a powder (279). Gramicidin forms a solvate with acetone which is apparently lost on drying. Different forms were obtained from various solvents (451). Ballard and Nelson (403) reported that anomolous results were obtained when anhydrous tetracycline pellets were implanted *in vivo* (rats). They suggested that the anhydrous tetracycline at body temperature was converted to the trihydrate. Higuchi and Shefter (452) recognized that many drugs exhibit a strong tendency to form discrete hydrate structures, but that much less was known concerning the formation of solvates with organic solvents. These investigators showed that the normal amyl alcohol solvate of fludrocortisone acetate had at least five times the solubility of the nonsolvated species, while there was a twofold increase with the ethyl acetate solvate. The anhydrous forms of caffeine, theophylline, glutethimide, and cholesterol showed a greater dissolution rate than did the corresponding hydrates.

A different approach to drug availability was reported by Sekiguchi and Obi (453). These investigators compared the absorption of sulfathiazole to an eutectic mixture of sulfathiazole. Eutectics with sulfathiazole were prepared using ascorbic acid, acetamide, nicotinamide, nicotinic acid, succinimide, or urea. The urea eutectic was studied *in vivo*. Where sulfathiazole had a melting point of about 200°, the eutectic mixture of 52% sulfathiazole and 48% urea by weight melted at 112°. It was reported that the solubility of sulfathiazole decreased slightly with a continued increase by weight of urea. In a study of the report Nelson (454) stated that the 8-hour cumulative urinary excretion of the eutectic was 50%, while the 8-hour cumulative urinary excretion of the normal sulfathiazole was 39%. In Nelson's studies he reported that using finely powdered sulfathiazole the 8-hour cumulative urinary excretion was 75%.

It is evident that similar studies will follow. A fruitful area should be complexation. Drugs forming clathrates, channel lattice type complexes, as well as the possible complexation of nonpolar aromatics with heterocycles could be investigated. It would be well at this point for the investigator to review the fusion studies of the Kofler group and the McCrone group.

Infrared Analysis of Pharmaceuticals III

Identification and Determination of Adrenocortical Steroids, Barbiturates, and Sulfonamides from Paper Chromatograms

By ALMA L. HAYDEN

The adrenocortical steroids: cortisone, hydrocortisone, and 17-hydroxy-11-desoxycorticosterone, have been identified and estimated from paper chromatograms in amounts between 50 mcg. and 1.5 mg. Recoveries of 90 to 105% of these steroids were obtained on the basis of infrared spectrophotometric determinations. Analyses were made of commercial tablets which contained (*a*) hydrocortisone and 17-hydroxy-11-desoxycorticosterone, or (*b*) the sodium salts of phenobarbital, butabarbital, and pentobarbital. The results agreed within 3.8% with those published earlier (9), or with the declared amounts. In addition, the identification and estimation of sulfanilamide in a sulfacetamide powder were achieved by these methods.

PAPER CHROMATOGRAPHY allows the rapid separation of microgram quantities of compounds. However, the coincidence of R_f and mobility values for a standard and a sample does not afford positive identification in all cases. The value of this separation technique is greatly enhanced when it is combined with other identification methods.

In addition to other applications, paper chromatography and infrared spectroscopy have been combined in the investigation of steroids in human placenta (1). Recently, the use of these

Infrared Analysis of Pharmaceuticals III

Identification and Determination of Adrenocortical Steroids, Barbiturates, and Sulfonamides from Paper Chromatograms

By ALMA L. HAYDEN

The adrenocortical steroids: cortisone, hydrocortisone, and 17-hydroxy-11-desoxycorticosterone, have been identified and estimated from paper chromatograms in amounts between 50 mcg. and 1.5 mg. Recoveries of 90 to 105% of these steroids were obtained on the basis of infrared spectrophotometric determinations. Analyses were made of commercial tablets which contained (*a*) hydrocortisone and 17-hydroxy-11-desoxycorticosterone, or (*b*) the sodium salts of phenobarbital, butabarbital, and pentobarbital. The results agreed within 3.8% with those published earlier (9), or with the declared amounts. In addition, the identification and estimation of sulfanilamide in a sulfacetamide powder were achieved by these methods.

PAPER CHROMATOGRAPHY allows the rapid separation of microgram quantities of compounds. However, the coincidence of R_f and mobility values for a standard and a sample does not afford positive identification in all cases. The value of this separation technique is greatly enhanced when it is combined with other identification methods.

In addition to other applications, paper chromatography and infrared spectroscopy have been combined in the investigation of steroids in human placenta (1). Recently, the use of these

methods in studies of triamcinolone and related steroids (2), and of caffeine, antipyrine, and phenacetin from human tissue (3) has been reported. Techniques have been published (4–6) whereby the spectra of 100 mcg. and less of some pure crystalline compounds in potassium bromide have been obtained. However, impurities in filter paper and solvents have made the analyses of microgram quantities from paper chromatograms extremely difficult. The instability of some compounds and solvents to evaporation techniques has magnified this problem.

In the present study, mixtures of cortisone and hydrocortisone, in amounts between 50 mcg. and 1.5 mg., were separated on washed Whatman No. 1 filter paper with a chloroform-formamide solvent system (7). After extraction from the chromatograms, the steroids were identified by their infrared spectra in potassium bromide plates and disks. The spectra of samples in amounts less than 100 mcg. were obtained using corresponding blanks in the reference beam and the Perkin-Elmer ordinate scale expander (8). The spectra of samples in amounts greater than 180 mcg. were obtained without compensation or spectrum expansion.

The combined method was applied to commercial tablets which contained hydrocortisone and 17-hydroxy-11-desoxycorticosterone, or pentaerythritol tetranitrate and the sodium salts of phenobarbital, butabarbital, and pentobarbital. The results of the analyses agreed within 3.8% with those reported previously (9), or with the declared amounts. In another application, a commercial sample of sulfacetamide was found to contain about 17% sulfanilamide.

EXPERIMENTAL

Preliminary Infrared Study of the Corticosteroids.—A preliminary study was made to determine the practical amounts of pure cortisone, hydrocortisone, and 17-hydroxy-11-desoxycorticosterone which could be identified by infrared spectroscopy. Dried residues of the steroids, from chloroform and from methanol solutions (0.50 mg. or 1.00 mg. per ml.), in amounts of 50 mcg. to 1.0 mg., were investigated. Amounts of 250 mcg. and above were hand-ground with 200.0 mg. of dry potassium bromide (Harshaw, infrared quality, 200/325 mesh) for exactly 2 minutes. Amounts of 50 to 250 mcg. were hand-ground with 40.0 mg. potassium bromide. The mixtures were dried at 105° for 30 minutes and cooled to room temperature.

A Beckman evacuable die, 0.5 inch in diameter, was used to press the mixtures. A force of 20,000 or 25,000 pounds was applied during evacuation. The 200-mg. loads were pressed into disks 12.7 mm. in diameter. Portions of the 40-mg. loads were pressed into 3 × 10 mm. plates in pressed paper or potassium bromide peripheries (10–12) 12.7 mm. in diameter. Approximately 30 to 35 mg. was needed to fill the 3 × 10 mm. window. The disks and plates were heated at 105° for 15 minutes, and were cooled to room temperature in a desiccator.

The infrared spectra were obtained on a Perkin-Elmer model 21 double-beam spectrophotometer which was equipped with sodium chloride optics, a microcell adapter, and an ordinate scale expander (8). The sample plates and disks were inserted in the sample beam with a holder which fitted the microcell adapter. An optical wedge was placed in the reference beam to compensate for opacity of the pressed paper peripheries. For amounts of 180 mcg. and above of the steroids, spectra of the region between 2 and 15 μ were obtained using the normal (1×) qualitative instrument settings. The spectra of amounts less than 180 mcg. were weak (less than 20% absorption) and poorly defined under the 1× conditions. Therefore, the ordinate scale expander (8) was employed to magnify electrically the pen movement, relative to the optical wedge movement, to five times (5×) its normal (1×) movement. The resulting spectra were similar to, but less defined than, those of amounts greater than 180 mcg.

Spectra of pure compounds which absorb less than 10% or 5% of the incident radiation may be expanded 10 and 20 times, respectively. However, interference from trace impurities in paper chromatogram extracts and poorly resolved spectra limit the usefulness of these expansions.

Paper Chromatography of the Corticosteroids.—Just prior to use, Whatman No. 1 sheets (8 × 8 in.) were eluted, continuously, with methanol for at least 4 hours in an ascending chromatograph tank (13). The sheets were air-dried for at least 30 minutes and were viewed in ultraviolet light (2453Å.). The strongly fluorescent solvent-front area (about 1 cm. deep) along the top edge of the sheet was discarded. The starting line was ruled on the side of each sheet 3 cm. from the edge opposite the solvent-front area. The sheets were used within 24 hours after washing.

About 200 ml. of chloroform (U.S.P. or A.C.S. specifications) was equilibrated with 50 ml. of redistilled formamide for at least 30 minutes. Chromatography tanks were lined with blotter paper and were equilibrated with the chloroform phase for 30 minutes prior to chromatography (13). A solution of the equilibrated formamide in methanol (30:70) was used to impregnate the washed sheets. Excess immobile phase was removed by placing the impregnated sheets between layers of paper towels.

Aliquots of methanolic solutions of cortisone and hydrocortisone (about 1.0 mg./ml.) were applied in mixtures along the starting line of the impregnated sheets. Aliquots containing 50 to 100 mcg. of the steroids were applied, with intermittent air-drying, in spots 1 cm. in diameter. Amounts of 180 mcg. to 1.0 mg. were applied in streaks, 1 cm. × 3 cm. or 1 cm. × 14 cm., in the same manner. Amounts between 100 and 180 mcg. were not studied. After application of the samples, portions of the formamide-methanol solution (0.01 or 0.20 ml.) were added to the spots or streaks to reduce sample adsorption at the starting line (14). The sheets were subjected to ascending chromatography for

about 1 hour. During this time, the solvent traveled approximately 18 cm.

The chromatograms were dried, partially, at room temperature for 30 minutes. The steroid zones were located by their ultraviolet absorbance, using a phosphorescent screen (15), and were outlined on tracing paper. The corresponding zones on the partially dried chromatograms were cut into small rectangular pieces and were suspended in 4.0 ml. of dilute hydrochloric acid (about 0.0025 *N*) in separators. The suspensions were extracted with four 4.0-ml. portions of chloroform, allowing at least 1 minute for each extraction. The extracts of each suspension were washed, successively, with the same 3.0-ml. portion of water, and were filtered through chloroform-washed glass wool into a 50-mm. mullite mortar. The 4.0-ml. extracts of each zone were concentrated, in succession, under nitrogen at about 35°. The extracts were evaporated to dryness only after addition of the final portion of chloroform. The residues were dried in vacuum over phosphorus pentoxide for 30 minutes.

Infrared Spectrophotometry of the Extract Residues.—The dried residues were made into plates or disks as described for the direct standards. For amounts of 180 mcg. and more, the normal (1×) spectra were obtained without blank compensation or ordinate expansion. The spectra of the extracted steroids, in amounts of 100 mcg. and less, were weak and poorly defined, and were affected by small amounts of impurities from the paper and solvents. As a result, compensation with a paper-blank extract and 5 × expansion of the ordinate scale were required to obtain identifiable spectra.

Preliminary studies revealed that compensated spectra may be obtained in two ways. In the instrument used, the microcell-sample position is recessed from the macrocell-sample and reference positions. As a result, the reference beam is larger and less intense per unit area at the sampling position than is the sample beam at the microcell-sample position. A standard disk or plate placed in the latter position absorbs about 1.1 times more strongly than when it is placed in the macro-sample position. Therefore, for compensation, a disk of given effective concentration (concentration × thickness) in the micro-sample position requires a disk 1.1 times as concentrated in the reference position (method I). In method II, since the beams at the macro-sample and reference positions are equivalent, a disk in the macro-sample position is compensated by one of the same effective concentration in the reference position (method II). The holders for the macro-sample and reference positions were rectangular metal plates, 74 × 50 mm., with a central 30 × 7 mm. aperture. Tension clips were soldered on each side of the aperture to position the disks or plates.

Therefore, for compensation, blank paper zones, taken from the same chromatogram and corresponding in weight to the 50 to 100-mcg. steroid zones, were extracted in the manner described above for the steroid zones. The dried residues were ground with 36 mg. (method I) or 40 mg. (method II) of potassium bromide. The mixtures were treated in the same manner as was described for the direct steroids.

In method I, uncompensated scans of the 2 to 15 μ region were made of the sample and of the blank plates in the microcell-sample position under 1 × conditions. At the wavelength of maximum transmission (usually near 5 μ) with the sample in the beam, the blank plate was adjusted in the reference beam to give approximately 95% transmission. The compensated spectrum was obtained between 2 and 15 μ using 1× instrument settings. At the wavelength of maximum transmission, the instrument conditions were changed to those of 5× expansion. The pen was adjusted to 95% transmission with the pen position control. The instrument was reversed to 2 μ without further change. A slow scan of the 2 to 15 μ region was made. In method II, uncompensated scans of the 2 to 15 μ region were made of the sample and of the blank plates in the macro-sample position under 1× conditions. All other operations were identical to those used in method I.

The spectra of the samples were compared with those of disks and plates of the direct standards. The estimated recoveries of cortisone and hydrocortisone were calculated from the normal 1× absorbance at 5.82 μ or 6.02 μ (9) by comparison with the direct standards. The absorptivity coefficients for the direct standards, K_s, were calculated from the equation

$$K_s = (A_s \times H_s)/(C_s \times L_s)$$

In this equation, A_s is the baseline absorbance and H_s is the band width at one-half the height of baseline absorbance of the chosen band, C_s is the ratio of the weight of the standard to the weight of potassium bromide, and L_s is the average thickness of the disk or plate area exposed to the sample beam. The recoveries of the chromatographed steroids were calculated by inserting the appropriate absorptivity coefficient in the following equation

$$\frac{A_u \times H_u}{L_u \times K_s} \times M \times \frac{100}{W} = \text{per cent recovery}$$

A_u and H_u represent the baseline absorbance and half-band width of the sample band, L_u is the average thickness of the exposed sample disk or plate, M is the weight of potassium bromide, and W is the weight of the applied sample.

Analyses of Commercial Products

Hydrocortisone Tablet.—A commercial tablet, declared to contain 20 mg. of hydrocortisone, was suspended in 10 ml. of 0.01 *N* hydrochloric acid. The suspension was extracted with four 25-ml. portions of chloroform. Each chloroform extract was washed with the same 5-ml. portion of 5% sodium carbonate and, finally, with 5 ml. of water. The chloroform was evaporated at about 35° under a stream of nitrogen. The residue was dissolved in absolute methanol and was diluted to 25 ml. in a volumetric flask. A 1.0-ml. aliquot was applied in a streak (1 × 14 cm.) to the starting line of a washed, impregnated sheet of Whatman No. 1 filter paper (8 × 8 inches). The sheet was subjected to ascending chromatography for 50 minutes, and the steroids were detected, extracted, and incorporated into disks (200 mg., 12.7 mm. in diameter) as described earlier.

The spectra were compared, under 1× conditions

between 2 and 15 μ, with those of standard hydrocortisone and 17-hydroxy-11-desoxycorticosterone. Quantitative baseline absorbance and half-band width measurements were made at 5.82 μ for hydrocortisone and at 5.99 μ for 17-hydroxy-11-desoxycorticosterone. The absorptivity coefficient, K_s, for the appropriate standard was inserted in the following equation to obtain the amount of steroid per tablet

$$\frac{A_u \times H_u}{L_u \times K_s} \times M \times \frac{V_t}{V_a} = \text{mg. per tablet}$$

The terms A_u, H_u, L_u, K_s, and M were described earlier. V_a represents the aliquot of the total volume, V_t, taken for analysis.

Tablets of "Triple-barb" (total, 8.0 mg.) and Pentaerythritol Tetranitrate (10.0 mg.).—A sample of powdered tablet mixture containing 8.0 mg. of "Triple-barb" (sodium salts of phenobarbital, butabarbital, and pentobarbital, in equal amounts) was suspended in 5.0 ml. of water in a separator, and 5.0 ml. of 10% sulfuric acid was added. The active ingredients were extracted with chloroform, and the barbiturates were trapped on a Celite-potassium phosphate column as described by Carol (16). The amount of pentaerythritol tetranitrate in a 25.0-ml. aliquot of the chloroform effluent was determined as described (16).

The barbiturates were eluted from the column with chloroform-acetic acid (150 + 15 ml.) and the solvents were evaporated at about 55° under a stream of air. The barbiturate residue was dissolved by warming in three portions of acetone-hydrochloric acid (15 + 0.5 ml.). The solutions were filtered through glass wool, and the combined filtrates were concentrated to about 2 ml. as described above. The concentrate was diluted to 5.0 ml. with acetone.

Immediately, the barbiturates were separated by a modification of the Sabatino procedure (17). A 0.50-ml. aliquot of the barbiturate solution was applied in a streak to washed filter paper. The filter paper was mist-sprayed with 0.5 M sodium carbonate and was subjected to continuous ascending chromatography (13) for 4 hours with ethylene chloride as the mobile solvent.

The chromatogram was air-dried, and the three ultraviolet absorbing zones were suspended in 5.0-ml. portions of 5% hydrochloric acid. The suspensions were extracted and the extracts were treated as described for the steroids. The extract residue of each barbiturate was dissolved in 0.50 ml. chloroform; 3.0 ml. n-heptane was added, and the solvents were evaporated under nitrogen at about 35°. Crystalline samples of the standards (about 250.0 mcg.) were treated in the same manner. Potassium bromide disks (200 mg., 12.7 mm. in diameter) were prepared of the solid residues. The disks of phenobarbital and butabarbital were heated at 105° for 30 minutes. Because of difficulty in controlling the polymorphic forms, the disks of pentobarbital were heated above the melting point of pentobarbital at 143° for 30 minutes. The disks were cooled to room temperature, and the uncompensated quantitative spectra were obtained between 5.3 and 6.6 μ using normal 1× instrument conditions.

From the baseline absorbances A_u of the bands near 5.65 and 5.85 μ, and the average thicknesses L_u of the disks, the amounts of the barbiturate sodium salts per tablet were calculated from the following equations

$$A_s/C_s \times L_s = K_s$$

$$\frac{A_u}{L_u \times K_s} \times M \times \frac{V_t}{V_a} \times \frac{T}{W} \times Z = \text{mg./tablet}$$

The terms A_u, L_u, M, V_t, and V_a were described earlier. T and W represent the average weight per tablet and the sample weight, respectively. Z is the ratio of the molecular weight of the sodium salt to that of the barbituric acid.

The identities of the chromatographed barbiturates were proved by comparing their spectra (1×) in the 2 to 15 μ region with those of the direct standards.

Mixture of Sulfacetamide and Sulfanilamide.—A 100.0-mg. sample of the commercial powder was dissolved in 1.0 ml. of ammonium hydroxide and the solution was diluted to 10.0 ml. with water. A methanol-washed filter paper sheet was impregnated with formamide-acetone (30:70) as described by Maienthal and co-workers (18). A 0.100-ml. aliquot of the sample solution was applied in a streak (1 × 14 cm.) as described previously. The filter paper was subjected to continuous ascending chromatography for 3 hours with chloroform-tertiary butyl alcohol (100 + 6 ml.) as the mobile solvent.

The sheet was air-dried in the dark for about 1 hour and was viewed, briefly, under ultraviolet light. The ultraviolet-absorbing sample zones were outlined, cut into small rectangles, and extracted by warming with four 10.0-ml. portions of acetone for 15 minutes. Each extract was filtered through glass wool, the filtrates were evaporated to near dryness, and the concentrate was transferred to a 50-mm. mortar with several small portions of acetone. The sample solutions and 2.0-ml. aliquots of standard sulfacetamide and of sulfanilamide in acetone (0.200 mg./ml.) were evaporated to dryness as described previously. The residues were dried at 80° in a vacuum oven for 1 hour. The cooled residues were triturated with 2 ml. of heptane for about 10 minutes and the solvent was evaporated at 35° under nitrogen.

Potassium bromide disks (200.0 mg., 12.7 mm. in diameter) were prepared of the sulfacetamide standard, and sample residues, and of the sulfanilamide standard. A potassium bromide rectangle (3 × 10 mm.) in pressed paper periphery was prepared of the sulfanilamide paper chromatography residue. Quantitative spectra were obtained of the heated standard and sample disks and plate between 8.0 and 9.75 μ. Measurements were made of the baseline absorbance and the band widths at two-thirds the height of absorbance of the 9.16 μ band. The per cent of each compound in the commercial mixture was calculated using the equation

$$\frac{A_u \times H_u}{L_u \times K_s} \times M \times \frac{V_t}{V_a} \times \frac{100}{W} = \text{per cent recovery}$$

The identities of the extract residues were proved by comparison of the spectra (1×) of their disks or plates in the 2–15 μ region with those of the direct standards.

RESULTS AND DISCUSSION

Table I shows that cortisone and hydrocortisone are well separated even in 1:8 and 11:1 mixtures. Except for slightly lower values for the 50-mcg. zones, the mobilities were reproducible.

In Fig. 1 are spectra of chromatographed cortisone (II, 180 mcg.) and hydrocortisone (IV, 1.46 mg.) obtained under normal 1× conditions. The uncompensated spectra are identical to those of the corresponding direct standards (I, 180 mcg.; and III, 470 mcg.) and to published spectra (12). Figure 2 gives expanded (5×) spectra of chromatographed cortisone (I, 50 mcg.) and hydrocortisone (II, 100 mcg.) compensated with corresponding blanks. In general, the expanded spectra are similar to but less resolved than those obtained under normal operating conditions. The background absorbance in the C—H stretching and bending regions is due to uncompensated impurities from the paper and solvent.

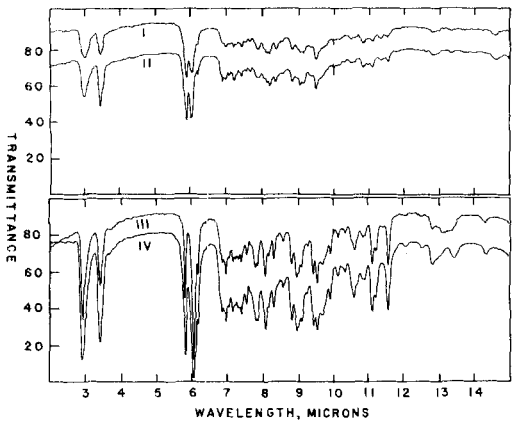

Fig. 1.—Infrared spectra of chromatographed cortisone (II) and hydrocortisone (IV) and the corresponding direct standards (I and III).

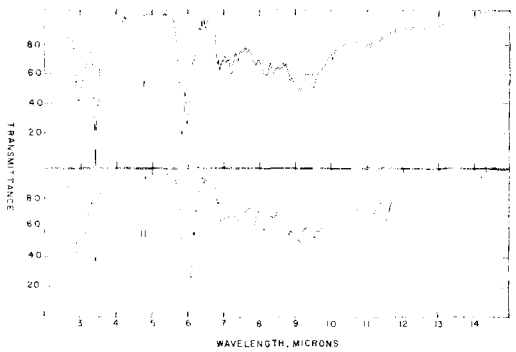

Fig. 2.—Expanded (5×) infrared spectra of chromatographed cortisone (I, 50 mcg.) and hydrocortisone (II, 100 mcg.)

The background absorbance was reduced by using freshly washed paper, by extracting chromatograms while they were still damp, by using a minimum volume of chloroform, and by evaporating the extracts immediately under nitrogen. Evaporation of washed commercial chloroform revealed a negligible residue. Where significant residues are obtained, the commercial chloroform should be redistilled or otherwise purified. The stopcocks were wetted with water only; other lubricants were avoided. All containers were rinsed with a suitable solvent before use. Background absorbance was greatly increased if ethyl alcohol was used as a rinse or as a stabilizer of the chloroform extracts. When the washed sheets were allowed to stand for days or weeks before use, the absorbance of paper blanks was increased.

Some estimations of the recoveries of the chromatographed cortisone and hydrocortisone were made by comparisons with the direct standards. The results of these analyses are given in Table II. Recoveries of 90 to 105% of the applied steroids were obtained. The lowest recoveries were obtained with amounts of 50 to 100 mcg. For best qualitative and quantitative results, it is recommended that amounts of 180 mcg. or greater of the steroids be used.

Paper chromatography of the hydrocortisone tablet extract revealed two ultraviolet absorbing zones. The more polar zone (2.0–4.4 cm.) corresponded to hydrocortisone in mobility. The less polar zone (9.3–11.7 cm.) had a mobility similar to 17-hydroxy-11-desoxycorticosterone. The infrared spectra of the extracted materials were identical to the standards. Quantitative measurements were made of the chromatographed steroids and the corresponding standards. Hydrocortisone and 17-hydroxy-11-desoxycorticosterone were present in the tablets in amounts of 46.1 and 53.9%, respectively. Previous analyses of this tablet by column chromatography and infrared spectrophotometry (9) revealed 47.5% hydrocortisone and 52.5% 17-hydroxy-11-desoxycorticosterone.

The paper chromatogram of the barbiturate fraction revealed three ultraviolet absorbing zones with mobilities similar to those of phenobarbital (2.0–3.8 cm.), butabarbital (4.1–6.1 cm.), and pentobarbital (6.4–8.8 cm.). The mobilities were dependent on the amount of immobile phase used to impregnate the paper. The infrared spectra of the paper chromatogram extracts were identical to those of the corresponding standards. The recoveries (Table III) agreed within 3.8% with the declared amounts.

The paper chromatogram of the sulfacetamide sample revealed two ultraviolet zones which corresponded in mobility to those of standard sulfacetamide (1.6–3.4 cm.) and sulfanilamide (0.0–1.6 cm.). The identities of these components were confirmed by comparing their infrared spectra with those of standard sulfacetamide and sulfanilamide. Sulfacetamide and sulfanilamide constituted 70.1 and 17.0%, respectively, of the total powder (Table III).

From these results, the general usefulness of the combined method is apparent. To the rapid and efficient paper chromatographic separation is added the specificity of the infrared spectra. The method should be adaptable to a variety of compounds. With modifications, such as the use of guide strips for color development, the study of ultraviolet transparent compounds could be made.

It is possible that improved qualitative and quan-

	Pentobarbital sodium	2.67	2.77	103.7
3	Sulfacetamide	100.00	70.10	70.1
	Sulfanilamide	0.00	17.00	17.0

[a] Pentaerythritol tetranitrate was present as 101.15% of declared amount.

titative results can be obtained on amounts less than 100 mcg. by using especially purified solvents and paper. Additional purification steps would be required in the analysis of compounds from biological media. It is anticipated that this method will be useful in the analyses of compounds from varied origins. Instruments equipped with beam condensers can be used if the aforementioned differences in beam sizes are considered.

SUMMARY

Cortisone and hydrocortisone were extracted from paper chromatograms and identified by their infrared spectra. The range of recoveries of amounts of 50 mcg. to 1.5 mg. was 90 to 105%. Analyses of commercial preparations, which contained corticosteroids, barbiturates, or sulfonamides, were achieved by paper chromatography and infrared spectrophotometry.

Relationship Between *in Vitro* Disintegration Time and *in Vivo* Release of Vitamins from a Triple-Dose Spaced-Release Preparation

By A. B. MORRISON, C. B. PERUSSE, and J. A. CAMPBELL

Studies were conducted on the relationship between *in vitro* disintegration time and *in vivo* release of riboflavin, thiamine, and niacinamide in a multivitamin product consisting of three component spheres which disintegrated at different times. *In vitro* disintegration times were determined using apparatus and fluids described in U.S.P. XVI. None of the three vitamins was fully available in the intact product, as measured by the rates of urinary excretion of riboflavin, thiamine, and N′-methylnicotinamide after dosing human subjects. Spheres which showed incomplete availability as measured by urinary excretion of riboflavin were also relatively unavailable when excretion of thiamine or N′-methylnicotinamide was used as the criterion of adequacy. No evidence was obtained that the delayed disintegration of some of the spheres produced sustained release properties *in vivo*. One of the spheres was recovered essentially intact from the feces of two subjects. It was concluded that measurement of riboflavin excretion provides a valid indication of physiological availability of vitamin preparations and that limits for *in vitro* disintegration time based on riboflavin excretion are also applicable to other vitamins.

EARLIER work from this laboratory (1, 2) demonstrated that sugar coated tablets must disintegrate within 60 minutes (30 minutes in simulated gastric juice and 30 minutes in simulated intestinal juice) in order to show full availability of riboflavin. In additional studies (3), it was concluded that enteric coated riboflavin preparations should withstand the action of simulated gastric juice for 60 minutes and then disintegrate within 30 minutes in simulated intestinal juice, in order to show full availability of riboflavin. Little information is available on the relationship between *in vitro* disintegration time and physiological availability for other vitamins. The appearance on the market of a new "spaced-release" vitamin preparation offered an opportunity to examine the validity of proposed limits for disintegration time, using other vitamins in addition to riboflavin. The present report deals with the results of these studies.

METHODS

The product was purchased on the retail market in the United States and consisted of three "spaced-release" spheres contained within a gelatin capsule. Each sphere contained 3.33 mg. of thiamine hydrochloride, 1.67 mg. of riboflavin, and 16.7 mg. of niacinamide; one-third of the total dose of each vitamin in the product. One sphere was designed to release its ingredients immediately, whereas the second and third spheres were designed to release the vitamins contained therein approximately 3 and 6 hours later, respectively. The three spheres differed from each other, therefore, only *in vitro* disintegration time.

Physiological availability values for riboflavin, thiamine, and niacinamide were determined with the intact preparation and each of the three spheres. The procedure used to determine physiological availability was the same as that described previously (4, 5). Riboflavin, thiamine, and N′-methylnicotinamide levels were determined in the urine of 5 to 7 normal male subjects before dosing and after administration of standard or test preparations. The amounts obtained in the urine after dosing were corrected by subtracting the appropriate blank values determined on the urine of the same subjects. The blanks were determined over several days, to reduce the effect of daily variation. The subjects received doses of 5 mg. of riboflavin or 50 mg. of niacinamide in rapidly disintegrating standard tablets, as well as in the intact product and its component spheres. Because each sphere contained only one-third of the total dose in the product, it was necessary to give three spheres of each type in this portion of the studies. To provide a valid comparison with the rates of excretion of riboflavin and N′-methylnicotinamide after giving the intact preparation, the subjects also received the standard doses of riboflavin and niacinamide in divided dose form, as described previously (4, 6).

In the thiamine studies, the dose was only one of each sphere, and the resultant urinary excretion of thiamine was compared with that found after giving 3.33 mg. of the vitamin in solution. The dose was intentionally kept low because of the fact that large doses of thiamine are not absorbed efficiently (5, 7). The availability of thiamine in the intact product was determined by comparing urinary excretion of thiamine after giving 10 mg. of the vitamin in divided doses with that found after giving the product. It was necessary to use the divided dose standard for this purpose because of previous findings (5) that administration of 10 mg. thiamine in divided dose form markedly increased urinary excretion of the vitamin over that found when the same total dose was given at one time.

Received September 6, 1961, from the Food and Drug Laboratories, Department of National Health and Welfare, Ottawa, Canada.
Accepted for publication October 16, 1961.

Riboflavin and thiamine in the product and in urine were determined by the U.S.P. XVI fluorometric procedure (8) and by the thiochrome method of Mickelsen, *et al.* (9), respectively. Niacin in the product was determined by the U.S.P. XVI procedure (8), whereas urinary N′-methylnicotinamide was determined by the fluorometric procedure of Pelletier and Campbell (10). Curves of net rate of excretion were plotted on semilogarithmic paper, as suggested by Swintosky, *et al.* (11).

In vitro disintegration times for the three spheres were determined using the apparatus and fluids described in U.S.P. XVI (8). Disks were used in both the gastric and intestinal juice phases of the test. The spheres were immersed in simulated gastric fluid for 30 or 60 minutes and the remainder of the time in simulated intestinal fluid. Disintegration times reported were means of two separate tests on six spheres each.

Sphere R was given to two subjects and the feces were collected for a period of 48 hours after dosing. Undissolved spheres were recovered from the feces and analyzed for thiamine, riboflavin, niacinamide, folic acid, and ascorbic acid. With the exception of folic acid, which was analyzed by the procedure of Pelletier and Campbell (12), procedures given in U.S.P. XVI (8) were used for these analyses.

RESULTS

The *in vitro* disintegration times of the various spheres are summarized in Table I. Sphere O, designed to release immediately the vitamins contained therein, had the shortest disintegration time, whereas spheres Y and R, which were designed to release their vitamins approximately 3 and 6 hours after ingestion, had disintegration times which were much longer. The length of time in simulated gastric juice did not significantly affect the time required for disintegration in simulated intestinal juice.

Mean physiological availability values are shown in Table I and curves of excretion rate are given in Figs. 1-3. The percentage urinary excretion values for the standard single doses of riboflavin, thiamine, and niacinamide were 58, 14, and 19%, respectively. None of the vitamins was fully available in the intact product. Thiamine and niacinamide were fully available in sphere O, but riboflavin showed somewhat reduced availability in this component. Riboflavin and niacinamide showed similar low availability values in sphere Y, whereas thiamine, although not fully available, gave a higher value. All three vitamins showed low availability in sphere R.

Values found for thiamine with sphere Y showed considerable intersubject variation due, in part, to the fact that one subject was consistently unable to obtain any thiamine from this component. This subject was also unable to obtain any thiamine from sphere R.

The curves of excretion rates (Figs. 1–3) showed that sustained urinary excretion of riboflavin, thiamine, and N′-methylnicotinamide was obtained by giving the vitamins in divided doses. The intact product, however, showed no evidence of sustained release properties, as measured by urinary excretion of the vitamins tested. As shown in Fig. 1, the maximum rate of excretion of riboflavin after administration of the standard was higher than that found with the intact product or its component spheres. Spheres O and R showed maximum riboflavin excretion 2 hours after dosing, whereas the peak of excretion did not occur until 6 hours after ingestion of sphere Y.

The rate of excretion of N′-methylnicotinamide after ingestion of sphere O was very similar to that obtained with the standard (Fig. 2). Spheres Y and R, however, gave very low excretion curves. As with riboflavin, sphere Y gave peak excretion of N′-methylnicotinamide 2–4 hours later than did the other spheres.

As shown in Fig. 3, the rate of excretion of thiamine after dosing with sphere O was similar to that obtained with the standard. The curves for spheres Y and R were irregular and indicated low availability of the products.

The results of the fecal recovery studies are shown in Table II. Both subjects who consumed pellets of sphere R for this study recovered them from the feces. The amounts of niacinamide and folic acid obtained in spheres which passed through the gastrointestinal tract exceeded those claimed on the label. As well, 90% of the riboflavin, 84% of the thiamine, and 78% of the amount of ascorbic acid claimed on the label were found in spheres which were recovered from the feces.

DISCUSSION

The data again (13) emphasize the fact that processes which interfere with the disintegration or solution of a vitamin product in the gastrointestinal tract may have a marked effect on availability of vitamins. If the spheres are considered simply as plain coated tablets with varying disintegration times, they provide further evidence for the validity of a 1-hour limit for the *in vitro* disintegration time of vitamin preparations. Riboflavin tended to be somewhat less available in the various spheres than were the other two vitamins perhaps, in part, because of reduced solubility. Nevertheless, the results indi-

cated that spheres which showed incomplete availability as measured by urinary excretion of riboflavin were also unavailable when excretion of thiamine or N′-methylnicotinamide was used as the criterion of adequacy. This finding would appear to allay the fears of Endicott and Kirchmeyer (14) that vitamins more soluble than riboflavin might yield an entirely different relationship between *in vitro* disintegration time and physiological availability.

The time limit given in U.S.P. XVI (8) for plain coated decavitamin tablets is 30 minutes in simulated gastric juice plus 2 hours in simulated intestinal juice. Sphere R would not pass such a test, but sphere Y would. The latter sphere, however, showed inadequate availability of all three vitamins tested. It is obvious that riboflavin, thiamine, and niacinamide in coated tablets which pass the U.S.P. test may not be fully available to the body.

Because of the resistant coatings used, it might appear more appropriate to consider spheres Y and R as enteric coated preparations. In a previous communication (3) it was suggested that enteric coated products containing riboflavin should withstand simulated gastric juice for at least 60 minutes and should then disintegrate within 30 minutes in simulated intestinal juice, to ensure full availability *in vivo*. The *in vitro* disintegration times for spheres Y and R exceeded this time limit, and both spheres showed incomplete availability of all three vitamins tested. These results suggest that the proposed time limit is also applicable to enteric coated preparations containing other vitamins.

If decavitamin preparations are enteric coated, the time limit given in U.S.P. XVI (8) is 5 hours (1 hour in simulated gastric juice plus 4 hours in simulated intestinal juice). Sphere R, which would have passed the U.S.P. XVI test, was recovered essentially intact from the feces of human subjects. These results indicate that the present U.S.P. time limit for enteric coated decavitamin preparations is too long, and that products which pass the test may not be available to the body.

The results of the fecal recovery studies indicated that tablets with an *in vitro* disintegration time similar to that of sphere R would exhibit very low availability not only of riboflavin, thiamine, and niacinamide, but also of folic acid and ascorbic acid. These findings suggest that the relationship between *in vitro* disintegration time and physiological availability for folic acid and ascorbic acid is similar to that obtained with riboflavin, thiamine, and niacinamide.

No evidence was obtained that the intact preparation possessed sustained-release properties, nor that the total dose was released at three separate times. Sphere R, which had the longest *in vitro* disintegration time, was recovered almost intact from the

feces of two subjects. It is obvious that the vitamins in this component of the product were largely wasted and that the sphere could not exert desired effects *in vivo*. The results obtained do not support claims that the product provides improved nutritional benefits with less loss of vitamins, and are in agreement with similar findings obtained previously with other sustained release vitamin preparations (4, 5). Furthermore, the data again (4) emphasize that it is most difficult to formulate vitamin preparations in true sustained-release form.

Kinetics of Copper Catalyzed Oxidation of 2,3-Dimercapto-1-propanol by Molecular Oxygen

By EDWARD G. RIPPIE† and TAKERU HIGUCHI‡

The rate of disappearance of the sulfhydryl groups of 2,3-dimercapto-1-propanol (BAL) in aqueous solutions in the presence of molecular oxygen and catalytic quantities of copper has been shown to depend directly on hydroxyl ion and BAL concentrations and on oxygen pressure. The concentration of BAL decreases logarithmically following a short induction period. The dependency on copper concentration was found to be approximately linear at low concentrations but showed an apparent limiting zero-order dependency at high levels of the metal. These findings suggest that some mechanism other than that proposed by Barron, *et al.* (1), must be responsible for the overall reaction.

BARRON, *et al.* (1), studying the oxidation of (BAL) by dissolved molecular oxygen in aqueous solutions in the presence of copper, manometrically, have reported that BAL and and similar dithiols apparently do not undergo oxidation by free oxygen in the absence of certain metal ions and that any observed oxidation in the apparent absence of these catalysts is due to residual trace quantities of metals (probably copper). They suggest a mechanism involving three stoichiometric reactions

Every dithol molecule oxidized, according to this mechanism, involves reaction with copper. Present findings based on iodometric determination of residual sulfhydryl groups appear to be in partial conflict with these suggestions. A possible alternate route is presented.

Apparatus.—A water-jacketed, glass reaction vessel was fitted with a water-sealed stirrer, manometer, and leveling bulb for maintenance of oxygen pressure, and a tube dipping below the level of the thiol solution for removal of samples at various time intervals. This apparatus was used in the experiments which were run with the oxygen pressure equal to atmospheric pressure.

A glass pressure vessel was used at elevated oxygen pressures. The bomb was fitted with a heavy rubber diaphragm through which samples could be withdrawn periodically by means of a hypodermic syringe. A Beckman model G pH meter equipped with a thermostated cell was used to determine the pH of reaction mixtures at the various temperatures. Titrations were carried out with a 2-ml. microburet with an immersion tip.

Procedure.—All studies were carried out in solutions thermostated to ±0.1°. The ionic strength was maintained constant at 0.5 by phosphate buffer to eliminate salt effects. Measured quantities of BAL were dissolved in the buffer solution containing the appropriate quantity of copper sulfate. The system was then flushed with oxygen, sealed, and stirred with the stirrer, or shaker in the case of the pressure bomb, with sufficient violence to assure saturation with respect to oxygen. Samples were withdrawn periodically for analysis.

Residual sulfhydryl content was determined iodometrically. An aliquot of the mixture was quenched by pipetting a sample of the reaction mixture into 0.1 *N* iodine solution, the excess iodine being back-titrated with 0.1 *N* thiosulfate. The insoluble disulfide present during the titration did not interfere with the end point, which was taken as the disappearance of the iodine color since starch indicator did not work well in the presence of oxidized BAL. A precision of ±1 μl. was obtained with a microburet fitted with an immersion tip.

Since in preliminary experiments it was found that hydrogen peroxide formed during the reaction interfered with the iodine titration, catalase was added (200 units per ml.) to all subsequent reaction solutions. Keilin (2) has shown that although both blood and liver catalase preparations increase the rate of thiol oxidation, the concentration necessary is 10^5 times higher than that required for the catalytic decomposition of hydrogen peroxide at an approximately similar rate. While Webb (3) found up to 90% inhibition of catalase by BAL, the amount remaining was presumed to be sufficient to decompose any peroxide formed. The addition of catalase did not appreciably alter the chemical kinetics of BAL oxidation but permitted us to follow the reaction closer to completion without interference by peroxide.

RESULTS AND DISCUSSION

Order of the Reaction with Respect to BAL.—The rate of disappearance of sulfhydryl groups in the presence of copper from stirred agueous solutions of BAL under constant oxygen tension appeared to be complex functions of time as is evident from data presented in Fig. 1. There seemed to be an initial autocatalytic lag phase followed by an apparently first-order disappearance of SH groups from the solution. The exact form and extent of the induction phase could not be established easily since the

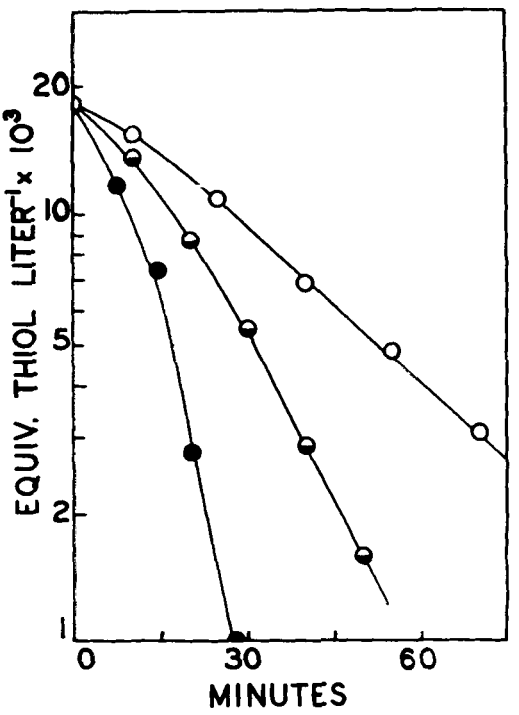

Fig. 1.—Semilog plots of thiol titer *vs.* time showing lag time. ○, 15°; ◒, 25°; ●, 35°; 2×10^{-5} *M* Cu(II); 760 mm. O_2 pressure; pH = 6.66.

experimental procedure employed did not permit determinations of an unambiguous zero time for the reaction. The induction period was also noted for systems followed manometrically, although Barron, *et al.* (1), do not report this.

The first-order phase of the observed reaction rate seemed to be truly first order. The slopes of the straight line portions such as are shown in Fig. 1 were found to be independent of initial BAL concentration within experimental error over a wide range of concentrations. This relationship was also found to be valid at different oxygen tensions as is evident from Fig. 2. For these runs, readings were taken after the initial phase so that only that part of the reaction which follows the first-order dependency is shown.

Effect of Oxygen Pressure.—The rate of the copper catalyzed oxidation of BAL appeared to vary directly with oxygen tension. This is evident in Fig. 3 where the first-order reaction rate constants calculated from the straight line portion from plots such as shown in Fig. 2 were plotted against pressure to yield a straight line passing through the origin. Numerical values of the rate constants and some of the experimental conditions are given in Table I.

For these runs, solutions of BAL were shaken violently in a glass reaction bomb under various oxygen pressures; aliquots were withdrawn and titrated periodically. Drop in oxygen pressure, due to consumption by the reaction and withdrawal of aliquots, introduced an estimated error of 2%. Pressures of oxygen were assumed to be partial pressures since the vapor pressure of water was negligible in this case.

Effect of Hydrogen Ion Concentration and Temperature.—The effect of pH on the rate of BAL oxidation was determined at 15, 20, and 25°. Figure 4 shows the collected results of these determinations in which the logarithm of the rate in reciprocal minutes has been plotted against the pH determined at the individual temperatures. The lines, which have an average positive slope of 0.73, are essentially parallel.

Figure 5 shows the results of heat of activation determinations at three pH's. The average value of the heat of activation, ΔHa, as determined from the slopes, was 12.6 Kcal. per mole. No account was taken of the effect of temperature on oxygen solubility or on the degree of ionization of BAL

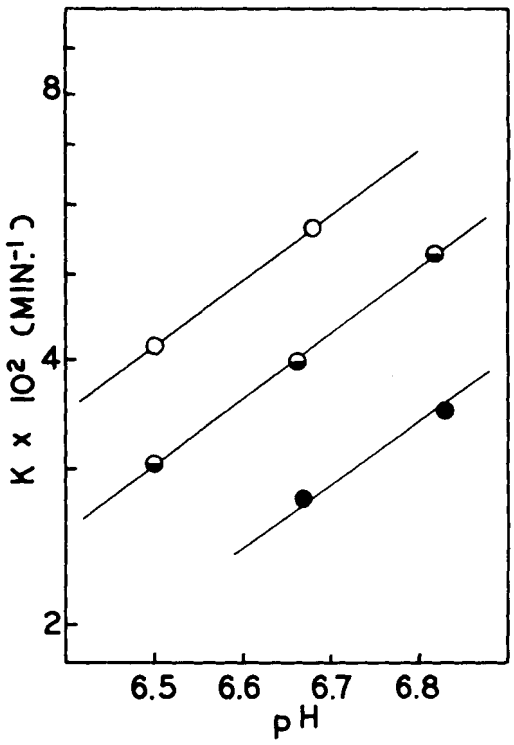

Fig. 4.—Semilog plots of first-order constants of BAL oxidation in reciprocal minutes against pH. The average slope of the lines is 0.73. Readings were taken at ○, 25°; ◒, 20°; ●, 15°; 1 atm. O_2 pressure; 2×10^{-4} *M* Cu(II).

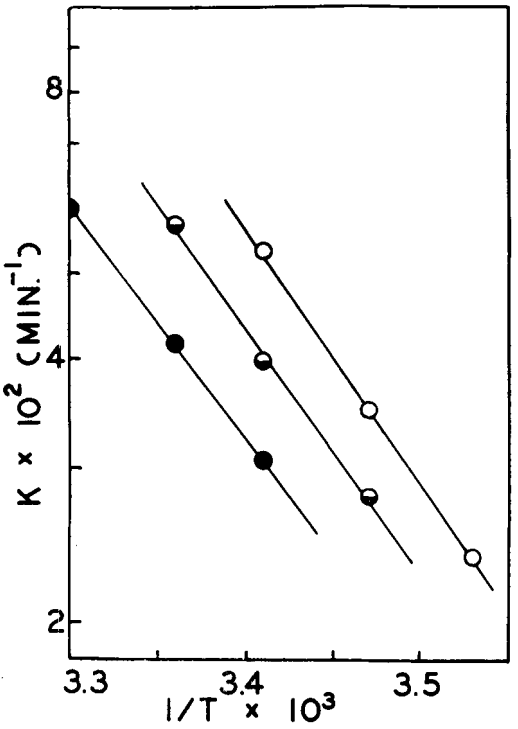

Fig. 5.—Typical Arrhenius plots obtained at different pH values. Solutions contained 2×10^{-5} *M* Cu(II); runs were made at ○, pH = 6.83, ◒, pH = 6.66, ●, pH = 6.50, under 1 atm. O_2.

in this calculation; therefore, the ΔHa given is the apparent heat of activation. The subtraction of the heat of solution of oxygen in water, −3.6 Kcal. per mole, from the apparent ΔHa yields a corrected value of 16.2 Kcal. per mole for the process. The heat of ionization of BAL, however, was not known and no correction has been made for its presumably small effect. Results of these experiments are given in Table II.

TABLE II.—EXPERIMENTAL RATES AT VARIOUS TEMPERATURES AND pH VALUES[a]

25	6.50	4.14
30	6.48	5.88

[a] Cu(II) = 2×10^{-5} *M*; O_2 pressure = 760 mm. Hg.

Effect of Copper Concentration on Reaction Rate.—Rate determinations made in the presence of varying copper concentrations yielded data shown plotted in Fig. 6, which indicate a nonlinear relationship between the two. The extrapolated value of the rate constant at zero copper concentration agreed with the experimentally determined rate of oxidation when a copper-free solution of BAL was oxidized in the presence of 1×10^{-3} molar potassium cyanide. In Fig. 7, the reciprocal of the observed rate constant has been plotted against the reciprocal of the copper concentration. Extrapolation of the resulting straight line plot to infinite copper concentration indicates a limiting rate constant equal to 7.81×10^{-2} min.$^{-1}$.

The saturation effect has been previously noted in studies on the cysteine-cystine system by Elliott (4) who found that the rate of oxidation by molecular oxygen was proportional to cupric ion at low concentrations, after which the rate was found to approach a limiting value. No mention was made of a possible cause of this phenomenon.

Consideration of the Overall Copper Catalyzed Reaction.—No limiting oxidation rate at high copper concentration, as is actually observed, would be expected from a totally copper-mediated mechanism such as has been proposed (1), as any increase in copper concentration would accelerate the oxidation further. One might expect, moreover, a limiting rate with respect to BAL, especially since the overall rate is directly dependent on oxygen. At BAL concentrations substantially in excess of the copper concentration, a BAL-copper complex could be expected to limit the breakdown rate because its concentration would not change appreciably with a change in BAL concentration. It is also apparent that if oxidation of the dithiol was totally mediated by copper, the overall rate would be rate-limited by either the rate of reduction of Cu(II) or its regeneration. In the former case, the observed rate would be substantially independent of oxygen tension;

in the latter, the rate should be largely zero order with respect to BAL.

As a result of the present studies, the following alternate reactions are proposed as possible components of the overall reactions. We are at present unable to write the total mechanism because of the apparent great complexity of the system. These reactions are, however, suggested on the basis of the present studies. Since the exact forms of cupric and cuprous copper have not been established, copper is shown only as to its oxidation state in the following reactions

$$Cu(II) + B(SH)S^- \xrightarrow{k_1} Cu(I) + B(SH)S\cdot \quad \text{(Step 1)}$$

$$B(SH)S\cdot + O_2 \xrightarrow{k_2} BS_2 + HO_2\cdot \quad \text{(Step 2)}$$

$$HO_2\cdot + B(SH)S^- \xrightarrow{k_3} B(SH)S\cdot + HO_2^- \quad \text{(Step 3)}$$

$$3\,Cu(I) + 3\,H^+ + HO_2\cdot \xrightarrow{k_4} 3\,Cu(II) + 2\,H_2O \quad \text{(Step 4)}$$

$$Cu(II) + B(SH)S\cdot \xrightarrow{k_5} Cu(I) + H^+ + BS_2 \quad \text{(Step 5)}$$

If these reactions are considered to be representative of the principal reactions occurring after lapse of the lag time, several observations can be rationalized.

It can be seen that, when the copper concentration is such that step 5 occurs at a rate still insignificant compared with step 2, the rate is apparently independent of copper concentration. This was the case experimentally. Nord (5) in his studies on the autoxidation of cuprous chloride, reported rapid air oxidation of the cuprous ion at hydrogen ion concentrations of 0.1 *M* and above which, if extrapolated to neutrality, would predict extremely slow reaction rates. He also reported a pH-independent oxidation of cuprous ion at hydrogen ion concentrations below 0.1 *M*. If this rather slow reaction were assumed to occur at neutrality and if cupric ion were the only oxidant of BAL, it would also fail to account for the rapid oxidation of the sulfhydryl compound noted in the present work.

The illustrated partial mechanism agrees with the experimentally observed first-order dependency on BAL. However, a discrepancy may be noted between the expected and observed slopes when the overall rate constants are plotted *vs.* pH. If the dissociation of the B(SH)S· species to $BS_2^{\cdot-}$ is necessary before the reaction with cupric ion, the reaction 5 will be a function of the pH and result in a negative deviation from slope 1.0, as observed. Hydrogen peroxide as such was not thought to contribute significantly to the reaction rate since no detectable

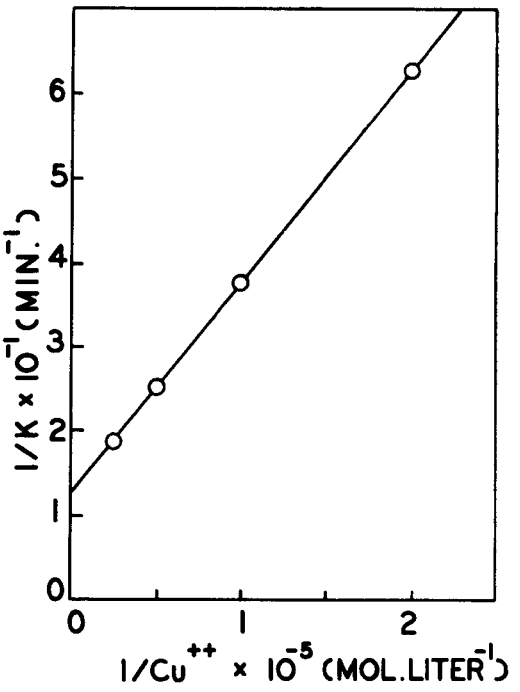

Fig. 7.—Plot of reciprocal first-order rate constant against reciprocal copper concentration, indicating limiting rate constant of 7.81×10^{-2} (min.$^{-1}$). Runs were made at 20°, pH = 6.66, under 1 atm. O_2.

change in the overall rate constant was found upon addition of catalase to the system.

Although this mechanism appears to be consistent with the experimental evidence, it is not necessarily unique since alternate mechanisms may be equally successful in explaining the experimental findings Moreover, the chemical equations suggested here should not be considered as the only ones occurring. There is a possibility that reactions, kinetically indistinguishable from those suggested, may take part in the oxidative breakdown.

Effects of Centrally-Acting Drugs on Human Motor and Psychomotor Performance

By DUANE G. WENZEL and CHARLES O. RUTLEDGE

The dose-effect and duration of action of several stimulants and tranquilizers were determined using motor and psychomotor performance tests with humans. Three doses of each of the following drugs were employed: placebo, caffeine, *d*-amphetamine, phenmetrazine, methyl phenidyl acetate, phenobarbital, chlorpromazine, meprobamate, and oxanamide. Phenmetrazine and methyl phenidyl acetate were also studied with additional tests designed to measure fatigue. Deanol and placebo groups were tested weekly for 8 weeks of daily administration crossing treatments at 4 weeks. The tranquilizers did not affect performance as measured by the tests employed, while all stimulants produced some improvements in all tests. Phenmetrazine and methyl phenidyl acetate were the most promising central stimulants tested. These were found to mitigate fatigue by elevation of the initial performance level and by decreasing the time-related decrement. The action of deanol was equivocal with some indication of an interaction between the drug and subject interest.

PROBLEMS inherent in the guidance of aircraft or anticipated spacecraft have increased to the point where, despite refinements in instrumentation, they have begun to exceed man's physiologic and psychologic limits. The obvious solution to the problem is to alter man himself. This might be accomplished through education and training and (or) through the mediation of centrally acting drugs. While it is perhaps self-evident that the improved control of rapidly moving objects is a worthwhile objective, an even more important objective could be the production of periods of enhanced efficiency under conditions of stress or fatigue. Although many studies have been conducted to determine the effects of centrally acting drugs upon human performance, most of these have been clinical in nature, lack proper controls, or they have been oriented toward the treatment of mental illness. It is therefore difficult to compare the effects of such drugs upon normal performance.

The minimum requirements for the proper evaluation of a drug affecting performance would seem to be that: the temporal and dose effects of the drug must be measured with several types of performance; the subjects employed must be adequate in number and be reasonably uniform, physiologically and psychologically; and the experimental design must provide adequate controls and employ suitable techniques to avoid bias.

In the studies which follow every effort was made to meet these requirements, although, as noted in the discussion, it became necessary to reach certain compromises dictated by the limitations of time.

EXPERIMENTAL

Central Stimulant Study.—Subjects consisted of 15 volunteer, male, college students between the ages of 22 and 27, and weighing between 145 and 185 pounds. All were experimentally naive prior to testing and were of approximately the same intellectual capacity as indicated by the rank in their class. Subjects were instructed in the test procedure by means of detailed printed instructions and an oral orientation period. They were then repeatedly tested in practice sessions until a stable level of performance was achieved for each test. Treatments consisted of the following drug doses: placebo; caffeine, 100, 200, and 300 mg.; *d*-amphetamine, 2.5, 5, and 10 mg.; phenmetrazine, 12.5, 25, and 50 mg.; and methyl phenidyl acetate, 5, 10, and 15 mg. Doses were selected by bracketing what was thought to be the amount of the drug which would induce definite physiological and psychological effects.

All testing was performed between 1:00 and 5:00 p.m. At approximately 12:00 p.m., 1 hour prior to the administration of the drug, subjects ate a light lunch consisting usually of a sandwich, a glass of milk, and some fruit. They were instructed to refrain from drinking caffeinated beverages and from smoking following breakfast. Five subjects were each tested four times in one afternoon at hourly intervals. The first test for all subjects, or control, was conducted one hour after lunch. Immediately

Received April 28, 1961, from the University of Kansas, School of Pharmacy, Lawrence.

Accepted for publication August 7, 1961.

Abstracted from a portion of the data contained in a thesis submitted to the Graduate School of The University of Kansas by Charles O. Rutledge for the degree of Master of Science in Pharmacology.

This work was supported by a contract between the Office of Naval Research and The University of Kansas.

The authors gratefully acknowledge the medical supervision of the drug administration by Dr. R. L. Hermes. Dr. Edward L. Wike of the Department of Psychology is thanked for his assistance with the statistical analysis. Paul W. Davis served as a technical assistant. Thanks are extended to the following individuals and firms for the drugs used in this study: Edward E. Frost, Jr., Smith Kline and French Laboratories for the *d*-amphetamine (Dexedrine); Joseph Marrus of Geigy Pharmaceuticals for the phenmetrazine (Preludin); Dr. Frank A. Travers of Ciba Pharmaceutical Products for the methyl phenidyl acetate (Ritalin); Dr. R. C. Pogge of the Wm. S. Merrell Co. for the oxanamide (Quiactin); and Dr. Adolph Surtshin of Riker Laboratories for the deanol (Deaner).

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

following this test a No. 1 pink capsule containing the drug was administered with a glass of water. The selection of the drug-dose was randomized and double-blind conditions were maintained throughout the study. Testing was repeated three times at hourly intervals following the first test and the administration of the drug.

As each subject was to be tested with each of 13 drug or placebo doses, it was anticipated that boredom or disinterest might influence the results after the novelty of early testing wore off. In an attempt to minimize this possibility and yet not introduce new factors of variability, two techniques were employed in order to maintain positive motivation. Competitive motivation was used to the extent that the three highest individual scores for each test were posted weekly with the previous record score. No further efforts were made to induce individual or group competition because such methods have been found to create variable secondary effects (1). Self-competition related to knowledge of performance (2) was difficult to induce because of the changing drug factor. Subjects were not allowed to observe another's performance nor did they receive information concerning their own scores except as indicated. The second measure designed to stimulate motivation was the encouragement of subjects to maintain a record of their own subjective responses to each treatment. They were informed that at the conclusion of the study they would be provided with their own test results and the drugs employed at each period. This procedure provoked considerable speculation and maintained interest in the effects of each treatment. Subjects were not informed of the drugs that were to be employed other than that moderate doses of nontoxic agents were to be used.

All experiments were conducted in an isolated laboratory equipped specifically for this purpose. The room was well lighted with overhead fluorescent lamps as the sole source of light. Room temperature was held between 70 and 72°F. Ambient noise consisted of the sound of the fan motor in the counter and the motors of the tracking test. These were kept running continuously throughout the entire afternoon of testing and provided a low steady noise level sufficient to mask external sounds. Conversation between subject and experimenter was not permitted except for necessary signals and instructions.

Tests

Tapping Rate.—A microswitch with a roller contact was used as a key in the tapping tests. The switch had a lever arm of 1 in., a pretravel distance of $^1/_4$ in., and required an actuating force of 140 Gm. The roller materially reduced finger friction and in the preliminary testing gave more consistent results than similar keys without the roller. It was mounted at table height so that the subject sat facing the switch with his arm comfortably bent at the elbow and his forefinger on the key. The thumb and remaining fingers were folded beneath the hand and kept in constant contact with the table. This precaution was necessary in order to avoid actuation of the switch with the muscles of the hand rather than of the finger. Use of the hand enabled subjects to obtain higher scores, especially in the 60-second test in which finger fatigue became marked. Conformity with this provision was assured by careful preinstruction and continual observation by the experimenter.

The key was wired into an electric timing circuit in such a manner that the first tap activated an adjustable timer previously set for the desired period over which the tapping rate was to be measured. Starting the timer simultaneously closed a relay connecting the key to an electric four-digit counter. The stopping of the timer at the end of the preset interval opened the relay and discontinued the counting. In this manner subjects could begin tapping whenever they felt that they were ready and the total count for the specified period was recorded automatically. The circuit for this counter system is shown in Fig. 1.

One objective of the tapping test was to determine the maximum speed at which a voluntary movement could be repeated. For this purpose the test must be conducted over an accurately measurable time interval yet one that is short enough to prevent fatigue. A 5-second period was employed. It was repeated four times at each of 4 hourly test periods.

The rate of tapping may also be used to observe the effect of fatigue on the motor activity of the discrete group of muscles controlling finger movement. For this purpose the test was conducted over a 60-second interval. Because of the problem of cumulative fatigue, it was possible to perform this test only twice in any one period, before and after an 8-minute interval during which the other tests were being performed.

Simple Visual Reaction Time.—The visual stimulus for this test consisted of the light from a 120-v., 6-watt, Sylvania S6 lamp mounted in a holder behind a 1-in., clear, jeweled lens. The lamp was placed in a cabinet about 3 ft. from the subject and was 6 in. above the desk top. The subject was seated before the light with his index finger on a snap-action switch having a pretravel distance of $^1/_{16}$ in. With the subject in position, the experimenter, seated behind the cabinet, gave a verbal signal of "ready," at which time he simultaneously closed a switch in a time-delay circuit. This circuit was previously and at random varied by the experimeter between time intervals of from 2 to 5 seconds. At the completion of the time-delay, the circuit to the lamp and a Beckman time interval meter model 7250C were activated, turning on the light and starting the counter. When the snap switch was then closed by the subject, the timer was stopped and the time was measured to 0.1 msec. The circuit diagram of this apparatus is presented in Fig. 1. Four replicates of this test were conducted at each test period.

Complex Reaction Time.—This test was modified from one described by Borkenstein (3) which was termed "choice reaction." The apparatus for this test consisted of a 9 × 9 inch panel of opalescent plexiglas mounted on the sloping front of the cabinet containing the simple reaction time light. The panel was divided into sixteen 1.5 in. square spaces in a 4 by 4 arrangement. Each space had a black 1-in. number arranged in the order from top row to bottom row: 9-6-3-5, 6-2-4-7, 7-8-9-8, and 5-2-3-4. These numbers were on the reverse side of the plexiglas panel and were not visible until individual lights, mounted separately behind each number, were lit. The lights could be lit in either of two manners. First, they could be lit two lights at a time in a con-

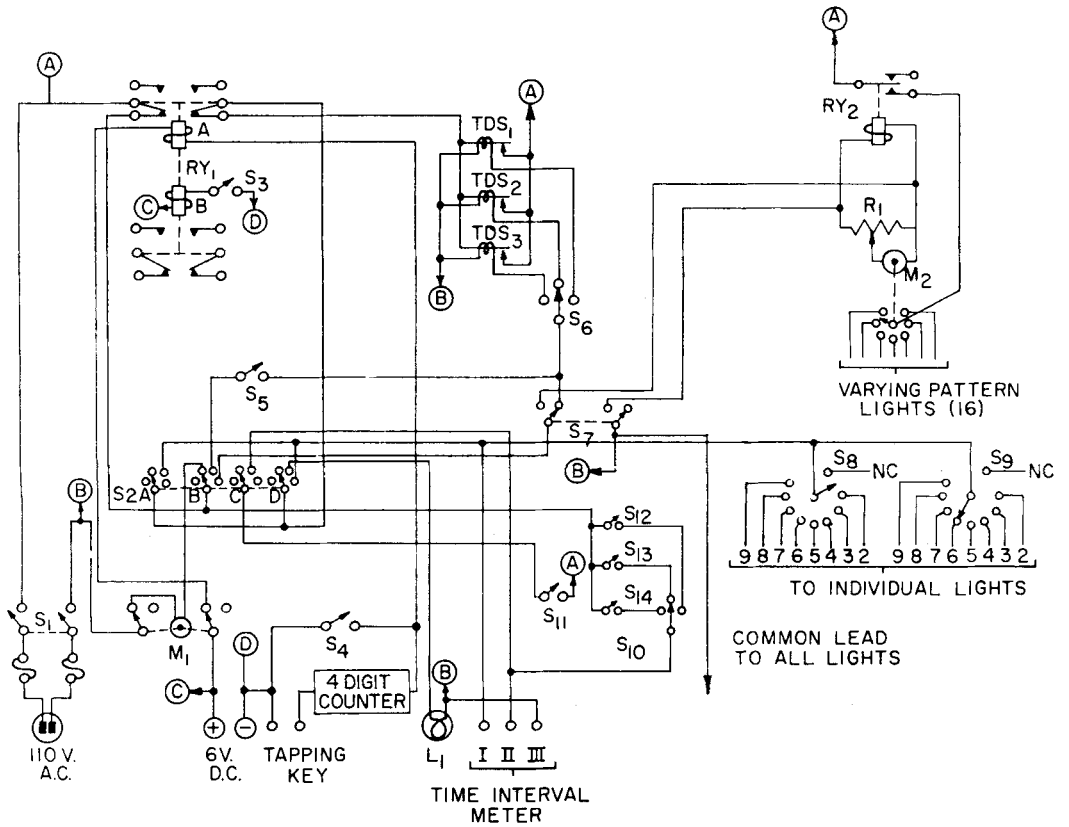

Fig. 1.—Circuit diagram of the unit controlling tapping tests and simple and complex reaction times. All switches except $S_{11, 12, 13, \text{and } 14}$ are mounted on the rear of the cabinet. S_1, SPDT switch controlling 110 v. a.c. power. S_2, 4P 4-position switch controlling test function; A, B, C, and D represent switch gangs; positions are 1, 2, 3, and 4 beginning to the left of the pole and proceeding clockwise; all gangs are shown in position 2; position 1, off; position 2, tapping rate; position 3, visual reaction time; and position 4, complex reaction time. S_3 and S_4, momentary SPDT, NO switches controlling RY_1 relay position. S_5, SPDT off-on time delay switch. S_6, SP 3-position switch for selection of time-delay circuit. S_7, DP 2-position switch to turn on motor switching varying pattern lights (M_2) and lights through relay RY_2 or to activate one of three time-delay switches ($TDS_{1, 2, 3}$). S_8 and S_9, SP 10-position switches controlling lighted number pair of complex reaction time test. S_{10}, SP 3-position switch for selection of odd, even, or odd-even pairs, as indicated by positions of S_8 and S_9. S_{11}, SPST momentary switch thrown by subject to complete visual reaction time. S_{12}, S_{13}, and S_{14}, SPST momentary switches thrown by subject to complete odd, even, or odd-even pairs for complex reaction time. RY_1, SP, 2-position, 2-section latching relay controlling a.c. power. RY_2, SP, 2-position relay to supply power to motor-driven switch prior to activating time delay switches by S_7. $TDS_{1, 2, 3}$, Amperite 2, 3, and 5-second delay relays. M_1, Industrial Timer Corp., TDAF-60-second series timer. M_2, varying pattern lights switch motor. I, Start position on Beckman time interval meter. II, Stop position. III, Common. Circled letters represent common connections.

tinuously varying pattern by means of a motor-driven rotating multicontact switch. Secondly, any two selected numbers could be lit by the experimenter following a time delay of from 2 to 5 seconds. The test was performed as follows: the subject sat facing the panel of numbers with his thumb and forefinger on a 1.25-in. control stick of a Grumann automatic pilot controller, model GR2. When the subject was ready, the experimenter threw the first switch, causing various pairs of numbers to flash off and on in an irregular manner. After approximately 10 seconds of this irregular flashing of the numbers, a second switch was thrown, activating the previously selected time delay relay and disconnecting the rotating switch. The panel of numbers now remained dark for the selected time period. This alerted the subject to be ready for the appearance of the two numbers previously selected by the experimenter. With the closing of the circuit lighting the selected pair of numbers, the Beckman time interval meter was activated. The subject at this time seeing a pair of numbers, had to decide whether the pair was even, odd, or an odd-even combination. For an even combination the stick switch was to be pressed to the right, for an odd combination to the left, and for an odd-even combination, forward. Moving the stick in the correct direction closed a microswitch which stopped the counter. If the wrong combination was chosen, the counter remained activated and the result was recorded as an error. The circuitry of this device is seen in Fig. 1.

It had been previously determined in an initial study of this apparatus that an individual's score for a given number pair was quite consistent, but that there were considerable differences in the times

between different pairs. For this reason, ten odd-even pairs in which the numbers were approximately the same distance apart on the panel had been tested repeatedly with a group of subjects. It was found that four of these pairs gave consistent reaction times varying between 825 and 875 msec. Each test consisted of five reaction times, two of which were obtained from the four consistent pairs. In the preliminary testing it was determined that the subjects were not aware of the fact that certain number pairs were being repeated.

Tracking Test.—The apparatus used to measure motor coordination was similar in principle to many previously employed and is shown in Fig. 2. The object of the test was to hold a 15 mm. spot of light from a pistol-like flashlight on a circular 1-cm. photocell that was moving at a distance of 2.5 ft. from the end of the light gun. The photocell unit consisted of a basic motor which moved a 7-in. arm through a vertical 70° arc, requiring 20 seconds for a complete cycle. To the end of this arm was connected a 15 r.p.m. synchronous motor, which in turn continuously rotated a second arm 6 in. in length, also in the vertical plane. At the end of the 6-in. arm was a 2-in. white circular target with a 1-cm. circular photocell in the center. The combined movements of both motors caused the photocell to travel at an irregular speed and in a varying pattern. The speed with which the photocell moved relative to the subject depended upon the relative motion of the component motors. When the directions of movement were the same, the photocell would move in a gradually accelerating or sudden burst of speed, or if moving in opposite directions, the photocell might almost stop or move very slowly. In order to induce irregularity further and prevent smooth continuous tracking, a universal joint was used to connect the 15 r.p.m. motor to the 6-in. target arm. By adjustment of this joint it was possible to cause the target to make a bobbing movement at four points with each circular motion of the 15 r.p.m. motor. As these irregular movements occurred at varying positions of the photocell and were dependent upon the relative positions of the two arms, the bobbing could not be anticipated. The entire apparatus

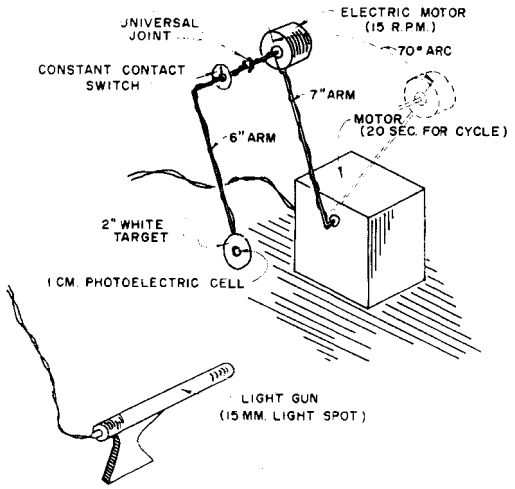

Fig. 2.—Diagram of mechanical portion of the tracking test apparatus.

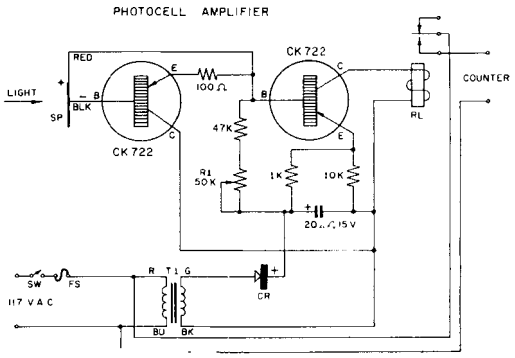

Fig. 3.—Circuit diagram of amplifier used to control the sensitivity of the tracking test photocell.

was placed in the rear of a blackened box with the open end to the front. The dimensions of the box were 26 in. high by 26 in. wide and 34 in. deep. A black screen with a slot through which the blackened rotating arm extended concealed the apparatus from the subject who saw only an erratically moving 2-inch white circular target with a 1-cm. black center.

The photocell was electrically connected through a constant contact rotating switch on the 6-in. arm to an amplifier relay circuit shown in Fig. 3. Adequate light upon the photocell induced a signal which, when sufficiently amplified, activated a relay and, in turn, closed a 60-cycle, 110 v. circuit connected to the Beckman time interval meter. Therefore, every second that the photocell was adequately illuminated, 60 counts would be recorded.

The experiment was performed with the subject sitting squarely before the target box having both feet flat on the floor. At a signal from the subject who was tracking the target, the experimenter threw a switch which simultaneously connected the Beckman time interval meter to the photocell circuit and started a 40-second timer. A perfect score for continuous contact throughout the 40-second period was a count of 2400. However, in order to allow for drug-induced increments or decrements in performance, the amplification of the photocell output was so adjusted that the average control score was less than half the perfect score. This test was repeated four times during each period.

Central Depressant Study

The study to determine the effect of central depressants upon performance was also conducted with 15 new subjects, but with the same experimental design and tests described for the stimulants. The drugs employed and their respective doses were: placebo, three doses; phenobarbital (as a standard sedative), 15, 30, and 45 mg.; chlorpromazine, 25, 50, and 100 mg.; meprobamate, 200, 400, and 800 mg.; and oxanamide, 200, 400, and 800 mg.

Central Stimulants Fatigue Study

This study was designed to elaborate further upon certain results obtained with the initial central stimulant experiments. One objective was to determine the effects of phenmetrazine and methyl phenidyl acetate upon muscular fatigue. Each of these drugs had appeared promising in the 60-second tapping test and no indication was found in the literature that they had been tested for this effect.

A second objective was to answer a hitherto unexplained question of how the central stimulants affect fatigue. The question was whether psychomotor drugs act to maintain the base-line level of performance by suppressing the sense of fatigue or whether, by actually raising the initial level of performance, they simply negate a fatigue-induced decrement. Two tests were conducted to determine these objectives. As the rate of tapping had been previously noted to decline steadily throughout the period of 60-second tapping, this test was extended to 3 minutes. Readings of the counts were made at half-minute intervals. The second test employed the tracking apparatus and was performed by extending the period of testing to 6 minutes, during which time readings were made at minute intervals. To induce fatigue further, the subjects were required to hold their arm with the light gun straight before them rather than with the elbow bent and touching the side.

Five subjects participated in this study. The treatments employed were: placebo, methyl phenidyl acetate 15 mg., and phenmetrazine 50 mg. Subjects received each treatment twice in randomized allocation and according to the manner previously described.

Chronic Deanol Study

Eighteen volunteer, male, college students between the ages of 21 and 33, weighing between 135 and 205 pounds, served as subjects. Orientation and tests were the same as for the studies with central stimulants and depressants. Subjects were randomly divided into two groups with nine subjects in each group. Group 1 received a daily capsule containing a placebo during the first four weeks and a capsule identical in appearance containing 75 mg. of deanol (dimethylaminoethanol) for the next four weeks. Group 2 received these treatments in the reverse order. Double blind conditions were maintained throughout. The five tests were administered in the same manner as in the central stimulant and depressant studies except that the testing of each subject was repeated at regular weekly intervals from the onset of treatment. In addition to the usual tests, subjects were also examined for changes in mood and any other subjective responses. For the analysis of a possible effect upon mood, the adjective check list of Nowlis (4) was employed. This list consisted of 145 adjectives descriptive of mood, feelings, or states of mind. Each adjective could be categorized as being either positive (cheerful, self-confident, etc.) or negative (depressed, unsure, etc.) in character. At each test period the subject checked those adjectives on the list which definitely described his feelings, using a single check were applicable, a double check mark where the adjective strongly applied, and a question mark when there was some uncertainty. In addition to the adjective list, subjects were further asked to describe any change from normal in their mental or physiological functions, such as the presence of pain, amount of sleep required, or changes in appetite, libido, study habits, and similar effects.

RESULTS

Central Stimulant Study.—In order to compensate for normal diurnal variations and to increase the precision of the tests of significance, the means of 12,480 raw scores were first adjusted for regression upon the corresponding control values. These adjusted scores were examined by an analysis of variance (5). The results are shown in Table I. The principal experimental variables were drugs, doses, and times. In each test, drugs constituted a significant source of variation. This means simply that not only were the drugs employed capable of affecting performance, but also that the tests selected were adequate to detect these changes. The absence of significant variations in dose response, except for the 60-second tapping rate, would indicate

[a] Controls are those test values obtained immediately preceding drug administration. [b] Trials 1, 2, and 3 are those test values obtained 1, 2, and 3 hours after drug administration. [c] Significantly different than placebo ($P < 0.05$). [d] Significantly different than placebo ($P < 0.01$).

that either the tests were not sufficiently sensitive to detect the overall effect of the dose as a variable or that the differences in the sizes of the dose were not adequate to demonstrate such an effect. This does not, of course, preclude the possibility that individual doses may induce significant variations from corresponding control values. The fact that time was significant for all tests except the reaction times tells that the length of time following drug administration also influenced the response.

In order to determine which drug-dose-time performances were significantly different from those of the placebo, the *t*-test of Dunnett (6) was applied to the differences between the mean test scores and control values for the drugs and placebo. These data are presented in Table II and in Figs. 4–13. From Table II it is apparent that the tracking test was the most sensitive gauge of stimulant drug activity and that the lowest dose of caffeine, 100 mg., and the highest doses of phenmetrazine and methyl phenidyl acetate, 50 mg. and 15 mg., respectively, were generally the most effective.

The numerical values employed in Table II and their graphic presentation in Figs. 4–13 demonstrate the discrete changes resulting from the drug-dose-time interaction. Although with such presentations the individual values and treatments may be observed to vary significantly from those of the corresponding placebo or control, total drug-dose effects are not easily compared. In order to simplify such a comparison, the time-effect was integrated by measuring the areas under the graph curves with a planimeter. These values, measured in square centimeters, were obtained from original graphs in which the coordinates measured 7.6 cm. and 15.3 cm. for the x and y axes, respectively. The values obtained are the algebraic sums of the areas above and below the zero or control level, and are presented in Table III.

The 5-second tapping test afforded an objective index of the speed of a simple repetitive muscular movement rather than a measure of precision. It is most apparent from Table III and from Figs. 4 and 5 that methyl phenidyl acetate and phenmetrazine can significantly improve 5-second tapping. As might be anticipated, peak activities appeared at the second hour posttreatment. While it is not

Fig. 4.—Five-second tapping rate.

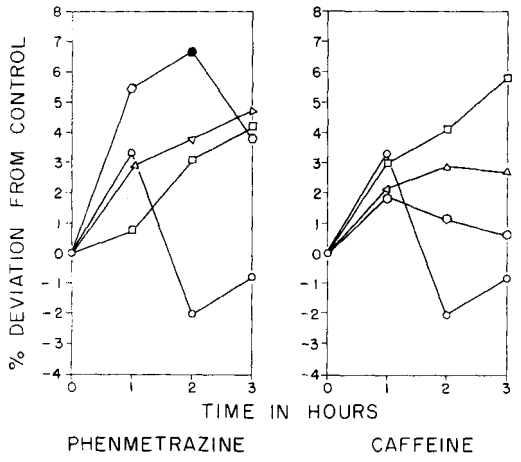

Fig. 5.—Five-second tapping rate.

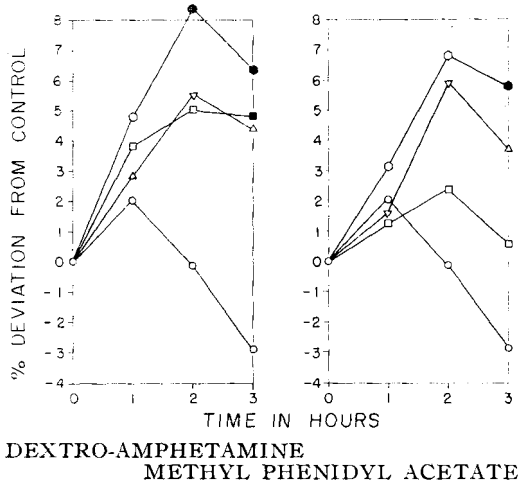

Fig. 6.—Sixty-second tapping rate.

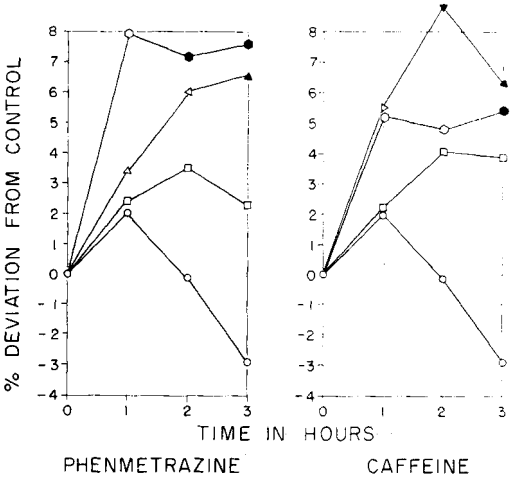

Fig. 7.—Sixty-second tapping rate.

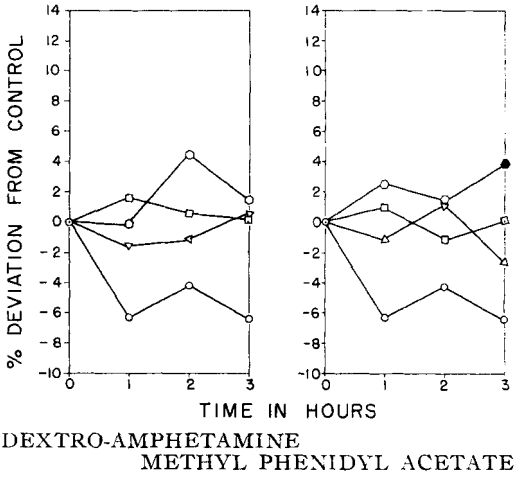

Fig. 8.—Simple visual reaction time.

surprising to find that central stimulants are capable of improving this type of performance, it is rather surprising that *d*-amphetamine did not cause a significant improvement. From Fig. 4 and Table II, it can be observed that *d*-amphetamine, while raising the level of performance over that of the placebo, was not as effective as the larger doses of phenmetrazine or of methyl phenidyl acetate. Further, these latter agents induce a dose-related effect. These differences may be the result of an improper selection of doses or they may reflect real differences in the actions of these drugs. The results with caffeine, although not significant, are most interesting because of the inverse relationship between dose and effect.

The information obtained from the 60-second tapping test is quite similar to that from the 5-second test, although the longer test appears to be a somewhat more sensitive measure of the drug effect. The principal difference in these two was the factor of fatigue in the longer test. All drugs demonstrated a significant improvement in performance at one or more of the times tested (Table II). From

TABLE III.—INTEGRATED DOSE-TIME EFFECTS OF CENTRAL STIMULANTS[a]

Treatments	Tracking Test	Five-Second Tap	Sixty-Second Tap	Visual Reaction	Complex Reaction
Placebo	17.9	2.0	1.9	−21.4	6.7
Caffeine, 100 mg.	56.0	32.5	27.6	−14.4	44.2
Caffeine, 200 mg.	41.1	21.0	55.5	−8.2	16.7
Caffeine, 300 mg.	12.2	12.6	40.9	1.0	−6.3
d-Amphetamine, 2.5 mg.	27.4	18.2	35.4	3.7	3.1
d-Amphetamine, 5.0 mg.	29.7	15.8	33.3	−9.9	−2.6
d-Amphetamine, 10.0 mg.	16.5	22.1	52.1	10.4	34.4
Phenmetrazine, 12.5 mg.	13.1	19.3	24.6	17.8	29.0
Phenmetrazine, 25.0 mg.	35.2	30.1	40.3	−2.5	31.9
Phenmetrazine, 50.0 mg.	49.2	45.8	60.4	5.4	−27.8
Methyl phenidyl acetate, 5.0 mg.	26.1	10.4	12.9	−0.3	−7.0
Methyl phenidyl acetate, 10.0 mg.	41.2	30.9	31.6	−1.7	−13.0
Methyl phenidyl acetate, 15.0 mg.	52.2	38.7	43.2	9.6	6.1

[a] The areas under curves were measured with a planimeter from original graphs in which the coordinates measured 7.6 cm. and 15.3 cm. for the *x* and *y* axes, respectively. Values are the algebraic sums of the areas above and below the zero or control level.

Table III and Figs. 6 and 7, it may be observed that the improvement was dose-related except in the case of caffeine. For reasons that are not apparent, the order of activity with caffeine was 100 < 300 < 200 mg.

The effects of the drugs upon both simple and complex reaction times were not as marked nor as consistent as those obtained with the tapping tests. This may be seen from examination of Tables II and III and Figs. 8–11. Generally some improvement over the control values can be noted, but of greater meaning is the fact that the time-related performance decrement of both tests, as seen by comparison with the placebo values, was prevented by most of the drug doses. Several effects stand out. First, in contrast to most of the other tests, in the simple reaction time, caffeine induced a slight improvement that was directly related to the dose. With the complex reaction time, however, the 100-mg. dose of caffeine produced significantly greater improvement than the higher doses, again demonstrating an inverse relationship between the dose and the effect of this drug. This effect of a high dose of a stimulant causing a decrease in the complex reaction time performance was marked with the 50-mg. dose of phenmetrazine.

From Tables II and III and Figs. 12 and 13, it is apparent that the tracking test was the most sensitive gauge of stimulant drug activity. Both methyl phenidyl acetate and phenmetrazine produced improvement in performance. In each case the effect was directly related to the size of the dose, and with the highest doses it was significant. Caffeine, on the other hand, once again demonstrated an inverse relationship between dose and effect with the 100-mg. dose inducing significant improvement. *d*-Amphetamine did not significantly affect this performance test at any dose nor at any time tested.

The side-effects observed with the central stimulants were minimal and usually consisted of no more than a marked increase in excitability and physical activity with the highest dose of each drug. All subjects were normotensive and no symptoms were elicited from the cardiovascular system other than moderate increases in the heart rate. One subject, who did not drink coffee, became quite agitated after the first dose of 100 mg. of caffeine and was given no further doses of this drug. Generally the subjective response to all the drugs was a feeling of well being, although the 300-mg. dose of caffeine had a tendency to induce nervous tension that might be best described as the "jitters."

Central Depressant Study.—Dunnett's *t*-test was applied to the data from the study of the central depressants in the same manner as previously described for the stimulants. The results are summarized in Table IV. Inspection of the mean values reveals that only one score was significantly improved. This was the simple reaction time with chlorpromazine 50 mg., at the 2-hour test period. Examination of the raw data from which this significant value was obtained gave no indication as to the reason for the apparent improvement.

While the values obtained in the various tests are seemingly quite variable in terms of the placebo effects, the per cent deviation from the control (initial) values are uniformly low (Table IV) in comparison with the results from the same tests using central stimulants (Table II). In the stimu-

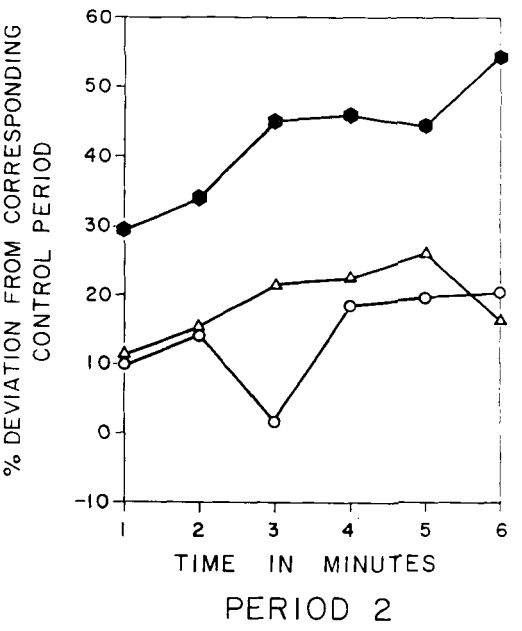
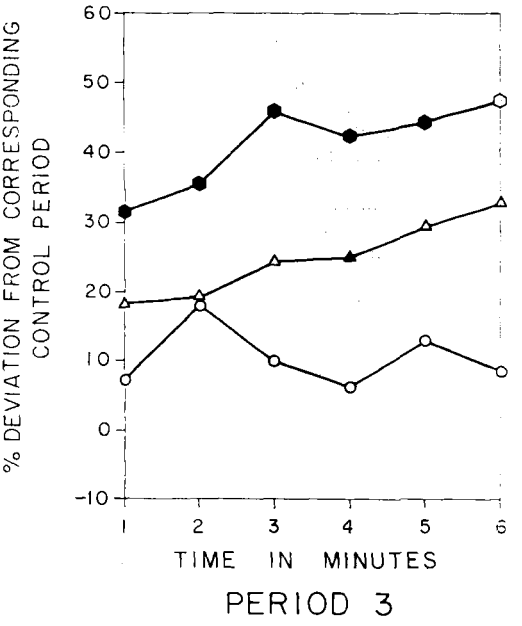
[a] Controls are those test values obtained immediately preceding drug administration. [b] Trials 1, 2, and 3 are those test values obtained 1, 2, and 3 hours after drug ad ministration. [c] Significantly different from placebo ($P < 0.05$).



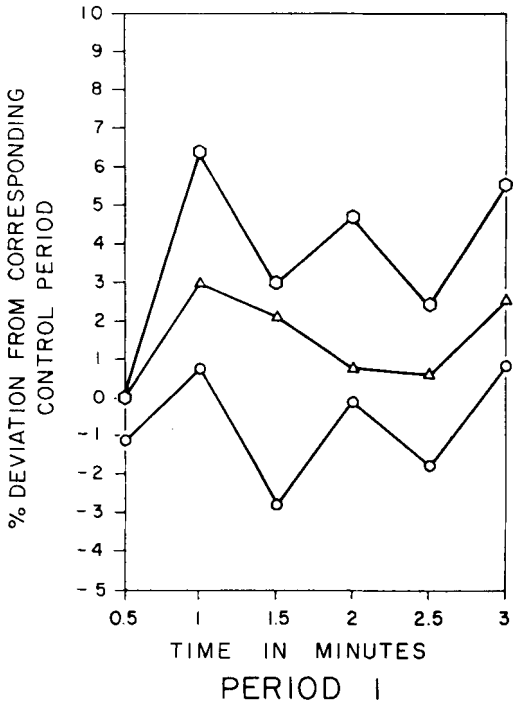
lant tests, the mean per cent deviation was frequently in the range of a 20 to 30% positive deviation, while with the central depressants, it seldom exceeded 8% in either direction.



Central Stimulants Fatigue Study.—The results of this study are presented in Figs. 14–19. While the manner in which the data are presented does not indicate any apparent time-related decrement in performance, it should be noted that the points in each curve represent the per cent deviation from the corresponding points measured during the control period. Therefore, while the relative values shown in the curves may indicate an increase or little change in performance, a plot of the absolute values would result in curves having a definite downward trend in almost all cases. With this in mind, it may be seen that phenmetrazine induced a greater percentage improvement with the 6-minute tracking test than with the 3-minute tapping test. The prevention of fatigue with the stimulants, as anticipated from the results of the previous 60-second tapping test, was most prominent 2 hours after taking the drug. In the 6-minute tracking test the results were significant ($P < 0.01$) at all times throughout the 2-hour period and in all but one point at 3 hours. In the 3-minute tapping, only two points in the 2-hour test period were significant at $P < 0.01$ and $P < 0.05$, while none were significant at period three. Methyl phenidyl acetate significantly improved performance only at one time, 3 hours after the drug in the 6-minute tracking test.

Chronic Deanol Study.—The results of the performance tests were analyzed with a nested 2 × 2 factorial type design in order to measure the significance of each of the following effects: drug effect *vs.* placebo; order of administration, i.e., drug first, placebo last *vs.* placebo last, drug first; and finally the interaction between the drug and the period tested, i.e., drug-test period differences (7).

The mean values for the motor and psychomotor tests at 4 and 8 weeks are presented in Table V. In



Figs. 14—16.—Six-minute tracking test; placebo, O; methyl phenidyl acetate 15 mg., △; and phenmetrazine 50 mg., ⬡.

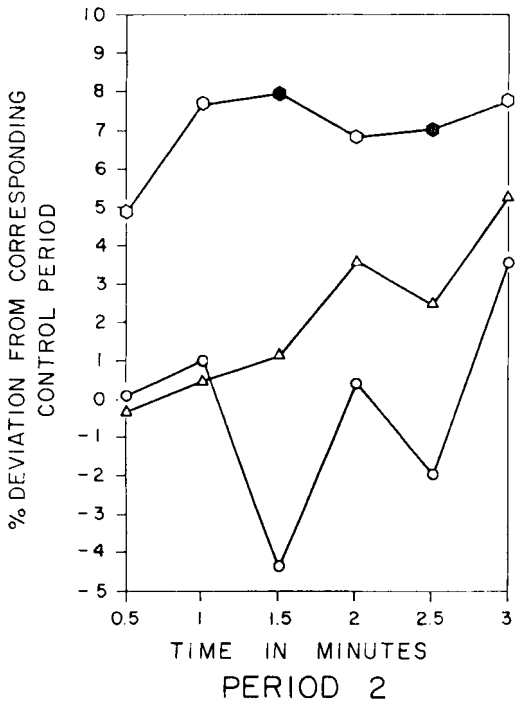


TABLE V.—MEAN CHRONIC DEANOL SCORES AT 4 AND 8-WEEK TEST PERIODS[a]

	Four Weeks		Eight Weeks	
	Placebo Group 1	Deanol Group 2	Placebo Group 2	Deanol Group 1
Tracking Test	660.2	720.7	649.8	635.2
5-Second tap	31.7	31.9	32.9	31.7
60-Second tap	326.0	333.4	329.1	321.2
Visual reaction	228.3	221.2	216.1	222.9
Complex reaction	814.2	764.0	728.3	733.2

[a] Group 1 received 75 mg./day of deanol for first 4 weeks while group 2 received a placebo. For the next 4 weeks, the treatments were reversed.

Table VI the analysis of variance of the data indicates a significant interaction only between order and drug for the pursuit test. It is apparent that the reason for the significance lies in the relatively high score obtained with the drug when it was administered in the first 4-week period. This score, when compared with the other three values in the pursuit test by a *t*-test, was found to be significant at $P < 0.001$ (8).

The results of the adjective check list test for mood were analyzed in several ways in order to obtain any possible indication of drug effect. As each adjective had a positive or negative mood characteristic, those that were checked were graded 3 points for a double check, 2 points for a single check and 1 point if they were undecided. The total number of positive points over the total negative points was expressed as the mood index. These values ranged from a low of 0.26 to a high of 79.0. Comparison of the 4 and 8-week values revealed no significant difference between drug and placebo. Neither was there any tendency for the mood index to increase during the 4 weeks of deanol administration when compared with the placebo administration. In some individuals, marked fluctuations in the mood occurred from week to week while with others, the values were relatively constant. Neither the direction nor the magnitude of the change could be related to the presence or absence of the drug nor to the period of testing. The comments of subjects concerning changes in mental or physiological functions were equally variable and unrelated to the drug or the period.

DISCUSSION

In any study of human behavior the selection of test procedures not only can influence the results but, unfortunately, is rather empirical. The general types of tests that may be employed can be categorized as: conditioned response, affect change, neurophysiological, perceptual, motor, mental, and perceptual-motor tests. Tests employed in these studies were selected in order to meet several criteria. Because of the large total number of individual drug-test scores (34,860) in addition to the pretest training, it was necessary to consider carefully the amount of time required for the actual performance of each test. In a more limited study, it might have been possible to select tests which would have been more sensitive to drug effects, although there is little information on this subject. Further requirements of each test were that the results must be reproducible, quantitative, and complement the other tests employed rather than measure essentially the same parameters. The simple visual reaction time met these requirements for reaction time tests. While the complex reaction time test employed was not a well-known procedure, it combined both simple mentation and reaction time, and it was thought that when compared with the results of the simple reaction time test it might serve to separate the complex reaction time into the time required for mentation and that needed to complete the simple reflex. Because of the variance within the complex reaction times, such a comparison was not feasible. The tapping tests provided objective indexes of motor activity in terms of the speed at which a simple voluntary movement could be repeated and the effect of fatigue upon an extended performance. The pursuit, perceptual-motor in nature, integrates visual perception with a complex motor response. It has been suggested that tests requiring a complex response are most sensitive to central drug effects (9, 10).

As caffeine was the first psychomotor drug to be known, a considerable number of performance tests have been conducted with this agent. Unfortunately, much of the evidence is conflicting. Its effect upon reaction time presents a case in point. In our study, caffeine induced a significant dose-related improvement in simple visual reaction time. It has, however, been reported to: decrease the reaction time (11–14), lengthen the reaction time (15, 16), produce no change in the simple reaction time after doses as large as 600–900 mg. of caffeine citrate (17–20), and to produce either a decrease or an increase dependent upon the size of the dose (21). Small doses between 60 and 240 mg. produced longer reaction times than the placebo, while larger amounts, 300–360 mg., shortened the times.

There are several possible reasons for these divergent results with such a seemingly simple test. In some of the investigations, cups of coffee were employed to measure the dose of caffeine, a technique which raises suspicion as to the actual amount of caffeine administered (13, 16). Further, the measurement of the reaction time (RT) is dependent upon numerous variables which makes the test fairly complex to administer. For one thing, it has been demonstrated that the reaction time is a function of the sense modality stimulated, auditory RT's being faster than visual RT's. Further, the number of sense organs stimulated affect the times, as any combination of auditory, visual, and electrical or shock stimuli induce faster RT's than do the individual stimuli. Additional factors influencing the RT include: stimulus duration and intensity, period of readiness, stress, age, body position, and the responding member (22). It is entirely possible that some of the reported effects may have been the result of uncontrolled variables. For example, the optimum period of readiness before the stimulus is presented has been determined to be between 1.0 and 4.0 seconds, a longer delay resulting in a lengthened RT. This was the approximate range employed in our study although, in some of the results cited, the authors have used indefinite periods of readiness or periods up to 10 seconds.

Perhaps the most significant finding with regard to caffeine was that in three of the five tests, that is 5-second tapping, complex reaction time, and the tracking tests, an inverse relationship was found to exist with regard to dose and effect. The only other drug which caused this effect was the 50-mg. dose of phenmetrazine in the complex reaction time. That increasing the dose of caffeine might be detrimental to performance has been previously reported for tracking tests (18, 22, 23). The doses employed in these observations were in the 200 to 300-mg. range. We observed that with a dose of 200 mg., performance was still improved and that it required 300 mg. to induce a modest and nonsignificant decrease in performance. Such minor differences could be related to subject or test variables.

The reason for the impairment of performance with a task such as tracking may be related to the fact that caffeine has been reported to reduce steadiness of the hand in doses of 300 mg. or more (13, 17, 18, 20, 21, 24–26). While there has been no mention of an improved steadiness with lower doses of caffeine, an inverse dose-effect relationship has been reported in a test of coordination in which the time required to thrust a stylus into a series of holes was measured. In this test, 60 to 120 mg. of caffeine improved the performance, while doses above 180 mg. slowed the response (21). This same

inverse effect that we also noted with the 5-second tapping test may help to explain reports that caffeine increases (17, 20, 21, 23), decreases (13), or produces no change (18, 27) in the tapping rate.

Obviously the effects of caffeine upon performance are dose-related and complex. It is suggested that the impaired steadiness or tremor induced by the high doses of caffeine may be the primary factor, or a direct extension thereof, in the tests in which the drug reduced performance, although it is difficult to equate muscle tremor directly with a test such as complex reaction time. Reasons for the improved performances with caffeine are presumably similar to those applying to the other psychomotor stimulants tested. It has been determined by others that caffeine heightens excitability, improves vigilance, facilitates simple intellectual tests, improves the mood, and decreases fatigue. Whether these are different expressions of the same effect is difficult to say, but any or all would likely have influenced the performance tests in this study. One may conclude that if caffeine is to be employed for the general improvement of performance, the dose should not exceed 100 mg. unless it can be definitely determined that the detrimental effect of larger doses is not a direct extension of the beneficial effect. In this case perhaps, the impairment can be negated through the concomitant administration of appropriate central depressants.

The results of the *d*-amphetamine testing were in general agreement with those previously reported. It had been found to induce somewhat equivocal results in the tapping rate. Both an increase (20) in the rate and no change (18, 28) have been reported. We observed a dose-related trend toward improvement which was not significant, although we did not use as high a dose as some of the reports which found improved performance. An important variable in this test is the state of fatigue. As indicated in the 60-second test, *d*-amphetamine produces a significant increase in the rate at both the 2 and 3-hour periods. Other workers have demonstrated that *d*-amphetamine can prolong the time that an individual can perform physically fatiguing work (29–32). Repeated testing, or testing with intervals longer than 5 seconds would be expected to increase further the minimal improvement which we noted in the 5-second test. While the *d*-amphetamine was not significantly effective in any test except 60 second tapping, which is a measure of fatigue, it has been reported that 5 mg. of the drug significantly improves the score in a multidimensional pursuit test (33). This difference may be attributed to the greater sensitivity of the multidimensional pursuit test.

Phenmetrazine and methyl phenidyl acetate significantly improved the performance in the 5 and 60-second tapping rate, visual reaction time, and the tracking test. It has been previously observed that subjects depressed with phenobarbital were able to perform simple arithmetic calculations faster when they received 20 mg. of methyl phenidyl acetate (34). Phenmetrazine was found to improve mental performance approximately 9% in well-rested subjects and 40% in the presence of fatigue (35). Studies comparable to those reported in this paper have not been disclosed, but within the limitations imposed by the drug doses and the tests employed, these agents gave indication of greater promise for the improvement of performance than did either caffeine or *d*-amphetamine.

The fact that the central depressants did not significantly affect the performance tests is not surprising. Low doses of central depressant drugs have been generally found to be without effect upon simple performance tests similar to the types which we used (36, 37). Kornetsky found that meprobamate did not affect learning or reaction times in a dose of 800 mg., but in a 1600-mg. dose, impairment of performance was observed (38). In general, tests requiring integration of several functions, such as a simulated automobile driving apparatus (8) or a multidimensional pursuit test (39) are sensitive to moderate central depression. While the statistical analysis of the data did not demonstrate any depressant drug effects, a less sophisticated approach of simply observing trends gives some indication of a depressed performance. For example, as seen in Table IV, the greatest reduction in performance with the complex reaction time occurred with the largest doses of the tranquilizers. Further, the two larger doses of chlorpromazine (50 and 100 mg.) produce a deteriorated performance in four out of the five tests. It had been reported that chlorpromazine at the 100-mg. level impairs the pursuit test, tapping rate, and hand steadiness (40).

The tranquilizers should not be necessarily considered as agents which reduce performance, as the ability to perform certain tasks may actually be improved in the presence of fear, anxiety, or tension. This action has been demonstrated with both oxanamide (41) and meprobamate (42) using subjects having demonstrable nervous tension. Unfortunately, the experimental production of anxiety or tension in human subjects has not been adequately studied. It has been demonstrated that with an increase in muscle tension, performance will improve, but beyond a certain amount of tension it will rapidly fall off (43). It was previously noted in the discussion of the central stimulants that increasing the dose of caffeine beyond 100 mg. generally resulted in a performance decrement. These larger doses of caffeine were also found to induce tremor and other signs of muscle tension. It is possible with high dosage levels of caffeine, and perhaps of other central stimulants as well, that the concomitant administration of a tranquilizer may improve the level of performance above that obtainable with a stimulant alone.

A number of investigators have suggested that both caffeine and the amphetamines prolong the period over which an individual can maintain the level of performance in physically fatiguing tests (29–31, 44–47). There has been little evidence, however, to indicate the exact mechanism by which fatigued performance is mitigated. These drugs may either maintain the base-line level of performance, thereby preventing a performance decrement, or they may elevate the initial performance level, thus allowing a decrement to occur without dropping below the base-line. Neither caffeine nor *d*-amphetamine were tested in this phase of the work as both phenmetrazine and methyl phenidyl acetate appeared to be equally or more active, resulted in a better dose-response relationship, and had not been previously tested for their effect upon fatigue. Phenmetrazine in a 50-mg. dose was significantly effective in both the 3-minute tapping and 6-minute

pursuit tests. From the initial points in Figs. 15, 16, 18, 19, it can be seen that the effect upon fatigue is accomplished in part by elevation of the initial level of performance and, as best seen in the tracking test curves, also by the time-related widening of the difference between the points for the placebo and phenmetrazine. This increase in difference reflects a reduction in the rate of fatigue-induced decrement.

From the results obtained with deanol, several possible conclusions may be reached. As there was no indication of activity with the mood test and most of the psychomotor tests, it may be concluded that in the dose and with the duration tested, deanol does not produce central stimulation of the magnitude observed with the other stimulants. The reason for the highly significant ($P < 0.001$) difference between the effect of deanol at the end of the first 4 weeks of the 8-week test period and at the end of the second 4 weeks, is not clear. If this difference is related to the drug, then there must have been an interaction between the drug and some unknown, uncontrolled factor that differed between the first and the last 4 weeks of testing. It is suggested that the factor might have been the heightened interest or motivation during the early stages of testing. Although this type of interaction has not been reported, it is of interest to note in Table V that both the drug and placebo scores in the pursuit test were highest at 4 weeks.

The observed effect of the deanol treatment upon mood and other subjective responses is at variance with reported results (48). The responses described by others: a more affable mood, greater ability to concentrate, the ability to stop smoking, increased tolerance of contact lenses, and less stimulation from amphetamines, were presumably obtained with low daily doses of from 10 to 30 mg. of the drug. Similar conclusions might be drawn from a casual or uncritical inspection of our own data. We found that nervousness was reported five times by individuals taking deanol and four times by the controls. An increased incidence of headaches was noted four times by the controls. An increased incidence of headaches was noted four times by deanol subjects and six by the placebo group. There were six reports that more sleep was needed with deanol and five with the placebo. Conversely, the need for less sleep was indicated nine times in the placebo group and eight times in the deanol subjects. An increase in libido was noted once in each group. It may be of some consequence that during the first 4 weeks both drug and placebo groups made a total of 96 comments concerning subjective responses, while during the last 4 weeks, only 54 comments were made. The suggestion, previously advanced, that the significant effect of deanol upon tracking performance during the first 4 weeks might be related to an interaction with a heightened initial interest, would tend to be supported by this evidence.

Any final interpretation of the experimental results, in terms of their possible application to useful tasks, must be predicated upon the specific tests which were employed. Because a particular drug could not be demonstrated to affect a specific test does not mean that activity might not be observed, perhaps, in a more appropriate or total measure of performance. Conversely, if a drug was demonstrated to be effective, it may generally be assumed that while more sensitive test procedures would also be affected, total performance may still not be improved.

Analysis of Phenobarbital in Relation to its Degradation Products

By FREDERICK TISHLER†, LEE F. WORRELL‡, and JOSEPH E. SINSHEIMER

The effect of the degradation products of phenobarbital upon six of its quantitative literature assays has been studied. Two new colorimetric procedures and an infrared method for the determination of phenobarbital are described and the effects of degradation products upon these assays is also discussed. Differential ultraviolet spectrophotometric analysis was found to be the assay procedure most useful for the determination of phenobarbital in the presence of its degradation products. This analysis has also been successfully applied to phenobarbital in various dosage forms.

THE LITERATURE contains little information of the effects of the degradation products of barbiturates upon the quantitative assays of the respective barbiturates. Jackson, *et al.* (1), have shown that the decomposition products of barbital did not interfere with its ultraviolet spectrophotometric assay as described by Goldbaum (2).

Since the instability of barbiturates (3-5) and the isolation of their decomposition products (6, 7) are well described in the literature, it was the purpose of this investigation to study the effects of the hydrolysis products of phenobarbital upon its most widely used quantitative assays. The decomposition products of phenobarbital which were used in this study included the following: phenylethylacetylurea, phenylethylmalonic acid, phenylethylmalonamide, α-phenyl-*n*-butyric acid, α-phenyl-*n*-butyramide, and urea.

The quantitative methods chosen for the study included: (*a*) the U.S.P. gravimetric assay (8), (*b*) a volumetric precipitation titration (9), (*c*) a nonaqueous titration (10), (*d*) the cobalt colorimetric procedure (11), (*e*) a direct ultraviolet spectrophotometric method (12), and (*f*) a differential ultraviolet spectrophotometric method (2, 13, 14). In addition to the above literature procedures, two new colorimetric assays were developed and their applicability for the analysis of phenobarbital in the presence of its degradation products was studied.

EXPERIMENTAL

Apparatus and Materials

A Beckman model DU spectrophotometer and a Zeromatic pH meter, and a Perkin-Elmer model 21 infrared spectrophotometer were the instruments used in this investigation. The melting points reported are corrected.

Phenobarbital, U.S.P. grade, was recrystallized from dilute ethanol, m.p. 176-178°.

Phenylethylacetylurea was prepared by thermal degradation of a 5 per cent aqueous solution of sodium phenobarbital and isolation of the precipitate. Recrystallization from dilute ethanol gave a melting point of 147-149° (3, 6, 7).

Phenylethylmalonic acid was prepared by the hydrolysis of the diethylester of the acid with potassium hydroxide according to the procedure of Tasselly, *et al.* (15). Recrystallization from benzene gave a melting point of 155-158° with liberation of carbon dioxide (6, 7).

Phenylethylmalonamide was prepared by heating the corresponding acid with phosphorus pentachloride on a steam bath for 6 hours. The phosphorus oxychloride formed was distilled off with the aid of a steam bath and water aspirator. The crude phenylethylmalonyl chloride was then added to a well cooled ether solution saturated with ammonia. The precipitated amide was dissolved in acetone and, after evaporation of the solvent, was recrystallized from dilute ethanol, m.p. 119-121° (6, 7).

α-Phenyl-*n*-butyric acid, m.p. 42-44°, and α-phenyl-*n*-butyramide, m.p. 83-84° were purchased from Eastman Organic Chemicals and recrystallized from dilute ethanol.

Urea, A.R., m.p. 132-133°, was used as purchased from Mallinckrodt.

Sörenson phosphate buffer, pH 7.38. The buffer is prepared by mixing 20 ml. of sodium acid phosphate solution (9.21 Gm. of $NaH_2PO_4 \cdot H_2O$/1000 ml.) and 80 ml. of dibasic sodium phosphate solution (9.47 Gm. of Na_2HPO_4/1000 ml.).

Elimination of Acidic Impurities

The following procedure was applied to mixtures of phenobarbital and its acidic degradation products, each of which was present in an amount equivalent to a 50% decomposition of 0.1 Gm. of phenobarbital: The mixture, after evaporation of any solvent, was mixed with three 10-ml. portions of petroleum ether (40-60°), in which phenobarbital is insoluble and α-phenyl-*n*-butyric acid is soluble. Each portion was decanted, filtered, and the petroleum ether solution discarded. The filter paper was washed with several portions of acetone and added to the petroleum ether-washed mixture. After evaporation of the solvent, 30 ml. of Sörenson phosphate

Received October 25, 1961, from the University of Michigan, College of Pharmacy, Ann Arbor.

‡ Present address: University of Texas, College of Pharmacy, Austin.

buffer (pH 7.38) was added and the mixture stirred with a magnetic stirrer for one-half hour. Twenty milliliters of chloroform was added and the mixture stirred for an additional 5 minutes. The chloroform layer was drawn off by use of a separator and the aqueous phase was extracted with two additional 20-ml. portions of chloroform. The combined chloroform extract, after evaporation of the solvent, was then employed in the various analyses.

Assays

Differential Ultraviolet Analysis.—A sample of about 0.100 Gm. of phenobarbital is dissolved in an ammonia-ammonium chloride buffer (pH 10.0 ± 0.2) in a 1000-ml. volumetric flask. One 10-ml. portion of this solution is diluted with the buffer, pH 10.0, in a 100-ml. volumetric flask. A second 10-ml. sample is transferred to a 100-ml. volumetric flask, diluted to volume with buffer, pH 10.0, and 10 ml. of 1.0 *N* hydrochloric acid (final pH 1.5 ± 0.2). The absorbance of the alkaline solution is determined relative to the acid solution in the reference cell at 241 mμ. A blank solution was prepared and was found to have no contribution due to reagents and solvents at 241 mμ.

Dimethylglyoxime-Thiosemicarbazide Colorimetric Procedure.—A sample of phenobarbital, 0.005 Gm./10 ml. of 0.1 *N* sodium hydroxide, is decomposed at 100° for 90 minutes. Five milliliters of 1.0 *N* hydrochloric acid is added immediately to stop the degradation. A 1-ml. quantity of dimethylglyoxime solution (3% w/v in concentrated hydrochloric acid) and 1.0 ml. of thiosemicarbazide solution (1% w/v in 70% ethanol) are added. The mixture is heated for 105 min. at 100°. After cooling, the solution is diluted to volume in a 25-ml. volumetric flask with distilled water and the absorbance determined at 532 mμ relative to distilled water.

Copper-Pyridine Colorimetric Procedure.—The sample of phenobarbital, approximately 0.050 Gm., is dissolved in 4 ml. of a 4% ammonium hydroxide solution. To this solution is added 2 ml. of a copper-pyridine reagent (2 ml. of pyridine and 25 ml. of a 3% copper sulfate solution). After 3 hours, the solution is filtered with aid of a filtering stick and washed with several small portions of distilled water. To the suspension of the colored precipitate in distilled water, 5 ml. of concentrated ammonium hydroxide solution is added, and the precipitate decomposed in a steam bath. The solution is quantitatively transferred to a 500-ml. volumetric flask and diluted to volume with distilled water. The amount of copper present is determined colorimetrically with sodium diethyldithiocarbamate by the procedure of Charlot and Bezier (16) on a 2-ml. aliquot sample. The amount of copper is related in turn to the concentration of phenobarbital present.

Quantitative Infrared Analysis of Phenobarbital in Combination with Phenylethylacetylurea.—*Method I.*—The sample to be determined is dissoved in an amount of reagent chloroform so that the concentration of phenobarbital is 1% or less. The absorbances at 5.75 and 6.39 μ are determined from the spectrum produced in an 0.1-mm. cell with chloroform as the blank and the results compared to standards. The 5.75 μ band represents the concentration of phenobarbital and the 6.39 μ band represents the concentration of the ureide.

Method II.—The spectrum is obtained as directed under *Method I.* The amount of phenobarbital present is calculated from its 5.75 μ band. A blank sample is made containing this amount of phenobarbital in chloroform and the unknown sample is run against this blank. The concentration of ureide is determined from its 5.83 μ band.

DISCUSSION

The quantitative literature assays of phenobarbital were tested for interference using an amount of each degradation product corresponding to a complete hydrolysis of phenobarbital. Several of the decomposition products were found to interfere with the assays. The acidic decomposition products interfered with the gravimetric, nonaqueous titration, and cobalt colorimetric procedures. The use of a Sörenson phosphate buffer, as described above, was found to be the method of choice for the removal of acidic decomposition products. Rotondaro (17) has employed a bicarbonate purification procedure but in our hands, inconsistent recovery of the barbiturate was obtained due to the variation in pH of the bicarbonate solution.

The ultraviolet spectra for the degradation products of phenobarbital under the same conditions used by Mattson (12) for his determination of barbiturates are given in Fig. 1. At the wavelength of 240 mμ used in this analysis, the ureide would cause the greatest interference. Since differential ultraviolet spectrophotometric methods have been shown to be more selective for barbiturates, the

TABLE I.—COMPARISON OF ASSAYS

Technique	Sensitivity, (Sample Size)	Accuracy and Precision, Av. % Recovery ± S. D.	
Gravimetric	0.200–0.250 Gm.	98.1 ± 0.7[a]	...
Volumetric precipitation	0.100 Gm.	101.9 ± 1.0	102.1 ± 1.1[b]
Nonaqueous titration	0.100 Gm.	99.9 ± 0.1	99.9 ± 0.2[c]
Cobalt colorimetric	0.005 Gm./25 ml.	100.2 ± 1.5	98.3 ± 1.7[c]
Differential ultraviolet method	0.001 Gm./100 ml.	99.9 ± 0.1	99.9 ± 0.1[b]
Dimethylglyoxime-thiosemicarbazide method	0.005 Gm./25 ml.	99.2 ± 0.9	...
Copper-pyridine method	0.005 Gm./50 ml.	99.8 ± 1.0	99.7 ± 1.0[b]
Infrared analysis	0.125 Gm./25 ml.	...	97.8 ± 1.0[d]

[a] The results in this column are based on the analysis of pure samples of phenobarbital. [b] Determined in the presence of all the degradation products. [c] Determined after the elimination of interfering degradation products. [d] Determined in the presence of phenylethylacetylurea.

influence of the degradation products on this technique was studied.

Williams and Zak (13) and Goldbaum (2) have employed the difference maxima obtained from the spectra of the first and second ionic species of the barbiturate for quantitative purposes, while Walker, *et al.* (14), used the difference maxima obtained from the nonionized and first ionized species for the determination of barbiturates in urine and blood. Since the difference maxima involving the second ionic species depends on the use of extremely basic and, therefore, unstable solutions of phenobarbital, this procedure was not employed. The method of Walker, *et al.*, was further investigated and modified as described in the experimental procedure. The absorbance of each of the degradation products at 241 mμ was found to be constant between the pH range of 1 to 12. Thus, the degradation products do not interfere with this differential method of analysis.

In addition to the literature assays, two new colorimetric procedures have been developed and their usefulness for the assay of phenobarbital in the presence of its degradation products was investigated. The dimethylglyoxime-thiosemicarbazide procedure is based upon a qualitative test of urea compounds as described by Ohkuma (18). Since this method depends on the decomposition of phenobarbital with the formation of urea and phenylethylacetylurea, a sample should be tested prior to hydrolysis for a positive reaction due to these degradation products. The other decomposition products do not interfere with the analysis. At the end of 1 hour, the blank used in this determination becomes cloudy. However, since the absorbance due to the blank is negligible at 532 mμ, distilled water is employed as the blank.

Copper-pyridine derivatives of barbiturates have been investigated by Zwikker (19), Fouchet (20), and Levi and Hubley (21). The formation of this phenobarbital derivative followed by the quantitative determination of its copper content was found to be useful for the determination of phenobarbital in combination with its degradation products.

Infrared spectroscopy was found to be a useful procedure in the qualitative and quantitative determination of phenobarbital both alone and in the presence of its main degradation product phenylethylacetylurea. Phenobarbital exhibits a carbonyl doublet which serves as a criterion of the purity of phenobarbital. When the ratio of the 5.75 and 5.89 μ carbonyl doublet for phenobarbital is not 1 to 1.26, the presence of ureide is indicated. Method I or method II can be used to determine the concentration of phenobarbital and phenylethylacetylurea. Method II should be employed when the concentration of the ureide is less than 0.25% since the 6.39 μ band of the ureide does not follow Beer's law below this concentration. A comparison of the methods investigated is summarized in Table I. The nonaqueous titration and the differential ultraviolet method are highly satisfactory with regard to accuracy, precision, and efficiency. Where degradation products are present, the differential ultraviolet method offers the additional advantage of eliminating a prior separation of interfering products. The differential ultraviolet procedure has been used in these laboratories in the kinetic study of the degradation of phenobarbital (22).

TABLE II.—DIFFERENTIAL ULTRAVIOLET ANALYSIS OF PHENOBARBITAL ELIXIR U.S.P.

Amount Present		4.00 Gm./L.
Found	1	3.98
	2	3.99
	3	3.98
	4	3.99
	5	4.00
Average		3.99 Gm./L.

To serve as a basis for the quantitative determination of phenobarbital preparations, the difference in molecular extinction coefficient, $\Delta\epsilon$, was determined from standard solutions. The average of 10 determinations gave a value of 9404 for a molar solution of phenobarbital at a pH of 10 ± 0.2 over that of a molar solution of a pH of 1.5 ± 0.2 at 241 mμ. To test the applicability of the differential analysis to a pharmaceutical formulation, phenobarbital elixir U.S.P. (8) was prepared and analyzed for its phenobarbital content. In Table II are presented the results of the analysis. No interference of the components of the elixir was found in the differential ultraviolet analysis, while Mattson (12) reported that the amaranth interfered with the direct ultraviolet procedure and an elixir base was necessary as a blank.

Ephedrine and amphetamine do not show changes in ultraviolet spectra under the conditions of the differential ultraviolet method, and therefore the general usefulness of this method is further illustrated in the analysis of phenobarbital combinations of the above compounds.

Pharmaceutical Investigation of Selected Alberta Bentonites I

Geology and Identification

By ARTHUR J. ANDERSON† and ELMER M. PLEIN

Bentonite samples were collected from a number of Alberta deposits. Of these, 23 were indexed in table form to show location and other information dealing with the parent beds. On a selected suite of samples, identification as bentonites was confirmed by differential thermal and X-ray diffraction techniques.

EARLY INFORMATION concerning bentonite deposits in western Canada for the most part is found as brief reports in publications of the Canadian government (1–4). Of particular value in this respect are the comprehensive surveys of Spence (5) and Spence and Light (6).

In 1949 the discovery of major oil reserves in Alberta brought an unprecedented demand for the high-swelling type of clay. With no known reserves of suitable quality in Canada, all supplies, of necessity, were imported from the United States. In recent years, however, intensive subsurface exploration programs carried out by commercial interests resulted in the location of a number of reserves considerably better in quality than those previously described. Of these, deposits uncovered at Rosalind and Onoway were considered sufficiently important to warrant commercial development. Mines and processing plants were established at both locations with production designed to meet the needs of the petroleum and associated industries.

Our interest in the material arose when claims were made that certain beds contained bentonite comparable in some respects to that obtained from the Black Hills region of Wyoming and South Dakota. A subsequent inquiry revealed that insufficient information was available to allow for an adequate pharmaceutical evaluation of bentonites from any of the known Alberta deposits. For that reason, a study was undertaken with a view to determining the presence of reserves of pharmaceutical grade clay in the province.

GEOLOGY

Byrne (7) states that in Alberta, thin beds of bentonite are fairly common throughout the Cretaceous and Tertiary eras. However, thick accumulations have been reported only from the upper Cretaceous, with the Edmonton formation undoubtedly being the most important for future prospecting (Fig. 1). The occurrences found in other levels of the upper Cretaceous as well as in the Paskapoo member of the Tertiary are considered to have little commercial importance.

EARLY INFORMATION concerning bentonite deposits in western Canada for the most part is found as brief reports in publications of the Canadian government (1–4). Of particular value in this respect are the comprehensive surveys of Spence (5) and Spence and Light (6).

In 1949 the discovery of major oil reserves in Alberta brought an unprecedented demand for the high-swelling type of clay. With no known reserves of suitable quality in Canada, all supplies, of necessity, were imported from the United States. In recent years, however, intensive subsurface exploration programs carried out by commercial interests resulted in the location of a number of reserves considerably better in quality than those previously described. Of these, deposits uncovered at Rosalind and Onoway were considered sufficiently important to warrant commercial development. Mines and processing plants were established at both locations with production designed to meet the needs of the petroleum and associated industries.

Our interest in the material arose when claims were made that certain beds contained bentonite comparable in some respects to that obtained from the Black Hills region of Wyoming and South Dakota. A subsequent inquiry revealed that insufficient information was available to allow for an adequate pharmaceutical evaluation of bentonites from any of the known Alberta deposits. For that reason, a study was undertaken with a view to determining the presence of reserves of pharmaceutical grade clay in the province.

GEOLOGY

Byrne (7) states that in Alberta, thin beds of bentonite are fairly common throughout the Cretaceous and Tertiary eras. However, thick accumulations have been reported only from the upper Cretaceous, with the Edmonton formation undoubtedly being the most important for future prospecting (Fig. 1). The occurrences found in other levels of the upper Cretaceous as well as in the Paskapoo member of the Tertiary are considered to have little commercial importance.

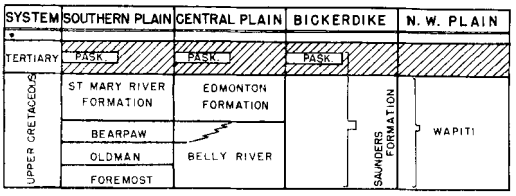

Fig. 1.—Stratigraph table of bentonite-containing formations in Alberta. *, Quaternary; Pask., Paskapoo.

In general, the Edmonton formation consists of poorly indurated shales and clays mixed with feldspathic siltstones and sandstones. Beds of relatively pure bentonite usually are found as lenses of varying widths. Coal seams are plentiful, and iron concretions are sometimes encountered.

EXPERIMENTAL

Collection and Preparation of Samples.—Since bentonite beds are known to vary widely in properties within short distances, a number of core samples are normally taken from each deposit to obtain an appraisal of clay quality throughout the occurrence. In this study, such a program was considered impractical because of transportation difficulties and the limited facilities available. Instead, every effort was made to obtain clean material, at varying depths below the surface of the deposit. In some instances a trenching procedure was employed to prevent contamination with surface sand. Several portions were gathered from different parts of each deposit and mixed to form a composite.

It was recognized that such samples were still not truly representative. For this reason, subsequent laboratory examination was considered to give only a general indication of the quality of the parent beds.

Twenty-nine samples were examined in the course of this work (Table I). Clays collected during field trips averaged between 8 and 10 lb. in weight, while samples received from other sources varied widely in size from 200 Gm. to 9 Kg. Coarse contaminants were removed by hand in the laboratory and the remaining material was dried in an oven at 90°. Each sample was reduced to a fine powder (200 mesh), mixed well to obtain a uniform blend, and then stored in a suitable glass, metal, or polythene container.

Identification of Clays.—Even though most of the samples used in this study were obtained from bentonite deposits which previously had been described by professional geologists, all clays were again identified as bentonite by qualified mineralogists either during or after collection. Recognized field tests were employed for this purpose.

After laboratory investigation had been conducted for some time it was felt that instrumental identification of the better and more interesting samples would be desirable. Arrangements were then made to have a suite of selected clays subjected to analysis by differential thermal and X-ray diffraction techniques.

Differential Thermal Analysis.—In recording the thermograms of the clay samples, a heating rate of 15° per min. was maintained over the entire temperature range (Figs. 2 and 3). Arrangement of the thermocouples, design of the block, and other details of the equipment used are described by Berkowitz (8).

[a] Samples not listed were rejected after preliminary examination. [b] Rosalind beds contain several grades of clay roughly classified on a color basis: green (1, 1A, 21, 22, 28), gray (2), and yellow (3). [c] A small sample of finely ground bentonite received from the American Colloid Co. for testing. When it proved satisfactory for use as a control, a larger quantity was supplied for this purpose (sample 29). [d] Not previously reported. [e] Fines collected from vent stack of Rosalind mill.

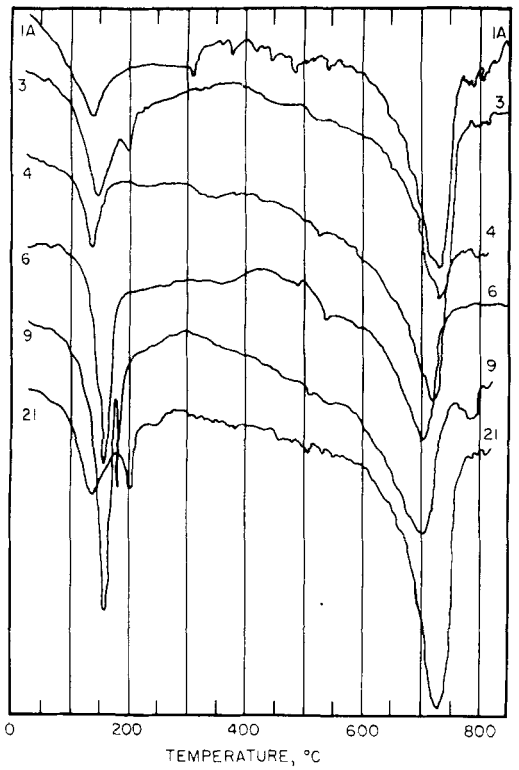

Fig. 2.—Differential thermal analysis of selected Alberta bentonites.

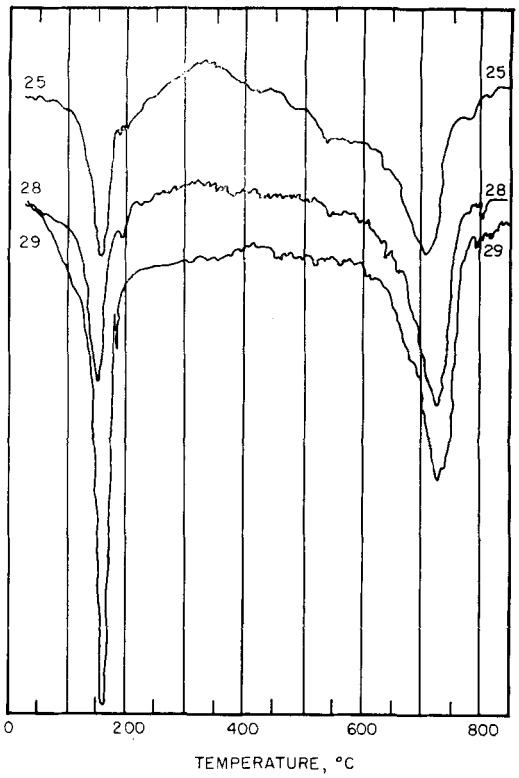

Fig. 3.—Differential thermal analysis of selected Alberta bentonites.

X-Ray Diffraction Analysis.—The clay portion of bentonite has been shown to consist primarily of montmorillonite. With the discovery that this material was actually crystalline in nature, it became possible to employ X-ray techniques to measure the characteristic angles of reflection of such rays from the atomic planes of the crystals.

A 2% (w/w) suspension of clay was prepared in a Waring Blendor (9). This mixture was transferred to a measuring cylinder and allowed to stand undisturbed for 8 hours and 10 min. By means of a pipet, 25 ml. of the suspension was then withdrawn from immediately below the surface and allowed to run into a clean Petri dish containing two glass microscope slides which were completely covered in the process. The assembly was then dried in an oven at 55–60°, and the slides removed with the aid of a razor blade to prevent chipping the oriented clay film. The prepared sample was then placed in a Phillips X-ray spectrometer and exposed to a monochromatic beam obtained through the use of a copper target and nickel filter. Scanning rate was set at 1° per min., through 40°, with the tracing recorded on a synchronized Brown strip chart recorder.

A diffraction tracing of the clay film was obtained, after which the slide was transferred to a glass desiccator and exposed to ethylene glycol vapor for 1 hour at room temperature. A second tracing was then prepared as before.

Basal (001) spacings and higher order reflections were calculated in each case and the values presented in Table II. As a matter of interest, Samples 28 and 29 were also heated to 550° for 30 min. and subsequently X-rayed. This latter procedure was undertaken to illustrate the reported collapse of montmorillonite under such conditions (10).

[a] Lattice spacings in Å.

DISCUSSION

The thermograms prepared in this series have generally similar shapes, although variation in certain details is observed. The initial endothermic

peak caused by loss of interlayer water occurs in all cases between 140 and 160°. Where present, the notch on recovery is attributed to the presence of calcium in the lattice. High temperature exotherms are not recorded because of difficulties encountered with the apparatus when temperatures were raised much above 800°.

Each sample was X-rayed before and after treatment with ethylene glycol, with the glycolated materials giving basal spacings slightly less than the accepted value of 17 Å. (11, 12). It was shown by Mackenzie (12) that this spacing would be reduced to lower values when insufficient ethylene glycol was present to complete the complex formation. However, before discarding the data, in question, a detailed study of the tracings was undertaken by Dr. L. B. Halferdahl.[1] While several of the clays showed quartz and/or gypsum peaks he was able to classify each of the samples as bentonite containing montmorillonite as the chief clay mineral. This finding, together with the evidence gathered from the differential thermal studies, was considered as sufficient to confirm the identity of the clays under study.

Further laboratory data designed to assist in evaluation of these clays as possible pharmaceutical agents will be reported in part II of this investigation.

Pharmaceutical Investigation of Selected Alberta Bentonites II

Limit Tests and Mechanical Analysis

By ARTHUR J. ANDERSON† and ELMER M. PLEIN

A collection of bentonite samples from known Alberta deposits was examined. Limit tests as described in the B.P. and U.S.P. were completed on each. Additional procedures were undertaken to assist in evaluation of physical properties of the clays. On the basis of this work, one sample was shown to be of pharmaceutical quality, with a second sample from the same commercially important deposit being excluded from this category on a minor technicality only.

TWENTY-NINE SAMPLES of bentonite taken from deposits throughout Alberta were examined in the course of this work. All clays were identified as bentonite by qualified mineralogists, with verification by differential thermal and X-ray techniques being made on a selected group of interesting samples (1).

A laboratory study of the collected materials was then made to determine the presence of reserves of pharmaceutical grade bentonite in the province. A rigorous chemical analysis was not undertaken since pharmaceutical requirements were based mainly upon the inherent physical properties of the clays. However, certain chemical procedures were completed to aid in characterization.

EXPERIMENTAL

All samples were dried at 90°, reduced to a fine powder (200 mesh) by passage through a laboratory hammer mill, and then mixed well to obtain a uni-

form blend. The materials were then stored in suitable closed glass, metal, or polythene containers.

After preliminary testing of several bentonites, a supply of Volclay B.C. grade[1] was chosen as most suitable for use as a control clay in this study.

Arsenic.—Since the B.P. (2) bentonite monograph contains a section limiting the maximum allowable arsenic content to not more than 8 p.p.m., it was felt that such data should be included in this study. For this purpose the quantitative procedure as detailed in the U.S.P. (3) was employed.

Nine Alberta clays, representative of deposits found in widely scattered areas of the province, were selected for this determination. Of these, seven clays yielded negative results, one a bare trace of color, and one a concentration of 1 p.p.m. of arsenic.

On the basis of the results obtained from the above sampling it was concluded that further testing was not indicated.

Alkalinity.—The B.P. states that a 2% w/v suspension of bentonite in distilled water should record a pH of 9.00–10.50. The U.S.P. requires a slightly narrower range of 9.00–10.00 for a 1 in 50 aqueous suspension.

Procedure

Two grams of clay was added in small portions to about 75 ml. deionized distilled water in a 100-ml. graduated cylinder. After all of the clay had been added and had settled to the bottom of the cylinder, more deionized water was added to the 100-ml. mark. The contents were then transferred to a Pyrex beaker containing a Teflon-coated stirring bar, and the assembly was placed on a magnetic stirrer. The contents were stirred at a rapid, uniform speed, and readings were taken with a Beckman Zeromatic pH meter using a calomel-glass electrode pair. The data are presented in Table I.

TABLE I.—pH VALUES OF ALBERTA BENTONITE AQUEOUS SUSPENSIONS[a]

Sample[b]	Mean	Range	Sample	Mean	Range
1	9.20	0.40	16	9.60	0.00
1A	8.87	0.20	21	9.15	0.00
3	8.93	0.12	23	9.70	0.00
4	9.35	0.10	24	9.83	0.05
5	9.27	0.05	25	9.70	0.00

7	8.54[c]	0.01	27	9.80	0.00
8	8.05[c]	0.10	28	9.00	0.00
9	8.80	0.00	29	9.50	0.00
10	9.03	0.20	30	9.22	0.05
11	8.60[c]	0.00	31	9.18	0.05
12	8.00[c]	0.15	32	9.37	0.05
15	8.62[c]	0.05			

[a] 2.0% w/v. [b] As indicated, certain samples were, for various reasons, discarded as unsuitable for laboratory testing. All clays were determined in triplicate with the exception of samples 8 and 23; in these two instances, duplicate readings only were recorded. [c] Considered as indicative of substandard bed.

Swelling Power.—To be acceptable as a pharmaceutical agent, a bentonite must show pronounced swelling ability upon hydration. The U.S.P. monograph describes a simple test designed to evaluate the swelling power of bentonite in distilled water. Readings are taken after 2 hours. The B.P. monograph sets a similar standard of quality. However, in this test the distilled water is replaced by a 1% sodium lauryl sulfate solution. The presence of the wetting agent assists materially in reducing the time needed to wet the powder. Furthermore, while the clay in this instance must also swell to the same apparent volume as before (24 ml.), the time required to do so is not specified.

The B.P. procedure was employed throughout in this determination. Clays were hydrated overnight and apparent volumes were read the next morning. Precautions were taken in each case to prevent loss of liquid through evaporation.

Six native bentonites were found to meet the official requirements of the test. However, a comparison of these values with those presented in Table I revealed little correlation between degree of alkalinity and swelling power. It was felt that this discrepancy could be due, in part at least, to excessive quantities of inert material in the native clays. Accordingly, a method for the removal of such substances was devised. This consisted of preparing 1 L. of a 4% (w/v) suspension of each clay sample in distilled water.[2] After sedimentation for 24 hours, the supernatant colloidal dispersion was removed by decantation and evaporated to dryness in an oven. The residue was then reduced to a 200-mesh powder and the B.P. test was employed, as before, to determine swelling power for each of the purified clays. Each sample was run in triplicate and the values averaged.

Apparent swelling volumes for each clay, before and after purification by water sedimentation, were compiled. These are presented in Fig. 1. Sample 7 could not be purified by this method since the total sample settled as "dead clay."

Mechanical Analysis.—During the preparation of bentonite dispersions it was observed that a marked difference in sand and silt content existed among the various samples. Since the presence of such inert material was considered undesirable in a pharmaceutical clay, a quantitative determination of sand, silt, and clay fractions of each sample was undertaken.

The U.S.D.A.[3] size limits for sand, silt, and clay fractions were employed (4). On this basis, 50 μ was taken as the dividing line between very fine sand and coarse silt. The lower limit for silt was set at 2 μ, and clay was considered to consist of all particles of diameters less then 2 μ.

Olmstead, Alexander, and Middleton (5) studied the application of the pipet method to mechanical analysis and developed an improved technique with a single pipet that was adapted by the Soils Laboratories of the U.S.D.A. Lyon and Buckman (6) suggested that the average surface soil could be considered to have a density of 2.65. Steele and Bradfield (7) later employed this factor to calculate sedimentation times at 25°. From this work it was determined that particles having a diameter of 2 μ and a density of 2.65 would require 41 minutes, 32 seconds at 25° to fall 1 cm. in a water medium.

[1] Received from the American Colloid Co., Merchandise Mart Plaza, Chicago 54, Ill.

[2] Because of their relatively high viscosity at this concentration, samples 1A, 21, 28, and 29 were further diluted to 2 L. to allow for satisfactory sedimentation.

[3] United States Department of Agriculture.

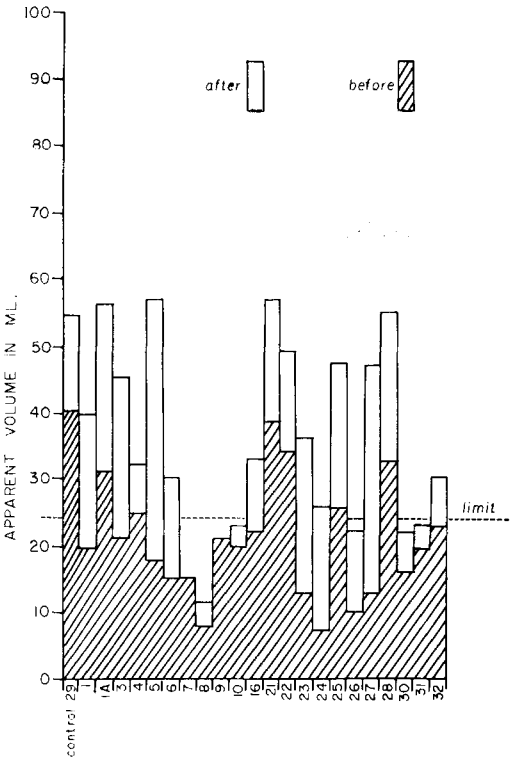

Fig. 1.—Swelling power of Alberta bentonites before and after purification by water sedimentation (2).

Procedure[4]

With the aid of a Waring Blendor, a 10-Gm. sample of air-dry clay was mixed to a smooth dispersion in 200 ml. of distilled water. The mixture was then transferred, with rinsings, to a 400-ml. electrolytic beaker, covered, and allowed to hydrate for 24 hours.

After hydration, 10 ml. of dispersing agent[5] was added to the system and the contents of the beaker were again transferred to a blending cup and stirred briskly for 20 minutes.

The dispersed sample was then washed onto a 300-mesh sieve,[6] the silt and clay passing through into a 1-L. graduated cylinder. Washing of the sieve contents was continued until the volume in the cylinder totaled 800 ml. Further washings were not collected, but the procedure was continued until the sand (and some coarse silt) was freed of any last traces of clay. Contents of the sieve were then washed into a tared aluminum dish, evaporated to dryness at 90°, and then dried to constant weight at 105°.

The silt and clay suspension was then made up to 1 L. with more distilled water, mixed well, and the cylinder placed in a suitable water bath at 25°. Sedimentation was calculated for 2-μ particles at 25° using the 2.65 density factor as recommended by Steele and Bradfield.

A 25-ml. automatic pipet with a filling time of 12 sec. was employed to obtain the clay aliquot at a depth of 8 cm. Filling of the pipet was accomplished by means of a controlled vacuum, and the contents were then transferred to a tared moisture dish. One rinse from the pipet was added and the dish was then placed in an oven at 90° until dry. Heating to constant weight was done at 105°.

All determinations were made at least in duplicate and reported in per cent on the basis of oven dry weight of the sample. In calculating the weight of clay obtained from the pipet aliquot, a correction factor was introduced to account for the weight of dispersing agent contained. The per cent of silt content was obtained by subtracting the sum of the percentages of sand and clay from 100. Values obtained are reported in Table II.

TABLE II.—PHYSICAL ANALYSIS OF ALBERTA BENTONITES

[a] Samples 29 and 32 were received as "grit free" powders due to their method of preparation.

Gel Formation.—Suspensions of swelling-type bentonite in suitable concentration will set to a gel, sometimes in a matter of seconds. Magnesium oxide has been shown to augment this effect significantly. An explanation of the phenomenon was later advanced by Hauser and Hirshon (8).

Both the B.P. and U.S.P. bentonite monographs contain provisions designed to set a minimum gel-forming standard for such clays. The test procedures are identical except for minor differences in wording. No more than 2 ml. of clear supernatant liquid should separate from the gel proper by the end of the test period.

For convenience, the B.P. procedure was followed in this study. Samples were prepared in triplicate, the results being averaged and presented in graphic form in Fig. 2.

[4] Based on the procedure employed in the Soils Laboratory, Research Council of Alberta, Edmonton, Alberta.

[5] Sodium hexametaphosphate, 35.70 Gm., and 7.94 Gm. of sodium carbonate per L. The sodium carbonate was employed as an alkaline buffer to prevent hydrolysis of the metaphosphate back to the *ortho* form.

[6] While the U.S.D.A. has set 50 μ as the lower limit of size for sand, a 300-mesh screen is usually employed for this purpose. Calibration of the screen used showed an average opening of 47.87 μ, indicating that at least a portion of the coarsest silt could be expected to remain in the sand fraction.

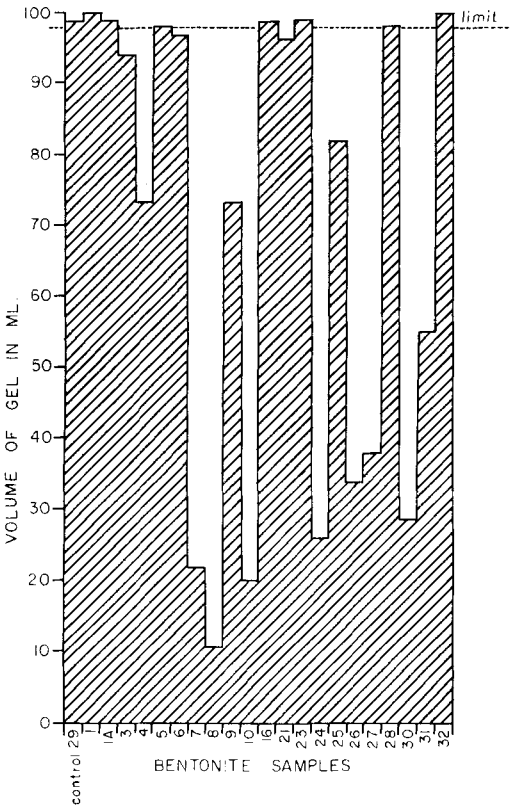

Fig. 2.—Gel formation of Alberta bentonites (2).

DISCUSSION

Alberta bentonites were found to be practically free of arsenic, making the clays suitable in this respect for use in medications to be taken internally. Alkalinity tests indicated that some samples were technically below standard. However, because the materials under test could not be considered as completely representative of each deposit, only five of the tabulated pH values were considered as probably indicative of substandard beds.

Swelling tests conducted on the clays indicate many are of the medium or low-swelling types. Six clays met official standards, four of which are from the Rosalind lease.[7] Preparation of clay concentrates by water sedimentation, with subsequent determination of swelling power of each, indicates that high-swelling fractions exist in a number of the known deposits. On that basis it would seem reasonable to anticipate that reserves of such high quality clay remain to be discovered in the province.

Twenty-one clays were examined for gel-forming ability. Seven of these were found to equal or exceed the official minimum requirements. It is interesting to note that of these, three clays had previously shown unsatisfactory swelling powers. Four of the seven samples which passed the gel-forming test were rich in clay content, but two of the seven were relatively poor in this respect. Such data only serve to accentuate the unpredictable nature of the native material.

On the basis of the official limit tests employed, only sample 28 was considered of pharmaceutical quality. Sample 1A, from the same beds was deficient in only one test, recording a pH of 8.87 instead of the required minimum of 9.00. Considering the method of collection, this deficiency could be considered a technicality.

While the B.P. "grit test" was not conducted on these materials, it is felt that the mechanical analysis procedure used was sufficiently stringent to afford an excellent indication of sand content to be found in the clays. Proper processing as a pharmaceutical grade bentonite would undoubtedly reduce this ingredient to a negligible quantity.

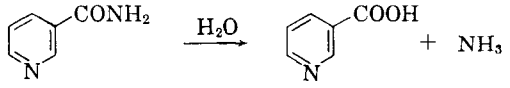
Rate Studies on the Hydrolysis of Niacinamide



By PER FINHOLT† and TAKERU HIGUCHI

The apparent first-order rate constant corresponding to the hydrolysis of niacinamide has been determined over the pH range 0.4–11.3 in purely aqueous solutions at 89.4°. Although the pH-rate profile shows a minimum between pH 4 and 6, the reaction velocity is relatively slow over the usual pharmaceutical range. Surprisingly, the second-order proton catalyzed rate constants for the free vitamin and its protonated form appear to be roughly the same. The hydrolytic reaction appears to be subject to both general acid and general base catalysis.

NIACINAMIDE is one of the most stable of the vitamins in common use. It has been reported (1) that a 10% niacinamide solution in water may be autoclaved at 120° for 20 minutes without any degradation occurring. The great stability of niacinamide is probably the reason why there has been so little work done on the kinetics of the niacinamide hydrolysis. The only kinetic study reported in the literature was made by Jellinek and Gordon (2), who studied the hydrolysis in hydrochloric acid solutions. They found that it differed from the hydrolysis of other amides such as benzamide in that the first-order rate constants for the hydrolysis did not pass through a maximum between 3 and 4 *N* hydrochloric acid. There was a steady increase in the rate constant with increasing hydrochloric acid concentration from 0.05 *N* up to 8.4 *N*. Jellinek and Gordon did not study the hydrolysis in less acidic solution nor in alkaline medium.

The scope of the present work was to study the hydrolysis of niacinamide both in acidic and in alkaline solution, and to determine to what extent the hydrolysis is catalyzed by hydrogen and hydroxyl ions and by general acids and bases. It is known from the literature that the hydrolysis of amides may be subject to general acid base catalysis. As an example may be mentioned the hydrolysis of chloramphenicol, which is catalyzed by ammonia and ammonium ions, mono- and dihydrogen phosphate ions (3), undissociated acetic acid, mono- and dihydrogen citrate ions, and monohydrogen oxalate, succinate, tartrate, fumarate, phthalate, malonate, glutarate, and adipate ions (4–6).

It is assumed that the breakdown of niacinamide can be attributed solely to the hydrolytic cleavage of the amide linkage according to the equation

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

EXPERIMENTAL

Materials.—The niacinamide used was niacinamide U.S.P. from Mallinckrodt, recrystallized from benzene. All reagents used were of analytical grade.

Assay.—The study of the hydrolysis of niacinamide required an assay method which permitted an accurate determination of niacinamide in the presence of nicotinic acid. For the separation of the two compounds an ion exchange procedure recommended by Sweeney and Hall (7) was used According to this, nicotinic acid at pH 4.5–5 was quantitatively adsorbed by the anion exchange resin IRA-400, while niacinamide was not adsorbed and was determined in the eluate.

For the determination of niacinamide in the eluate, ultraviolet spectrophotometry was used. The absorption spectrum of niacinamide has a maximum at 262 mμ. The molar absorptivity is dependent on pH, as seen from Fig. 1. The protonated form of the amide has a higher molar absorptivity than the nonprotonated form. In order to convert the amide completely to its protonated form, 10% concentrated hydrochloric acid was added to the eluate before the reading in the spectrophotometer, a Cary recording model 11MS,

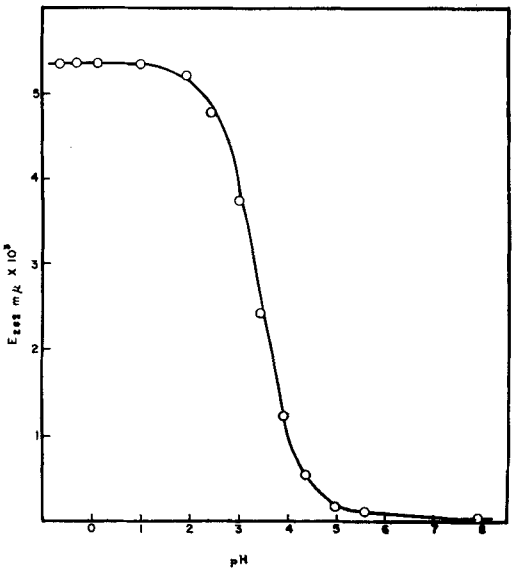

Fig. 1.—Plot showing the pH dependency of the molecular extinction coefficient of niacinamide at the absorption maximum at 262 mμ.

was made. A linear relationship between $A_{262m\mu}$ and concentrations of niacinamide ranging from 1 to 5 mg. in 100 ml. was found.

The complete assay method was as follows: An aliquot part of the sample, usually 2.00 ml., is added to the ion exchange column (Fig. 2) and adjusted to a pH of about 5. The column is washed with water. To the washings are added 10 ml. of the concentrated hydrochloric acid and water to 100 ml., and the absorbance measured in U.V. The content of niacinamide in the solution is read from a standard curve.

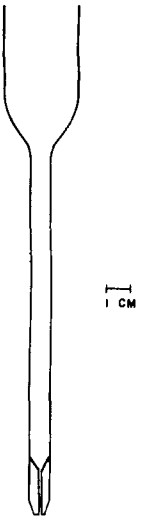

Fig. 2.—Ion exchange tube used for the separation of niacinamide and nicotinic acid.

By analyzing 30 samples with known content of niacinamide and niacin, 99–100.3% (average 99.6%) of the niacinamide was recovered. Sweeney and Hall found that about 0.8% of the niacinamide was hydrolyzed during the ionic exchange procedure. According to our results the amount hydrolyzed was even less. In no case will the hydrolysis on the column have any influence on the results of our kinetic studies.

High amounts of electrolytes in the solution on the column may, to some extent, displace the nicotinate ion from the column. With normal sodium chloride, for example, it was possible to elute nicotinic acid quantitatively. To analyze samples containing relatively high amounts of electrolytes it was, therefore, first necessary to determine the amount of the sample which may be collected through the column without getting any nicotinic acid in the eluate.

The procedure described proved to be satisfactory even in the presence of catechol, since this compound was firmly adsorbed by the resin.

Hydrolysis Experiments.—In most cases the following procedure was used: 122 mg. (0.001 *M*) of niacinamide was dissolved in 100 ml. of the appropriate buffer solution. The solution was placed in 5-ml. ampuls and heated to 89.4° in a constant temperature bath. Ampuls were taken out of the bath at appropriate intervals, cooled in ice, and the solution was analyzed. When a mixture of catechol and catecholate was used as buffer, the air in the ampuls was replaced by nitrogen.

In cases where the half-life was shorter than 2–3 hours, e.g., in strongly alkaline solution, the following technique was used: the alkaline buffer solution was heated to 89.4° in a 100-ml. volumetric flask in a constant temperature bath, and 122 mg. of niacinamide dissolved in 1 ml. of the same solution were added. Five-milliliter samples were withdrawn at appropriate intervals, mixed with a calculated amount of 50% sulfuric acid, and cooled in ice.

As far as those experiments are concerned where the main purpose was determination of the catalytic effect of a certain buffer, a series of solutions of different buffer concentrations but the same pH and ionic strength were required. To be able to calculate the composition of these solutions the pKa of the acid component in the buffer mixture was determined at 90° and at the actual ionic strength. The following equations were used for the actual calculations

At pH values less than 4

$$pH = pKa + \log \frac{[base] + [H^+]}{[acid] - [H^+]}$$

At pH values 4–8

$$pH = pKa + \log \frac{[base]}{[acid]}$$

At pH values greater than 8

$$pH = pKa + \log \frac{[base] - [OH^-]}{[acid] + [OH^-]}$$

[acid] and [base] are the measured amounts of the acid and the base component of the buffer mixture.

pH was determined at 90° with a Beckman expanded scale pH meter.

Determination of pKa of the Prontonated Form of Niacinamide.—The pKa of the protonated form of niacinamide was determined spectrophotometrically at room temperature, using the equation

$$pKa = pH - \log \frac{a_{NH^+} - a}{a - a_N}$$

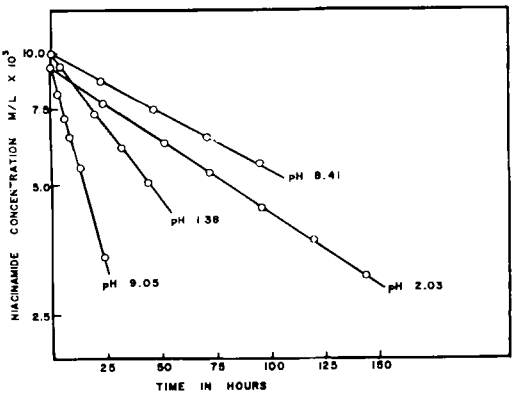
where a_{NH^+} = molecular extinction coefficient of the protonated form of niacinamide, a_N = molecular extinction coefficient of the nonprotonated form of niacinamide, a = the observed molecular extinction coefficient, and a_{NH^+} and a_N were determined in solutions of pure NH^+ and N. A pKa of 3.40 was found.

pKa was determined electrometrically at 25° and at 90° ($\mu = 0.5$). The following values were found: pKa at 25° = 3.42 and pKa at 90° = 3.12.

RESULTS AND DISCUSSION

Order of Reaction with Respect to Niacinamide.—The rate of disappearance of niacinamide from the solutions was found to be strictly first order with respect to niacinamide at pH values from 0.4 up to 11.3. There was a linear relationship between time and logarithm of residual niacinamide concentration, as shown in Fig. 3.

Primary Salt Effect.—In strongly acidic solution the first step in the hydrolytic process was presumed



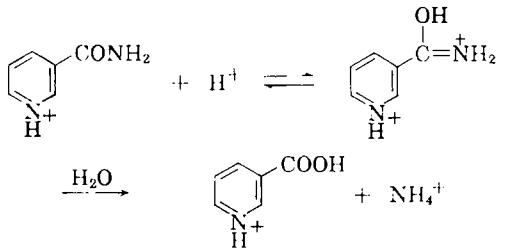


Fig. 3. Plots showing the overall first-order character of the hydrolysis of niacinamide at different pH values and 89.4°. For the actual runs 0.05*N* perchloric acid (pH 1.38), 0.5*M* phosphate (pH 2.03), 0.05*M* borate (pH 8.41), and 0.15*M* catecholate (pH 9.05) were used.

to be a reaction between hydrogen ions and the protonated form of the amide

Since a reaction between two charged species was involved in the hydrolytic process, a primary salt effect was expected. The existence of such an effect is obvious from Fig. 4 where the log of the rate constant k has been plotted against the square root of the ionic strength μ. The k values were found by making runs using 0.1 *N* hydrochloric acid or 0.02 *N* perchloric acid or 0.2 *N* perchloric acid to which different amounts of sodium chloride had been added. According to the theory of Brönsted and Bjerrum, there is a linear relationship between log k and the square root of the ionic strength when two charged species react in dilute solution ($\sqrt{\mu} < 0.2$). At higher concentrations the situation is more complex. It is therefore rather surprising that we find a nearly linear relationship between log K and $\sqrt{\mu}$ at $\sqrt{\mu}$ values from 0.2 up to 1, as shown in Fig. 4. Because of the primary salt effect in acid solutions all experiments in the acid region were carried out at the same ionic strength, namely $\mu = 0.5$.

In alkaline solution (pH 7–12) niacinamide will exist in the noncharged form. Experiments carried out in strongly alkaline solution showed, as expected, that there was no primary salt effect under these conditions. The same half-lives were found with 0.1 *N* sodium hydroxide as with 0.1 *N* sodium hydroxide containing 0.5 *M* sodium chloride (Fig. 5); and the same values were obtained with 0.025 *N* barium hydroxide as with 0.025 *N* barium hydroxide containing 0.5 *M* sodium chloride.

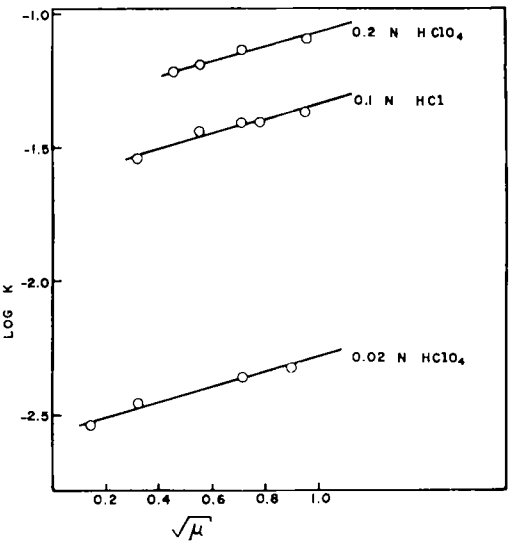

Fig. 4. Plots showing the effect of the ionic strength (μ) on the rate of niacinamide hydrolysis in strong acids at 89.4°. The ionic strength of the acids was varied by addition of different amounts of sodium chloride.

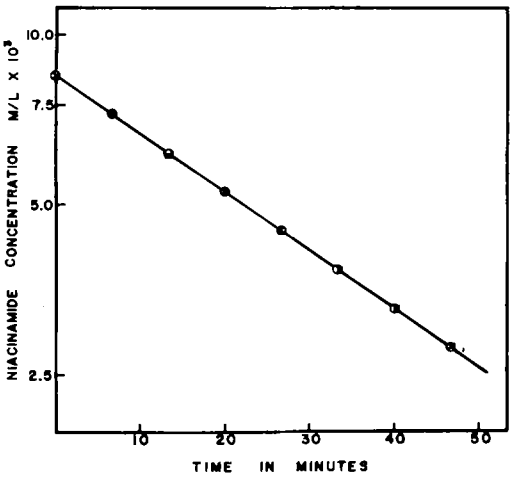

Fig. 5.—Plot showing the rate of niacinamide hydrolysis in 0.1*N* sodium hydroxide (o) and in 0.1*N* sodium hydroxide containing 0.5*M* sodium chloride (x). The coincidence of the experimentally determined points shows that the rate of niacinamide hydrolysis is independent of ionic strength.

Catalytic Effect of Hydrogen Ions and Hydroxyl Ions on the Hydrolysis of Niacinamide. The catalytic effect of hydrogen ions on the hydrolysis of the protonated form of niacinamide was determined by using hydrochloric acid or perchloric acid ($[H^+] \gtrsim 0.1$) as solvents. See Table I. At these high hydrogen ion concentrations niacinamide will exist only in the protonated form.

The catalytic effect of hydroxyl ions was determined by using solutions of sodium hydroxide or barium hydroxide as solvents. See Table II.

Catalytic Effect of General Acids and Bases on the Hydrolysis of Niacinamide. The catalytic

effect of certain buffers was determined by making runs with each buffer, varying the total buffer concentration but keeping the pH and the ionic strength constant in each series. By plotting the observed k values against buffer concentration, straight lines were obtained, the slopes of which were a measure of the catalytic activity of the buffers.

Figure 6 shows that phosphate buffers with pH 10.19 and pH 10.33 have a catalytic effect on the hydrolysis of niacinamide. At pH 8.64 the effect is very small. The phosphate buffers with pH 8.64 were solutions of Na_2HPO_4. The catalytic constant of HPO_4^- is obviously very small compared to the catalytic constant of $PO_4^{\equiv}$. The small slope of the line corresponding to pH 8.64 may be attributed partly to the amount of $PO_4^{\equiv}$ ions present in the Na_2HPO_4 solutions.

For the hydrolysis of niacinamide in the actual phosphate buffers the following equation is valid

$$k = k_0 + k_{HPO_4^-}[HPO_4^-] + k_{PO_4^{\equiv}}[PO_4^{\equiv}] \qquad \text{(Eq. 1)}$$

At pH 10.33 and pH 10.19 $k_{HPO_4^-}[HPO_4^-]$ is negligible compared to $k_{PO_4^{\equiv}}[PO_4^{\equiv}]$ and may be omitted, thus giving

$$k = k_0 + k_{PO_4^{\equiv}}[PO_4^{\equiv}] \qquad \text{(Eq. 2)}$$

k_0 is equal to k at zero buffer concentration, i.e., equal to the intercept of the lines with the y-axis.

$[PO_4^{\equiv}]$ may be calculated from the equation

$$\frac{[PO_4^{\equiv}]}{C - [PO_4^{\equiv}]} = \frac{ka_3}{[H^+]} \qquad \text{(Eq. 3)}$$

where C = total buffer concentration and ka_3 = $10^{-10.72}$ (89.4° and μ = 0.75).[1]

Using Eqs. 2 and 3, the run at pH 10.33 gives $k_{PO_4^{\equiv}}$ = 6.8, the run at pH 10.19 gives $k_{PO_4^{\equiv}}$ = 6.5. Average $k_{PO_4^{\equiv}}$ = 6.65 hr.$^{-1}$ mol.$^{-1}$ L.

Figure 7 shows the catalytic effect of phosphate buffers pH 6.40–7.70. There is an increase in k with increasing buffer concentration especially at

[1] A 0.2 M phosphate buffer pH 10.19 has μ = 0.74.

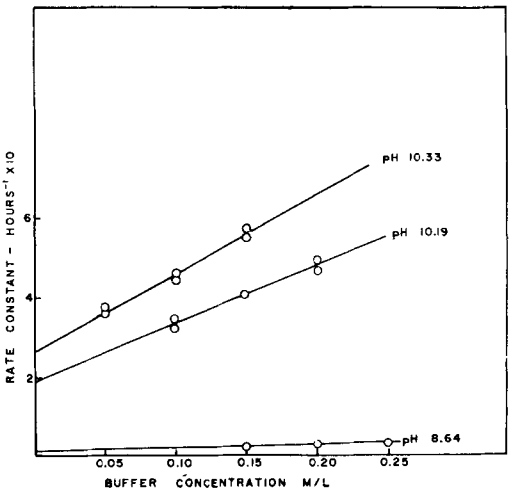

Fig. 6.—Plots showing the effect of phosphate concentration on the pseudo first-order rate constant of niacinamide hydrolysis at fixed pH values. All the runs were made at 89.4° and at ionic strength of 0.75.

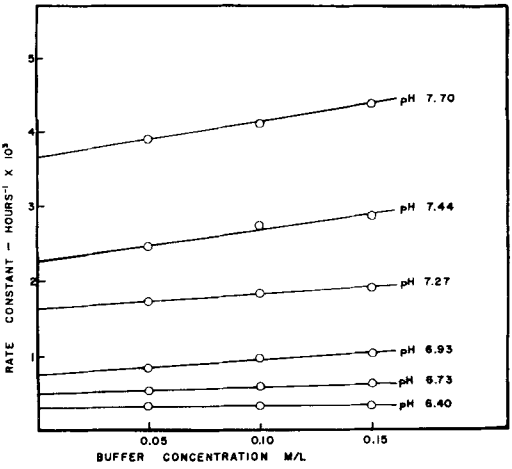

Fig. 7.—Plots showing the effect of phosphate concentration on the pseudo first-order rate constant of niacinamide hydrolysis at fixed pH values. All the runs were made at 89.4° and at ionic strength of 0.75.

the highest pH values. The catalytic effect of these buffers seems, however, to be mainly due to the catalytic effect of the $PO_4^{\equiv}$ ions present. The following calculation indicates this.

At pH 7.7 the increase in k going from zero buffer concentration up to 0.15 M is 0.72 × 10^{-3}. At pH 7.7 $[PO_4^{\equiv}]$ = 1.26 × 10^{-4} calculated according to the equations

$$[PO_4^{\equiv}] = \frac{ka_2 \times ka_3}{[H^+]^2}[H_2PO_4^-]$$

$$\frac{0.15 - [H_2PO_4^-]}{[H_2PO_4^-]} = \frac{ka_2}{[H^+]}$$

where ka_2 = $10^{-6.45}$ (90° and μ = 0.75). $k_{PO_4^{\equiv}}$ × $[PO_4^{\equiv}]$ = 6.65 × 1.26 × 10^{-4} = 0.84 × 10^{-3}, i.e., nearly equal to the increase in k.

A similar calculation using the results from the experiments at the lower pH values show that in most cases the increase in k is a little higher than what would have been expected if $PO_4^{\equiv}$ was the only catalytic species.

The catalytic effect of $H_2PO_4^-$ is shown in Fig. 8. If we assume that the increase in k may be attributed solely to a catalytic effect of $H_2PO_4^-$ on the nonprotonated form of niacinamide, calculation gives as result

$$k_{H_2PO_4^-} = 4.4 \times 10^{-4} \text{ hr.}^{-1} \text{ mol.}^{-1} \text{ L.}$$

Figure 9 seems to indicate that $H_2PO_4^-$ has a more pronounced catalytic effect on the hydrolysis of the protonated form of niacinamide than on the hydrolysis of the nonprotonated form. There also seems to be a catalytic effect of the undissociated phosphoric acid on the protonated form of the amide.

Higuchi and collaborators (6) have shown that the "half salt" of dibasic carboxylic acids, such as oxalic, succinic, tartaric, fumaric, phthalic, malonic, glutaric, and adipic acid has a strong catalytic

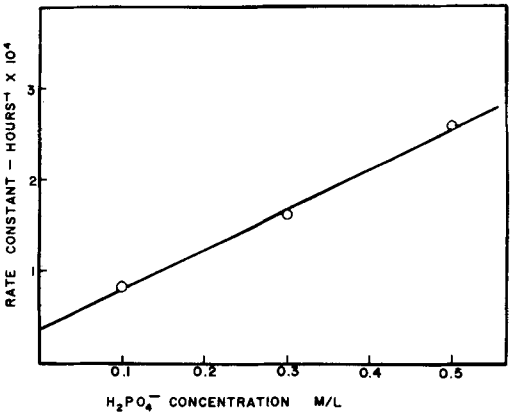

Fig. 8.—Plot showing the effect of dihydrogen phosphate concentration on the pseudo first-order rate constant of niacinamide hydrolysis at 89.4° and at ionic strength of 0.5 and pH-4.50.

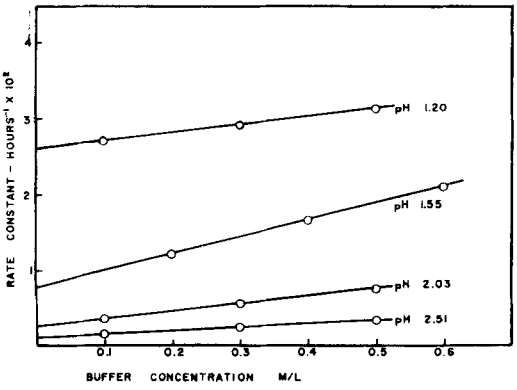

Fig. 9.—Plots showing the effect of phosphate concentration on the pseudo first-order rate constant of niacinamide hydrolysis at fixed pH values. All the runs were made at 89.4° and at ionic strength of 0.5.

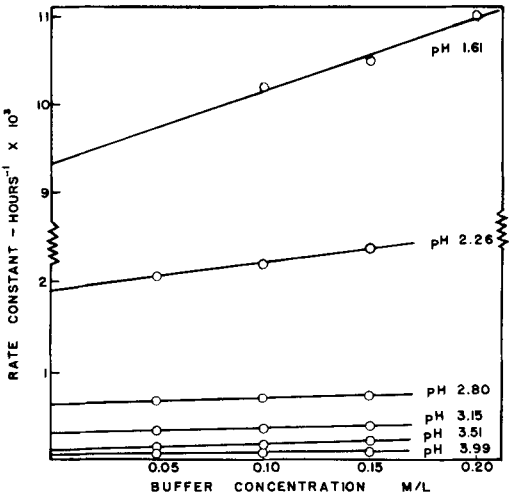

Fig. 10.—Plots showing the effect of oxalate concentration on the pseudo first-order rate constant of niacinamide hydrolysis at fixed pH values. All the runs were made at 89.4° and at ionic strength of 0.5.

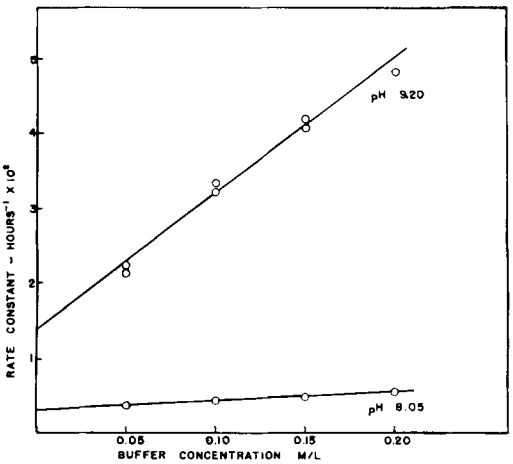

Fig. 11.—Plots showing the effect of catecholate concentration on the pseudo first-order rate constant of niacinamide hydrolysis at fixed pH values. All the runs were made at 89.4° and at ionic strength of 0.2.

effect on the hydrolysis of chloramphenicol. A similar effect could not be demonstrated for the "half salt" of oxalic acid on the hydrolysis of niacinamide (Fig. 10, curve marked pH 2.80). With decreasing pH, i.e., with an increase in the concentration of undissociated oxalic acid and of protonated niacinamide, there is a slight increase in the catalytic effect of the oxalate buffers.

Catechol catalyzes, according to Higuchi and collaborators (6), the hydrolysis of phosphonate esters. In the present work the influence of catechol on niacinamide hydrolysis has been studied (Fig. 11). The great difference in slope between the two lines on Fig. 11 seems to indicate that the catalytic effect of the catecholate buffers must be attributed mainly to the double charged catechol

anion. pKa of catechol was determined to be 8.65 at 89.4° and $\mu = 0.2$, which was the ionic strength used in the hydrolysis experiments.

The evaluation of the catalytic effect of borate buffers gives rise to certain problems, because these buffers do not contain only undissociated H_3BO_3 and $H_2BO_3^-$ ions, but also the ions BO_2^- and $B_4O_7^=$. The actual concentration of each of these ions cannot be determined and it is therefore impossible to make an accurate calculation of the ionic strength of the buffer solutions and to calculate the catalytic constant of each species. The first of the difficulties mentioned may be handled by using the buffer in a relatively low concentration and adding a relatively great amount of a neutral salt. The ionic strength will then be determined mainly by the neutral salt. In our experiments the total buffer concentration never exceeded 0.15 *M* and sodium chloride was added to $\mu = 0.75$.

pKa of boric acid was determined to be 8.42 at 90° and $\mu = 0.75$. It is obvious from Fig. 12 that the catalytic effect of borate buffers is due mainly to the "borate" ions, not to undissociated boric acid. A calculation of the catalytic constant of the borate ions, assuming they all exist as $H_2BO_3^-$, gave results varying from 0.7×10^{-1} (at pH 7.65) up to 1.2×10^{-1} (at pH 8.77).

pH-Rate Profile of Niacinamide Hydrolysis.—The pH-rate profile (Fig. 13) shows the relation between pH and log k at zero buffer concentration. pH of the strongly acid solutions at 89.4° and $\mu = 0.5$ were calculated from the equation

$$\text{pH} = -\log [H^+] + 0.08$$

The above relationship between pH and $[H^+]$ was obtained as the result of pH measurements in acids of known hydrogen ion concentration at 89.4° and $\mu = 0.5$. In a similar manner we found the following relationship between pH and $[OH^-]$ at 89.4° and $\mu = 0.75$

$$\text{pH} = 12.0 + \log [OH^-]$$

This equation was used for calculating the pH of the strongly basic solutions.

In the alkaline region the phosphate and borate buffers were adjusted to an ionic strength of 0.75. The ionic strength of the catecholate buffers was 0.20. The pH of these buffers at $\mu = 0.75$ were found to be equal to the pH at $\mu = 0.20$ less 0.15.

At zero buffer concentration the following reactions will contribute to the overall velocity of the hydrolysis

$N^+ + H^+ \rightarrow$ products, rate constant: k_{H^+}'
$N + H^+ \rightarrow$ products, rate constant: k_{H^+}''
$N^+ + H_2O \rightarrow$ products, rate constant: k_{H_2O}'
$N + H_2O \rightarrow$ products, rate constant: k_{H_2O}''
$N^+ + OH^- \rightarrow$ products, rate constant: k_{OH^-}'
$N + OH^- \rightarrow$ products, rate constant: k_{OH^-}''
N^+ = protonated form of niacinamide
N = nonprotonated form of niacinamide
$[N_T] = [N] + [N^+]$

The overall velocity is equal to the sum of the rates of all these reactions

$$-\frac{d[N_T]}{dt} = k_{H^+}'[N^+][H^+] + k_{H^+}''[N][H^+] + k_{H_2O}'[N^+][H_2O] + [k_{H_2O}''][N][H_2O] + [k_{OH^-}'][N^+][OH^-] + [k_{OH^-}''][N][OH^-] \quad \text{(Eq. 4)}$$

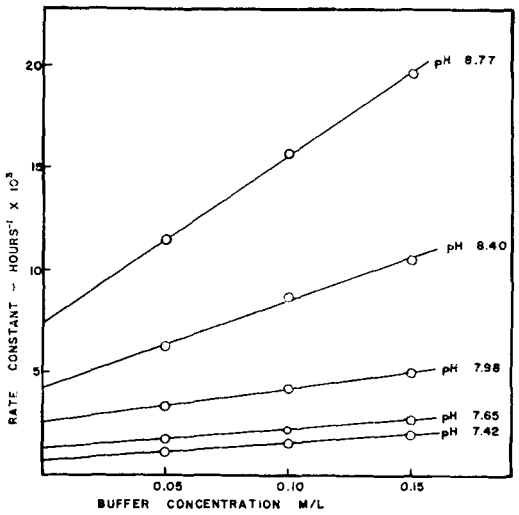

Fig. 12.—Plots showing the effect of borate concentration on the pseudo first-order rate constant of niacinamide hydrolysis at fixed pH values. All the runs were made at 89.4° and at ionic strength of 0.75.

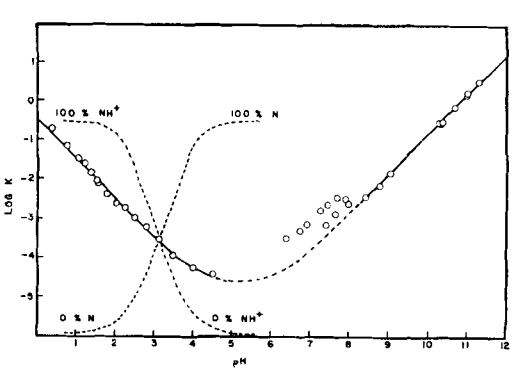

Fig. 13.—Plot showing the relation between pH and the log of the pseudo first-order rate constant of niacinamide hydrolysis at 89.4° and zero buffer concentration. The dotted S-shaped curves show the amount of the protonated (NH^+) and nonprotonated (N) form of niacinamide in relation to pH.

In fairly strongly acidic solution the last four terms of Eq. 4 will be negligible compared to the first two terms and may be omitted, thus giving

$$-\frac{d[N_T]}{dt} = k_{H^+}'[N^+][H^+] + k_{H^+}''[N][H^+]$$

Because of the overall first-order character of the hydrolysis the following equation is valid

$$-\frac{d[N_T]}{dt} = K[N_T] \quad \text{(Eq. 5)}$$

Combining the last two equations and the equation

$$k_a = \frac{[N][H^+]}{[N^+]}$$

gives

$$k = [H^+]\frac{k_{H^+}'[H^+] + k_{H^+}''(K_a)}{[H^+] + k_a}$$

The fact that the pH-rate profile is a nearly straight line from pH 0.4 to pH 3.5 shows that k_{H^+}' and k_{H^+}'' must be of the same order of magnitude, thus giving

$$k = [H^+][k_{H^+}'] = [H^+]\, k_{H^+}''$$

$$\log k = -pH + 0.08 + \log k_{H^+}'$$

If k_{H^+}'' had been different from k_{H^+}' there would have been a break in the curve around pH = pKa = 3.1.

In fairly strongly basic solution the five first terms in Eq. 4 may be omitted. Doing this and combining with Eq. 5 gives

$$k = k_{OH^-}''\,[OH^-]$$

$$\log k = pH - 12 + \log k_{OH^-}''$$

In accordance with this last equation the pH-rate profile is a straight line between pH 8.4 and 11.3. Between pH 6.4 and 8 however, the experimentally determined k values deviate from the straight line. The deviations were greatest when phosphate was used as buffer [the 6 points lying farthest away from the dotted line (Fig. 13) correspond to k values obtained from experiments with phosphate as buffer]. The deviations were relatively small when borate was used as buffer (corresponding to the 3 points closest to the dotted line). With catechol catecholate as the buffer, the deviation was intermediate (the point with the coordinates 7.9–2.5).

In the pH region 6.4–8 the data suggest that reactions other than the hydrolysis catalyzed by hydroxyl ions and the buffers may participate significantly. It is difficult to say what these reactions are. One must keep in mind, however, that in the pH region 6.4–8 the half-life of niacinamide is very long, 10–100 days. This means that the niacinamide solutions in our experiments had to be heated at 89.4° from one to several weeks. During this long period of heating the solution will attack the glass surface and extract products such as silicates and metals, which may well have a catalytic effect. Phosphates are known to be especially aggressive against glass. In addition to this, the glass surface itself may act as a catalyst, thus promoting a heterogeneous catalysis.

The pH-rate profile seems to level off earlier than would have been the case if k_{H_2O}' and k_{H_2O}'' had been negligible. This means that at pH 4.5–6 the overall velocity is mainly determined by the noncatalyzed hydrolysis.

SUMMARY AND CONCLUSIONS

1. The hydrolysis of niacinamide was found to be first order with respect to niacinamide over a wide range of hydrogen ion concentration (pH 0.4–11.3).

2. The rate of the hydrolysis has a minimum at pH 4.5–6. In this region, the half-life of niacinamide was about 1000 days at 89.4°.

3. The hydrolysis is catalyzed by hydroxyl ions and hydrogen ions. The catalytic constant of the hydroxyl ions was found to be $k_{OH^-} = 14.6$ L. hr.$^{-1}$ mol.$^{-1}$ at 89.4°. The catalytic effect of the hydrogen ions was determined to be nearly the same for the hydrolysis of the protonated form of niacinamide as for the hydrolysis of the nonprotonated form, $k_{H^+} = 3.6 \times 10^{-1}$ L.hr.$^{-1}$ mol.$^{-1}$ at 89.4°.

4. The hydrolysis is catalyzed by general acids and bases. The highest effect was produced by the triply charged phosphate ion. Considerable effects by the doubly charged catechol ion and the borate anions were also noted. Mono- and dihydrogen phosphate ions were found to have a very small effect on the hydrolysis of the nonprotonated form of niacinamide. Monohydrogen phosphate seemed to have a somewhat stronger effect on the hydrolysis of the protonated form. The hydrolysis of this form also appeared to be slightly catalyzed by undissociated phosphoric acid and oxalic acid.

5. A positive, primary salt effect was noted in strongly acidic solution; but none in strongly alkaline solution was noted.

Immunochemical Study of the Diphtheria Toxin-Fluorescent Antitoxin System

By W. F. HEAD, Jr.†

Six fluorescent diphtheria antitoxins were prepared. These products were then examined for excess adsorbed fluorescein, chemically bound fluorescein, and reactivity toward diphtheria toxin and toxoid. Particular attention was paid to antitoxic potency loss inasmuch as it was desired to find optimum methods of preparation wherein maximum labeling and, therefore, higher sensitivity could be obtained with maximum retention of activity. The fluorescence of the floccules formed at the equivalence point in the immunochemical titration of toxin with fluorescent antitoxin was shown to be directly proportional to the biological potency of the toxin.

COONS and Kaplan (1) were the first to demonstrate the fluorescent antibody technique by determining the localization of specific antigens in tissues using the homologous fluorescent antibody. Many similar diagnostic tests have appeared in the literature (2–7) since that time; however, only empirical data are available for preparation of fluorescent antibodies and quantitative information concerning the antigen-fluorescent antibody reactions is lacking entirely.

The excellent sensitivity afforded by fluorescence measurements combined with the high degree of specificity involved in antigen-antibody reactions would seem to justify examination of quantitative data for possible application as an analytical method. The principle of such a quantitative procedure rests upon the proportionality of the biological potencies of various toxins or toxoids to the weights of antigen-antibody complexes at the equivalence points in their titrations. It is also necessary that the ratio of antigen to antibody at these points be constant. If these requirements are met, a randomly fluoresceinated antibody should carry amounts of fluorescein into the precipitated complex which are proportional to potency. This has been accomplished in connection with antibody-dye complexes on a colorimetric basis (8).

EXPERIMENTAL

Materials.—Diphtheria antitoxin concentrate (Lilly lot No. 729077) was used for the preparation of all fluorescent antitoxins. This material had a potency of 3,800 guinea pig protective units per ml., 3,700 *Lf* (flocculating) units per ml., and a *Kf* value of 4 minutes. The total protein content, chiefly gamma globulin, was 20%. The antitoxin was of equine origin. Various diphtheria toxins and toxoids were also supplied by Eli Lilly and Co.

Fluorescein amine and fluorescein isothiocyanate were obtained from Nutritional Biochemicals Corp. Reagent grade formamide was purchased from Matheson, Coleman, and Bell.

Preparation of Fluorescent Antitoxins.—The initial preparation was made by coupling fluorescein isocyanate to the antibody molecule as previously described (1). The dialysis purification was carried out at room temperature until no appreciable fluorescence was observed in the external fluid (17 to 20 days). The product was adjusted to a convenient volume with 0.9% saline and made 1:10,000 in thimerosal. All subsequent preparations were made by essentially the same process with the exception of using fluorescein isothiocyanate and maintaining a cold temperature, 4 to 6°, throughout the process, including the dialysis.

Titration of Diphtheria Toxin or Toxoid with Homologous Fluorescent Antitoxin.—A classical Ramon titration was employed wherein small increments of antitoxin were added to constant amounts (0.5 ml.) of toxin or toxoid in several tubes. The tubes were brought to equal volume, 2 to 4 ml. depending on antitoxin potency, with phosphate buffer, pH 7.4, 0.066 *M*, then either incubated at 50° for 2 hours and stored overnight under refrigeration or incubated overnight at 50° and allowed to stand an additional day at room temperature to reach equilibrium. These procedures were used to insure quantitative precipitation of floc. Usually, toxin flocs were refrigerated and toxoid flocs were developed at room temperature. It was found that toxoid flocs with fluorescent antitoxin were partially redissolved when cold, and additional floc would form as the tubes warmed to room temperature. The precipitates were separated by centrifuging and were resuspended and washed once with 1 to 3 ml. of 0.9% saline to remove residual unreacted fluorescent material.

Measurement of Floc Fluorescence.—In order to measure the fluorescein, the flocs had to be redissolved after washing. A study was undertaken to find the appropriate solvent. Of 25 solvents tested, formamide proved to be the most acceptable, dissolving large quantities of floc and simultaneously enhancing fluorescence because of its basic qualities.

The flocs were dissolved with either 3 or 4 ml. of formamide. Fluorescent intensity measurements

Received June 14, 1961, from the Analytical Research Department, Eli Lilly and Co., Indianapolis, Ind.
Accepted for publication August 7, 1961.
† Present address: School of Pharmacy, Auburn University, Auburn, Ala.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.
Grateful thanks are given to Mr. Max M. Marsh for his interest, encouragement, and aid in this work. To Mr. Robert Jeffery and Dr. Roland Hodgson (deceased), a debt of gratitude is also due for supplying the various biologicals and performing some of the tests.

were taken with an Aminco-Bowman spectrophotofluorometer using an activation wavelength of 490 mμ. The emission intensity at 525 mμ was recorded with the appropriate sensitivity setting. To standardize the instrument, a formamide solution of fluorescein, containing 0.333 mcg./ml., was used. A typical fluorescent floc emission spectrum is shown in Fig. 1.

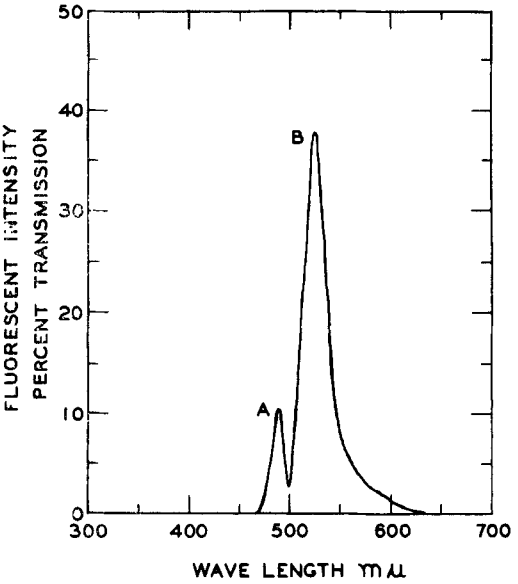

Fig. 1.—Emission spectrum of a fluorescent diphtheria floc. Activation 490 mμ. A, Activation crossover peak; B, fluorescent emission peak.

Standard Curves.—The fluorescent intensities of all flocs, adjusted to the same instrumental sensitivity setting, were plotted *vs.* the corresponding flocculating units of antitoxin added. These curves, as seen in Fig. 2, have the general shape of the diphtheria precipitin curve obtained by weight or nitrogen analysis. If toxins or toxoids of different potencies were used, a plot of the various maximum fluorescent intensities at the equivalence points in the individual titration curves *vs.* potency, either in *Lf* units or guinea pig protective units, would be linear with zero intercept. The slope would be determined by the degree of fluorescein labeling of the antitoxin. This concept is shown in Fig. 3. Construction of these standard curves with each fluorescent antitoxin was not necessary for quantitative potency determinations; it was even more accurate to test a standard toxin along with an unknown and compare equivalence point floc fluorescence and potency on a proportional basis.

Comparison Analytical Method.—The standard *Lf* test was used as a reference method with which to compare the fluorescent antibody method and to determine flocculating power of various antigens and antitoxins. This method is a titration similar to that already described using small increments of standard antitoxin or toxin. The tubes were incubated at 50° and constant observation maintained until the first floccules appeared. The tube showing the first trace of floc is the equivalence point tube and the time required for flocculation

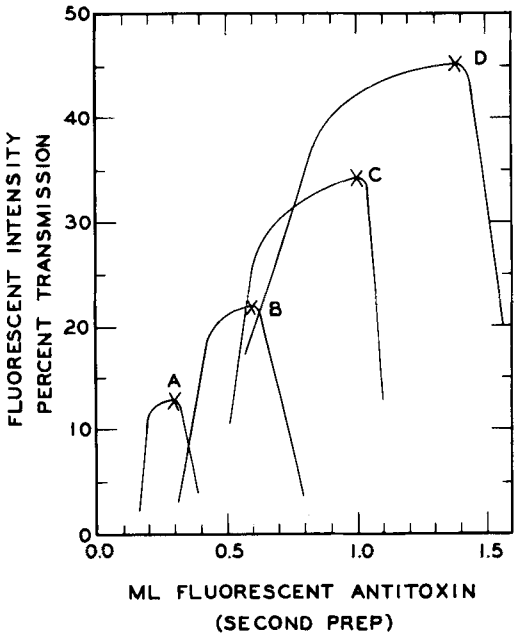

Fig. 2.—Precipitin curves obtained by measurement of floc fluorescence. Curve A, diphtheria toxin potency, 27.5 *Lf*/ml.; curve B, diphtheria toxin potency, 55 *Lf*/ml.; curve C, diphtheria toxin-potency, 82.5 *Lf*/ml.; curve D, diphtheria toxin potency, 110 *Lf*/ml.; × indicates the equivalence points.

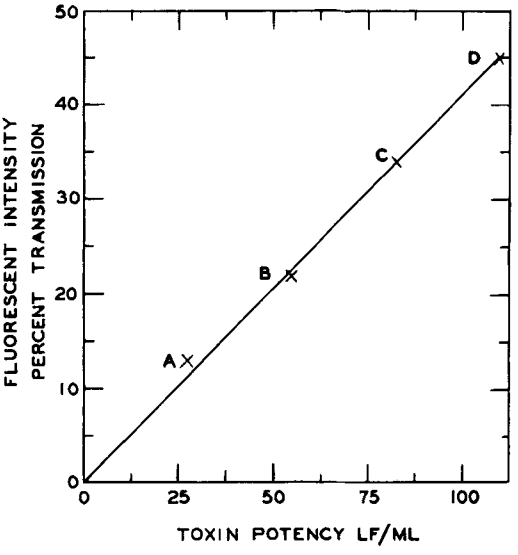

Fig. 3.—Equivalence point fluorescence (Fig. 2) *vs.* toxin potency. A, B, C, D, toxin potencies (same as Fig. 2).

to occur is the *Kf* value. This value is indicative of the degree of denaturation, a longer time being required for flocculation by a more highly denatured toxin or antitoxin. The standard antitoxins or toxins were National Institutes of Health primary standards or secondary standards derived from them.

[a] Diphtheria antitoxin concentrate. [b] Specifically precipitable nitrogen. [c] Number of fluorescein molecules per antitoxin molecule. [d] Not determined. [e] These values determined with use of toxin, giving greater precipitability than the last three, which were determined with the use of toxoid. [f] Preparation made from No. 3. [g] Nitrogen content per *Lf* toxoid, used in calculating this value, was calculated from data obtained from the reaction of No. 4 and No. 6 antitoxins with the same toxoid.

Determination of Specifically Precipitible Nitrogen and Fluorescein to Antitoxin Ratios.—Since diphtheria antitoxin concentrate contains a considerable amount of inert globulin, gross fluorescence and total protein measurements will not give much information concerning that fluorescein bound to antitoxic globulin molecules. To obtain these data, a method described by Kabat and Mayer (9) was used. This technique enables the determination of the amount of antitoxin precipitated. Fluorescence measurements of the dissolved flocs reveal the amount of fluorescein present. From these figures, the degree of labeling is easily calculated. The molecular weight value of the antitoxin molecule is 184,000 (10).

RESULTS AND DISCUSSION

First Fluorescent Antitoxin.—By means of *Lf* tests, this material was found to have lost 58% of its potency against toxin and 100% of its antitoxoid activity. The *Kf* value was 25 minutes. In addition to potency loss, only a slight similarity to typical precipitin curves could be obtained. The material, after standing for a few weeks under refrigeration, deposited an appreciable amount of granular fluorescent material and was considered to be an altogether unsatisfactory preparation. A summary of the proportion of reactants and the characteristics of this and all other fluorescent antitoxins prepared is given in Table I.

Second Fluorescent Antitoxin.—Toxoid flocculating power was again destroyed, but 72.5% of the toxin flocculating ability was retained. The *Kf*, being 15 minutes, was still 11 minutes longer than the original unconjugated antitoxin. A standard curve was prepared using this antitoxin with good linearity and zero intercept. Twenty-five *Lf*, corresponding to approximately 0.25 mg. toxin protein, was the smallest amount of toxin that could be accurately assayed. Since the *Kf* of this fluorescent antitoxin was still comparatively long, it was possible that excess fluorescein had been used and was occupying specific reactive sites in the molecule without contributing materially to the fluorescence of the flocs.

Third Fluorescent Antitoxin.—The method of preparation was the same as the method employed for the second fluorescent antitoxin except that twice as much diphtheria antitoxin concentrate was used. Again, 100% toxoid activity was lost, but only 20.5% toxin activity was lost. The *Kf* decreased to 10 minutes. A standard curve was prepared using dilutions of toxin as before. Surprisingly, the slope of this curve was almost identical with the slope of the curve obtained with the second preparation instead of being approximately one-half as great. When the overall fluorescence of this third antitoxin was compared to the fluorescence of the second preparation, the latter showed appreciably more gross fluorescence by a ratio of 82 to 49. This greater fluorescence must be accounted for in some immunochemically inactive manner. Either this fluorescein is bound to the inert globulin present or is physically adsorbed on the globulin and antitoxin and is released upon reaction. The latter seems much more probable since the two proteins have no apparent chemical differences other than the spatial arrangement of polypeptide chains. Verification of this was obtained by setting up tests using identical quantities of toxin and titrating with the second and third antitoxin. The floc fluorescence and the fluorescence of the supernatants were measured. It was found that floc fluorescence was the same for both materials and the fluorescence of the supernatants was in the same approximate ratio as the unreacted antitoxins. Control tubes of toxin, antitoxin, and buffer were mixed in the same proportion as in the floc tests immediately preceding the fluorescence measurement. Aliquots were taken from these tubes before flocculation could occur and in this manner served to compensate for any buffer effects, slight toxin fluorescence, etc., that might be misinterpreted. The ratios of fluorescence for the two antitoxins were 1.65 for unreacted or unflocculated controls and 1.58 for the supernatants after flocculation.

By using the control tests, a greater amount of fluorescence was consistently observed in the supernatant fluids, even after removal of some fluorescein in the flocs, than was present in the unflocculated control tubes. This could be explained by the adsorption of fluorescein to the antitoxin surface and in some manner not exhibiting fluorescence. During the reaction with toxin the fluorescein could be liberated into solution This bound fluorescein might also be located at or near reactive sites in the molecule since dilution alone does not cause an increase in fluorescence. The location of fluorescein near these sites would also explain the increase in *Kf* observed, since the antigen molecule would have to displace fluorescein before complex formation could occur.

To verify further that the degree of labeling of the two antitoxins was the same, the number of

fluorescein molecules per antitoxin molecule was experimentally determined. The second fluorescent antibody contained an average of 5.35 fluorescein molecules to 1 antitoxin molecule while the ratio was 5.4 to 1 for the third fluorescent antitoxin. This very similar labeling probably occurs because the amount of fluorescein used in both preparations was in excess of that required, the larger excess being adsorbed to a greater extent in the second preparation.

Fourth Fluorescent Antitoxin.—The presence of physically adsorbed fluorescein has been confirmed in the literature (11) for a different protein. By treatment with charcoal, a large percentage of this adsorbed material was removed. The fourth fluorescent antitoxin was made from the third preparation by shaking it with activated charcoal for 3 hours and filtering all traces of charcoal. This product showed a 50% decrease in overall fluorescence from the third preparation but only a 29.8% loss of *Lf*, which is comparable to the literature value. Immunochemically inert fluorescein had definitely been removed. Tests run on supernatants after flocculation showed no release of adsorbed fluorescein as had been noted previously. In addition, this material had good toxoid flocculating power, which had not been observed with the previous preparation, and typical precipitin curves could be obtained. The *Kf* with toxin had decreased to 8 minutes and toxoid *Kf* was in the range of 30 to 45 minutes. The toxoid reactivity loss from the original unlabeled antitoxin was 44% which is the same overall loss of toxin reactivity. An "unknown dilution" of toxin was assayed within 98.6% of its value as determined by *Lf* tests using a comparison standard toxin test run simultaneously. Toxoid could also be quantitated and tests on a series of dilutions gave a typical standard curve. Analysis showed an average of 5.25 molecules fluorescein to each molecule antitoxin. The charcoal adsorption evidently did not remove any significant quantity of chemically bound fluorescein. The activity and characteristics of this material show that it should be possible to prepare an antitoxin without the charcoal adsorption step provided excess adsorbed fluorescein can be avoided.

Fifth Fluorescent Antitoxin.—Reactants were used in proportions calculated to yield a product having a 1:1 ratio of fluorescein to protein. Examination showed that 100% of toxin and toxoid reactivity was retained in the process of synthesis and the *Kf* was 5 minutes. The molecular ratio of fluorescein to antitoxin was found to be 1.5 to 1. Supernatant examination after flocculation showed only a very slight liberation of bound fluorescein during reaction. The fast reaction and full retention of activity made this the best lot of antitoxin prepared at this point. The fluorescence level, however, was quite low, corresponding to the weak staining antibody discussed by Goldwasser (12).

Sixth Fluorescent Antitoxin.—The ratio of reactants was chosen to give a 5:1 fluorescein to protein product. One hundred per cent biological activity was retained for both toxin and toxoid. An examination of the supernatant after flocculation showed definite liberation of fluorescein during reaction, although this amount was much smaller than with the third antitoxin. The ratio of fluorescein to antitoxin in this preparation was 4.25 to 1. Flocculation fluorescence readings with this material read about 17% lower than those obtained with the fourth fluorescent antitoxin and the degree of labeling was 19% less, showing good correlation.

SUMMARY

Several fluorescent diphtheria antitoxins were prepared in order to determine the optimum conditions for obtaining a highly fluorescent antibody without denaturing the protein to the extent of losing significant flocculating power. The amount of fluorescein derivative used to prepare the fluorescent antitoxins was found to determine the *Kf* value and the amount of toxin or toxoid flocculating potency lost. There was an optimum amount of fluorescein which would couple chemically with the antitoxin, this value being an average of five molecules fluorescein to each antitoxin molecule. If amounts in excess of this were used, physical adsorption occurred which greatly decreased antitoxic potency. Antitoxoid potency was very easily destroyed by overlabeling. Some of the adsorbed fluorescein did not exhibit fluorescence until it was released by the reaction of the antitoxin with toxin or toxoid. It did not contribute to the fluorescence of the flocs and could be removed by competitive adsorption with activated charcoal.

The fluorescent antibody technique was shown to be applicable not only as a diagnostic or qualitative test but as a sensitive quantitative method of analysis as well. A comparison standard test, run simultaneously with the unknown, was more reliable than a standard curve procedure since varying conditions could be automatically controlled.

Separation of Tabletted Mixtures of Barbiturates, Aspirin, Phenacetin, Caffeine, Codeine, and Quinine by Ion-Exchange Paper Chromatography

By HAROLD V. STREET and S. K. NIYOGI

The resolution of a mixture of tablet fragments containing amobarbital, acetylsalicylic acid, acetophenetidin (phenacetin), caffeine, codeine, and quinine into its constituent parts by application of chromatography on modified cellulose ion-exchange papers is described. Horizontal circular and ascending cylindrical chromatography is employed. A complete qualitative analysis takes about 4 hours.

MODIFIED CELLULOSE ion-exchange paper sheets were first used for chromatography by Knight (1, 2) who described their use for the separation of mixtures of amino acids and of mixtures of metallic cations. Street and Niyogi (3–5) have described the use of these modified cellulose papers for chromatographic and ionophoretic separations of various toxic compounds.

Because chromatography on ion-exchange papers with aqueous "solvents" gives rise to a very rapidly moving "solvent" front, it was thought the procedure might be useful for a rapid identification of some of the tablets which are commonly encountered in toxicological analysis. In this type of work, it is necessary for the toxicologist to carry out an analysis of any fragments of tablets which may be found in, say, stomach contents or cups and drinking glasses.

The types of tablets most frequently encountered in toxicological analysis are those containing barbiturates or salicylates. These tablets may, in addition, contain acetophenetidin (phenacetin), caffeine, codeine, and quinine. Using mixtures containing equal proportions of these compounds, it is a relatively easy matter to separate and identify the components by chromatography on ion-exchange paper. However, in many of the tablets, the proportion of one compound to another is such that swamping of the minor component occurs. For example, in tablet A,[1] the ratio of acetylsalicylic acid to quinine is 48 to 1, so that if a chloroform extract of the tablet is applied directly to the paper, the quinine cannot be seen because of the presence of such a relatively large amount of salicylate which spreads over a large area of the paper and obliterates the quinine spot. If the amount applied is reduced so that the salicylic acid spot is of "normal" size, then the amount of quinine is too small to be detected.

When acetylsalicylic acid and quinine are present in equal amounts, no difficulty is encountered. It follows, therefore, that in order to detect the presence of quinine in tablet A, some preliminary differentiation procedure must be used, such as extraction with alkali to remove acetylsalicylic acid. This procedure will, of course, hydrolyze the aspirin to salicylic acid which, however, is easily recognized on the chromatogram by its bright blue fluorescence in 254 mμ light.

It has been found that by extraction of tablet fragments with chloroform and then extracting this chloroform with alkali, the two groups so obtained, namely neutral and acidic, can be applied to an anion-exchange paper and the various components identified. Quinine and codeine can be identified in the residue by chromatography on a cation-exchange paper. Horizontal circular chromatography as described by Kawerau (6) has been used with hand-cut, slotted, Whatman diethylaminoethyl cellulose ion-exchange paper, together with a simultaneous ascending "run" on Whatman cellulose citrate ion-exchange paper. The following account is a description of the procedures carried out for the identification of the compounds referred to above.

It is important to note that the work described here refers to modified cellulose ion-exchange paper and not to paper impregnated with ion-exchange resins.

EXPERIMENTAL

Materials and Reagents

Horizontal circular chromatography apparatus manufactured by Shandon Scientific Co., Cromwell Place, London, England. Whatman DE20 anion-exchange modified cellulose paper; the sheets were cut into circular disks of 26 cm. diameter, slots were cut as described by Kawerau (6). Whatman CT30 cation-exchange modified cellulose paper.

Received August 14, 1961, from the Department of Forensic Medicine, University of Edinburgh, Scotland.
Accepted for publication October 16, 1961.

[1] Anadin (International Chemical Co., Ltd.) tablets contain in each: aspirin, 4 gr.; phenacetin, 2 gr.; caffeine, 1/4 gr.; and quinine sulfate, 1/12 gr.

Ultraviolet lamp emitting 254 mμ radiation. Chloroform. Sodium hydroxide, 2.5% (w/v) and 10% (w/v) aqueous solutions. Hydrochloric acid, 5 *N* solution. Ammonia, 0.2 *N* and concentrated solutions. EDTA, 0.1 *M* solution of the disodium salt of ethylenediaminetetra acetic acid. Iodoplatinate reagent; mix together 5 ml. of 5% (w/v) platinic chloride, 45 ml. of 10% (w/v) potassium iodide, and 100 ml. of water.

Procedure

Extraction.—A mixture of one-fifth of a tablet of tablet A, one-fifth of a compound tablet of codeine B.P., and 10 mg. of amobarbital was ground up in a mortar with 2 ml. of chloroform, and filtered. The mortar was rinsed with a further 2 ml. of chloroform which was poured through the filter. The filtrate was shaken vigorously with 0.5 ml. of 2.5% sodium hydroxide solution and the mixture centrifuged. The upper alkaline layer (solution I) was removed and set aside for chromatography. The chloroform layer was washed first with 4 ml. of water and then with 0.5 ml. of 5 *N* hydrochloric acid solution, and the mixture was centrifuged. These washings were discarded. The washed chloroform layer containing acetophenetidin and caffeine was set aside for chromatography (solution II).

The residue of the tablet fragments, after chloroform extraction, was shaken with 10 ml. of 10% sodium hydroxide solution and filtered. The filtrate was extracted by shaking with 10 ml. of chloroform. A 1-ml. portion of the separated chloroform layer was taken to dryness and redissolved in a drop or two of chloroform. This solution was used for chromatography (solution III).

Chromatography.—Solutions I and II were applied to two separate sectors of a circular sheet of Whatman DE20 ion-exchange paper. Chromatography was carried out in 0.2 *N* ammonia solution for 105 min. and the paper examined in 254 mμ light. The results of such a run are illustrated in Figs. 1 and 2.

Solution III was subjected to ascending chromatography on Whatman CT30 ion-exchange paper in 0.1 *M* EDTA for 18 minutes. The paper was examined, while wet, in 254 mμ light; it was then dried and stained with the iodoplatinate reagent to reveal the positions of the alkaloids. The results of this procedure are shown in Fig. 3.

DISCUSSION

The results show that with the DE20 paper, using dilute ammonia as solvent, barbiturate and salicylate can be separated in the alkali extract. Identification of the particular barbiturate can be carried out by the methods of Street (7, 8). Acetophenetidin and caffeine, both of which are present in the residual chloroform solution after alkali and acid extraction, can also be resolved on DE20 paper. Because there is a large amount of salicylate present in the tablet fragments, this compound is also seen in the "neutral" fraction. It does not interfere and is easily distinguished by its bright blue fluorescence in 254 mμ light.

It is interesting to note that in spite of the presence of a relatively large amount of acetophenetidin, this does not interfere with the resolution of acetophenetidin and caffeine in the "neutral" fraction. This

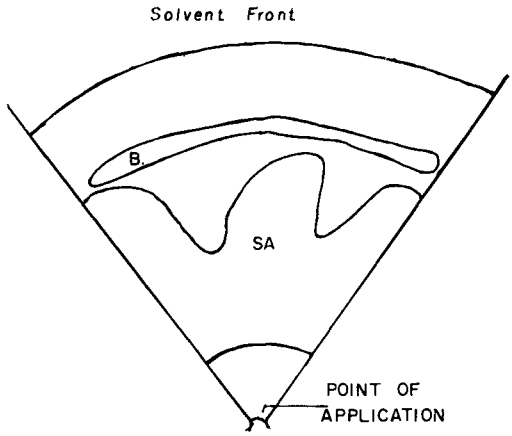

Fig. 1.—Horizontal circular chromatography of solution I on diethylaminoethyl cellulose ion-exchange paper in 0.2 *N* ammonia. Time of run, 105 min. SA, salicylate (blue fluorescent area); B, barbiturate (dark-purple absorbing area). Compounds revealed by inspection in 254 mμ light.

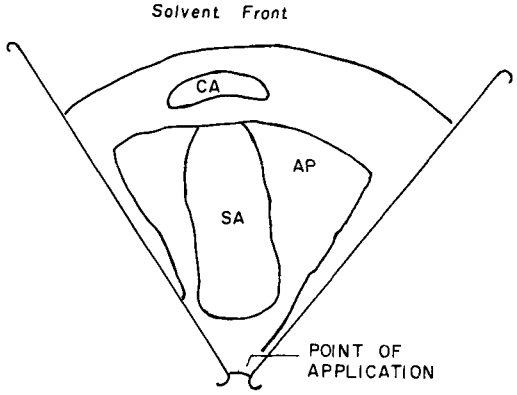

Fig. 2.—Horizontal circular chromatography of solution II on diethylaminoethyl cellulose ion-exchange paper in 0.2 *N* ammonia. Time of run, 105 min. SA, salicylate (blue fluorescent area); AP, acetophenetidin (dark-purple absorbing area); CA, caffeine (dark-purple absorbing area). Compounds revealed by inspection in 254 mμ light.

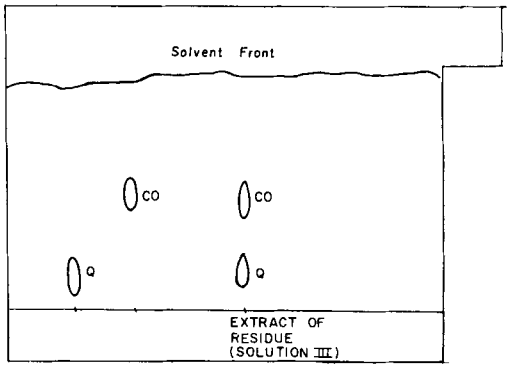

Fig. 3.—Ascending cylindrical chromatography of solution III on cellulose citrate ion-exchange paper in 0.1 *M* EDTA. Time of run, 18 minutes. Q, quinine; CO, codeine. Compounds revealed by dipping the paper in the iodoplatinate reagent.

means that it is possible to apply a large amount of this fraction to the paper.

Codeine and quinine are extracted by chloroform from the residue of tablet fragments after addition of alkali. These two alkaloids are clearly resolved on CT30 paper in about 20 minutes. Some quinine is also present in the initial chloroform extract of the tablets but is removed from the "neutral" fraction by washing with dilute acid.

Diffusion of Sodium Salicylate and Salicylic Acid within Hydrophilic Ointments

Measurement with a New Diffusion Cell

By J. A. WOOD†, L. WAIT RISING, and NATHAN A. HALL

A cell has been designed to measure diffusion of medicaments within dermatologic vehicles to eliminate the influence of an external medium which differs from the vehicle. The cell consisted of two Lucite plastic compartments separated by a cellophane membrane. A medium containing a medicament was placed in one compartment and diffusion occurred into the other compartment which contained the same vehicle without the medication. The cell was used in a study of the diffusion of sodium salicylate and salicylic acid in various components of hydrophilic ointments made with three nonionic surface-active agents: Tween 40, Atlas G-7596-J, and Brij 35.

IN VITRO investigations of the efficiency of medicated dermatologic vehicles have usually utilized a system in which the drug diffuses from the vehicle into a dissimilar medium. Events which occur in this external medium provide the data for the evaluation of the vehicle. Workers in this field have noted the desirability for additional knowledge of diffusion within the base and its physicochemical properties (1–3). It is possible that in many reported experiments the results obtained have been more dependent upon the rate of diffusion in the external medium than upon the rate of diffusion in the vehicle being tested. Fuller, *et al.* (1), suggested that the rate of absorption of a drug from a locally applied vehicle will depend on the rate of the slowest of the processes involved in the transfer of medicament to the tissue fluids. Thus, *in vitro*, the limiting influence could occur in the external medium, at the interface, or in the preparation containing the medicament. One significant physical property is diffusion of drug molecules within the vehicle.

A cell has been developed which makes possible the measurement of diffusion of a drug within its vehicle and it has been applied to diffusion measurements of salicylic acid and sodium salicylate in hydrophilic ointments prepared with three different emulsifiers. Studies involved media of increasing complexity from simple aqueous solutions to fluid emulsions to semisolid hydrophilic ointments.

The Diffusion Cell.—Since free diffusion studies in liquid media require rather elaborate methods to avoid boundary disturbances due to the effect of convection currents, vibration, and gross movement of the apparatus, Geddes (4) suggested separation of the phases by a porous diaphragm to eliminate practically all boundary disturbance. Preliminary studies indicated that methods which brought

means that it is possible to apply a large amount of this fraction to the paper.

Codeine and quinine are extracted by chloroform from the residue of tablet fragments after addition of alkali. These two alkaloids are clearly resolved on CT30 paper in about 20 minutes. Some quinine is also present in the initial chloroform extract of the tablets but is removed from the "neutral" fraction by washing with dilute acid.

Diffusion of Sodium Salicylate and Salicylic Acid within Hydrophilic Ointments

Measurement with a New Diffusion Cell

By J. A. WOOD†, L. WAIT RISING, and NATHAN A. HALL

A cell has been designed to measure diffusion of medicaments within dermatologic vehicles to eliminate the influence of an external medium which differs from the vehicle. The cell consisted of two Lucite plastic compartments separated by a cellophane membrane. A medium containing a medicament was placed in one compartment and diffusion occurred into the other compartment which contained the same vehicle without the medication. The cell was used in a study of the diffusion of sodium salicylate and salicylic acid in various components of hydrophilic ointments made with three nonionic surface-active agents: Tween 40, Atlas G-7596-J, and Brij 35.

IN VITRO investigations of the efficiency of medicated dermatologic vehicles have usually utilized a system in which the drug diffuses from the vehicle into a dissimilar medium. Events which occur in this external medium provide the data for the evaluation of the vehicle. Workers in this field have noted the desirability for additional knowledge of diffusion within the base and its physicochemical properties (1–3). It is possible that in many reported experiments the results obtained have been more dependent upon the rate of diffusion in the external medium than upon the rate of diffusion in the vehicle being tested. Fuller, *et al.* (1), suggested that the rate of absorption of a drug from a locally applied vehicle will depend on the rate of the slowest of the processes involved in the transfer of medicament to the tissue fluids. Thus, *in vitro*, the limiting influence could occur in the external medium, at the interface, or in the preparation containing the medicament. One significant physical property is diffusion of drug molecules within the vehicle.

A cell has been developed which makes possible the measurement of diffusion of a drug within its vehicle and it has been applied to diffusion measurements of salicylic acid and sodium salicylate in hydrophilic ointments prepared with three different emulsifiers. Studies involved media of increasing complexity from simple aqueous solutions to fluid emulsions to semisolid hydrophilic ointments.

EXPERIMENTAL

The Diffusion Cell.—Since free diffusion studies in liquid media require rather elaborate methods to avoid boundary disturbances due to the effect of convection currents, vibration, and gross movement of the apparatus, Geddes (4) suggested separation of the phases by a porous diaphragm to eliminate practically all boundary disturbance. Preliminary studies indicated that methods which brought

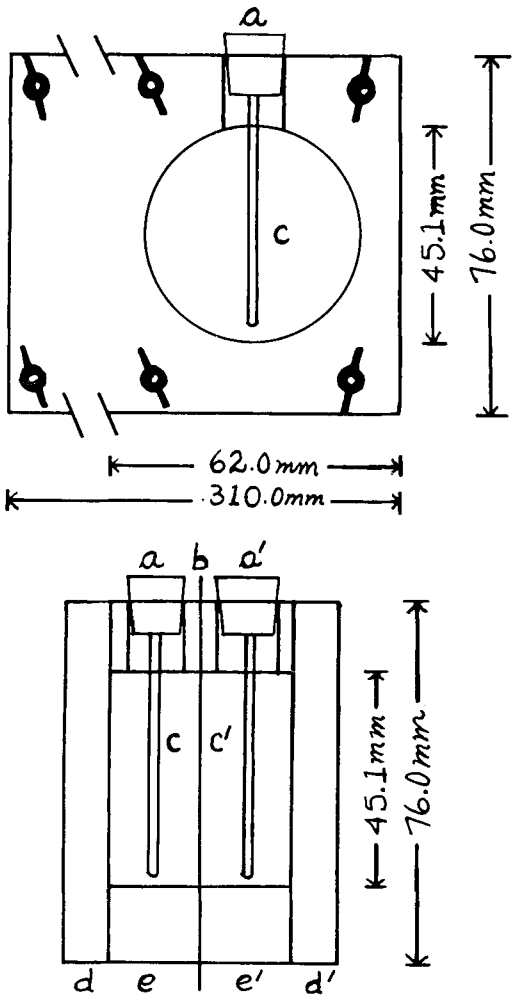

Fig. 1.—One section of the five-cell Lucite diffusion unit showing side view (top) and end view (bottom). d,d' is 3/8 inch clear Lucite and e,e' is 3/4 inch clear Lucite.

medicated and nonmedicated portions of ointment (semisolid) into contact were suitable for visual observation of diffusion, but not suitable for removing samples for analysis. In order, therefore, to maintain stable boundary conditions in the liquid vehicles, and to permit separation of the two parts of the semisolid diffusion system, an intervening cellophane membrane was used. The vehicle was thus separated into two aliquots, one on each side of the membrane. At the beginning of each experiment, only one aliquot contained medicament. Samples could be removed at different time intervals for analysis to give the diffusion rate.

The diffusion apparatus consisted of a Lucite unit containing five diffusion cell compartments. Each cell was cylindrical in shape (Fig. 1) with an opening (12.5 mm. diameter) (a,a') in each section of the cylinder (c,c') for filling the cell and subsequently removing its contents. Stirring rods were inserted into rubber stoppers and installed in the openings (a,a'), serving both as stirring devices and as closures for the cells. To assemble the apparatus, the cellophane[1] (b) was placed at the center of the four components (Fig. 1, end view), and the unit was assembled by tightening the wing nuts on the bolts holding the unit together. The assembled unit, ready for use, was photographed for Fig. 2. The internal dimensions were such that when 28.5 ml. of liquid was placed in each side of the cell (c,c') and stirring rods positioned, the cell was completely filled to the bottom of the openings and the membrane (16 sq. cm.) was completely covered.

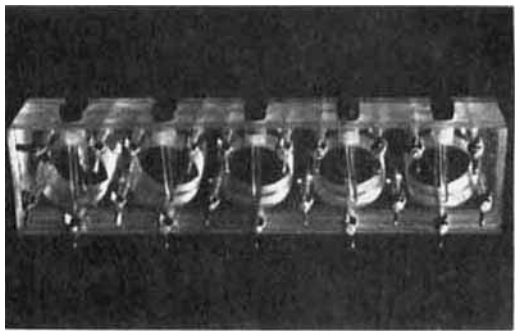

Fig. 2.—The assembled Lucite plastic diffusion cell unit.

For semisolid media the diffusion cell differed in only one respect from that used for the liquid systems; namely, the center components were constructed from 3/8 inch Lucite. The depth of each half of the cell was thus 3/4 inch instead of 3/4 inch. Stirring rods were of no use, but openings to each cell compartment (6 mm. in diameter) were provided to permit the escape of ointment from the slightly overfilled cells. Slight overfilling with consequent pressure exerted on complete assembly was utilized to assure intimate contact between the ointment contained in each cell compartment and the cellophane membrane. The shallow-depth cell was used to facilitate chemical analysis because of the relatively short depth of penetration of medicament into the receptor ointment.

Diffusion Media.—Diffusion experiments were conducted on media which were variations of components of the terminal medium. The terminal medium was a modified form of hydrophilic ointment U.S.P. XV (5) of the following formula

	Quantity, Gm.
Surface-active agent[2]	5.0
Propylene glycol	12.0
Liquid petrolatum	25.0
Stearyl alcohol	25.0
Preserved water C.F. (6)	33.0

The simplest medium was preserved water C.F. (6), and other components of the formula were added to give media of increasing complexity until the hydrophilic ointment was formed. The quantities of ingredients in the simpler media were in the same ratio as in the terminal media. Three series of experiments were performed, differing only in the surface-active agent used as the emulsifier. Com-

[1] The humectant was removed by continuous rinsing with distilled water followed by rinsing with the diffusion medium.

[2] Tween 40 (polyoxyethylene sorbitan monopalmitate), Atlas G-7596-J (polyoxyethylene sorbitan monolaurate), or Brij 35 (polyoxyethylene lauryl ether), all supplied by Atlas Powder Co., Canada, Ltd., Brantford.

TABLE I.—RATE OF DIFFUSION OF SODIUM SALICYLATE AND SALICYLIC ACID AND THE VISCOSITY OF THE DIFFUSION MEDIA

[a] Upper case letters indicate sodium salicylate and lower case salicylic acid. Arabic numerals indicate the emulsifier used in each series: 1, Tween 40; 2, Atlas G-7596-J; 3, Brij 35; Aa, preserved water C.F.; Bb, same as A plus propylene glycol; Cc, same as A plus emulsifier; Dd, same as B plus emulsifier; Ee, same as D plus liquid petrolatum; Ff, same as E plus stearyl alcohol, a hydrophilic ointment.

ponents of each medium are indicated in Table I which presents the results.

Medicaments.—Sodium salicylate U.S.P. and salicylic acid U.S.P. were incorporated into the diffusion media to form the medicated preparations. Salicylic acid, a commonly used agent in dermatology, was selected for its low aqueous and higher lipid solubility and sodium salicylate for its reverse solubility characteristics. The concentration of medicament was arbitrarily set at 12% for sodium salicylate, and because of its low water-solubility, the salicylic acid concentration was 0.2% in the fluid preparations and 1% in the semisolid medicated preparations.

The Diffusion Procedure.—The diffusion procedure for liquid preparations was as follows: The cell unit was immersed almost to the top in a constant-temperature water bath at 30°. Exactly 28.5 ml. of diffusion medium was transferred to the receptor side of the first cell and the stopper and stirring rod were positioned without pressure. Exactly 28.5 ml. of medicated preparation were transferred to the donor side of the first cell, the time of completion noted, and the stopper and stirring rod positioned without pressure. The other cells were filled in succession in the same manner. At 15-minute intervals for sodium salicylate and 30-minute intervals for salicylic acid, the solution in each side of each cell was stirred 10 times. Sixty minutes after the sodium salicylate diffusion had started (120 minutes for salicylic acid), the two solutions were removed completely from each cell (donor and receptor), placed in appropriately labeled flasks, and reserved for analysis and examination. On completion of the analysis of the five receptor solutions, they were combined and the five donor solutions were combined. These two solutions, donor and receptor, were then subjected to determination of density, pH, surface tension, and viscosity.

For diffusion experiments involving the semisolid terminal media, the diffusion cell chambers were filled by the use of a spatula as the unit was assembled. Care was exercised to avoid air spaces in the material and between the ointment and the cellophane. After an appropriate diffusion period in an incubator at 30° (18 hours for sodium salicylate and 60 hours for salicylic acid), the preparations were carefully removed, weighed, and placed in suitable containers for analysis and examination.

Physical Properties.—Certain physical data were routinely compiled for each diffusion study. These were density, pH, surface tension, and viscosity. The solubility of the medicament in the vehicle (7) was also determined. The Brookfield UL adapter for use with the Brookfield Synchro-Lectric viscometer, Model LVT, for the measurement of ultra low viscosities, was used to determine the viscosities of all of the fluid preparations. Corrected apparent viscosities were calculated for the emulsified media according to Bowles' method (8). Approximate viscosities for the semisolid preparations were determined using the model RVT viscometer. Only viscosity values are recorded in the results since it was the only property paralleling the differences in diffusion rates.

Method of Analysis.—Salicylate concentrations were determined colorimetrically by measurement of color produced by the reaction of ferric chloride with salicylates. The readings were taken at 525 mμ with a Beckman model B spectrophotometer. The emulsion preparations could not be assayed by direct dilution because of the insoluble components. Preparations emulsified with Tween 40 and G-7596-J were broken down by heating with 2 *N* sodium hydroxide, thus permitting separation of the aqueous phase. Since Brij 35 was stable to alkaline hydrolysis, the aqueous phase was separated by saturation with sodium chloride.

RESULTS AND DISCUSSION

The rates of diffusion of sodium salicylate and salicylic acid in the various media and the viscosities of these media are shown in Table I. The rates of diffusion are compared in Fig. 3.

The results of the investigation showed, as expected, that in water and solutions of propylene glycol in water, the rate of diffusion was very closely related to the viscosity of the medium. When

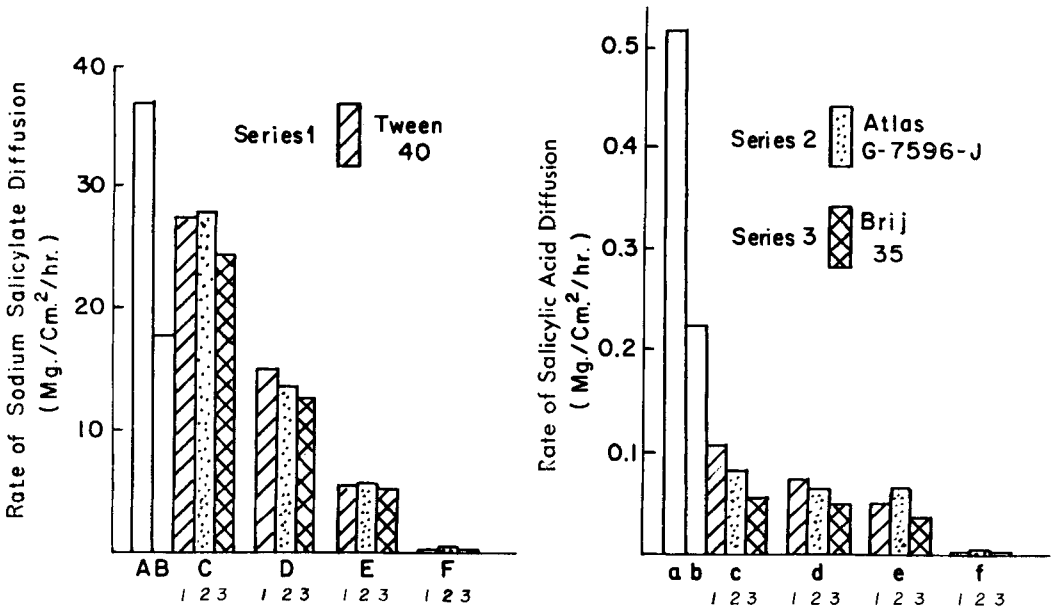

Fig. 3.—The effect on sodium salicylate and salicylic acid diffusion of adding each formula component in the three series and relating these to diffusion in Aa and Bb. Aa = Preserved water; Bb = A + propylene glycol; Cc = A + surfactant; Dd = C + propylene glycol; Ee = D + liquid petrolatum; Ff = E + stearyl alcohol.

a surface-active agent was added, the change in viscosity was similar to the change produced by the propylene glycol, but the reduction in the rate of diffusion resulting was only approximately half the reduction caused by propylene glycol. Since aqueous solutions of surface-active agents form micelles, these could be responsible for a measured viscosity which has less effect on a diffusing molecule or ion than the viscosity due to a substance like propylene glycol which does not form micelles. The bulk viscosity of propylene glycol solution, measured with the viscometer, approximates a microscopic viscosity. In the surface-active agent solutions containing micelles, a much greater difference exists between the bulk and microscopic viscosities. The fact that the diffusion effects of propylene glycol and a surface-active agent are additive only to a low degree also is probably related to the same phenomenon.

In contrast to the sodium salicylate diffusion system, once the surface-active agent is added to the salicylic acid diffusion system there is a marked reduction in the diffusion rate and only relatively small changes result from the additon of propylene glycol and liquid petrolatum. Since it can be shown that salicylic acid is solubilized by the micelles of surface-active agents, the presence of micelles in which salicylic acid is preferentially soluble would retard the diffusion process.

All components in each series which increased viscosity caused a reduction in the rate of diffusion from that in simple aqueous solution. The largest reduction was due to stearyl alcohol which transformed the media from liquid to semisolid with a consequent very large increase in viscosity. The effect due to differences in the surface-active agents were slight (see Fig. 3). It may be noted, however, that all preparations containing Brij 35 were somewhat more viscous than those containing the other two emulsifiers and, generally speaking, the rate of diffusion in media containing Brij 35 was slightly lower.

Selection, Evaluation, and Control of the Assay of the Pharmaceutical Product I

Reproducibilities of Assay and Drug Recovery from Dosage Forms

By EDWARD R. GARRETT†

Studies have been conducted on the variation of fill weight and drug content among units of hard filled capsules, soft elastic capsules, and compressed tablets. The cases in point were exploratory dosage forms of the antibiotic fumagillin. Consideration of the dosage form and the excipients dictated the methodology. Statistical treatment of the data has permitted conclusions as to optimum amounts of solvent for the separation of the active ingredient, the number of dosage units necessary to assay within a desired confidence limit, the reproducibility of fill weight among units, and the homogeneity of the fill mix. The evaluation of the variability among the data also permitted the most economic utilization of assay facilities in stability studies.

A BASIC FUNCTION of the control laboratories in the pharmaceutical industry is to assay and control the final product so that it conforms to those specifications which have been established to insure that (*a*) the composition is and remains as specified, (*b*) the pharmaceutical utility is retained, and (*c*) the pharmaceutical elegance of color, taste, and form persists; all for the duration of the pharmaceutical lifetime of such a product.

Routine assay procedures for final products must be carefully designed so that they are simple, efficient, and economical. These considerations necessitate the application of statistical techniques for the proper evaluation of assay procedures and the determination of errors of assay. Thus, the degree of confidence in product composition, stability estimates, and biological potency may be ascertained.

This paper considers the fundamental problems of recovery of drug from the final pharmaceutical dosage form, the number of such dosage forms to be used in assay, and the variability in content that may be encountered among units of the same dosage form. Dosage forms considered are hard filled capsules (HFC), soft elastic capsules (SEC), and compressed tablets (CT). The procedures of the simple statistics used are easily followed from many of the fine texts available (1).

The particular drug considered in these studies was the antibiotic fumagillin (2–4) in exploratory preparations of HFC, SEC, and CT. The initial reason for this comparative study was to establish the minimum and most economical procedures for the evaluation of the drug's stability in its final dosage form.

EXPERIMENTAL

The ultraviolet spectrophotometric absorbance of fumagillin at 351 mμ in 95% ethanol-water was chosen as the method of determining fumagillin content since these values have been correlated with biological activity (2). Photolytic, oxidative, and thermal degradation of fumagillin in solution and as crystalline material diminishes the absorbance at 351 mμ (2–4). The Beckman ultraviolet spectrophotometer, model DU, was used.

The procedures devised for the spectrophotometric determination of fumagillin content follow.

Hard Filled Capsules.—The theoretical composition of the HFC was 12 mg. fumagillin, 10 mg. ascorbic acid, 226 mg. lactose, 1.3 mg. calcium stearate, with a fill weight of 259 mg. An initial study was conducted on 10 capsules where each capsule was weighed on an analytical balance and subsequently emptied into a beaker by tapping or gouging with the end of a fine spatula. The capsule was washed twice with 95% ethanol, the spatula was rinsed with

[a] A 10-ml. quantity of 95% ethanol was used to extract fumagillin from each of capsules 1–7; 50 ml. from each of capsules 8–10. [b] Measured at 4×10^{-4} capsule contents per ml. final solution.

solvent, and all washings and contents were collected so that a total of 10 ml. solvent to extract was used in seven cases and a total of 50 ml. was used to extract in the other three cases. The material was allowed to settle and the contents of the beaker were decanted through No. 2 Whatman filter paper. The residue was washed with two 2-ml. portions of ethanol, filtered, and the filtrate was made up to 100 ml. in a volumetric flask with 95% ethanol. A 10-ml. aliquot of this solution was made up to 250 ml. The result was that there was 4×10^{-4} of the original capsule per ml. of final solution. This concentration could be spectrophotometrically read in the appropriate absorbance range (*ca.* 0.5) at 351 mμ. The weight of the empty capsule was determined after drying at room temperature so that the net weight of fill could be obtained. These data are given in Table I.

A similar experiment was conducted on each of six HFC except that the volume of 95% ethanol used to extract the fumagillin was varied. See Table II.

TABLE II.—ABSORBANCES OF HFC FUMAGILLIN AT 351 mμ EXTRACTED WITH VARYING AMOUNTS OF 95% ETHANOL

Capsule No.	95% Ethanol Used in Extraction, ml.	Absorbance at 351 mμ[a]
11	10	0.418
12	20	0.442

16	75	0.493
17	100	0.489

[a] At 4×10^{-4} capsule contents per ml. of final solution.

Soft Elastic Capsules.—The theoretical composition of the SEC was 12 mg. fumagillin, 10 mg. ascorbic acid, 160 mg. peanut oil, 5.27 mg. Cotoflake, with a fill weight of 196 mg. Each of 10 capsules was weighed on an analytical balance and cut almost in half over a beaker with a sharp, clean razor blade. Extreme care was taken to get no oil on the fingers. The entire capsule was dropped into the skellysolve B rinsings of the razor blade edge (*ca.* 15 ml.) and swirled to remove the contents. The SEC shell was removed and rinsed with a few ml. of fresh skellysolve B which was then added to the contents of the beaker. The shell was dried in a hood at room temperature and re-weighed to obtain the net weight of the fill. The skellysolve B was evaporated from the beaker in the hood at room temperature, and 50 or 100 ml. of 95% ethanol was added to attempt dissolution. Subsequent filtration and preparation of the solution for spectrophotometric assay was the same as for that previously given for the HFC with 4×10^{-4} of the original capsule contents per ml. of final solution. The data are given in Table III.

Compressed Tablets.—The theoretical composition of the CT was 12 mg. fumagillin, 10 mg. ascorbic acid, 226 mg. lactose, 9.8 mg. sucrose, 6.5 mg. starch, 2.3 mg. calcium stearate, with a weight of 277 mg. Each tablet was weighed on an analytical balance and dropped into 95% ethanol. The tablet was extracted with various amounts of ethanol as specified in Table IV. Subsequent filtration and preparation of the solution for spectrophotometric assay was the same as for that previously given for the HFC with 4×10^{-4} of the original tablet per ml. of final solution. The data are given in Table IV.

CALCULATIONS AND RESULTS

The data of Table I indicate a large difference in measured absorbance between HF capsules 1–7 (average $A/W = \bar{x}_1 = 1.4945$ for $n_1 = 7$) extracted with 10 ml. 95% ethanol and capsules 8–10 (average $A/W = \bar{x}_2 = 1.8761$ for $n_2 = 3$) extracted with 50 ml. 95% ethanol. Application of the t test confirms this difference. The calculated t is $(\bar{x}_2 - \bar{x}_1)/\sigma \cdot \sqrt{n_1 n_2/(n_1 + n_2)} = 3.73$ at 8 degrees of freedom. This exceeds the critical value from the t tables, i.e., 2.31 for 5% probability of no difference between the extraction procedures. It is thus necessary to

% Deviation of single absorbance from mean, 100 ($\sigma/\bar{x}$)	1.39%[b]	6.21%	1.34%

[a] Theoretical fill weight given in parentheses. [b] Includes only those HFC extracted with 40 or more ml. of 95% ethanol. [c] SEC No. 4 in Table III is excluded.

determine the minimum amount of 95% ethanol necessary for complete extraction of fumagillin from the contents of the hard filled capsules. These data are reported in Table II and readily show that 40 or more ml. of 95% ethanol is necessary for relatively complete extraction of fumagillin from one capsule.

From the data of Table III we have, for capsules numbered 1 through 5, the average $A/W = \bar{x}_1 = 2.6731$ for $n_1 = 5$, and for capsules numbered 6 through 10, the average $A/W = x_2 = 2.7893$ for $n_2 = 5$. The calculated t for 8 degrees of freedom does not exceed the Table's value of t. It is concluded that either 50 or 100 ml. of 95% ethanol will give satisfactory extraction of fumagillin from the contents of each soft elastic capsule.

The data of Table IV for compressed tablets were obtained from extractions with 50, 75, and 100 ml. of 95% ethanol. An analysis of variance of these data calculated as absorbance per unit weight of fill, A/W, is given in Table V. The calculated F value for the ratio of variance among extractions to variance within extractions is 41 for 2 and 6 degrees of freedom. The F value at the 1% level from the tables is 10.9. It can be concluded that the variation among volumes of extraction is highly significant with respect to the variation within extraction by the same volume of 95% ethanol. This does not necessarily mean that the use of 100 ml. rather than 50 ml. of ethanol introduces a large error in this case, only that our methods of measurement are precise enough to evaluate the differences. In fact, the difference in extractability is extremely small, percentage wise, only 2.5% between the mean A/W values for 50 ml. and 100 ml. ethanol extractions (see Table IV).

The per cent standard deviation, $100 \times \sigma/\sqrt{(A/W)}$, among all the tablets is 1.2%. This includes the possible heterogeneity of fumagillin in the tablet mix, the procedural error, and the variation among volumes of ethanol used in extraction.

The reproducibility of the fill weight and the absorbance of extracted fumagillin in each of the HFC, SEC, and CT preparations of fumagillin are summarized in Table VI. The 1.4% probable deviation in absorbance from capsule to capsule, HFC, is the same as the estimated probable deviation in fill weight, which indicates that the fill may be of homogeneous fumagillin content as a first approximation provided that sufficient volumes of extracting solvent are used. This is confirmed by the consistency of the absorbances of capsules 14 through 17 in Table II.

DISCUSSION

These investigations and the simple statistics involved contribute a great deal of information. They permit an evaluation of the best methodology for the assay of the pertinent component of a finished pharmaceutical.

The fundamental step is to separate the drug from the assay-interfering substances of the final product and prepare it appropriately for assay. In the cases of the HFC and SEC preparations, this involved a physical manipulation of each unit. Spectrophotometric assay procedures necessitated the preparation of homogeneous solutions. Alcoholic solution with subsequent filtration was a satisfactory method to separate the fumagillin from the excipients of the HFC fill and the tablets.

The oil base and nature of the SEC demanded the use of an oil-miscible solvent for separation and skellysolve B was an appropriate choice.

Simple statistical evaluations permitted the choice of optimum amounts of solvent to use in the assay procedures.

The single tablet or capsule technique clearly showed a high reproducibility of fumagillin content in a single HFC and tablet (Table VI).

The determination of variations in fumagillin content per unit dosage form, fill weight, and the ratio of these two values demonstrated that modern pharmaceutical processing may produce a high degree of homogeneity in the prefill mix and a high degree of reproducibility per unit HFC and tablet.

The knowledge of a standard deviation, σ, permits determination of the number, n, of units to be used to give a control value within the error range desired, i.e. $\sigma/\sqrt{n}$. For example, if 2% error were acceptable, the absorbance values from nine soft elastic capsules should be averaged which would reduce the 6% standard deviation of a single capsule cited in Table VI. This would be a valid procedure if the variation among capsules can be attributed solely to the error in the assay of a single capsule.

The greatest limitation on elegant stability studies on finished pharmaceutical products is the expense of assay. Certainly in the case of these HFC and CT preparations, assay of single unweighed units at timed intervals under accelerated or storage conditions would minimize cost and yet give excellent stability data.

The evaluation of the data for the SEC show that this preparation is not as suitable. The variation in reproducibility of fill weight is relatively high 2.6% (Table VI), and the total fumagillin content

varies even more (6.2%), even with the exclusion of the anomalous capsule No. 4 of low fill weight. Capsule No. 4 may either have a reasonable probability of occurrence or may be a maverick, possibly due to either improper weighing or being the first or last capsule prepared from the lot. Good control practice would demand repeat assays to clarify this.

Preparation and Properties of New Gastric Antacids V

Aluminum-Magnesium Hydroxide Dried Gels

By STEWART M. BEEKMAN

The preparation of nine aluminum-magnesium hydroxide gels in the Al:Mg atomic ratio range of 2:1, 1:1, and 0.5:1 by a new process is described. The determination of the antacid activity by the modified *in vitro* method of Holbert, Noble, and Grote shows that dried gels stabilized with glycine or sorbitol have antacid characteristics similar to clinically proved liquid aluminum-magnesium hydroxide gel. Blends of the various components separately dried are shown to be relatively ineffective by comparison. The new blends of old antacids are predominantly simple mixtures and not new compounds. Unstabilized dried gels show a substantial aging effect.

In 1944 Rossett and Flexner (1) concluded that mixtures of milk of magnesia with aluminum hydroxide gel were more effective gastric antacids than aluminum hydroxide gel alone. They reached these conclusions as a result of *in vivo* experiments on humans together with extensive clinical experience. They suggested smaller and less frequent doses of the mixtures. They pointed out the avoidance of the undesirable high initial pH rise from the milk of magnesia alone, and the offsetting of the constipating effect of aluminum hydroxide. The outstanding clinical effectiveness of liquid aluminum-magnesium hydroxide gels have been reported by others (2–4) for the treatment of peptic ulcer, hyperacidity, heart burn, spasticity, and gastritis. Properly formulated they are very prompt and prolonged in antacid activity, maintain the gastric pH between 3 and 5, and do not exhibit significant diminution of antacid action on aging.

This investigation had as its purpose the preparation of aluminum-magnesium hydroxide gels in dry form which approaches the antacid activity of the clinically proved fluid gels.

EXPERIMENTAL

Preparation of Dried Gels.—Three series of aluminum-magnesium hydroxides were prepared. In each series the amount of aluminum to magnesium was varied in the atomic ratios of 2:1, 1:1, and 0.5:1.

The first series (AMH) consisted solely of aluminum and magnesium hydroxide. The second series (AMHG) was formulated to contain approximately 20% of glycine in the dried gel. The third series (AMHS) was prepared to contain 20% of sorbitol.

The method of preparation of all nine dried gels was similar. Highly reactive aluminum hydroxide containing some carbonate and pure gelatinous magnesium hydroxide were separately precipitated, the combined slurries were filtered and washed free of soluble salts, the mixed hydrogels were subjected to highly intensive shear at room temperature and reduced to finely divided powder form by either spray drying or low temperature air drying together with fine pulverizing. Glycine crystals or sorbitol solution was added to the mixed hydrogels before milling.

Physical Properties.—All the dried gels are soft, white, smooth, fine, tasteless, and odorless powders which react readily with gastric strength acid-containing pepsin. The AMH dried gels are somewhat less dense than those containing sorbitol or glycine. The pH of aqueous suspensions of the AMHG series is about 9.0—the others are about 9.6. The carbonate (as CO_2) content ranges from about 5.0 to 12% depending mainly on the method of drying. Dried gels containing glycine or sorbitol are less

chalky. Spray dried samples have spherical shaped particles and are more free flowing.

Table I shows the composition of the nine aluminum-magnesium hydroxide dried gels as well as typical acid-consuming capacity values.

Infrared Studies.—Rock salt infrared spectra (2 to 15 μ) were run on samples of AMH-21, AMHG-21, AMHS-21, aluminum hydroxide dried gel U.S.P., magnesium hydroxide N.F., glycine N.F., and crystalline D-sorbitol. Nujol and hexachlorobutadiene (HCBD) mulls were made and samples run at capillary thicknesses *vs.* air.

Comparison of the various spectra shows that both AMH-21 and AMHS-21 are simple mixtures. The spectra of AMHG-21 indicates that it is predominantly a simple mixture of the three components, although there is strong evidence of a new glycine derivative—the percentage being fairly small.

Dry Blends.—In order to make a comparison between the antacid activity of the nine dried gels shown in Table I with usual dry blends, it was necessary to prepare nine such blends using aluminum hydroxide dried gel U.S.P., magnesium hydroxide N.F., glycine N.F., and crystalline sorbitol. The blends were made with finely powdered components.

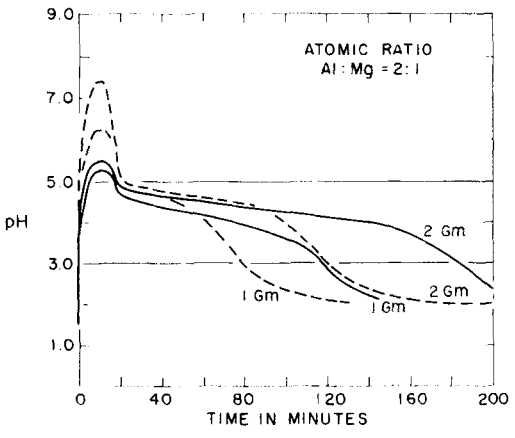

Fig. 1.—Antacid activity of aluminum-magnesium hydroxide dried gel Type F-AMH-21 (—) compared with dry blend of $Al(OH)_3$ U. S. P.-$Mg(OH)_2$ N. F. (- - -). Procedure of Holbert, Noble, and Grote modified.

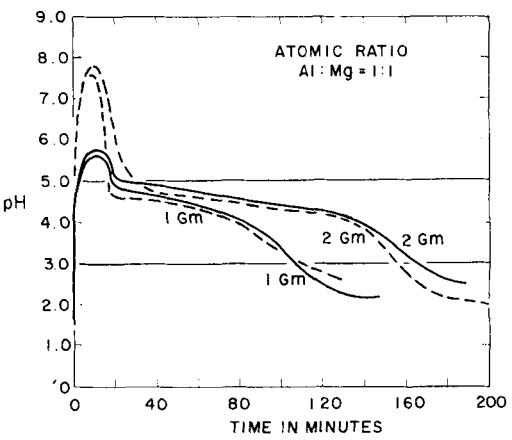

Fig. 2.—Antacid activity of aluminum-magnesium hydroxide dried gel Type F-AMH-11(—) compared with dry blend of $Al(OH)_3$ U. S. P.-$Mg(OH)_2$ N. F. (- - -). Procedure of Holbert, Noble, and Grote modified.

Antacid Activity.—The principal method used to evaluate the antacid activity of the nine aluminum-magnesium hydroxide dried gels, as well as the corresponding dry blends, was the dynamic, stringent procedure of Holbert, Noble, and Grote modified, which was described in considerable detail in the first paper in this series of *in vitro* studies (5). Samples were evaluated on the basis of 1.0 and 2.0-Gm. dose levels. The results for the various dried gels are plotted in Figs. 1-9.

Effect of Age.—To determine the effect of time on samples of aluminum-magnesium hydroxide dried gels stored in closed glass containers at ambient temperatures, the antacid activity of 1.0-Gm. samples was determined by the Holbert, Noble, and Grote method after 5 months' storage, and compared with values obtained on freshly prepared samples. The criteria used for aging is the total time that a 1.0-Gm. sample maintains the pH above 3.0 when tested by the modified Holbert, Noble, and Grote procedure. The results are shown in Table II.

Comparison with Dry Blends.—The antacid activity of 5-month-old samples of all nine AMH dried gels are compared with corresponding dry blends in Table II also.

Comparison with Liquid Gels.—For comparison

purposes the antacid activity data by the modified Holbert, Noble, and Grote method is plotted in Fig. 10 for 5, 10, and 15-ml. samples of a very reactive liquid aluminum-magnesium hydroxide gel having an Al:Mg atomic ratio of 1:1.

RESULTS

From consideration of the antacid activity data for the various aluminum-magnesium hydroxide dried gels and dry blends which are plotted in Figs.

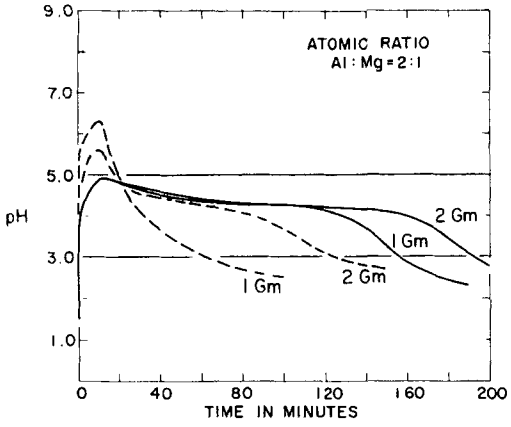

Fig. 7.—Antacid activity of aluminum-magnesium hydroxide-sorbitol dried gel Type F-AMHS-21 (—) compared with dry blend of $Al(OH)_3$ U. S. P.–$Mg(OH)_2$ N. F.–sorbitol (- - -). Procedure of Holbert, Noble, and Grote modified.

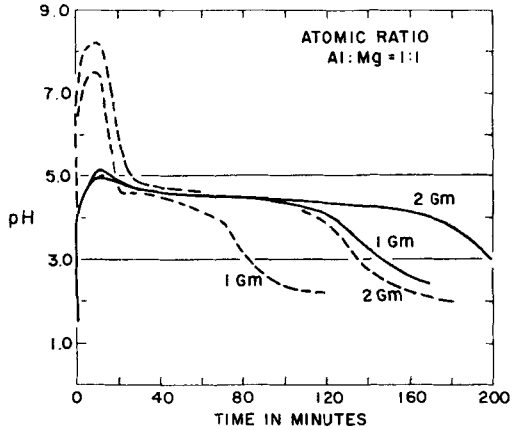

Fig. 8.—Antacid activity of aluminum-magnesium hydroxide-sorbitol dried gel Type F-AMHS-11 (—) compared with dry blend of $Al(OH)_3$ U. S. P.–$Mg(OH)_2$ N. F.–sorbitol (- - -). Procedure of Holbert, Noble, and Grote modified.

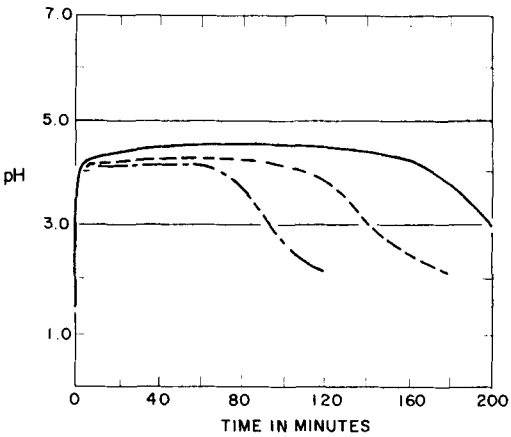

Fig. 10—Antacid activity of liquid aluminum magnesium hydroxide gel. Procedure of Holbert, Noble, and Grote modified. —, 15 ml.; - - -, 10 ml.; — — —., 5 ml.

1–9 and compared in Table II, one may draw several conclusions as follows: (*a*) Aluminum-magnesium hydroxide dried gels prepared by the new process described are much more prolonged in antacid activity in the optimum pH range of 3 to 5 than corresponding dry blends containing the same basic components in the same proportions. They also do not cause such a high undesirable initial rise in pH. (*b*) Unstabilized aluminum-magnesium hydroxide dried gels in the Al to Mg atomic ratio range of 2:1 and 1:1 show a fairly substantial diminution in antacid activity after 5-months' aging. This is a characteristic also of aluminum hydroxide dried gel U.S.P. Acid consuming capacity tests do not show this aging effect. (*c*) Glycine and sorbitol are both excellent stabilizers of the complex aluminum-magnesium hydroxide gel micellar structures during the desiccation process. On freshly prepared samples AMHG and AMHS dried gels have about the same antacid activity as an equal weight of unaged, unstabilized AMH dried gel, although they contain only 80% as much aluminum and magnesium hydroxide. When 5-month-old samples of all dried gels are compared on an active ingredient basis, the AMHG and AMHS dried gels in the Al:Mg ranges of 2:1 and 1:1 are 55–62% more active and 29–33% when the Al:Mg ratio is 0.5 to 1.

DISCUSSION

Aluminum-magnesium hydroxide dried gels AMHG and AMHS approach the theoretical requirements for an ideal antacid in dry form because of the following factors: (*a*) they are very rapid in raising the pH of gastric juice to the optimum pH range of 3 to 5, (*b*) they have extremely long periods of times of reaction in this optimum range, (*c*) the high initial rise in pH characteristics of similar materials dry blended is avoided, (*d*) they are nonsystemic and hence cannot upset the acid-base

balance of the blood, (*e*) they exhibit very little diminution of antacid activity on aging, (*f*) they are not adversely affected by pepsin in antacid action, (*g*) they are nonirritating to the gastrointestinal tract, (*h*) they have a desirable mild astringent effect, (*i*) they have minimal constipating or laxative effects, (*j*) they are palatable with very little chalkiness, (*k*) they rehydrate and swell in water to provide a gelatinous, positively charged protective coating for inflamed membranes, and (*l*) they may be produced at moderate cost because of the uncomplicated chemical nature of the compounds employed.

SUMMARY

The preparation of a group of new highly reactive and stable aluminum-magnesium hydroxide gels in powder form has been described. The determination of their antacid activity by a very stringent *in vitro* procedure indicates that they compare favorably with clinically effective liquid aluminum-magnesium hydroxide gels. The dried gels are effective over a wide range of proportions of the two antacid components. The new dried gels which are predominantly simple mixtures and not new compounds approach the ideal for an antacid in dry form.

Preparation and Properties of New Gastric Antacids VI

Low Sodium Aluminum Hydroxide Gel and Dried Gels

By STEWART M. BEEKMAN

The preparation of a new low sodium aluminum hydroxide concentrated gel is described, which when diluted to U.S.P. concentration contains about 0.6 mg. of sodium per 30 ml. The preparation of six new aluminum hydroxide dried gels containing 0.19 to 0.50 mg. of sodium per Gm. is also described. They include an aluminum hydroxide dried gel U.S.P. as well as four combinations with magnesium hydroxide and one with magnesium carbonate. The antacid activity of the various preparations was determined by a very stringent *in vitro* procedure. The activity of the combination dried gels compares favorably with the liquid gel. They are rapid and very prolonged in the optimum pH range of 3 to 5.

RECENT reports (1, 2) in the medical literature have stressed the need for low sodium antacids in liquid and tablet form for the treatment of patients who may have peptic ulcers or bleeding esophogeal varices concomitant with liver or heart disease that may require sodium restriction. Rimer and Frankland (1) who have given this problem detailed study comment that "in prescribing antacids, one may unwittingly violate the first principle of therapeutics and do unnecessary harm to the patients." Bleifer and associates (2) report that "it is obvious that unrestricted use of these materials (antacids) can jeopardize investigative sodium studies as well as therapeutic salt restricted programs."

Rimer and Frankland reported on the analyses of 18 of the most widely used aluminum hydroxide preparations in liquid and tablet form and found that the liquids contain 11.9 to 269.7 mg. of sodium per 30 ml. and from 5.1 to 192 mg. of sodium per 8 tablets. Bleifer, *et al.*, found that four of the popular liquid aluminum hydroxide gels contained 29–39 mg. of sodium per 30-ml. dose. Since the daily dose for patients with acute ulcers may be 500 ml. or more, the amount of sodium ingested from this source alone may be

Preparation and Properties of New Gastric Antacids VI

Low Sodium Aluminum Hydroxide Gel and Dried Gels

By STEWART M. BEEKMAN

The preparation of a new low sodium aluminum hydroxide concentrated gel is described, which when diluted to U.S.P. concentration contains about 0.6 mg. of sodium per 30 ml. The preparation of six new aluminum hydroxide dried gels containing 0.19 to 0.50 mg. of sodium per Gm. is also described. They include an aluminum hydroxide dried gel U.S.P. as well as four combinations with magnesium hydroxide and one with magnesium carbonate. The antacid activity of the various preparations was determined by a very stringent *in vitro* procedure. The activity of the combination dried gels compares favorably with the liquid gel. They are rapid and very prolonged in the optimum pH range of 3 to 5.

RECENT reports (1, 2) in the medical literature have stressed the need for low sodium antacids in liquid and tablet form for the treatment of patients who may have peptic ulcers or bleeding esophogeal varices concomitant with liver or heart disease that may require sodium restriction. Rimer and Frankland (1) who have given this problem detailed study comment that "in prescribing antacids, one may unwittingly violate the first principle of therapeutics and do unnecessary harm to the patients." Bleifer and associates (2) report that "it is obvious that unrestricted use of these materials (antacids) can jeopardize investigative sodium studies as well as therapeutic salt restricted programs."

Rimer and Frankland reported on the analyses of 18 of the most widely used aluminum hydroxide preparations in liquid and tablet form and found that the liquids contain 11.9 to 269.7 mg. of sodium per 30 ml. and from 5.1 to 192 mg. of sodium per 8 tablets. Bleifer, *et al.*, found that four of the popular liquid aluminum hydroxide gels contained 29–39 mg. of sodium per 30-ml. dose. Since the daily dose for patients with acute ulcers may be 500 ml. or more, the amount of sodium ingested from this source alone may be

500–2500 mg. per day. Many physicians try to restrict the sodium intake from all sources to 210 mg. per day.

The purpose of this paper is to report the results of an investigation which had as its goal the preparation of clinically effective aluminum hydroxide gel and various dried gels with low sodium contents.

EXPERIMENTAL

Aluminum Hydroxide Gel.—A stable, highly reactive aluminum hydroxide was precipitated from the system K_2CO_3-$KHCO_3$-$AlCl_3$ using sodium free aluminum chloride and deionized water. The gel was filtered, washed free of soluble salts, and subjected to high shear at room temperature under aseptic conditions. For the preparation of aluminum hydrogels having uniform physical and chemical properties it is necessary to control many variables carefully including concentration and precise metering of reactants, temperature, degree and type of agitation, reaction rate, method of introducing reactants, pH change, and aging. The resulting snow white, homogeneous hydrogel contains about 9% aluminum hydroxide as aluminum oxide, and when diluted to 4.0% aluminum oxide forms a flowable, slow settling aluminum hydroxide U.S.P. of proper viscosity characteristics. It is designated as type F-1000 LS. Table I shows the analysis of a typical sample diluted to U.S.P. concentration.

Aluminum Hydroxide Dried Gel.—Aluminum hydroxide gel similar to that described above was carefully dried by low temperature circulating air and pulverized to a finely divided form. The resulting soft, white, bulky powder meets the requirements for a fairly reactive aluminum hydroxide dried gel U.S.P. It is also designated as type F-1000 LS. The analysis of a typical sample is seen in Table I.

Aluminum-Magnesium Hydroxide Dried Gels.—Low sodium magnesium hydroxide was precipitated, mixed with low sodium aluminum hydroxide gel, combined with either glycine or sorbitol, subjected to intensive mixing, and reduced to dry powder form. Four different dried gels were prepared. Two were stabilized with glycine and two with sorbitol. The preparations were made with Al:Mg atomic ratios of 2:1 and 1:1. In Table I the analyses of typical samples are shown.

Aluminum Hydroxide-Magnesium Carbonate Dried Gel.—Magnesium carbonate gel was prepared by the low temperature precipitation in the system K_2CO_3-$MgCl_2$, intimately combined with low sodium aluminum hydroxide gel, and the resulting mixture spray dried to finely divided form. The analysis of a typical sample of this dried gel which is designated as Type F-MA11-LS may be seen in Table I.

Sodium Content.—The sodium content of the various samples was determined by means of a Beckman model B spectrophotometer with flame attachment. The results are also shown in Table I.

Antacid Activity.—The acid consuming capacity (ACC) values for all samples are shown in Table I. Since all samples were completely soluble in 0.1 *N* hydrochloric acid at 37.5°, the ACC values are approximately equivalent to the amount of aluminum and/or magnesium present in the various products.

Reheis and Mutch reaction velocity values (3) were determined on all samples. They were seen to be rapidly reactive. The least reactive was the aluminum hydroxide dried gel U.S.P.

The principle method of measuring the antacid activity was the modified Holbert, Noble, and Grote procedure previously described, using an automated apparatus developed for the purpose. Figure 1 shows the results on 5, 10, and 15-ml. samples of an aluminum hydroxide gel U.S.P., Type F-1000 LS. In Fig.2 the antacid activity of new and 4-month-old samples of an aluminum hydroxide dried gel U.S.P., Type F-1000 LS is plotted on the basis of 1.0 Gm. Figure 3 shows the results obtained on 1.0-Gm. samples of the two aluminum-magnesium hydroxide glycine dried gels. The data for the two aluminum-magnesium hydroxide sorbitol dried gels is seen in

Fig. 4. Lastly, the antacid activity of the F-MA11-LS dried gel is seen in Fig. 5.

In Table II the antacid characteristics of the various low sodium dried gels are compared on the basis of 1.0-Gm. dose levels. The data is derived from the time-pH curves shown in Figs. 2–5.

RESULTS

Aluminum Hydroxide Gel.—The data presented show that a concentrated aluminum hydroxide gel may be prepared which when diluted to U.S.P. concentration of 4.0% aluminum oxide contains about 0.6 mg. of sodium per 30 ml. It can be seen that a massive 500-ml. daily dose would add only 10 mg. of sodium to the dietary intake, and hence could not be expected to cause edema or ascites in heart or liver disease patients. The gel is prepared from nonsodium reactants and should add less than two cents to the manufacturing cost of a standard 12-oz. bottle of liquid antacid.

Aluminum Hydroxide Dried Gels.—The sodium content of the various dried gels is seen in Table I to vary from 190 to 500 p.p.m. which would add, e.g., only 1 to 2.5 mg. of sodium for 8–10-gr. tablets. As might be expected from data presented in previous papers (3–5) in this series of *in vitro* studies, the aluminum hydroxide dried gels containing either magnesium carbonate or magnesium hydroxide stabilized with glycine or sorbitol exhibit antacid activities which are similar to reactive liquid aluminum hydroxide gel. The aluminum hydroxide dried gel U.S.P. type F-1000 LS prepared as above was much more reactive than most aluminum hydroxide dried gels U.S.P. that we have evaluated by our automated *in vitro* technique. However, after 4 months' aging it had declined in initial speed of reaction some 25%, and 14% in duration of antacid action above pH 3.0.

DISCUSSION

Nature of Aluminum Hydrogels.—The low sodium antacids prepared in this study compare favorably in all important properties with similar preparations manufactured with sodium salts. The nature of aluminum hydrogels are such that they readily adsorb foreign cations and anions from the systems in which they are made. Many of these ions are strongly bound and are not readily desorbed by washing copiously with pure water. Nor is it entirely desirable to do so, since their excellent antacid action and stability depends in large measure on the nature and amount of these adsorbed impurities.

Economics and Demand for Low Sodium Gels.—The substitution of potassium salts for sodium salts requires some minor changes in their manufacturing process particularly in the precipitation step and adds to the raw material cost because they are heavier in molecular weight and higher in price than sodium salts. Since other costs such as processing, container, shipping, etc., are similar for both systems, the price of low sodium products to the pharmaceutical manufacturer probably should not exceed 25% of the prices for present sodium-containing aluminum hydroxide gels.

One important variable is the potential volume for such low sodium products. As Bleifer, *et al.* (2), point out "the small concentrations of sodium present are in no way contraindicated in the overwhelming majority of cases in which antacid therapy is needed."

It may be uneconomical for manufacturers to make and pharmacists to stock both regular and low sodium grades. It is possible that a demand will be made in the future for sodium content statements on labels of all antacids destined for therapeutic use.

SUMMARY

1. A new concentrated aluminum hydroxide gel has been prepared which contains about 19 p.p.m. of sodium when diluted to U.S.P. strength of 4.0% aluminum oxide. The physical properties of the gel such as viscosity, settling characteristics, taste, and color are excellent. The antacid activity characteristics were determined by a very stringent *in vitro* procedure and seem to compare well with usual high sodium aluminum hydroxide liquid preparations similarly tested.

2. The preparation of six new aluminum hydroxide dried gels containing 190 to 500 p.p.m. of sodium is described. Four co-dried mixtures of aluminum hydroxide with magnesium hydroxide and glycine or sorbitol as well as a co-dried blend with magnesium carbonate are seen to have antacid characteristics similar to liquid aluminum hydroxide gels. An aluminum hydroxide dried gel U.S.P. with fairly good antacid properties is also described.

Aggregation in Oil-in-Water Emulsions

Effects of Dioctyl Sodium Sulfosuccinate Concentration

By W. I. HIGUCHI, RYUZO OKADA, and A. P. LEMBERGER

A procedure was developed which is suitable for the study of aggregation in oil-in-water emulsions. It involves the preparation of a relatively monodispersed emulsion (droplet sizes around 1 μ diameter) by the electrical dispersion technique and the determination of the distribution of sizes of the aggregates with the Coulter counter. The method was applied to the study of aggregation in hexadecane-in-water emulsions containing dioctyl sodium sulfosuccinate[1] (AOT) at varying concentrations. It was found that at low AOT concentrations ($\lesssim$0.1%) the emulsions were completely deaggregated. As the AOT concentration increased beyond this value, aggregation set in and progressively increased over the entire range of AOT concentration studied (up to 1.5%). In this system, aggregation was found to be completely reversible, the equilibrium being reached in all cases in a few days.

THE AGGREGATION of droplets in an emulsion or of particles in a suspension may alter the dynamic behavior of the system in at least two basic ways. First, the rate of creaming or sedimentation in dilute systems will be very much greater when aggregation is present (1). Since gravitational effects are much greater in creamed or sedimented systems, the rates of coalescence in emulsions and the caking rates in suspensions will be expected to take place more rapidly. Secondly, aggregation may affect the rheology (2) of the system. In general one would expect either thixotropic or pseudoplastic behavior in aggregating systems. The greatest amount of aggregation should be present at zero shear, and as the shear rate increases, deaggregation will increase as the forces of shear tend to pull apart the aggregates. Whether the system will be thixotropic or pseudoplastic depends upon how rapidly the aggregation-deaggregation equilibrium is established.

Since both the physical stability and flow properties of emulsions and suspensions are of great interest to the development pharmacist, a basic quantitative study of aggregation is essential. To the authors' knowledge, all past studies (1, 3, 4) of this problem for particles and droplets in the micron range or greater have not been of direct nature. Generally, creaming or sedimentation rates were followed and the aggregation behavior deduced in a qualitative or semiquantitative fashion. Because the situation in detail is very complex, to understand truly the important factors involved in aggregation, the phenomenon itself should be studied as directly as possible.

The purpose of this communication is twofold. A main purpose is to present a procedure which is well suited to quantitative studies of emulsion aggregation. It involves the preparation of a relatively narrow size range oil-in-water emulsion and the rapid counting and sizing of the droplets as a function of time. Secondly, the method is applied to the investigation of the the effects of the surfactant (dioctyl sodium sulfosuccinate) concentration on aggregation and deaggregation in hexadecane-in-water emulsions.

THEORY AND PAST EXPERIMENTS

Aggregation in emulsion systems is the formation of agglomerates without coalescence, i.e., without the actual rupture of the interfacial film and the subsequent formation of larger droplets. When contact of phases is prevented by a sufficiently high barrier, which may be either electrical or steric in nature, coalescence can be prevented. However, aggregation may take place in these systems if the attractive droplet-droplet forces[2] predominate at long range.

This long range attraction may be looked upon as arising from either or both of two distinct sources. First of all, two droplets will attract each other appreciably (attractive energies $\gtrsim kT$, where k = Boltzmann's constant and T = absolute temperature) even at distances large compared to molecular dimensions. These forces are the London dispersion forces accentuated as a result of the integration of the molecule-molecule interactions over the volumes of the two droplets. Studies both theoretical (5, 6) and experimental (3) clearly expose the existence of these macroscopic forces. The second contribution to droplet-droplet attraction might arise if, in the region between the two particles, the interfacial film of one droplet attracts the film of the other. This would be expected to be most important when the

[1] Marketed as Aerosol OT by American Cyanamid Co.

[2] These may include interactions involving adsorbed films when surfactants are present or if surface solvation is important.

absorbed surfactant films on oil droplets in water expose relatively hydrophobic and/or nonionizing functional groups toward the water phase. "Soluble" surfactants which, when adsorbed onto oil droplets, are able to expose an abundance of hydrophilic groups to the water should, in general, not contribute to droplet-droplet attraction, and therefore aggregation. On the contrary, by means of their charges or/and hydrophilic bulk, they should contribute to the prevention of close approach of the droplets.

If, then, the repulsive forces (electrical or steric) are not as long ranged as the above attractive forces, the droplets may find themselves energetically more comfortable in the aggregated states.

Cockbain (1) has interpreted his creaming rate studies of benzene- and paraffin-in-water emulsions in the following way: conventional low molecular weight ionic stabilizers, both cationics and anionics, prevent both coalescence and aggregation at low stabilizer concentrations ($\lesssim$0.1% or so), but at higher concentrations (~0.1 to 1% or so) aggregation occurs in all cases. At much higher concentrations the droplets deaggregate in some cases. Because without exception aggregation was found with all surfactants studied, the practical importance of Cockbain's observations are clear.

EXPERIMENTAL

General Considerations.—The following novel measures were taken to permit a direct study of aggregation and deaggregation. To eliminate as much as possible the effects of the distribution of sizes, narrow size range emulsions were prepared by the high voltage electrical dispersion method described by Nawab and Mason (7). To follow aggregation, the Coulter counter[3] (8) was employed to determine both droplet concentration and size distribution changes as a function of time.

Preparation of Emulsions.—Hexadecane was redistilled Eastman practical grade. The American Cyanamid "100% pure" Aerosol OT (AOT) was specially purified (8) by fractional precipitation from methanol and water-methanol solvent mixture. The water used was doubly distilled.

Hexadecane containing 2.0% by weight AOT was placed in a syringe, as shown in Fig. 1. A No. 25 needle, with the tip evenly cut off perpendicular to its axis, permitted a flow of about 20 drops per second with no applied voltage to the needle. The hexadecane solution was sprayed onto a 1% aqueous AOT solution with 6 kv. applied to the needle. The aqueous solution was grounded as shown and was agitated with a magnetic stirrer. The needle tip-to-solution surface distance was 2.5 cm. These conditions were selected to give the best appearing spray. The spraying was continued until about 40% by volume hexadecane had been emulsified. This was the stock emulsion used in the studies. It was kept in a polystyrene bottle at 30°C. in a rotating wheel type constant temperature bath which provided gentle agitation.

Calibration and Use of the Coulter Counter.—The 30-μ aperture was used throughout these studies. The threshhold scale of the instrument was calibrated with polystyrene latices,[4] 1.17 and 1.83 μ diameters,[5] at all sensitivity and attenuator settings used in our studies except for those corresponding to low sensitivities. These latter settings were calibrated by the data themselves by determining the scale factors which gave the same count *vs.* threshhold values. It was assumed that the pulse height was proportional to the volume of the particle passing through the aperture. This is the usual assumption which may be justified theoretically in an approximate manner. Also, employing blood cells as a third calibration point this assumption has been approximately verified by us in at least one instance.

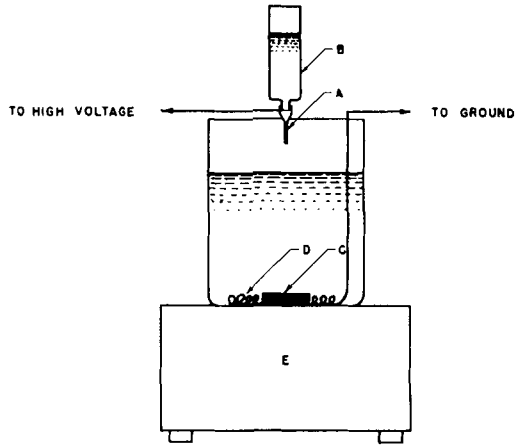

Fig. 1.—Apparatus for the preparation of emulsions by electrical dispersion. A, hypodermic needle; B, syringe; C, stirring bar; D, grounding coil; E, stirrer.

In Fig. 2, results of a typical calibration run of a mixture of 1.83 and 1.17 μ latices in 0.90% saline solution are shown. The curve shown is the derivative[6] of the cumulative count curve (counts *vs.* threshhold curve), which is the one directly obtained with the instrument. Since the standard deviation of the latex sizes was known to be considerably less than the peak widths and since these particles did not appear to be agglomerated to any extent, the peak widths are believed to be a measure of the resolving power of the instrument. Thus, it is apparent that the resolving power of the instrument was about 0.2 μ in this range.

Procedure for Deaggregation Studies.—The stock emulsion (see above) was diluted to 1.0 and 2.0% by volume hexadecane with water containing varying amounts of AOT so that the final emulsions contained AOT ranging from about 0.05 to 1.5% by weight. About 10 ml. of these emulsions was pipetted into leak-tight vials of about 15-ml. capacity. The vials were fixed to wheels rotating at 30 r.p.m. in a constant temperature bath maintained at 30°C.

[3] Coulter Industrial Sales, Elmhurst, Ill.

[4] Kindly supplied by J. W. Vanderhoff, Dow Chemical Co., Midland, Mich.

[5] These are electron microscope values. It was assumed that the aqueous suspension sizes were the same.

[6] These and those for the emulsions were obtained by numerical difference methods. While the distribution "curves" should really be histograms for this reason, intervals taken on the *x*-axis were generally small enough so that the "smoothing" introduced little error for our purposes.

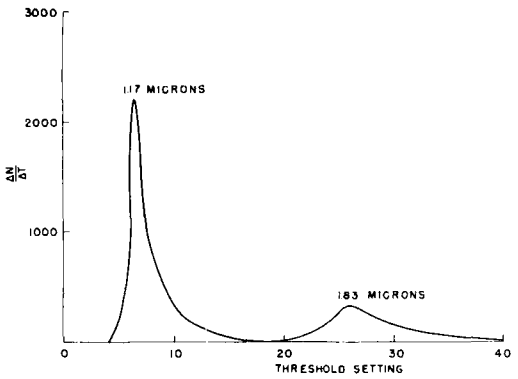

Fig. 2.—Differential count curve for a mixture of 1.17 and 1.83 μ diameter polystyrene spheres obtained with the Coulter counter. The ordinate is the derivative of the cumulative count curve with respect to the threshold setting.

Samples were removed from time to time and the size analyses with the Coulter counter carried out in the following way. The 1.0 and 2.0% hexadecane emulsions were diluted by about a factor of 1000 to provide a low enough concentration suitable for the Counter. To accomplish this without sacrifice of volumetric accuracy, the dilution was carried out in two steps, *viz.*, 1 to 10 with water followed by a 1 to 100 in 0.90% saline.

Procedure for Aggregation Studies.—Emulsions in which aggregation was completely absent (AOT concentrations $\lesssim 0.09\%$) were aggregated to varying degrees by addition of solid AOT. These were handled in the same manner as in the deaggregation experiments. Samples were taken over a period of about 10 days.

RESULTS

Figure 3 gives the number-diameter distribution curve for the completely deaggregated emulsion. Complete deaggregation was observed for the 1.0 and 2.0% emulsions when the AOT concentration was 0.09% or less. This curve shows the remarkable ability of the high voltage technique to prepare emulsions with a very high population of essentially a single size. It should be emphasized, however, and it is apparent from the curve, that the mass distribution curve will appear considerably different, being much broader. In all cases, at maximum deaggregation the 0–5 μ range accounted for only about 50% of the total hexadecane used in the preparation. Most of this discrepancy could be accounted for by extrapolation of the distribution curve to about 10 μ. Presumably, some of these large droplets were formed not in the spraying but from the portions of the hexadecane which dropped from the needle prior to and after the high voltage was applied and which were subsequently emulsified by the stirring.

Figures 4–7 give the distribution curves showing deaggregation as a function of time for the 1.0% emulsions at different AOT concentrations. After about 10 days, aggregation-deaggregation equilibrium was apparently reached in all cases. Distribution curves obtained at later times did not show further deaggregation. It is noteworthy that only after the stock emulsion had itself equilibrated for about 1 week did the results of the deaggregation experiments become reproducible. Apparently the redistribution kinetics of the AOT was very slow in this concentrated and highly aggregated system.

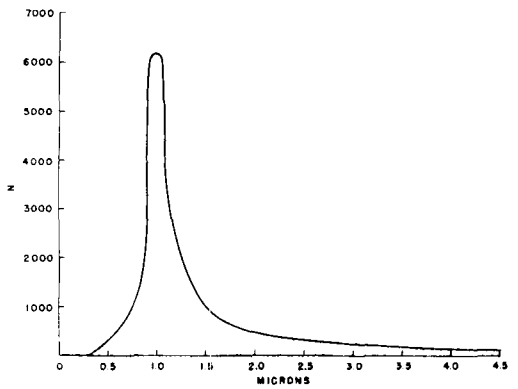

Fig. 3.—The droplet diameter distribution curve for the completely deaggregated hexadecane-in-water emulsion prepared by the electrical dispersion method.

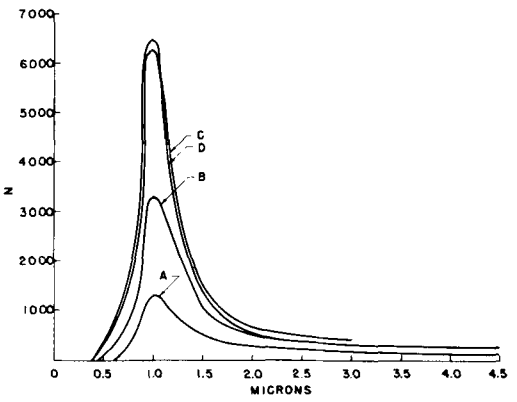

Fig. 4.—Deaggregation in 1.0% hexadecane emulsion containing 0.045% AOT when diluted from stock emulsion. A, initial; B, 3 days; C, 6 days; D, 9 to 12 days.

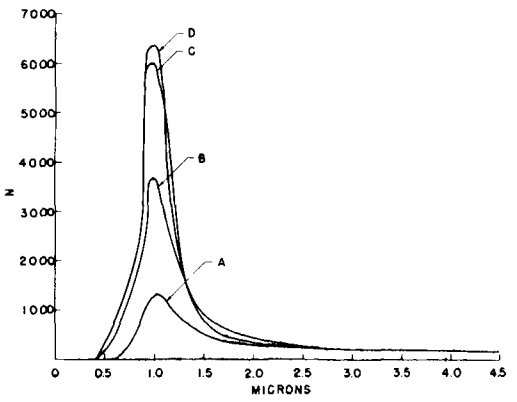

Fig. 5.—Deaggregation in a 1.0% hexadecane emulsion containing 0.09% AOT. A, initial; B, 3 days; C, 6 days; D, 9 to 12 days.

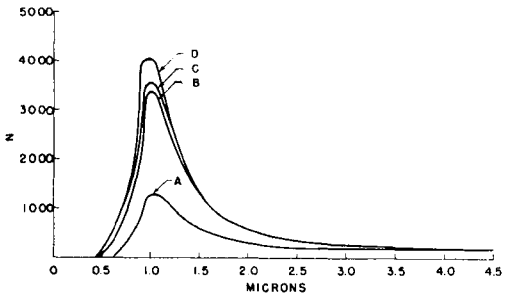

Fig. 6.—Deaggregation in a 1.0% hexadecane emulsion containing 0.50% AOT. A, initial; B, 3 days; C, 6 days; D, 9 to 12 days.

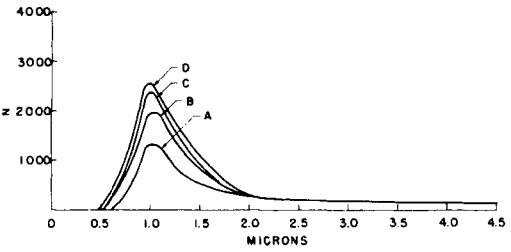

Fig. 7.—Deaggregation in a 1.0% hexadecane emulsion containing 1% AOT. A, initial; B, 3 days; C, 6 days; D, 9 to 12 days.

It can be seen from Figs. 4–7 that during the initial periods of deaggregation not all of the final mass of the completely deaggregated emulsion can be found in the 0–5 μ range. This is in contrast to the aggregation data for the 2.0% emulsions summarized in Figs. 8 to 11, in which cases the disappearance of the single particles in the 1 μ size region may be accounted for by the increases in concentration of particles in the 1.5 to 4 μ size range. The difference in behavior may be explained by the existence of very large aggregates in the stock emulsion. These would be expected to deaggregate much more slowly than the smaller aggregates.

That aggregation-deaggregation was completely reversible was demonstrated by the following experiment. A completely deaggregated 2.0% hexadecane

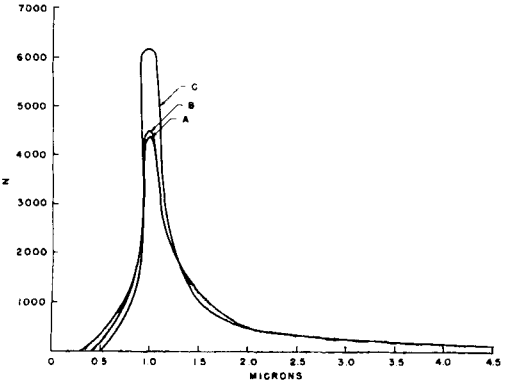

Fig. 8.—Aggregation in an initially completely deaggregated 2.0% hexadecane emulsion containing 0.18% AOT. C, initial; B, 2 days; A, 4 to 7 days.

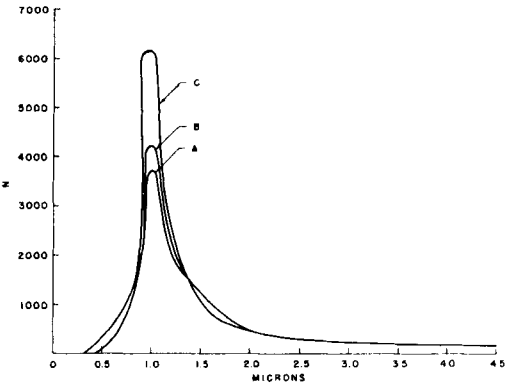

Fig. 9.—Aggregation in a 2.0% hexadecane emulsion containing 0.29% AOT. C, initial; B, 2 days; A, 4 to 7 days.

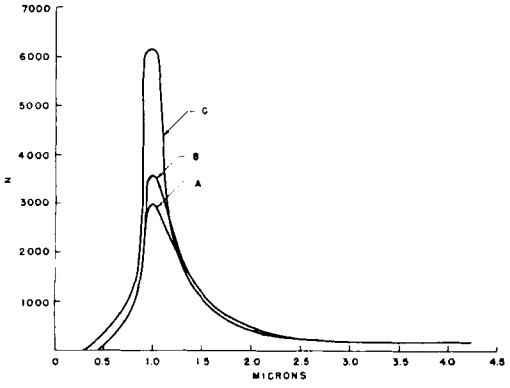

Fig. 10.—Aggregation in a 2.0% hexadecane emulsion containing 0.49% AOT. C, initial; B, 2 days; A, 4 to 7 days.

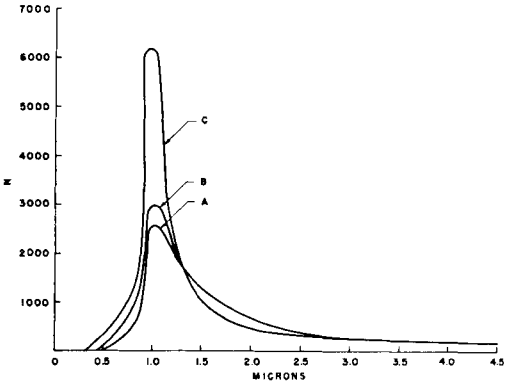

Fig. 11.—Aggregation in a 2.0% hexadecane emulsion containing 0.99% AOT. C, initial; B, 2 days; A, 4 to 7 days.

emulsion containing 0.09% AOT was partially aggregated by addition of enough AOT so that the AOT concentration was 0.18%. This emulsion was then diluted by a factor of two with water. The initial and final emulsions gave identical size distribution curves.

Earlier in these studies there was some concern as to whether the degree of aggregation in the 1.0 and 2.0% emulsions may have been altered by the dilution steps (see *Procedure*) themselves. Specifically, the questions were (*a*) did the first dilution step deaggregate the emulsions to any extent and (*b*) did the high salt concentration in the second step of dilution induce coalescence, further aggregation, or deaggregation? By varying the time of mixing from a few minutes to 30 minutes, no effect of the first dilution step on the results was observed. Also for periods up to 1 hour, no change in the counting was observed after the second dilution. Furthermore, the manner of introduction of sample and the degree of stirring during the introduction was unimportant for the second dilution. Thus, true pictures of the 1.0 and 2.0% emulsions were very likely obtained by the procedure employed.

DISCUSSION

Method.—The above results demonstrate that this procedure is suitable for quantitative aggregation studies. It should prove to be useful and practical in the evaluation of additives as to their ability to prevent aggregation and coalescence. The relative rapidity of the measurements permits the determination of the distribution of sizes within minutes. This is not only convenient but allows studies of relatively rapidly changing systems with apparently little disturbance to the systems themselves.

Mechanism of Aggregation in Hexadecane Emulsions Stabilized by AOT.—Cockbain (1) has proposed that aggregation in this system results possibly from polymolecular adsorption of the surfactant on the droplet surface. He suggests that after the formation of a monolayer, which exposes primarily hydrophilic groups to the aqueous phase, a second layer begins in which the molecules are oriented in the reverse direction, i.e., with the hydrophobic groups oriented toward the aqueous phase. Thus, interactions between these hydrophobic portions of the second layer of the droplets may account for aggregation.

While the above picture may be the correct one, the following alternative mechanism similar to that of Greiner and Vold (4) may be proposed which does not invoke the second and hydrophobic layer concept. At sufficiently low surfactant concentrations (<0.1% AOT), a monolayer or less of surfactant is adsorbed and aggregation is prevented by the repulsive long range interaction of the electrical double layers around the droplets. The double layer arises because the sulfonate ion is preferentially adsorbed and the sodium ions are distributed according to the Poisson-Boltzmann equation. If the counterion (Na^+) concentration is low enough, the thickness of the electrical double layer will be great and thus long range repulsion will prevail and cancel out the London attractive forces to within about kT for all interparticle distances. Thus aggregation is prevented at low AOT concentrations.

Now as the AOT concentration increases, the Na^+ concentration increases in the system. This increase in Na^+ concentration is approximately equal to the AOT concentration increase up to the critical micelle concentration (CMC), beyond which the increase in Na^+ will be slower because the dissociation of the Na^+ from the micelles will be limited. As the Na^+ concentration increases, the thickness of the double layer will decrease by at least, approximately, the inverse square root of the Na^+ concentration. When the thickness of this electrical layer is sufficiently reduced so that the range of the repulsive forces have become sufficiently reduced, the London attractive forces will predominate by more than kT at some interparticle distances. This is the secondary minimum phenomenon (3, 5, 6). Under these conditions aggregation may take place. The depth of this minimum and, hence, the forces of particle-particle attraction will increase with increasing Na^+ concentration. Thus aggregation increases with increase in the AOT concentration.

Recently Schenkel and Kitchener (3) studied the aggregation in water of 10 μ diameter polystyrene spheres, the surfaces of which were fully sulfonated chemically (therefore not unlike our system electrically). They found that aggregation (increased sedimentation rate) became important when the added potassium nitrate concentration exceeded about 3×10^{-4} M. Aggregation increased to about 4×10^{-3} M salt. These investigators point out that this behavior is in accordance with the theoretical predictions of Verwey and Overbeek (6) that coarse particles (micron range) should exhibit a secondary minimum of about 6 kT deep in 1×10^{-4} M one-to-one electrolyte. These electrolyte concentrations are approximately in the same range as the Na^+ concentration at which aggregation begins in our hexadecane-water system. In our studies, the Na^+ concentrations were actually a little greater, *viz.*, about 2 to 4×10^{-3} M in Na^+. So, if anything, the conditions in our systems were actually somewhat more conducive to aggregation. Perhaps a smaller London constant is appropriate for the hexadecane-water system. This may account for the difference.

The above discussion shows that it is very likely that the aggregation phenomenon may be basically an electrically induced one and that it appears to be unnecessary to postulate film-film attraction. It is quite possible that both mechanisms are important, since increasing ionic strength invariably increases the tendency for the aggregation of the surfactant itself. More basic studies are needed to provide definite answers to this problem.

Application of Absorbancy Ratios to the Analysis of Pharmaceuticals IV

Analysis of Ternary Mixtures

By M. PERNAROWSKI†, A. M. KNEVEL, and J. E. CHRISTIAN

Four equations that may be used in the analysis of ternary mixtures are derived. All of these equations are based on the relationship between absorbancy ratio values and the relative concentration of one of the components in the ternary mixture. To indicate the applicability of these equations, three ternary mixtures were investigated, one in the ultraviolet region and two in the infrared region of the electromagnetic spectrum. Methods of plotting data are discussed and the utility of such plots under specific analytical situations are pointed out.

PREVIOUS PAPERS in this series dealt with the analysis of binary and certain types of ternary mixtures by the absorbancy ratio method of analysis (1–3). Comprehensive derivations and a survey of the literature may be found in the original work of the author (4). For the purposes of this paper, Q value implies an abbreviation for absorbancy ratio value. Similarly, the absorbancy ratio value obtained by, for example, dividing the absorbancy observed at 250 mμ by that observed at 275 mμ, the solute and the solution being the same for both measurements, is symbolized as $Q{:}250{:}275$. A Q curve illustrates the relationship between absorbancy ratio values and the relative concentration of binary or ternary mixtures. Other terminology and symbology shall be that suggested by the National Bureau of Standards (5). The symbol for cell length (b) shall not be used in the derivations below since the value is assumed to be equal to unity.

THEORY

When the three components of a ternary mixture have individual spectral characteristics such that each interferes during analysis with the other two at all wavelengths, then the equations derived below may be used for the simultaneous determination of the substances. As in most of the derivations in this series, it is assumed that two of the three components in the mixture have a characteristic isoabsorptive point. Figure 1 illustrates the type of spectral characteristics suited to the equations below.

The total absorbancy at λ_5 (A_5) is equal to the sum of the absorbancies due to X, Y, and Z. The following equation is, therefore, valid

$$A_5 = a_7\,Cx + a_5\,Cy + a_1\,Cz \qquad \text{(Eq. 1)}$$

Cx, Cy, and Cz are the concentrations of X, Y, and Z in the mixture. Preceding each of these symbols are the absorbancy index values for the three components at this wavelength. For exactly the same reasons

$$A_4 = a_6\,Cx + a_6\,Cy + a_2\,Cz \qquad \text{(Eq. 2)}$$

Continuing the derivation in the same way as indicated in the first paper in this series (1), Eq. 1 is divided by Eq. 2. The concentration terms are converted to fractional quantities by dividing each term of the equation by $Cx + Cy + Cz$. This results in the following equation

$$\frac{A_5}{A_4} = \frac{a_7\,Fx + a_5\,Fy + a_1\,Fz}{a_6\,(Fx + Fy) + a_2\,Fz} \qquad \text{(Eq. 3)}$$

However

$$Fy = 1 - Fz - Fx \qquad \text{(Eq. 4)}$$

The right-hand member of Eq. 4 is now substituted for Fy in Eq. 3 and the terms are collected. Each term is now divided by a_6.

$$\frac{A_5}{A_4} = \frac{\dfrac{a_7\,Fx}{a_6} + \dfrac{a_5\,(1 - Fz - Fx)}{a_6} + \dfrac{a_1\,Fz}{a_6}}{\dfrac{a_6\,(1 - Fz)}{a_6} + \dfrac{a_2\,Fz}{a_6}} \qquad \text{(Eq. 5)}$$

The spectral characteristics in Fig. 1 indicate that a_7/a_6 is the absorbancy ratio value for pure X (Qx) at these two wavelengths. Similarly, a_5/a_6 is the absorbancy ratio value for pure Y (Qy). The absorbancy ratio value for the mixture is equal to A_5/A_4 and may be designated as Qo. These symbols are substituted into Eq. 5 and the equation is rearranged

$$Qo = \frac{Fx(Qx - Qy) + Fz\,(a_1/a_6 - Qy) + Qy}{1 + Fz\,(a_2/a_6 - 1)} \qquad \text{(Eq. 6)}$$

Equation 6 contains two unknowns and, therefore, cannot be used to determine the components in the mixture. Another equation is required to complete the analysis. This equation may be derived from the spectral characteristics of the three components at λ_3 and λ_4 in exactly the same manner as shown above. Therefore

$$Qo_1 = \frac{Fx\,(Qx_1 - Qy_1) + Fz\,(a_3/a_6 - Qy_1) + Qy_1}{1 + Fz\,(a_2/a_6 - 1)} \qquad \text{(Eq. 7)}$$

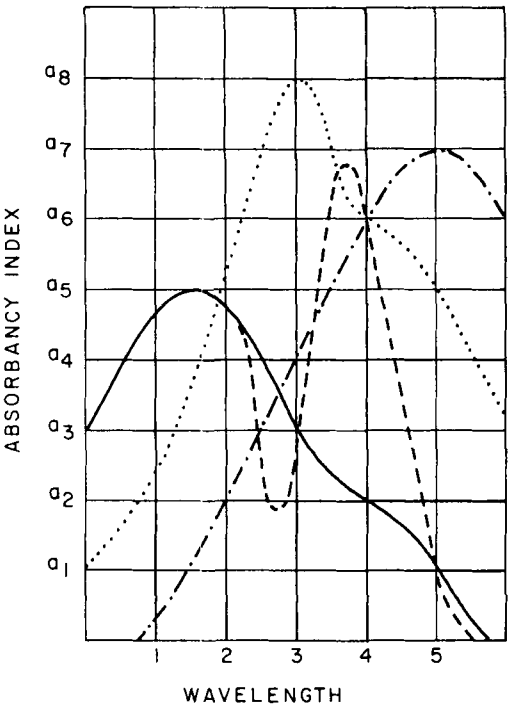

Fig. 1.—Hypothetical spectrophotometric curves of X (—·—·—), Y (. . . . .), and Z (——) illustrating spectral characteristics necessary for ternary Q analysis. The spectrum for Z (– – –) illustrating a common isoabsorptive point is also shown.

Equations 6 and 7 may now be solved simultaneously for the fraction of two of the three components in the mixture.

The above equations are simplified considerably if the three components in the mixture have a common isoabsorptive point. The total absorbancies at λ_3 and λ_4 may be defined as above except that the absorbancy index value of component Z at λ_4 is equal to a_5. By carrying out the derivation in exactly the same manner as above, Eqs. 6 and 7 become

$$Qo = Fx\,(Qx - Qy) + Fz\,(Qz - Qy) + Qy \quad \text{(Eq. 8)}$$

and

$$Qo_1 = Fx\,(Qx_1 - Qy_1) + Fz\,(Qz_1 - Qy_1) + Qy_1 \quad \text{(Eq. 9)}$$

These two equations may now be solved simultaneously for the fractions of X and Z in the mixture.

The disadvantages of this type of analysis are apparent from the above equations. Two simultaneous equations must be solved in order to complete the analysis. This, however, is somewhat simpler than the solution of three equations simultaneously as would normally be required for a three-component mixture. The major disadvantage occurs when there is no common isoabsorptive point in the spectra of the three components. When this occurs, absorbancy index values at three wavelengths for one of the three components are required to apply the above equations.

The first paper in this series (1) showed that a plot of the absorbancy ratio values of binary mixtures *vs.* the relative concentration of such mixtures was a straight line if one of the two wavelengths used in the analysis represented an isoabsorptive point. A similar situation holds for ternary mixtures. If the fraction of one of the components in a ternary mixture is held constant, a plot of absorbancy ratio *vs.* the fraction of one of the other two components results in a straight line. An examination of Eq. 6 will indicate the reason for this. With Fz a constant, this equation assumes the form of $y = mx + b$. The slope and intercept of this line will depend on the fraction of Z in the mixture. If a series of solutions are prepared, each series containing a fixed quantity of Z and varying quantities of X and Y, and the absorbancy ratios derived from these plotted *vs.* the relative concentration of either X or Y in the mixture, a series of straight lines will result. These lines will intersect at some point either on the graph or at an extrapolated distance from it.

A similar condition holds for Eq. 8. In this case, however, a series of straight lines will result which have the same slope but different intercepts. This occurs because of the isoabsorptive point at λ_4. The analytical use of this type of plot and of that above will be discussed in more detail below. The most important consideration here is that if independent analysis of Z is possible by other means, the above equations, based on the principles of Q analysis laid down in earlier publications (1–3) may be used to analyze for the other two components in the mixture and hence obviate the necessity of solving simultaneous equations.

EXPERIMENTAL

The apparatus and general techniques used in the analysis of the ternary systems described below have been reported in previous publications (1, 2). Two ternary systems were analyzed in order to show the validity of the above equations.

Analysis of Mixtures Containing Phenyl Salicylate, Salicylic Acid, and Gentisic Acid.—These three substances are not appreciably soluble in water. Stock solutions, therefore, were prepared with the aid of alcohol. Since the latter two substances under investigation are acidic, the spectral characteristics can be expected to vary with the pH of the solution being studied. All solutions, therefore, were prepared in such a way that each contained 1.00% concentrated hydrochloric acid in the final dilution. The spectrophotometric curves for these three substances are shown in Fig. 2. Salicylic acid, phenyl salicylate, and gentisic acid absorb ultraviolet radiant energy most strongly at 303, 307, and 330 mμ, respectively. Minima occur at 272, 260, and 270 mμ for phenyl salicylate, salicylic acid, and gentisic acid, respectively. An isobsorptive point for these three substances occurs at 314 mμ.

Three wavelengths, 303 mμ (the peak for salicylic acid), 314 mμ (the isoabsorptive point), and 330 mμ (the peak for gentisic acid) were chosen for the analysis. Q:303:314 and Q:330:314 values for these three substances were determined and are reported in Table I.

It was pointed out above that a series of straight lines result when the absorbancy ratio is plotted *vs.* the per cent of one of the components in the mixture

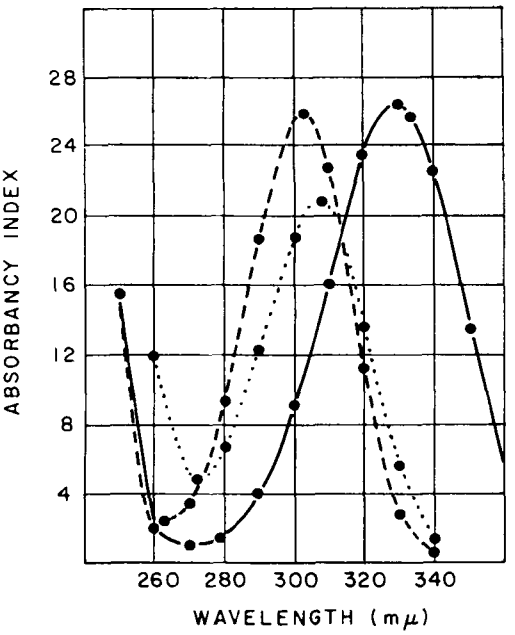

Fig. 2.—Spectrophotometric curves for phenyl salicylate (. . . . .), salicylic acid (– – – –), and gentisic acid (——) in 0.1 *N* hydrochloric acid.

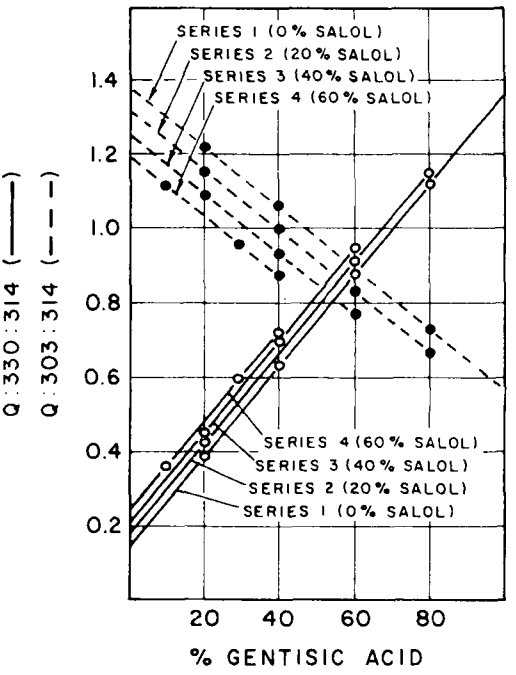

Fig. 3.—*Q* curves for gentisic acid, salicylic acid, and phenyl salicylate (salol).

if one of the three components in such a mixture is held constant. Four series of solutions were so prepared that the first contained 0% phenyl salicylate, the second 20% phenyl salicylate, the third 40% phenyl salicylate, and the fourth 60% phenyl salicylate. The amounts of salicylic acid and gentisic acid within a series were allowed to vary. For any particular series, therefore, the amount of phenyl salicylate is a constant. The variables in the series are the quantities of gentisic acid and salicylic acid. *Q*:330:314 and *Q*:303:314 values were determined for all solutions and the results plotted in the usual way. These results are shown graphically in Fig. 3 and the equations for these lines are indicated by the data tabulated in Table II. Within experimental limitations, the slopes of these lines are equal. Hence, the lines are parallel. The intercepts of the lines differ, indicating the validity of Eqs. 8 and 9. These equations may now be rewritten in their numerical form. All slope values (that is, the difference between two *Q* values as shown in Eqs. 8 and 9) were determined by the method of least squares from data accumulated on mixtures. There is, therefore, a slight difference between these values and those obtained from the data in Table I. As stated in previous papers (1, 2), the method of least squares gives a more accurate estimate of the slope and hence such values are carried into future calculations

$$Q{:}330{:}314 = 1.224\ Fx + 0.141\ Fz + 0.143$$

and

$$Q{:}303{:}314 = -0.809\ Fx - 0.318\ Fz + 1.383$$

Fx and *Fz* represent the fractional quantities of gentisic acid and phenyl salicylate, respectively. Experimentally, absorbancies are measured at the three wavelengths indicated above, the absorbancy ratio values calculated, and the above two equations solved simultaneously to determine the quantity of gentisic acid and phenyl salicylate in the mixture. The amount of salicylic acid is obtained by subtracting the sum of the fractional quantities of these two components from 1.

Five solutions containing these three substances were prepared and analyzed. The results obtained are shown in Table III.

Simultaneous Analysis of Quinine, Brucine, and Strychnine.—The simultaneous analysis of brucine and strychnine by the absorbancy ratio technique was described in a previous publication (2). If the alkaloid quinine is added to such a binary mixture, the resulting ternary mixture can be analyzed by

Table I.—*Q* Values for Phenyl Salicylate, Salicylic Acid, and Gentisic Acid[a]

Compound	*Q*:330:314	*Q*:303:314
Phenyl salicylate	0.282 ± 0.004	1.071 ± 0.002
Salicylic acid	0.143 ± 0.001	1.383 ± 0.006
Gentisic acid	1.367 ± 0.004	0.571 ± 0.004

[a] Each *Q* value is the mean of five determined values the standard deviation is reported after each value.

Table II.—Equations of *Q* Curves Shown in Fig. 3

4	20.0	20.2	40.0	39.4	40.0	40.4
5	0.0	0.1	40.0	41.7	60.0	58.2

TABLE IV.—EQUATIONS OF *Q* CURVES SHOWN IN FIG. 4

Series	% Quinine in Mixture	Line *Q*:7.78:6.83 *vs.* % Brucine Slope	Intercept
1	0	1.096	0.612
2	25	1.269	0.625
3	50	1.491	0.626
4	70	1.564	0.623

applying the principles inherent in Eq. 6. This, however, presupposes that the cinchona alkaloid can be determined at some wavelength at which brucine and strychnine transmit all or nearly all of the radiant energy passing through the solution.

Infrared spectra of solutions of quinine (0.5 to 2.0 Gm. quinine per 100 ml. of chloroform) were compared with spectra of brucine and strychnine and, on this basis, it was apparent that quinine can be analyzed in the presence of these two substances by measuring absorbancies at 6.13 μ. Solutions of quinine in chloroform were first considered. A linear relationship was observed between the absorbancy at 6.13 μ and the concentration of quinine (C_q) in the solution expressed in terms of Gm. per 100 ml. The equation of this line was found to be: $A_{6.13\,\mu} = 0.283\ Cq + 0.025$. It should be pointed out that th s equation is valid only for the conditions of operation cited earlier (2). The intercept of the above equation indicates that there is a slight deviation from Beer's law at this wavelength. To avoid gross errors in the analysis, this equation was used to calculate Cq for all determinations at this wavelength.

Equation 6 presupposes a knowledge of absorbancy index values for quinine at the two wavelengths at which brucine and strychnine are analyzed (6.83 and 7.78 μ). In a manner similar to that described above, the absorbancies of solutions of quinine at these two wavelengths were plotted *vs.* the concentration (Cq) in Gm. per 100 ml. of chloroform. The equations of the two straight lines are: $A_{6.83\,\mu} = 0.173\ Cq$ and $A_{7.78\,\mu} = 0.095\ C_q + 0.004$. Both equations indicate that Beer's law is obeyed at these wavelengths.

The inherent qualities of Eq. 6 were discussed above. To check the validity of these observations in the infrared region of the spectrum, four series of solutions were prepared in a manner analogous to that described under the section on the analysis of phenyl salicylate, salicylic and gentisic acids. *Q*:7.78:6.83 values were determined for each of the solutions within a series and the results plotted in the usual way. These results are shown graphically in Fig. 4 and in tabular form in Table IV. This table shows the slopes to be different and the intercepts the same. This, however, is a rather unique case. It was pointed out above that there should

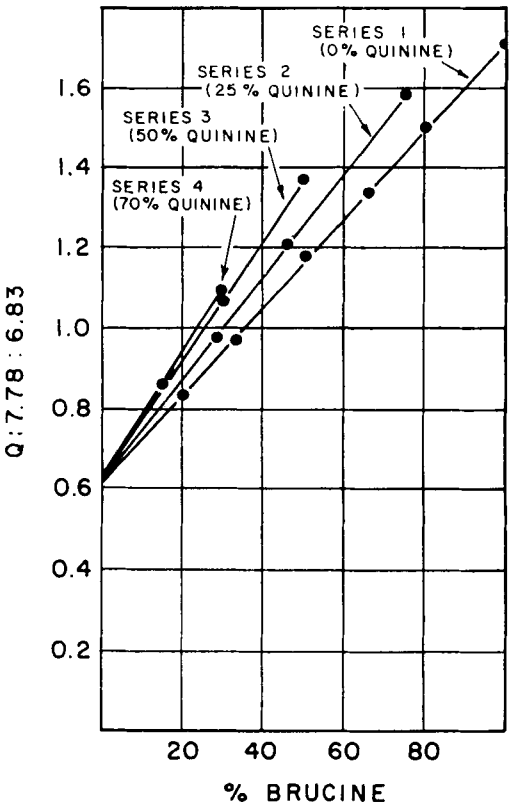

Fig. 4.—*Q* curves for brucine, strychnine, and quinine.

be a point of intersection in lines such as these. In this case, this point occurs at or near the intercept. In other ternary mixtures, however, this would not be the case. The *Q* value at the point of intersection would not necessarily coincide with the intercept value.

On the basis of the data reported here or in a previous publication (2), Eq. 6 may be rewritten as follows

$$Q{:}7.78{:}6.83 = \frac{1.096\ Fb + Fq\ (0.095/0.371 - 0.612) + 0.612}{1 + Fq\ (0.173/0.371 - 1)}$$

Fb is the fraction of brucine in the ternary mixture and *Fq* the fraction of quinine in the same mixture. Experimentally, the numerical value of *Fq* is obtained by determining the absorbancy of the mixture at 6.13 μ, applying the necessary correction factors cited above, and dividing the value obtained for Cq by weight of the sample taken in the analysis.

TABLE V.—RESULTS OF THE ANALYSIS OF MIXTURES CONTAINING QUININE, BRUCINE, AND STRYCHNINE

Solution	Quinine		Brucine		Strychnine	
	Present, %	Found, %	Present, %	Found, %	Present, %	Found, %
1	50.0	47.0	30.0	31.9	20.0	21.1
2	25.0	24.2	28.7	29.4	46.3	46.4
3	0.0	0.0	80.1	80.8	19.9	19.2
4	40.1	41.3	9.6	10.1	50.3	48.6
5	50.0	51.6	50.0	51.6	0.0	0.0

This value is now substituted into the above equation, the Q:7.78:6.83 value calculated from the absorbancies observed at 7.78 and 6.83 μ, and the fraction of brucine in the mixture calculated by solving this equation. The fraction of strychnine in the mixture can now be determined by subtracting the sum of Fb and Fq from 1.

A number of solutions containing quinine, brucine, and strychnine were prepared and analyzed. The results obtained for five of these solutions are shown in Table V.

DISCUSSION

The absorptiometric principles involved in the analysis of ternary mixtures do not differ from those for binary mixtures. While the equations derived appear to be more complicated, they are still based on Beer's law and the principles of absorbancy ratio analysis outlined in previous publications (1, 2). The comments in these two publications are as applicable here as they were to the analysis of binary systems. The pertinent factors cited therein included slope of the Q curve, accuracy of the absorbancy measurement, relative concentrations of the active ingredients, nature of the pharmaceutical, and spectral characteristics of the components of the mixture.

Several points arise, however, from the experimental data accumulated on ternary mixtures. It was pointed out above that a straight line results if the Q values of ternary mixtures in which one of the components is held constant are plotted *vs.* the relative concentration of one of the components in the mixture. This is shown graphically in Figs. 3 and 4. The question arises as to the utility of such plots. Three possible situations can result from such plots. The first involves the case where all three components have an isoabsorptive point in common, the second where only two of the three components in the mixture have a common isoabsorptive point, and the third where no suitable isoabsorptive point occurs.

If the absorbancy ratio values of ternary mixtures and the relative concentrations are compared in the usual way, and only two of the three components share an isoabsorptive point, then a point arises in the series of curves plotted at which all mixtures have the same absorbancy ratio value. Such a point may represent experimental or hypothetical mixtures. In the case of quinine, brucine, and strychnine, the point at which all lines intersect represented an experimental condition. It should be evident that such a point could occur (on extrapolation) to the left of the Y axis if a different ternary mixture were investigated. The utility of such a point of intersection is not difficult to ascertain. In the vicinity of such a point, an analysis of the ternary mixture by the principles laid down herein would yield poor analytical results. This occurs simply because any number of mixtures have the same Q value. This then indicates that the presence of such a point on the graph is not desirable if the entire range of the mixture (0 to 100%) is to be investigated. It is important to consider, therefore, the relative concentrations of the three components in the mixture. If these are such that Q values obtained on analysis are sufficiently removed from this point of intersection, then the analysis will yield satisfactory results. For example, a 1-1-1 mixture might be easily analyzed, but it would be impossible to analyze accurately a 3-2-1 mixture. By plotting results in the manner shown in Fig. 4, the feasibility of the analysis can be quickly established.

A somewhat different situation occurs in the case of phenyl salicylate, salicylic and gentisic acids. These three substances have a common isoabsorptive point and hence the slope of the Q curves is a fixed quantity. This value is always equal to the slope of the Q curve for the binary mixture composed of two of the three substances in the ternary mixture. The absorbancy index value for the third component at the first wavelength used for the calculation of the Q values is, therefore, the significant constant. If the value of a_1/a_6 approaches that of Qy (see Eq. 6), then the analysis will not be very accurate primarily because the third component is not altering the intercept value of the Q curves to a significant extent. This results in a situation where many mixtures have essentially the same Q value. If a_1/a_6 and Q_y differ drastically (but again not so drastically that their determination becomes difficult) then the analysis can be expected to yield results in keeping with good analytical practice.

To summarize, therefore, a series of Q curves for ternary mixtures gives the analyst an indication of the accuracy with which the analysis can be conducted. If a point of intersection is present on the graph, the analyst can expect that analysis of mixtures having compositions defined by the graph in the vicinity of this point will not be accurate. The greater the difference between a_1/a_6 and Qy (on the basis of Eq. 6) the better the results will be.

The reader may well ask what would happen if no suitable isoabsorptive point is present in the spectra of two of the three substances. This obviously complicates the equations derived in this paper but, again, if one of the components is held constant, a plot of absorbancy ratio *vs.* the per cent of one of the other components in the ternary mixture should result in a curve. In the second paper in this series (2), the potassium bromide technique was used in the analysis of two sulfa drugs. This binary mixture can, in fact, be considered as a ternary mixture containing potassium bromide, sulfathiazole,

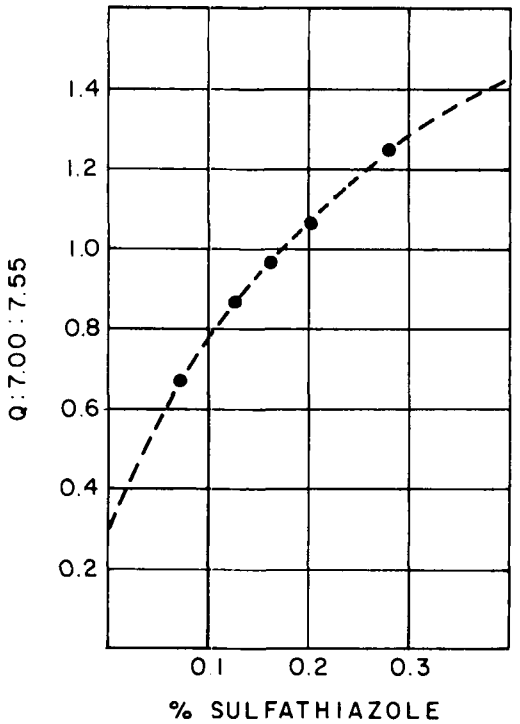

Fig. 5.—Q curve for sulfathiazole, sulfapyridine, and potassium bromide.

and sulfapyridine. Potassium bromide has linear but significant absorption (as mentioned in the earlier paper) but is also present in what might be considered as constant quantities. The pellets prepared for this investigation contained very near to 99.6% potassium bromide and 0.4% active ingredient or ingredients. Since it was only the latter value that was representative of the two variables, the 99.6% of potassium bromide was a constant. It was mentioned in the earlier publication that neither of the two wavelengths (7.00 and 7.55 μ) used in the analysis represented an isoabsorptive point. A plot of Q:7.00:7.55 *vs.* the % of sulfathiazole in a ternary mixture containing the components under discussion should result in a curve. This is the case and such a curve is shown in Fig. 5. Once such a curve is constructed, it can be used to determine the concentration of sulfathiazole (and sulfapyridine, by proper choice of wavelengths) in unknown mixtures.

The major disadvantage of this type of analysis is the need for a simultaneous solution of two equations. The constants required for these equations are relatively easy to accumulate primarily because most of these are absorbancy ratio values and hence concentration independent. Equation 6 or its equivalent does provide an alternative approach. If the third substance in a mixture can be determined by some other method of analysis in such a way that the other two components do not interfere, then the other two components in the ternary mixture can be resolved by application of the above equation. Such situations often arise in pharmaceutical analysis. If one of the three components in the mixture is acidic, for example, then a volumetric method of analysis might be used to determine its concentration. From a knowledge of the initial weight of the sample, the fraction of this acidic substance in the mixture can be determined. Equation 6 will now yield relative values for the other two components. These, however, can be easily converted to absolute values on the basis of the weight of the sample taken in the analysis.

The accuracy of this technique does not approach that found in the case of binary mixtures. The ternary mixtures investigated could be analyzed to within approximately 2 to 3% of theory. Since this presupposes no separation of the components, the accuracy is probably better than that obtained by more conventional techniques.

CONCLUSION

A number of equations have been derived to show the applicability of the absorbancy ratio technique to the analysis of ternary mixtures. Such mixtures can be resolved to within 2 to 3% of theory provided the spectral characteristics of the individual components meet the criteria listed above. Other limitations of this technique are discussed.

Free Radical Studies by Electron-Spin Resonance of Some Derivatives of Phenothiazine

By DAVID W. SCHIESER† and L. DALLAS TUCK

The existence of stable free-radical semiquinoid intermediates in the oxidation of several N-substituted phenothiazine derivatives of therapeutic importance has been demonstrated by means of electron-spin resonance. The spectra differ from those of the parent compound in the lack of hyperfine structure.

BY MEANS of electron-spin resonance, stable semiquinone free radicals have been shown to be formed upon oxidation of certain N-substituted derivatives of phenothiazine. This is an extension of work reported elsewhere (1) on phenoxazine, phenothiazine, and some ring-substituted derivatives of the latter. The compounds of the present study, which are of medical importance because of their tranquilizing, antihistaminic, and antinauseant effects, are (I) prochlorperazine, (II) chlorpromazine, (III) trifluprom azine, and (IV) perphanazine. As is seen by their structural formulas in Fig. 1, compounds I and IV contain the common structure of an *n*-propyl chain on the nitrogen, terminated by a piperazine ring, and differing from each other by the substitution in the 4-position. Compounds II and III contain a dimethylaminopropyl chain on the nitrogen, and differ from each other by the nature of the substituent β to the nitrogen.

EXPERIMENTAL

The spectrometer used in this research is described elsewhere (1). Measurements were made as the derivative of the absorption at a frequency of 9400 megacycles per second and at a magnetic field strength of approximately 3300 gauss.

All of the free radical solutions were prepared by dissolving approximately 100 mg. of the solid parent compound in 10 ml. of concentrated sulfuric acid. In all cases but one, it was found that the sulfuric acid was able to oxidize rapidly the drugs to the free radical state. In the case of trifluprom azine, the free radical was produced only after addition of 0.1 ml. of 30% hydrogen peroxide to the acid solution.

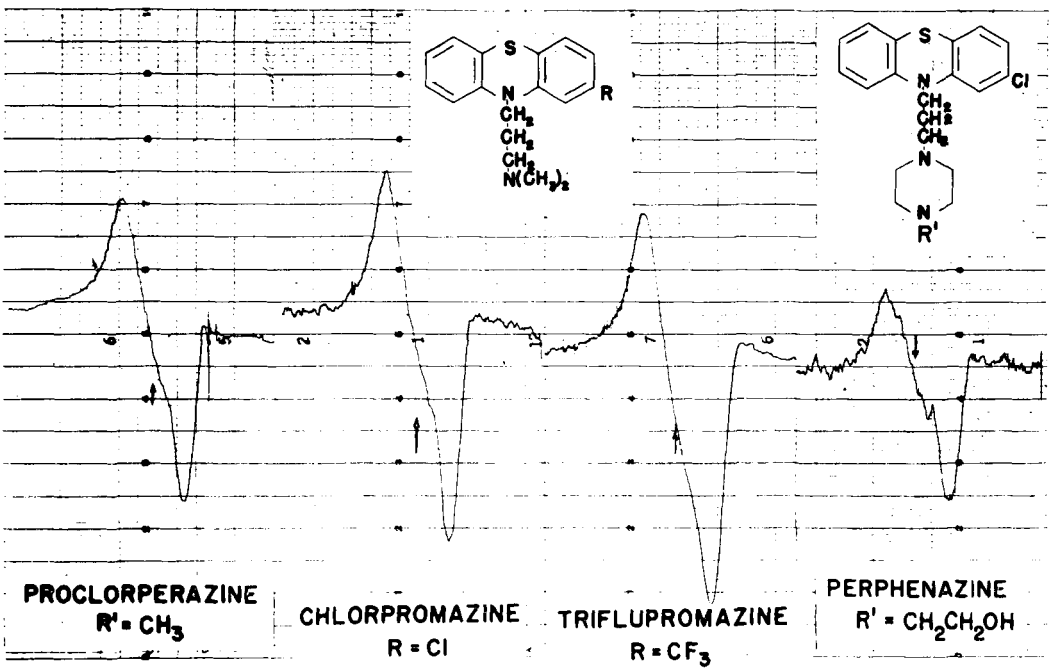

Fig. 1.—Electron-spin resonance spectra of free radicals formed by oxidation of prochlorperazine, chlorpromazine, trifluprom azine, and perphenazine. Each horizontal division is 7.4 gauss. Low magnetic field is to the right on this figure.

Perphenazine	2.0029

determined by comparison with diphenylpicryl hydrazyl, whose resonant position in the magnetic field is indicated in each spectrum by an arrow.

It is seen that the nature of the substituent has almost no perceptible effect on the appearance of the spectrum and has only a minor effect on the *g* value. These spectra appear to consist of a single absorption line, different from that of phenothiazine and its ring-substituted derivatives, all of which give a spectrum of four well-resolved lines. The latter spectra have been interpreted in terms of the hyperfine splitting by the nitrogen nucleus together with the proton on this position in acid solution. In each of the present spectra, the slight inflection point suggests that the spectrum is the summation of three equally weighted broad component lines arising from splitting by the nitrogen nucleus. The breadth of the lines in this degree appears to be due to the hyperfine splitting by the protons in the side rings and in the complex chain attached to the nitrogen. Other contributory factors to the line breadth are the nature of the solvent system and the magnetic dipole-dipole interaction from neighboring molecules. However, these factors must not play an important role in the present case, as the conditions were comparable with those under which four well-resolved lines were obtained with phenothiazine and other compounds.

Further discussion of these effects will appear in a subsequent publication in which a series of N-alkyl-substituted radicals are studied (2).

Further work is planned to ascertain the concentration of free radical under various conditions of solvent and acidity, and therefrom the semiquinone formation constants (dismutation constants) will be computed.

Simplified Method for the Measurement of Actomyosin Contraction

By DUANE G. WENZEL and HARBANS LAL

ACTOMYOSIN, the principal contractile protein in muscle, exists in the form of contractile filaments. It is possible to extract these filaments, fragmented transversely but otherwise undamaged, from muscle fiber. The microscopic filaments may then be realigned into a three-dimensional network capable of sustaining tension. It was demonstrated some years ago that threads formed from this actomyosin responded to the addition of adenosine triphosphate (ATP) with spectacular shortening (1). These first threads, however, were composed of poorly oriented actomyosin filaments and did not develop any appreciable tension (2). Close packing of the filaments by treatment with glycerol, drying, and stretching produced threads capable of developing tension (3). It was later demonstrated that relatively strong fibers could be formed by lateral compression of surface-spread layers of actomyosin (4).

The actomyosin model is similar, in many respects, to its intact muscle counterpart. Histologically, of course, the original muscle fiber also possesses a sheath or sarcolemma. The response of the model to ATP is, for all practical purposes, the same as that of the muscle fiber. Because of the relative simplicity of this system and because a specific muscle component may be studied independently, the actomyosin threads or fibers have become popular models for the study of muscle pharmacology.

Received August 17, 1961, from the University of Kansas, School of Pharmacy, Lawrence.
Accepted for publication September 7, 1961.

A number of methods have been employed to measure the contractile response of actomyosin. A simple procedure introduced by Hayashi (5) and later modified by Robb, *et al.* (6), employs a vertical fiber supporting a glass weight. This fiber was prepared in a Langmuir trough and then transferred to a beaker containing the bath solution. The response of the system was determined by measuring the movement of the weight with a microscope having a calibrated eyepiece. This method has several disadvantages. First, the actomyosin fiber must be transferred from the trough to the contraction chamber and must further be extensively manipulated in order to be loaded. Second, the vertical position of the fiber can affect the response to ATP through variable buoyancy and the weight of the thread itself.

In an attempt to eliminate the above disadvantages, a new method for the preparation of the actomyosin fiber and a new measuring apparatus were introduced (7). In this method the surface film of actomyosin is not completely compressed to a thick fiber, but instead is formed into a wider band of a constant width and minimal thickness. This assures a uniform diffusion of ATP into the center of threads or fibers which are still thick enough to support a weight. It has been suggested that during the isotonic contraction of actomyosin, the "unplasticized" core of the fiber not reached by ATP may interfere with the shortening (8). This method utilizing the wide band of actomyosin also permits horizontal attachment of the band between a fixed support extending from the bottom of the

A number of methods have been employed to measure the contractile response of actomyosin. A simple procedure introduced by Hayashi (5) and later modified by Robb, *et al.* (6), employs a vertical fiber supporting a glass weight. This fiber was prepared in a Langmuir trough and then transferred to a beaker containing the bath solution. The response of the system was determined by measuring the movement of the weight with a microscope having a calibrated eyepiece. This method has several disadvantages. First, the actomyosin fiber must be transferred from the trough to the contraction chamber and must further be extensively manipulated in order to be loaded. Second, the vertical position of the fiber can affect the response to ATP through variable buoyancy and the weight of the thread itself.

In an attempt to eliminate the above disadvantages, a new method for the preparation of the actomyosin fiber and a new measuring apparatus were introduced (7). In this method the surface film of actomyosin is not completely compressed to a thick fiber, but instead is formed into a wider band of a constant width and minimal thickness. This assures a uniform diffusion of ATP into the center of threads or fibers which are still thick enough to support a weight. It has been suggested that during the isotonic contraction of actomyosin, the "unplasticized" core of the fiber not reached by ATP may interfere with the shortening (8). This method utilizing the wide band of actomyosin also permits horizontal attachment of the band between a fixed support extending from the bottom of the

trough and an elongated arm of a 500-mg. capacity Roller-Smith torsion balance. Comparison of the results obtained using vertical fibers to those using horizontal bands indicates a definite reduction in the scatter of observation with the latter method (7). Loading of the band is accomplished by moving the balance arm to the desired number of milligrams. Contraction of the actomyosin band then initiates an electromechanical feed-back mechanism causing the trough to move in a direction equal to and opposite to that of the contraction. Movements of the trough are recorded with an oscillograph after suitable amplification.

The purpose of the present study was to determine the feasibility of measuring the contraction of horizontal actomyosin bands with a microscope having a calibrated eyepiece.

EXPERIMENTAL

The apparatus employed consisted of three major components. A Langmuir trough of methyl methacrylate polymer,[1] similar to that of Bing and co-workers, was employed (7). The inner dimensions were 48 × 12.5 × 1.75 cm. A separate chamber in which the band contracts was formed by the addition of an inner wall about half the height of the trough. This chamber had the dimensions of 12.5 × 3.8 × 0.9 cm. A series of holes, 3 mm. in diameter and 0.5 cm. apart, were bored along the longitudinal axis of this chamber. These served to fix a small plastic[1] block, 6 mm. in height, which was fitted with a peg to be plugged into one of the holes. The trough was mounted on a platform fixed to a small scissors-type auto jack which was used to raise the chamber into position beneath the balance arm. A Roller-Smith torsion balance with a 500-mg. capacity was fastened on a rack over the trough, as shown in Fig. 1. The weighing pan of the balance was replaced with an aluminum spatula which extended vertically over the contraction chamber. The flat blade of the spatula was bent at a right angle to the shaft in order to provide support for the actomyosin band. Measurement of the movement of the band was accomplished with a stereoscopic microscope as described by Robb and Mallov (6). The system employed thus combines the simplicity of the visual method for microscopically measuring movement of the actomyosin fiber with the improved horizontal loaded actomyosin band.

Actomyosin was extracted from fresh dog heart in the usual manner and a band was formed in the trough as previously reported (7). This band was attached to the block fixed in the base of the bath and to the movable balance arm. A load of 10 mg. was placed on the band by movement of the weighing spring of the torsion balance. The zero point of the calibrated microscope eyepiece was then focused on the edge of the movable arm. Ten milliliters of the chamber solution were removed and replaced with a concentrated solution of the sodium salt of ATP (sigma) to make a final concentration of 0.005 *M*. Measurements were recorded at 2, 4, 8, 16, and 32 minutes following addition of the ATP. Five bands prepared from freshly extracted actomyosin were tested on the same day. The per cent shortening from the original length was determined for each band. Initial band lengths

[1]Tradename, Plexiglas.

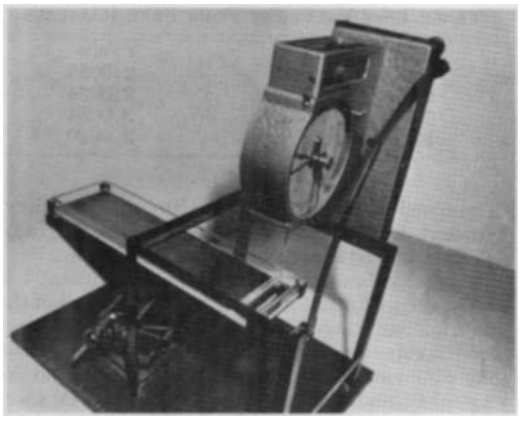

Fig. 1.—Apparatus for the measurement of actomyosin band contractions. Stereoscopic microscope used to perform actual measurements is not shown.

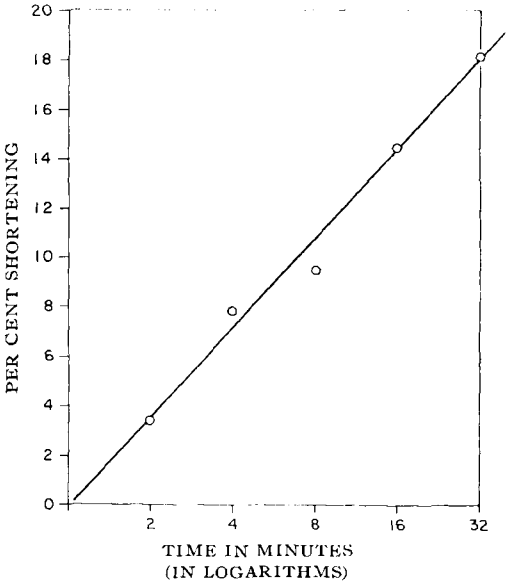

Fig. 2.—Mean per cent shortening of five actomyosin bands at several times.

for the five bands ranged between 20 and 25 mm. The mean per cent shortenings obtained with these five bands plotted against the logs of the times tested are shown in Fig. 2.

From the linearity of the response it is apparent that the method described can be employed to measure effectively the rate and extent of loaded, isotonic actomyosin contractions.

Stabilization of Trypsin in Ointment Bases

By JESS A. BUSH†

Calcium has been used to stabilize trypsin in a polyethylene glycol ointment base. The samples were kept at room temperature and at 37° for a period of 6 months. Results of assays on these samples are reported. Eighty per cent of the trypsin activity was retained in the presence of calcium, including the samples stored at 37° for 6 months.

THE USE of proteolytic enzymes to remove necrotic tissue often present in burns, amputation stumps, wounds, and many other conditions is becoming more widespread. Incorporation of the enzyme into an ointment base provides a convenient method for use. Packaging is also simplified, since it is less expensive to put the preparation in one container than to package buffer and enzyme separately. An ointment is ready for immediate use, but when separate solutions are provided, the enzyme must be dissolved in the buffer before use.

The stabilization of the enzyme in the ointment base is of the utmost importance. Trypsin has been shown to be stable for several months in a Carbowax base ointment at 4° or less (1). However, at room temperatures proteolytic activity is lost. Calcium^{2+} (2, 3) has been used to stabilize trypsin. By incorporating calcium^{2+} into an ointment base, the proteolytic activity may be preserved for long periods of time at room temperature and at 37°.

EXPERIMENTAL

Ointments were prepared using polyethylene glycol ointment U.S.P. Fifty milligrams of noncrystalline trypsin isolated from beef pancreas was dissolved in one ml. of water and added to 27 Gm. of the ointment. This trypsin assayed 2000 Armour units/mg. Calcium chloride dihydrate was added in 1 ml. of water. After careful mixing of the ointment, the pH was adjusted to 6.7–6.8 using 0.1 *N* sodium hydroxide or 0.1 *N* hydrochloric acid. A pH meter was used for this adjustment. Buffers were not used because their influence on the stability of trypsin is not known. Water was added to bring the weight of each ointment to 30 Gm.

One set of ointments was stored at room temperature, another at 37°, and a third, which contained no calcium, at 3°. Table I lists the amount of calcium chloride dihydrate added and the proteolytic activity retained in the various ointments.

Assays were conducted using the hemoglobin method of Kunitz (4). For the assay of each sample, 2 levels of ointment were run in duplicate. Values given are the average per cent of proteolytic activity retained for each ointment after the time lapse indicated. Results agreed within ±10%. The reference standard was a highly purified crystalline trypsin which assayed 4000 Armour units/mg. It was standardized against tyrosine several times during the experimental work. The ointment kept in the refrigerator was used as the method control sample.

TABLE I.—PER CENT TRYPSIN ACTIVITY RETAINED

Temp., ° C.	Calcium Chloride Dihydrate, mg./30 Gm.	2 wk.	5 wk.	26 wk.
3	0.0	97.0	102.0	98.0
RT	0.0	80.0	71.0	63.0
RT	200.0	100.0	96.0	80.0
RT	400.0	100.0	99.0	83.0
37	0.0	81.0	51.0	32.0
37	200.0	95.0	80.0	80.0
37	400.0	95.0	85.0	82.0

Samples for assay were weighed, dissolved in water, and pipetted into the assay medium. A blank was prepared for both levels of each ointment by adding 5% trichloroacetic acid to the sample immediately after the ointment in water was added to the hemoglobin.

DISCUSSION AND SUMMARY

Results in Table I show that in the presence of calcium, trypsin losses are greatly reduced. There are slightly lower losses with the higher level of calcium, but the method of assay is not accurate enough to make this significant. However, there is definitely a difference between the samples containing calcium and those containing no calcium at both room temperature and at 37° after 5 weeks, or longer.

Twenty per cent loss after 6 months with calcium present is almost within the error of assay. The use of a 10–20% overage in the original preparation of the ointments would bring the results within labeled potency.

A method of stabilization of trypsin in an ointment base has been reported. It may be useful for further studies on stabilizing trypsin or other enzymes in ointments.

Qualitative Color Test for Identification and Differentiation of Some Fluorinated Steroids

By E. IVASHKIV

A qualitative colorimetric test has been developed for the identification and differentiation of fludrocortisone acetate, triamcinolone, and triamcinolone acetonide in pharmaceutical formulations. The test is based on a newly discovered reaction for fluorinated steroids and depends upon the formation of an amber color from fludrocortisone acetate, a yellow chromogen from hydrolyzed triamcinolone, and a pink color from triamcinolone acetonide by reaction of phenol, hydroquinone, and the phosphoric-sulfuric acid mixture.

MANY color reactions of steroids are used in qualitative tests to demonstrate the presence of these various steroids in pharmaceutical preparations. For example, *m*-dinitrobenzene-potassium hydroxide (1) and 2,6-di-*tert*-butyl-*p*-cresol (2) are useful identity tests for various fluorinated steroids.

This investigation is a study of the newly discovered color reaction for fluorinated steroids with phenol, hydroquinone, and the phosphoric-sulfuric acid mixture as a specific method of identification and differentiation of fludrocortisone acetate, triamcinolone, and triamcinolone acetonide in pharmaceutical formulations.

EXPERIMENTAL

Method

Reagents and Equipment.—Sulfuric-phosphoric acid solution. To 850 ml. of concentrated sulfuric acid, 150 ml. of 85% phosphoric acid is added and mixed.

Phenol liquid, 85%, reagent grade.

Tetramethylammonium hydroxide solution, 10 ml. of 10% aqueous reagent is diluted to 100 ml. with ethanol.

Methylene chloride (dichloromethane), spectrophotometric grade.

Hydroquinone, purified.

Florisil, 60/100 mesh.

Purification column. The column consists of a glass tube of 10 mm. inside diameter and 150 mm. in length with a constricted end to retain the adsorbent. The column is packed with Florisil to the height of 40 mm. and is washed with 10 ml. of methylene chloride prior to use.

Test tubes, screw cap, 25 × 150 mm.

Unless specified, all chemicals are reagent grade.

Procedure

Sample Preparations.—*Creams, Lotions, and Ointments.*—A sample equivalent to 2 mg. of steroid is weighed into a test tube. Methylene chloride 20 ml., is added and the tube is covered with a plastic cap. The steroid is extracted by shaking for 2 minutes. Lotion samples are centrifuged at 1500 r.p.m. for 3 minutes. The upper, aqueous layer is discarded by means of an aspirator. Cream and ointment samples are filtered through No. 3 filter paper.

The methylene chloride solution is poured into a purification column. When the flow rate is slower than 75 drops per minute, it can be increased by the air pressure bulb fitted at the top of the column. The column is washed with 3 × 10 ml. of methylene chloride. The solvent is forced out by means of the rubber pressure bulb and the steroid is eluted with 10 ml. of methanol.

Suspensions and Sprays.—A sample is diluted with methanol to give the concentration of about 200 mcg. of steroid/ml.

Tablets.—A powdered sample equivalent to 4 mg. of triamcinolone or 1 mg. of 9α-fluorohydrocortisone is weighed into a test tube. Ethyl acetate, 10 ml. is added and the tube is covered with the plastic cap. Steroids are extracted by shaking for 3 minutes. The sample is filtered through No. 3 filter paper.

Color Development.—Aliquots of the sample extracts are placed in three test tubes designated A, B, and C. A 2-ml. portion of the methanolic sample or 1 ml. of the ethyl acetate tablet extract are the sample aliquots used. Glacial acetic acid (1 ml.) is added to tube A and the mixture is heated in a boiling water bath for 1 minute. Alcoholic tetramethylammonium hydroxide (1 ml.) is added to tube B and the tube is incubated at 50° for 15 minutes.

To all three tubes, 0.5 ml. of phenol, about 50 mg. of hydroquinone, and 5 ml. of sulfuric-phosphoric acid are added. The test tubes are mixed and heated in a boiling water bath for about 1 minute to speed up the color development.

A pink color in tubes A and C and yellow chromogens in tube B prove the presence of triamcinolone.

A pink color in all tubes indicates the presence of triamcinolone acetonide.

An amber color in tube A and orange-red color in tubes B and C indicate the presence of fludrocortisone acetate in a sample.

RESULTS AND DISCUSSION

The results summarized in Table I indicate that this method is useful for the identification and differentiation of fludrocortisone acetate, triamcinolone, and triamcinolone acetonide in a variety of formulated products.

For good color development, the steroid tested has to be free from interfering substances. This is accomplished by centrifugation or filtration to remove insoluble matter and, if necessary, absorption on a Florisil column, followed by elution of the steroid fraction.

Methylene chloride was the solvent selected for the extraction of creams, lotions, and ointments because it appeared to be better than other solvents tested, both from the standpoint of extraction efficiency and the removal of impurities from the Florisil column. The steroids were eluted from the

Fludrocortisone acetate	Tablet	A	OR	OR
Triamcinolone	Tablet	P	Y	P

[a] A, Amber; OR, orange-red; P, pink; Y, yellow.

column with methanol, but acetone or ether could also be used for this purpose. Dimethylformamide, an excellent solvent for the elution of steroids from Florisil columns, could not be used because it gives a yellow color with the steroids in the presence of tetramethylammonium hydroxide and sulfuric acid. Ethyl acetate was used for tablet extractions because no further purification of these extracts were required.

Either Florisil or aluminum oxide may be used as an adsorbent for fluorinated steroids. Florisil has been chosen in this method because of the easy removal of interfering substances from creams, lotions, and ointment formulations.

Triamcinolone and triamcinolone acetonide produce the same pink color in the presence of phenol, hydroquinone, and sulfuric-phosphoric acid. However, if a triamcinolone sample is heated in the presence of the alkaline solution at 50° for 15 minutes prior to the addition of reagents, yellow chromogens are obtained because triamcinolone is unstable in alkaline solutions at elevated temperatures. Experiments have shown that extensive degradation occurs at the temperature of 60° and above. Triamcinolone acetonide is slightly affected at 60° in the presence of tetramethylammonium hydroxide. Tetramethylammonium hydroxide has been chosen for the degradation purpose because it produces no heat after the addition of a sulfuric-phosphoric acid mixture. Heating fludrocortisone acetate at 100° in the presence of glacial acetic acid for 1 minute converts it to the free alcohol. Triamcinolone and triamcinolone acetonide are not affected when heated in the acid solution.

The color test was applied to various other steroids which are also used in pharmaceutical preparations. The results of these tests are given in Table II.

TABLE II.—COLOR PRODUCED WITH PHENOL, HYDROQUINONE, AND SULFURIC-PHOSPHORIC ACID

Name of Steroid	Developed Color
Cortisone acetate	Amber
Fluoxymesterone	Orange to red
Hydrocortisone	Orange to red
Prednisolone	Red to orange

The presence of both phenol and hydroquinone in the reaction mixture is very important. Either phenol or hydroquinone produces the same color, but a combination of both chemicals gives about twice the color intensity. About 50 mg. of hydroquinone and 0.5 ml. of phenol proved to be the most suitable for the color development. Sulfuric acid of at least 40% strength is needed for the reaction, but the 85% mixture gives the best results. An increase in the concentration of sulfuric acid speeds up the reaction, but concentrations above 85% give lower color intensities. Phosphoric acid is used for dilution purposes to keep the water content in the reaction mixture to a minimum.

The temperature is an important factor in the color development. An increase in temperature accelerates the degree of reaction, but considerable quantities of chromogens are destroyed when the reaction mixture is heated at high temperatures. Since the color development is more rapid at 100° this temperature has been chosen for completing the test in a minimum of time.

Although relatively large samples of steroids (2 to 4 mg.) have been used for analysis, it has been possible to detect as little as 10 γ/ml. of steroid in the final solution by this method.

Photometric Microtitration of Catechols (Epinephrine)

By MURRAY M. TUCKERMAN

Catechols in a buffered aqueous solution may be quantitatively titrated with ferrous ethylenediamine sulfate standard solution. The photometric end point is determined at 530 mμ, the wavelength of maximum absorption for the purple complex formed between ferrous ion and catechols. Advantages over the U.S.P. assay for epinephrine are (*a*) sensitivity is increased and (*b*) an epinephrine reference standard is not needed.

IN THE ASSAY of dosage forms it is customary to seek a representative average sample by combining 20 or more dosage units. Occasionally, however, it is necessary to assay a single dosage unit or part of such a unit. As part of a project for the assay of single dosage units, a paper concerning anesthetics derived from aminobenzoic acid in cartridges for dental anesthesia was published in 1959 (1). The present paper proposes a method for assay of the catecholamine vasoconstrictor frequently present in such preparations.

The proposed method is based on the U.S.P. colorimetric epinephrine assay (2) which is adapted from a paper by Doty (3). In this method, epinephrine in a solution suitably buffered about pH 8.5 forms with ferrous ion a color having maximum absorbance at 530 mμ. Doty reports that the color is given by all catechols tested but not by phenols or by dihydroxy phenols in which the phenolic groups are not *ortho* to each other. The reaction is stoichiometric, 0.5 mole of ferrous ion being required per mole of catechol.

The U.S.P. requires about 200 mcg. of epinephrine in the sample. The color developed is compared with color developed in a similar manner with U.S.P. epinephrine bitartrate reference standard. By using a suitable standard, acceptable accuracy may be obtained with a sample as small as 50 mcg. When epinephrine is used as a vasoconstrictor in preparations for dental anesthesia, the recommended concentrations are 1:50,000 (20 mcg./ml.) or 1:100,000 (10 mcg./ml.). As high as 1:20,000 (50 mcg./ml.) are found in commercial preparations. Only at the highest concentration is the colorimetric method, as specified in the U.S.P., satisfactory for a 1-ml. sample.

METHOD

Reagents.—Epinephrine bitartrate reference solution, dissolve 18.2 mg. of U.S.P. epinephrine bitartrate reference standard plus 200 mg. $NaHSO_3$ in enough water to make 50.0 ml. Epinephrine working standard, dilute 5.00 ml. of epinephrine bitartrate reference solution with enough water to make 50.0 ml. (1:50,000). Buffer stock solution, dissolve 42 Gm. of $NaHCO_3$ and 50 Gm. of $KHCO_3$ in about 180 ml. of water, dissolve 37.5 Gm. of aminoacetic acid and 17 ml. of strong ammonia solution, U.S.P. (28% NH_3) in about 180 ml. of water, mix the solutions, and dilute to 500 ml. Buffer solution, pH 9.0, dilute 10 ml. of the buffer stock solution to 100 ml. Standard ferrous salt solution, dissolve 47.8 mg. of ferrous ethylenediamine sulfate $FeC_2H_4(NH_3)_2(SO_4)_2 \cdot 4H_2O$, standard of reference grade (G. Frederick Smith Chemical Co., 1867 McKinley Ave., Columbus, Ohio), 5 ml. 0.1 *N* hydrochloric acid, and 0.5 Gm. $NaHSO_3$ in water to make 100.0 ml. Each ml. contains 1.25 μm. of ferrous ion equivalent to 2.50 μm. of catechol.

Equipment.—Gilmont micropipet-buret, 0.1-ml. size (Manostat Corp., 20 N. Moore St., New York 3, N. Y.). Beckman B spectrophotometer with 1/4 in. wooden blocks in cell compartments to raise cells in light path and reduce required volume.

Procedure.—Pipet into the reference cell 1.00 ml. water, 1.0 ml. of buffer solution, and 0.5 ml. of diluent, and mix. Pipet into the sample cell 1.00 ml. of sample, 1.0 ml. of buffer solution, and 0.5 ml. of diluent, and mix. With the wavelength setting at 530 mμ and a sensitivity of 1, the slit width required for balancing the instrument with the reference solution in the light path is about 0.18 mm. Record the absorbance of the sample solution. Add at least three aliquots of standard ferrous salt solutions so that the total added is less than 50% of the volume calculated to be required at the end point, with no aliquot less than 0.005 ml., recording the absorbance of the sample after each addition. Add enough standard ferrous salt solution so that the total added is 1.5 times the amount calculated to be required by the sample, record the absorbance of the sample, then add at least two additional 0.01-ml. aliquots, recording the absorbance after each addition. Plot total volumes added *vs.* absorbance. The first set of points will define a line of positive slope; the second set, a horizontal line. The intersection of the two lines defines the end point (4). Calculate the amount of catechol present in the sample. A complete discussion of photometric titration, including typical curves, is given by Goddu and Hume (4).

Assays of commercial lots were run in the same manner using isopropyl alcohol as the diluent to keep the anesthetic bases in solution.

Results of assays are given in Tables I and II.

DISCUSSION

The maximum observed absorbance for 1:100,000 solutions was about 0.040 with 0.005-ml. increments of titrant producing increments in absorbance of about 0.007. The maximum observed absorbance for 1:50,000 solutions was about 0.080 with 0.01-ml. increments of titrant producing increments of absorbance of about 0.015. The maximum observed absorbance for 1:20,000 solution was about 0.190 with 0.02-ml. increments of titrant producing increments in absorbance of about 0.040. Despite the low photometric accuracy in each individual observation that might be expected at these low ab-

[a] 1-Nordefrin, an isomer of epinephrine, present as vasoconstrictor.

sorbance readings, the relative standard deviation of the results did not exceed 5% in any determination and was usually about 2%. It may be concluded, therefore, that the reproducibility of the assay using 10 mcg. of epinephrine in the sample is of about the same order as the U.S.P. photometric method using 200 mcg. of epinephrine in the sample.

The actual titration requires about 10 minutes. If preparation of solutions and calculations of results are included, three samples may be completed in an hour.

The method allows the smaller laboratory to assay all catechols without the necessity of maintaining a reference standard for each. The single ferrous salt standard is all that is required. The primary standard grade of ferrous ethylenediamine sulfate is stable and has an infinite shelf life. Both in stability and cost it is to be preferred to a catecholamine reference compound.

The proposed method also has served as a check on the U.S.P. epinephrine bitartrate reference standard. By comparison with the standard ferrous salt, the reference standard is not less than 99.5% pure.

Identification and Purity Test for Ergonovine and Methylergonovine

By THOMAS G. ALEXANDER

A method is described for the separation and identification of those "water-soluble" ergot alkaloids of pharmaceutical interest; namely, ergonovine, ergonovinine, methylergonovine, and methylergonovinine.

THE IDENTIFICATION tests in the official compendia (1, 2) fail to distinguish between ergonovine (the principal oxytocic agent of ergot), methylergonovine (a synthetic homolog), and the dextrorotatory, physiologically inactive isomers, ergonovinine and methylergonovinine. This study was undertaken for the purpose of developing a suitable test for the identification of ergonovine and methylergonovine in pharmaceuticals, and for the detection of possible contaminants and breakdown products. In searching for such a test, several of the paper chromatographic procedures reported in the literature were investigated. With each of the partitioning procedures described by Foster, *et al.* (3), Macek (4), Voigt and Weiss (5), and Alexander and Banes (6) we could effectively separate the dextrorotatory alkaloids from their diastereoisomers. Attempts to separate ergonovine and methylergonovine from each other by these and similar procedures were unsuccessful. The reverse-phase paper chromatographic procedure described by Stoll and Rüegger (7) included an overnight equilibration of the spotted paper in the vapors of the mobile phase. It was our experience that, with this procedure, each of the isomers would partially convert to its diastereoisomer. Pöhm and Fuchs (8) and Horak and Kudrnac (9) described methods incorporating benzene into the mobile solvent. In the hands of the author, these ergot alkaloids decomposed in the presence of benzene.

Berg (10) described a method for the separation of water-soluble ergot alkaloids as well as the products of hydrolysis, ergine, and lysergic acid. Circular wick paper chromatographic technique was used. Papers were impregnated with pH 6.4 buffer and chromatograms developed with water-saturated methylene chloride. The method described below is an adaptation of Berg's system incorporating the simpler ascending paper chromatographic techniques described by Mitchell (11) and the "moist-paper" technique described by Levine and Fischbach (12).

MATERIALS AND METHOD

Mobile Solvent.—Mix 50 ml. of ethylene chloride, 50 ml. of *n*-butyl acetate, 7 ml. of pyridine, and 2 ml. of water in a separator. Allow to settle, draw off the bottom layer through a glass wool filter, and discard the top layer.

Standard Solutions.—Dissolve 10 mg. of methylergonovine maleate N.F. XI, or ergonovine maleate U.S.P. XVI in 2.0 ml. of alcohol. This is *standard solution A*. Dilute 1.0 ml. of standard solution A to 25 ml. with alcohol to obtain *standard solution B*.

Sample Solution.—Dissolve ergonovine maleate or methylergonovine maleate powder in a suitable quantity of alcohol to obtain a solution strength of 5 mcg. per μl. To analyze an injection solution, render a suitable portion alkaline with sodium bicarbonate, extract with chloroform, evaporate the extract to dryness, and dissolve the residue in a quantity of alcohol sufficient to obtain a solution strength equivalent to 5 mcg. ergonovine maleate or methylergonovine maleate per μl. To analyze tablets, prepare chloroform extracts as described under *Identification* in the N.F. monograph for methylergonovine maleate tablets (2). Dissolve the dried residues in a quantity of alcohol sufficient to obtain a solution strength equivalent to 5 mcg. per μl.

Procedure.—Arrange a chromatographic tank suitable for ascending paper chromatography. Add mobile solvent, seal the tank, and equilibrate for 1 hour. Pour about 10 ml. aqueous buffer solution pH 4.6 [such as U.S.P. phthalate buffer (13)] over premarked paper. After draining for 30 seconds, place the paper between sheets of paper toweling. Blot the surface with the toweling for some seconds to remove as much moisture as will be absorbed, and repeat using fresh towels. Spot 0.010 ml. of each of the standard solutions and volumes of sample solutions equivalent to 50 mcg. ergonovine maleate or methylergonovine maleate. Rewet the spots with water from a capillary tube. In addition, spot methyl red U.S.P. XVI, T.S., at the edge of the paper to aid in following the solvent front. The paper should feel definitely moist and limp, but not so wet as to transfer water to the fingers. Place the paper in the chromatographic tank and reseal.

When the solvent front is within 2 cm. of the top of the paper (about 1 hour), remove it and dry in a hood. Examination under ultraviolet light should show one primary spot with an R_f and an intensity corresponding to that of the respective standard A spot. Any other spot occurring on the sample chromatogram represents impurities. The standard B (2 mcg.) spot is used to estimate roughly the quantity of any such impurities.

The lysergic acid moiety of these ergot alkaloids will react with strongly acidic *p*-dimethylaminobenzaldehyde to give a blue color. By spraying the developed chromatogram with an alcoholic, acidic solution of this aldehyde, as described by Hellburg (14), and photographing the dried chromatogram, permanent records may be obtained.

RESULTS AND DISCUSSION

Typical R_f values obtained are 0.19 for ergonovine, 0.35 for methylergonovine, 0.44 for ergonovinine, and 0.60 for methylergonovinine. Any water-insoluble ergot alkaloids present as contaminants will be indicated by spots located at the solvent front. Ergonovinine and methylergonovinine used in the study were prepared by the method described by Kleiderer (15) whereby 5 mg. of the levorotatory isomer is dissolved in 1 ml. of methyl alcohol, two drops of concentrated ammonia added, and the solution kept at room temperature overnight.

Received July 19, 1961, from the Department of Health, Education, and Welfare, Food and Drug Administration, Division of Pharmaceutical Chemistry, Washington 25, D. C.
Accepted for publication August 14, 1961.

About half of the alkaloids are converted to the dextrorotatory form by this procedure.

When attempting to adapt Berg's system to a simpler apparatus, ergonovine and methylergonovine were well separated; but spots were very diffuse and the developing solvent failed to ascend the paper evenly. More satisfactory chromatograms were obtained by diluting the developing solvents with *n*-butyl acetate. Less volatile chlorinated solvents would not separate ergonovine and methylergonovine. Of the volatile chlorinated solvents, only methylene chloride or ethylene chloride would separate the homologs and then only when they constituted half, or more, of the developing solvent.

By simultaneously increasing the acidity of the impregnating solution and the basicity of the mobile solvent as compared to conditions prescribed by Berg, less diffuse spots were obtained while maintaining about the same R_f values. In analyzing alkaloid samples by the procedure described above, unsatisfactory chromatograms were occasionally obtained where the alkaloids had migrated excessively or insufficiently during development. The mobility of the alkaloids could be increased by raising the pH of the mobile solvent or decreased by lowering the pH. The R_f values reported are typical of those obtained. When desired for special cases, greater than usual separation of ergonovine and methylergonovine, or greater separation of a pair of diastereoisomers, can be achieved by such a pH adjustment.

Several techniques were tried for conditioning the paper prior to development. Among these is the commonly used technique whereby papers are impregnated, dried, spotted, moistened by equilibration, and developed. Most satisfactory results were obtained by the "moist-paper" technique described above. Grossly diffuse spots are obtained if the papers are too wet when placed in the tank and immobility of the spots will result if the paper is too dry.

A methylergonovine maleate tablet mix and several injection solutions, of both ergonovine maleate and methylergonovine maleate, were prepared to simulate market products. These were then analyzed by the procedure described in this paper. The results indicated that there is no deterioration of alkaloid during analysis and that the excipients do not interfere. The procedure described in this paper was successfully applied to 14 commercial samples. Neither of the four samples of alkaloid salts, nor any of the seven tablet samples analyzed, contained more than trace quantities (about 1%) of the respective diastereoisomer. Only one of three injection solutions tested contained any dextrorotatory isomer and that, only after a year of storage under refrigeration. The chromatogram for another one of these injection solutions exhibited faint spots representing material not containing the lysergic acid moiety. These may have represented oxidized alkaloids.

Correlation Between Solubility Parameters and Dielectric Constants

Sir:

There is general agreement that one of the fundamental problems in pharmaceutical research involves the description of solubility phenomena. In attempting to explain these phenomena we usually resort to either qualitative description in terms of relative "polarity" or more quantitatively with the aid of the thermodynamic approach embodied in Hildebrand's solubility parameter concept (1). It is the purpose of this communication to present some of our observations relevant to these two approaches.

Some earlier solubility studies of pharmaceutical importance (2–4) have illustrated the existence of a peak solubility of solutes when the components of cosolvent mixtures were varied in concentration. In these cases, the treatment of solubility offers no quantitative explanation for this behavior.

Moore (5), however, suggested a semiempirical use of dielectric constants to solvent mixtures to predict the acceptability of cosolvent blends to maintain solubility. Although the peak solubility or dielectric requirement had not been determined, this work illustrates the usefulness of employing an appropriate dielectric constant in the choice of a solvent or solvent mixture for the maintenance of solubility for a given solute. A more comprehensive study reported by Semenchenko (6) shows that the solubility of some 41 solutes have been measured as a function of the dielectric constant of the solvent system and claims that "... an ascending branch and descending branch are observed, including a peak value for the solubility ...." In this case, a distribution curve is described wherein the peak value is dependent on the characteristics of both the solute and solvent system and can be considered the dielectric requirement of the solute.

On the other hand, Chertkoff and Martin (7) recently applied the solubility parameter concept (1) in their studies of the solubility of benzoic acid in mixed solvent systems. This was an attempt to extend Hildebrand's theory of solubility to "semipolar" solutes. They, too, find a peak solubility as a function of solubility parameters of the solvent system in accord with the theoretical curve predicted by Hildebrand's equation.

In treating solubility data, whether in terms of dielectric constants or solubility parameters, the end results are similar. This immediately suggests that at least an empirical relationship exists between the two concepts. The following paragraphs present further observations to substantiate this contention and show the utility of such a relationship.

The first example is illustrated in Fig. 1 which shows a plot of both solubility parameters and dielectric constants *vs.* the number of carbon atoms for a homologous series of *n*-alkyl alcohols (8). When the solubility parameter and dielectric constant of one member is matched

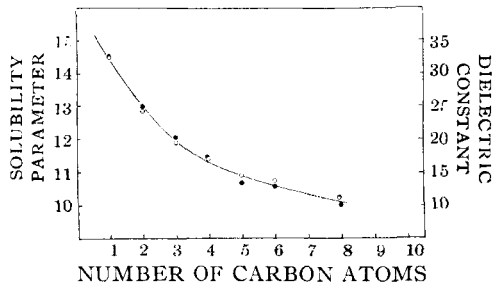

Fig. 1.—An illustration of the superimposition of curves when either the solubility parameter, O, or dielectric constant, ●, of a series of *n*-alkyl alcohols is plotted *vs.* the number of carbon atoms.

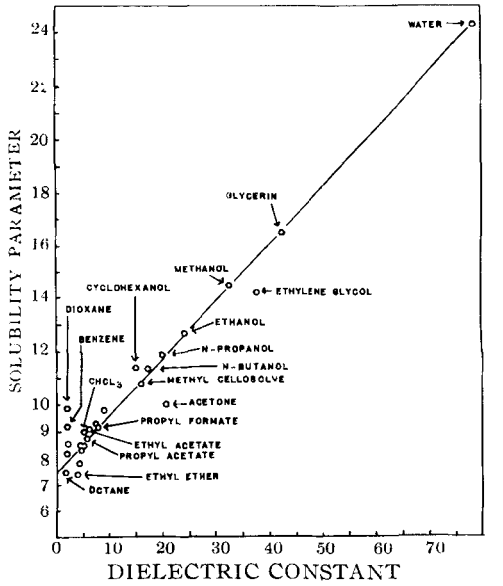

Fig. 2.—A plot of solubility parameters of common solvents *vs.* their respective dielectric constants to show the linear trend.

on a sliding ordinate, the two curves become superimposable. Obviously, a plot of solubility parameters *vs.* dielectric constants for these alcohols would result in a straight line.

Furthermore, by extending representative solvents beyond mere alcohols to include various classes of solvents, a similar straight line plot of solubility parameter *vs.* dielectric constant should also result. This was essentially found to be the case with 25 solvents and is illustrated in Fig. 2. The equation for this straight line can be written

$$\delta = 0.22\,\epsilon + 7.5 \qquad \text{(Eq. 1)}$$

where δ is the solubility parameter and ϵ is the dielectric constant. The intercept value is obtained in the extrapolation to $\epsilon = 1$.

To show the utility of this equation, we have analyzed the data on the solubility of phenobarbital from several sources. The results are summarized in Table I. It can be seen that irrespective of the composition of solvent mixtures showing peak solubility for phenobarbital, there are striking similarities when their dielectric constants are compared.

Similarly, using data reported by Chertkoff and Martin (7) one can calculate the dielectric requirement of benzoic acid. Equation 1 predicts a value of 18.2 from the reported solubility parameter of 11.5 for benzoic acid. Analysis of solubility data given by Seidell (9) predicts a dielectric requirement of about 20 for benzoic acid. These examples are given to illustrate how completely independent sources of data aid to confirm the validity of Eq. 1.

There are some obvious advantages to the correlation of solubility parameters with dielectric constants. For example, the range of solubility parameters is quite small with values falling between 7.5 for "nonpolar" compounds, and about 24.3 for water. The dielectric constant spectrum, on the other hand, varies from about 2 to 80, giving over a fivefold expansion of a reference scale from that of solubility parameters and would follow a regular order with respect to "polarity."

TABLE I.—SUMMARY OF PROPERTIES OF SOLVENTS SHOWING PEAK SOLUBILITY FOR PHENOBARBITAL

Composition, v/v	Dielectric Constant[a]	Solubility Parameter[b]	Ref.
Ethanol-water (9:1)	26.6	13.23	2
Ethanol-glycerin (8:2)	25.7	13.15	2
Ethanol-propylene glycol (1:1)	26.5	13.23	3

[a] Experimentally measured by the resonance method. [b] Determined from Eq. 1.

Secondly, dielectric constants of solvents are more easily determined experimentally than solubility parameters. Furthermore, the solubility parameters of solids can ordinarily be obtained only after elaborate approximations of physical data are made. Thus, it appears that measurement of dielectric constants provides convenient means for determining apparent solubility parameters through Eq. 1, with all the incumbent advantages for applications of such knowledge.

It is obvious from Fig. 2 that, in general, the solvents which associate primarily through hydrogen bonding give the best correlation between reported solubility parameters and their respective dielectric constants. Fortuitously, these are the solvents of pharmaceutical importance.

Greatest deviation from the linear trend in Fig. 2 occurs with the nonpolar solvents which are of less pharmaceutical significance. The values for these solvents all fall in clusters in a small segment in the lower portion of the spectrum of dielectric constants. This scatter may be due, in part, to the diversity of chemical types and the slight variations in the reported values of solubility parameters, especially when different methods were employed for their determination.

It would be of interest to determine under what circumstances the solubility parameter concept might be extended into the semipolar and polar solvents and to determine if the empirical Eq. 1 has any physical significance. Each is currently being investigated in these laboratories and our findings shall be reported.

Gasket Insert Modification of U.S.P. Tablet Disintegration Apparatus

Sir:

The U.S.P. XVI apparatus for tablet disintegration testing specifies a basket rack assembly consisting of six open glass tubes each 7.75 cm. long and having an inside diameter of approximately 21.5 mm. Each tube is provided with a slotted and perforated cylindrical disk 9.5 mm. thick and 20.7 mm. in diameter.

The procedure directed for disintegrating uncoated and plain coated tablets is to place one tablet in each of the six tubes of the basket, add a disk to each tube, and then operate the apparatus as indicated in the tablet disintegration test monograph.

It has been our experience that many tablets will lie flat on the bottom wire screen, or because of gummy and gelatinous ingredients or ingredients of an adhesive character, either will adhere to the rising and falling disks, or will adhere to the bottom stainless steel wire cloth. In any case, the tablet disintegration system intended by the U.S.P. does not apply. Instead, the net result may be a flattening out of the tablet core caused by the constant action of the falling disk on the same point of the tablet surface. With other tablets, an indeterminate soft mass results which makes exact timing of the disintegration end point difficult.

We have found that by inserting a thin, flexible rubber gasket in the bottom of the glass tubes in contact with the lower stainless steel wire cloth, an increased turbulence is effected in the immersion fluid as the basket rack assembly rises and falls. This turbulence causes the tablets to "bob" up and down, increases the rate of flow of fluid around the tablets, creates more uniform attrition to all of the tablet surfaces, and prevents adhesion of the tablets to the bottom wire cloth. Thus it has served to obviate the use of the disks in tablet disintegration testing in most cases.

As an additional application, the introduction of these gasket inserts permits the use of the U.S.P. disintegration apparatus for establishing *in vitro* disintegration patterns for timed-release and sustained-action tablets. The rate of flow of the fluids around the tablets simulates the flow rate realized in the rotating bottle method (1) recommended by Krueger and Vliet to the P.M.A. Contact Section (2).

The dimensions of the flexible rubber gasket inserts are as follows: external diameter, 21.5 mm.; internal diameter, 15.0 mm.; wall thickness, 3.25 mm.; gasket thickness, 3.5 mm.

Review Article

Current Status of Research on the Alkaloids of *Vinca rosea* Linn. (*Catharanthus roseus* G. Don)

By GORDON H. SVOBODA, IRVING S. JOHNSON, MARVIN GORMAN, and NORBERT NEUSS

THE PANTROPICAL apocynaceous plant *Vinca rosea* Linn. is an erect, everblooming pubescent herb or subshrub, 1 to 2 ft. high. It is cosmopolitan in the tropics and is widely cultivated in gardens throughout the world as an ornamental. The pink and the white color varieties are found in the natural state, while three seed hybrids, *viz.*, blush pink with red eye, crimson, and white with red eye, are also commerically available.

Generally accepted synonyms for the genus *Vinca* are *Pervinca*, *Lochnera*, and *Catharanthus*. Pichon (2) has shown that the genera *Vinca* and *Lochnera* differ in 34 morphological characteristics and should not be used as synonyms. He furthermore found that *Catharanthus* G. Don predated *Lochnera* Reichb. by 7 months. While it would appear that the correct botanical name for this plant is *Catharanthus roseus* G. Don, we shall continue to use the more common *Vinca rosea* Linn. synonymously.

An early description of the medicinal properties of this plant mentions that an infusion of the leaves was used in Brazil in the treatment of hemorrhage and scurvy, as a mouthwash for toothache, and for healing and cleaning chronic wounds (3). Recently it has been reported that the total alkaloids possess a limited antibiotic activity against *V. cholera* and *M. pyogenes* var. *aureus*, as well as a significant and sustained hypotensive action (4). A recent review by Farnsworth (5) contains an exhaustive summary of early descriptions of medicinal properties of the plant, as well as those of other members of these genera.

The folklore reputation which this plant enjoyed as an oral hypoglycemic agent (6) prompted its phytochemical examination in two different laboratories, independently and unknown to each other. While neither group could substantiate this reported activity in either normal or experimentally-induced hyperglycemic rabbits, the Canadian group of Noble, Beer, and Cutts observed a peripheral granulocytopenia and bone marrow depression in rats associated with certain fractions (7, 8). Continued investigation led to their preparation of vincaleukoblastine (VLB) sulfate,[1] an alkaloid capable of producing severe leukopenia in rats (9–11). The Lilly group had demonstrated that certain alkaloidal fractions gave a reproducible effectiveness in DBA/2 mice infected with the P-1534 leukemia, a transplanted acute lymphocytic leukemia (12–15). An intensive phytochemical examination resulted in obtaining leurosine,[1] a new dimeric alkaloid closely chemically related to VLB, as well as VLB sulfate. The effectiveness of both of these alkaloids against the P-1534 leukemia in DBA/2 mice was first demonstrated in these laboratories.

Received from the Organic Chemical Development and Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, Ind.

Paper XIII (a review) in the series; the preceding paper appeared in THIS JOURNAL (1).

[1] The A.M.A. Council on Drugs has approved vinblastine, vinleurosine, vinrosidine, and vincristine as generic names for these alkaloids. VLB is supplied as Velban (vinblastine sulfate, Lilly).

Our early recognition of the fact that the "indefinite" survivors observed with certain amorphous fractions were due neither to VLB nor leurosine, nor to their combination, further stimulated the phytochemical search for the compound(s) responsible for this profound activity. These efforts culminated in the discovery of leurosidine[1] and leurocristine (16).[1]

PREPARATION OF ALKALOIDS

The earliest chemical investigation of this plant was conducted by Greshoff (17) who reported the presence of alkaloids, but who was unable to obtain pure crystalline compounds. Cowley and Bennett (18) prepared a crystalline tartrate and two sulfates from the total alkaloidal extract, but did not describe their physical or chemical properties. More recently, several groups of investigators have obtained the following alkaloids: ajmalicine (19), akuammine (19), tetrahydroalstonine (20), serpentine (19, 20), lochnerine (21), and reserpine (22), as listed in Table I. Inasmuch as these alkaloids are well documented, they do not merit further discussion.

During the course of our investigation, Beer obtained VLB as the sulfate (9), the preparation of which we were able to duplicate. Kamat and co-workers (23) reported on two amorphous and two crystalline alkaloids, one of which they described in detail and named vindoline, apparently being identical to our vindoline (24). An alkaloid, independently named lochnericine, has been reported by Nair and Pillay (25), and appears to be identical with our lochnericine (24). The occurrence of vindolinine was established simultaneously by Janot and co-workers (26) and our group, and the name was selected by mutual agreement.

The alkaloids reported to date solely from these laboratories include: leurosine, virosine, perivine, catharanthine, isoleurosine, lochneridine, sitsirikine, vincamicine, catharine, vindolicine (27), leurosidine, leurocristine (16), carosidine, carosine, pleurosine, neoleurosidine, vincarodine, catharicine, vindolidine, and neoleurocristine (1). These alkaloids, along with VLB and the three co-discovered ones, vindoline, lochnericine and vindolinine, are listed in Table II, along with their empirical formulas, m.p.'s, pK'a's, specific rotations, and ultraviolet absorption maxima.

TABLE I.—ALKALOIDS FROM *Vinca rosea* LINN.

Name	Formula
Ajmalicine	$C_{21}H_{24}N_2O_3$
Tetrahydroalstonine	$C_{21}H_{24}N_2O_3$
Serpentine	$C_{21}H_{22}N_2O_3$
Lochnerine	$C_{20}H_{24}N_2O_2$
Akuammine[a]	$C_{22}H_{26}N_2O_4$
Reserpine[a]	$C_{33}H_{40}N_2O_9$

[a] Akuammine (vincamajoridine) and reserpine have not been encountered in our investigation, while the presence of the other four has been confirmed.

Figure 1 represents the scheme used in the extraction of the drug. The process consists essentially of separating the plant alkaloids into those whose tartrates are soluble in organic solvents and those which are not, under the existing conditions. The basis for this method, in which the tartaric acid serves to bind the stronger bases in the crude drug, affording an initial separation of the weak and strong bases during extraction, was first described in 1957 (28) in a paper dealing with the root bark alkaloids of *Alstonia constricta* F. Muell.

The final purification of most of the alkaloids listed in Table II was achieved by elution chromatography on alumina deactivated by treatment with 10% acetic acid. The eluting solvents used were benzene, benzene-chloroform mixtures, chloroform, and chloroform-methanol mixtures. In order to obtain a number of the alkaloids it was necessary to subject certain selected post-VLB column fractions to a gradient pH technique, which is described as follows: A 10-Gm. sample of the crude amorphous chromatographic fraction was dissolved in 500 ml. of benzene. Any benzene-insoluble material which would result was removed by filtration and discarded. The alkaloids were extracted into 500 ml. of 0.1 *M* citric acid by a reduced pressure steam distillation. Insoluble material was removed by filtration and discarded. The filtrate volume was then adjusted to 500 ml. with water. The resulting clear acidic solution was extracted at pH levels of 2.80, 3.40, 3.90, 4.40, 4.90, 5.40, 5.90, 6.40, and 7.50 (± 0.02), with 500-ml. portions of benzene. The pH of the aqueous phase was raised by the addition of ammonia. The benzene extracts were dried over sodium sulfate and were concentrated *in vacuo* to dryness. The alkaloids were crystallized therefrom by the addition of either methanol or acetone.

It must be stated that no one column operation yielded every alkaloid that is listed as being obtained from a particular starting fraction. The following schemes, as presented in Figs. 2 and 3, will serve to illustrate the manner in which all of these alkaloids were obtained.

BIOLOGICAL PROPERTIES

Four of the recently isolated alkaloids from *Vinca rosea* Linn. have been of particular biological interest in these laboratories because of

TABLE II.—NEW ALKALOIDS FROM *Vinca rosea* LINN.

Name	Formula	M.p., °C.[a]	$[\alpha]_D^{26}$ $CHCl_3$	pK'a in DMF	U.V. $\lambda_{max.}^{EtOH}$, mμ[a]
Leurosine	$C_{46}H_{58}N_4O_9$[b]	202–205 (decompn.)	+72	5.5, 7.5 (H_2O)	214, 259
Vincaleukoblastine	$C_{46}H_{56}N_4O_9$	211–216 (decompn.)	+42[c]	5.4, 7.4 (H_2O)	214, 259

[a] The melting points were determined on a Kofler microstage. The ultraviolet absorption spectra were obtained using a Cary model 14 spectrophotometer. [b] While these molecular formulas agree well with the analytical results for each particular alkaloid, it should be noted that they are to be considered as proximate at this time, in light of our experience with the other dimeric alkaloids (58). [c] Determined on VLB etherate. [d] On the basis of mass spectrometric evidence obtained by H. Budzikiewicz and J. M. Wilson of Stanford, we now prefer the C_{20} formulation rather than the C_{19} first reported (27).

their effects as chemotherapeutic agents in experimental neoplasias. These are: vincaleukoblastine, leurosine, leurocristine, and leurosidine. The transplantable tumor used as a bioassay for these alkaloids is the P-1534 leukemia. This is an acute lymphocytic leukemia which, in our laboratory, is transplanted only in DBA/2 mice. It has been used to detect and predict clinical activity of a number of antineoplastic compounds (13, 15, 29–34).

The techniques by which drugs are assayed with this and other tumors in our laboratory have been previously described (15).

The activity observed with the initial total extract of the plant and with the first crude fractions is shown in Table III. This led to the production of leurosine and VLB. Their activity against the P-1534 leukemia and other murine tumors has been described in detail (15, 34). Briefly, animals implanted with the P-1534 leukemia and treated with VLB survived 40–150% longer than saline-treated controls, when VLB was administered at levels ranging from 0.05–0.6 mg./Kg. Similar results were obtained with leurosine by therapy with levels ranging from 3.0–7.5 mg./Kg. (Table IV). A number of other transplantable tumors were also affected, including Freund, Ehrlich, and S-180 ascites tumors, B82A leukemia, and the Walker carcinosarcoma 256.

Extensive experimental evaluation indicated the "indefinite" survivors, obtained by administering certain of the crude extracts to animals implanted with the P-1534 leukemia, were not due to VLB or leurosine.

Continuing chemical investigation of those fractions (Table V), which gave high prolongation or indefinite survival of P-1534 animals, with such activity as a bioassay, led to the production of leurocristine and leurosidine (16). The activity of these alkaloids will be described in detail elsewhere, but prolongations ranging from

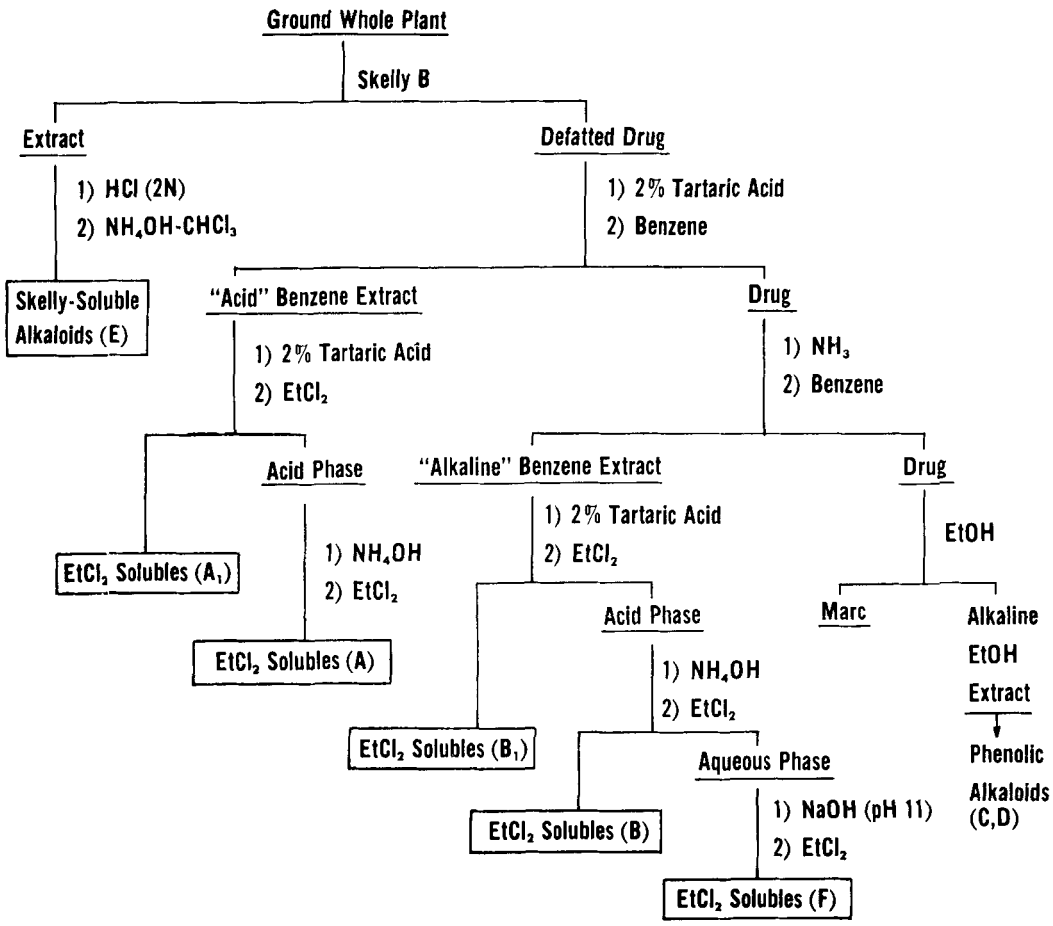

Fig. 1.—Extraction scheme.

30–220% over controls were obtained with leurocristine at levels from 0.05–0.35 mg./Kg., and 20–130% at levels from 2.0–10 mg./Kg. with leurosidine (Table VI) (35). At the higher levels of these ranges, 60–100% of the animals may be "cured" and survive indefinitely. The experimental tumor spectra of leurocristine and leurosidine are slightly broader than VLB and leurosine (Table VII).

With the exception of leurosine, all of these alkaloids may significantly prolong life of P-1534 animals, even when treatment is delayed until the animals are in near terminal states. In addition, in the case of leurocristine and leurosidine, very preliminary studies suggest that if such animals survive, they may become resistant to additional challenges with the same tumor. "Curing" of strain specific tumors in highly inbred strains of laboratory animals is in itself rare, but resistance to subsequent challenges of the same tumor is almost unique. It is unknown whether such reactions can be extrapolated usefully to any clinical situation, either concerning neoplasia or transplantation phenomena.

Pharmacological and toxicological studies with these alkaloids have not been published in detail. Vincaleukoblastine and leurocristine have been more extensively studied (36). Acute i.v. LD_{50}'s for VLB and leurocristine in mice are approximately 17.0 and 2.0 mg./Kg., respectively. Multiple doses of VLB caused marked leucopenia in rats and dogs at 0.50 and 0.1–0.2 mg./Kg., respectively, causing death in some instances. Leurocristine, leurosidine, and leurosine do not exert leucopenic effects in rats and dogs to this same degree. Transient rises in blood pressure of dogs receiving VLB or leurocristine have been observed. Leurocristine has also been observed to cause a slight paralysis of hind limbs in mice with a single i.v. administration of 2.0 mg./Kg. Other studies of possible neurological effects of these alkaloids are in progress.

Clinically, VLB has been more extensively studied than any of the other alkaloids. The

most striking results of VLB therapy have been obtained in the treatment of Hodgkin's disease (37–41). Patients have been maintained in clinical remission for periods of over a year. Choriocarcinoma and carcinoma of the breast have also been treated effectively with this compound (42, 43). In all of these studies, beneficial results have been obtained even in tumors resistant to other commonly used chemotherapeutic agents.

A number of other types of tumors have also been observed to respond to VLB therapy. These include carcinomas of the bronchus and colon. Isolated instances of responses in seminoma, teratoblastoma, and melanoma have been reported.

Some investigators have obtained temporary remissions in various types of leukemia, including acute lymphocytic, acute monocytic, and myeloblastic. The remissions have not generally included complete bone marrow remissions. The results obtained with VLB in leukemias and tumors of the gastrointestinal and genitourinary tract do suggest the need for further evaluation in numbers of patients treated and types of treatment regimens.

Only the most preliminary clinical studies have been made with leurocristine. These reports suggest a striking percentage of complete hematological remissions in acute lymphocytic leukemia

and responses in a spectrum of solid tumors (44–51). Proper placement of leurocristine in the clinical armamentarium against the oncological process must await further clinical study. At the present time there is no clinical information available concerning leurosine or leurosidine.

The mechanisms by which these agents exert antitumor effects are unknown. Tissue culture studies with VLB suggested an interference in metabolic pathways leading from glutamic acid to the citric acid cycle and to urea. Extension of these studies to experimental *in vivo* systems tend to confirm the *in vitro* results (15, 34, 52). Similar findings have also been made clinically (41, 53). Various abnormal mitotic figures including

C-mitosis, ball metaphase, etc., have been obtained both *in vitro* and *in vivo* (15, 34, 52, 54). It seems unlikely that the therapeutic responses obtained are due to these cytological effects, since these are observed clinically and experimentally in tumors in the absence of any oncolytic effects.

Experimental studies in combination with other known cancer drugs, and the lack of cross resistance to them clinically, suggest mechanisms different than those of any such known compounds. In spite of the probable close structural relationships among these four alkaloids, there appears to be a lack of cross resistance and probable different mechanisms of action among them. These agents, regardless of mechanism, represent new and hitherto unknown leads towards effective chemotherapeutic treatment of a variety of human neoplasms.

CHEMISTRY

Prior to the discovery of the oncolytic properties of certain alkaloidal extracts prepared from the plant *Vinca rosea* Linn., a number of miscellaneous plant extracts had been reported to have some degree of antitumor activity (55). In several instances the pure chemical substance (s) had been isolated, *viz.*, podophyllin (56) and colchicine (57), and had been subjected to clinical testing.

Preliminary studies showed that the *Vinca rosea* Linn. alkaloids were not related to other naturally occurring oncolytic agents (12, 15) and that, by and large, they were indole and dihydroindole in character (58). Table I lists a number of alkaloids from this plant which had been described by earlier workers (14). They are all found in other genera and species of the *Apocynaceae*, and their structures are well

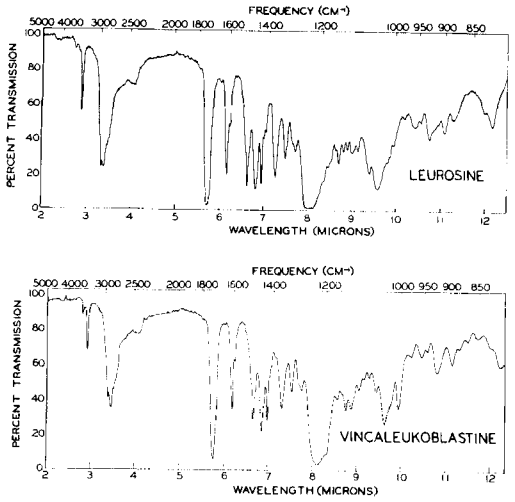

Fig. 4.—Infrared spectra of leurosine and vincaleukoblastine.

documented. The remaining alkaloids (Table II) were of unknown structure and it seemed pertinent, on the basis of the unique biological properties of certain of these alkaloids, to undertake a detailed study of their chemistry, with particular emphasis on leurocristine (16), VLB (59), leurosine (12), and leurosidine (16).

Investigation of the physical properties of leurosine and VLB (58) indicated that they were nonsymmetrical dimeric alkaloids. Titration showed the presence of two basic nitrogens, pK'a 5.5 and 7.0, one of which would quaternize when treated with methyl iodide or similar reagents. Analyses of the free bases, sulfates, dihydrochlorides, and quaternary salts indicated that they were $C_{46}H_{56-58}N_4O_9$ compounds (59). A study of the infrared spectra of the bases further supported this contention (thus the intensity of the indole N—H was approximately one-half that expected for a typical indolic C_{21} alkaloid) and indicated that VLB contained a hydroxyl group ($\lambda_{max.}^{CHCl_3}$ 2.8, 10.0 μ) that was not present in leurosine. Aside from this difference, the infrared spectra were very similar (Fig. 4) (58).

Comparison of these spectra with those of several other *Vinca rosea* alkaloids, notably catharanthine and vindoline (Table II), clearly indicated a close interrelationship between these compounds. When the infrared spectrum of a solution containing equimolar quantities of catharanthine and vindoline was compared to those of leurosine and VLB, it was virtually superimposable from 2–8 μ and quite similar up to 16 μ (Fig. 5). It was therefore assumed that the double molecules leurosine and VLB were composed of catharanthine and vindoline moieties, with minor molecular modification, bonded together in some unique manner (58). With this thought in mind, we turned our attention to the study of these two smaller molecules.

Catharanthine (I) was found to be a $C_{21}H_{24}N_2O_2$ compound and to form a methiodide readily. The physical characteristics of the quaternary salt showed that the basic nitrogen (pK'a 7.0) was analogous to the one forming the salt in the dimeric compounds. The ultraviolet spectrum was typical of an unsubstituted indole, while the infrared spectrum showed indole N—H (2.9 μ), carbomethoxyl moiety (5.78, 8.05 μ), and a triplet at 6.8 μ, characteristic of the Iboga-type alkaloids. The presence of a single double bond was seen from hydrogenation studies which yielded dihydrocatharanthine (II), thereby indicating that the parent base was pentacyclic (24).

Treatment of dihydrocatharanthine (II) under reflux with hydrazine in absolute ethanol, or saponification followed by brief acid treatment, resulted in decarboxylation in a manner analogous to that reported for voacangine (III) and related alkaloids (60, 61).

The new descarbomethoxy base, epi-ibogamine (IV), $C_{19}H_{24}N_2$, was further characterized as the hydrochloride $C_{19}H_{24}N_2 \cdot HCl$ (62). The analogous reaction on catharanthine (I) was unsuccessful; however, by the use of vigorous conditions (refluxing in concentrated hydrochloric acid) a poor yield (*ca.* 1%) of descarbomethoxycatharanthine (V) could be obtained. This compound was hydrogenated (platinum dioxide in alcohol) and afforded epi-ibogamine (IV). The failure of catharanthine to decarboxylate readily may be explained if the position of the double bond is as shown in (I). The corresponding intermediate for this type of reaction (60, 62) would require the highly strained structure shown in (VI).

The position of the carbomethoxyl at C-18 was also shown by the formation of the tetrahydro-1, 3-oxazine (VII) of catharanthinol (VIII), (the lithium aluminum hydride reduction product of I). This derivative was obtained by the treatment of catharanthinol with dry hydrogen chloride in acetone (63). As expected, the compound does not have any indole N—H or OH absorption in the infrared spectrum; $C_{23}H_{28}N_2O_2$ (62).

The relationship of catharanthine (I) and its derivatives to the corresponding Iboga alkaloids [*e.g.*, ibogamine (IX) and coronaridine (carbomethoxyibogamine) (X)] was indicated from the similarities of their infrared spectra and

finally proved by the isolation of the indoloquinoline (XI) (64) from the selenium dehydrogenation of epi-ibogamine (IV). This product (XI) was found to be identical in every respect (X-ray powder pattern, infrared, ultraviolet, and mass spectra) with an authentic sample obtained by dehydrogenation of ibogamine (IX) (64).

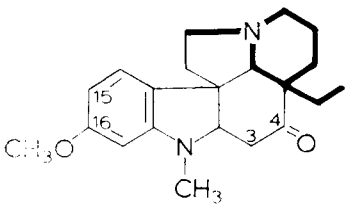
The position of the endocyclic double bond was indicated by the NMR spectrum of catharanthine (I) which has shown the presence of an ethyl group (methyl triplet centered at 1.10 δ with peaks separated by 7 c.p.s.) and a single proton on a double bond (peak at 5.90 δ). The position of the double bond was corroborated by products resulting from dehydrogenation of catharanthine (I) and dihydrocatharanthine (II), using palladium on carbon (62).

The former gave a good yield of 3-ethyl pyridine (XII) at 150–160°, while the latter required a temperature of 230–250° to afford 3-methyl-5-ethyl pyridine in a manner similar to that previously described for voacangine (III) (65). The formation of (XII) is explained by the fission of the C-1–C-2 allylic bond, while in dihydrocatharanthine (II) the bond breaks as in voacangine (III) between C-1 and C-18.

The hydrogenation of catharanthine led to

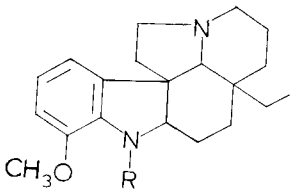
XIV

only one isomer (*vide supra*). From the models of (I), it is apparent that the hydrogen must come in from the side nearest to N_b to give the axial ethyl group shown in (II). Therefore, dihydrocatharanthine (II) and epi-ibogamine (IV) are epimeric at C-4 with coronaridine (X) and ibogamine (IX), respectively, since the C-ethyl group in the Iboga alkaloids, *e.g.*, ibogaine (XIII) has been shown to be equatorial (66), and catharanthine must be Δ^3-dehydrocoronaridine (62).



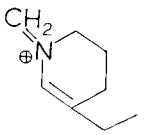
With this information in hand, attention was turned to the structure elucidation of vindoline. Vindoline (XIV), the most abundant alkaloid in the leaves, was found to be a $C_{25}H_{32}N_2O_6$ dihydroindole compound (24). Its basic nitrogen did not form a methiodide in analogy to the nitrogen pK'a 5.4 in the dimeric alkaloids. The nature of the six oxygens was determined by the formation of suitable derivatives. Thus, treatment of vindoline with acid (8 min. reflux—N_2) afforded desacetylvindoline (XV), $C_{23}H_{30}N_2O_5$, corresponding to the loss of an acetyl group. This was further corroborated in the infrared spectrum by the appearance of a hydroxyl band (2.7 μ) and corresponding reduction of intensity of the carbonyl band (24).

The presence of the methyl ester was shown by lithium aluminum hydride reduction of the base with simultaneous removal of the acetyl to yield vindolinol, $C_{22}H_{30}N_2O_4$ (24). The infrared spectrum of vindoline, in which a broad band at 3.5–4.0 μ was conspicuous, showed that the fifth oxygen was a hydrogen-bonded hydroxyl. Formation of the diacetate $C_{27}H_{34}N_2O_7$ (acetic anhydride in pyridine) was accompanied by the disappearance of this broad band in the infrared spectrum (24). From the study of the ultraviolet and infrared spectra, the sixth oxygen was shown to be present as an aromatic methoxyl on a dihydroindole chromophore. The confirmation of the assignment of the oxygen functional groups was obtained from the NMR spectra (XIV) (Fig. 7) (67). Vindoline consumed one mole of hydrogen at atmospheric pressure, showing it to be a pentacyclic compound and afforded dihydrovindoline (XVI) which could be converted to an amorphous hygroscopic hydrochloride. Pyrolysis of this salt at 195–200° in vacuum gave a distillate from which a $C_{21}H_{28}N_2O_2$ compound (XVII) was obtained in 15% overall yield by direct crystallization from hexane. The methoxydihydroindole portion of this compound was the same as in vindoline (XIV), and the second oxygen was found to be present as a ketonic carbonyl ($\lambda_{max.}^{CHCl_3}$ 5.85 μ) (67).



Careful comparison of the mass spectra of the pyrolysis ketone (XVII) and dihydrovindoline (XVI) with that of N-methyl desacetyl aspidospermine (XVIII) (68) indicated the presence of the latter ring system in vindoline and its derivatives, since in all three compounds identical intense peaks were found at m/e 124, 174, 188, and 298 (68).

The position of the carbonyl in (XVII) was assigned on the basis of the presence of the peak at m/e 298 (M-42) (XXII) which suggested that this group involved either C-3 or C-4. Position 4 was selected for two reasons: the typical ABX pattern at low field (3 to 3.5 δ) in the NMR spectrum (also consistent with structure XVII) indicated three protons between the carbonyl group and nitrogen; and equilibration with CH_3OD/methoxide resulted in the introduction of only two deuterium atoms per molecule (M = 342). The peak at m/e 124 (XIX) comprises the atoms outlined by heavy lines in structure (XVII) while the 174 (XX) and 188 (XXI) peaks contain the dihydroindole moiety (as indoles) with one or two carbons, respectively, of the "tryptophan" dimethylene bridge attached. The fragment of mass 298 (XXII) involves the loss of the two-carbon bridge (C-3 and C-4) containing the oxygen functions (except the aromatic methoxyl) of each derivative. The only other major peak in the ketone occurs at m/e 166 (XXIII) which shifts to m/e 168 in the deutero derivative. Structure (XXIII) is assigned to it since this peak corresponds to fragment (XXIV) of mass 152 (69) in the spectrum of aspidospermine (XXV). The fragmentation is more complex in dihydrovindoline, giving rise to a series of peaks at m/e 398, 311, 284, and 224 in addition to those already mentioned. The proposed structure for vindoline is consistent with the formation of these additional ions.



The position of the aromatic methoxyl was shown to be at either C-15 or C-16 by examination of the typical 1, 2, 4 aromatic proton pattern (*ortho* splitting J = 8 c.p.s., *meta* splitting J = 2.5 c.p.s.). The final selection of C-16 is based on the comparison of the infrared and ultraviolet spectra of vindoline with 6-methoxy-N-

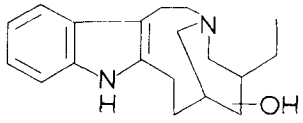
methyldihydroindole (XXVI) and by the isolation of *ind*-N-methylnorharmine (XXVII); m.p. 112–114°, hydrochloride m.p. 232–236°, molecular weight (M) 212 (by mass spectrometry), $\lambda_{max.}^{EtOH}$ 243 (37,500), 303 (15,100), 336 (4,300), from a soda lime distillation of vindoline at 325°. This derivative also indicates the position of the N-CH_3 as being on the anilino nitrogen. A second product (XVII) which was identical to the C_{21} ketone obtained above was also isolated from the soda lime reaction. Examination of the NMR spectrum of vindoline (XIV) (Fig. 7) allows the assignment of each proton as shown. The following assignments, however, deserve some comment. The unsplit peak of the proton on the carbon bearing the acetoxyl moiety shifts to 4.07 δ in desacetyl vindoline (XVIII). The protons of the methylene portion of the C-ethyl group are not equivalent and are found as a 12-band multiplet centered at 1.35 δ (J = 7.5 c.p.s.). The methyl triplet, however, is almost symmetrical in vindoline, being found at an exceptionally high field 0.48 δ (J = 7.5 c.p.s.) for a grouping of this type. This high field appears to be due to increased shielding by ring currents from the aromatic ring. The coupling constant of the two *cis* vinyl protons is J = 10 c.p.s., and one of these (5.88 δ) is further split by two non-equivalent adjacent protons (3.4 δ) with coupling constants J = 5 and 2 c.p.s. (67).

The mass spectral evidence, besides indicating the ring system of vindoline, shows that the oxygen functions other than the aromatic methoxyl can only be present at positions 3 and 4, and therefore must be arranged as shown in structure (XIV) to be consistent with NMR data. The formation of the ketone is also easily explained from this formulation (dehydration, hydrolysis, decarboxylation) (67). The stereochemistry of vindoline is as yet tentative and rests on evidence which will be presented elsewhere.



It is interesting to note that vindolinine (24, 70), another *Vinca* alkaloid with a slightly modified aspidospermine (XXV) skeleton, contains a double bond at the same position as vindoline (XIV). The structure of this compound is most probably best represented by (XXVIII) or (XXIX) and was arrived at by a joint effort of Djerassi's group at Stanford, Le Men and coworkers in Paris, and the writers at the Lilly Laboratories (71). The structural assignment of this compound is unique in that it is based largely on interpretation of mass spectrometric fragmentation patterns, combined with NMR measurements, without utilization of classical chemical degradations. In all, over 30 derivatives were studied, and these were obtained by the suitable use of acetylation, reduction, and acylation reactions (71).

XXXVIII

As mentioned above, spectral evidence strongly suggested that the dimeric alkaloids were composed of a molecular combination of catharanthine (I) and vindoline (XIV). This assumption could be further substantiated by the products of acid cleavage (concentrated hydrochloric acid, stannous chloride, tin, reflux) carried out on the dimeric alkaloids. In each case there was obtained upon chromatography of the reaction mixture an indole compound (*vide infra*), followed by vindoline derivatives. Vincaleukoblastine (XXX) and leurosine (XXXI) afforded desacetylvindoline (XV), thus proving the identity of the dihydroindole portion of these alkaloids. The corresponding fraction from the cleavage of leurocristine yielded des-N(*a*)-methyldesacetylvindoline (XXXII), M = 400, $C_{22}H_{28}N_2O_5$. The mass spectrum, as well as ultraviolet and infrared spectra, demonstrate the relationship of this compound to desacetylvindoline. Both VLB (XXX) and leurocristine (XXXIII) yield the same tetracyclic indole derivative velbanamine (XXXIV), $C_{19}H_{26}N_2O$, the infrared spectrum of which clearly shows the oxygen to be present as a hydroxyl (72).

A related tetracyclic indole derivative, cleavamine (XXXV), $C_{19}H_{24}N_2$ was obtained from the cleavage of leurosine. (The correct formula of leurosine is still in doubt due to difficulty of preparing a solvent-free sample.) Isolation of cleavamine demonstrates the relationship of the indole portion of C_{46} alkaloids to catharanthine (I) since it was also obtained by a similar acid treatment of the latter. Cleavamine is believed to possess structure (XXXV) and velbanamine appears to be its dihydrohydroxy derivative (XXXIV). The mass spectra indicate the same carbon skeleton for the two compounds and are consistent with the proposed structures (72).

The cleavage reaction demonstrates that leurocristine (XXXIII) differs from VLB (XXX) only in the vindoline portion of the molecule. The nature of this difference was demonstrated in the following manner.

Analyses of leurocristine base (XXXIII), sulfate, and monomethiodide, are consistent with a formulation of $C_{46}H_{54}N_4O_{10}$. Its ultraviolet spectrum $\lambda_{max.}^{EtOH}$ 220 mμ (log a_M 4.65), 255 mμ (log a_M 4.21), 296 mμ (log a_M 4.18) and $\lambda_{max.}^{EtOH}$ 275 mμ (log a_M 4.02) is quite different from that of VLB (XXX) and also indicates a different substitution on $N_{(a)}$ of the dihydroindole moiety (16).

The infrared spectra of VLB and leurocristine (Fig. 6) are quite similar with the exception of the presence of a strong additional band, $\lambda_{max.}^{CHCl_3}$ 5.94 μ in the spectrum of the latter. The NMR spectra differ in that the N—CH_3 proton resonance at 2.73 δ present in VLB is missing in leurocristine; and, conversely, in place of only one low field, 9.8 δ proton in VLB, there are two in leurocristine at 9.5 and 8.9 δ.

Lithium aluminum hydride reduction of the two alkaloids afforded good yields of the same pentahydroxy derivative, $C_{42}H_{54}N_4O_6$ (XXXVI). This formulation is consistent with the reduction of two methyl esters, one acetate and an *N*-formyl group in the case of leurocristine. The NMR spectrum of (XXXVI) shows, accordingly, only two methyl signals, aromatic OCH_3 at 3.8 δ and N—CH_3 at 2.73 δ. The N—CHO of leurocristine is therefore at the anilino nitrogen in place of the N—CH_3 in VLB and further, since the indole cleavage products (velbanamine) are identical, then leurocristine is des-$N_{(a)}$-methyl $N_{(a)}$-formyl VLB (72).

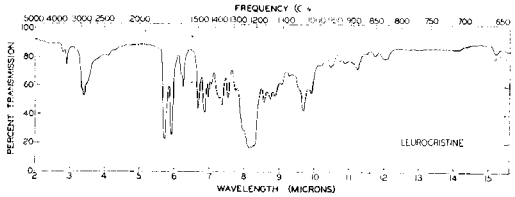

Fig. 6.—Infrared spectrum of leurocristine.

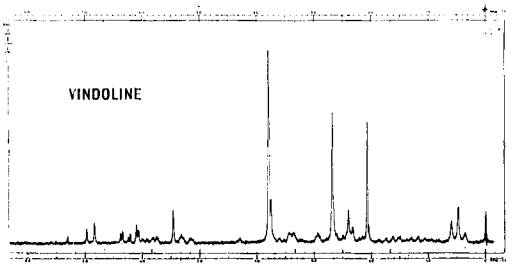

Fig. 7.—NMR spectrum of vindoline. Low field-OH not shown; peak at 7.32δ due to chloroform.

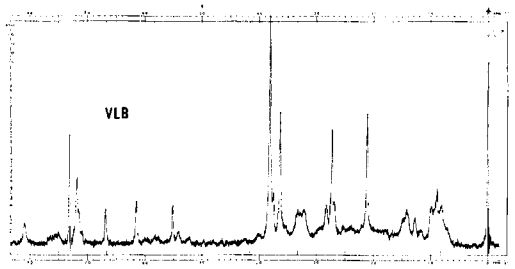

Fig. 8.—NMR spectrum of VLB. Low field-OH not shown; peak at 7.32δ due to chloroform.

The mode of attachment of the indole portion of the dimeric alkaloids to the dihydroindole fragment must be through the C-15 aromatic carbon since the NMR spectrum shows only two protons in a 1 : 4 relationship in the aromatic portion of the molecule rather than the 1, 2, 4 three-proton pattern present in vindoline (Figs. 7 and 8).

These data clearly indicate the partial structures (XXX) and (XXXIII) for VLB and leurocristine, respectively. On the basis of biogenetic considerations (free radical photosynthesis), as well as the mode of cleavage of these alkaloids, we are prompted to propose either C-3′ or C-4′ as the most likely site of attachment in the indole moiety and possible positions of the tertiary hydroxyl. The elucidation of this problem is at present in progress in these laboratories.

Little is known of the chemistry of the remaining alkaloids in Table II; however, they can be classified into three general groups. A number of the bases are closely related to the VLB-leurosine group of alkaloids (1, 27). The resemblance is seen in their infrared, ultraviolet, and NMR spectra, as well as from some results of acidic cleavage of several of these. Thus, leurosidine and isoleurosine both yield desacetylvindoline and an as yet unidentified indole derivative when treated as described above. The members of this group are listed in Table VIII.

The second group consists of monomeric alkaloids which range from C_{19} to C_{25} compounds (Table IX).

The infrared and ultraviolet spectra of perivine indicate that it is closely related to vobasine (XXXVII) (73), a 2-acyl indole alkaloid.

TABLE VIII.—VLB-LEUROSINE-LIKE ALKALOIDS

1. Vincaleukoblastine
2. Leurosine
3. Leurocristine
4. Leurosidine
5. Isoleurosine
6. Catharine
7. Carosine
8. Pleurosine
9. Catharicine
10. Neoleurocristine
11. Neoleurosidine

TABLE IX.—MONOMERIC ALKALOIDS

1. Perivine
2. Virosine
3. Catharanthine
4. Vindoline
5. Lochnericine
6. Vindolinine
7. Lochneridine
8. Sitsirikine

Perivine also contains an ethylidene group, N-methyl ester, and a 2-acyl indole chromophore.

Sitsirikine appears to be an as yet undescribed yohimbine isomer.

The remaining alkaloids are present in trace quantities and little is known about them. Lochnericine and lochneridine are related and possess the chromophore shown in (XXXVIII).

The third group consists of dimeric alkaloids which are not indole-indoline in nature (Table X).

TABLE X.—MISCELLANEOUS DIMERIC ALKALOIDS

1.	Vindolicine
2.	Vindolidine
3.	Vincamicine
4.	Vincarodine
5.	Carosidine

Of these only the first two are fairly well characterized, and they appear to be symmetrical dimers of vindoline.

Vincarodine appears to be related to vincine obtained from *V. minor* Linn. (74, 75).

Further work is planned in these laboratories toward structural elucidation of these alkaloids, with particular emphasis being placed on the interrelationships of the growing number of indole-indoline compounds.

Stability of Cyanocobalamin in Liver Preparations for Use in the Treatment of Pernicious Anemia

By H. W. LOY, O. L. KLINE, and S. S. SCHIAFFINO†

A deficiency of vitamin B_{12} has been found in a significant number of commercially available injectable products containing liver extract with added cyanocobalamin, with or without other added ingredients. In a study of the stability of cyanocobalamin when added to liver injectable preparations, with and without added folic acid, mixtures were stored in the dark at room temperature and examined at intervals throughout 1 year. No appreciable loss in cyanocobalamin occurred during the first month. Solutions stored at pH 5.0 were relatively stable for 12 months. At pH 6.5, destruction occurred within 3 months in some samples. Greater destruction occurred when the pH was raised to 8.0. Progressive destruction was observed in unstable samples after 6- and 12-month periods. With some preparations, destruction increased when folic acid was present, and in some instances when solutions were in contact with rubber stoppers.

CYANOCOBALAMIN in aqueous preparations has been found to be more stable than the hydroxo analog (1, 2) and, also, more stable in the absence of its analogs (3). Its stability in solutions decreased under certain conditions in the presence of other water-soluble vitamins (4–12) and in the presence of degradation products of these other vitamins (9, 13–15). The effect of impure phenol (16), other components of aqueous solutions (2, 17–21), light (22, 23), and oxygen (4, 24) on the stability of vitamin B_{12} also has been reported.

Procedures for predicting the stability of vitamins, including vitamin B_{12}, have been devised (25, 26) which involve studies at elevated temperatures. A report of studies on oral multivitamin preparations revealed that potencies of several vitamins, including vitamin B_{12}, were markedly affected by shelf age and storage conditions for certain types of products (27). The authors called attention to the responsibility of the manufacturer for maintenance of potency of these products throughout normal shelf life, and suggested that an expiration date on the label would be helpful in ensuring that a product meets its label claim.

Despite the availability of much information relating to the stability of vitamin B_{12} in various pharmaceutical preparations, that dealing with the stability of cyanocobalamin when added to liver solutions is limited.

There are on the market injectable preparations containing liver extract with added cyanocobalamin that are labeled for use in the treatment of pernicious anemia. Some of these products also contain added minerals, folic acid, and other vitamins. It has been shown conclusively in this laboratory that cyanocobalamin is unstable in many of the products with labeled potencies varying from about 10 to 120 mcg. of vitamin B_{12} per ml. It is not unusual to find deficiencies of vitamin B_{12} ranging from 20 to 50% and, in some instances, as great as 90% or more. A marked difference may occur in the degree of deterioration among vials bearing the same code. Deterioration frequently progresses during storage, even at 10°. We also have found that when a 1- or 2-ml. portion has been withdrawn from a 10-ml. multiple-dose vial, the vitamin B_{12} potency in the remainder may decrease as much as 25% after a 1-week storage period at 10°. Gakenheimer (16) has called attention to the influence of liver solutions upon the stability of added cyanocobalamin and pointed out that in a given liver extract which may retain its vitamin B_{12} activity for 1 year, added cyanocobalamin may not be stable. He emphasized that liver solutions must be pretested for compatibility when vitamin B_{12}, with or without folic acid, is to be added.

Our findings led us to carry out a study on the stability of cyanocobalamin when added to liver solutions, with and without the addition of folic acid.

Received November 15, 1961, from the Department of Health, Education, and Welfare, Food and Drug Administration, Bureau of Biological and Physical Sciences, Division of Nutrition, Washington, D. C.

Accepted for publication November 27, 1961.

Presented in part to the Association of Official Agricultural Chemists, Washington, D. C., meeting, October 1961.

† Present address: Department of Health, Education, and Welfare, National Institutes of Health, National Cancer Institute, Research Grants Branch, Bethesda, Md.

EXPERIMENTAL

Assay Methods

Vitamin B_{12}.—The A.O.A.C. (microbiological) method (28) was used. There was good agreement between the microbiological results and those obtained by the U.S.P. (spectrophotometric) method (29), slightly modified, on the cyanocobalamin stock solution and the control samples of cyanocobalamin and cyanocobalamin-folic acid.

Folic Acid.—The U.S.P. (chemical) method (30), slightly modified, was used. There was good agreement between the chemical results and those obtained spectrophotometrically on the folic acid stock solution and the control samples of cyanocobalamin-folic acid.

Stock Solutions

Cyanocobalamin and folic acid were of U.S.P. XV grade and all reagents were of analytical grade. Distilled water used as a solvent had a specific conductance of 0.5 micromho. Sterile solutions were used and all operations (including the subsequent preparation of sample solutions and filling and stoppering of vials) were conducted under aseptic conditions.

Liver, cyanocobalamin, and folic acid solutions were buffered with 0.05 *M* sodium acetate. Redistilled phenol was used at 0.5% concentration as the bacteriostatic agent in the preparation of each solution since it was already present in the liver solutions.

Acetate Buffer.—A 0.05 *M* solution of sodium acetate was adjusted to pH 6.5 with acetic acid.

Liver.—Solutions were taken from intact vials of U.S.P. XV grade liver injection and liver injection crude. These solutions were from various lots of samples that had accumulated in the laboratory and represented preparations from a number of manufacturers. Selection of the lots was arbitrary and stock solutions prepared from these lots did not represent any one manufacturer's product, and also were not necessarily identical with solutions used commercially. Each of six stock solutions was prepared by compositing three different lots of liver preparations and adjusting the slightly acidic solutions to pH 6.5 with sodium hydroxide solution.

Cyanocobalamin.—This solution, adjusted to pH 6.5 with acetic acid, contained 150 mcg. of cyanocobalamin per ml.

Folic Acid.—This solution contained the equivalent of 15 mg. of folic acid per ml. Folic acid was suspended in water, sodium hydroxide solution added until solution was complete (about pH 8.0), and adjustment to pH 6.5 was made with acetic acid.

Sample Solutions

At pH 6.5.—This pH was selected because it was near the value we had obtained for many liver-cyanocobalamin injectable solutions examined, some of which also contained folic acid. Most of the samples examined were within a pH range of 6.2–6.9, with an extreme range of 5.0 to 9.0.

(*a*) *Liver.*—Each of the six samples consisted of a portion of the respective liver stock solution.

(*b*) *Cyanocobalamin Control.*—Stock solutions of acetate buffer and cyanocobalamin were mixed in the ratio of 2:1.

(*c*) *Cyanocobalamin-Folic Acid Control.*—Stock solutions of acetate buffer, cyanocobalamin, and folic acid were mixed in the relation of 1:1:1.

(*d*) *Liver-Cyanocobalamin.*—Stock solutions of acetate buffer, liver, and cyanocobalamin were mixed in the relation of 1:1:1.

(*e*) *Liver-Cyanocobalamin-Folic Acid.*—Stock solutions of liver, cyanocobalamin, and folic acid were mixed in the relation of 1:1:1.

At pH 5.0.—A portion from the control under (*b*) and from each of samples 1, 3, and 6 under (*d*) was adjusted to pH 5.0 by the addition of acetic acid (about 0.3 ml./100 ml. solution).

At pH 8.0.—Portions similar to those taken for pH 5.0 adjustment were adjusted to pH 8.0 by the addition of 0.5 *M* tribasic sodium phosphate (about 0.2 ml./100 ml. solution).

Procedure

An 11-ml. portion of the respective sample or control solution was added to each vial used in the different phases of the study and the vial sealed immediately with a rubber stopper. Vials were Kimble[1] serum bottles, Neutraglas, narrow mouth, short form, No. 14196 for the 10-ml. size, and No. 14200 for the 20- and 50-ml. sizes. The respective volume of air in the 10-, 20-, and 50-ml. vials was 3, 16, and 50 ml. The 20- and 50-ml. vials were used to determine if any increase in the amount of enclosed air affected the stability of the cyanocobalamin control solution and the liver-cyanocobalamin sample solutions 1, 3, and 6 when stored at pH 6.5. Rubber stoppers were West[2] No. 124 (pink) stock. They were washed in a warm solution of sodium lauryl sulfate and rinsed repeatedly with distilled water. They were then immersed in distilled water, autoclaved, and rinsed. This latter process was repeated. A sufficient number of vials was prepared so that after portions were removed for assay, the remaining contents of an entered vial were discarded.

Determinations were made of the initial vitamin B_{12} and folic acid potencies of the vial contents from each series of solutions under study. Thereafter, determinations were made at intervals of 1, 3, 6, and 12 months with the vials stored upright so that the rubber stoppers were never in contact with the solutions. Storage was in the dark at 23.5 ± 1.5°. One set of vials for each phase of the study was stored in an inverted position to determine if potency was affected by contact of the solution with the vial stopper. These were examined only at the end of the 12-month storage period.

RESULTS

Liver Solutions.—Considerable destruction of vitamin B_{12} occurred in four of the six samples during twelve months storage in vials in upright position as shown in Table I. In fact, some loss was apparent at the end of the first month. Two of these unstable solutions were appreciably affected by contact with the stopper in the inverted vials.

Cyanocobalamin in Control Solutions.—There was no loss of cyanocobalamin activity in the control solutions throughout the 12-month storage period

(Tables II–V). Cyanocobalamin alone in aqueous solution was stable at pH 5.0, 6.5, and 8.0; at pH 6.5 in the presence of folic acid; and in all solutions in contact with vial stoppers.

Liver Solutions with Cyanocobalamin.—Stability of vitamin B_{12} in the six samples stored at pH 6.5 in 10-ml. upright vials is shown in Table II. No appreciable destruction of vitamin B_{12} occurred during the first 3 months. At the end of 6 months, there was a loss in potency of 10%, or more, in four samples. Three of these samples continued to lose potency during the next 6 months. Vitamin B_{12} in the four unstable solutions was markedly affected by contact with the stopper.

TABLE II.—STABILITY OF VITAMIN B_{12} IN LIVER SOLUTIONS CONTAINING CYANOCOBALAMIN AT pH 6.5[a]

[a] Stored in 10-ml. vials in the dark at room temperature.

It is shown for the three samples listed in Table III that the increase in amount of air enclosed in vials has no deleterious effect upon vitamin B_{12}. The results obtained on these samples correspond closely with those from the same three samples contained in 10-ml. vials included in Table II.

There was a marked change in the stability of two of these same three solutions stored in 10-ml. vials when the pH was altered, as shown in Table IV. At pH 5.0, the loss of vitamin B_{12} was 10% or less in samples 1 and 3, even when stored 12 months in contact with the vial stopper. The loss was drastic, however, in these two samples when the pH was raised to 8.0. The greatest stability occurred in sample 6. Even when inverted for 12 months, at pH 8.0, the loss in vitamin B_{12} was only 15%.

Liver Solutions with Cyanocobalamin and Folic Acid.—During the first month, as shown in Table V, there was little effect upon stability of vitamin B_{12} from the addition of folic acid to the six samples stored at pH 6.5 in upright 10-ml. vials. A loss in

[a] Stored in 10-ml. vials in the dark at room temperature.

potency was apparent, however, in all samples at the end of 3 months. There was no further loss between 3 and 6 months except in samples 3 and 4, but there was marked destruction of vitamin B_{12} in the first four samples at the end of 12 months. Greater destruction occurred in some solutions when the vials were inverted. This was most noticeable in samples 5 and 6.

Folic acid was stable in all solutions in upright vials during the first month (Table VI). A loss in potency was apparent at the end of 3 months and continued throughout further storage. Except for samples 4 and 5, the loss of folic acid activity observed in the liver-vitamin solutions was the same as in the control solution. Inversion of the vials had no noticeable effect on the folic acid activity of any of the solutions.

DISCUSSION

In the examination of the effect of liver solutions upon stability of cyanocobalamin, no single commercial product has been used. It was convenient to utilize combinations of commercial products available as samples in this laboratory, combined arbitrarily to provide a sufficient amount of test material for the six stock solutions that were studied. Therefore, the data presented here do not relate specifically to any particular manufacturer.

The factors, aside from composition, considered of possible importance in this study were the amount of air space, the pH of the solution, time of storage, and the possible effect of the rubber closures. It is apparent that a variation in the amount of oxygen contained in the vial was not directly related to the degree of deterioration of vitamin B_{12}. On the other hand, stability was markedly affected by pH of the solution. It was clear also that in some instances, particularly in the presence of folic acid, the rubber closure did affect the rate and degree of deterioration.

The most important factor, however, is some characteristic of the liver products used. There is no basis in results of this study for suggesting the nature of the variant in the liver products that is related to cyanocobalamin deterioration. Without knowledge of the method of manufacture or the source material, it is not possible to do other than point to the liver preparation as a principal source of the factor responsible for the decreased stability of vitamin B_{12} in these preparations.

The study reported here has been carried out under well-controlled conditions and demonstrates, beyond question, the magnitude of the losses of vitamin B_{12}, and in some cases folic acid, that can be expected when liver preparations that are incompatible with these compounds are used. It is emphasized again, as Gakenheimer (16) stated in 1952, that liver solutions to be used in injectable preparations with added cyanocobalamin require pretesting for compatibility.

SUMMARY

1. A study was conducted for a period of 12 months to obtain further information on the stability of cyanocobalamin when added to liver injectable preparations, with and without the addition of folic acid.

2. Loss of vitamin B_{12} potency in some of the liver solutions occurred during 3 months storage and continued in these preparations during further storage.

3. In the solutions tested, potency decreased when the pH was increased from 5.0 to 6.5 and from 6.5 to 8.0.

4. The loss of vitamin B_{12} was greater in some preparations when folic acid was added.

5. There was further loss of vitamin B_{12} in some samples when the solutions in the vials were in contact with the rubber stopper.

Stability of Anionic Complexes of Some Barbituric Acid Derivatives and Silver

By JAMES P. LEYDA† and LOYD E. HARRIS

Stability constants for the anionic silver complexes for a series of barbituric acid derivatives were determined potentiometrically. The titration efficiency or per cent recovery was shown to be acceptable for reproducible results and accurate calculation of the stability constants. The effect of silver ion on the stability of barbital was determined. The presence of silver ion was shown not to interfere with the assay of barbital in alkaline solution. A structure for the anionic silver barbiturate complex was proposed.

NUMEROUS procedures for the qualitative and quantitative analysis of barbituric acid derivatives are found in the literature which employ metal ion interactions. These methods include complexation by silver, cobaltous, cupric, and mercuric ions.

In 1934, Budde (1) first employed silver nitrate as a titrant for barbiturates in alkaline solution. The appearance of a permanent turbidity was used as the end point. This turbidity is caused by the formation of the insoluble disilver barbiturate.

Danielsson (2) modified the original Budde method by replacing the sodium carbonate solution with a solution of potassium metaborate. Potassium chromate was used as the indicator. At the end point in this method one mole of silver ion is equivalent to two moles of 5,5-disubstituted barbituric acid.

Potentiometric titration procedures have recently been reported employing silver complexation in barbiturate analysis. Gautier, *et al.* (3), titrated the protonated pyridine which forms after the interaction of silver ion with barbiturate in anhydrous pyridine. Perelman (4, 5) and Poethke and Furst (6) have potentiometrically titrated barbiturates with silver nitrate in a sodium carbonate solution.

The aims of this investigation were to determine the stability of the monosilver barbiturate anionic complexes of a series of nine barbiturates and the effect of the silver complex on the stability of barbital.

EXPERIMENTAL

Reagents.—The barbiturates used in this investigation were recrystallized from ethanol-water mixtures with the exception of butethal which was recrystallized from an ether-petroleum ether (b.p. 30–60°) mixture. Sodium carbonate monohydrate and potassium nitrate were of analytical reagent grade and were not further purified.

The silver nitrate solution was obtained from the Ohio State University reagent laboratory and was standardized against ammonium thiocyanate using acidified ferric alum as the indicator.

Apparatus.—A 5-ml. buret graduated in 0.01-ml. increments; magnetic stirrer; Rubicon model B and a Leeds-Northrup potentiometer with a General Electric galvanometer as the null instrument; silver electrode, prepared from 24-gauge silver wire; calomel electrode, containing a saturated potassium chloride solution; Beckman DU spectrophotometer, and Beckman pH meter, model GS.

Potentiometric Procedure.—An accurately weighed sample (between 15 and 80 mg./100 ml.) was dissolved in a sufficient amount of an alkaline carbonate solution (pH 11.0, 0.16 *M* sodium carbonate and 0.1 *M* potassium nitrate) to make 100 ml. A 25-ml. aliquot of the sample solution was placed in a 180-ml. titration vessel and titrated with the standardized 0.1 *N* silver nitrate solution. After each addition of titrant the E.M.F. was measured using a silver electrode as indicator electrode and a calomel reference electrode. The titration was continued until the permanent turbidity appeared, which was the visual end point described by Budde. A plot of Δ mv./Δ ml. *vs.* ml. of titrant determined the end point used in the calculation of titration efficiency and stability constants. At the end point, the average Δ mv./Δ ml. was about 300. A typical titration curve for barbital appears in Fig. 1.

Calculation of Stability Constants.—The reactions which lead to the formation of the monosilver barbiturate anionic complex in alkaline solution is shown by the following sequence

$$\mathrm{BarbH} + \mathrm{Na_2CO_3} \rightleftarrows \mathrm{Barb^-\ Na^+} + \mathrm{NaHCO_3}$$

$$\mathrm{Barb^-\ Na^+} + \mathrm{AgNO_3} + \mathrm{Na_2CO_3} \rightleftarrows \mathrm{BarbAg^-\ Na^+} + \mathrm{NaNO_3} + \mathrm{NaHCO_3}$$

The equilibrium constant (instability constant) which defines the reaction is

$$K_{ins} = \frac{[\mathrm{Barb^-}][\mathrm{Ag^+}]}{[\mathrm{BarbAg^-}]}$$

The stability constant of this anionic complex is the reciprocal of the K_{ins}

$$K_s = \frac{[\mathrm{BarbAg^-}]}{[\mathrm{Barb^-}][\mathrm{Ag^+}]}$$

Kolthoff (7) has given an equation for the calcula-
